AN ANTIGEN EXPRESSED BY PRIMATE NEOCORTICAL NEURONS IN SPECIFIC LAMINAE IS A PROTEOGLYCAN. M. Murtaugh*, A. F. Pimenta, P. L. Strick and P. Levitt, Department of Anatomy and Neurobiology, The Medical College of Pennsylvania, Philadelphia, PA 19129 and VA Med. Ctr./ Depts of Neurosurg. & Physiol., SUNY-HSC @ Syracuse, Syracuse, NY 13210.

The monoclonal antibody 8B3 recognizes an antigen present in the cortices of rhesus monkey, cat and rat. The antigen, which is expressed in mature and immature tissue, appears to be selectively associated with the cell surface of somata and dendrites in subpopulation(s) of neurons in all cerebral cortical areas.

Initial biochemical characterization of the antigen recognized by the 8B3 antibody has been performed using cat cerebral cortex. Western blot analysis reveals a large species macromolecule that migrates in gradient SDS-PAGE above 300,000 kilodaltons. Subcellular fractionation shows that the 8B3 antigen is both membrane-associated and soluble. Enzyme digestion of these fractions with glycosaminoglycan lyases chondroitinase ABC and chondroitinase AC II at optimal pH results in a complete loss of immunoreactivity. Treatment with other lyases did not result in loss of immunoreactivity or molecular mass shift. Given the unique anatomical distribution of 8B3, the data suggest that this antigen is a novel chondroitin sulfate proteoglycan that adds to the growing family of membrane-associated, large macromolecules, that are anatomically specified in the brain. Supported by MH45507.

QUANTAL RELEASE AT INDIVIDUAL TERMINALS IS SPECIFIED BY POSTSYNAPTIC NEURONS OF APLYSIA.

Daniel Gardner, Dept. of Physiology, Cornell Med Coll, NY, NY 10021.

In *Aplysia* buccal ganglia, strengths of the same identified synapses vary from animal to animal. Additionally, the synaptic strengths of similar IPSCs vary in each ganglion, apparently specified by the postsynaptic neuron. Using quantal analyses as reported recently for hippocampal LTP, but in a preparation lacking questioned activation and saturation, I ascribe differences in synaptic amplitude to varying numbers of quanta released by presynaptic terminals, rather than to postsynaptic factors.

Recording from B4, B5, and two voltage-clamped postsynaptic cells allows analysis of four similar synapses sharing common presynaptic and postsynaptic cells. Mean and variance of g_{peak} yield quantal parameters consistent with a simple binomial, assuming that fluctuations of sequential PSCs represent differences in quantal release, rather than receptor number, desensitization, or noise. PSC ensemble variance time course is consistent with this view. The indirect analysis permits factoring g_{peak} into presynaptic $m/(1-p)$ and largely postsynaptic $\gamma(1-p)$ factors.

$\log_e [m/(1-p)]$ was correlated with $\log_e [g_{peak}]$ ($r=0.87$, slope = 1.1), consistent with different quantal release underlying different mean synaptic strength. In contrast, $\gamma(1-p)$ was independent of g_{peak} ($r=0.19$).

Pairing quantal values by common pre- or postsynaptic cells shows that $m/(1-p)$ is similar for presynaptic endings converging on a single follower ($P=0.0001$) but different for endings of the same presynaptic cell on different targets ($P=0.34$); no pairing specificity is seen for $\gamma(1-p)$.

As in hippocampus, varying postsynaptic specification of release from presynaptic terminals may involve dynamic retrograde modulation.

TONIC TRANSMITTER RELEASE IS INHIBITED IN LIGHT ADAPTED PHOTORECEPTORS DURING POST-ADAPTATIONAL FACILITATION IN BLOWFLY VISUAL INTERNEURONS. M. Weckström*, M. Juusola*, E. Kouvalainen* and M. Järviheito. Department of Physiology and Department of Zoology, University of Oulu, SF-90220 Oulu, Finland.

The transmitter release of photoreceptors to second order neurons (LMCs) in dipteran insects has been proposed to be tonic even in complete darkness. We have verified this by observing a post-adaptational facilitation (PAF) in responses of the LMCs. After a strongly adapting light stimulation the subsaturating responses of the LMCs to test stimulus increase in size with longer latency. At the same time the conspicuous dark membrane noise typical of LMCs vanishes. This PAF effect in LMCs can be traced back to the post-adaptational hyperpolarization induced in pre-synaptic photoreceptors by the Na/K-pump (Jansonius, *J Comp Physiol A* 167:461-467, 1990). Conceivably, the pump potential in photoreceptors hyperpolarizes the transmitter releasing axon terminals beyond the activation threshold of calcium channels thus stopping the transmitter release. The increase in response size of LMCs to test stimulus during the PAF can be interpreted in terms of calcium channels' inactivation properties.

HYPERTONIC SOLUTIONS MAY INCREASE QUANTAL SIZE AT FROG NEUROMUSCULAR JUNCTIONS BY ACTIVATING PROTEIN KINASE A. W. Van der Kloot and D.D. Branisteanu*. Depts. of Physiology, SUNY, Stony Brook NY 11794 and Institute of Medicine and Pharmacy, Iassy, Romania

Permeable cAMP derivatives roughly double quantal size at frog neuromuscular junctions. So does pretreatment in a hypertonic solution containing 200 mM NaCl; if 200 mM Na gluconate is used quantal size is increased fourfold. H8 (N-[2-methylamino)ethyl]-5-isoquinolonesulfonamide) inhibits protein kinases. When hypertonic gluconate solution contained 100 μ M H8 the quantal size increase was significantly less. The (Rp)-diastereomer of cAMPS (cyclic adenosine 3',5'-phosphothoate) blocks PKA activation by cAMP and 100 μ M lessened the increase in quantal size produced by hypertonic solution. The (Sp)-diastereomer activates PKA; (Sp)-cAMPS added to Ringer doubled quantal size.

The phosphodiesterase inhibitor IBMX in Ringer has no effect on quantal size. Quantal size was increased significantly in experiments in which preparations were exposed for 10 min to hypertonic solution containing IBMX and then kept in IBMX solution for 40 min (controls were in IBMX only after hypertonic exposure).

CALCIUM-DEPENDENT NEUROSECRETION RECONSTITUTED IN XENOPUS OOCYTES: THE ROLE OF SYNAPTOPHYSIN. J. Alder, B. Lu+, P. Greengard+, and M. Poo. Dept. of Biol. Sciences, Columbia Univ. N.Y., 10027 and + Lab. of Molecular and Cellular Neurosci., Rockefeller Univ. N.Y., 10021.

Total rat cerebellar mRNA was injected into stage VI *Xenopus* oocytes, and Ca-dependent neurosecretion was assayed 2 d later. Our aim is to reconstitute the molecular mechanism responsible for Ca-dependent secretion at the presynaptic nerve terminal in the *Xenopus* oocyte (Cavalli, et al., EMBO J., in press), which is more accessible to experimental manipulation than a neuron. We found oocytes injected with cerebellar mRNA expressed 5-fold higher uptake of radioactive glutamine over control oocytes, and a significantly higher fraction of radioactivity was secreted in the presence of 10 μ M Ca ionophore (A23187) with 10 mM Ca than with 5 or 0 mM Ca. Background release of radioactivity from sham-injected oocytes showed no Ca-dependency. Co-injection of cerebellar mRNA with antisense oligonucleotides corresponding to the first 19 nucleotides of synaptophysin significantly inhibited the Ca-dependent secretion from the mRNA-injected oocytes ($15.0 \pm 5.2\%$ of control secretion \pm s.e., n=21). Co-injection of sense-oligos was without effect ($96.0 \pm 14.6\%$ of control n=12). Western blot analysis indicated that mRNA-injected oocytes expressed synaptophysin, and that such expression was abolished in oocytes co-injected with antisense. The effect of antisense injection was on secretion rather than glutamine uptake. Finally, co-injection of anti-synaptophysin antibody also produced significant inhibition ($9.4 \pm 5.3\%$ of control n=19) of Ca-dependent secretion, while only a small effect was observed for injection with antibody to GFAP ($76.8 \pm 7.4\%$ of control n=10). These results suggest that the presence of synaptophysin in its functional form is required for Ca-dependent secretion of radioactivity from the oocyte. Whether the secreted substance is in the form of a neurotransmitter or neuropeptides derived from the precursor glutamine is currently under investigation.

231.4

FEEDBACK CONTROL OF TRANSMITTER RELEASE AT THE NEUROMUSCULAR JUNCTION OF THE RAT. D.F. Wilson Zoology Dept. Miami Univ., Oxford, OH, USA 45056.

The presynaptic regulation of transmitter release in the rat diaphragm was examined by testing the effects of nicotinic and muscarinic antagonists on evoked transmitter release. Nicotinic antagonists (α -bungarotoxin, d-tubocurarine, and hexamethonium) and muscarinic antagonists (atropine and scopolamine) were tested on evoked transmitter release in an attempt to determine if presynaptic nicotinic or muscarinic receptors are present on the nerve terminal and whether they serve a role in regulating transmitter release. Intracellular recording techniques were used to monitor end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs) in the isolated cut-muscle rat diaphragm-phrenic nerve preparation. Quantal release in the presence and absence of the antagonists were examined. In the presence of each of the nicotinic antagonists a significant increase in quantal release was observed. The muscarinic antagonists, atropine and scopolamine failed to exhibit presynaptic effects in a concentration range that did not affect the nicotinic postsynaptic receptors. In higher concentrations atropine enhanced release but this action was associated with nicotinic blockade and inhibition of acetylcholinesterase. These results suggest that the nerve terminal lacks muscarinic receptors but contains nicotinic receptors that serve a negative feedback role (Supported by NIH grant NS-27260).

231.6

ANTISENSE GAP-43 mRNA BLOCKS EVOKED RELEASE OF DOPAMINE FROM PC12 CELLS. K.J. Ivins, S.A. Fidel, K.A. Neve, and R.L. Neve. Dept. of Psychobiol, UCI, Irvine, CA.

The neuronal growth associated protein GAP-43 has been implicated in the release of neurotransmitters from permeabilized synaptosomes. We previously reported the generation of PC12 cells stably transfected with human sense or antisense GAP-43. The spontaneous and evoked release of dopamine from these cells has been measured using HPLC. Spontaneous release of dopamine from cells overexpressing GAP-43 (i.e. transfected with sense GAP-43) was greater than the release from control cells. Depolarization of cells with 56 mM K⁺ caused a 5-10 fold stimulation in dopamine release from control cells and from cells transfected with GAP-43, but evoked release of dopamine from cells transfected with antisense GAP-43 was greatly reduced or absent. Similarly, the ability of the calcium ionophore A23187 to stimulate dopamine release from cells transfected with antisense GAP-43 was decreased or absent. These results indicate that GAP-43 is involved in the release of dopamine from PC12 cells and suggest that GAP-43 may function in neurotransmitter release at a step beyond an increase in intracellular calcium.

SYNCHRONOUS SPONTANEOUS SYNAPTIC RELEASE OF GABA IN CULTURED RAT HIPPOCAMPAL NEURONS.

J. Vautrin, Anne Schaffner and J.L. Barker. Laboratory of Neurophysiology, NINDS, NIH Bethesda, MD 20892.

Edwards et al. (*J. Physiol.* 430:213, 1990) reported that release of γ -aminobutyric acid (GABA) by hippocampal neurons is quantal. A quantal process varies by integer multiples of a defined amplitude and one expects amplitudes of unitary postsynaptic responses (PRs) to form a bell-shaped distribution. In fact, the amplitude distribution of single events due to release of GABA by hippocampal neurons recorded in the slice or in culture (reported here) are skewed and not bell-shaped. GABAergic PRs were analyzed in rat hippocampal neurons cultured for 1-3 weeks and recorded using patch electrodes containing CsCl. The PRs analyzed decayed with a time constant longer than 20ms at 22-25°C, were bicuculline-sensitive and reversed at E_{Cl} . The positive correlation between amplitude and rise time of individual PRs occurring spontaneously in tetrodotoxin indicates that electrotonic factors cannot account for smaller amplitudes and/or longer rise times. Careful observation of time courses strongly suggests that most PRs are composed of subunits that vary in number and synchronization. This suggests that the actual quantal size may be even smaller than the mode (or the mean) of the PR amplitude distribution (Ropert et al. *J. Physiol.* 428:707, 1990; Otis et al. *Brain Res.* in press, 1991).

TETRODOTOXIN-SENSITIVE CALCIUM-DEPENDENT RELEASE OF 3H-GLUTAMATE FROM BATRACHOTOXIN-TREATED RAT BRAIN SYNAPTOSOMES. T.J. Turner & K. Dunlap. Department of Physiology, Tufts University School of Medicine, Boston, MA 02111

We are using 3H -glutamate release from synaptosomes as a model system to study regulation, especially that mediated by presynaptic receptors, of Ca-dependent neurosecretion at central synapses. An effective means of depolarizing synaptosomes is to elevate external $[K^+]_o$, since the membrane potential of these structures approximates E_K . However, any presynaptic modulation mediated by alterations of K channel activity will be occluded by a "High K" paradigm. An alternative approach was developed, taking advantage of the toxicology of action-potential Na channels found in nerve endings. Synaptosomes, preloaded with 3H -glutamate in Na-containing buffer were pelleted and resuspended in Na-free, N-Methyl Glucamine (NMG) based saline. Batrachotoxin (BTX, 5 μ M), a persistent activator of Na channels, was added and the synaptosomes were incubated 30 min. on ice. A superfusion device designed to measure 3H -glutamate release on a subsecond time scale was used to evoke release by switching the superfusion buffer from NMG to a Na-containing saline with 2.4 mM Ca^{2+} . The kinetics of evoked 3H -glutamate release were biphasic, similar to those obtained using High K depolarization, although the amplitude was reduced. The release was Ca-dependent and was blocked by tetrodotoxin, whereas release evoked in a similar manner in Gramicidin-treated synaptosomes was not altered by tetrodotoxin. These results are consistent with depolarization mediated by Na influx through BTX-modified Na channels, enabling us to study the roles of K and Ca channels in presynaptic modulation of neurosecretion.

231.11

RESIDUAL CALCIUM AND ENHANCEMENT OF TRANSMITTER RELEASE: EVIDENCE FROM INVERTEBRATE AND VERTEBRATE SYNAPSES FOR CAUSALITY AND UNIVERSALITY. K.R. Delaney, W.G. Regehr and D.W. Tank. Biophysics Res. Dept., AT&T Bell Labs, Murray Hill, NJ 07974.

We have directly demonstrated that elevated presynaptic residual calcium, measured with fura-2, shows a linear correspondence with short-term synaptic enhancement at the crayfish neuromuscular junction (nmj) (Delaney et al. 1989, *J. Neurosci.* 9(10): 3558). We have now addressed two related questions: (1) does the raised presynaptic calcium cause the enhancement, or is the observed correlation simply an epiphenomenon, and, (2) do synapses in other species show the same linear relationship?

To address the issue of causality, we have modified the calcium handling capabilities of presynaptic terminals in the crayfish nmj using microinjected calcium buffers and changes in temperature. Both synaptic enhancement and calcium decay kinetics following brief trains of action potentials are similarly affected by these manipulations which change calcium accumulation and removal rates. This strongly suggests that the residual calcium is a causal link in the expression of the synaptic enhancement.

To address the issue of universality, we have performed experiments at the guinea pig hippocampal mossy fiber synapse similar to our earlier experiments on crayfish. At this mammalian synapse we also observe a linear relationship between presynaptic residual calcium levels and synaptic enhancement similar to that seen at crayfish nmj. This suggests that some of the mechanisms of calcium-induced short-term enhancement of synaptic transmission may be phylogenetically widespread and perhaps universal.

CHARACTERIZATION OF VESICULAR RELEASE FROM INDIVIDUAL BOVINE ADRENAL MEDULLARY CELLS.

J.A. Jankowski, T.J. Schroeder*, K.T. Kawagoe*, R.T. Kennedy, and R.M. Wightman. Dept. of Chemistry, Univ. of North Carolina, Chapel Hill, NC 27599-3290.

Release of catecholamines from individual bovine adrenal medullary cells that have been physically stimulated has been measured using carbon-fiber microelectrodes placed adjacent to the cell. The calcium-dependent release was observed as sharp spikes, or changes in current, corresponding to the oxidation of catecholamines which has been confirmed by cyclic voltammetry. With temporal resolution on the order of microseconds per point, individual spikes were determined to be the result of single secretory events. The average spike area was $1.03 + 0.08$ pC (avg + s.e.m.) corresponding to the average adrenal vesicle content of 5 attomoles of catecholamine. A probability density function derived for the distribution of spike areas confirmed the observation of single secretory events based on a gaussian distribution of vesicle radii and a constant vesicular concentration. Both the direct chemical measurements and mathematical modeling are consistent with exocytotic release from the individual cells.

231.10

CALCIUM AND SODIUM EFFECTS ON VASOPRESSIN SECRETION FROM NEUROHYPOPHYSIAL NERVE ENDINGS. E. Stuenkel and J. J. Nordmann*, Dept. of Physiology, Univ. of Michigan, Ann Arbor MI 48109 and Centre de Neurochimie du CNRS, 67084 Strasbourg Cedex, France.

Neurohormone/neurotransmitter release is highly dependent on the free $[Ca^{2+}]_i$ at release sites in nerve endings and suggests that the kinetics of release should be related to the kinetics of Ca^{2+} entry, rise in $[Ca^{2+}]_i$ and to processes which restore $[Ca^{2+}]_i$ to prestimulatory levels. We have examined in isolated rat neurohypophysial nerve endings the kinetic relationship between averaged $[Ca^{2+}]_i$, $[Na^+]_i$, and vasopressin (VP) release to depolarizing stimuli. VP release was quantified with high temporal resolution from isolated endings while $[Ca^{2+}]_i$ and $[Na^+]_i$ were monitored in single endings using fura-2 and SBFI. Elevation of $[K^+]_o$ leads to a dose-dependent, dihydropyridine- (DHP) sensitive, increase in $[Ca^{2+}]_i$ that is sustained throughout the depolarizing stimulus. Under voltage clamp, depolarizing voltage steps evoke changes in $[Ca^{2+}]_i$ reflecting the amplitude of the Ca^{2+} current and suggest an absence of voltage- or Ca^{2+} -induced Ca^{2+} release. Susceptibility of the sustained Ca^{2+} increase to DHP or removal of Ca^{2+} demonstrates the sustained increase results from continued influx via "L-type" Ca^{2+} channels. VP release to a sustained depolarizing stimulus results in a transient release response ($t_{1/2} = 7$ sec). Subsequent to secretory decline an additional depolarizing step produces a further increase in $[Ca^{2+}]_i$ and a resurgent, transient, increase in release. In contrast, treatments which evoke substantial increases in $[Na^+]_i$ but little change in $[Ca^{2+}]_i$ show dramatic release responses which show little secretory decline. Recovery and restimulation to elevated $[Na^+]_i$ shows little decrement in subsequent secretory responses. The kinetic difference in the Na^+ - and Ca^{2+} -evoked secretory responses suggests that the Ca^{2+} -evoked secretory decline does not result from depletion of releasable granules, saturation of available release sites or complete inactivation of Ca^{2+} influx.

231.12

THE ROLE OF RESIDUAL CALCIUM IN SYNAPTIC PLASTICITY AT THE HIPPOCAMPAL MOSSY FIBER SYNAPSE. W.G. Regehr and D.W. Tank. Biophysics Res. Dept., AT&T Bell Laboratories, Murray Hill, NJ 07974.

We have examined the role of presynaptic residual calcium ($[Ca^{++}]_{res}$) in use-dependent changes in synaptic strength at mossy-fiber synapses between hippocampal dentate granule cells and CA3 pyramidal cells. Mossy fiber terminals in guinea-pig hippocampal slices were labeled with fura-2 using our localized-perfusion loading technique and $[Ca^{++}]_{res}$ levels in individual terminals were measured while stimulating the mossy-fiber pathway and recording field excitatory post synaptic potentials. Action potential trains that did not induce LTP produced a transient buildup of $[Ca^{++}]_{res}$ that correlated with short-term increases in synaptic connection strength. The properties of this accumulation and its relationship to synaptic enhancement are similar to what is observed at other synapses (see Delaney et al. accompanying abstract) and suggest that the rise in $[Ca^{++}]_{res}$ causes the enhanced release. The enhancement is very calcium sensitive: a two-fold increase in transmitter release was accompanied by a 10-30 nM increase in $[Ca^{++}]_{res}$.

Despite the strong sensitivity of synaptic enhancement to $[Ca^{++}]_{res}$, sustained increases in $[Ca^{++}]_{res}$ are not responsible for the maintained synaptic enhancement observed during mossy-fiber LTP. Following induction of mossy-fiber LTP, $[Ca^{++}]_{res}$ decayed to prestimulus levels while enhancement of synaptic transmission persisted.

Our methods presently enable us to measure transient 20-50 nM increases in $[Ca^{++}]_{res}$ in single nerve terminals produced by a single action potential. We are attempting to use such measurements of $[Ca^{++}]_{res}$ to indirectly measure changes in presynaptic calcium current, another possible mechanism for the maintenance of LTP.

231.13

MODELING A SYNAPTIC CHEMICAL COMPUTATION: THE BUILDUP AND DECAY OF PRESYNAPTIC CALCIUM. D.W. Tank, W.G. Regehr & K.R. Delaney, Biophys. Res. Dept., AT&T Bell Laboratories, Murray Hill, NJ 07974.

Calcium influx produced by action potentials invading a presynaptic nerve terminal produces a buildup of intracellular free calcium ions that modulates the strength of synaptic transmission produced by subsequent action potentials. Like the buildup and decay of charge on nerve cell membranes, this buildup and decay of intracellular calcium ions implements two computationally important dynamic functions: integration, and short-term (decaying) memory. To study how cellular properties alter this simple form of chemical computation and more accurately interpret our experimental results (see accompanying abstracts), we have developed a theoretical model and computer simulation for the presynaptic terminals we study based on solving calcium and buffer reaction-diffusion equations for a set of spherical shells. The model predicts that the decay of elevated calcium concentration produced by short trains of action potentials should be approximated by an exponential decay with a time constant proportional to calcium buffer concentration, consistent with the changes in calcium kinetics we have observed when exogenous buffers are introduced into the nerve terminal. Computer simulations also demonstrate that the sodium ion buildup we have measured during long action potential trains, could, by reversal of the sodium/calcium exchange, lead to a second, longer, time constant in the calcium decay, corresponding to post-tetanic potentiation, as experimentally observed. To test the model, we are also attempting to predict the calcium accumulations produced by long trains from measurements of accumulations produced by single action potentials. We also examined to what extent spatial and temporal averaging affect our fluorometric ion concentration measurements.

231.15

RELEASE OF ACETYLCHOLINE FROM THE PREGANGLIONIC CHOLINERGIC FIBERS OF THE RAT MAJOR PELVIC GANGLION (MPG). G.T. Somogyi and W.C. de Groat, Departments of Pharmacology and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh PA, 15261.

Cholinergic modulation of ^3H -acetylcholine (ACh) release was studied in the rat MPG, which was prelabelled with ^3H -choline. In a superfused system two consecutive electrical field stimulations (S_1 and S_2) noticeably increased ^3H -ACh outflow in the presence of 10 μM hemicholinium-3 (S_2/S_1 ratio 0.85 ± 0.04). ACh release was not dependent on the frequency of stimulation, 0.3 Hz producing the same volley output as 10 Hz. TTX (1 μM) or omission of Ca^{2+} completely abolished ACh release. Oxotremorine (1 μM) a muscarinic agonist decreased (0.69), whereas the antagonist atropine (1 μM) slightly increased the release of ACh (0.94). The cholinesterase inhibitor, physostigmine (1-5 μM), the nicotinic agonist, DMPP (10 μM) as well as the nicotinic antagonist, d-tubocurarine (50 μM) did not change ACh release. 4-aminopyridine a K^+ channels blocker significantly increased the release of ACh (1.85). 7 days after decentralization of the MPG the release of ACh was completely abolished. It is concluded that measurable amounts of ACh can be released by electrical stimulation in a single parasympathetic ganglion and that release occurs from the preganglionic nerve terminals rather than from the cholinergic cell bodies. The release is subject to modulation via muscarinic receptors, but not by nicotinic receptors. Supported by NSF Grant BNS-890-8934; NIH Grants DK 37241, DK 42369 and Clinical Research Center Grant MH 30915.

231.17

THE VARIABILITY OF TRANSMITTER RELEASE PROBABILITY AT CENTRAL SYNAPSES BETWEEN LOCAL INTERNEURONS IN THE LOCUST. G. Laurent, California Institute of Technology, Biology Div., CNS Program, 139-74, Pasadena CA 91125.

Quantal analysis was applied to inhibitory synapses between spiking and nonspiking local interneurons in the locust central nervous system. Paired intracellular recordings were made from pre- and postsynaptic neurons *in vivo*, and IPSP amplitude distribution histograms were constructed from large samples. Clear and regularly interspersed peaks in the histograms were found and taken to indicate quantal release. A simple binomial model (implying uniformity of release probability) was then used to fit the probability distribution of peak amplitudes. The average values obtained for n and p were 13.1 ± 2.8 and 0.452 ± 0.16 ($n=10$) respectively. When several targets to a single spiking interneuron were found, the binomial n and p describing each synapse were compared. Whilst each distribution could be described by a simple binomial model, both n and p (and also their product m), however, differed between the different synapses made by the same presynaptic neurone. This suggests that, for a given interneuron, though the probability of release at all release sites of one synapse may be equal, this probability may differ from one synapse to the next.

231.14

INHIBITION OF QUANTAL GLUTAMATE RELEASE AT HIPPOCAMPAL SYNAPSES: CONTRIBUTION OF MECHANISMS OCCURRING DOWNSTREAM FROM Ca^{2+} INFLUX. K.P. Scholz and R.J. Miller, Dept. of Pharm. and Physiol. Univ. of Chicago, 60637.

The mechanisms responsible for the inhibition of quantal glutamate release during presynaptic inhibition were studied using whole-cell voltage-clamp techniques in cultured rat hippocampal pyramidal neurons. Small spontaneous inward current transients were identified as miniature excitatory post-synaptic currents (mEPSCs) by several criteria, including reversal potential, insensitivity to TTX and sensitivity to glutamate receptor antagonists. In the presence of high divalent cations (6mM Mg^{2+} and 3 mM Ca^{2+}) spontaneous action potentials were suppressed. Addition of the adenosine receptor agonist cyclopentyladenosine (CPA, 100-200 nM) reduced the frequency of mEPSCs to $62 \pm 9\%$ of control ($n=6$). This result was not accompanied by a shift in the cumulative histogram of mEPSC amplitudes, indicating a presynaptic origin for the reduction in frequency. The effects of CPA on mEPSC frequency were blocked by pretreatment with pertussis toxin. Divalent cation Ca^{2+} channel blockers were used to characterize the response further. Co^{2+} (1 mM) or Cd (100 μM) had variable effects on the frequency of mEPSCs, ranging from no effect to as much as 80% inhibition. In the presence of these agents, CPA induced a further reduction in the frequency of mEPSCs (to $70 \pm 7\%$ of control; $n=5$), with no consistent change in amplitude. These results suggest that adenosine receptors may act through a G-protein to inhibit some component of the quantal release apparatus. The purified component of black-widow spider venom alpha-LTX (gift of J. Meldolesi), induced a dramatic increase in the frequency of mEPSCs, even in the presence of Ca^{2+} . We are currently testing whether CPA can reduce this action in an attempt to assess whether CPA alters the sensitivity of the release apparatus to Ca^{2+} .

231.16

BIFEMELANE ENHANCES GLUTAMATE RELEASE FROM MOSSY FIBER SYNAPTOSOME OF GUINEA-PIG HIPPOCAMPUS: INVOLVEMENT OF PROTEIN KINASE C. Y. Kuraishi, M. Ueda, T. Fujii* and M. Satoh, Dept. of Pharmacol., Fac. of Pharm. Sci., Kyoto Univ., Kyoto 606, Japan.

Bifemelane (BIF), which has an anti-amnesic action, enhances the long-term potentiation of the mossy fiber-CA3 pyramidal, but not the Schaffer collateral-CA1 pyramidal, system in the hippocampus. As a step to elucidate the mechanism of its selective action on the CA3, the effects of BIF on the mossy fiber terminals were examined. Mossy fiber synaptosomal fraction (P3) and conventional synaptosomal fraction (P2) were prepared from guinea-pig hippocampus. P3 fraction was richer in dynorphin A(1-8), dynorphin B and zinc than P2 fraction. BIF (0.01-1 μM) increased dose-dependently the 30 mM K^+ -evoked release of glutamate (Glu) from P3 fraction *in vitro*, without effect on Glu release from P2 fraction at 1 μM . Such increasing effect of 1 μM BIF on K^+ -evoked Glu release from P3 fraction was abolished by H-7 (100 μM), which also suppressed the increase of K^+ -evoked Glu release by phorbol 12,13-dibutyrate (1 μM). BIF (1 μM) translocated protein kinase C (determined by binding assay using [^3H]phorbol 12,13-dibutyrate) from cytosol to membrane in P3, but not P2, fraction. The present results suggest that BIF directly acts on mossy fiber terminals to increase depolarization-induced Glu release, which may at least partly mediated by translocation of protein kinase C.

231.18

INFLUENCE OF CALMODULIN INHIBITORS ON STRIATAL NEUROTRANSMITTER SYNTHESIS AND RELEASE. S.L. Garber, C. Ndubuka, R. McCormick* and M.H. Makman*, Depts. of Biochemistry, Molecular Pharmacology and Neuroscience, Albert Einstein College of Medicine, NY, NY 10461.

These studies concern the role of calmodulin and second messenger systems in synthesis and release of transmitters in rat striatal synaptosomes. Dopamine (DA) and serotonin (5HT) formation were measured by (1) decarboxylation of ^{14}C -labeled amino acid (AA) precursor, (2) conversion of ^3H -AA precursor to DA and 5HT and (3) net *in vitro* increase in endogenous synaptosomal DA and 5HT, purified by HPLC. Release of endogenous DA and 5HT and labeled DA, 5HT, glutamate (GLU) and γ -aminobutyric acid (GABA) were also measured. The calmodulin inhibitor calmidazolium (CMZ) at 10 μM inhibited basal as well as forskolin-stimulated synthesis of both DA and 5HT, while DA and 5HT release were stimulated by CMZ. DA and 5HT synthesis were also inhibited by another calmodulin inhibitor, W7 (N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide), and by inhibitors of cyclic AMP-dependent protein kinase. CMZ stimulated release of GABA and GLU. W7, however, inhibited depolarization-induced release of GABA and GLU, indicating differential effects of CMZ and W7 on calmodulin and related processes. These results for transmitter release correspond to and may be mediated by effects on Ca^{2+} metabolism (see Ndubuka and Makman, this vol.). Also, there are several different sites at which calmodulin-dependent processes influence synthesis and release of neurotransmitters.

231.19

STRIATAL INTRASYNAPTOSOMAL CALCIUM CONCENTRATION AND CALCIUM FLUX: INFLUENCE OF CALMODULIN INHIBITORS.

C. Ndubuka and M.H. Makman*. Depts. of Mol. Pharmacol. and Biochem., Albert Einstein Col. Med., NY, NY 10461.

This study evaluates the influences of the calmodulin inhibitors, calmidazolium (CMZ) and N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide (W7) on calcium ion fluxes and concentration in striatal synaptosomes. $^{45}\text{Ca}^{2+}$ fluxes were measured at various times (1s to 15 min) in normal and in high potassium (K^+) medium. Intra-synaptosomal $[\text{Ca}^{2+}]$ was measured with the Ca^{2+} -sensitive fluorescent dye, Fura-2. CMZ and W7 affected Ca^{2+} fluxes differently. High K^+ alone increased $^{45}\text{Ca}^{2+}$ influx. CMZ alone caused a smaller but significant increase in Ca^{2+} influx. The effects of CMZ plus high K^+ on Ca^{2+} influx were additive. W7 did not significantly alter basal Ca^{2+} influx. However, W7 inhibited the high K^+ -induced increase in $^{45}\text{Ca}^{2+}$ influx. Qualitatively, these results agreed with the effects of W7 and CMZ on intrasynaptosomal $[\text{Ca}^{2+}]$. Quantitatively, however, the effects were appreciably different in the two Ca^{2+} assays, possibly due to the proportion or compartment of synaptosomes measured by each assay. $^{45}\text{Ca}^{2+}$ efflux was not influenced by either W7 or CMZ. We conclude that the calmodulin inhibitors influence striatal intrasynaptosomal Ca^{2+} by at least two mechanisms: a) inhibition of calmodulin-dependent Ca^{2+} channel activation; and b) inhibition of calmodulin-dependent intracellular Ca^{2+} sequestration.

COCAINE IN UTERO ENHANCES STRIATAL DOPAMINE RELEASE IN ADULT RATS. M. Coleman-Hardee*, J. Peris, and W.J. Millard. Univ. Florida, J. Hillis Miller Health Ctr., Gainesville, FL 32610.

Although considerable work has focused on the effects of adult exposure to cocaine on dopamine (DA) neurotransmission and behavior, less has been written on the effects of cocaine treatment *in utero* on DA release or behavior. We measured the effect of repeated cocaine exposure of impregnated mothers on $[\text{H}^3]\text{-DA}$ release from the brains of their offspring. Mother rats were divided into groups of saline *in utero* vs cocaine *in utero* (40 & 80 mg/kg; sc) and treated during the 20 day gestation period. At birth, offspring were taken from the mother and cross-fostered with non-cocaine treated nursing mothers. At three months of age, pups were given either a cocaine (10 mg/kg; ip) or saline injection and were sacrificed 24 hours later. $[\text{H}^3]\text{-DA}$ release was measured from superfused 400 μm striatal slices under basal conditions and after exposure to amphetamine (2 μM , 2.5 min) or electrical stimulation (5 Hz, 60 sec). In all saline offspring, one injection of cocaine produced a 47% increase in amphetamine-stimulated $[\text{H}^3]\text{-DA}$ release, ($F(1,9)=6.00$; $p<.05$), as seen before (Peris & Zahner, 1987). Amphetamine-stimulated release was also significantly increased by 44% in rats treated *in utero* with cocaine compared to animals from saline-treated mothers ($F(1,17)=6.55$; $p<.05$), regardless of whether rats were injected 24 hrs earlier with saline or cocaine. Neither basal nor electrically-stimulated release was affected by the cocaine *in vivo* or *in utero* treatments. Total tissue tritium levels were significantly decreased 35% in animals treated cocaine *in utero*, ($F(1,17)=7.21$; $p<.05$). Behavior testing must be performed to see if this increased release is correlated with any behavioral changes.

CHARACTERIZATION OF GLUTAMATE RELEASE FROM PREOPTIC AREA SYNAPTOSOMES OF OVARIAN STEROID-PRIMED FEMALE RATS.

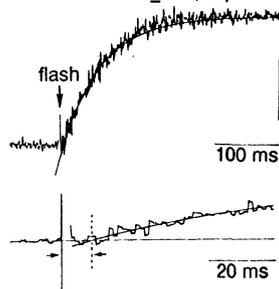

A.M. Etgen, A. Fleischmann and M.H. Makman*. Depts. of Psychiatry, Biochemistry, Molecular Pharmacology and Neuroscience, Albert Einstein Col. Med., NY, NY 10461.

Progesterone (P) treatment of estradiol (E_2)-primed, ovariectomized (OVX) rats *in vivo* was previously found to enhance the glutamate (GLU)-induced release of GABA, but not of GLU itself, from preoptic area (POA) synaptosomes incubated *in vitro*. Further studies have indicated that $\text{E}_2 + \text{P}$ enhances GABA release via a Ca^{2+} -independent, carrier-mediated process that is inhibited by 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS), a Cl^- -channel antagonist. Release of $^3\text{H}\text{-GLU}$ from POA synaptosomes, derived from OVX rats treated with $\text{E}_2 + \text{P}$, was induced by GLU and by the GLU carrier agonist D-aspartate (D-ASP). The excitatory amino acid (EAA) receptor agonists N-methyl-D-ASP and kainate were without effect while quisqualate exerted a small stimulatory effect on $^3\text{H}\text{-GLU}$ release. Release of $^3\text{H}\text{-GLU}$ induced by GLU itself or by D-ASP was not blocked by the EAA receptor antagonists, D-2-amino-5-phosphonovaleric acid, 6,7-dinitroquinoxaline-2,3-dione or kynurenate. GLU-induced release of $^3\text{H}\text{-GLU}$ was Ca^{2+} -independent and blocked by DIDS. GLU altered neither basal nor K^+ -induced increase in intrasynaptosomal $[\text{Ca}^{2+}]$, as measured by the fura-2 method. It is suggested that GLU-induced release of $^3\text{H}\text{-GLU}$ in POA synaptosomes involves an atypical Cl^- -dependent GLU carrier that may play a role in steroid-modulated amino acid release.

Ca STIMULATES SECRETION IN RAT PITUITARY CELLS WITHIN MILLISECONDS P. Thomas, J.G. Wong & W. Almers, Dept. Physiol. & Biophys., U. Washington, Seattle WA 98195

Neurons release transmitter in <1ms after cytosolic $[\text{Ca}^{2+}]$ (Ca_i) rises. To see how fast peptidergic endocrine cells secrete, we measured the membrane capacitance (C, proportional to cell surface) after flash photolysis of caged Ca . We voltage-clamped rat melanotrophs in whole-cell (-60mV, 32°C) and dialyzed them with 0.1mM fura-2, 10mM "cage" (DM-nitrophen) with 5mM CaCl_2 , 4mM MgCl_2 , 2 mM ATP plus buffer (pH 7.2) and Cs-glutamate to isotonicity. A <1ms UV flash transiently raised Ca_i to >1 μM (fura-2) and increased C (shown at slow and fast speed). C was well fitted with an exponential starting after a delay (arrows). Means (\pm S.E.) in 7 cells were: time constant 63 ± 8 ms, amplitude 300 ± 50 fF (750 vesicles), maximal dC/dt 5000 ± 1000 fF/s or 12,500 vesicles/s. Conclusions: Ca_i stimulates secretion 60,000 fold over biochemically-measured basal rates in <20 ms. It does so with a delay (10 \pm ms) that is more than 10 fold longer than at fast synapses, but the delay is too short for vesicles to move significant distances along microtubules. Hence most of the vesicles released here are probably already docked at the cell membrane. Supported by AR-17803.

EFFECTS OF Ca^{2+} - AND Na^+ -DEFICIENT CONDITIONS ON GABA RELEASE AND CORTICAL SYNAPTIC EXCITATION OF CELLS IN STRIATUM. S. Bernath, E.S. Nisenbaum, E.S. Vizi*, M.J. Zigmond, and T.W. Berger. Dept. of Behavioral Neuroscience, University of Pittsburgh, Pgh, PA, U.S.A. 15260, and *Institute of Experimental Medicine, Hung. Acad. Sci., Hungary.

We investigated the role of extracellular Na^+ in Ca^{2+} -independent release of GABA by measuring $[\text{H}^3]\text{GABA}$ efflux from slices of rat striatum. In a parallel series of experiments, electrophysiological activity of single striatal cells was recorded extracellularly using a corticostriatal slice preparation. In the presence of low $[\text{Na}^+]$ (27.25 mM, substituting choline Cl for NaCl) we observed that: (a) both spontaneous and electrically evoked GABA efflux increased, (b) only evoked GABA release was sensitive to TTX. In addition, in the corticostriatal slice preparation, synaptically-evoked action potentials of striatal cells gradually disappeared, but recovered upon returning to normal media. Total omission of Na^+ increased spontaneous GABA efflux more than 17-fold and blocked electrically evoked GABA release. In Ca^{2+} -free conditions (+1 mM EGTA): (a) electrically-evoked GABA efflux was enhanced in the presence of normal $[\text{Na}^+]$, but decreased in low $[\text{Na}^+]$; (b) in normal $[\text{Na}^+]$ an outburst of action potentials lasting 10-20 sec was induced, after which no spontaneous or synaptically-evoked activity was observed. This effect was prevented by Mg^{2+} (10 mM) or TTX (5 μM). Together, these results suggest that depolarization-evoked release of GABA in Ca^{2+} -free conditions can occur as a result of Na^+ influx in the absence of action potential events. Supported by NINDS (NS19608) and NIMH (MH00343).

IN VITRO PATCH CLAMP ANALYSIS OF BACLOFEN EFFECTS IN THE RAT NUCLEUS TRACTUS SOLITARIUS (NTS) - COMPARISON OF SENSITIVITY OF SYNAPTIC AND DIRECT ACTIONS. P.A. Brooks, S.R. Glaum, R.J. Miller & K.M. Spyer, Dept. Physiol. RFHSM, London & Dept. Pharmac/Physiol. Sci., U of Chicago, IL 60637, U.S.A.

Baclofen, acting at GABA_B receptors in the NTS, causes increases in blood pressure and heart rate (Florentino et al, *Brain Res.* 535:264, 1990). We have used a brainstem slice preparation to examine responsiveness of NTS neurones and spontaneous or evoked synaptic potentials/currents (PSPs/PSCs). Current or voltage clamp recordings were made in whole cell patch clamp mode with intracellular solutions containing K-gluconate and ATP. All neurones (n=75) displayed spontaneous excitatory PSPs/PSCs and in some neurones (n=43), inhibitory PSPs/PSCs were also observed. Evoked PSPs/PSCs were obtained by electrical stimulation in the region of the tractus, and had both excitatory and inhibitory components. These could be studied in isolation by perfusing bicuculline or CNQX containing solutions respectively.

Concentrations of baclofen above 2 μM caused membrane hyperpolarisation of outward currents which were insensitive to TTX and Co^{2+} and were accompanied by decreased resistance. At lower concentrations the baclofen was effective at blocking both spontaneous and evoked EPSPs and IPSPs at concentrations down to 250nM. IPSPs were more sensitive than EPSPs (ED_{50} 300vs. 750nM).

The pre- and postsynaptic effects of baclofen could be antagonised by 2-OH-Saclofen (400 μM) confirming action at the GABA_B receptor subtype. Supported by NIH XXXXX, MRC Programme Grant & Wellcome Travelling Fellowship to PAB.

C-FOS ACTIVATION REFLECTS EXTRACELLULAR DOPAMINE LEVELS IN THE RAT CAUDATE-PUTAMEN AS MEASURED BY BRAIN DIALYSIS

Carboni E.*, Morelli M., Cozzolino A.*, Pinna A.*, Tanda G.* and Di Chiara G.. Institute of Experimental Pharmacology and Toxicology, University of Cagliari, Italy.

A combined study on the extracellular concentration of dopamine (DA) measured in freely moving rats and the activation of the nuclear proto-oncogene c-fos, was performed in the rat caudate-putamen (CPU) of the same animal in order to evaluate pre and post synaptic effects of drugs influencing DA activity. MAO inhibitors, pargyline (75 mg/kg) or clorgyline (10 mg/kg) increased DA extracellular concentration by 100% and 80% over basal values, respectively. The DA uptake inhibitor GBR 12909, increased DA extracellular concentration by 150% and 400% depending on the dose used (5 and 20 mg/kg). Histochemical visualization of c-fos like-immunoreactivity in the CPU, revealed significant activation of c-fos in pargyline and clorgyline treated rats; after GBR 12909 (5 mg/kg) stronger activation was observed. After 20 mg/kg of GBR 12909, dense and numerous c-fos granuli were found all over the CPU. Blockade of D-1 receptors by SCH 23390 (0.1 mg/kg) prevented GBR 12909-induced c-fos activation although it increased extracellular levels of DA by 20 folds; the D-2 antagonist (-)-sulpiride (50 mg/kg), which increased extracellular DA levels by 50 folds, decreased but not abolished c-fos activation. The results show a good correlation between extracellular DA concentration and c-fos activation. Moreover the differential effect on c-fos activation of D-1 and D-2 receptor blockade indicates that D-1 receptor stimulation is crucial for c-fos activation while D-2 receptors play a permissive role.

POSTSYNAPTIC MECHANISMS: SIGNALING PATHWAYS

WHOLE CELL RECORDING OF SEROTONIN RESPONSES IN RAT HIPPOCAMPUS. Rodrigo Andrade, Dept. of Pharmacological and Physiological Sciences, St. Louis Univ. School of Med., St. Louis, MO 63104.

Recent implementations of the patch clamp technique have allowed for recordings in adult rats brain slices. However little is known regarding how results obtained using this technique compare with those obtained using microelectrodes. To address this issue whole cell recordings were used to examine the effects of serotonin(5-HT) in the CA1 region and to compare them to results previously obtained using microelectrodes.

Whole cell recordings were obtained from slices prepared using conventional methods. Patch pipettes contained 140 mM KMeSO₄; 5mM KCl; 2mM MgCl₂; 0.5mM EGTA; 10mM HEPES; 2mM ATP and 0.5 mM GTP and had resistances of 1.5 to 7 MΩ. Cell membrane potential and input resistance were comparable to those seen with microelectrodes.

Two distinct responses to serotonin are present in the CA1 region, a 5-HT_{1A} induced membrane hyperpolarization and a slower 5-HT₄ receptor mediated depolarization and decrease in the AHP. The 5-HT_{1A} response was readily observed in all cells tested and was stable for over 1 hr. Using this technique it could be readily demonstrated that the hyperpolarization was mediated by an inwardly rectifying potassium conductance and signalled by a G protein. In contrast the 5-HT₄ depolarizing responses were seen infrequently and the rapid wash-out of the AHP precluded repeated testing of the effects of serotonin on this afterpotential. Thus both techniques offer different advantages for studying the effects of serotonin in the hippocampus.

GABA_A AND GABA_B RECEPTORS ARE LOCALIZED AT SEPARATE SYNAPSES ON CA1 HIPPOCAMPAL PYRAMIDAL CELLS. J.M. Solis and R.A. Nicoll, Dept. Pharmacol. and Physiol., UCSF, San Francisco CA 94143.

Application of GABA evokes three responses in neurons of the hippocampal slice, hyperpolarizing GABA_A and GABA_B responses and depolarizing GABA_A responses. We have used two procedures to address the synaptic localization of these effects: 1. focal electrical stimulation in the presence of CNQX and APV and 2. nipecotic acid (NIP), an uptake inhibitor that can release cytoplasmic GABA by heteroexchange (Johnston et al., J. Neurochem. 26:83, 1976).

Focal stimulation could evoke pure monosynaptic hyperpolarizing GABA_A IPSPs from all regions of the cell. Depolarizing IPSPs were not observed. Sites were found in the dendritic region, especially s. lacunosum-moleculare, which evoked pure GABA_B IPSPs. Local application of NIP evoked responses with characteristics compatible with the activation of GABA_A and GABA_B receptors. These actions of NIP were reduced by SKF 89976A, a GABA uptake inhibitor that is not taken up, or by low Na⁺ solutions. In addition, outside-out patches responded to GABA but not to NIP. These results suggest that the responses to NIP occur indirectly from release of GABA. We have used the GABA releasing properties of NIP to examine the distribution of synaptic GABA receptors facing GABAergic terminals. Hyperpolarizing GABA_A mediated responses could be evoked from all regions of the cell. Depolarizing GABA_A mediated responses were not observed. GABA_B responses could be induced in the dendritic region, with pure responses occurring mainly in s. lacunosum-moleculare. The fact that focal stimulation and NIP can evoke pure GABA_A and GABA_B responses indicates that the receptors for these responses are segregated at some synapses. The failure to evoke depolarizing responses suggests that they are mediated by extrasynaptic GABA_A receptors.

ALKALINE EXTRACELLULAR pH SHIFTS EVOKED BY GLUTAMATE AND GABA IN RAT HIPPOCAMPAL SLICE. JCT Chen & M Chesler Depts Physiol & Biophys/Neurosurg NYU Med Ctr 550 1st Ave NY NY 10016.

Activity dependent alkaline shifts (AS) have been described in many brain regions (1) and are particularly large in hippocampus (2). We studied the pharmacologic basis of this response using pH microelectrodes in the CA1 layer of hippocampal slices. Baseline extracellular pH was 7.20±0.13 (±SD, n=54 slices). Schaffer collateral stim (20 Hz, 10s) evoked an AS of 0.052±0.031 pH units, (n=138) followed by a variable, small acidification. Local pressure ejection of glutamate (GLU) or GABA elicited a similar AS, which averaged 0.052±0.032 (n=110) and 0.073±0.035 (n=137) pH units respectively. Picrotoxin (100 μM) did not affect the stimulus or GLU evoked AS, but abolished the GABA evoked response, indicating that the latter was mediated by GABA-A receptors.

Since bicarbonate generated pH shifts depend on the dehydration of carbonic acid, we tested the sensitivity of the GABA response to inhibitors of carbonic anhydrase. Acetazolamide (1 μM) or benzolamide (0.1 μM) completely blocked the GABA evoked AS. By contrast, similar concentrations of these agents enhanced the stimulus and GLU evoked AS up to 8.5-fold. These results indicate that the GABA evoked AS shift is most likely generated via bicarbonate efflux across GABA-A anion channels, as noted in cerebellum (3). By contrast, the excitatory synaptic and GLU evoked AS are generated by a distinct, bicarbonate independent mechanism.

Transmitter dependent shifts in extracellular pH are particularly relevant in that the activity of the NMDA receptor is sensitive to pH changes in the physiological range (4). Our results suggest that both excitatory and inhibitory activity can give rise to pH changes which may modulate NMDA receptor dependent processes.

232.4

GABA_A RECEPTOR-MEDIATED SHUNTING INHIBITION OF PERFORANT PATH EXCITATORY INPUT TO DENTATE GYRUS GRANULE CELLS.

K.J. Staley and L. Mody. Dept. of Neurology & Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA.

The depolarizing postsynaptic potential elicited in granule cells by stimulation of perforant path fibres in the outer molecular layer of the dentate gyrus recorded in 400 μm hippocampal slices with the whole-cell method was increased by 55% following blockade of GABA_A receptors, despite a Cl⁻ reversal potential 20 mV positive to RMP (-85 mV). Effective shunting by GABA_A conductances of more depolarizing conductances mediated by dendritic glutamate receptors requires that GABA_A conductances have a similar time course and relatively larger amplitude than the excitatory conductances.

The compound postsynaptic conductance (PSC) was analyzed at -35 mV with Cs-gluconate electrode solutions and specific blockers of GABA_A, NMDA and nonNMDA receptors. The time course of the PSCs mediated by NMDA and GABA_A receptors were identical. The nonNMDA receptor-mediated conductance had more rapid kinetics. The ratios of peak PSCs were 8:1.5:1 for GABA_A:nonNMDA:NMDA receptors. This relationship was constant over a wide range of compound postsynaptic current amplitudes (90-400 pA). Even at the Cl⁻ reversal potential the GABA_A shunt produced a 50-100% decrease in the amplitude of excitatory currents measured at the soma.

Thus, the GABA_A receptor-mediated conductance had the characteristics necessary to shunt the glutamate-mediated PSC. The synaptically driven firing of granule cells at high stimulus intensities is due to the faster kinetics of nonNMDA vs GABA_A conductances rather than differences in input-output relationships for inhibitory and excitatory conductances. Supported by a Dana Postdoctoral Fellowship (K.J.S.) and NIH grant NS 12151 (L.M.).

232.5

GLYCINERGIC IPSC KINETICS IN THE GOLDFISH MAUTHNER CELL ARE INDEPENDENT OF GLYCINE UPTAKE. *M.J. Timus, W. Young, H. Korn, and D.S. Faber.* Dept. Physiol. SUNY, Buffalo, NY, and Pasteur Inst., Paris.

Earlier we reported that blocking Na⁺-dependent glycine uptake by replacing the extracellular Na⁺ with Li⁺, choline, or n-methylglucamine did not alter the time course of inhibitory responses evoked by the collateral network in the goldfish Mauthner (M-) cell. But it did enhance conductance changes produced by glycine iontophoresis. We have extended these studies by i) using two additional uptake blockers, p-chloromercuriphenyl sulphate and sarcosine, and ii) examining the effect of all types of blockers on inhibitory responses evoked by single and repetitive Villin stimulations to produce small, graded conductances involving few inhibitory interneurons. The falling phase of the collateral IPSC could generally be fit accurately with a single exponential function and was not significantly altered by any of the uptake blockers (at -75mV, $\tau \sim 10$ ms). IPSCs generated by Villin stimulation decayed in two phases, with a larger rapid component followed by a slower one ($\tau_{fast} = 5.7 \pm 0.9$ ms, $\tau_{slow} = 132 \pm 43$ ms, current ratio -2.8 ± 1.4 , n=5), neither being altered by any of the uptake blockers. Repetitive stimulation of the Villin (5-7 stimuli, 500Hz) produced a more complex response with a larger and longer slow decaying phase that was not significantly changed by the blockers. We conclude that high affinity uptake of glycine does not play a role in determining the time course of the inhibitory synaptic currents even after repetitive stimulations, which may cause a buildup of transmitter in the synaptic cleft. Monte Carlo simulations of quantal glycinergic synaptic responses, using a range of binding and conformational rate constants, are consistent with rapid clearance of transmitter by diffusion alone.

232.7

EXCITATION OF GABAERGIC INTERNEURONS BY ACETYLCHOLINE IN RAT HIPPOCAMPUS. *T.A. Pitler & B.E. Alger,* Dept. of Physiol., Univ. of Maryland School of Medicine, Baltimore, MD 21201.

Cholinergic agonists modulate GABAergic responses. Some reports show inhibition of GABAergic IPSPs with application of cholinergic agonists, while others suggest ACh enhances GABA release. We used intracellular recording techniques in the rat hippocampal slice to examine these apparent discrepancies.

Carbachol inhibited the evoked GABAergic IPSP, but increased picrotoxin-sensitive spontaneous membrane potential fluctuations. Using Cl⁻-containing electrodes to invert GABA_A-mediated events, we observed an atropine-sensitive increase in frequency of spontaneous IPSPs (dependent on interneuron firing) with carbachol application or stimulation of cholinergic afferents. Spontaneous IPSPs were blocked by picrotoxin or TTX. The increase in spontaneous IPSPs was not secondary to postsynaptic muscarinic actions since similar results were obtained under whole-cell voltage-clamp or when postsynaptic responses were blocked. Enhancement of spontaneous IPSPs was not blocked by CNQX and APV, ruling out indirect cholinergic excitation of interneurons by glutamatergic synapses.

We conclude that GABAergic interneurons possess muscarinic receptors, that activation of these receptors increases the excitability of interneurons and that synaptically released ACh increases interneuronal activity. Depression of the evoked IPSP by application of cholinergic agonists is presumably through the inhibition of excitatory synapses which drive interneurons.

LARGE INCREASES IN INTRACELLULAR Ca²⁺ REQUIRE POSTSYNAPTIC ACTION POTENTIALS IN HIPPOCAMPAL PYRAMIDAL NEURONS *W.N. Ross, D. Jaffe, N. Lasser-Ross, J. Lisman and D. Johnston,* Dept. of Physiology, New York Medical College, Valhalla, NY 10595, Div. of Neuroscience, Baylor College of Medicine, Houston, TX 77030, and Dept. of Biology, Brandeis Univ., Waltham, MA 02254.

A high speed CCD camera was used to measure the spatial and temporal characteristics of intracellular Ca²⁺ transients in individual hippocampal neurons injected with Fura-2. Subthreshold depolarizations produced only a small rise in Ca²⁺. Suprathreshold depolarizations, which evoked trains of action potentials (APs), produced large (10-fold higher) changes in [Ca²⁺]_i. In the same neurons, we studied the Ca²⁺ elevation produced by tetanic synaptic stimulation (50-100Hz). This produced large Ca²⁺ transients only when the postsynaptic depolarization was sufficient to evoke APs. The increase in Ca²⁺ concentration was correlated with APs rather than with the period of the tetanus. If APs were abolished by reducing the stimulus strength or hyperpolarizing the cell, the Ca²⁺ changes were about 10-fold smaller. Since Ca²⁺ entry produced by tetanic stimulation in the absence of APs was small, we studied a larger synaptic event, the paroxysmal depolarizing shift (PDS), after addition of picrotoxin. Even during these large synaptic events, Ca²⁺ changes were about 4-fold smaller when the PDS did not elicit APs. Generally, results in CA3 and CA1 cells were similar. These results suggest that Ca²⁺ transients resulting from activation of voltage-gated Ca²⁺ channels are driven primarily by Na⁺ spikes (see also Jaffe et al., this volume). Furthermore, these results demonstrate that suprathreshold synaptic stimulation is required to produce significant Ca²⁺ changes, consistent with a literal Hebbian mechanism of synaptic potentiation. (NS16295, MH09996, and MH44754)

232.6

ADENOSINE MAY LIMIT ACTIVATING BRAINSTEM INFLUENCES IN GENICULOCORTICAL NEURONS THROUGH TWO IONIC MECHANISMS *H.C. Pape.* Abt. Neurophysiologie, Ruhr- Univ., D-4630 Bochum, Germany

Adenosine (Ado) is considered as part of a negative feedback system which modulates neuronal activity depending upon the available energy. Local application of Ado (2-5 mM) to relay neurons in the guinea pig dorsal lateral geniculate nucleus (LGNd), maintained *in vitro* as slices, elicited a membrane hyperpolarization associated with an increase in potassium (K⁺) conductance. The K⁺ currents induced by activation of Ado and GABA_B receptors were non-additive. Blockage of K⁺ currents through barium unmasked an Ado evoked decrease in input conductance associated with a 1-2 mV hyperpolarization from -60 mV. The response was highly voltage dependent, appeared as an outward current negative to -66 mV, and was due to a reduction of the hyperpolarization activated cation current, I_h, whose amplitude and rate of rise were decreased by Ado. The adenylyl cyclase (AC) inhibitor 2',3'-dideoxyAdo (100 μM) limited the decrease in I_h, while the AC stimulant forskolin (25 μM) increased I_h. The increase in K⁺ conductance and the decrease in I_h were mimicked by agonists (CPA, CHA; 50-300 μM) and blocked by an antagonist (DPCPX; 1-10 μM) selective for the A₁ receptor subtype.

While activity of the brainstem system is capable in the thalamus to create a state which is conducive of wakefulness (Steriade & Llinás, *Physiol.Rev.*, 68: 649, 1988), the metabolic state of LGNd relay neurons may limit their responsiveness to brainstem inputs. An increased level of Ado inhibits single spike firing and promotes burst activity through a membrane hyperpolarization due to an increased K⁺ conductance. The additional decrease in I_h directly inhibits the dampening influence of monoaminergic receptor activation on rebound burst oscillations.

232.8

ACTIVITY-DEPENDENT DEPRESSION OF GABAERGIC IPSCS IN RAT HIPPOCAMPUS. *D.S.F. Ling and L.S. Benardo.* Dept. of Pharmacology, SUNY-HSCB, Brooklyn, NY 11203.

Synaptic inhibition in hippocampal neurons consists of two distinct components: a fast inhibitory postsynaptic potential (IPSP) mediated by GABA_A receptors and a slow IPSP mediated by GABA_B receptors. Both of these inhibitory events appear vulnerable to activity-dependent depression since repetitive stimulation significantly reduces their amplitudes. To evaluate this in more detail, synaptic currents were recorded in CA1 pyramidal cells using whole-cell techniques in thick (400 μM) rat hippocampal slices (Blanton et al., *J. Neurosci. Meth.*, 30: 203, 1989). These cells had resting membrane potentials greater than -55 mV and input resistances >150 MΩ. Orthodromic stimulation of stratum radiatum evoked a fast EPSC followed by a fast and a slow IPSC. Stimulus frequencies >0.1 Hz seemed to reduce slow IPSCs, while fast IPSCs appeared depressed at frequencies >1-3 Hz. Precise determination of the degree of depression was limited due to temporal overlap of currents. Application of excitatory amino acid antagonists CPP and CNQX (10 μM) allowed IPSCs to be viewed in isolation, but was insufficient to quantitatively define the activity-dependent reduction of each component of inhibition. Subsequent blockade of GABA_B currents with intracellular cesium allowed examination of the remaining fast IPSC, while bath application of picrotoxin blocked GABA_B events, isolating slow IPSCs, thereby permitting unambiguous assessment of depression of the respective IPSC components.

232.10

THE DISTRIBUTION OF DENDRITIC CALCIUM ENTRY PRODUCED BY ACTION POTENTIALS IN A MODEL HIPPOCAMPAL CA3 NEURON. *D.B. Jaffe, W.N. Ross, and D. Johnston,* Div. of Neurosci., Baylor College of Medicine, Houston, TX 77030 and Dept. of Physiology, New York Medical College, Valhalla, NY 10595.

Action potentials (APs) produce large transient increases in [Ca²⁺]_i in the proximal dendrites of hippocampal pyramidal neurons. Smaller Ca²⁺ transients are observed in the soma and distal processes (Regehr et al., 1989 and Ross et al., this volume). The distribution of the Ca²⁺ transients described above may be accounted for by a low density of Ca²⁺ channels in distal processes or by attenuation of Na⁺-dependent APs propagating into distal dendrites. A computational model of a CA3 pyramidal neuron constructed using CABLE (Hines, 1989) was used to model Ca²⁺ transients produced by activation of voltage-gated Ca²⁺ channels in response to EPSPs or trains of APs. Free parameters were adjusted to produce repetitive, overshooting APs in response to a depolarizing current step. Two distributions of Na⁺ and Ca²⁺ channels were considered. The first was a uniform Na⁺ channel density in all compartments and a Ca²⁺ channel density reduced by 90% in distal dendrites. In the second, the Ca²⁺ channel density was uniform while the Na⁺ channel density was restricted to the soma and proximal dendrites. Both models qualitatively reproduced the dendritic distribution of Ca²⁺ transients. In addition, subthreshold depolarizations, evoked intrasomatically or synaptically produced small Ca²⁺ transients in all dendritic compartments. The model suggests that the distribution of Ca²⁺ transients measured in the imaging experiments could be explained not only by a gradient of Ca²⁺ channel density, but also by attenuation of APs propagating to distal dendrites. (NS16295, MH09996, and MH44754).

CALCIUM-DEPENDENT SLOW AFTER-DEPOLARIZATION IN RAT LOCUS COERULEUS NEURONS. S.S. Osmanović and S.A. Shefner. Dept. Patho-Physiology, Med. Faculty Belgrade, Yugoslavia and Dept. Physiology and Biophysics, University of Illinois, College of Medicine. Chicago, IL 60612.

Intracellular recordings were made from rat locus coeruleus (LC) neurons in a totally submerged brain slice preparation. We have previously reported that trains of action potentials in LC neurons elicit a long-lasting, biphasic, post-stimulus hyperpolarization (PSH) mediated by two different Ca^{2+} -activated K^+ conductances. In the present experiments, reduction of PSH with externally applied Ba^{2+} or TEA, unmasked a large, slow depolarization following a train of action potentials in all cells tested ($n=20$). In order to elicit this after-depolarizing potential (ADP), the current stimulus had to exceed a certain threshold level. The ADP lasted for up to several minutes, during which time neuronal excitability was increased, resulting in prolonged high frequency firing. The ADP was associated with an increase in conductance. A single-electrode voltage clamp circuit was used to record the current underlying the ADP. The reversal potential of this current was -48 mV ($n=4$) and did not change when the intracellular Cl concentration was altered. The ADP was not affected by $1 \mu M$ tetrodotoxin, but was inhibited by the Ca^{2+} channel blocker Cd^{2+} ($200 \mu M$). Intracellular injection of the Ca^{2+} chelating agent EGTA depressed ADP. These data suggest that in LC neurons, Ca^{2+} influx during an action potential train can activate a slow inward current which may be similar to the Ca^{2+} -activated nonspecific cation current which has been described in other preparations. Grant Support: AA-5846.

EXPERIENCE-DEPENDENT REGULATION OF PROTEIN KINASE C ACTIVITY IN THE OLFACTORY BULB AND STRIATE CORTEX OF DEVELOPING RATS. S. Elkabes*, L.A. Cherry, A.A. Schoups and I.B. Black. Dept. Neuroscience and Cell Biology, UMDNJ / Robert Wood Johnson Medical School, Piscataway, NJ, 08854.

Transduction of environmental signals into neuronal information involves complex processes mediated by regulatory molecules. Protein Kinase C (PKC) is one such molecule that has been implicated in mechanisms underlying synaptic function.

As a first approach in elucidating its role in synaptic plasticity during development, we have studied experience-induced alterations in PKC activity in the rat olfactory bulb by neonatal, unilateral odor deprivation and in the developing striate cortex by visual deprivation.

PKC associated with soluble and particulate fractions of olfactory bulb or striate cortex homogenates was partially purified by DEAE-cellulose chromatography. Activity was measured by incorporation of ^{32}P from $[\gamma\text{-}^{32}P]ATP$ into Histone H1 (type III-S) in the presence or absence of Ca^{2+} , phosphatidylserine and diolien. Our studies indicate that soluble and membrane-bound PKC activity is gradually decreased 21 and 50 days following neonatal closure of one naris by cauterization. In addition, preliminary results suggest that PKC activity in striate cortex of rats reared in complete darkness for four weeks following birth is also decreased. These findings raise the possibility that experience-dependent regulation of PKC activity is similar in different brain regions during development.

G-PROTEINS IN DIABETIC ENCEPHALOPATHY: MOLECULAR MECHANISMS UNDERLYING THE FUNCTIONAL ALTERATIONS. A.M. Di Giulio, C. Finco*, M.L. Malosio*, M.P. Abbracchio, B. Paternieri*, F. Cattabeni, P. Mantegazza and A. Gorio. Dept. of Medical Pharmacology, Univ. of Milano, v. Vanvitelli 32, 20129 Milano, Italy.

We have previously shown that 5 and 14 weeks after diabetes induction by a single s.c. injection of alloxan (100 mg/kg), there is a progressive functional reduction of the Gi/o system in the rat striatum. ADP-ribosylation experiments of striatal pertussis toxin sensitive Gi/o subunits have indicated that 14 weeks following diabetes induction there is a 50% reduction of ^{32}P incorporation. To test whether these data could be explained by a reduced Gi/o protein synthesis, we performed Western and Northern blotting experiments. The Western blotting analysis indicates that the amounts of Gi, Go and Gs proteins are apparently unchanged in diabetic animals. The mRNA analysis indicates that the expression of Gi and Gs is apparently normal in diabetic animals, whereas the 5.7 kb transcript of Go shows a 30% reduction in diabetic animals 14 weeks after the induction of diabetes. These data would suggest a specific alteration of the Go system in diabetic encephalopathy.

232.12

EXTRACELLULAR CALCIUM IS NEEDED FOR POSTSYNAPTIC INDUCTION OF LONG-TERM DEPRESSION (LTD) AT CA1 SYNAPSES IN RAT HIPPOCAMPAL SLICES. G. Christoff*, A. Nowicky*, S. Bolsover* & L. Bindman. Dept. of Physiology, University College London, London WC1E 6BT, U.K.

Long-term depression of EPSPs evoked by stratum radiatum stimulation at 0.1 Hz can be induced postsynaptically, by antidromic conditioning trains (6 at 100 Hz for 0.5 s every 10 s) applied to CA1 axons in slices *in vitro*, either in normal bathing medium or in one containing high $[Mg^{2+}]$ to reversibly block all synaptic activity during conditioning (Pockett et al., 1990, Exp. Brain Res. 80, 196-200).

To test whether Ca^{2+} entry was required for postsynaptic induction of LTD, we repeated the experiments in a bathing medium with high $[Mg^{2+}]$ and either 2 mM Ca^{2+} or 0 Ca^{2+} . LTD of the depolarizing slope of the EPSPs was obtained in the presence of extracellular Ca^{2+} (mean EPSP slope $52.6\% \pm 11.4\%$ SEM of its control at 30 min post-conditioning, $n=7$) but not in 0 Ca^{2+} (mean EPSP slope $102.7\% \pm 2.8\%$ of its control at 30 min postconditioning, $n=6$) establishing that extracellular Ca^{2+} is needed for induction of LTD. Postsynaptic Ca^{2+} entry during depolarization persisted in high Mg^{2+} solutions, as shown by FURA2 measurements in organotypic slices.

BIOCHEMICAL PROBES THAT REVEAL RECEPTOR-G PROTEIN COUPLING. M. Diversé-Pierluissi*, M.F. Gov*, and K. Dunlap. Physiology Departments, Tufts Medical School, Boston, MA 02111 and *Univ. of North Carolina, Chapel Hill, NC 27599-7545.

Norepinephrine (NE) and GABA inhibit voltage-dependent calcium channels in dorsal root ganglion (DRG) neurons. Distinct receptors mediate the inhibition and activate pertussis toxin (PTX)-sensitive G proteins. To determine whether the two receptors share a common G protein, we have developed methods for specifically labeling receptor-coupled pools of G protein. In one approach, DRG neurons are preincubated with PTX, with or without the transmitter(s). When present, the transmitter activates (dissociates) those G proteins that transduce the stimulus, thereby protecting them from ADP-ribosylation by the toxin. Following preincubation, transmitter is removed and membranes prepared and exposed to activated toxin with a radioactive ADP-ribosylation substrate. We find: 1) In the absence of transmitter, a 2 hour preincubation with PTX reduces the substrate available for labeling by $>80\%$. 2) Inclusion of either NE or GABA increases the available substrate by >7 fold; we believe that those G proteins protected by the transmitter during the preincubation period are now available to incorporate radioactivity. 3) Specific receptor agonists and antagonists demonstrate that the protection displays the appropriate NE and GABA receptor pharmacology. 4) NE and GABA protect more than a single G protein substrate, suggesting that a given receptor interacts with more than one G protein. 5) The two transmitters appear to protect the same substrates, implying that individual (or highly similar) G protein subtypes can interact with more than one receptor *in vivo*.

232.16

SOME CHARACTERISTICS OF G-PROTEIN COUPLING BETWEEN RECEPTORS AND POTASSIUM CONDUCTANCE OF THE LATE IPSP. R.H. Thalmann and M.I. Al-Dahan* Baylor College of Medicine, Houston, TX 77030.

In some dorsal root ganglion neurons, pertussis toxin (PTX) blocks the ability of $GTP\gamma S$ to promote functional coupling between G-proteins and their effector channels. We examined the generality of this phenomenon to potassium (K) channels of the late IPSC in hippocampal CA3 pyramidal neurons. After gigohm seals were established in slices from one month old rats, whole cell current underlying the late IPSP, the late IPSC, was recorded via pipettes containing gluconate as the major anion, and calcium buffered to 100 nM. Artificial CSF at $32^\circ C$ was drawn over both sides of the slices via nylon meshes. Following a pulse ($50V$, $50\mu sec$) delivered to the mossy fiber pathway, the late IPSC peaked at 200 mSec and 75 ± 25 pA (holding potential = -60 mV). $GTP\gamma S$ (0.5 - 1.0 mM) in the recording pipette activated an outward current of 50 - 100 pA, after which the late IPSC could no longer be elicited. Intra-hippocampal injection of $2 \mu g$ PTX 3 days prior to recording blocked the late IPSC. Surprisingly, specific 3H -baclofen binding was reduced by only 18% , and $G\alpha 01$, $G\alpha 02$, and $G\alpha i$ were only partially ADP-ribosylated (ADP-ribosylation assay performed by Juan Codina). These PTX injections did not block the activation of outward current by $GTP\gamma S$. Thus, PTX did not block the ability of $GTP\gamma S$ to promote G-protein coupling with the K channels of the late IPSC. Supported by NIH grant NS-21713.

DOPAMINE ENHANCES BOTH ELECTROTONIC COUPLING AND CHEMICAL EPSP AT MIXED SYNAPSES ON THE MAUTHNER (M) CELL.

A. Pereda, A. Triller, H. Korn and D. S. Faber. *Neurobiology Lab., Dept. Physiology, SUNY-Buffalo, Buffalo NY 14214, USA, and Lab. Cellular Neurobiologie, Dept. Biotechnologies, Institut Pasteur, Paris, France.*

Previous work has shown that intracellular injections of cAMP and the catalytic sub-unit of cAMP-dependent protein kinase into the M-cell lateral dendrite enhanced both the electrotonic coupling potential and the chemical glutamatergic component of the mixed EPSP evoked by stimulating the posterior eighth nerve. Dopamine is generally believed to act through mechanisms that involve cAMP as a second messenger. Dopaminergic innervation of the M-cell was demonstrated by using a polyclonal anti-dopamine revealed with an avidine biotine complex (ABC) immunoperoxidase method and confirmed with an anti-tyrosine hydroxylase. Near the distal part of the lateral dendrite, immunoreactive fibers meander between the large myelinated club endings of the eighth nerve. As determined with electron microscopy, they contain some small vesicles, and they never establish synaptic contact with the M-cell, remaining in its synaptic bed, at a distance from its plasma membrane. Extracellular pressure-application of dopamine (10 mM in a vehicle solution of 130 mM NaCl, 10 mM Hepes and 1mM Ascorbic Acid) produced enhancements of both components of the mixed EPSP, which averaged 28.7% (range: 7.6 to 44.2) for coupling and 36.6% (range: 13.1 to 85.7) for the chemical component (n=10). Resting potential remained unchanged and antidromic spike height (a measure of M-cell input resistance) decreased, the average change being -6.3%. Following post-synaptic injections of the protein kinase inhibitor (Walsh), dopamine applications did not produce any enhancement of either component of the synaptic response, implicating a post-synaptic site of action. These results suggest that dopamine modulates this synaptic input via the cAMP second messenger system of the M-cell.

ACETYLCHOLINE RECEPTORS: MUSCARINIC II

233.1

MUSCARINE INCREASES CATION CONDUCTANCE AND DECREASES POTASSIUM CONDUCTANCE OF RAT LOCUS COERULEUS NEURONS IN VITRO. K.-Z. Shen and R.A. North. Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

Whole-cell patch clamp recordings were made from locus coeruleus neurons in rat brain slices. Muscarine (30 μ M) evoked an inward current at -60 mV, which was usually associated with a decrease in membrane conductance of some cells. This current persisted in TTX (1 μ M) and cadmium (200 - 300 μ M), and in solutions that were magnesium-free, low (14 mM) in chloride, calcium-free and high (10 mM) in magnesium; it was reduced by 78.4 \pm 2.7 % in solution containing low (20 mM) sodium concentration. In control conditions, the muscarine induced current often showed two reversals, at about 0 mV and at a potential tens of millivolts negative to E_K (about -100 mV). When sodium was substituted by Tris, the reversal potential was close to E_K , and the current was blocked by barium (100 μ M) and cesium (3 mM). When cesium replaced potassium in pipets and external solution, the muscarine current became linearly dependent on potential and reversed at 10 mV. The results indicate that muscarine produces an inward current by decreasing potassium conductance and by increasing cation conductance.

ACETYLCHOLINE-ACTIVATED SINGLE CHANNEL CURRENTS IN CULTURED APLYSIA NEURONS. M. Fejtli and D. O. Carpenter. Wadsworth Laboratories and School of Public Health, Albany, NY 12201.

Acetylcholine (ACh) activates Na⁺, K⁺ and Cl⁻ currents, all of which show desensitization. To reveal the underlying ion channel behavior responsible for that decay, we employed the single channel patch clamp technique on cultured *Aplysia* neurons. Ganglia from juvenile *Aplysia* were dissected and the isolated neurons plated on poly-L-lysine coated cover slips. Cell-attached patches were obtained with electrodes pulled from borosilicate glass and filled with artificial sea water containing either 0.5 μ M ACh or 5 μ M ACh.

We successfully recorded outward currents while holding the pipette potential between -10 and -150 mV. We never observed single channel events by hyperpolarizing the cell. Some patches showed openings at 0 mV, whereas the remainder showed openings at -40 mV or even lower. This may reflect the difference between K⁺ and Cl⁻ currents, but the reason for the lack of inward currents caused by positive pipette potentials is unclear. Outward currents were in the range from 1 pA to 5 pA and the slope conductance was about 60 pS. With increasing the hyperpolarization 2 or 3 channels opened simultaneously, independent of the agonist concentration used. We obtained 2 patches from the same cell with 0.5 μ M ACh and 5 μ M ACh, respectively. The 5 μ M patch showed higher unitary currents than the 0.5 μ M patch, but only in the range from -40 mV to -60 mV. Open time and closed time histograms could be best fitted with a double and single exponential probability density function, respectively. Since we recorded in steady state (the patches lasted between 5 and 10 minutes), non-desensitizing concentration of ACh must be used to provide sufficient channel openings. We observed bursts and long closed periods even with 0.5 μ M ACh. Thus, the long closed periods reflect a desensitized state and lower agonist concentration is necessary to study non-desensitizing channel behavior.

Heterogeneity of Muscarinic Depolarizations in Guinea Pig Celiac Neurons in Primary Culture. J.S. Coggan, S.L. Purnyn* and D.L. Kreulen. Department of Pharmacology, University of Arizona Coll. of Med., Tucson, AZ, 85724.

Voltage and current responses induced by muscarinic agonists were examined in celiac ganglion neurons in primary culture. Muscarinic agonists induced a depolarization which in 80% of cells was associated with only an increase (30%) in input resistance and in 20% of the cells was associated with an initial increase followed by a decrease (36%) in input resistance. The order of potency of agonists (900 ms application) used was ACh > oxotremorine-M > muscarine. During current clamp, muscarine (100 μ M) increased the tendency of cells to fire repetitively and this effect was blocked by atropine (1 μ M). Under whole cell voltage clamp, muscarine (1.5 sec application) induced inward currents with latency of less than 100 ms and durations of 20 - 30 s. Amplitudes of these currents diminished with hyperpolarization and disappeared near -65 mV, without evidence of reversal. Maximal responses occurred at 500 μ M with an EC50 of 60 μ M. In 27% of cells examined, muscarine also induced a longer latency, slower inward current of a time-course similar to the secondary changes in input resistance observed with current clamp. Support:HL27781.

OOCTE EXPRESSION OF ACETYLCHOLINE-INDUCED INWARD CURRENTS FROM PHYLOGENETICALLY PRIMITIVE METAZOANS. Ian G. Welstord. Dept of Biology Bradley Univ., Peoria, IL 61625.

As a prelude to the molecular characterization of AChRs from divergent animal phyla, studies were undertaken to begin to characterize the physiological and pharmacological profiles of ACh-induced currents expressed in *Xenopus laevis* oocytes injected with total cellular RNA isolated from CNS tissue of the coelenterate, *Cyanea*, the annelid, *Nereis*, and the echinoderm, *Asteris*. The ACh-induced inward currents from each organism ranged from 50 to 250 nA and had linear I-V curves over the range of holding voltages between -100 and +10 mV. The sensitivity of each current to curare and alpha bungarotoxin was tested at holding potentials ranging from -100 to -20 mV. The currents from both *Asteris* and *Nereis* exhibited very similar sensitivities to alpha bungarotoxin (20 \pm 5% decrease over control current levels for *Nereis* and 35 \pm 8 % decrease in *Asteris*; mean \pm SEM, n=5 oocytes) at all holding voltages tested. In contrast, *Cyanea* demonstrated marked voltage-dependence of blockade with alpha bungarotoxin, showing significant blockade at -80 mV (60 \pm 7 % decrease over controls), no blockade at -60 mV (8 \pm 5% decrease) and mild augmentation of inward current (20 \pm 10% increase) at +20 mV. *Cyanea* currents were relatively insensitive to curare at all holding potentials tested (range 27 -19 % decrease over controls) while currents from *Nereis* and *Asteris* demonstrated marked voltage-dependence to curare blockade. Currents from both organisms were insensitive to curare at -80 mV (0-5 % decrease) but blockade steadily increased at more positive holding potentials, reaching a maximal value at -20 mV (48 \pm 10 % decrease in *Asteris* and 53 \pm 6 % decrease in *Nereis*). ROLE OF RECEPTOR RESERVE IN THE DETERMINATION OF AGONIST/ANTAGONIST SUBTYPE SELECTIVITY IN CHO CELLS EXPRESSING HUMAN MUSCARINIC RECEPTORS (m1-m5). R.D. Schwarz, D.K. Boyd, C.J. Spencer*, and G.L. Woodward*. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI, 48105.

Molecular characterization of muscarinic receptors based upon cloning, sequencing, and expression studies has shown that there are five subtypes of receptors (m1-m5). Recently, each subtype of human receptor has been stably expressed in CHO cells (Bonner and Brann, NIH). Using whole cell [³H]-N-methyl-scopolamine (NMS) binding in these cells, the five subtypes were found to have K_d values of 0.11 - 0.63nM and B_{max} values ranging from 210 - 2450 fmoles/mg protein. Displacement of [³H]-NMS by known muscarinic agonists showed that none were truly subtype selective. For antagonists, pirenzepine, methoctramine, and hexahydro-sila-difenidol showed selectivity for m1, m2, and m3 respectively. To correlate the binding with functional activity, phosphatidylinositol (PI) turnover (m1, m3 m5) and adenylate cyclase activity (m2, m4) were measured. However, it was found that agonist potency and efficacy were markedly affected by differences in total receptor number among the subtypes, while antagonist results were not. For example, in PI turnover, alkylation of 90% of m1 receptors with propylbenzyl choline mustard rightshifted the EC₅₀ for carbachol from 1.6μM to 109.6μM and decreased production of total [³H]-inositol phosphates by almost 80%. Thus, differential receptor reserve must be taken into account when using functional measures to determine subtype selectivity.

233.7

MUSCARINIC RECEPTORS IN LOCUST GANGLIA ARE COUPLED TO PHOSPHATIDYL INOSITOL TURNOVER AND TO ADENYLATE CYCLASE. S. Qazi* and G. G. Lunt. Department of Biochemistry, University of Bath, Bath, BA2 7AY, U.K.

We have previously obtained preliminary evidence that muscarinic receptors in the supraoesophageal ganglion of the desert locust (*Schistocerca gregaria*) are coupled to phosphatidyl inositol turnover and to adenylate cyclase. We have extended these studies and have shown the incorporation of [³H]inositol into inositol phosphates, particularly IP₃. The incorporation is enhanced by carbachol and a further enhancement is seen in the presence of Li⁺ (10mM). The stimulated incorporation is blocked by atropine. Pilocarpine is more effective than carbachol in the stimulation experiments. In the same tissue a carbachol inhibition of adenylate cyclase activity is seen that is reversed by atropine. Both pilocarpine and oxotremorine are more effective inhibitors than carbachol. Examination of the effects of a wide range of muscarinic agonists and antagonists suggests that the pharmacological profile of the locust cyclase-coupled muscarinic receptor is different from the well-characterised mammalian receptor classes.

We are grateful to ICI Plant Protection Division and the SERC for support.

233.9

MUSCARINIC RECEPTORS COUPLED TO IP₃ IN ACUTELY DISSOCIATED HIPPOCAMPUS CA1 NEURONS OF RAT. T. Nakaye*, M. Wakamori*, N. Harata*, H. Uneyama*, Y. Kataoka* and N. Akaike. Dept. of Neurophysiology, Tohoku Univ. Sch. of Med., Sendai 980. *Dept. of Pharmacology, Nagasaki Univ. Fac. of Med., Nagasaki 852, Japan.

There are a few reports that ACh hyperpolarized CA1 neurons followed by the depolarization in mammalian hippocampus slice preparation. In this study, we investigated intracellular mechanisms of the controversial ACh responses in pyramidal neurons dissociated from rat hippocampus CA1 region. ACh evoked hyperpolarization under current-clamp condition and outward current (I_{KACH}) at a holding potential of -60 mV under "perforated" patch-clamp. Muscarine played as ACh agonist, and I_{KACH} was inhibited more preferentially by pirenzepine than by AF-DX-116. Fura-2 fluorometric measurement showed that ACh increased the intracellular Ca²⁺ concentration ([Ca²⁺]_i) even in Ca²⁺ free extracellular solution. Cholera toxin and pertussis toxin had no effect on I_{KACH}. Calmodulin antagonists (W-7, chlorpromazine, trifluoperazine) inhibited I_{KACH} in a concentration-dependent manner, whereas a protein kinase inhibitor (H-7) had no effect on it.

These observations suggested us following intracellular pathway of ACh response mediated by M1 receptor. Phospholipase C is activated by G_i, and inositol trisphosphate (IP₃) releases Ca²⁺ from intracellular stores. This free Ca²⁺ activates calmodulin kinase followed by protein phosphorylation and K channel opening.

233.6

IDENTIFICATION OF THE MUSCARINIC RECEPTOR SUBTYPE STIMULATING ADENYLATE CYCLASE ACTIVITY IN RAT OLFACTORY BULB. M.C. Olanas and P. Onali, Dept. of Neurosciences, University of Cagliari, Italy.

The pharmacological profile of the muscarinic stimulation of adenylate cyclase (a.c.) activity in rat olfactory bulb (o.b.) was investigated by using antagonists selective for the different muscarinic receptor subtypes. The potency of the compounds in antagonizing the acetylcholine (ACh) inhibition of a.c. in rat striatum and heart were also determined under similar conditions. Schild analysis showed that the ACh stimulation of a.c. was counteracted with high affinity by both the M2 antagonists methoctramine (pA₂ = 8.08) and AF-DX 116 (6.84) and the M3 antagonists 4-DAMP (8.30), hexahydro-sila-difenidol (7.21) and p-fluoro-hexahydro-sila-difenidol (7.13). The M1 antagonist pirenzepine exhibited the lowest potency (6.45). In striatum, ACh inhibition of a.c. was blocked by the M3 antagonists more potently than the M2 antagonists, whereas in the heart the opposite was observed. These data indicate that, whereas the striatal and cardiac inhibitory receptors can be classified as M3 and M2, respectively, the stimulatory receptors of o.b. show a pharmacological profile different from that typical of either the M1, M2 or M3 subtype.

233.8

ACTIVATION OF MUSCARINIC RECEPTORS INDUCES BOTH INOSITOL PHOSPHATE FORMATION AND Ca²⁺ UPTAKE IN PORCINE ADRENAL CHROMAFFIN CELLS. Y. Xu and E. J. Forsberg. Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

Activation of muscarinic receptors on porcine adrenal chromaffin cells evokes the secretion of catecholamines and ATP, and also evokes an increase in intracellular free Ca²⁺ ([Ca²⁺]_i) in a manner largely dependent on extracellular Ca²⁺. In contrast to secretion induced by nicotine and high K⁺, which is inhibited by nifedipine in a dose dependent fashion in the range of 0.1 to 10 μM, secretion induced by a muscarinic agonist, methacholine, can not be blocked by nifedipine in the same concentration range. These results indicate that muscarinic responses, unlike responses induced by nicotine and high K⁺, are not mediated by L-type voltage-gated Ca²⁺ channels. Moreover, unlike nicotine-induced responses, methacholine-induced responses are not blocked by prior depolarization of the cells, again suggesting that voltage-gated Ca²⁺ channels are not involved (Xu, Duarte and Forsberg, J. Neurochem., in press). Methacholine (0.5 mM) induced an increase in Ca²⁺ uptake by 2 fold and also activated Mn²⁺ uptake as measured in fura-2 loaded cells. The effect of methacholine on inositol phosphate formation was also examined. Methacholine at 0.5 mM induced a rapid increase in inositol 1,4,5-trisphosphate (I(1,4,5)P₃) by a factor of about 2. It also caused an increased production of IP₃ and I(1,3,4)P₃. These findings strongly support the hypothesis that predominantly Ca²⁺ influx but also the release of Ca²⁺ from internal Ca²⁺ stores contribute to the secretion and [Ca²⁺]_i signals induced by activation of muscarinic receptors.

233.10

USE OF M₁/M₂ CHIMERIC MUSCARINIC RECEPTORS FOR THE DELINEATION OF STRUCTURAL DOMAINS INVOLVED IN LIGAND SELECTIVITY AND FUNCTIONAL REGULATION. J. Lai, S.W. Ma*, S. Waite*, L. Nunan*, J.W. Bloom*, H.I. Yamamura and W.R. Roeske. Departments of Pharmacology and Internal Medicine, University of Arizona, Tucson, AZ 85724.

Several chimeric M₁/M₂ muscarinic receptors were expressed in murine fibroblasts (B82) transfected with various recombinant murine m1/m2 genes. These chimeric receptors and the native M₁ and M₂ receptors all have similar affinities for non-selective ligands such as [³H](-)JMQNB (K_d=358-519 pM) and atropine (K_i=0.51-0.99 nM). The binding properties of a number of agonists and selective antagonists to these receptors were analyzed. Preliminary data based on the binding studies of pirenzepine and AF-DX 116 suggest that the high affinity, selective binding of AF-DX 116 to the M₂ receptors may reside between the 1st and 4th transmembrane domains whereas that for pirenzepine to the M₁ receptors may reside between the 4th and 6th transmembrane domains. The latter region also modulates the binding of the agonist carbachol (CCh). When this region is derived from the M₁ receptors, the agonist exhibits multiple affinity states (K_H=2.5 μM; K_L=53.6 μM). A single affinity state for the agonist is observed, however, when the same region is derived from the M₂ receptors (K_i=6 μM). Substitution of the N terminal to 4th transmembrane domain of the M₁ receptors with that of the M₂ receptors reduces the potency (7 fold) and efficacy (3 fold) of CCh in inducing inositol lipid (PI) hydrolysis but enhances CCh induced cAMP formation (7 times that of the M₁ receptors at 1 mM CCh). This may suggest that the M₁ receptor mediated cAMP production is not entirely a secondary effect of PI hydrolysis mediated by the receptor. Supported in part by AHA, NHLBI and NIMH.

233.11

ASYMMETRY IN THE ALLOSTERIC INTERACTIONS BETWEEN AGONISTS AND GUANYL NUCLEOTIDES AT CARDIAC MUSCARINIC RECEPTORS. P. Chidiac* and J.W. Wells. Department of Pharmacology and Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada M5S 1A1

The muscarinic agonist carbachol and the guanyl nucleotides GDP, guanosine-5'-O-(3-thiotriphosphate) (GTP γ S), and guanylyl imidodiphosphate (GNP-PNP) were studied for their effects on the binding of N-[³H]methylscopolamine ([³H]NMS) and [³⁵S]GTP γ S to highly washed left ventricular membranes from Syrian hamsters. The specific binding of 1 nM [³H]NMS was inhibited by carbachol to yield Hill coefficients less than one. An overall decrease in the affinity of the agonist was observed in response to each nucleotide. The specific binding of 160 pM [³⁵S]GTP γ S similarly was inhibited by the unlabeled nucleotides to yield Hill coefficients less than one. An overall decrease in the affinity of GDP was observed in response to carbachol, which had no effect on the binding of either GMP-PNP or GTP γ S. The allosteric interaction between agonist and guanyl nucleotide at receptors linked to G proteins commonly is rationalized in terms of an equilibrium between free receptors (R) and free G proteins (G) and an RG complex. The model predicts that the effect of an agonist on the binding of a nucleotide to the relevant G protein will mirror the effect of the nucleotide on the binding of the agonist to its receptor. The asymmetry inherent in the failure of carbachol to perturb the binding of GTP γ S and GMP-PNP suggests that the dispersion of affinities revealed in binding of carbachol and guanyl nucleotides does not reflect the coexistence of coupled and uncoupled receptors and G proteins.

233.13

ALLOSTERIC MODULATION OF MUSCARINIC RECEPTORS BY PROTAMINE. J. Hu*, S.-Z. Wang*, C. Forray and E.E. El-Fakahany. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

A large number of diverse pharmacological agents bind to a secondary domain on the muscarinic receptor to allosterically influence the interaction of ligands at the primary binding site. Based on common structural features of these antagonists we examined the interaction of protamine, an endogenous polycationic peptide and polyamines with muscarinic receptors in rat heart. Our results provide several lines of evidence that protamine allosterically modulates the conformation of muscarinic receptors in a marked negative cooperative manner. It decelerated the dissociation of [³H]NMS in a concentration-dependent manner, with a 50% inhibition of ligand dissociation at 20.2 ± 5.3 μ g/ml. Inhibition of [³H]NMS binding by protamine at equilibrium showed a distinct plateau which increased in magnitude at higher ligand concentrations. Scatchard analysis of saturation isotherms of [³H]NMS binding indicated that protamine did not alter maximal ligand binding. However, it decreased the affinity of [³H]NMS in a concentration-dependent manner, but with a ceiling effect. This allosteric effect of protamine is selective for muscarinic m2 receptors as compared in Chinese hamster ovary cells transfected with the muscarinic m1, m2, m3 and m4 genes. Arginine residues play an important role in this allosteric interaction. No effects of polyamines were observed on [³H]NMS binding. This is the first report on the allosteric modulation of a G-protein-coupled receptor by an endogenous peptide.

SINGLE CHANNEL CURRENTS ACTIVATED BY PHYSOSTIGMINE (PHY) IN HIPPOCAMPAL NEURONS ARE BLOCKED BY BENZOQUINONIUM (BZQ) BUT NOT BY METHYLLYCAONITINE (MLA). E.X. Albuquerque^{1,2}, A. Maelicke³ and E.F.R. Pereira^{1,2}. ¹Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD, USA, 21201; ²Lab. Mol. Pharmacol. II, IBCCF, RJ, 21944, Brazil; ³Inst. Physiol. Chem., Johannes-Gutenberg Univ. of Med. Sch.; Duesbergweg, D-6500 Mainz, Germany.

It has been shown that PHY activates nicotinic acetylcholine receptors (AChR) on muscles (*Mol. Pharmacol.*, 28:527, 1985). However, studies performed on *Torpedo* demonstrated that the agonistic action of PHY could not be blocked by α -BGT, d-TC or by a monoclonal antibody to the well-established agonist binding sites of the AChR. Thus, PHY might be activating the AChR by a second pathway (Okonjo *et al.*, *in press*). Here, we evaluated single channel currents activated by PHY (10 μ M) in outside-out patches excised from fetal rat hippocampal neurons grown in culture for 20-30 days. The effects of BZQ (3-30 μ M) and MLA (2 nM) on these currents were also analyzed. All solutions contained TTX (0.1 μ M), atropine (1 μ M) and APV (50 μ M), and were delivered via a glass mini-pipe connected to a perfusion system. PHY activated most 30-pS single channel currents which appeared as both brief and long events. Kinetic analysis revealed that channel open, closed and burst times could be fit by double exponential functions. Open times (τ_o) were voltage-dependent and increased with membrane hyperpolarization. BZQ (3-30 μ M) significantly reduced the τ_o of these channels in a concentration- and voltage-dependent manner. The higher the membrane hyperpolarization, the greater the blockade, such an effect being reversed at positive potentials, which indicates that BZQ is an open channel blocker. The agonist effect of PHY, in contrast to that of (+)anatoxin-a, was not blocked by MLA (2 nM), reinforcing the notion that PHY binding sites on the AChR may be different from those of ACh. DIFFERENT ALLOSTERIC MODULATORS INTERACT AT A COMMON SITE ON CARDIAC MUSCARINIC RECEPTORS. John Ellis and Margaret Seidenberg*. Neuroscience Research Unit, Department of Psychiatry, University of Vermont, Burlington VT 05405.

A number of compounds from diverse pharmacological groups interact allosterically with muscarinic receptors. However, it is not known whether the allosteric effects of these different modulators are mediated by a common site, or indeed whether any modulator interacts at a well-defined site. Many of the allosteric ligands act at concentrations where nonspecific effects might occur. We have noted that different allosteric modulators affect rat cardiac muscarinic receptors to different extents. That is, gallamine, TMB-8, and THA slow the dissociation of [³H]NMS (reduce the apparent k_{off}) by more than 90%. On the other hand, obidoxime slows the dissociation by only about 50%, even at maximal concentrations. If these allosteric modulators interact in a competitive manner at the allosteric site, one would expect obidoxime to be able to partially reverse the allosteric effects of the other ligands (the situation is mathematically analogous to the case of a partial agonist interacting with a full agonist). We have observed that obidoxime does partially reverse the allosteric effects of gallamine, TMB-8, and THA, in a concentration-dependent manner that suggests a common site of action. This finding is encouraging for studies aiming to manipulate receptor function via the allosteric site. (Supported by R01AG05214)

ACRIDINE ARAPHANES: A NEW CLASS OF DRUGS USED TO EVALUATE PHARMACOPHORE INTERACTIONS WITH CHOLINERGIC RECEPTORS.

K.P. Shaw^{1,5}, S. Pou^{4*}, R.S. Aronstam² & E.X. Albuquerque^{1,3}. Depts. ¹Pharmacol. Exp. Ther. Sch. Med. & ²Pharmacol., Sch. Pharm., Univ. MD, Baltimore, MD 21201; ³Pharmacol. Toxicol., Med. Coll. Georgia, Augusta, GA 30912; ⁴Lab. Mol. Pharmacol. II, IBCCF, RJ, Brazil 21941; ⁵NDMC, Taipei, Taiwan, ROC.

Structure-activity relationship studies have shown that agonists of muscarinic receptors bind simultaneously to three sites. In addition, hydrophobicity is important to muscarinic antagonists. A novel series of bis-ammonium acridine derivatives with a variable number of carbons (n) in the alkyl chain was synthesized and characterized by hydrophobicity, electrostatic interaction and steric rigidity. Biochemical studies showed that as n increases from 2 to 4 the affinity of the compound to the muscarinic receptor enhances by \approx 10-fold such that 1,4-butane acridine araphane (1,4-BAA) is the most potent in this series ($IC_{50} \approx 10^{-9}$ M). Increasing n to 7 decreases the affinity by \approx 300-fold. When n = 9 (1,9-nonane acridine araphane: 1,9-NAA) the affinity suddenly increases to values similar to 1,4-BAA. The length of the alkyl chain also affects the binding of these compounds to nicotinic receptors. Acridine araphanes have at least two nitrogens protonated, with pK_a values between 11.6 and 8.2. According to quantum mechanics calculation by computer-aided molecular modeling, protonation occurs at N_r (nitrogen in acridine ring). By geometry optimization, the acridine rings are relatively parallel when n=2-4, the inter- N_r s distance being from 3.6 to 5.8 Å. They tend to become coplanar as n increases to 7 because of double bond formation between N_r (nitrogen in alkyl chain) and C_9 and extension of the distance inter- N_r s to 7.7 Å. After n=9, the rings fold together, decreasing the inter- N_r distance (6.2 Å). In conclusion, hydrophobic regions and a distance from 5.8 to 6.8 Å between inter-cationic (N_r) sites and hydrophobic groups are critical to determine the antagonist potency of the acridine araphanes which appear as a new class of cholinergic probes. INTERACTION OF 4-DAMP MUSTARD WITH MUSCARINIC RECEPTORS IN THE BRAIN, HEART AND SALIVARY GLANDS. F.J. Ehler¹, H.H. Hsu², A.L. Hunter³ and E.A. Thomas³. Department of Pharmacology, College of Medicine, University of California, Irvine, CA 92717.

A 2-chloroethylamine derivative (4-DAMP mustard; N-(2-chloroethyl)-4-piperidinyl diphenylacetate) of the selective muscarinic antagonist 4-DAMP (N,N-dimethyl-4-piperidinyl diphenylacetate) was synthesized, and its conversion to an aziridinium ion and interaction with muscarinic receptors was investigated. When dissolved in aqueous solution at pH 7.4 and 37°C, 4-DAMP mustard released an equivalent amount of chloride. The release of chloride was consistent with a first order process having a half-time of approximately 15 min. Under the same conditions, the peak concentration of the aziridinium ion was reached at approximately 45 min and corresponded to about 60% of the initial concentration of 4-DAMP mustard. The concentration of the aziridinium ion decayed to half of its peak concentration at approximately 4 hr after dissolution. Treatment of the isolated rat ileum with 4-DAMP mustard caused an irreversible blockade of contractions elicited by the muscarinic agonist oxotremorine-M, and this blockade persisted after extensive washing. When homogenates of the brain, heart and submaxillary gland were incubated with 4-DAMP mustard (10 nM) for 1 hr, washed extensively, and then assayed for muscarinic receptor binding properties, a decrease in the binding capacity of the muscarinic antagonist [³H]N-methylscopolamine was observed. We conclude that 4-DAMP mustard forms an aziridinium ion that binds irreversibly to muscarinic receptors.

CHOLINERGIC PARTICIPATION IN MASCULINE SEXUAL BEHAVIOR REGULATION IN RATS. S. Retana*, E. Domínguez* and J. Velázquez-Moctezuma. Dept. Biol. Reprod. Universidad Autónoma Metropolitana-Iztapalapa. C.P. 09340. México City. MEXICO.

The role of the cholinergic system in the regulation of masculine sexual behavior (MSB) remains controversial. Contradictory reports in the literature suggest that both muscarinic and nicotinic receptors systems could be involved. In this study, we analyzed the acute effect of several doses of a muscarinic antagonist, scopolamine (Sco), as well as, the effect of its chronic administration. Additionally, the acute effects of several doses of nicotine were also assessed. Acute administration of Sco induced a dose-dependent decrease of the percentage of rats displaying MSB, as well as an increase of mounts and intramissions latencies. MSB after finishing the chronic administration of Sco showed an increase of intramission frequency as well as an enlargement of ejaculation latency. The main effect of acute nicotine administration was a trend towards the inhibition of ejaculation frequency.

ACETYLCHOLINE RECEPTORS: MUSCARINIC III

DISTINCT KINETIC PROPERTIES OF N-[³H]-METHYLSCOPOLAMINE BINDING AFFORD DIFFERENTIAL LABELING AND LOCALIZATION OF M1, M2, AND M3 MUSCARINIC RECEPTOR SUBTYPES IN THE PRIMATE BRAIN. D. D. Flynn, G. Maxwell, A. A. Valshnav, M. Basile, and D. C. Mash. Depts. of Pharmacology & Neurology, University of Miami School of Medicine, Miami, FL, 33101.

Three classes of muscarinic receptors in mammalian brain have been postulated on the basis of equilibrium and kinetic binding data (Ciraldo et al., 1987; Ehler et al., 1989). However, equilibrium binding assays alone have not permitted a clear demonstration of M1, M2, and M3 receptor subtype localization in the brain because of the overlapping selectivities of muscarinic antagonists. In this study, we demonstrate that the distinct kinetics of N-[³H]-methylscopolamine (NMS) binding permit receptor subtype-selective labeling in the primate brain. Equilibrium and kinetic binding conditions were established using cells (AL9) transfected with the genes for the m1, m2, m3 and m4 receptor subtypes. For autoradiographic studies, the m1 receptor was directly labeled with 3 nM [³H]-pirenzepine. The m2 receptor was labeled with short pulses of 0.5 nM [³H]-NMS after preincubation with 0.3 μM pirenzepine to occlude m1 and m3 sites. Selective labeling of the m3 receptor was obtained by incubating cell membranes or sections with 0.25 nM [³H]-NMS followed by a 60 minute dissociation in the presence of 1 μM atropine. The distribution of M1 and M2 receptor subtypes corresponded well to previous autoradiographic studies (Mash et al., 1988). The distribution of the M3 receptor subtype was largely coincident with the pattern of the M1 sites labeled by [³H]-pirenzepine with some notable exceptions. The M3 receptor subtype was elevated over the dorsolateral prefrontal cortex and the CA2 sector of the primate hippocampus. Peak densities of M3 sites were apparent throughout the dorsal sector of the caudate, while M1 receptors were most prevalent in the ventromedial sector. These results provide pharmacological and anatomic evidence for M1, M2 and M3 subclasses of muscarinic receptors in the primate brain. (Funded by NS19605 and NS25785.)

Effects of DFP Treatment on m3 Receptors: An Autoradiographic Analysis

K.A. Frey, MD, PhD and J.K. Zubieta, MD Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Prior studies from our laboratory have demonstrated significant reductions in muscarinic receptor binding in rat brain after 7 days of treatment with the acetylcholinesterase inhibitor DFP. The changes appear to involve both high and low affinity sites defined by pirenzepine (PZ) and AF-DX 116 competition of [³H]scopolamine binding. We have now extended these results by studying the effects of DFP treatment on muscarinic m3 receptors defined by the regional distribution of [³H]4-DAMP binding in the presence of unlabeled PZ and AF-DX 116. The specific binding of [³H]4-DAMP (5 nM), a muscarinic receptor antagonist with affinity for m3, m1, and m2 receptors, was significantly decreased (20-30%) in the striatum and cerebral cortex following cholinesterase inhibition. When unlabeled AF-DX 116 (3.5 μM) was added to eliminate m2 subtype binding, detectable down-regulation was present but of reduced magnitude in cerebral cortex. After addition of cold PZ (1 μM) to eliminate m1 binding, relative down-regulation was enhanced in both striatum and cortex. The selective m3 autoradiograms obtained after the addition of both unlabeled PZ and AF-DX 116 did not reveal significant down-regulation after DFP treatment in any of the forebrain areas studied. The present results suggest differences in the regulation of muscarinic cholinergic receptor subtypes following acetylcholinesterase inhibition. Down-regulation of muscarinic receptors by DFP treatment appears to involve m1 and m2 subtypes to differing extent, but does not affect m3 muscarinic cholinergic receptors.

Autoradiographic Characterization of m3 Muscarinic Cholinergic Receptors in Rat Brain

J.K. Zubieta, MD and K.A. Frey, MD, PhD, Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109

The binding characteristics of [³H]4-DAMP, a muscarinic antagonist with high affinity for m1 and m3 and intermediate affinity for m2 receptor subtypes, were studied in an attempt to visualize the distribution of the m3 site in rat brain. Equilibrium binding conditions and optimal post-incubation wash times were determined for 20 μm-thick cryostat sections. Autoradiographic saturation analysis demonstrated apparently homogeneous populations of binding sites with K_D varying between 4 nM in striatum and 12 nM in the hypoglossal nucleus. Displacement of 2 nM [³H]4-DAMP with unlabeled pirenzepine (PZ), an m1-selective muscarinic antagonist, revealed evidence of high and low affinity sites in striatum (K_H 20 nM, K_L 500 nM; attributable to m1 and m3 sites) while only the low affinity site (m2 or m3) was observed in the hypoglossal nucleus. Displacement of [³H]4-DAMP with AF-DX 116, a selective m2 antagonist, revealed single site competition with K_I of 6 to 7 nM in all regions studied. On the basis of these findings, selective m3 autoradiographic images were generated by incubation in 5 nM [³H]4-DAMP in the presence of both 1 μM PZ and 3.5 μM AF-DX 116 to block binding to the m1 and m2 subtypes, respectively. The distribution of m3 receptors defined in this manner is diffuse throughout the nervous system, but is quantitatively minor in comparison to levels of other subtypes. These results indicate that the binding of [³H]4-DAMP in the absence of unlabeled selective inhibitors is predominantly to non-m3 receptors.

234.4

AUTORADIOGRAPHIC ANALYSES OF THE BINDING OF NIPECOTIC ACID ESTERS TO MUSCARINIC RECEPTOR SUBTYPES IN MOUSE BRAIN. C.N. Hinko, A. El-Assadi*, A.M. Crider* and W.S. Messer. College of Pharmacy, Univ. of Toledo, Toledo, OH 43606 and College of Pharmacy, Northeast Louisiana Univ., Monroe, LA 71209.

Prior studies have shown that the ethyl ester of (-)nipecotic acid (NA), (+)ethyl nipecotate hydrogen tartrate ((+)ENT), possesses anticonvulsant activity but also elicits signs of cholinergic stimulation such as tremors, salivation, lacrimation and diarrhea in mice. The ethyl ester of (+)NA, (-)ethyl nipecotate hydrogen tartrate (-)ENT, has minimal anticonvulsant effect and no obvious cholinergic action. The *m*-nitrophenyl ester of (-)NA, (-)*m*-nitrophenyl-3-piperidine carboxylate HCl (-)MNPC-HCl, and the *m*-nitrophenyl ester of (+)NA, (+)MNPC-HCl, are both active as anticonvulsants with no obvious cholinergic effect. In the present study the binding of the ethyl and *m*-nitrophenyl esters of (+)NA and (-)NA to muscarinic receptors in the mouse brain was examined through quantitative autoradiography. The overall order of potency for inhibition of [³H]-1-quinuclidinyl benzilate ([³H]-1-QNB) binding to mouse brain sections was (+)ENT > (-)ENT > (+)MNPC-HCl > (-)MNPC-HCl. Regional quantification of the autoradiograms indicated that (+)ENT bound with highest affinity to midbrain nuclei (eg. lateral hypothalamus, IC₅₀ = 5.0 μM) and with lowest affinity to forebrain nuclei (eg. dentate gyrus, IC₅₀ = 25 μM). (-)ENT displayed slightly less selectivity and a lower affinity for muscarinic receptors with IC₅₀ values for the lateral hypothalamus and dentate gyrus of 91 and 170 μM, respectively. Both (+)MNPC-HCl and (-)MNPC-HCl bound with even lower affinity and a relative lack of selectivity. Analysis of the data yielded a Hill coefficient of less than 1 for (+)ENT, and of slightly less than 1 for (-)ENT. The Hill coefficients for both (+)MNPC-HCl and (-)MNPC-HCl were close to unity. These data provide support for (+)ENT as an M2-selective agonist. (-)ENT appears to be M2 selective but has lower affinity than (+)ENT, while (+) and (-)MNPC-HCl bind weakly to muscarinic receptors and in a nonselective manner. The observed order of affinity for binding to muscarinic receptors is in agreement with their previously observed tendency to produce cholinergic side effects.

234.5

THE DISTRIBUTION OF M3 MUSCARINIC RECEPTOR SUBTYPE AND m3 MESSENGER RNA IN HUMAN OCULAR STRUCTURES

N. Gupta, S. Prasad, B. McAllister*, S.M. Drance*, and M.S. Cynader. Dept. of Ophthalmology, University of British Columbia, 2550 Willow St., Vancouver, Canada.

We localized M3 muscarinic receptor subtype and its messenger RNA in human eye sections by using *in vitro* autoradiography and *in situ* hybridization respectively. M3 binding sites were detected with [³H]4-diphenylacetoxy-N-methylpiperidine methiodide ([³H]4DAMP) (M1 and M3 antagonist) in the presence of unlabelled pirenzepine (M1 antagonist). M3 binding sites were highly concentrated in the ciliary body and iris, and were also present in the corneal epithelium, anterior lens epithelium, retina, retinal pigment epithelium, and choroid. m3 messenger RNA was localized with a human m3 specific [³⁵S]-labelled oligonucleotide probe. The specificity of this probe was verified by Northern blotting of total RNA extracted from the human anterior segment. m3 transcript was localized in each of the structures found to have M3 binding sites, but in addition, m3 transcript was noted in the corneal endothelium and the trabecular meshwork. These two complementary techniques show the presence of M3 muscarinic receptor subtype and its messenger RNA in several defined human ocular structures. Comparison of these results with the known distributions of M1 and M2 subtypes suggests the potential for selective targeting of these muscarinic receptor subtypes in ocular drug therapy.

BINDING OF VESAMICOL TO RAT BRAIN PREPARATIONS. S. O. Bryant*, R.-H. Wang*, R. J. Watson* and E. M. Meyer.

University of Florida College of Medicine, Gainesville, FL 32610.

Vesamicol (AH5183) is a potent inhibitor of acetylcholine transport into cholinergic vesicles that may be useful for *in situ* quantification of cholinergic innervation. However, while its binding to purified cholinergic synaptic vesicle preparations is well characterized by the work of Parsons and co-workers, its binding to more complex preparations such as mammalian brain is less well understood. We found that the (-)-vesamicol bound to rat brain preparations in a high affinity (K_D = 30 nM), stereospecific manner and that binding was most concentrated in a vesicle-enriched fraction. Displacement with several vesamicol analogs (kindly provided by Dr. Stanley Parsons) paralleled that seen in electroplax-derived vesicles. However, there was also a low affinity binding component (K_D = about 500 nM) that was neither stereospecific nor concentrated in vesicle fractions. High affinity binding was most concentrated in the cerebellum, a region with sparse cholinergic innervation, followed by striatum, hippocampus and cerebral cortex, in that order. However, the ratio of high/low affinity binding was highest in striatum, followed by cerebrum and cerebellum. These results suggest that (-)-vesamicol may be useful for the antemortem diagnosis of Alzheimer's disease, but only if performed under the appropriate conditions to control for non-specific binding.

234.6

MUSCARINIC RECEPTOR SUBTYPES IN HUMAN EYE.

Alicia M. Bogardus*, Barbara J. Feldmann*, Elizabeth WoldeMussie*, and Daniel W. Gil. Allergan, Inc., Irvine, CA 92715.

Muscarinic receptor agonists act at several sites in the eye to regulate intraocular pressure. They contract the ciliary muscle, enhancing outflow of aqueous humor (AH). They also mobilize calcium in non-pigmented epithelial (NPE) cells, which secrete AH into the eye. The subtypes involved in these actions have a M3 pharmacology. To better understand muscarinic actions in the eye, we are identifying ocular muscarinic receptors at the molecular biological level, using the polymerase chain reaction (PCR). Primer pairs corresponding to regions of unique sequence encoding the amino terminal and third cytoplasmic loop of each of the five muscarinic receptors were used. These were incubated with cDNAs generated from 1) ciliary muscle obtained from donor eyes, 2) early passage cultures of human ciliary smooth muscle cells, and 3) a transformed NPE cell line. In each cDNA, a fragment encoding the Hm3 muscarinic receptor was amplified. A low level of the Hm2 subtype was also detected in the ciliary muscle sample. Fragment identities were confirmed by size and digestion with restriction enzymes. The PCR data is consistent with pharmacological evidence that the Hm3 receptor regulates intraocular pressure.

EXCITATORY AMINO ACIDS: PHARMACOLOGY IV

235.1

DECREASE IN TOLERANCE DEVELOPMENT TO CHRONIC MORPHINE WITH COMPETITIVE AND NON-COMPETITIVE NMDA RECEPTOR ANTAGONISTS.

Paul J. Tiseo and Charles E. Inturrisi Dept. of Pharmacology, Cornell University Medical Center, New York, N.Y. 10021

Recent reports have demonstrated that pretreatment with the NMDA receptor antagonist MK-801 can decrease the rate of tolerance development and physical dependence observed with chronic morphine administration (Trujillo and Akil, *Science*, 251, 1991). As the psychomimetic effects produced by MK-801 (MK) and the other non-competitive NMDA antagonists may limit their clinical usefulness, the current focus is on the development of competitive antagonists with fewer limiting side effects. The purpose of this study was to determine if the competitive NMDA antagonist LY-274614 (LY), (Eli Lilly and Co.), could alter the development of morphine tolerance and to compare MK and LY with respect to behavioral profiles and tolerance development when administered prior to morphine on a repetitive dose schedule. Adult male SD rats were administered saline (SAL) (1 ml/kg), MK (0.2 mg/kg i.p.), or LY (1, 3 mg/kg, i.p.) 30 min prior to morphine administration (10 mg/kg, s.c., b.i.d.) for 10 days. Behavioral and analgesic responses (hot-plate, 52.5° C) were assessed at 60 min post-morphine on alternate mornings for the duration of the study. Tolerance development was quantitated by measuring the AUC (%MPE vs time). SAL animals rapidly developed tolerance to the analgesic effects of morphine and reliably returned to baseline HP latencies (%MPE=0) by day 6. Animals pretreated with MK or LY demonstrated significantly less tolerance with the LY effects being dose related, and with neither the MK nor the high dose LY animals returning to baseline during the study. Analysis of tolerance using AUC shows that SAL animals have an AUC that is 22% of the maximum possible area, while the LY-1 mg, the LY-3 mg, and the MK animals have AUC's of 40%, 85% and 75% of the maximum area respectively. Thus, although MK and LY bind to different sites on the NMDA receptor, both are able to decrease the development of tolerance to morphine. However, the more favorable side effect profile of LY may provide a clinical advantage in analgesic studies. (Supported in part by DA-01457)

235.2

PHARMACOLOGICAL SPECIFICITY OF DRUG DISCRIMINATION BASED ON THE N-METHYL-D-ASPARTATE ANTAGONIST NPC 12626. D.J. Bobelis* and R.L. Balster. Depts. of Pharmacology & Toxicology and Psychology, Virginia Commonwealth Univ., Richmond, VA 23298-0613.

A drug discrimination based upon the competitive N-methyl-D-aspartate (NMDA) antagonist 2-amino-4,5-(1,2-cyclohexyl)-7-phosphonoheptanoic acid (NPC 12626) was assessed for pharmacological specificity by stimulus generalization testing of a number of representative drugs from a variety of pharmacological classes. Adult male Sprague-Dawley rats were trained to discriminate 20 mg/kg i.p. NPC 12626 from saline on a standard two-lever fixed ratio 32 schedule of food reinforcement as described previously (Willett, Bobelis and Balster, *Psychopharmacology* 99:458-462, 1989). During test sessions the competitive NMDA antagonists NPC 12626 (3-100 mg/kg), cis-4-phosphonomethyl-2-piperidine carboxylic acid (CGS 19755, 1-10 mg/kg i.p.) and D,L-(E)-2-amino-4-methyl-5-phosphono-3-pentenoic acid (CGP 37849, 0.3-5.6 mg/kg i.p.) all completely substituted for the training dose of NPC 12626 with ED50 values of 16.4, 2.30 and 0.90 mg/kg, respectively. In contrast, drugs that failed to substitute for NPC 12626 when tested at two or more doses included MK-801, dextromethorphan, amphetamine, ketocyclazocine, morphine, muscimol, diazepam, valproate, phenytoin, chlorpromazine, physostigmine, baclofen, methocarbamol, L-phenylisopropyladenosine and imipramine. These results provide evidence that the discriminative stimulus produced by NPC 12626 is unique and specific, shared fully only by other competitive NMDA antagonists. (Supported by NIDA Grants DA-01442 and DA-07027)

235.3

PHARMACOLOGICAL SPECIFICITY OF N-METHYL-D-ASPARTATE DISCRIMINATION IN RATS. D. M. GRECH, J. WILLETTS AND R. L. BALSTER. Department of Pharmacology & Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0613.

The pharmacological specificity of N-methyl-D-aspartate (NMDA) discrimination was examined in male Sprague-Dawley rats trained to discriminate 30 mg/kg NMDA from saline under a 2-lever FR-32 reinforcement schedule. Drugs with diverse central actions were evaluated in substitution tests. Morphine, (+)amphetamine, caffeine, picrotoxin and pentylentetrazol failed to substitute for NMDA, each producing an average of less than 40% NMDA-lever responding. The cholinergic antagonist mecamylamine and the cholinomimetic agents, (-)nicotine and physostigmine, produced 40-60% NMDA-lever responding, however, arecoline failed to substitute for NMDA. Pentobarbital and the benzodiazepine inverse agonist, methyl-6,7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate, (DMCM) produced greater than 97% NMDA-lever responding but only at doses which markedly disrupted behavior. These results provide evidence for considerable pharmacological specificity of the NMDA discriminative stimulus in rats. (Supported by NIDA Grants DA-0142 & DA-07027).

235.5

NMDA CONVULSIONS PRODUCED BY ICV ADMINISTRATION IN RATS: DIFFERENTIAL SENSITIVITY TO VARIOUS ANTAGONISTS. L. Robles, E. Echevarria and F.C. Tortella. Neuropharmacol. Br., Walter Reed Army Inst. Res., Washington, DC 20307.

Parenteral administration of NMDA produces severe clonic (popcorn) convulsions and lethality in rodents. We previously reported the effect of centrally (icv) administered NMDA to produce similar convulsions in rats (Robles et al., Neurosci. Abst., 1990). This study further characterizes the icv NMDA convulsion. In rats icv NMDA (0.78-12.5 nM) dose-dependently elicits popcorn convulsions (CD50=2.8 nM; 15-20 sec latency). Unlike sc or iv NMDA, maximally effective icv doses (6.25-12.5 nM) are not lethal and exhibit a unique sensitivity to various NMDA antagonists. Namely, while the competitive antagonist APV (1-25 ug, icv) or the glycine antagonists HA966 (75-150 ug, icv) and 7-chlorokynurenic acid (1-25 ug, icv) provide 100% protection against the icv NMDA convulsion, the noncompetitive antagonists MK801 (0.5 mg/kg, sc) or PCP (5 mg/kg, sc), given at 5x their respective anticonvulsant ED50 doses, are ineffective. Thus, these results suggest the possible existence of a NMDA recognition site insensitive to non-competitive NMDA antagonists.

235.7

CIRCLING INDUCED BY AN INTRACEREBRAL INJECTION OF THE RECEPTOR NMDA ANTAGONIST MK801: IMPLICATION OF DOPAMINERGIC SYSTEM? J.A. St-Pierre*, D. Gaudin, L. Grégoire*, and P.J. Béjard. Centre de Recherche en Neurobiologie, Hôpital de l'Enfant-Jésus, 1401, 18^{ème} Rue, Québec, Canada G1J 1Z4, Département de Pharmacologie, Université Laval.

It is admitted that systemic injection of MK801 induces an ipsilateral rotation in the rats with an unilateral nigrostriatal lesion produced by 6-OHDA (Clineschmidt B.V. et al., Drug Dev. Res. 2:135-145, 1982; Kashiwara K. et al., Brain Res. 528:80-82, 1990).

The present investigation is aimed at elucidating the site of action of this non-competitive NMDA antagonist on the nigrostriatal dopaminergic pathway. Female rats were lesioned with 6-OHDA 8µg/2µl in the left substantia nigra. At least one month later they were tested with apomorphine (0.25mg/kg s.c.). Microinjection of MK801 was performed by four guide-cannulae implanted stereotaxically into the striatum (5.0µg/1.0µl) and into the substantia nigra pars reticulata (5.0µg/0.5µl). Both sites were chosen for their implication in the dopamine-induced circling. Analysis of results show that intrastriatal injection of MK801 on either side (intact or lesioned) induced practically no circling response. On the other hand, a similar injection in the substantia nigra reticulata caused a robust response to the side contralateral to the injection. There was no difference between the intact and the lesioned side. However, the systemic administration of MK801 (100µg/kg i.p.) in the lesioned rats induced a remarkable ipsilateral rotation (referred to the lesion) response. The same type of injection in non-denervated rats increased locomotion without direction predominance.

Taken together, our results suggest that MK801 administered systemically may interact with the dopaminergic pathway on the intact side to induce circling. However, results of the intracerebral injections suggest that output neurons of the substantia nigra reticulata which receive an important glutamatergic input from the subthalamic nucleus may play an important role in the response to this antagonist. SELECTIVE NMDA ANTAGONISTS AFFECT THE URINARY BLADDER FUNCTION THROUGH THE CENTRAL NERVOUS SYSTEM IN THE RAT. Y. Gotoh*, M. Ishida and H. Shinozaki. The Tokyo Metro. Inst. Med. Sci. Tokyo 113, Japan.

Systemic administration of selective NMDA antagonists reduced the spontaneous contraction of the rat urinary bladder in a dose dependent manner, while it increased the gastric motility. Specific NMDA antagonists and broad-type glutamate blockers such as kynurenate and CNQX showed reverse actions on the stomach and bladder in the rat, respectively. Recently peripheral distribution of NMDA receptors has been reported, therefore, we examined the site of inhibitory actions of these glutamate blockers on the bladder micturition. Under urethane anesthesia (1.5 g/kg, s.c.), a catheter was introduced into the bladder through the apex of the bladder in order to record to the intravesical pressure. The bladder contraction was elicited by stimulation of the distal end of the pelvic nerve, which was preganglionically cut near the pelvic plexus. CPP, kynurenate and MK-801 did not affect the urinary bladder contraction elicited by electrical stimulation of the distal end of the pelvic nerve. On the other hand, MK-801 and CPP reduced the urinary bladder contraction elicited by the proximal stimulation of the pelvic nerve. These results suggest the possibility that selective NMDA antagonists affect the micturition function through the central nervous system.

DEXTROROTATORY OPIOIDS AND PHENCYCLIDINE EXERT ANTICONVULSANT ACTION IN RAT PREPIRIFORM CORTEX. J.E.Ishmael-Roth, P.H.Franklin and T.F.Murray. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

Although the anticonvulsant action of the dextrorotatory opioids, dextrorphan (DX) and dextromethorphan (DXM), is comparable to that of other putative noncompetitive NMDA antagonists, such as phencyclidine (PCP) and MK-801, the underlying mechanism is less certain (Tortella et al., Life Sci., 42:2509,1988). We have recently described a specific binding site for [³H]dextrorphan in rat forebrain membranes, that exhibited a pharmacological profile consistent with the labelling of NMDA receptors (Franklin and Murray, Eur.J.Pharmacol. Mol.Pharmacol.Sect., 189:89,1990). In the present study we investigated the ability of DX, DXM and PCP to suppress seizures induced by a unilateral, focal injection of bicuculline methiodide (118 pmol) into the rat prepiriform cortex.

All compounds protected against bicuculline-induced seizures in a dose dependent manner. DX and PCP potently suppressed seizures with complete efficacy; ED₅₀ values ± S.E. were 16.5 ± 2.9 nmol and 19.3 ± 4.5 nmol respectively. DXM was approximately 4-fold less potent than DX, with an ED₅₀ value of 65.0 ± 3.2 nmol. These anticonvulsant potencies correspond to the respective affinities of DX, DXM and PCP for the [³H]dextrorphan binding site in forebrain membranes. The anticonvulsant action of these compounds therefore appears to be a consequence of noncompetitive antagonism of NMDA receptors. This observation is consistent with a proposed NMDA receptor modulated output pathway thought to be essential for the generation of seizures from this brain area.

NMDA RECEPTOR ANTAGONISTS ARE ANTINOCICEPTIVE IN THE MOUSE FORMALIN MODEL DURING ACUTE AND CHRONIC ADMINISTRATION. K.J. Elliott**, D.J. Cerbone*, K.M. Foley** and C.E. Inturrisi. Dept. of Pharmacology, Cornell U. Med. Coll. and Memorial Sloan-Kettering Cancer Center*, New York, NY.

The formalin test results in excitatory amino acid (EAA) release. The EAA-NMDA receptor antagonist, AP5 given IT, is antinociceptive in the formalin test (Murray, C.M. et al. Pain 44:179, 1991). We compared the effect of acute and chronic ip MK-801 (MK, non-competitive NMDA antagonist) and LY274614 (LY, competitive) on formalin-induced licking and flinching in mice. Acute MK and LY blocked flinching behavior in a dose-dependent manner. The ED50 (95% CI) for acute MK is .74 mg/kg (.31 - 1.74) and the ED50 for LY is 7.07 mg/kg (5.19 - 9.64). Response to licking behavior was much more variable but both MK and LY suppressed licking behavior at all doses after acute and chronic administration. Chronic ip MK blocked flinching behavior in a dose-dependent manner with an ED50 of .91 mg/kg (.62 - 1.33) while LY did not. With chronic dosing MK (2.5 - 5.0 mg/kg) resulted in persistent agitation and ataxia while LY (10-20 mg/kg) resulted in initial somnolence which resolved prior to the formalin challenge. Further analgesic evaluation of competitive NMDA antagonists such as LY is required as MK has limiting behavioral side effects. (Supported in part by DA01457 (CEI) and CA09461 (KJE.)

PHENCYCLIDINE-INDUCED ACTIVATION OF A₁₀ DOPAMINE NEURONS IS BLOCKED BY COMPETITIVE NMDA-RECEPTOR ANTAGONISTS. E.D. French, Department of Pharmacology, University of Arizona, College of Medicine, Tucson, AZ 85724

Phencyclidine (PCP) is a non-competitive antagonist of glutamate activation of NMDA receptor-ion channel function. *In vitro* studies have shown that PCP binding within the channel can be positively or negatively affected by NMDA receptor agonists and antagonists, respectively. Thus, the present study sought to examine the consequences of competitive NMDA receptor blockade *in vivo* on PCP-induced alterations of A₁₀ neuronal activity.

Male rats anesthetized with chloral hydrate were prepared for extracellular recording from A₁₀ neurons identified by well-characterized electrophysiological criteria. All drugs were injected I.V. and dose-response comparisons were constructed from cumulative dosing regimens. The high affinity and selective competitive NMDA antagonists, CGS 19755 and (±)CPP were administered in incremental doses, with 45 min from the last CGS or CPP dose to the first dose of PCP.

PCP alone produced a bimodal change in A₁₀ firing characterized by a low dose excitation followed by an attenuation of this effect with increasing doses. After 40 mg/kg of CGS or CPP the stimulatory effects of PCP were completely attenuated but the inhibitory component remained. 10 mg/kg of CGS produced only a partial blockade of PCP. CGS and CPP alone failed to alter A₁₀ activity at either dose, and at the highest dose did not antagonize morphine-induced activation of dopamine cell firing.

These findings provide functional evidence to suggest that competitive NMDA antagonists can block the effects of PCP on NMDA-ion channel function. This finding along with previously published observations strongly suggest that the activation of the mesolimbic-mesocortical dopaminergic system elicited by PCP is mediated through an NMDA receptor mechanism.

COMPARISON OF COMPETITIVE AND PCP-LIKE, NON-COMPETITIVE NMDA ANTAGONISTS ON TWO SHORT-TERM MEMORY TASKS IN PIGEONS IN RELATIONSHIP TO THE NMDA ANTAGONIST DOSE. J.D. Leander, N.A. Moore* and P.L. Ornstein. Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, IN 46285 and Lilly Research Laboratories, Windlesham, Surrey, U.K.

NMDA antagonists show promise as novel therapeutic agents for the treatment of a variety of neurodegenerative conditions. Since NMDA antagonists have been reported to impair the development of long-term potentiation and various learning and memory tasks, the purpose of the present studies was to compare competitive and PCP-like, non-competitive NMDA antagonists on two different memory tasks. The two were a spatial alternation task and a variable delay matching task. The data from these two memory tasks were compared to the doses of antagonists necessary to antagonize the behavioral suppressant effects of NMDA in birds responding under a multiple schedule of grain presentation. On both memory tasks, the non-competitive NMDA antagonists (PCP and MK-801) increased errors and decreased rates of responding at the same doses that antagonized the behavioral effects of NMDA. In marked contrast, the competitive NMDA antagonists (LY233053 and LY274614) antagonized the behavioral suppressant effects of NMDA at doses >20-fold lower than the doses that impaired memory performance. These data show that competitive NMDA antagonists may be far less disruptive of memory processes than non-competitive antagonists and thus suggest that they may have wider therapeutic indexes in man than has been seen with the PCP-like compounds.

235.13

THE NMDA RECEPTOR DOES NOT MEDIATE THE BEHAVIORAL EFFECTS OF PCP. L.M. Wyatt and A.B. Norman. Departments of Psychiatry and of Anatomy and Cell Biology, University of Cincinnati College of Medicine, Cincinnati, OH 45267

PCP acts as a non-competitive antagonist of the NMDA receptor at the associated ion channel. The psychotomimetic actions and behavioral effects in animals are assumed to be mediated through this site. Metaphit, an irreversible antagonist of PCP receptors, should therefore be expected to bind to the ion channel of the NMDA receptor and to block its actions. Male Sprague-Dawley rats were given 2 μmoles metaphit i.c.v., sacrificed 24 hours later, the appropriate brain regions dissected, and [³H]MK801 and [³H]TCP binding assessed. There was no significant decrease in [³H]MK801 binding in any brain region used. [³H]TCP binding was decreased 66% in the striatum, 39% in the hippocampus, and 16% in the cortex. K_D was not changed in any region. Competition of PCP for [³H]MK801 binding in rat cortical homogenates demonstrated a single population of binding sites consistent with the NMDA receptor. In contrast, competition of PCP for [³H]TCP demonstrated 2 sites, K_H=2.5 nM, K_L=756 nM, %R_H=23%. Metaphit treatment eliminated the [³H]TCP binding site with high affinity for PCP. The remaining site had characteristics consistent with the NMDA receptor. Furthermore, metaphit treatment antagonized the locomotor effects of PCP (9 mg/kg, i.p.) but did not antagonize the behavioral effects of MK801 (0.5 mg/kg, i.p.). Therefore, the non-NMDA, high affinity PCP, metaphit sensitive [³H]TCP binding site may mediate PCP behaviors. [supported by The Huntington's Disease Society of America]

EFFECT OF CHRONIC MK801 TREATMENT ON MK801-INDUCED BEHAVIORS AND QUINOLINIC ACID-INDUCED NEUROTOXICITY IN RAT BRAIN. A.B. Norman, L.M. Wyatt, M.J. Gerwe* and L.M. Ford. Dept. of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Acute treatments with the noncompetitive NMDA glutamate receptor antagonist MK801 can prevent neurodegeneration mediated via the NMDA receptor. However, some disease processes are ongoing and clinical use of such drugs may require chronic treatments. Chronic treatments with antagonists of other receptors can produce tolerance to the effects of antagonists and supersensitivity to agonists. We therefore investigated the behavioral and neurochemical effects of chronic treatments with MK801.

Male Sprague-Dawley rats received 28 daily injections of MK801 (1 mg/kg/day i.p.) or vehicle. The behavioral effects of MK801 were significantly modified following chronic MK801 treatments with a tolerance to the locomotor stimulating effects. Furthermore, MK801 produced a marked stimulation rather than inhibition of rearing behavior following chronic MK801 treatments. However, there were no significant changes in the B_{max} or K_D of [³H]MK801 binding sites in rat brain homogenates. Two days following the last treatment with MK801 or vehicle rats received bilateral intrastriatal quinolinic acid (QA: 75, 100 or 150 nmol) lesions or vehicle. 21 days postlesion striata were removed and the binding of [³H]SCH23390 to D₁ dopamine receptors was determined as a quantitative index of neurotoxicity. QA produced a significantly greater decrease in [³H]SCH23390 binding in striata of rats withdrawn from chronic MK801 treatment than in controls. Therefore, chronic MK801 treatment produces tolerance to some of the behavioral effects and increases the sensitivity to QA-induced neurotoxicity.

PHENCYCLIDINE AND SIGMA LIGANDS HAVE OPPOSING EFFECTS ON NMDA ACTIVITY. C.S. Hornfeldt and A.A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

Phencyclidine (PCP) and related compounds bind to a high affinity site associated with the NMDA channel, inhibiting NMDA activity, and to a low affinity site thought to be the σ-receptor. σ-ligands also bind to a high and low affinity site, corresponding to the σ-receptor and the PCP binding site, respectively. Electrophysiologic evidence indicates σ-receptors modulate NMDA activity which may be potentiated or inhibited by haloperidol, a σ-antagonist. These data suggest that, because of different binding affinities to high and low affinity sites, the effect of a specific compound on NMDA activity may be highly dose-dependant (*Eur J Pharmacol* 179; 441, 1990). Previous behavioral studies, however, have found σ-ligands to be without effect on NMDA-induced behaviors (*Eur J Pharmacol* 159; 149, 1989). We wished to test the hypothesis that PCP and 1,3-di-o-tolylguanidine (DTG), a σ-ligand may, at different doses, have opposing effects on NMDA activity in a behavioral model. Mice were pretreated with an intrathecal injection of PCP or DTG. After 5 min, each animal was re-injected intrathecally with NMDA (0.25 nmol) and the number of bites and scratches counted during the next 1 min. Pretreatment with a low dose of DTG (5 nmol) caused a potentiation of NMDA behaviors which was reversed by simultaneous pretreatment with haloperidol (2.5 nmol). In contrast, pretreatment with a high dose of either DTG (25 nmol) or PCP (3 nmol) inhibited NMDA behaviors. This inhibition was potentiated by simultaneous pretreatment with haloperidol. PCP (0.2 pmol) also potentiated NMDA behaviors but only when coadministered with NMDA. This potentiation was inhibited by pretreatment with haloperidol. These results support the hypothesis that PCP and σ-receptor ligands have opposing effects on NMDA activity that can be monitored in the same behavioral assay system (NIDA 04090, 04190, 00124).

NEUROPROTECTION BY MK801 IN TEMPERATURE MAINTAINED GERBILS. Boast, C.A. and Hoffman, C.* Wyeth-Ayerst Research, Princeton, NJ 08543-8000.

Hypothermia reduces ischemic brain damage (Welsh et al, JCBF 1990, 10:557), confounding interpretation of the neuroprotective effects of novel drugs. Specifically, the neuroprotectant MK801 has been shown to cause hypothermia. Some have claimed that when body temperature (BT) is maintained, MK801 is not a neuroprotectant, (Buchan & Pulsinelli, J. Neurosci. 1990 10:311; Corbett et al, Brain Res. 1990 514:300), while others have claimed it still is (Gill & Woodruff, Eur. J. Pharmacol., 1990 176:143; Neill et al., SN Abstr. 1990 16:278).

Gerbils received bilateral carotid occlusion (BCO) for 5 or 10 min (halothane), while on a heating pad at 37 C. Immediately after surgery the animals were restrained, a rectal temperature probe inserted, and BT maintained using a thermistor controlled heat lamp and cooling fan. When more cooling was required, an animal was placed in a refrigerator with the heat lamp and fan. In free regulating animals (10 min BCO), 3 mg/kg i.p. MK801 at the time of occlusion significantly reduced brain damage. When BT was maintained (5 min BCO) at 38.5 C, no reduction in brain damage was seen up to 10 mg/kg i.p. When BT was maintained (5 min BCO) at 36.5 C, 10 mg/kg i.p. significantly reduced brain damage. Thus, although a higher dose of the drug is required, MK801 can reduce ischemic brain damage in the absence of hypothermia.

EVIDENCE THAT IN PHYSIOLOGICAL CONDITIONS NMDA RECEPTORS PLAY FUNDAMENTALLY DIFFERENT ROLES IN THE HIPPOCAMPUS AND IN THE CEREBRAL CORTEX. N.Ludvig, P.K.Mishra, R.L.Burger and P.C.Jobe. Dept. of Basic Sciences, University of Illinois College of Medicine at Peoria, Peoria, IL 61656.

Combined EEG and intracerebral microdialysis techniques were used to compare the effects of NMDA in the hippocampus and in the cerebral cortex, in freely behaving rats. The recording electrodes were implanted chronically in either structure. At the beginning of the experiments, a loop-type microdialysis-probe was inserted into the recording site. For a 2 hour period, artificial cerebrospinal fluid was perfused (10 ul/min). After this period, a selected dose of NMDA (concentration range: 0.01 - 10.0 mM) was included into the perfusion fluid for 5 min, then washed out.

In hippocampus the drug provoked epileptiform electrical activity in a dose-dependent manner; 1.0 mM concentration was the lowest dose to induce such EEG changes. In contrast, in the sensorimotor cortex 1.0 mM or higher concentrations of NMDA induced marked reductions in both EEG amplitude and frequency. These electrographic changes were indistinguishable from those characteristic of K^+ -induced spreading depression. In this area, NMDA did not produce epileptiform spike activity. Subsequent analyses of the microdialysates and complementary electron microscopic studies indicated that the depressant effect of NMDA in cortex was neither due to an increased release of GABA nor to a neurotoxic action.

Interestingly, dibutyl cyclic AMP appeared to potentiate the effects of NMDA, at least in hippocampus, indicating that NMDA receptor functions may be under the regulation of a cyclic AMP-dependent mechanism. A differential operation of such regulatory mechanisms in the cerebral cortex and in the hippocampus may underlie in the apparently different roles of NMDA receptors in these structures.

235.17

BINDING OF A NOVEL, SELECTIVE SIGMA SITE LIGAND, [³H] 3-PHENYL-1-(1,2,5,6-TETRAHYDRO-1-PROPYL-3-PYRIDINYL)-1-PROPANONE OXIME (PD 128298) TO RAT BRAIN MEMBRANES. C.M. Hanchin*, L.L. Coughenour*, H. Teclé*, W.H. Moos and F.M. Hershenson. Departments of Pharmacology and Chemistry, Parke-Davis Pharmaceutical Research Division, Warner Lambert Co., Ann Arbor, MI 48106-1047.

A series of tetrahydropyridine oximes recently has been described as potent and selective inhibitors of [³H]1,3-di-tolylguanidine (DTG) and [³H]-(R)-3-(1-propyl-3-piperidinyl)phenol ((+)-3PPP) binding (Pei et al., Ab# MEDI 124, 201st ACS National Meeting, 1991). PD 128298, a high affinity member of this series, was tritium labeled, and its binding to rat whole brain homogenates was characterized using methods described for [³H](+)-3PPP binding (Largent et al., J Pharmacol Exp Ther. 238: 739, 1986). Binding of [³H]PD 128298 was saturable and reversible. Scatchard analysis revealed a single, high affinity binding site with a $K_d = 2$ nM and a $B_{max} = 0.1$ pmoles/mg wet wt. tissue. The rank order of potency (IC_{50}) of agents to inhibit the binding was haloperidol (0.35 nM) > pentazocine (68 nM) > (+)-3PPP (145 nM) ~ DTG (180 nM) > dextromethorphan (584 nM) > phencyclidine (3660 nM). Binding was 500 to 60,000 fold selective for other receptors including phencyclidine, serotonin-2, dopamine D_2 , alpha-1 and alpha-2 adrenergic, muscarinic, nicotinic and sodium channel site 2. [³H]PD 128298 should provide a useful tool for studying sigma site pharmacology and mechanisms.

ISCHEMIA INDUCED EXCITATORY AMINO ACID RELEASE FROM THE GERBIL HIPPOCAMPUS: EFFECTS OF ANESTHESIA AND GM1 GANGLIOSIDE. G. Lombardi, G. Cherici* and F. Moroni. Dept. of Pharmacology, University of Florence, 50100 Florence, Italy.

The ischemia-induced release of aspartate (ASP) and glutamate (GLU) was studied both in freely moving and in chloral hydrate anesthetized gerbils having a transverse microdialysis tubing in their hippocamp. The amino acids were measured in the dialysis fluid (Ringer) using HPLC and fluorimetric detection. Transient forebrain ischemia was obtained by occluding both common carotid arteries for different periods (3-8 min). This occlusion was performed 2 h after the implantation of the dialysis tube in anesthetized and 24 h later in freely moving (locally anesthetized) animals. Two hours after cannula implantation the appearance of ASP and GLU in the perfusion fluid was 1.8 ± 0.2 and 8.9 ± 0.9 μ M respectively, while at 24 h it was 0.87 ± 0.1 and 4.4 ± 1.7 μ M. When the animals were pretreated with GM1 ganglioside (30 mg/Kg/day i.p. for 2 days) the output of ASP and GLU 2 h after cannula implantation was approximately 50% lower than in controls. Common carotid occlusion for 8 minutes in anesthetized animals increased EAA appearance in perfusates 3 to 4-fold. This increase (measured as the area under the curve) was significantly reduced by GM1 ganglioside pretreatments. In freely moving animals 5 min of common carotid occlusion caused a 3 to 4-fold increase in EAA output lasting approximately 20 min. However in most of the animals a further peak of EAA appeared 2-3 h later. The meaning of this late EAA output in unanesthetized animals is currently under investigation.

235.16

α KETOGLUTARATE UPTAKE INTO GLUTAMATERGIC NERVE TERMINALS: AUTOREGULATION OF EXCITATORY NEUROTRANSMISSION. J. Lehmann, E. Osei*, and C. Tsai. Division of Behavioral Neurobiology, Dept of Mental Health Sciences, Hahnemann University, Philadelphia PA 19102, and Research Department, Ciba-Geigy Corp., Summit NJ.

[¹⁴C] α Ketoglutarate ([¹⁴C] α KG) uptake by crude synaptosomes (P_2 fraction) was sodium-dependent but insensitive to malate and phthalonate, unlike mitochondrial [¹⁴C] α KG uptake. The excitatory amino acids L-glutamate, L-aspartate, and kainate inhibited [¹⁴C] α KG uptake into synaptosomes. Following cortical lesions, uptake of [¹⁴C] α KG into striatal synaptosomes was decreased in parallel with [³H]L-glutamate uptake. Thus, this well-documented glutamatergic projection would appear to contain a high-affinity α KG uptake system.

Taken together, these data are suggestive of a receptor-mediated interaction of excitatory amino acids with nerve terminals, resulting in inhibition of α KG uptake. Since α KG may serve as a precursor for neurotransmitter glutamate and/or aspartate, the inhibition by excitatory amino acid of α KG uptake may represent a homeostatic negative feedback loop, i.e., an "autoreceptor".

235.18

NEOMYCIN IS AN AGONIST AT THE POLYAMINE SITE OF THE NMDA RECEPTOR.

L.M. Pullan, R.J. Stumpo, R.J. Powell*, K.A. Paschetto*, M. Britti* Dept. of Pharmacology, ICI Americas, Inc., Wilmington, DE 19897

The aminoglycoside antibiotic neomycin, enhances the binding of the non-competitive antagonist [3H]TCP (1-[1-(2-thienyl)cyclohexyl]piperidine) to the NMDA (N-methyl-D-aspartate) receptor. The maximal enhancement is greater than that seen with the polyamine spermidine, and the enhancement by neomycin of [3H]TCP binding is competitively inhibited by spermidine. These results suggest that neomycin may be a full agonist and spermidine may be a partial agonist at the site where polyamines enhance [3H]TCP binding. Other aminoglycosides also enhance [3H]TCP binding with efficacies (neomycin>gentamycin=kanamycin) roughly proportional to the number of primary amine groups. The polyamine antagonist arcaine inhibits the enhancement by spermidine or neomycin. The inhibition of [3H]TCP binding by arcaine is competitively reduced by neomycin and spermidine. Neomycin, in contrast to spermidine and spermine, does not enhance the binding of the NMDA receptor competitive antagonist [3H]CPP (3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid). However, neomycin does inhibit the ascending arm of the biphasic spermidine enhancement of [3H]CPP binding, while not affecting the descending arm. Thus it appears that neomycin binds to the site where polyamines modulate [3H]TCP and [3H]CPP binding at the NMDA receptor, but neomycin may not cause the conformational change through which spermidine enhances [3H]CPP binding.

235.20

EFFECTS OF OXIRACETAM AND PIRACETAM ON THE RELEASE OF DIFFERENT NEUROTRANSMITTERS FROM HIPPOCAMPAL SLICES AND SYNAPTOSOMES. M. Raiteri, M. Marchi, G. Lunardi*, and A. Augliera*. Istituto di Farmacologia e Farmacognosia, Viale Cembrano 4, 16148 Genova, Italy.

The *in vitro* effects of some nootropic drugs on the release of both ³H-D-aspartate (³H-D-ASP) and endogenous glutamate (GLU) from hippocampal slices has been previously reported. Oxiracetam increased in a concentration-dependent way (0.01 - 1 μ M) the depolarization-evoked release, but not the spontaneous release, of ³H-D-ASP and endogenous GLU. Piracetam also increased the K^+ -evoked release of H-D-ASP but its effect was consistently less pronounced (Marchi et al. EJP 185, 247, 1990). We have extended this study on synaptosomes and found that oxiracetam and piracetam did not increase the ³H-D-ASP release in this preparation. We report here also the data on the effects of these two drugs on the release of ³H-ACh, ³H-GABA and ³H-NE from synaptosomes and slices of rat hippocampus.

MODIFICATION OF RECEPTOR-G PROTEIN FUNCTION IN NG108-15 CELL MEMBRANES BY LOW pH TREATMENT. D. E. Selley and S.R. Childers. Dept. Physiology/Pharmacology, Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Pretreatment of rat brain membranes at pH 4.5 increases GTP regulation of opioid agonist binding and blocks G_s -stimulated adenylyl cyclase (AC). To determine the effect of low pH treatment in a cell culture system, membranes from the δ opioid receptor-containing NG108-15 cell line were treated at pH 4.5 and assayed for [3H][D-Ser²-Leu⁵-Thr⁶]-enkephalin ([3H]DSLET) binding and AC activity. Although low pH treatment did not affect the binding of the δ -selective agonist in the absence of sodium or guanine nucleotides, this treatment increased sodium inhibition of [3H]DSLET binding between 3-100 mM NaCl. Inhibition of [3H]DSLET binding by guanine nucleotides was not observed in the absence of sodium in either control or low pH-treated NG108-15 cell membranes. In the presence of NaCl, however, inhibition of [3H]DSLET binding by GTP was slightly increased by low pH treatment. Assays of AC activity in low pH-treated NG108-15 membranes indicated that this treatment did not alter basal or forskolin-stimulated AC, but markedly reduced AC stimulated by G_s , using NaF or PGE₂. Inhibition of forskolin- and PGE₂-stimulated AC by DSLET was relatively unchanged by pH 4.5 treatment of membranes. These results indicate that effects of low pH treatment on NaCl/GTP regulation of agonist binding and on G_s function in NG108-15 cell membranes are similar to the effects of this treatment on rat brain membranes.

M₁ MUSCARINIC ANTAGONISTS INTERACT WITH σ RECOGNITION SITES. Diane L. DeHaven-Hudkins¹ and Robert L. Hudkins².

¹Department of Enzymology and Receptor Biochemistry, Sterling Research Group, Malvern, PA 19355-1314 and ²Department of Medicinal Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0540.

The receptor binding profile of representative compounds for σ and muscarinic M₁ and M₂ sites was studied in an attempt to determine if a correlation exists between muscarinic and σ binding affinity, and if a relationship exists between σ binding affinity and a particular muscarinic receptor subtype. A variety of M₁-selective muscarinic antagonists potentially inhibited binding to σ sites in brain. Both basic ester and non-ester type M₁-selective antimuscarinics exhibit affinity for the σ site, while the classical antimuscarinic antagonists atropine and QNB, and the tricyclic pirenzepine, were ineffective in binding to this site. The only agonist which displaced σ binding was the selective M₁ agonist McN-A-343. We also observed a significant correlation between the IC₅₀ values for σ compounds to inhibit [3H]pirenzepine binding and their IC₅₀ values to inhibit carbachol-stimulated phosphoinositide turnover. These observations may aid in elucidating the relationship of σ binding to inhibition of phosphoinositide turnover stimulated by cholinergic agonists.

CHARACTERIZATION AND AUTORADIOGRAPHIC ANALYSIS OF ³H-NALTRINDOLE IN THE RAT, E.J. Drower*, M.S. Dappen*, C. Dorn, C. Markos, M.F. Rafferty* and P.C. Contreras*, Central Nervous Systems Disease Research* and Radiochemistry Division, G.D. Searle & Co. Skokie, IL, 60077.

Naltrindole has been characterized as a select δ -opioid receptor antagonist in several isolated smooth muscle systems. We now report the biochemical characterization of ³H-naltrindole (³H-NTI) as conducted in a crude rat brain homogenate and slices. Binding of ³H-NTI was temperature dependent with increased affinity at higher temperatures. Scatchard analysis revealed a single population of binding sites displaying a K_d of 0.06 nM and B_{max} of 100 fmole/mg protein. Delta selectivity was confirmed by the rank order of IC₅₀ values of select δ and μ ligands; DSLET (0.3 nM), DPDPE (6.2 nM), levorphanol (39 nM) and DAMPGO (685 nM). Saturation isotherms of ³H-NTI was also conducted on both thaw-mounted brain slices and brain paste yielding an approximate K_d of 0.3 nM for each. Autoradiographic distribution of ³H-NTI was performed in the presence and absence of levorphanol to determine specific binding. Binding sites labeled by ³H-NTI were localized in the caudate putamen, nucleus accumbens and outer layers of the cortex.

ALTERATIONS IN G-PROTEIN EXPRESSION IN NEONATAL RAT BRAIN FOLLOWING MORPHINE TREATMENT R. Basheer*, K. Espinoza* and A. Tempel. Lab. of Molecular Pharmacology, Hillside Hosp., Glen Oaks, NY 11004.

G-Proteins have been identified as membrane transducing components in receptor-mediated events. Opiate receptors are representatives of a class of neurotransmitter-binding proteins that are coupled to G-proteins. Previous work has suggested that opiate receptor density is mediated through the cAMP system via G-binding proteins. We have shown that chronic morphine treatment of rat pups produces a significant decrease in brain μ opioid receptor density with no change in receptor affinity. This downregulation is in direct contrast to what is observed in the adult brain where no significant change in opiate receptors can be demonstrated. Our hypothesis is that the factors that influence this difference in neonates are related to the G-protein/cAMP system. In order to understand the interaction between opioid receptors and G-proteins, our preliminary approach was to quantitate mRNA of G-proteins in the developing rat brain before and after morphine treatment. Changes in the levels of G-protein mRNA will be correlated with receptor density changes. Data from these studies may provide insight into the interaction between the opiate receptor and the membrane associated signal transducing systems during addiction. (Supported by NIDA Grant DA-05440).

IN VIVO MOUSE BRAIN LOCALIZATION OF [3H]DPDPE TO DELTA OPIOID RECEPTORS. S.J. Weber, D.L. Green*, V.J. Hruby*, H.I. Yamamura and T.P. Davis. Depts. Pharmacology and Chemistry, University of Arizona College of Medicine, Tucson, AZ 85724.

The opioid receptors μ , δ , and κ have been shown to have distinct patterns of distribution within the brain. In particular, the highest concentrations of the δ receptors are found within the striatum (i.e., caudate nucleus and putamen) and frontal cortex (layers I-II and V-VI). The intent of this study was to examine regional brain distribution of [3H]DPDPE following i.v. administration and compare results to δ receptor localization. Three groups of anesthetized CD1 male mice were studied. Group I was administered (i.v.) a known amount of [3H]DPDPE (20 Ci/mmol; 0.4 nmol/100 g). Groups II and III were pretreated with naloxone (NLX, 10 mg/kg, i.v.) or the specific δ receptor antagonist naltrindole (NTI, 10 mg/kg, i.v.) before [3H]DPDPE. Mice were sacrificed, a sample of blood taken, the brain perfused with saline, removed and rapidly dissected. Brainstem, cerebellum, frontal cortex, hippocampus, striatum and remaining brain were solubilized and counted. No significant difference in the levels of [3H]DPDPE between regions was seen (0.070-0.083%/g tissue) at 10 min, but the striatum was highest. NLX pretreatment resulted in significant ($p < 0.01$) reductions of [3H]DPDPE in all regions with the largest percent reduction in striatum (73.5%). NTI pretreatment had little effect on detectable levels of [3H]DPDPE in the cerebellum and brainstem but significant ($p < 0.05$) reductions occurred in the frontal cortex and striatum (24.0 and 37.4%, respectively). These results suggest that the pattern of i.v. [3H]DPDPE distribution to the brain is similar to δ opioid receptor autoradiographic localization. (Supported by NIDA-DA06284)

236.6

Differential Antagonism Of [D-Ala², Glu⁴]deltorphin- and [D-Pen², D-Pen³]enkephalin Mediated Antinociception by [D-Ala², Cys⁴]deltorphin in the Mouse. P. Horan, J. Taylor, A. Misicka*, A.W. Lipkowski*, V.J. Hruby* and F. Porreca Departments of Pharmacology and Chemistry*, University of Arizona, Tucson, AZ 85724.

Supraspinally in mice, two opioid δ receptor subtypes can be demonstrated on the basis of sensitivity to the irreversible antagonists, [D-Ala², Leu⁵, Cys⁶]enkephalin (DALCE) and 5'-naltrindole isothiocyanate (5'-NTII). These δ receptors are selectively activated by [D-Pen², D-Pen³]enkephalin (DPDPE, DALCE-sensitive site) and [D-Ala², Glu⁴]deltorphin (DELT II, 5'-NTII-sensitive site); no antinociceptive cross-tolerance occurs between DPDPE and DELT II. It is not known if a sulfhydryl group, perhaps critical for ligand binding, is located in or around the binding site of the 5'-NTII sensitive δ receptor. To test this hypothesis, cysteine has been substituted for glutamic acid in the 4 position of DELT II, and the agonist and potential antagonist properties of this compound ([D-Ala², Cys⁴]deltorphin)(Cys⁴-DELT) were tested against intracerebroventricular (i.c.v.) DPDPE and DELT II. I.c.v. Cys⁴-DELT produced a dose-related antinociceptive effect (55°C water tail-flick test) in male, ICR mice; the A₅₀ (95% C.L.) was 0.78 (0.24-2.54) nmol/mouse, and peak effect was at +10 min with the agonist effect dissipating by 30 min. Pretreatment with an A₅₀ dose of Cys⁴-DELT (3 nmol) blocked the antinociceptive effect of DELT II tested 4, 8, 12 and 24 hrs later, but not that of an equianalgesic dose of DPDPE up to pretreatment times of 120 hrs. The differential antagonism of DPDPE and DELT II by Cys⁴-DELT suggests the presence of a sulfhydryl group in the 5'-NTII-sensitive δ opioid receptor and supports a structural basis for opioid δ subtypes.

SWIM-STRESS INDUCED ANTINOCICEPTION IN MICE IS MEDIATED BY A SUBTYPE OF OPIOID δ RECEPTOR. Kenneth D. Wild, Todd W. Vandergraf* and Frank Porreca. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

Supraspinal antinociception produced by opioid δ agonists has recently been shown to be associated with subtypes of δ receptors which can be distinguished on the basis of sensitivity to the novel, irreversible δ antagonists, [D-Ala², Leu⁵, Cys⁶]enkephalin (DALCE) and naltrindole-5'-isothiocyanate (5'-NTII). These δ receptor subtypes are selectively activated by [D-Pen², D-Pen³]enkephalin (DALCE-sensitive δ receptor) and [D-Ala²]deltorphin II (5'-NTII-sensitive δ receptor); no antinociceptive cross-tolerance occurs between these agonists. Cold-water swim-stress (CWSS) has been previously shown to produce antinociception in mice, apparently resulting from endogenous activation of opioid δ receptors. The present experiments attempted to identify the opioid δ receptor subtype associated with CWSS. Male, ICR mice (20-30 g) were exposed to water (5°C) for 3 min and tested after a further 10 min in the 55°C water tail-flick test. CWSS produced a time-related antinociceptive effect which was maximum at approximately 10 min and which dissipated by 15 min after swim. The antinociception was antagonized by naloxone (1 mg/kg, *s.c.*, -13 min) or the δ antagonist, ICI 174,864 (4.4 nmol, *i.c.v.*, -18 min) but not by the μ antagonist β -funtalrexamine (18.8 nmol, *i.c.v.*, -24 hr, a time and dose which blocks μ agonist effects). Additionally, CWSS-induced antinociception was antagonized by 5'-NTII (17.5 nmol, *i.c.v.*, -24 hr), but not by DALCE (4.46 nmol, *i.c.v.*, -24 hr). Under these conditions, CWSS-induced antinociception is mediated by activation of the 5'-NTII-sensitive δ receptor in mice.

INTERACTION OF [³H]-DTG WITH σ_2 RECEPTORS IN RAT HEART MEMBRANE PREPARATIONS. M. Dumont and S. Lemaire. Department of Pharmacology, University of Ottawa, Ottawa, Ontario Canada K1H 8M5.

Using membrane binding techniques, we have characterized the binding properties of [³H]-1,3 di(2-tolyl) guanidine ([³H]-DTG) in membrane preparations of rat heart. Binding assays were performed with 2 ml-aliqots of membrane (1 mg protein) in 5 mM Tris-HCl (pH 7.4) at 37°C for 30 min followed by filtration through polyethyleneimine treated glass microfiber filters. Scatchard plot analysis of [³H]DTG binding revealed the presence of one high affinity saturable binding site with a Kd of 7.1 nM and a Bmax of 86 pmol/g protein. The drug specificity profile of the receptor correlated with that of the σ receptor with the following order of potency: DTG > haloperidol > (-)butaclamol > (+)butaclamol > (-)SKF-10047 > PCP > TCP > MK-801 > (+)SKF-10047. [³H]DTG binding was sensitive to the Ca²⁺ channel blocker, verapamil but not to the K⁺ channel blocker, 4-aminopyridine. The reverse stereoselectivity of [³H]DTG binding for (-)SKF-10047 indicated that the cardiac σ receptor belongs to the σ_2 subtype. The presence of verapamil-sensitive σ_2 receptor in the heart indicates that it may be involved in some of the cardiovascular effects of the non-selective drug of abuse, PCP. Supported by the HSFO.

ALTERATIONS IN LOCAL CEREBRAL GLUCOSE UTILIZATION FOLLOWING UNILATERAL MICROINJECTION OF δ OPIATE LIGAND IN THE SUBSTANTIA NIGRA. R.W. Clement, A.G. Hohmann, and J.M. Walker. Schrier Research Laboratory, Department of Psychology, Brown University, Providence, RI, 02912.

Previous studies demonstrate that unilateral microinjection of opioid ligands in the substantia nigra (SN) result in contralateral circling behavior in the rat; however, the mechanisms for this behavior differs with the particular class of receptors involved. Whereas μ and δ opiates exert effects through dopaminergic neurons of the pars compacta, kappa opiates increase movement by their actions on nondopaminergic neurons in the pars reticulata. The current study investigates regional activity following unilateral intranigral application of δ opioid ligands using the quantitative autoradiographic 2-deoxy-D-[1-¹⁴C]glucose method as adapted for use in freely moving rats. Subjects were microinjected with 10nmol of the delta ligand [D-penicillamine^{2,3}]enkephalin (DPDPE) in a volume of 0.5 μ l normal saline just prior to infusion of 125 μ Ci/Kg of 2-deoxy-D-[1-¹⁴C]glucose. Behavioral data was concurrently obtained via microcomputer and confirms the potent locomotor stimulation induced by DPDPE. Regional cerebral glucose utilization was determined. Following application of DPDPE in SN, bilateral effects were observed in the nucleus accumbens, habenula, superior colliculus, ventral tegmental area (VTA), and the cingulate cortex. Unilateral differences in glucose utilization were not apparent. Since there are few δ receptors in the VTA (Mansour, et al. TINS, 11:308 '88), it seems unlikely that δ opiates had direct effect on this structure by spreading from the microinjection site in the adjacent substantia nigra.

σ RECOGNITION SITES IN BRAIN AND PERIPHERAL TISSUES: CHARACTERIZATION AND EFFECTS OF CYTOCHROME P450 INHIBITORS. L.C. Fleissner*, F.Y. Ford-Rice, M.A. Ator* and D.L. DeHaven-Hudkins. Dept. Enzymology & Receptor Biochemistry, Sterling Research Group, Malvern, PA 19355.

Binding to σ sites in guinea pig and rat was characterized with the [³H]ligands (+)pentazocine and DTG. The affinities of selected σ reference compounds and cytochrome P450I1D1 inhibitors, and the effects of cytochrome P450 induction were also determined. The K_d values for [³H](+)pentazocine-labelled σ sites were similar in all tissues, but the number of sites varied, with an order of liver > testes > brain > heart. The B_{max} values for [³H]DTG-defined σ sites were greatest in testes, followed by liver, brain and heart, while the K_d values in liver and testes were two-fold lower than those in brain and heart. The rank order of potency for reference compounds was similar in brain, liver and testes. Following induction with phenobarbital or β -naphthoflavone, the number of σ sites was unchanged in brain but increased in liver. The potency of representative compounds to displace σ binding in guinea pig liver failed to correlate with the affinities of these compounds to inhibit cytochrome P450I1D1 activity in human liver. These results suggest that σ sites in the periphery are similar to those in brain, and that the σ binding site is not identical with cytochrome P450I1D1.

236.10

CHARACTERIZATION OF THE DOSE-DEPENDENT ANTAGONISM OF SPINAL OPIOID RECEPTORS BY NALOXONE AND NALTRINDOLE. FURTHER EVIDENCE FOR DELTA RECEPTOR SUBTYPES? Tony L. Yaksh, Donna L. Hammond and Paul J. Tiseo. Dept. of Anesthesiology, U. C. San Diego and the University of Chicago.

The possibility that delta-opioid receptor subtypes or coupled μ /delta receptor complexes were mediating antinociception in the rat spinal cord was investigated using the intrathecal (i.t.) administration of highly and partially selective μ and delta opioid receptor agonists and antagonists. The μ agonist DAGO and the delta ligand DPDPE, as well as the partially selective agonists morphine (μ / δ) and DADLE (δ / μ) were examined using the hot-plate test (52.5°C). The i.t. doses producing a maximal response (DAGO, 0.3 μ g; DPDPE, 60 μ g; morphine, 10 μ g; and DADLE, 1 μ g) were then systematically challenged with either naloxone (NAL), or the more selective delta opioid antagonist naltrindole (NTL). The time course of drug administration was designed such that the times of both agonist and antagonist peak effects coincided. NAL antagonized the analgesic response of all the agonists tested with the antagonist dose-response curves of all agonists virtually overlapping. In contrast, the degree of antagonism produced by NTL varied greatly. The MPE produced by DPDPE was significantly attenuated in a dose-related manner whereas the response produced by DAGO was unaffected. However, when DADLE was challenged by NTL, the response was also completely unaffected. Interestingly, morphine demonstrated a surprising sensitivity to NTL with the high dose (30 μ g) reducing the MPE of morphine to 46%. The NAL results suggest that a strong μ component is involved in the analgesic response produced by all the agonists, including the δ -preferring agonists DADLE and DPDPE. In a similar fashion, the NTL results suggest that a delta component is involved in the analgesia produced by the μ -preferring morphine. Such results may support the existence of a μ /delta receptor complex in the spinal cord of the rat whose mediation of analgesic effects can be antagonized by both NAL and NTL. Finally, the fact that DADLE is unaffected by NTL in this study suggests that although DADLE shows a strong delta selectivity *in vitro*, it does not appear to be binding to the same delta receptor that NTL does in the rat spinal cord.

EFFECTS OF 1,3-DI-O-TOLYLGUANIDINE, A SIGMA LIGAND, ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT BRAIN. A.G. Hohmann¹, R.R. Matsumoto¹, M.K. Hemstreet¹, S.L. Patrick¹, J.E. Margulies², R.P. Hamer², and J.M. Walker¹. ¹Schrier Res. Lab., Dept. of Psych., Brown Univ., Providence, RI 02912. ²Dept. of Anat. and Reprod. Biol., Univ. Hawaii Sch. Med., Honolulu, HI 96822.

The 2-deoxy-D-[1-¹⁴C]glucose ([¹⁴C]DG) method was used to examine the effects of the relatively selective sigma (σ) ligand 1,3-di-o-tolylguanidine (DTG) on cerebral metabolism in freely moving rats. Each animal received an i.p. injection of DTG (0.2 [n=8], 1 [n=5], or 5 [n=5] mg/kg) or normal saline (n=6) 20 min prior to the infusion of [¹⁴C]DG. DTG induced dose-dependent changes in local cerebral glucose utilization (LCGU) in certain motor and limbic structures. For most structures, the maximum effect occurred at 1mg/kg. The most profound increases in LCGU were found in regions that are rich in σ receptors. These include cerebellar and related nuclei (interpositus, lateral and medial cerebellar n., vestibular n., olivary n., red n.), ambiguus n., facial n., motor trigeminal n., hippocampus (CA2, CA1, CA3, DG), n. basalis of Meynert, interpeduncular n., substantia nigra pars compacta and pars reticulata. It is unlikely that the observed alterations in LCGU resulted from artifacts of the procedure, since the pattern of changes induced by DTG is not typical of alterations produced by changes in blood pressure, pCO₂ or body temperature. The areas affected by DTG are similar to those previously reported for other σ ligands (Puppa & London, *Br. Res.* 505: 283, '89). The increased functional activity in the substantia nigra pars compacta is consistent with data from microdialysis experiments which suggest a dopamine-releasing effect of DTG and (+)-pentazocine following parenteral administration (Walker et al. this meeting). Future studies employing additional selective σ ligands at different doses must be carried out in order to confirm whether these changes in LCGU are σ -mediated.

236.13

FUNCTIONAL ANTAGONISM OF SIGMA RECEPTORS BY A NOVEL ISOTHIOCYANATE LIGAND. MK Hemstreet¹, L Bluth^{2*}, BR DeCosta³, WD Bowen², and JM Walker¹. ¹Program in Neural Science and ²Division of Biology and Medicine, Brown University, Providence, RI 02912, and ³National Institutes of Health, Bethesda, MD 20892.

Both the *in vivo* and *in vitro* characteristics of a novel isothiocyanate (ITC) ligand for sigma receptors (BD713) were examined in male Sprague-Dawley rats. In radioligand binding assays, brain membranes were pretreated for 10 min. with either BD713 or a structurally-related sigma compound lacking the ITC moiety; membranes were then repeatedly washed. Under these conditions there was no remaining sigma binding of the non-ITC compound, but wash-resistant blockade of sigma sites was evident following BD713. This reduction in sigma binding following BD713 pretreatment may be due to covalent attachment of the ITC compound to sigma receptors following interaction with the ligand binding region. The specificity of BD713 does not overlap with phencyclidine receptors, as seen by minimal attenuation of [³H]TCP binding following pretreatment with the ITC compound.

In behavioral experiments, animals were pretreated with BD713 by unilateral intracerebral administration either into the red nucleus or the substantia nigra. These sites were chosen because of the predictable and quantifiable nature of the behaviors elicited by microinjection of sigma ligands into these structures. Control injections consisted of vehicle or the reversible sigma ligand, (+)pentazocine. Following a 5hr. pretreatment interval, animals received a second microinjection into the same structure, with all rats receiving (+)pentazocine as the second injection. Only BD713 pretreatment produced a functional antagonism of the *in vivo* actions of (+)pentazocine, with significant attenuation of cervical dystonia following intrabulbar administration ($p < 0.05$) and of contralateral rotatory behavior following intranigral injection of the reversible sigma ligand ($p < 0.01$). These results imply that the behavioral actions of sigma ligands may be due to occupation of sigma receptors, rather than nonspecific actions of these compounds; experiments are currently underway to address this possibility.

236.15

CHARACTERIZATION OF [³H]DTG AND [³H](+)-3-PPP BINDING SITES OF NB41A3 NEUROBLASTOMA, C6 GLIOMA, AND NG108-15 HYBRID CELLS. B.J. Vilner and W.D. Bowen. Section of Biochemistry, Division of Biology and Medicine, Brown University, Providence, RI 02912.

We have characterized the binding of sigma ligands to crude membrane homogenates from NB41A3 neuroblastoma, C6 glioma, and NG108-15 hybrid cells (50 mM Tris-HCl, pH 8.0). [³H]DTG bound with K_d (nM) and B_{max} (fmol/mg protein) of 62 ± 6 and 7324 ± 670 (NB41A3), 101 ± 7 and 5507 ± 537 (C6), and 75 ± 1 and 3134 ± 229 (NG108-15), respectively. The corresponding values for [³H](+)-3-PPP were 137 ± 11 and 2256 ± 642 , 500 ± 31 and 6268 ± 682 , and 183 ± 25 and 1673 ± 344 , respectively. Competition studies with various sigma ligands vs. 5 nM [³H]DTG gave the following rank order of potency: DTG > haloperidol > (-)-pentazocine > (+)-3-PPP = fluphenazine > (+)-pentazocine > (-)-SKF 10,047 > (+)-SKF 10,047. Ligands for opiate (DAGO, DSLET, morphine), PCP (MK-801), dopamine (apomorphine) and amino acid (GABA, glutamate) receptors failed to displace [³H]DTG binding at 10 μ M. Low affinity for (+)-pentazocine ($K_i = 1.7-3.3 \mu$ M) and (+)-SKF 10,047 ($K_i = 19.3-91.8 \mu$ M), and much higher affinity for the corresponding (-)-enantiomers suggest that these cells express sigma-2 receptors similar to those found in PC12 cells (*Brain Res.* 527:244-253, 1990). However, the affinity of (+)-3-PPP ($K_i = 286-493$ nM) is significantly lower than reported for the PC12 cell site. This may suggest a sub-form of sigma-2 site and deserves further investigation. Finally, binding of [³H]DTG to intact cells under physiological conditions suggests that these are cell surface receptors. The presence of sigma-like binding sites on cell lines of both glial and neuronal origin will facilitate studies of the biochemical and physiological processes mediated by this receptor. (PHS Grant NS-26746)

236.17

KAPPA AND DELTA OPIOID RECEPTORS: RELATIONSHIP TO RAT MIDBRAIN DOPAMINERGIC NEURONS. S.G. Speciale, M. Sadeq, K.F. Manave and D.C. German. Dept. of Psychiatry, UT Southwestern Med. Cntr., Dallas, TX.

We have described the relationship between mu opioid receptors and midbrain dopaminergic (DA) neurons (Speciale et al., *Neurosci. Abstr.* 15: 230, 1989). Receptor densities (fmol/mg tissue) ranged from 40-150 within specific DA nuclei. The present study extends this investigation. Brain sections were incubated in 5 nM [³H]-U-69593 for kappa (κ) binding, or 6 nM [³H]-DPDPE for delta (δ) binding, and standard *in vitro* autoradiographic methods used. The κ receptors were specifically localized within the midbrain DA regions: throughout the rostral-caudal extent of nucleus A9, and within several nucleus A10 subnuclei (e.g., paranigral and interfascicular nuclei) at densities of 6.6 ± 0.6 ; within nucleus A8, however, the density was 4.1 ± 0.4 . There were low densities of δ receptors uniformly throughout the midbrain DA regions. Within nuclei A8, A9 and A10 the binding was ≈ 7 , and slightly higher within the caudal nucleus A9. These results demonstrate a heterogeneous distribution of opioid receptor subtypes within the midbrain DA nuclear regions. Supported by DA-05314.

IONTOPHORETIC EFFECTS OF PUTATIVE SIGMA LIGANDS ON RAT CEREBELLAR PURKINJE CELLS. W.J. Martin, B.R. deCosta* and J.M. Walker. Schrier Research Laboratory, Dept. of Psychology, Brown University, Providence, RI 02912. *Laboratory of Medicinal Chemistry, NIDDK, NIH, Bethesda, MD, 20892.

The early ligands for the σ receptor were tainted by a lack of selectivity, leading to attempts to develop more selective ligands for the site. The purpose of this study was to quantify the electrophysiological responsiveness of rat cerebellar Purkinje cells to iontophoretic application of more selective σ ligands. Male Sprague-Dawley rats were anesthetized with Urethane (1.25g/kg, i.p.), 1,3-di-o-tolylguanidine (DTG), dextrallorphan (DEX), (+)-pentazocine (PENT), (+)-3-(3-Hydroxyphenyl)-N-propylpiperidine ((+)-3-PPP), and a novel diamine, BD1008, were ejected from a multi-barrel pipette onto individual Purkinje cells. Significant drug effects were determined according to a 12% change in the frequency of baseline firing. Inhibitions were seen following ejections of DTG (68%, n=19), BD1008 (60%, n=15), DEX (52%, n=21) and PENT (20%, n=15). These inhibitions were dose-dependent and occurred with changes in the frequency of cell firing, but without changes in spike amplitude or duration, indicating that local anesthesia effects were not responsible for observed inhibitions. The effects of (+)-3-PPP were atypical, inducing excitations in 29% of cells studied (n=21). Vehicle controls for pH, as well as controls for current were employed. The results of this study indicate that σ ligands are predominantly inhibitory on Purkinje cells in the rat cerebellum, with the exception of (+)-3-PPP, which is excitatory. However, it cannot be concluded that the effects of (+)-3-PPP were σ -mediated or that this drug is acting on the same σ receptor as the other ligands. These data are consistent with the possibility that BD1008 is a potent σ ligand.

236.16

RELATIONSHIP OF KAPPA OPIOID RECEPTOR BINDING AND INHIBITION OF ADENYLYL CYCLASE IN GUINEA PIG BRAIN. C.S. Konkoy and S.R. Childers. Dept. Physiology/Pharmacology, Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Previously, we showed that κ -selective ligands inhibit adenylyl cyclase (AC) in guinea pig cerebellar membranes. The present studies explore the relationship between κ binding sites and inhibition of AC. Various κ opioids displaced [³H]U-69,593 (U-69) binding at a single site with sub-nM affinities. These agonists were several hundred fold weaker in inhibiting AC, but the rank order of AC inhibition paralleled the displacement of [³H]U-69 binding except for α -neo endorphin. The correlation of AC and binding IC₅₀ values was significant except for α -neo endorphin, which was relatively weak at inhibiting AC despite a K_i value of .08 nM vs. [³H]U-69 binding. A correlation between [³H]U-69 binding and U-50,488H (U-50)-inhibited AC was determined across 11 regions of the guinea pig brain. κ -inhibited AC was highest in the cerebellum, absent in thalamus and sup. colliculus, and moderate in other regions. In most regions, [³H]U-69 binding correlated with the efficacy of U-50-inhibited AC. However, hippocampus had high levels of U-50-inhibited AC despite low levels of [³H]U-69 binding, while cortex exhibited a high density of [³H]U-69 sites but a relatively low level of U-50-inhibited AC. Irreversible reaction of cerebellar κ receptors with β -CNA blocked both [³H]U-69 binding and U-50-inhibited AC, with no effect on agonist potency, thus suggesting a relatively small κ receptor reserve for this effector system.

Supported by PHS grants DA-02904 and DA-05400 from NIDA.

CHARACTERIZATION OF KAPPA OPIOID RECEPTOR SUBTYPES IN GUINEA PIG BRAIN AND ILEUM. W.E. Polgar*, S.R. Brandt*, J.L. Webster*, I. Berzetei-Gurske and L. Toll. Neuroscience Dept. SRI International, Menlo Park, CA 94025.

Recent studies have clearly demonstrated the presence of κ_1 and κ_2 opioid binding sites. κ_2 sites, have been labeled with [³H]bremazocine, or [³H]EKC, in the presence of reversible or irreversible blockers of μ , δ and κ_1 . We have used [³H]bremazocine binding to guinea pig brain membranes and directly compared reversible and irreversible blockade of μ , δ and κ_1 for analysis of κ_2 receptors. We have also used selective antagonists to look for κ_2 receptors in guinea pig ileum. Our results showed similarity between the two methods of incubation conditions. Using either method of tissue incubation, many ligands tested displayed shallow inhibition curves, suggesting the presence of additional sites. This was most dramatically demonstrated by the dynorphin gene products tested. Each dynorphin analog inhibited a maximum of 60-70% of the [³H]bremazocine binding, even after μ , δ and κ_1 are blocked. These results suggest that even κ_2 binding is heterogeneous. Because dynorphin does not inhibit a portion of " κ_2 " binding, this portion should not be considered a κ subtype.

236.19

KAPPA OPIOID RECEPTOR SUBTYPE IN RAT SPINAL CORD: COINCIDENCE WITH AUTONOMIC REGIONS. M.A. Romagnano, E.K. Richfield, L.S. Brady, and R.W. Hamill. Neurology Dept. Monroe Community Hospital/Univ. of Rochester, N.Y. 14620 and Unit on Functional Neuroanatomy, NIMH, Bethesda, MD. 20892

The distribution of the kappa opioid receptor subtype was examined throughout spinal cord levels C8-S2-4 in the rat using the *in vitro* receptor autoradiography technique. Fresh frozen horizontal serial sections were incubated with 10nM [³H]bremazocine in the presence of either unlabeled DAGO and DADLE or BIT and FIT (mu and delta opioid receptor subtype blockers). Adjacent sections were coincubated with naloxone (10μM) or levorphanol (1μM) to determine nonspecific binding. Following incubation, slides were apposed to ³H-Hyperfilm (Amersham) and allowed to expose for 3-4 months.

In upper and lower thoracic spinal cord, moderate-dense binding was found in lamina VII in nucleus intercalatus and nucleus intercalatus, pars paraependymalis. Moderate-dense kappa binding was present in the dorsal commissural nucleus while moderate binding found throughout the gray matter. Specific dense kappa binding was found in laminae I and II in upper and lower thoracic and lumbosacral spinal cord. Moderate-dense kappa binding was found in the sacral parasympathetic nucleus, dorsal gray commissure, and within bands traversing the intermediate zone. The rest of lumbosacral spinal cord gray matter contained moderate kappa binding. The dorsal root ganglia at all spinal cord levels contained moderate to moderate-dense kappa binding. These data establishing the presence of the kappa opioid receptor subtype in spinal cord regions involved in autonomic functions support the involvement of opioid peptides in autonomic regulation.

236.21

NALOXONE INDUCED ANALGESIA: INVOLVEMENT OF KAPPA OPIATE RECEPTORS. M. Bianchi* and A.E. Panerai. Dept. Pharmacology, Univ. of Milano, 20129, Milano, Italy.

The analgesic effect of naloxone has been consistently demonstrated in post-stressful experimental or physiological conditions. Several hints suggest the involvement of opiate receptors of the kappa subtype in this effect. We show now in rats that acute naloxone, at the dose of 30mg/kg, exerts an analgesic effect as measured on the hot plate, that peaks thirty minutes after administration, and is reversed by the kappa opiate receptor antagonist MR 1452. Consistently with this observation, the analgesic effect of naloxone was observed also after the subcutaneous administration of the drug for five days, and this effect too was reversed by the kappa opiate receptor antagonist. The analgesia observed is not limited to naloxone, but another opiate receptor antagonist, naltrexone, exhibit an analgesic effect, that is reversed by the kappa opiate receptor antagonist. We conclude that naloxone induced analgesia is part of the activation of a complex pattern of mechanisms that might be not strictly related to stress, and involves kappa opiate receptors.

236.23

CHARACTERIZATION OF KAPPA OPIOID BINDING SITES ON MURINE LYMPHOCYTES. L. D. Saripalli and J. M. Bidlack. Dept. of Pharmacology, Univ. of Rochester, Rochester, NY 14642.

Membranes from the R1.1 murine lymphoma cell line, prepared in 50 mM Tris-HCl, pH 7.5, bound [³H]naloxone in a saturable and specific manner. Scatchard analysis of [³H]naloxone binding at 25°C to R1.1 cell membranes showed a curved plot, suggesting multiple binding sites. Competition experiments with opioids, specific for μ, δ, and κ brain opioid binding sites, indicated that some of the [³H]naloxone binding was to κ opioid binding sites, while the remaining [³H]naloxone binding was only inhibited by naloxone. The κ opioid binding site was further characterized using [³H]U69,593, a selective κ opioid agonist. Specific [³H]U69,593 binding increased linearly with protein concentration. At 25°C, binding equilibrium was attained within 20 min, and was stable for up to 120 min. Scatchard analysis of [³H]U69,593 binding to R1.1 cell membranes showed a linear plot with a K_d value of 0.23 ± 0.018 nM and B_{max} value of 30.3 ± 47 fmol/mg protein. The δ-selective opioid peptides, [D-Pen², D-Pen⁵]enkephalin (DPDPE) and ICI 174,864, at concentrations up to 10 μM did not inhibit 0.4 nM [³H]U69,593 binding. Micromolar concentrations of the μ-selective opioid peptide [D-Ala², (Me)Phe⁴, Gly(ol)⁶]enkephalin (DAGO) were needed to inhibit [³H]U69,593 binding. The IC₅₀ values for the κ-selective opioids U50,488H, nor-binaltorphimine (nor-BNI), and (-) pentazocine were in the low nM range, while the IC₅₀ value of (+) pentazocine was 26 times greater than the (-) isomer. Protease-resistant analogues of dynorphin also inhibited [³H]U69,593 binding to R1.1 cell membranes. These results indicate that R1.1 lymphoma cells exhibit κ opioid binding sites that have similar characteristics to brain κ opioid receptors. (Supported by USPHS grant DA04355).

EFFECT OF KAPPA AGONISTS, PD 117302 AND CI-977, ON GLUTAMATE-STIMULATED PHOSPHATIDYLINOSITOL (PI) METABOLISM IN NEURONAL CULTURES. D. L. Yourick, M. A. DeCoster and F. C. Tortella. Dept. Med. Neurosci., Walter Reed Army Inst. Res., Washington, D. C. 20307-5100.

Neuroprotective and anticonvulsant effects of the novel kappa opioid agonists, PD 117302 and CI-977, have been described. We have also shown that a reduction in intracellular calcium may be involved in this neuroprotective action. The effects of these kappa opioids on glutamate-induced inositol phosphate (IP) accumulation were evaluated in primary rat cortical neuronal cultures. Glutamate (40 μM) increased IP accumulation to 1523% of basal; addition of 50 nM PD 117302 or CI-977 with glutamate decreased this stimulation by 57 and 48% respectively. In control experiments, both drugs were seen to stimulate IP accumulation alone, indicating that kappa receptors may be linked to PI metabolism. These results 1) suggest that kappa opioid-induced reductions in glutamate-stimulated IP accumulation may represent a mechanism by which intracellular calcium is decreased and 2) provide a molecular basis for the role of second messengers in the neuroprotective actions of these novel kappa opioid drugs.

PHARMACOLOGY AND BINDING OF KAPPA₃ OPIATE RECEPTORS IN MICE. J. Cheng, C.G. Pick and G.W. Pasternak. The Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Depts. of Neuroscience and Pharmacology, Cornell Univ. Medical College, New York, NY 10021.

Naloxone benzoylhydrazone (NalBzoH) labels both μ and κ₃ receptors in calf brain membranes. In the present study we demonstrate the presence of κ₃ receptors in mouse brain and examine κ₃ analgesia in genetically distinct strains of mice. Like the calf, the density of κ₃ sites in mouse brain was quite high, typically twice that of μ receptors. The selectivity of κ₃ binding also was similar to that in calf. The poor affinity of a number of selective drugs (morphine, U50,488H, DPDPE) supported the existence of a distinct κ₃ site. NalBzoH (50 mg/kg, s.c.) elicited a potent κ₃ analgesia in CD-1 mice (55%), as previously reported. However, its analgesic potency in additional strains varied considerably. In fact, no tailflick analgesia was observed in C57 or CXBK mice. The sensitivity of Swiss (30%) and Balb/C (15%) were intermediate. Whole brain binding studies did not demonstrate significant differences in either the affinity or B_{max} of the various strains. The fact that the behavioral differences were not accompanied by the changes in the binding values may have a number of reasons. The receptors responsible for analgesia may represent a small percentage of the total or the effectiveness of the κ₃ system may be modulated by changes downstream from the receptor.

237.1

DIFFERENTIAL EFFECTS OF MU AND DELTA OPIATES IN THE RAT HIPPOCAMPAL SLICE. G.B. Watson and T.H. Lanthorn. CNS Diseases Research, Searle R & D, Skokie, IL 60077.

Various opiate agonists and antagonists were examined for their ability to alter extracellular CA1 evoked population spike amplitude. DPDPE, DSLET, DTLET, DAMGO and Leu- and Met-enkephalin all increased the amplitude of the evoked primary population spike. In addition, those compounds with delta receptor selectivity of < 100 induced secondary population spike(s). In contrast to DPDPE, (D-al²)-deltorphin II (10-1000 nM), another compound with high affinity and selectivity for delta receptors, had no agonist-like effect on primary population spike amplitude. The effects of DPDPE were antagonized by the delta antagonist naltrindole (NTI), while the agonist actions of DSLET were relatively insensitive to NTI. The actions of DSLET were antagonized by the mu antagonist naltrexone. Taken together, these results suggest that the actions of delta selective compounds like DPDPE can be differentiated from mu receptor-mediated actions. In addition, the lack of activity of deltorphin II and the apparent lack of delta activity of DSLET suggest that one subtype of delta receptor mediates this activity. This appears to be most like the proposed delta_{noncomplexed} site.

INTERACTIONS BETWEEN OPIATE AND ACETYLCHOLINE RESPONSES ON MEDIAL VESTIBULAR NEURONS. D.Q. Carpenter, D.G. Tieman, and N. Hori. NYS Dept. Health and School of Public Health, Albany, NY 12201.

We have recorded electrical activity and responses to transmitters and peptides on rat brain slices of medial vestibular nucleus. These neurons exhibit an endogenous pacemaker discharge which varies with membrane potential but is independent of manipulations which block synaptic transmission. With ionophoretic application of neurotransmitter agonists the neurons are excited by the excitatory amino acids and acetylcholine and inhibited by GABA. Morphine and leucine enkephalin altered the spontaneous activity of every neuron tested and these effects were blocked by naloxone. Most (>90%) were excited by morphine, but some cells showed either pure inhibition or a biphasic excitation/inhibition. When morphine was bath perfused a few neurons showed a significant and maintained increase in spontaneous discharge frequency. In the presence of morphine most showed a clear increase in amplitude of response to acetylcholine but not to quisqualate. This effect on acetylcholine response was dose dependent. Naloxone, which blocked all opiate effects, also reduced the response to acetylcholine in the presence or the absence of morphine. These observations show that medial vestibular neurons exhibit excitatory opiate receptors on almost all neurons and that there is an interaction between opiate and acetylcholine responses which has not been described elsewhere.

237.5

PRE- AND POSTSYNAPTIC EFFECTS OF OPIOIDS MEASURED IN PATCH/SLICE RECORDINGS OF THE RAT NUCLEUS TRACTUS SOLITARIUS (NTS). H.W. Rhim, M. McCarron, S.R. Glaum and R.J. Miller. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago IL 60637.

The NTS mediates central respiratory, cardiovascular and gastrointestinal homeostasis. Opioid-containing nerve terminals and opioid receptors are widely distributed in the NTS (Atweh et al., Brain Res. 124:53,1977). Exogenous opioid agonists produce potent respiratory and cardiovascular effects by unknown mechanisms within the NTS (Hassen et al., Peptides 4:621,1983). We therefore examined the effects of morphine (MOR, 10µM), the selective mu agonist D-Ala-MePhe-Gly-ol-enkephalin (DAGO, 0.1-10µM), the selective delta agonist D-Pen-D-Pen-enkephalin (DPDP, 4µM) and the selective kappa agonist dynorphin (DYN, 4µM) on synaptic transmission in the NTS.

Whole cell patch recordings were made with K-gluconate filled electrodes (3-5 Mohm) containing (mM): K-gluconate 145; MgCl₂ 2; HEPES 5; K₂ATP 5; CaCl₂ 0.1; EGTA 1.1.

All neurons (n=34) displayed spontaneous (sp) EPSPs. In addition, approximately half of the cells exhibited spIPSPs at their resting membrane potential (-65 to -50mV). Application of 10µM MOR (n=3) reduced the amplitude of both spPSPs and PSPs evoked by electrical stimulation of the tractus solitarius. The effect of MOR was not mimicked by DYN (4µM, 5/6 cells) or DPDP (4µM, 23/24 cells). In contrast, DAGO (0.1-10µM) reduced both evoked and spPSPs in 32/34 cells. Accompanying this response was a dose-dependent hyperpolarization (23/32 cells) with a reversal potential of -97mV and a decrease in R_{in}. Naloxone (10-30µM) reversibly inhibited the effects of MOR and DAGO. These data suggest that mu opioid receptor activation can depress synaptic transmission in the NTS.

237.2

8-BROMO-cAMP BLOCKS OPIOID ACTIVATION OF A VOLTAGE-GATED POTASSIUM CURRENT IN ISOLATED HIPPOCAMPAL NEURONS T.L. Wimpey and C. Chavkin. Dept. of Pharmacology, University of Washington, Seattle, WA 98195

We have previously shown that mu-selective opioid agonists activate both an inward rectifying and a voltage-gated potassium conductance in acutely dissociated hippocampal neurons. We now report that the opioid-activated voltage-gated potassium conductance is blocked by the membrane permeable cAMP analogue 8-Bromo-cAMP. Hippocampal neurons acutely dissociated from adult rats were voltage-clamped using the whole cell patch clamp technique. The neurons were continuously superfused with oxygenated buffer containing TTX (1 µM) and cadmium (500 µM) to block sodium and calcium currents respectively; drug responses were determined by pressure application through drug pipettes. Only dissociated neurons that were not pyramidal in appearance were chosen for recordings. As previously reported the opioid-responsive neurons make up only a small fraction of the total neuronal population in this brain region. Only about one in six of the selected neurons responded to opioid application. PL017 or another mu selective agonist DAMGO increased outward potassium currents recorded during depolarizing voltage steps in these neurons. This effect was blocked by simultaneous application of the antagonist naloxone. Application of 8-Bromo-cAMP from a second drug pipette reversed the opioid action and blocked the effect of subsequent opioid application. In contrast, 8-Bromo-cGMP failed to inhibit opioid activation of the voltage-gated potassium current. This is the first demonstration of an opioid-regulated membrane conductance that is sensitive to cAMP levels. Supported by DA04123.

EFFECTS OF PHOSPHATASE INHIBITION ON THE TRANSIENT DESENSITIZATION OF µ-OPIOID RECEPTORS IN RAT LOCUS COERULEUS. P.B. Osborne and J.T. Williams. Vollum Institute, Oregon Hlth. Sci. Univ, Portland, OR 97201.

The locus coeruleus (LC) is a noradrenergic nucleus in the brainstem that is thought to play a role in mediating opiate withdrawal responses. In slice preparations agonists to both µ opioid receptors and α₂ adrenoceptors hyperpolarize LC neurons by increasing a potassium conductance. In a previous microelectrode study it was shown that exposure of neurons to supermaximal concentrations of µ receptor agonists resulted in a transient desensitization of opioid receptors but had little or no effect on hyperpolarizations caused by adrenoceptor agonists.

To study this effect further, experiments were conducted using whole cell patch clamp recording in rat brain slices. Outward currents induced by test doses of Met-enkephalin (ME) (300nM) were compared before and after a 5 min exposure to a desensitizing dose of ME (30 µM). 3 min after washout of the high dose, the current induced by the low dose was reduced by 77%. Recovery occurred over 15min but was always incomplete. Addition of the phosphatase inhibitor microcystin (100nM) to the electrode solution prolonged the time taken to recover from desensitization. Microcystin at this concentration fully inhibits type 1 and type 2a phosphatases but not Ca/calmodulin-dependent type 2b phosphatases. With both microcystin and the Ca chelator BAPTA (10mM) in the electrode solution the amount of desensitization was increased and further slowing of the recovery from desensitization was observed. These results indicate that dephosphorylation of an as yet unidentified substrate appears to be necessary for the reversal of µ opioid receptor desensitization. Supported by USDHHS DA 04523 and MH45003.

THE INFLUENCE OF OPIATE ANTAGONISTS ON DYNORPHIN-INDUCED ELECTROPHYSIOLOGIC EFFECTS. H. Ristic and L. Isaac, Department of Pharmacology, Univ. Ill. Col. of Medicine, Chicago, IL 60612

Dynorphin A is thought to be the endogenous ligand for the kappa opiate receptor. When applied directly onto the spinal cord it results in a reversible depression of the dorsal root potential (DRP). Our goal was to determine whether this effect is opiate receptor mediated.

A laminectomy was performed on urethane anesthetized rats. Lumbar spinal roots were isolated, cut and placed on platinum wire electrodes. The DRP was recorded before and following application of saline, DYN (1-13), DYN (2-13), U-50488H (U50), morphine (MOR), naloxone (NAL), nor-binaltorphimine (NOR-BNI) or a combination of these drugs.

Saline, NAL and NOR-BNI had no influence on the DRP. The non-opiate peptide DYN (2-13) did not influence the DRP. Naloxone, at doses which blocked MOR, also did not influence the response to DYN. On the other hand, the kappa antagonist NOR-BNI blocked both DYN- and U50-induced depression of the DRP and itself in high doses depressed the DRP.

These data suggest that a kappa opiate receptor component is involved in DYN-induced depression of the DRP.

NALOXONE PARADOXICALLY PROLONGS THE ACTION POTENTIAL AFTER ACUTE GM1 GANGLIOSIDE TREATMENT OF SENSORY NEURONS BUT CONTINUES TO ANTAGONIZE OPIOID-INDUCED SHORTENING. K.-F. Shen and S.M. Crain. Dept. Neuroscience, Albert Einstein Coll. Med., Bronx, N.Y. 10461.

Low (nM) concentrations of opioid agonists prolong the calcium-dependent component of the action potential duration (APD) of many mouse dorsal-root ganglion (DRG) neurons in culture (Shen & Crain, Br. Res. 491, 1989), whereas higher (μ M) levels shorten the APD. Both effects are blocked by naloxone (1-10nM). Opioid-induced APD prolongation appears to be mediated by excitatory opioid receptors that are positively coupled via a cholera toxin-A-sensitive G_s protein to cAMP-dependent ion conductances (S. & C., Br. Res. 525, 1990); opioid-induced APD shortening, by inhibitory receptors linked to pertussis toxin-sensitive G_i/G_o . Cholera toxin B-subunit, which binds to GM1 ganglioside, also selectively blocks opioid-induced APD prolongation (S. & C., Br. Res. 531, 1990). After brief treatment with GM1 ganglioside (>10nM for a few min), the opioid agonists, dynorphin (1-13) or morphine prolonged the APD at fM vs. the usual nM concentrations (S. et al., Br. Res., in press). Furthermore, the opioid antagonists, (-) naloxone or diprenorphine (1-30nM), but not (+) naloxone, unexpectedly prolonged the APD of the GM1-treated cells, yet still continued to antagonize opioid-induced APD shortening. These results suggest that the supersensitivity of GM1-treated DRG neurons to the excitatory effects of opioid agonists and antagonists is due to a remarkably increased efficacy of excitatory opioid receptor activation of G_s , rather than simply to increased binding affinity. Similar supersensitivity develops after chronic opioids (C. & S., SN abstr., 1991). (Supported by NIDA grant DA 02031.)

237.9

ACTIVATION OF MU AND DELTA OPIOID RECEPTORS ON F11 NEUROBLASTOMA CELLS INCREASES VOLTAGE-DEPENDENT K^+ CURRENTS. S.F. Fan¹, K.-F. Shen¹, M.A. Scheideler^{2*} and S.M. Crain¹. Dept. of¹ Neuroscience, Albert Einstein Coll. Med., Bronx, NY, 10461 and² CNS Div., NovoNordisk AIS, 2860 Soeborg, Denmark

The F11 cell line is a fusion product of embryonic rat dorsal root ganglion (DRG) cells with the mouse neuroblastoma cell line N18TG-2 (Platika et al., PNAS '85). This cell line is derived from sensory neurons (Boland & Dingleline, Dev. Br. Res. '90), and expresses μ & δ opioid receptors that are negatively coupled to adenylate cyclase (Francel et al., J. Neurochem. '87; Dawson & Scheideler, in Biochem. & Physiol. of Substance Abuse, 2, R.R. Watson, ed., CRC Press, '90). The present study presents direct binding measurements & electrophysiologic evidence of μ & δ opioid receptor expression. Tight-seal patch-clamp recordings of F11 cells after several days in a differentiating culture medium (low serum, cAMP and NGF) showed that: (1) the outward K^+ current during pulsed depolarization in most of these cells was increased by either the δ agonist, DPDPE (1 μ M) or the μ agonist, DAGO (1 μ M), but none were responsive to both opioids; (2) cells without any processes responded neither to DPDPE nor to DAGO. The opioid-induced increase in voltage-dependent membrane K^+ current in F11 cells resembles the inhibitory effect elicited by μ and δ opioid agonists in primary cultures of mouse DRG neurons (Wertz and Macdonald, JPET '83; Shen & Crain, Br. Res. '89). The F11 cell line may therefore provide a valuable model system for correlative pharmacologic, electrophysiologic and biochemical analyses of opioid functions in sensory neurons. (Supported by NIDA research grants DA05203 and DA 02031 to S.M.C.)

ONTOGENY OF THE ZETA (ζ) RECEPTOR IN RAT CEREBELLUM. P.J. McLaughlin, D.M. Gibo^{*} and I.S. Zagon. Dept. of Neuroscience and Anatomy, Penn State Univ. College of Medicine, Hershey, PA 17033.

An opioid growth factor (OGF), [Met⁵]-enkephalin (MET), serves as an important regulatory peptide of nervous system development. OGF interacts with the zeta (ζ) receptor to inhibit growth processes. The ontogeny of the ζ receptor during cerebellar development has been examined. Tissues from rat pups were collected at embryonic (E) days 15, 18, and 20, as well as postnatal days 1, 3, 6, 10, 15, 18, 21, 35, and adult; whole brains were assayed at E15 and E18, whereas cerebella were studied from day E20 onwards. Specific and saturable binding of ³H-MET was detected in the whole brain at E15 and E18 (6.2 fmol/mg protein). The embryonic cerebellum (E20) contained 6.0 fmol/mg protein. Binding capacity markedly increased from birth to day 10, with 29.8 fmol/mg protein measured on day 10. Binding decreased substantially by day 15 (7.0 fmol/mg protein), and was not detected by weaning. These data are consistent with the timetable of cerebellar neurogenesis defined in earlier studies, and correlates closely with the extent of the germinative pool of cells (i.e., external germinal (granule) layer).

Supported by NIH grant NS20500.

237.8

CHRONIC OPIOID-TREATED SENSORY NEURONS BECOME SUPPERSENSITIVE TO THE EXCITATORY EFFECTS OF OPIOIDS AS OCCURS AFTER ACUTE ELEVATION OF GM1 GANGLIOSIDE LEVEL. S.M. Crain and K.-F. Shen. Dept. of Neuroscience, Albert Einstein Coll. Med., Bronx, N.Y. 10461.

Chronic DADLE- or morphine-treated DRG neurons (1 μ M for 1 wk in culture) become tolerant to opioid inhibitory effects, i.e., shortening of the action potential duration (APD) (Crain et al., Br. Res., 1988), and supersensitive to opioid excitatory effects, i.e., prolongation of the APD. Dynorphin (1-13) or morphine prolong the APD of treated DRG neurons at fM levels, whereas nM levels are required in naive cells (C. & S. TIPS, 1990), and the opioid antagonists, naloxone or diprenorphine (1-10 nM) unexpectedly prolong the APD of most of the treated cells. Similar opioid supersensitivity occurs after acute treatment of naive DRG neurons with GM1 ganglioside (Shen et al., Br. Res. in press; S. & C., SN abstr, 1991). Furthermore, whereas cholera toxin-B subunit (1-10 nM) blocks opioid-induced APD prolongation in naive DRG neurons (presumably by interfering with endogenous GM1 modulation of excitatory opioid receptor functions: S. & C., Br. Res. 531, 1990), even higher concentrations of CTX-B were ineffective in chronic opioid-treated neurons. These and related data suggest that excitatory opioid supersensitivity of chronic opioid-treated DRG neurons may be due to a cAMP-dependent increase in GM1 ganglioside levels that greatly enhances the efficacy of excitatory opioid receptor activation of G_s . Our results may clarify mechanisms of opioid dependence and the paradoxical supersensitivity to naloxone which triggers withdrawal symptoms after opiate addiction. (Supported by NIDA grant DA 02031.)

237.10

OPPOSITE MODULATION OF SUBSTANCE P RELEASE FROM RAT TRIGEMINAL NUCLEUS CAUDALIS SLICES BY KAPPA AND DELTA OPIOID-RECEPTORS. H. Suarez-Roca and W. Maixner. Dept. of Pharmacology and Dental Research Center, University of North Carolina, Chapel Hill, N.C. 27514.

We previously reported that the release of substance P (SP) from trigeminal nucleus caudalis (TNC) slices is inhibited and facilitated by activation of distinct populations of μ -opioid receptors with nM concentrations of morphine. In addition, SP release is respectively inhibited and facilitated by activation of δ - and κ -opioid receptors with μ M concentrations of morphine (Suarez-Roca et al., Neurosci. Abs. 16:367, 1990). In the present study, we have examined the effect of nM concentrations of U50488H (κ -opioid receptor agonist) and D-Pen¹, D-Pen², enkephalin (DPDPE, δ -opioid receptor agonist) on K^+ -evoked SP release from rat TNC slices. Immunoreactive SP was measured in perfusates. U50488H produced facilitation of SP release with a maximal effect at 30 nM. Naloxone (30 nM; non-selective) and nor-binaltorphimine (3 nM κ -BNI; κ -selective) blocked U50488H facilitatory effect whereas β -funaltrexamine (20 nM β -FNA; μ -selective), naloxonazine (1 nM; μ_1 -selective), and ICI174,864 (0.3 μ M; δ -selective) were inactive. DPDPE inhibited SP release with a maximal inhibition at 3 nM. DPDPE inhibition of SP release was blocked by naloxone and ICI174,864 but not by κ -BNI, naloxonazine, or β -FNA. Both U50488H and DPDPE produced U-shaped concentration-response curves that were completely autoinhibited at 100 nM. These findings support our previous observations that activation of κ - and δ -opioid receptors respectively enhances and reduces the release of SP in TNC and that opioids produce bi-directional modulatory effects that are concentration- and receptor-subtype-dependent. (Supported by DE08013 & OAS Fellowship).

237.12

HYPOTHALAMIC LOCALIZATION OF KAPPA, DELTA AND MU OPIOID RECEPTORS IN THE SONGBIRD BRAIN. P. Deviche and P. Cotter*. Inst. Arctic Biology, Univ. Alaska Fairbanks, Fairbanks, AK 99775.

To determine the distribution of opioid binding sites in the songbird hypothalamus, whole brain sections obtained from dark-eyed juncos (*Junco hyemalis*) were incubated with tritiated ligands that bind either to kappa (ethylketocyclazocine), mu (DAGO) or delta (DPDPE) opioid receptors. Nonspecific binding was defined as the difference between the total binding and the binding measured in the presence of high concentrations of appropriate unlabelled ligands. Preliminary studies using brain homogenate sections showed that the binding of the 3 labelled ligands is specific, time-dependent, and saturable ($K_m \leq 5$ nM; $B_{max} \leq 120$ fmol/mg protein). Within the hypothalamus, specific kappa, delta, and mu binding sites are discretely and differently distributed. In particular, there is a high density of delta sites in the n. paraventricularis (PVN). Immunocytochemical studies demonstrate that the junco PVN contains opioid peptides including methionine-enkephalin and dynorphin (1-13), suggesting that these peptides influence PVN activity. The PVN, which contains steroid receptors, may be a region where steroids and opioids interact functionally.

237.13

CHARACTERIZATION OF OPIOID RECEPTORS IN PHEOCHROMOCYTOMA CELLS. M.E. Abood and J.S. Eubanks*. Dept. of Pharm., Med. Coll. of Virginia, Richmond, VA 23298.

PC12 rat pheochromocytoma cells are useful as a model system for neuronal development. In one subclone of PC12 cells, PC12h, low levels of δ -type opioid receptors markedly increase in response to nerve growth factor (NGF) (Inoue, N. and Hatanaka, H. *J. Biol. Chem.* 257: 9238 1981). We are currently investigating the consequences of the appearance of opioid receptors in PC12h cells and examining concurrent changes in the expression of opioid-regulated genes. After 10 days of treatment with NGF, the number of opioid receptors (as measured by ^3H -diprenorphine binding), increases from a B_{max} of 40 to 220 fmols/mg protein, with concentrations up to 10 nM. Above 10 nM, a second site appears. The NGF-induced increase in receptor binding was reproducible in several experiments. The induction of binding does not necessarily mean these sites are functional receptors. In order to estimate whether these receptors are coupled to a potential second messenger, we took advantage of two known properties of δ receptors in cell lines, desensitization and down-regulation in response to opioid agonists. In preliminary experiments, the receptors in the cells show a time-dependent reduction in affinity for agonist, followed by a loss of receptor binding on the cell surface upon exposure to etorphine. Such results indicate that the receptors on NGF-treated PC12h cells are capable of responding to opioid agonists. Along with the increase of opioid binding following NGF treatment we find changes in the message levels of G proteins and other opioid-related molecules.

237.15

VISUALIZATION OF ^{125}I - β -ENDORPHIN OPIOID RECEPTOR SITES IN NG108-15 AND SK-N-SH NEUROBLASTOMA CELLS BY MICROSCOPIC AUTORADIOGRAPHY. Ric. I. Cone, Jelyeh Lamah*, Stuart A. Rosenfeld* and Wolfgang Sadée*. Departments of Pharmacy and Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446 (USA).

Detection of opioid receptors by microscopic autoradiography on intact SK-N-SH and NG108-15 neuroblastoma cells was obtained with the use of ^{125}I - β -endorphin (βE) as tracer, together with $\beta\text{E}(6-31)$ to block high affinity non-opioid binding. Labeling was blocked by $10\ \mu\text{M}$ diprenorphine.

Previously, we have measured μ and δ opioid receptor sites in intact SK-N-SH and NG108-15, using ^{125}I - βE ($K_d = 3$ & 7 nM, respectively), and demonstrated rapid loss of δ receptor sites from the cell surface of NG108-15 following pretreatment with DADLE (Cone & Sadée, submitted). Using microscopic autoradiography, opioid receptor binding will be examined following differentiation with retinoic acid, and pre-treatment with opioid agonists, and cDNA libraries will be screened for opioid receptor expression in pCDM8-transfected COS-7 cells.

Supported by a US Public Health Research Grant from the National Institute on Drug Abuse, DA 04166.

OPIOID REGULATION OF PRO-ENKEPHALIN MRNA LEVELS IN RAT PRIMARY FOREBRAIN NEURONAL CULTURES. S.R. Childers, T. Sexton and D.R. Marckel. Dept. Physiology/Pharmacology, Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

The role of opioid-inhibited adenylyl cyclase (AC) in the regulation of pro-enkephalin (PE) mRNA levels was examined in primary neuronal cultures from neonatal rat forebrain. The opioid peptide agonist dynorphin A_{1-13} (DYN) inhibited cAMP accumulation in intact cells by 40%-60%, and directly inhibited AC in isolated membranes by 15%. In these cultures, PE mRNA levels were induced 2-5-fold by either dibutyryl cAMP or forskolin. Addition of $1\ \mu\text{M}$ DYN decreased forskolin-stimulated PE mRNA by 20%-60%, producing maximal effect between 1-4 hr. This effect was specific for neuronal cultures, since no effect of opioids was observed in glial cultures. Blockade of protein synthesis by cycloheximide increased PE mRNA levels but the inhibitory actions of DYN were still evident. The inhibitory action of DYN was blocked by naloxone and by pertussis toxin treatment of the cultures. Although DYN was effective in reducing forskolin-stimulated PE mRNA levels, the opioid agonist had no effect on dibutyryl cAMP-stimulated message. These results demonstrate that opioid receptor inhibition of AC may be the mechanism by which opioids regulate PE mRNA levels, providing a negative feedback mechanism to control their own synthesis. In addition, these results demonstrate a function for AC in brain which could regulate neurotransmitter expression and play an important role in long-term neuronal homeostasis.

237.14

OPIATE RECEPTORS IN NEURONAL AND ASTROGLIAL PRIMARY CULTURES FROM DIFFERENT BRAIN REGIONS - association with dopamine (D1) receptor adenylyl cyclase. Peter S. Eriksson*, Elisabeth Hansson¹ and Lars Rönnbäck^{1,2}. Institute of Neurobiology¹ and Department of Neurology², University of Göteborg, 400 33 Göteborg, Sweden.

Primary cultures enriched in neurons or astroglial cells from three phylogenetically different regions of the rat brain, the cerebral cortex, the striatum and the brain stem, were used to investigate the presence of opiate receptors coupled to adenylyl cyclase. Morphine (MO) was used as a μ receptor agonist and D-al 2 -D-leu-enkephalin (DADLE) was used as a δ receptor agonist. In the neuronal cultures both ligands inhibited the prostaglandin (PGE1) stimulated intracellular cAMP accumulation dose dependently with the most prominent effects seen in the striatum cultures and with DADLE being more potent than MO. The opiate receptor antagonist naloxone reversed the effects. MO and DADLE added together inhibited the PGE1 stimulated cAMP accumulation less than the sum of each drug. Therefore, it might be that these opioid receptors are co-localized on the same neuron. Striatal neurons contained DA receptors coupled to cAMP as second messenger. The DA D1 receptor-stimulated adenylyl cyclase activity was inhibited by the μ and δ opioid receptor ligands. Thus, interactions at the adenylyl cyclase level seem to exist between D1, μ and δ opiate receptors. In the astroglial enriched cultures DADLE inhibited the PGE1 induced cAMP accumulation, however with a less prominent effect in the brain stem cultures. MO did not influence the basal or the PGE1 stimulated intracellular cAMP accumulation in the cultures used. DADLE was less effective to inhibit the PGE1 induced cAMP accumulation in the astroglial cultures than in the neuronal enriched cultures. Our results thus suggest the presence of δ receptors on astroglial cells in culture while no μ receptors with cAMP as second messenger were identified.

MORPHINE REGULATION OF PROTO-ONCOGENE C-FOS AND PRO-OPIO-MELANOCORTIN EXPRESSION IN HUMAN NEUROBLASTOMA SH-SY5Y CELLS. S.L. Chang, J.E. Zadina¹, L. Spriggs*². Dept. of Physiology, LSU Sch. of Dentistry, New Orleans, LA. 70119, ¹VAMC, Dept. of Med. and Neuroscience Program, Tulane Univ. Sch. of Med., New Orleans, LA. 70146, and Dept. of Pharmacology, Tulane Univ. Sch. of Med., New Orleans, LA. 70112.

Morphine has been previously demonstrated to increase expression of the proto-oncogene *c-fos* in rat brain. The *FOS* nucleoprotein complex was then proposed to couple morphine binding to alteration of expression of proenkephalin (PE) and pro-opiomelanocortin (POMC), whose promoter contains an AP-1 sequence. (BBRC 157:698, 1988). The SH-SY5Y human neuroblastoma cells express predominantly μ -subtype opiate receptors (JBC 261:1065, 1986) with receptor density increased by retinoic acid and decreased by PMA (Excerpta Medica 914:151, 1990). In this study, we examined the time course of change in *c-fos* and POMC mRNA concentrations upon morphine treatment in SH-SY5Y cells. For undifferentiated cells, the *c-fos* mRNA levels were elevated by morphine ($10\ \mu\text{M}$) rapidly and transiently during the initial period. By 2-6 hours, *c-fos* mRNA levels were reactivated and remained elevated for 7 days, the length of the testing period. The POMC mRNA levels were also activated upon chronic morphine treatment. These results indicated that chronic exposure to morphine can result in prolonged activation of *c-fos* and POMC mRNA in SH-SY5Y cells.

MORPHINE EFFECTS ON PROTEIN PHOSPHORYLATION AND ADENYLYL CYCLASE ACTIVITY IN RAT THALAMIC MEMBRANES. L. M. Fleming and S. R. Childers. Dept. Physiol./Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103, Dept. Pharmacology, Univ. Florida Coll. Med., Gainesville, FL 32610.

We previously reported that opioid-inhibited adenylyl cyclase (AC) decreased protein phosphorylation of two proteins (MW 63 and 85 kDa) by cAMP-dependent protein kinase. Chronic (but not acute) administration of morphine increased phosphorylation of these two protein bands. This chronic effect of morphine occurred in a short time period, with maximal effects 1-2 days after morphine pellet implantation. The increase in protein phosphorylation was not caused by an increase in cAMP-dependent protein kinase. However, preliminary results showed an increase in AC basal activity in thalamic membranes from chronically morphine-treated rats. This effect occurred within 9-24 hours, using periodic morphine injections. Maximum stimulation of AC by forskolin was not changed by morphine treatment, but when expressed as % of basal AC, forskolin-stimulated AC was blunted. Inhibition of AC by D-al 2 enk was not changed by morphine treatment. Lineweaver-Burke analysis indicated a change in the kinetics of AC in thalamus from these animals. These results suggest that subchronic administration of morphine may alter the parameters of opioid-inhibited AC in thalamic membranes, and may explain the observed increase in phosphorylation of membrane phosphoproteins.

EFFECTS OF LHRH AND ESTRADIOL ON cAMP IN OPIOID-RESPONSIVE NEUROBLASTOMA CELLS. A. Ratka and J.W. Simpkins, Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610.

SK-N-SH neuroblastoma cells, which express opioid receptors were evaluated for the inhibitory effects of opiates on cyclic AMP (cAMP) accumulation. Prostaglandin E₁ (PGE₁, 1 μM) caused dramatic increase in cAMP level. Treatment with morphine (MOR, 10 μM) significantly inhibited the stimulatory effect of PGE₁ (from 2066.9±244.8 to 1179.2±196.3 pmol/mg protein). Estradiol (E₂) dose of 5 nM given for 1 hr., 8 hrs. and 6 days and the dose of 0.5 nM for 1 hr. significantly potentiated PGE₁ effect. In all cells pretreated with E₂ the inhibitory effect of MOR was not changed. Treatment with LHRH (1 ng/ml for 10 min.) increased PGE₁ stimulation of cAMP from 1879.6±118.9 to 2475.9±146.0 pmol/mg protein. The same LHRH treatment resulted in significant reduction of the inhibitory effect of MOR on cAMP level. Ten times higher dose of LHRH or longer duration of LHRH treatment had no effect on cell responses to either PGE₁ or MOR. When LHRH was added to E₂-treated cells, MOR-induced inhibition of cAMP accumulation decreased from 43-50% to 14-26%. LHRH antagonist (10 ng/ml, 10 min.) attenuated the stimulatory effect of PGE₁ on cAMP (2247.2±126.4 vs 3292.5±156.3 pmol/mg protein). The antagonist did not change either E₂ or MOR effects on cAMP accumulation. We conclude that in cells which express opioid receptors (1) the stimulatory effects of PGE₁ on cAMP accumulation is potentiated by E₂, (2) activation of LHRH receptors resulted in significant potentiation of PGE₁ effect and attenuation of the inhibitory effect of MOR on cAMP level, while antagonism of LHRH receptors reduced the effect PGE₁, (3) E₂ may modify the function of opioid receptors via LHRH, the neurons which are present in SK-N-SH cultures.

CATECHOLAMINE RECEPTORS: DOPAMINE II

238.1

ALTERNATIVE DOPAMINE D3 RECEPTOR mRNA SPLICE FORMS IN RAT AND HUMAN. L.A. Snyder, J.L. Roberts, S.C. Sealton. Fishberg Research Center for Neurobiology, Mt. Sinai Medical School, New York, NY 10029

The molecular cloning of the rat dopamine D3 receptor (D3R) was recently reported (Nature 347:146,1990). Based on the published amino acid sequence, degenerate oligonucleotides for polymerase chain reaction (PCR) were designed to the N-terminal region and to the putative second cytoplasmic loop. In PCR reactions using rat cDNA as a template, two reaction products were observed; one of the expected size of the D3R, and another approximately 100 bp smaller. Multiple subcloned PCR products were sequenced and a cDNA with a 113 bp deletion, that was otherwise identical to the published D3R, was found. The 113 bp is flanked by the nucleotide sequence AGGT, a consensus sequence for an RNA splice donor/acceptor site. The segment deleted, encompassing the first extracellular loop and third transmembrane domain, alters the reading frame, introducing 19 amino acids not found in the full length D3R, followed by a premature stop codon. Partial length clones of the human D3R were also isolated by PCR. Sequence analysis revealed that these D3R splice variants have been evolutionarily conserved. Supported by NIH grants K11 DK01854 and MH 45212.

ISOLATION AND CHARACTERIZATION OF THE RAT DOPAMINE D4 RECEPTOR. K.L. O'Malley, S. Harmon, L. Tang, S. Han, and R.D. Todd. Departments of Anatomy and Neurobiology, Genetics and Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Ongoing molecular studies have shown an unexpected variety of dopamine receptors generated from multiple genes and/or alternative splicing of RNA transcripts. Here we describe the isolation and characterization of a new D2 family gene which is expressed both in the CNS and the periphery. A rat genomic library was screened at low stringency using a DNA fragment corresponding to transmembrane domains VI and VII of D_{2A} (Bunzow et al., 1988) and D3 (Sokoloff et al., 1990). Three types of clones were isolated, two corresponding to the previously isolated genes, D_{2A} and D3, and the third representing a novel D2-family receptor. DNA sequence analysis revealed the greatest identity with D2 dopamine receptors followed by the alpha adrenergic and muscarinic receptors. The gene is composed of several exons some of whose splice junctions have been conserved within this family. Subsequent to this finding Van Tol et al. (1991) reported the cloning of a human D4 dopamine receptor. Sequence comparison indicates the novel rat receptor reported here is analogous to that of D4. In contrast to the human studies, the rat D4 is expressed primarily in the heart.

238.2

EXPRESSION OF AN ALTERNATELY SPLICED D3 DOPAMINE RECEPTOR. M.W. McLane*, T.E. Norris, and M.M.S. Lo. ICI Americas, Inc., Wilmington, DE 19897.

Using RT-PCR methods, we have isolated a rat cDNA clone, pD3b, that is an alternately spliced form of the D3 dopamine receptor that has been recently reported. The D3b cDNA's coding region is 1284 bp long and is identical to the original D3 sequence except for an in-frame deletion that removes an internal eighteen amino acids. Nuclease protection assays will be done to confirm that the D3b transcript is authentic and coexists with the D3 form in the rat brain region containing olfactory tubercle. A broader tissue survey by RT-PCR will also determine if the D3b transcript is CNS specific.

238.4

CLONING AND FUNCTIONAL CHARACTERIZATION OF THE DOPAMINE D4 RECEPTOR. C. Bouvier*, H.H.M. Van Tol*, J. Bunzow*, R.A. Johnson*, H. Niznik* and O. Civelli. Vollum Institute, Oregon Health Sciences University, Portland, OR 97201, Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8

A new dopamine receptor has been cloned from a human neuroepithelioma SK-N-MC cDNA library on the basis of its homology to the D₂ receptor. This new receptor, the D₄ receptor, has a higher degree of sequence similarity with the D₂ and D₃ than with the D₁ or D₅ receptors. It is encoded by a gene which organization is similar to that of the D₂ and D₃ receptors. The D₄ receptor, when expressed through DNA transfection in COS-7 cells, has a pharmacological profile resembling that of the D₂ receptor. Most importantly, the D₄ receptor binds the antagonist clozapine with a ten fold higher affinity than does the D₂ receptor. This suggests that the D₄ receptor may serve as the primary target for clozapine, an antipsychotic devoid of extrapyramidal side effects. The ability of the D₄ receptor to induce second messengers has been studied in SK-N-MC cells and in transfected GH₄C₁ cells. In GH₄C₁ cells, stimulation of the D₄ receptor by dopamine results in an inhibition of the forskolin-stimulated cAMP levels. In SK-N-MC which harbor endogenous D₁ and D₄ receptors, the D₁ dependent dopamine-stimulated cAMP levels are inhibited by the co-stimulation of the D₄ receptor. These results show that the D₄ receptor is able to modulate adenylyl activity in a way similar to that of the D₂ receptor, studies of the D₄ activity on other second messenger systems will be discussed.

238.5

TWO HUMAN PSEUDOGENES HOMOLOGOUS TO THE D5-DOPAMINE RECEPTOR. B.F. O'Dowd*, T. Nguyen*, H. Jin*, L. Grupp and P. Seeman. Addiction Research Foundation (ARF) and the Department of Pharmacology, University of Toronto, Toronto, Canada M5S1A8.

Receptors for the neurotransmitter dopamine belong to the family of receptors characterized by having seven transmembrane (TM) regions and by acting through G-proteins. Molecular cloning studies have now identified five structurally homologous genes for the biosynthesis of human dopamine receptors, namely D1, D2, D3, D4 and D5. Two of these dopamine receptors (D1 and D5) are encoded by genes intronless in their coding regions. In an attempt to ascertain whether there are other intronless genes with homology to the gene encoding the D5 receptor we used a cloning method based on the polymerase chain reaction (PCR). Human genomic DNA was subjected to amplification by PCR with oligonucleotides based on the D5 receptor nucleotide sequence. Amplification of nucleotide sequences between these oligonucleotides, from TM1 to the carboxy tail, has allowed for the isolation of two independent intronless genes with close homology to the D5 receptor, namely PG-1 and PG-2. The deduced amino acid sequences of each of these genes, PG-1 and PG-2, shows an overall homology to the D5 receptor of 90%. However, the genes PG-1 and PG-2 each contains a stop codon in their coding regions that would render these genes incapable of encoding functional receptors. Thus, in common with the family of human genes encoding the phosphoglycerate kinases, human dopaminergic genes are represented by intron-containing genes (D2, D3 and D4), by intronless genes (D1 and D5), and the pseudogenes PG-1 (Ψ DSA) and PG-2 (Ψ DSB). Southern blot analysis, using PG-1 as a probe, has also detected hybridizing bands in rat and mouse genomic DNA. Funded by ARF and MRC (Canada).

Differential Distribution of D₂ and D₄ Dopamine Receptor mRNAs in the Rat Brain: An *in situ* Hybridization Study. A. Mansour, J. Meador-Woodruff, S. Burke*, J. Bunzow*, H. Akil, H.H.M. Van Tol*, O. Civelli, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109-0720; The Oregon Health Sciences University, Portland, OR, 97201.

Several dopamine receptors (D₁ - D₅) have recently been cloned and appear to be part of a larger family of G-protein coupled seven transmembrane (TM) receptors found in the CNS. The present *in situ* hybridization study compares the distribution of the D₂ and D₄ receptors which are highly homologous to one another, but differ pharmacologically, with the D₄ having a 10 fold greater affinity for clozapine (Van Tol et al, 1991, Nature, 350; 610-614). Using adjacent rat brain sections and standard *in situ* hybridization procedures (Mansour et al, 1990, J. Neurosci., 10; 2587-2600), the D₂ receptor mRNA was localized with a 495 bp cRNA generated to the third cytoplasmic loop and TM VI and VII of the rat D₂ receptor, while the D₄ mRNA was visualized with a riboprobe generated to a 420 bp fragment of the human D₄ receptor that corresponds to TM VI and VII and the entire 3' untranslated region. *In situ* hybridization studies demonstrate that the two mRNAs are differentially distributed with the D₂ receptors being particularly abundant in the striatum and substantia nigra, while the D₄ receptors are more widely distributed with relatively high levels in the cortex, hypothalamus, amygdala, hippocampus and pineal gland. The relative lack of D₄ receptors in the nigrostriatal system and its distribution within cortical and limbic areas is of particular interest given clozapine's therapeutic effects and its relative lack of extrapyramidal side effects.

238.6

Localization of D₄ and D₅ Dopamine Receptor mRNAs in the Human Brain. J. Meador-Woodruff, A. Mansour, C. Work*, H.H.M. Van Tol*, D. Grandy, O. Civelli, and S.J. Watson. Department of Psychiatry and Mental Health Research Institute, University of Michigan, Ann Arbor MI, 48109-0720; Oregon Health Sciences University, Portland OR, 97201.

The dopamine receptor, pharmacologically resolved into D₁ and D₂ subtypes, has been more recently shown to consist of a family of 7-transmembrane domain, G-protein-coupled receptors. To date, five distinct genes encoding different dopamine receptors have been cloned. We have previously reported on the distribution of the mRNAs encoding D₁ and D₂ receptor mRNAs in brain. In this preliminary investigation, we compare the distributions of the mRNAs encoding the D₄ and D₅ receptors in the human nigrostriatal system. While both D₄ and D₅ receptor mRNAs were identifiable in the caudate and the putamen, only D₄ receptor mRNA could be visualized in the pars compacta of the substantia nigra. These results suggest that both D₄ and D₅ receptors exist as postsynaptic receptors in the striatum, while the D₄ receptor may also function as an autoreceptor in the midbrain. Based on transfection studies, the D₄ receptor appears to be pharmacologically more D₂-like, and the D₅ more D₁-like. The present results are in agreement with these findings: anatomically, D₄ receptor mRNA is similarly distributed to that corresponding to the D₂ receptor, while D₅ mRNA has a similar localization as D₁ receptor mRNA. More detailed mapping studies of the distributions of these mRNAs are underway in both the human and the monkey brain.

238.8

Structural Determinants of Dopamine Receptor Binding: Site-Directed Mutagenesis of the Human D₂ Receptor. F. Meng*, A. Mansour, J. Meador-Woodruff, L.P. Taylor*, and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109-0720; The Oregon Health Sciences University, Portland, OR, 97201.

Site-directed mutagenesis studies with the β_2 -adrenergic receptor have identified several amino acid residues that are critical for agonist binding (Strader et al 1989, J. Biol. Chem. 264; 13572-8 and 16470-7). These include an aspartate in transmembrane (TM) three that interacts with the cationic anion and two serines and in TM5 that interact with hydroxyl moieties located on the aromatic ring of catecholamine agonists. In the present study we have mutated the homologous residues in the human D₂ receptor by site-directed mutagenesis to determine if dopamine agonists bind in a similar manner in the D₂ receptor. In addition Met (116 and 117) were mutated to evaluate whether residues near Asp (114) of the D₂ receptor are critical in differentiating dopaminergic from adrenergic agonists. The results suggested the following - 1. Removal of the charge with mutation of Asp (114) to either Asn or Gly led to a total loss of both agonist and antagonist binding. 2. Methionine mutations Met 116 to Leu or Met 117 to either Cys or Gly to make the D₂ binding pocket more closely resemble the β_2 -adrenergic receptor did not result in a change in selectivity toward noradrenergic agonists or antagonists. 3. Mutations of Ser (194) and Ser (197) to Ala produced a greater loss of affinity for agonists as compared to antagonists with Ser (197) being particularly important for dopamine receptor binding. The affects of these mutations varied with agonist or antagonist tested and will be discussed in relation to ligand structure and their interaction with the putative binding pocket.

SEROTONIN RECEPTORS: 5HT₃

239.1

CHARACTERIZATION OF A SOLUBILIZED SEROTONIN 5HT₃ RECEPTOR FROM BRAIN. K.J. Miller and M. Teitler. Dept. of Pharmacology and Toxicology, Albany Medical College, 47 New Scotland Avenue, Albany, N.Y. 12208.

Bovine area postrema has been found to contain a high density of 5HT₃ receptors (1). Thus this may be a useful source of brain 5HT₃ receptors for molecular characterization of this ligand-gated ion channel. 5HT₃ receptors were solubilized from bovine area postrema using CHAPS, according to the method of Miquel et al., 1990 (2). Recovery of the 5HT₃ receptor from the soluble preparation was approximately 50% ($B_{max} = 50 \pm 6$ fmol/mg). Scatchard analysis revealed an equilibrium dissociation constant (K_D) for [³H]-GR65630 of 1.0 ± 0.3 nM. Kinetic studies determining association and dissociation rate constants revealed a K_D of 0.5 nM. The affinities of prototypical 5HT₃ receptor agonists and antagonists for the solubilized receptor were essentially identical to the affinities for the membrane-bound receptor. Gel filtration chromatography of the soluble extract indicated a major peak of specific [³H]-GR65630 binding corresponding to a molecular mass of about 600 kDa, as well as several smaller peaks. WGA-agarose affinity chromatography of the soluble extract resulted in a significant enrichment of the specific binding activity. These results are qualitatively similar to those reported by Miquel et al., using a neuroblastoma-glioma cell line as their 5HT₃ receptor source, and indicate that purification and detailed molecular neurobiology of brain 5HT₃ receptors should be feasible using the bovine area postrema 5HT₃ receptor preparation. Supported by MH-40716 1. M. Teitler and E. Weisberg, Biotech Update, January, p.1 (1991) 2. Miquel, et al., J. Neurochem., 55, 1526-1536 (1990).

THE EFFECT OF WAY-100,289, A NOVEL 5-HT₃ RECEPTOR ANTAGONIST, ON A9 AND A10 DOPAMINE (DA) NEURONAL ACTIVITY: ACUTE AND CHRONIC STUDIES. C. W. Uzzle and J. T. Haskins.

Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000
WAY-100,289 (WAY; Endo-N-[8-methyl-8-azabicyclo[3.2.1]octan-3-yl]amino]carbonyl]2-cyclopropylmethoxy]benzamide) binds with high affinity and selectivity to the 5-HT₃ receptor subtype and is a functional antagonist of the 5-HT₃ site in both *in vitro* and *in vivo* models. 5-HT₃ receptors have been identified in brain areas receiving DA input and 5-HT₃ antagonists can alter DA metabolism. It was therefore of interest to compare the effects of WAY with those of the standard 5-HT₃ antagonist BRL-43694 (BRL) and GR-38032 (GR) on central DA neuronal activity following acute or chronic administration. Following acute i.v. administration neither BRL, GR nor WAY had any significant effect on A10 neuronal activity. When administered prior to the DA agonist apomorphine (APO), however, all compounds potentiated the inhibitory effects of APO, although this potentiation did not reach statistical significance. The effects of WAY, GR and haloperidol (HAL) on the number spontaneously active A9 and A10 DA neurons were also determined following chronic (21 days) administration at doses of 5.0, 5.0 and 0.5 mg/kg i.p., respectively. HAL produced a significant reduction in the number of spontaneously active DA neurons in both the A9 and A10 areas. No other significant effects were noted. Additional doses of WAY are being examined to determine their effects, if any, following chronic administration.

239.3

5-HYDROXYTRYPTAMINE (5HT) RECEPTORS AND HYPERLOCOMOTION IN RODENTS. **D.M. Jackson***, **B. Chieng***, **D.M. Gillies*** and **E.J. Mylecharane*** Astra Research Centre AB, Södertälje, Sweden and Pharmacology Department, Sydney University, NSW, Australia.

5HT plays a role in regulating locomotor function in rodents. In this study we report some studies utilizing intracerebroventricular injections of 5HT agonists and antagonists into various parts of the rat brain. We have earlier shown that the 5HT_{1A/B} agonist RU24969 stimulates activity in mice via a mechanism sensitive to dopamine (DA) D1 and D2, α 1 and 5HT_{1B} receptor antagonists and is dependent on intact stores of DA and to some extent noradrenaline. RU24969 (0.1 to 10 μ g/side) injected into the accumbens (Acb) of rats had little or no effect on locomotion, but it produced marked and prolonged hyperlocomotion when injected into the ventral tegmental area (VTA, 1 and 5 μ g/side). The simultaneous injection of (-)-propranolol into the VTA (5 μ g/side) blocked RU24969's effect, suggesting that 5HT_{1B} receptors modulating locomotion are located on the cell bodies rather than in the terminal regions of the mesolimbic pathways. To investigate the role of 5HT₃ receptors, 2-methyl-5HT (0.001 to 0.1 μ g/side), odansetron (0.001 to 0.1 μ g/side) or granisetron (0.001 to 1 μ g/side) were injected into the Acb, but had no significant effect on either basal motor activity or on hyperlocomotion induced by subsequent injection of d-amphetamine (20 μ g/side). However, injection of 2-methyl-5HT into the VTA (0.01 or 0.1 μ g/side) produced locomotion. These findings suggest that 5HT_{1B} and 5HT₃ receptors within the VTA play a role in modulating locomotor function in rats, probably by regulating DA release within, *inter alia*, the Acb. Supported in part by a grant from the ARC, Australia.

EFFECTS PRODUCED BY CHRONIC TREATMENT WITH GRANISETRON ALONE OR IN COMBINATION WITH HALOPERIDOL ON MIDBRAIN DOPAMINE CELLS **R.Y. Wang, Y. Minabe and C.R. Ashby, Jr.** Dept. of Psychiatry and Behav. Sci. SUNY at Stony Brook, Putnam Hall-South Campus, Stony Brook, NY 11794-8790.

Evidence obtained from recent studies suggests that 5-HT₃ receptor antagonists may represent a new class of antipsychotic drugs (APDs). The aim of the present study was to evaluate the antipsychotic potential of granisetron (BRL) using an electrophysiological model. Rats were randomly allocated to one of the following treatment groups: control (1 ml/kg of 0.9% saline), haloperidol (HAL, 0.5 mg/kg, i.p.), BRL (0.1, 1.0 or 10 mg/kg, i.p.) or BRL + HAL. The experimenter was "blind" as to the drug treatment of the animal. Standard electrophysiological techniques were used to record A9 and A10 DA cells in chloral hydrate anesthetized rats. Chronic administration of 0.1 or 1 (but not 10) mg/kg BRL selectively decreased the number of spontaneously active A10 DA cells compared to controls, mimicking the effect produced by chronic treatment with the atypical APD clozapine. However, unlike the effect produced by APDs, this BRL-induced effect was not reversed by apomorphine (APO, 50 μ g/kg, i.v.). This suggests that the chronic BRL-induced effect on DA cells is not the result of depolarization inactivation. Acute BRL (0.01, 0.1 or 1 mg/kg, i.v.) significantly potentiates the inhibitory action of APO on A10 DA cells. The chronic co-administration of HAL + BRL either attenuated or prevented completely the HAL-induced decrease of the number of spontaneously active DA cells. Our results are consistent with the report showing that 5-HT₃ receptor antagonists markedly attenuate or reverse the DA hyperactivity induced by various drugs including HAL. In conclusion, the results of this study suggest that whereas chronic BRL at low doses may possess atypical antipsychotic potential, the administration of BRL and HAL diminishes the antipsychotic effect of either drug.

EVIDENCE FOR MODULATION OF DOPAMINE RELEASE BY 5-HT₃ RECEPTORS WITHIN THE NUCLEUS ACCUMBENS

G.A. Kennett* and **T.P. Blackburn*** (Spon: D.C. Rogers), SmithKline Beecham Pharmaceuticals, The Pinnacles, Harlow, Essex, CM19 5AD, UK.

The possibility that 5-HT₃ receptors within the nucleus accumbens modulate dopamine (DA) release was studied.

Male SD rats were implanted with dialysis probes in the right nucleus accumbens. On the next day these were perfused with artificial CSF (0.5 μ l/min). Dialysates were collected every 20 min and DA, DOPAC and HVA determined by HPLC-ECD. Injection of the 5-HT₃ receptor antagonists BRL 46470 (Thomas et al., 1990) or odansetron (0.01 and 0.1 mg/kg s.c.) did not alter DA release over the next 40 mins. Dose-dependent increases in DA release, however, were observed following infusion of the putative 5-HT₃ agonists 2-methyl-5-HT and phenylbiguanide (PBG) into the nucleus accumbens for 40 min, although the effect of PBG perfusion was much larger. The response to 1 mM 2-methyl-5-HT was significantly attenuated by BRL 46470 0.01 and 0.1 mg/kg s.c. given 40 min pretest. Odansetron was also effective but only at the higher dose of 0.1 mg/kg. However BRL 46470 0.1 mg/kg s.c. did not affect the response to PBG (0.1 mM). 2-Methyl-5-HT had little effect on DOPAC or HVA levels but PBG reduced both markedly. These results suggest that PBG may have an amphetamine-like or re-uptake inhibitor action as suggested by Schmidt and Black (1989). They also support evidence of presynaptic modulation of mesolimbic dopamine release by 5-HT₃ receptors and imply that these may be located within the nucleus accumbens.

239.4

THE ACTION OF SEROTONIN IN THE RAT MEDIAL PREFRONTAL CORTEX: MEDIATION BY SEROTONIN₃-LIKE RECEPTORS. **C.R. Ashby, Jr., E. Edwards and R.Y. Wang.** Dept. of Psychiatry and Behav. Sci., SUNY at Stony Brook, Stony Brook, NY 11794-8790.

The aim of the present study was to test the hypothesis that 5-HT₃-like receptors play a major role in mediating the inhibitory action of 5-HT in the rat medial prefrontal cortex (mPFC). Experiments were carried out in chloral hydrate anesthetized male Sprague-Dawley rats, using the techniques of single unit recording and microiontophoresis. The iontophoresis of 5-HT inhibited current-dependently mPFC cell firing. This effect was significantly attenuated by concurrent iontophoresis of selective 5-HT₃ receptor antagonists such as granisetron, ICS 205930 and zacopride, but not by 5-HT_{1,2} receptor antagonists such as metergoline, pindolol, ritanserin and spiperone. The blockade of 5-HT's action by the 5-HT₃ receptor antagonists reached 60-80%. Furthermore, the i.v. administration of zacopride (5-50 μ g/kg), but not metergoline (4-2400 μ g/kg) or ritanserin (5-2000 μ g/kg), markedly attenuated the suppressive action of 5-HT on mPFC cell firing. In addition, the suppression of mPFC firing produced by electrical stimulation of the caudal linear raphe nucleus (CLI), where ascending 5-HT fibers pass, was significantly blocked by the iontophoresis of granisetron and by i.v. administration of S-zacopride (0.1 mg/kg). Interestingly, i.v. injection of ritanserin (0.5-1.5 mg/kg) also significantly attenuated CLI-induced suppression of mPFC cell activity, whereas the iontophoresis of ritanserin or another 5-HT₂ receptor antagonist (+)MDL 11939 failed to alter CLI-induced effect. Overall, our results suggest that 5-HT's action in the mPFC may be primarily mediated by 5-HT₃-like receptors. Moreover, the blockade of CLI-induced effect by systemic ritanserin may be an indirect effect. (Supported by USPHS grants MH-41440 and MH-00378).

AS-5370 ANTAGONISES THE 5-HT₃ RESPONSE OF THE RAT VAGUS.

N. R. Newberry*, C. J. Watkins*, R.A. Leslie and D.G. Grahame-Smith* (SPON: Brain Research Association) Oxford University-SmithKline Beecham Centre for Applied Neuropsychobiology, Oxford, OX2 6HE, England.

AS-5370, N-(1-methyl-4-(3-methyl-benzyl)hexahydro-1H-1,4-diazepin-6-yl)-1H-indazole-3-carboxamide 2HCl, is a potent and long lasting 5-HT₃ antagonist (Ito T, *et al.*, 1990, Eur. J. Pharmac., 183, 1214-1215). We have assessed its potency to antagonise the 5-HT₃ receptor mediated depolarisation of the rat vagus nerve *in vitro*.

The methods for grease-gap recording from the desheathed vagus nerve (taken from male Sprague-Dawley rats) were similar to those previously described (Newberry *et al.*, 1991, Brit. J. Pharmac., 102, 615-620). Using 1 minute superfusions of 5-HT, we studied its dose-response curve before and after a 1 hour incubation of the preparation with or without an antagonist.

The mean EC₅₀ for 5-HT was 0.7 μ M (range 0.2-1.9, n=32). Repeating the dose-response curve in the absence of antagonist gave a mean dose-ratio of 1.5 (n=6). AS-5370 (0.1-3.0 nM) (a kind gift from Dainippon Pharmaceutical Co.) produced a dose dependent depression of the maximum response to 5-HT (n=16) with an IC₅₀ of 0.3-1.0 nM. This contrasted with another 5-HT₃ antagonist d-tubocurarine (0.3-3 μ M) which produced parallel shifts of the dose-response curve to 5-HT (pK_B = 7.1, IC₅₀ = 0.3-1.0 μ M, n=13).

The data suggest that AS-5370 is a potent, noncompetitive 5-HT₃ antagonist on the rat vagus nerve.

Expression of Tryptophan Hydroxylase in the NG108-15 cell line by 5-HT₃ Receptor Stimulation. **J.C. Poblete*, X. Zhang*, J. Rubinstein*, E.C. Azmitia*, and P.M. Whitaker-Azmitia*** 1. Dept. of Biology, New York University, NY, NY 10003, and 2. Dept. of Psychiatry, SUNY-Stonybrook, Stonybrook, NY 11794.

The neuroblastoma x glioma hybrid NG108-15 cell line has been shown to possess serotonergic, cholinergic and peptidergic properties (Ghahary et al. Cell. Mol. Neurobiol. 9(3), 1989). In addition, undifferentiated NG108-15 cells have detectable levels of 5-HT. The purpose of this study is to investigate the serotonergic identity of this cell line after treatment with dibutyryl-cAMP (dBcAMP), which induces NG108-15 cellular differentiation, and with phenylbiguanide (PBG), a 5-HT₃ agonist. The serotonergic property of the NG108-15 cell line was determined by utilizing a new antibody (WOH-66) developed against tryptophan hydroxylase, an enzyme localized specifically in serotonergic neurons. Glial properties of this cell line were determined using antibodies against S100 protein and glial fibrillary acid protein (GFAP). The neuronal characteristic of this cell line was determined using an antibody against neuron specific enolase. Undifferentiated cells were incubated for 2,4,6,8 days with PG (100nM) and dBcAMP (10mM), and then fixed in 4% paraformaldehyde (0.1M PBS, pH 7.4) and processed for immunocytochemical staining using the HRP-ABC method. Staining for S100, GFAP and neuron-specific enolase was observed in all cells in control and both treatment groups (PG and dBcAMP). However, staining for tryptophan hydroxylase was more intense in PG-treated cells than in control and dBcAMP-treated cells. This observation indicates that the NG108-15 cell line possesses 5-HT₃ receptors, which when stimulated, increase the expression of tryptophan hydroxylase. Support: NICHD and NSF 88-12892.

EFFECTS OF PRENATAL TREATMENT WITH A 5-HT₃ AGONIST AND ANTAGONIST ON THE DEVELOPMENT OF NOCICEPTIVE PATHWAYS. J. Bell, X. Zhang, and P.M. Whitaker Azmitia. Dept. Psychiatry and Behavioral Science, SUNY at Stony Brook, Stony Brook NY 11794.

In previous studies we have found that the development of ascending serotonergic pathways are regulated through the balance of two high affinity receptors—one the 5-HT_{1A} receptor which releases a growth factor, and a receptor which regulates the release of 5-HT and is inhibitory to growth. In the current study, we examined the types of 5-HT receptors regulating the development of descending 5-HT pathways. Using two tests, tail flick and the binding of ³H-paroxetine (a 5-HT uptake inhibitor) as a measure of 5-HT terminal density, we tested the effects of chronic prenatal exposure to both phenylbiguanide (PG), a 5-HT₃ agonist and MDL-72222 (MDL), a 5-HT antagonist, on both nociception and receptor development in the spinal cords of neonatal rat pups. Pregnant Sprague Dawley rats were either given 5mg/kg PG, 5mg/kg MDL or a vehicle control (s.c.) starting on gestation day 12 and continuing to birth. Pups were assessed for tail flick latency on postnatal D10, D18 and D30 or their spinal cords were removed on D18 and D30 for paroxetine binding. PG animals showed significant increases in analgesia on D10 [p<.03] and D30 [p<.003] while MDL animals showed significant decreases in latency on D10 [p<.001] and D18 [p<.008]. ³H-paroxetine binding for both groups revealed significant elevations in 5-HT terminal density in the spinal cords of D18 animals when compared to controls (PG [p<.009] and MDL [p<.03] respectively). These findings show that the development of this system can be altered by prenatal treatment with agents acting on the 5-HT₃ receptor. Support by NICHD.

PHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF 5-HT₃ RECEPTORS OF RABBIT, MOUSE AND GUINEA-PIG NODOSE GANGLION NEURONES. H.M. Malone*, J.A. Peters* and J.J. Lambert. Department of Pharmacology, University of Dundee, Ninewells Hospital, Dundee, DD1 9SY, Scotland, U.K.

Mammalian primary visceral afferents express 5-HT₃ receptors which mediate membrane depolarization via an integral cation channel. We have utilized whole-cell recordings to investigate and compare the properties of 5-HT₃ receptors of cultured adult rabbit, mouse and guinea-pig nodose ganglion neurones (NGN's) voltage-clamped at -60mV. In rabbit, mouse and guinea-pig NGN's, 5-HT (10 μ M) induced an inward current associated with a conductance increase which was abolished by 1nM, 3nM and 300nM ondansetron respectively. A marked differential sensitivity in the 5-HT₃ antagonist potency of (+)-tubocurarine [(+)-Tc] and cocaine was observed between the three species, as the IC₅₀ values for (+)-Tc in mouse, rabbit and guinea-pig NGN's were 1.6nM, 170nM and 9 μ M, and for cocaine, 4.6 μ M, 80nM and 2 μ M respectively. Ion substitution experiments indicate the 5-HT₃ activated ion channel in rabbit NGN's to be permeable to small monovalent cations with permeability ratios relative to sodium (P_x/P_{Na}) of 1.17, 1.13, 1.11 and 0.94 for Cs⁺, K⁺, Rb⁺ and Li⁺ respectively, assuming Cl⁻ to be impermeant. The organic cation derivatives, ammonium (1.73) and methylamine (1.26) were more permeant than sodium, whereas ethylamine (1.07) and dimethylamine (0.93) were approximately equipereant. Supported by the Wellcome Trust.

5-HT₃ SEROTONIN AGONISTS AS DISCRIMINATIVE STIMULI R.A. Glennon*, R. Young, M. Dukat* Department of Medicinal Chemistry, MCV/VCU; Richmond, VA 23298

The drug discrimination paradigm has proven of considerable utility in neuropharmacology. Specifically, in the realm of 5-HT research, various 5-HT₁ and 5-HT₂ agonists have been used as training drugs. To date, there are no reports of 5-HT₃ agonists being used in a similar manner. Male SD rats were trained to discriminate the 5-HT₃ agonist 2-methyl 5-HT (5 mg/kg) from saline using a VI 15s schedule of reinforcement employing standard two-lever operant techniques. The 2-methyl 5-HT stimulus (ED₅₀ = 2.6 mg/kg) generalized to the new 5-HT₃-selective agonist *meta* chlorophenylbiguanide (*m*CPBG; ED₅₀ = 1.7 mg/kg). The stimulus was potently antagonized by zacopride and ICS 205-930 (ID₅₀ = 6.3 and 11 μ g/kg, respectively). Even at doses 10,000 times the ID₅₀ dose of ICS 205-930, its quaternary salt (which does not readily penetrate the blood-brain barrier) never fully (max 38% inhibition) attenuated the 2-methyl 5-HT stimulus, suggesting that the stimulus is likely centrally mediated. Animals have also been trained to discriminate *m*CPBG from saline. These studies are the first to report the use of 5-HT₃ agonists as training drugs; this procedure should be useful in the future study and development of 5-HT₃ agonists and antagonists. [Supported in part by NS 23520.]

NG108-15 CELLS AS A MODEL SYSTEM FOR STUDYING THE EFFECTS OF 5-HT₃ RECEPTORS ON BRAIN DEVELOPMENT P.M. Whitaker-Azmitia, X. Zhang and J.E. Rubinstein. Dept. of Psychiatry, State University of New York, Stony Brook, NY, 11794.

We have recently found a role for 5-HT₃ receptors in regulating development of serotonergic neurons (Bell and Whitaker-Azmitia, abs. this meeting). NG 108-15 cells, a hybridoma cell line, have previously been shown to express high amounts of 5-HT₃ receptors. We have therefore tested these as a system to further study the role of these receptors in development.

NG-108-15 cells were grown in culture for 1 to 4 days, in the presence of varying concentrations of phenylbiguanide (PG), a 5-HT₃ agonist. The number of cells was assayed using a colorimetric assay. A significant decrease in cell growth (73% of control, p<.005) was observed. The maximum decrease was observed by three days, and the maximum response induced by 100 nM PG with 50% of maximum observed at 10 nM. These effects were reversed by 10 nM MDL 7222 - a 5-HT₃ antagonist. PG did not stimulate phospholipase C or adenylate cyclase in these cells. We are currently studying the effects of ion channel antagonists, such as nimodipine, to block the effect.

5-HT₃ RECEPTORS IN GUINEA-PIG COELIAC NEURONS. A. Surprenant, S. Matsumoto and V. Gerzanich. Vollum Institute and Dept. of Anatomy, School of Dentistry, Oregon Hlth. Sci. Univ., Portland, OR 97201

Whole cell and outside out single-channel recordings were made from adult coeliac ganglion neurons maintained in culture for 12 - 72 h. Using internal Cs-gluconate solution without ATP or GTP, 5-HT evoked desensitizing inward currents at the holding potential of -70 mV in all neurons; EC₅₀ was 2 μ M for steady-state and 6 μ M for peak current. Time constant for recovery from desensitization by 100 μ M 5-HT was 10 s. IV relationship showed inward rectification and a reversal potential of -1 mV. 5-HT (3 μ M) induced channel openings of at least three unitary amplitudes; unitary conductance of the predominant channel type was 10 pS. Macroscopic and single-channel currents were blocked by ICS 205-930 (100 nM) and GR 38032F (1 μ M). Thus, adult coeliac ganglion cells possess the 5-HT₃ ligand-gated ion channel whose properties are similar to 5-HT₃ receptors in enteric neurons.

IN VITRO PHOSPHORYLATION OF PROTEIN KINASE C SUBSTRATES BY ISOZYMES TYPE I, II AND III. F.M.J. Heemskerk, P.N.E. de Graan and F.L. Huang. NICHD, NIH, Bethesda, MD 20892.

In brain two protein kinase C (PKC) substrates, B-50 (GAP-43) and MARCKS, have been extensively characterized. Both are acidic proteins, with apparent Mr (by SDS-PAGE) of 48 and 87 kDa, respectively. Previously B-50 has been shown to be phosphorylated in vitro at one site, bovine MARCKS can be phosphorylated at 4 sites by PKC. We have investigated whether there might be differences in substrate specificity and preference for phosphorylation site using highly purified PKC isozymes. We isolated synaptosomal plasma membranes (SPM) to study the phosphorylation of these proteins in the membrane-associated state and compared their kinetics of phosphorylation with those of histone IIS. PKC type II and III were found to have 2-3 times higher activity than type I, using either histone or SPM proteins as substrates. Tryptic peptides of phosphorylated SPM-proteins were analyzed by two dimensional peptide mapping. Phosphorylation of B-50 by each of the isozymes showed only one phosphopeptide. MARCKS gave multiple phosphopeptides, but no differences were detected among samples phosphorylated by each PKC isozyme. Using highly purified B-50 or a 25 amino acid synthetic peptide, containing the 4 reported phosphorylation sites in MARCKS, we found a similar lack of substrate specificity for the PKC isozymes. Although there was an apparent preference for a particular site over the others, all three PKC isozymes phosphorylated these sites in the same order of preference. These results suggest that there is little evidence for a difference in preference of any PKC isozyme for one of these substrates, or even a phosphorylation site. It seems likely that the functional specificities of the various PKC isozymes are determined by their unique localization and sensitivity to second messengers, rather than their substrate specificity.

240.3

PROTEIN KINASE C DELTA AND EPSILON ARE INCREASED IN PC12 CELLS EXPOSED CHRONICALLY TO ETHANOL. P.J. Petersen*, C. J. Henrich* and R. O. Messing. E. Gallo Clinic & Research Ctr., UCSF, San Francisco, CA 94110.

Chronic ethanol exposure increases expression of L-type Ca^{2+} channels in neural tissues. In PC12 cells, this is prevented by inhibitors of protein kinase C (PKC). Therefore we examined whether ethanol regulates PKC. Exposure to 100 mM ethanol for 6 days increased phosphorylation of KRTLRR, a selective PKC substrate, by 32 ± 4% in digitonin-permeabilized cells, whereas ethanol exposure for 10 min had no effect. Ethanol could increase PKC-mediated phosphorylation by increasing PKC activation or PKC levels. Ethanol did not alter enzyme affinity for Ca^{2+} , phosphatidylserine, diacylglycerol, or histone, and did not change cellular levels of diacylglycerol. However, ethanol treatment for 6 days caused an increase in PKC activity in cell homogenates, with a significant increase of 21 ± 2% with 50 mM ethanol, and a maximal increase of 32 ± 2% with 100 mM ethanol. This effect was time-dependent and was significant 2 days after exposure to 200 mM ethanol. Ethanol (200 mM, 6 days) also increased the number of binding sites for [³H]phorbol 12,13-dibutyrate by 82% without changing binding affinity, suggesting that increases in PKC activity reflected increased PKC levels. Using isozyme specific antibodies we found that PC12 cells contained PKC α , δ , ϵ , and ζ immunoreactivity. Treatment with 100 mM ethanol for 6 days increased immunoreactivity only to PKC δ and PKC ϵ , by 39 ± 9 and 54 ± 5 %, respectively. Therefore, chronic exposure to ethanol appears to increase levels of PKC δ and ϵ , and thereby enhance PKC-mediated phosphorylation in PC12 cells.

PHOSPHATIDYLCHOLINE POTENTIATES THE SYNERGISTIC ACTIVATION OF PROTEIN KINASE C. S.G. Chen, D. Kujju*, S. Halt*, and K. Murakami. Dept. of Biochem. Pharmacol. State Univ. New York, Buffalo, NY 14260.

Cis-fatty acid has been recently shown to activate protein kinase C (PKC) synergistically with diacylglycerol. This synergistic activation does not require Ca^{2+} but micromolar concentrations of Ca^{2+} strongly enhance the PKC activity. Among the PKC subtypes, types III (α) PKC is particularly sensitive to the synergistic activation mode; micromolar range of cis-fatty acid is sufficient to activate this subtype of PKC in the presence of diacylglycerol. This activation is dependent on the presence of phosphatidylserine (PS) and diacylglycerol but significantly reduces the PS requirement. These observations suggest that the generation of three second messengers, i.e., the increase in the intracellular Ca^{2+} concentrations, and the formation of both cis-fatty acid and diacylglycerol in the cell are necessary for the full activation of this PKC subtype.

We have further characterized the synergistic activation of PKC subtypes by cis-fatty acid and diacylglycerol with respect to the requirement of phospholipids. Phosphatidylcholine (PC), a neutral phospholipid, was found to support the synergistic activation of PKC. This PC potentiation effect is totally dependent on the presence of cis-fatty acid; PC does not activate PKC at all in the absence of cis-fatty acid, but it significantly stimulates the cis-fatty acid-induced PKC activity in concert with Ca^{2+} . Diacylglycerol plays a modulatory role; it further stimulates the PC potentiated cis-fatty acid activation of PKC. The synergistic activation in the presence of PC is equivalent to that observed in the presence of PS. There are several differences, however, between PC- and PS- supported synergism including Ca^{2+} sensitivity and autophosphorylation of the PKC subtypes. In vitro mechanism of the synergy is thus quite different from the previously reported PKC activation mechanisms. These unexpected observations of PC effect on the synergism suggest that neutral phospholipids may also participate in the activation of PKC.

INCREASED [³H]-FORSKOLIN AND [³H]-PHORBOL 12,13 DIBUTYRATE BINDING IN THE HIPPOCAMPUS FOLLOWING EXCITOTOXIC LESION OF THE RAT MEDIAL SEPTUM. K. Horsburgh^a, F.M. Inglis^b, and J. McCulloch^b, ^aUniversity of California, San Diego, Dept. of Neurosciences, 0624, School of Medicine, La Jolla, CA 92093 and ^bWellcome Surgical Institute, University of Glasgow, U.K. G61 1QH

The rat septo-hippocampal pathway provided a model system in which to examine possible alterations of ligand binding to second messenger systems following denervation. Quantitative autoradiography of [³H]-forskolin binding to G_s-adenylate cyclase and [³H]-phorbol 12,13 dibutyrate (PDBu) binding to protein kinase C was examined 21 days following stereotaxic injection of ibotenate (n=7) or phosphate buffer (n=7) into the rat medial septum. Ibotenate lesion of the rat medial septum was confirmed histologically in cresyl violet stained brain sections adjacent to those used in ligand binding studies. [³H]-Forskolin binding was significantly decreased at the lesion site (-19%) whilst a significant increase in [³H]-forskolin binding was observed in the polymorph layer of the dentate gyrus (19%) in the ibotenate-lesioned group compared to shams. A significant increase in [³H]-PDBu binding was demonstrated in the superficial layers of entorhinal cortex (29%) following lesion of the medial septum. There were no alterations in [³H]-forskolin or [³H]-PDBu binding in any other brain region post-lesion. The heterogeneous alterations in second messenger ligand binding sites and the direction of the responses may be supportive of plastic modifications of second messenger systems in the hippocampus following denervation.

240.4

CYCLIC AMP-DEPENDENT PROTEIN KINASE: AN INTERMEDIARY IN THE MODULATION OF GABA_A RECEPTOR FUNCTION IN CEREBELLAR PURKINJE CELLS. J.E. Cheun and H.H. Yeh. Dept. Neurobiology and Anatomy, Univ. Rochester Med. Ctr., Rochester, NY 14642.

Work from our laboratory has demonstrated a synergistic interaction between beta-adrenoceptor activation and GABA_A receptor-mediated chloride current (I_{GABA}) in Purkinje cells acutely dissociated from the rat cerebellum. Because beta-adrenoceptors are coupled positively to adenylylase and because cyclic AMP has the potential to initiate many intracellular events through phosphorylation, ongoing experiments are focusing on testing the participation of the cAMP cascade in modulating the functional efficacy of the GABA_A receptor as part of an effort to elucidate the underlying cellular and molecular mechanisms.

Isolated Purkinje cells were recorded under voltage-clamp in the whole cell configuration and I_{GABA} examined under conditions which activated the cAMP cascade. Both forskolin (≤ 200 μ M) and 8-Br cAMP (≤ 1 mM) reversibly potentiated I_{GABA} , suggesting that an elevated level of intracellular cAMP affected either through triggering the adenylylase or through transmembrane delivery can lead to an enhancement of GABA_A receptor function.

To test the hypothesis that cAMP-dependent phosphorylation is involved in the potentiation of I_{GABA} , the catalytic subunit of the cAMP-dependent protein kinase (PKA) was included in the pipet solution and allowed to dialyze into cells. The amplitude of I_{GABA} increased after 4-5 minutes following rupture of the membrane to achieve the whole-cell mode. The time course of the change in I_{GABA} amplitude is consistent with that of intracellular dialysis having occurred since it correlated well with the results of a separate study in which lucifer yellow was included in the recording solution. In the absence of PKA, I_{GABA} remained at a relatively constant level throughout the duration of recording. These data suggest that phosphorylation may be involved in the modulation of I_{GABA} by cAMP. Supported by PHS grants NS24830 and NS 01340.

Visualization of calcium/calmodulin-dependent protein kinase type II mRNA using a sensitive non-radioactive in situ hybridization technique. E. M. McGowan, P.C. Emson and M. Rigby¹, MRC Group, Dept. of Neuroendocrinology, AFRC, Babraham, Cambridge, U.K. ¹Merck, Sharpe and Dohme, Harlow, Essex, U.K.

Calcium/calmodulin-dependent protein kinase type II (CAM II kinase) is a multimeric enzyme consisting of two principle subunits, an alpha (α) subunit of 58kDa and a beta (β) subunit of 58/60kDa. The two subunits are differentially expressed throughout the central nervous system and also in peripheral tissues. A sensitive non-radioactive *in situ* hybridization technique, using alkaline phosphatase coupled oligonucleotides, was used to visualize the respective α and β CAM II kinase mRNAs in the gerbil forebrain. The strongest hybridization signal for both the α and β CAM II kinase antisense oligos was seen in the hippocampal formation. The alkaline phosphatase signal was concentrated in the cell bodies of the pyramidal cells of the CA1-CA4 field and the granule cells of the dentate gyrus, in contrast to observations made using radio-labelled probes where CAM II Kinase α mRNA was readily identified in the dendrites. Elsewhere in the forebrain strong staining for both enzyme subunit mRNAs was detected in the cerebral cortex and amygdala, with lower levels of staining in the thalamus. In addition only mRNA for the β subunit was detected in the granule and Purkinje cells of the cerebellum. Currently, observed changes in the levels of α and β CAM II kinase mRNAs are being studied in the gerbil hippocampus following an ischemic insult.

AGE-RELATED CHANGES IN [³H]PHORBOL BINDING AND PROTEIN KINASE C IMMUNOREACTIVITY IN FISHER-344 RAT BRAIN. K.A. Yurko, M.R. Pisano*, E. Yadin and E. Friedman. Departments of Pharmacology and Psychiatry, Medical College of PA, Phil., PA 12129. Protein kinase C (PKC), a major neuronal kinase, plays a key role in many neurochemical processes that have shown age-related changes. [³H]PDBu binding in 6- and 24-month-old Fischer-344 rat brains (10 μ m coronal slices) was examined. The effects of Carbachol stimulation (CARB, 10 μ M) and of calorie restricted diet across these age groups was also investigated. Significant age-related increases in [³H]PDBu binding were observed in the dentate gyrus of rats fed an unrestricted or a calorie-restricted diet. In the amygdala, significant age-related increased binding was seen in the unrestricted diet condition. Stimulation with CARB significantly increased [³H]PDBu binding, regardless of age, in the unrestricted diet condition, in both these brain regions. In the restricted diet condition, the effect of CARB stimulation on binding was reduced across both age groups in these brain areas. No significant differences in binding across age and diet conditions, with or without CARB stimulation, were seen in caudate, ventral thalamus or corpus callosum. Immunoreactivity of PKC isozymes (α, β, γ) from 6- and 24-month-old rats, under either diet condition, is currently being studied. These age-related changes in [³H]PDBu binding may reflect associated changes in membrane phospholipids or diacylglycerol production necessary for functional PKC.

240.9

PROTEIN KINASE C-RELATED SIGNAL TRANSDUCTION PATHWAY IS TRIGGERED BY SUBNANOMOLAR CONCENTRATION OF VIP IN ASTROCYTES.

Z. Olah*¹, S. Komoly*², D. Warren*³, D.E. Brenneman*³, D.V. Agoston*³. LCO, NCI¹; LBNP, NINDS² and LDN, NICHD³, NIH, Bethesda, MD 20892. Neurotransmitters and neuropeptides can trigger the release of glia-derived factors that are important to neuronal growth and survival. Vasoactive intestinal peptide (VIP) has been shown to release a complex array of substances that can influence the survival of spinal cord neurons grown in dissociated cell cultures. This secretagogue action of VIP, observed at a concentration of 0.1 nM, is 1000-fold less than that required to produce a significant elevation in cAMP, the recognized second messenger for the VIP receptor. Previous studies have shown that astroglia exhibit two subtypes of VIP-receptors, a low affinity site with a K_d of 0.8 μ M and a high affinity site with a K_d value of 70 pM. We have investigated the possibility that a protein-kinase C (PKC)-related signal-transduction mechanism may mediate the actions at the high affinity VIP receptor in rat cortical astrocytes. Western blotting with a pan-PKC specific antibody has shown that the subcellular localization of this enzyme is cytosolic in control astrocytes. Stimulation of cells with 0.1 nM VIP resulted in a partial translocation of the PKC immunoreactivity from the soluble to a nuclear fraction, which can be mimicked by treatment with low concentration of TPA (1 nM). Endogenous substrates of PKC were also studied by incubating cytosolic and nuclear extracts from VIP-treated and control astrocytes in the presence of [γ -³²P]ATP. Specific phosphoprotein bands were detected at 40, 30, and 24 kD in the absence of Ca²⁺ (but in the presence of phosphatidylserine and diacylglycerol), suggesting the presence of Ca²⁺-independent PKC forms. No additional substrates (i.e. the 80 kD phosphoprotein) were seen in the presence of both Ca²⁺ and phospholipid, although presence of this PKC form could be detected by externally added histone H1 phosphorylation. All PKC forms could be down-regulated by a short pre-treatment with 250 nM TPA. These data suggest that a PKC-related signal transduction mechanism mediates the action of VIP at the high affinity receptor in astrocytes.

240.11

EXPRESSION OF AN UNREGULATED PROTEIN KINASE C IN CORTICAL NEURONS, FROM A HSV-1 VECTOR, CAUSES A LONG TERM, ACTIVITY DEPENDENT INCREASE IN NEUROTRANSMITTER RELEASE. A.I. Geller, J. Bryan*, O. Ashe*, M.J. During, and R.L. Neve. Div. Cell Growth and Regulation, Dana Farber Can. Inst., Boston MA 02115; Dept. Neurosurg., Yale Univ. Sch. of Med., New Haven CT. 06510; Dept. Psychobiol., U. CA., Irvine CA. 92717

We are investigating the role of signal transduction pathways in mediating long term changes in mammalian neuronal physiology. The strategy is to express catalytic domains of signal transduction enzymes in neurons using our HSV-1 vector system (Science 241, 1667, 1988; Proc. Natl. Acad. Sci. 87, 1149, 1990; Biochem. Pharm. 40, 2189, 1990). The catalytic domains encode unregulated enzymes that are always active, thereby stably activating a signal transduction pathway; the effect of a particular pathway on neuronal physiology is then studied. Following this strategy, the rat protein kinase C β -II catalytic domain (pHSVpkc Δ) was fused to a 10 aa peptide recognized by an antibody. pkc Δ protein was expressed, for at least 1 week, in cultured sympathetic and occipital cortex neurons, and was predominantly localized to cell bodies. Depolarization (high K or veratridine) revealed a long term increase in monoamine or excitatory amino acid neurotransmitter release from sympathetic or cortical neurons, respectively, infected with pHSVpkc Δ , but not from cultures infected with pHSVpkc (full length pkc), pHSVpUC (pUC19 polylinker), or mock infected. The increase in release required calcium. The catalytic domain of calcium/calmodulin protein kinase II (pHSVCaCKA) also caused a long term, activity dependent increase in release, but of smaller magnitude. In the basal state, pHSVpkc Δ or pHSVCaCKA did not alter release; in contrast, an adenylate cyclase catalytic domain increased release in the basal state, but not following depolarization. These results suggest that the cAMP pathway and the calcium activated protein kinases cause specific and distinct long term changes in neuronal physiology. The underlying biochemical mechanisms are under investigation.

240.8

QUANTITATIVE RECEPTOR AUTORADIOGRAPHY OF PROTEIN KINASE C / [3H]-PDBU BINDING SITES FOLLOWING UNILATERAL FIMBRIECTOMY IN RATS BRAIN. A.R. Parent and R. Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, 6875 Lasalle Blvd., Verdun, Quebec, Canada, H4H 1R3.

Cellular responses to neurotransmitter receptor activation depend upon the integrity of receptor coupling with their associated signal transduction mechanisms. Protein kinase C (PKC) is an important second messenger directly involved in receptor transduction mechanisms of various neurotransmitters. On the basis our interest in the neurochemical features of Alzheimer disease (AD) in which deficits in muscarinic receptors possibly coupled to PKC were reported, we determine the activity of PKC in fimbriectomized rats, a model of the hippocampal cholinergic deafferentation observed in AD. Ten days after lesion, PKC was evaluated using membrane binding assays and quantitative receptor autoradiography, using the selective ligand [³H]-phorbol 12,13-dibutyrate (PDBu). While binding affinities were similar in most brain regions (6 nM), [³H]-PDBu binding density was greatest in the hippocampus (30 pmol/mg protein) followed by frontal cortex (15 pmol), temporo-occipital cortex (8 pmol), thalamus-hypothalamus (6 pmol), cerebellum (6 pmol) and brainstem (3 pmol). On the ipsilateral side of the fimbriectomized animals, the apparent density and affinity of [³H]-PDBu binding were not modified in the hippocampus. However, the distribution of [³H]-PDBu binding was enlarged in the ipsilateral septal areas. Thus, deafferentation of the hippocampus does not affect PKC activities in this region measured by [³H]-PDBu binding. However, the distribution of cell expressing [³H]-PDBu / PKC binding may be enlarged in the septal area suggesting the possible sprouting of transected septo-hippocampal neurons in response to lesion.

REGULATION OF THE NEUROTRANSMITTER RELEASE MACHINERY BY SIGNAL TRANSDUCTION PATHWAYS: EXPRESSING UNREGULATED SIGNAL TRANSDUCTION ENZYMES AND PARVALBUMIN IN AXON TERMINALS, FROM HSV-1 VECTORS. J. Bryan* A.I. Geller, O. Ashe* C.L. Wilcox, R.L. Neve, and M.J. During. Dana Farber Can. Inst., Boston MA. 02115; Dept. Microbiol. U. CO., Denver CO. 80262; Dept. Psychobiol., U. CA., Irvine CA. 92717; Dept. Neurosurg., Yale Univ. Sch. of Med., New Haven CT. 06510.

Signal transduction pathways may regulate the neurotransmitter release machinery in the axon terminal. We have expressed, from HSV-1 vectors, catalytic domains of signal transduction enzymes. These unregulated enzymes activate specific signal transduction pathways, but they are localized to neuronal cell bodies. To deliver the catalytic domains to axon terminals, the catalytic domains of adenylate cyclase, calcium/calmodulin dependent protein kinase II, and protein kinase C were fused to the process targeting domain of GAP-43 (the 10 N terminal aa), which we have shown targets foreign proteins to processes. Activating each of these three signal transduction pathways in axon terminals may change the phosphorylation state of specific components of the neurotransmitter release machinery, and thus alter neurotransmitter release. To study the role of calcium in regulating release, we expressed parvalbumin, a calcium binding protein localized to GABAergic neurons. Parvalbumin was expressed, for at least 1 week, in both cell bodies and processes of cultured sympathetic and occipital cortex neurons. Parvalbumin caused a long term increase in monoamine or excitatory amino acid neurotransmitter release from sympathetic or cortical neurons, respectively, in both the basal state, and following depolarization (high K or veratridine). Cultures infected with pHSVpUC (pUC19 polylinker), or mock infected did not alter release; the increased release was dependent on calcium. These studies may provide insights into the roles of specific signal transduction pathways in the long term regulation of the neurotransmitter release machinery, in the axon terminal.

A MECHANISTIC MODEL FOR THE ARACHIDONIC ACID-DIACYLGLYCEROL SYNERGISTIC ACTIVATION OF PROTEIN KINASE C IN NEURONAL SYSTEMS. David S. Lester, Thomas J. Nelson*, and Daniel L. Alkon* Neural Systems Section, NIH, Bethesda, MD, 20892.

Diacylglycerol (DAG) and arachidonic acid (AA) are established activators of the Ca²⁺/phospholipid-dependent protein kinase, protein kinase C (PKC). Using a model membrane bilayer system, we have found that in the presence of suboptimal activating concentrations of DAG (1 mol% of total lipid, similar to what is reported for physiological systems), addition of AA (1.1-22 μ M) activates PKC phosphorylation of exogenous and endogenous substrates in a synergistic manner. This synergistic activation is not related to phosphoprotein substrate requirements, nor does the AA compete with phorbol ester at the DAG-phorbol ester binding site of PKC. Based on enzymatic assays, the AA seems to make the lipid activator, DAG, more available such that more PKC can be bound and activated. This study supports the notion that there are more than one pathway to activate PKC all of which involve phospholipase(s) A₂ and/or C. We have used the associative learning cellular system of the Type B photoreceptor of the sea snail, *Hermisenda*, to propose a model for how two external stimuli (light and rotation) can have convergence of their effects (depolarization and GABA) and these phospholipase pathways to activate the enzyme, PKC. Physiological evidence from our laboratory and others support the notion that this synergistic interaction between AA and DAG may be an important mechanism in neuronal systems.

CELLULAR ACTIONS OF PHARMACOLOGICALLY DISTINCT FORMS OF PROTEIN KINASE C. F.J. Thomson*, M.S. Johnson*, D.J. MacEwan*, G. Fink and R. Mitchell* MRC Brain Metabolism Unit, 1 George Square, Edinburgh EH8 9JZ, U.K.

We have developed various cellular models of protein kinase C (PKC) action which have allowed us to explore, in a physiological context, the selective pharmacology of different species of PKC. Depolarisation-induced $^{45}\text{Ca}^{2+}$ influx through dihydropyridine-sensitive Ca^{2+} channels into anterior rat pituitary tissue and into GH₃ cells were differentially influenced by phorbol esters and putative PKC inhibitors. In GH₃ cells, 4 β -, but not 4 α -phorbol 12,13-didecanoate (PDD) inhibited K^{+} -induced $^{45}\text{Ca}^{2+}$ influx in a staurosporine- and H7-sensitive manner. In pituitary tissue, by contrast, PDD enhanced K^{+} -induced $^{45}\text{Ca}^{2+}$ influx in a staurosporine-sensitive, but H7-insensitive manner. We have also found certain PKC actions in other models to show differential sensitivity to H7. For example, H7 blocked phorbol 12,13-dibutyrate (PDBu)-induced release of luteinizing hormone (LH) but not growth hormone (GH), whereas staurosporine inhibited both. These results were supported by the fact that both Ca^{2+} -independent and Ca^{2+} -dependent PDBu-stimulated kinase activities were blocked with similar potency by staurosporine, whereas Ca^{2+} -independent kinase activity was found to be much more resistant to H7 relative to Ca^{2+} -dependent activity. These pharmacologically different PKCs in anterior pituitary also differ in their cellular targets. Phospholipase A₂ (PLA₂) inhibitors (eg quinacrine) blocked PDBu-induced LH but not GH release suggesting that in gonadotrophes, but not somatotrophes, an H7-sensitive PKC(s) can act to modulate PLA₂ activity. These data suggest that PKC species may differ in their sensitivity to PKC inhibitors, and that they may have distinct cellular targets.

ACUTE AND CHRONIC EFFECTS OF CALCIUM ANTAGONISTS ON PROTEIN PHOSPHORYLATION IN THE RAT HIPPOCAMPUS. F.J. Hoffman Jr.* and R.A. Janis. Miles Institute for Preclinical Pharmacology, West Haven, CT 06516 USA.

Nimodipine has neuroprotective and cognition enhancing effects, but the mechanisms by which it exerts these effects are not known. Protein kinase C (PKC) and calcium are implicated in both ischemic cell damage and neuroplasticity, and therefore, the effects of acute and chronic nimodipine treatment were studied. Chronic nimodipine treatment (40 mg implants for 2 and 4 weeks) was found not to affect the phosphorylation of major substrates by PKC in the rat hippocampus as studied by two-dimensional electrophoresis and direct counting of the gels. The acute effects of nimodipine and other calcium antagonists were also studied. K^{+} -induced depolarization (50 mM) of rat hippocampal slices resulted in significant changes (33 to 38%) in the phosphorylation state of the major PKC substrates MARCKS (myristoylated, alanine-rich C-kinase substrate) and neuromodulin. Pretreatment of the slices with 500 μM Cd²⁺, but not 300 nM nimodipine, 10 μM ω -conotoxin GVIA, or MK-801, blocked the K^{+} -induced change in phosphorylation. The results suggest that K^{+} -induced changes in phosphorylation of MARCKS and neuromodulin are mediated by calcium influx mechanisms other than, or in addition to, those sensitive to the organic antagonists employed.

240.17

THE DISTRIBUTIONS OF INHIBITOR-1 AND DARPP-32 IN BRAIN AND PERIPHERAL TISSUES OF VARIOUS SPECIES H.C. Hemmings, Jr., J.-A. Girault, A.C. Nairn and P. Greengard. Lab. of Mol. and Cell. Neuroscience, The Rockefeller Univ., New York, NY 10021

The distribution of inhibitor-1 (I-1) and of DARPP-32, two homologous, cAMP-regulated inhibitors of protein phosphatase-1 (PP-1), was analyzed in various brain regions and peripheral tissues of several species by immunoblotting using specific antibodies. In rat CNS, a single I-1 immunoreactive protein of $M_r=30,000$, was widely distributed. In contrast, DARPP-32 was highly concentrated in the basal ganglia. I-1-immunoreactive proteins were detected in brain tissue from frog ($M_r=27,000$), turtle ($M_r=29,000/33,000$), canary ($M_r=26,000$), pigeon ($M_r=28,000$), mouse ($M_r=31,000$), rabbit ($M_r=26,500$), cow ($M_r=27,000$) and monkey ($M_r=27,500$), but not from goldfish. In peripheral tissues of the rabbit, I-1 was identified in skeletal muscle, liver, fat, kidney, heart, spleen and pancreas. In other species, I-1 was detected in the same peripheral tissues with the exception of rat liver, cow liver and spleen, and pigeon and turtle fat, spleen and pancreas. DARPP-32 was detected in brain tissue of all the species tested except frog, but was absent from most peripheral tissues. Both I-1 and DARPP-32 were concentrated in the cytosol and synaptosomal cytosol of rat caudate-putamen. The developmental expression of I-1 and DARPP-32 in rat caudate-putamen differed. I-1 peaked in the first postnatal week at twice the level found 1 week before birth, and then declined and stabilized by the third postnatal week. In contrast, DARPP-32 increased to a peak level by the third postnatal week, and remained elevated thereafter. Since I-1 and DARPP-32 have distinct but partially overlapping distributions and developmental expression in rat CNS, and have distinct distributions in various peripheral tissues, it appears that their functions are not fully interchangeable.

240.14

POSSIBLE INVOLVEMENT OF PROTEIN KINASE C (PKC) AND cAMP IN THE CONTRACTILE RHYTHMIC ACTIVITY OF THE CNIDARIAN, RENILLA KOELLIKERI. E.W. Awad*, M. Anttil and T. Cabana. Dept. Sci. Biol., Univ. de Montreal, Qc., Canada, H3C 3J7.

Previous studies have reported modulatory effects of epinephrine, norepinephrine, serotonin and the neuropeptide Antho-RFamide on the colonial muscular activity of the sea pansy, *Renilla koellikeri*. In an effort to establish a relationship between these neuroactive substances and specific receptors, the possible involvement of the second messengers diacylglycerol and cAMP was examined. A force transducer and a chart recorder were used to monitor colonial contractile rhythmic activity. Phorbol 12,13-dibutyrate and 1,2-dioctanoyl-sn-glycerol induced tonic contractions and an increase in the amplitude of rhythmic contractions. These responses were reduced by the absence of Ca²⁺ and the presence of PKC inhibitors. Basic cAMP levels measured in colonial tissues by competitive protein binding assay were sensitive to several serotonergic and adrenergic agents. These results suggest the presence of PKC- and cAMP-mediated mechanisms involved in the modulation of rhythmic contractile activity of the sea pansy.

240.16

IBOTENATE STIMULATES PROTEIN PHOSPHORYLATION IN CULTURED HIPPOCAMPAL PYRAMIDAL NEURONS. W.K. Scholz. Dept. Pharmacol. and Physiol. Sci., Univ. Chicago, 947 E. 58th St., Chicago, IL 60637.

Previously we showed that glutamate stimulation of cultured pyramidal neurons resulted in the elevation of calcium and diacylglycerol (DAG), and the phosphorylation of 3 proteins: MARCKS, a 120- and a 48-kDa protein. When pyramidal neurons were stimulated in an extracellular solution containing 50 nM calcium (approximately equal to the resting level in these cells), generation of DAG and phosphorylation still occurred, although the response was reduced (Scholz and Palfrey, J. Neurosci., in press). This suggests that a metabotropic type glutamate receptor, one which is associated with the hydrolysis of inositol phospholipids, might be partially responsible for the phosphorylation observed. The ability of glutamate agonists to activate phospholipases in 1.26 mM and 50 nM calcium was investigated. NMDA and quisqualate did not stimulate the generation of inositol phosphates in normal or low calcium in pyramidal neurons. Kainate stimulated inositol phosphates production in the presence of 1.26 mM Ca but not in 50 nM Ca. Ibotenate was able to stimulate the generation of inositol phosphates with similar maximal responses in normal and low extracellular Ca. The maximal response to ibotenate was approximately equal to that of glutamate, when pyramidal neurons were stimulated in 50 nM Ca. Glutamate and ibotenate stimulated generation of inositol phosphates could be partially blocked (approximately 40% reduction) by prior treatment of neurons with pertussis toxin (250 ng/ml) suggesting that a G-protein might be involved. The second product of inositol phospholipid hydrolysis, DAG, directly binds and activates protein kinase C. Indeed we have shown that 1) ibotenate stimulates the phosphorylation of the same three PKC substrates as glutamate, 2) kainate stimulates phosphorylation only in the presence of 1.26 mM Ca and 3) NMDA and quisqualate were ineffective in stimulating phosphorylation. Thus stimulation of pyramidal neurons with glutamate leads to the phosphorylation of specific proteins. This occurs through the activation of ionotropic (kainate) receptors, which depolarize the neuron resulting in Ca-activation of phospholipases and metabotropic (ibotenate) receptors, which directly activate phospholipases possibly through a G-protein.

D1 AGONIST 38393 INCREASES THE STATE OF PHOSPHORYLATION OF ARPP-21 IN NIGRAL SLICES. K. Tsou and P. Greengard. Lab. of Molecular & Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

ARPP-21 is a cAMP-regulated phosphoprotein ($M_r=21,000$ in SDS-PAGE) that has a distribution in brain similar to that of DARPP-32. It is enriched in the medium spiny neurons in the striatum and in the striato-nigral projection nerve terminals in the pars reticulata of the substantia nigra. ARPP-21 is phosphorylated by cAMP-dependent protein kinase on a seryl residue located at position 55 of its 88 amino acid sequence. Both forskolin and 8Br-cAMP increase its state of phosphorylation in striatal and nigral slice preparations.

In the present study, rat nigral slices were first preincubated in warm, oxygenated RPMI 1640 culture medium containing 0.5 mM IBMX for 45 min. Drugs were added to the medium for 10 min. The tissue was frozen in liquid nitrogen and homogenized by sonication in 5 mM Zn acetate. Proteins were extracted in acid, and back phosphorylated by exogenous catalytic subunit of cAMP dependent protein kinase and $\gamma^{32}\text{P}$ -ATP. The phosphorylated ARPP-21 was immunoprecipitated by a polyclonal anti-ARPP-21 antibody. The immunoprecipitate was subjected to SDS-PAGE and autoradiography. D1 agonist 38393 (10^{-6}M) increased the state of phosphorylation of ARPP-21 by 25% on average (range 11-50%). This effect could be blocked by pretreatment of the nigral slices for 5 min with the D1 antagonist SCH 23390 (10^{-5}M). This result indicates that ARPP-21 is a dopamine regulated phosphoprotein.

240.19

EFFECTS OF CALRETININ ON BRAIN PHOSPHOPROTEINS: COMBINED INHIBITORY AND STIMULATORY ACTIONS. L. Winsky, T. Yamaguchi¹ and D.M. Jacobowitz. Lab. of Clinical Science, NIMH, Bethesda, MD 20892

Calretinin is a neuronal calcium binding protein of the EF hand type. As with calbindin-D28k, its closest homolog, the function of calretinin remains to be elucidated. The present study investigated whether calretinin, like some other calcium binding proteins (calmodulin, calcineurin), might produce effects on protein phosphorylation. Synaptic membranes were prepared by sucrose density centrifugation and samples were incubated in buffer containing combinations of 5 mM EGTA or 200 μ M calcium with calretinin alone or in combination with other effectors. Results indicated a dose dependent inhibitory effect of calretinin on the appearance of a 39 kDa synaptic membrane phosphoprotein with 30-50 % inhibition produced by 100 nM calretinin. Phosphorylation of the 39 kDa band was stimulated by calcium but was not affected by calmodulin or a protein kinase C inhibitor at doses producing clear effects on other proteins. These compounds also did not affect the inhibitory action of calretinin on the phosphorylation of the 39 kDa band. Calretinin in combination with either calmodulin or phosphatidyl serine produced additive stimulatory effects on several phosphoprotein bands. These results suggest that calretinin could produce some physiological action through effects on protein phosphorylation.

240.21

INSULIN AND IGF-1 STIMULATE TYROSINE PHOSPHORYLATION OF PHOSPHATIDYL INOSITOL 3-KINASE IN NEONATAL RAT NEURONS. R.A. Patel¹, P. Kurian², M. K. Raizada, and F. T. Crews. Departments of Pharmacology and Physiology, College of Medicine, University of Florida, Gainesville, FL 32610.

In the central nervous system insulin and insulin-like growth factor 1 (IGF-1) are known peptide growth factors which can stimulate neurite outgrowth and induce specific neuronal proteins. Both insulin and IGF-1 seem to require the tyrosine kinase activity of their respective receptors to influence physiological processes. However, the identification of the cellular targets involved in the signal transduction pathways for these growth factor receptor tyrosine kinases have not been elucidated. Recently, phosphatidylinositol 3-kinase (PtdIns 3-kinase), a novel enzyme which specifically phosphorylates the *myo*-inositol ring of phosphatidylinositol (PtdIns), phosphatidylinositol 4-phosphate [PtdIns(4)P], and phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P₂] on the three position has been implicated in the transduction of mitogenic and oncogenic signals. To determine if PtdIns 3-kinase was involved in neuronal growth factor responses, we investigated the effects of insulin and IGF-1 on phosphatidylinositol 3-kinase activity. Treatment of neonatal rat neurons with various concentrations of insulin and IGF-1 resulted in increased immunoprecipitable PtdIns 3-kinase by anti-phosphotyrosine monoclonal antibodies in a concentration-dependent manner. These studies indicate that PtdIns 3-kinase activity is present in non-mitogenic neonatal rat neurons and that it is tyrosine phosphorylated by the tyrosine kinase growth factor receptors for insulin and IGF-1. To determine if the increased tyrosine phosphorylation of PtdIns 3-kinase increased activity *in vivo*, intact neurons were stimulated with insulin in the presence of ³²P-orthophosphate. Insulin receptor stimulation increased the formation of 3-polyphosphoinositides. Specifically, insulin stimulation increased the levels of both phosphatidylinositol 3-phosphate [PtdIns(3)P] and phosphatidylinositol 3,4-bisphosphate [PtdIns(3,4)P₂] as determined by SAX-HPLC. These results indicate that insulin and IGF-1 hormonal stimulation of neonatal rat neurons increases the formation of the unique 3-phosphorylated phosphoinositides and that growth factor signals in neonatal rat brain which do not involve mitogenic responses do stimulate PtdIns 3-kinase activity.

240.20

Ca²⁺/PHOSPHOLIPID-DEPENDENT PROTEIN PHOSPHORYLATION IN RAT BRAIN AFTER LONG-TERM TREATMENT WITH ANTIDEPRESSANTS M. Asakura^{*}, H. Asou, J. Nakanishi^{*}, T. Tsukamoto^{*}, H. Matsui^{*}, M. Ino^{*}, J. Shimada^{*} and K. Hasagawa^{*} Department of Neuropsychiatry and Division of Clinical Pharmacology of Medical Sciences, St.Marianna University School of Medicine, 2-16-1 Sugao, Miyamae-ku, Kawasaki, Kanagawa, 216 Japan

The Ca²⁺/phospholipid-dependent phosphorylation plays an important role for the regulation of transmembrane signal transduction systems in the brain. In the present study, we examined the influence of long-term treatment with antidepressants on the Ca²⁺/phospholipid-dependent protein phosphorylation in the cerebral cortex and hippocampus of the rat. The proteins were separated by the reverse phase HPLC procedure of the ammonium sulfate precipitate fraction from the membrane and soluble fractions of the brain regions. Long-term treatment with imipramine or chlorimipramine increased the Ca²⁺/phospholipid-dependent phosphorylation of the 47 kDa and 26 kDa protein bands on the SDS-PAGE- autoradiogram from the membrane fraction of cerebral cortex. The effect appeared to be associated with the long-term treatment with antidepressant agents since we did not observe the increase in the photoactivated incorporation of 47 kDa and 26 kDa proteins after acute treatment with the agents.

SECOND MESSENGERS VII

241.1

EFFECT OF UCB 11056, A NEW ANTIDEMENTIA DRUG, ON NOREPINEPHRINE (NE) AND FORSKOLIN (FSK) - INDUCED FORMATION OF CYCLIC AMP (cAMP) IN HIPPOCAMPAL TISSUE. A. El Tamer^{a,b}, J. C. Corey^a, E. Wulfert^{a,b} and I. Hanin^a. ^aLoyola Univ. Chicago Stritch Sch. Med., Maywood, IL 60153 and ^bUCB s.a. Pharmaceutical R&D, Brussels, Belgium.

We observed a significant increase in cAMP levels (+25%) in rat hippocampus within 10 min post-intraperitoneal injection of ucb 11056 (5.4 and 10.0 mg/kg). To determine whether this effect is mediated via adrenergic β -receptor activation, hippocampal slices (0.5 mm), prepared from naive rats, were first pre-equilibrated in Krebs Ringer buffer at 37°C for 75 min. They were then challenged for 20 min with ucb 11056 (5, 10 and 50 μ M), NE (10 μ M), FSK (1 μ M), or a combination of ucb 11056 with either of the two other drugs. cAMP levels were measured using radioimmunoassay. Increases in cAMP levels, expressed as pmol/mg protein, were as follows:

ucb11056(μ M)	Δ Increase vs baseline (12 \pm 1.5)	Δ Increase vs NE (10 μ M) (19.8 \pm 2.34)	Δ Increase vs FSK (1 μ M) (45.8 \pm 6.4)
5	0	5.0 \pm 0.25	17.4 \pm 3.2
10	0	9.0 \pm 0.75	25.0 \pm 2.2
50	5.6 \pm 0.1	17.0 \pm 1.2	37.6 \pm 3.4

Number of samples were 5-25 per group. These combined data show that ucb 11056: 1) increases rapidly cAMP levels in the rat hippocampus *in vivo*; and 2) potentiates both NE and FSK-activated cAMP formation *in vitro*. These data suggest that ucb 11056 might be acting as a permissive agent favoring cAMP generation in the brain.

241.2

HIGH AFFINITY LIGAND BINDING BY THE DETERGENT-SOLUBILIZED CANNABINOID RECEPTOR. D.B. Houston and A.C. Howlett, Department of Pharmacological and Physiological Science, Saint Louis University Medical Center, 1402 S. Grand Blvd., St. Louis, MO 63104.

A receptor which specifically binds the active component of marijuana, delta-9-tetrahydrocannabinol (THC) and several more potent synthetic analogs has been previously characterized in rat brain by our laboratory. The cannabinoid receptor is a member of the family of receptors linked to GTP-binding proteins, as it is coupled to G_i to inhibit adenylate cyclase activity in brain and neuronal cells. Binding with the cannabinoid agonist [³H]CP-55,940 reveals a receptor density of 1-2 pmoles/mg of protein in rat brain membranes. Scatchard analysis indicates a K_d for [³H]CP-55,940 of 0.8 nM. Affinity for agonist ligands is decreased by non-hydrolyzable GTP analogs, confirming the regulation of the cannabinoid receptor by a G-protein. We were able to solubilize the receptor from rat brain membranes using the zwitterionic detergent CHAPS. The solubilized receptor was assayed by binding to [³H]CP-55,940 with bound and free ligand separated on small gel filtration columns. A detergent:protein ratio of 0.5:1 resulted in almost 50% of membrane receptor appearing in solubilized form. The solubilized receptor exhibits high affinity agonist binding in the presence of Mg²⁺, which is decreased in the presence of guanine nucleotides, suggesting that the associated G-protein is also solubilized with the receptor. The agonist binding characteristics of the solubilized receptor are similar to those seen in membranes. The K_i for binding of desacetyllevonantradol (DALN), another cannabinoid agonist, is 0.8 nM, comparable to that seen for receptor in membranes. The apparently successful solubilization of the cannabinoid receptor will enable us to develop a purification scheme for the receptor and associated G-protein(s). Supported by NIDA grants DA03690 and DA06312.

THYROID HORMONE REGULATION OF G-PROTEIN AND ADENYLATE CYCLASE GENE EXPRESSION IN RAT BRAIN. S. F. Colin and E. J. Nestler, Laboratory of Molecular Psychiatry, Yale University School of Medicine, New Haven, CT 06508

Past studies have established that hypothyroidism induces an approximate two-fold increase in levels of $G_{i\alpha 2}$, $G_{i\alpha 3}$, and G_{β} mRNA and protein in peripheral tissues without affecting levels of $G_{s\alpha}$. In the current study, we have examined the effects of hypothyroidism on G-proteins in rat brain. After three weeks of treatment with the anti-thyroid drug 6-n-propyl-2-thiouracil (resulting in serum $T_4 < 0.7 \mu\text{g/dl}$), we found a 30-40% increase in cerebral cortical mRNA levels of $G_{i\alpha 1}$, $G_{i\alpha 2}$, and G_{β} (in comparison to euthyroid controls) as determined by Northern blotting. As with past studies in adipose and heart tissue, hypothyroidism did not affect $G_{s\alpha}$ mRNA. Similar changes in G-protein mRNA levels were noted in hippocampus. Hypothyroid regulation of adenylate cyclase and protein kinase A subunits is under current investigation.

In parallel studies we have shown that chronic lithium (1 mM for 4 weeks), but not acute (1 mM for 6 days) or chronic low dose (0.5 mM for 4 weeks) lithium, induces a 20% decrease in $G_{i\alpha 1}$ and $G_{i\alpha 2}$, and a 50% increase in adenylate cyclase types 1 and 2, mRNA and protein (PNAS submitted). Together, these results indicate that regulation of G-protein and adenylate cyclase gene expression may underlie clinical phenomena such as hypothyroid-induced depression and the efficacy of lithium therapy and thyroid supplement in the treatment of affective disorders.

241.5

S-ADENOSYL-METHIONINE (SAM) MODULATION OF β -ADRENOCEPTOR MEDIATED CYCLIC AMP PRODUCTION: POSSIBLE RELATIONSHIP TO METHYLATION OF THE CARBOXYL TERMINUS OF A SMALL G-PROTEIN. P. Zhong and K.J. Kellar, Department of Pharmacology, Georgetown University School of Medicine, Washington DC 20007.

We demonstrated previously that SAM potentiates β -adrenoceptor-mediated cyclic AMP production in rat brain slices without affecting the basal cyclic AMP level (Zhong et al., Soc. Neurosci. Abstr. 16:1302, 1990). SAM does not alter the affinity, nor the B_{max} of β -adrenoceptor binding sites in rat brain; nor is cyclic AMP production by forskolin affected by SAM. Therefore, the possibility of modulation of G-protein functions by SAM has been explored. In solubilized extracts from cerebral cortex slices incubated with [^3H]methyl-SAM, immunoprecipitation under non-denaturing conditions with antisera raised against the different α and the common β subunits of G_s , G_i and G_o did not reveal significant methylation of these subunits. Next, the incorporation of base-volatile [^3H]methyl groups into brain slices was examined by a diffusion assay (Clarke et al., PNAS 85:4643, 1988). A major methylation peak was found in a 25 kD fraction of the labeled membrane protein. Binding of ^{32}P -GTP in a 25 kD fraction of protein from solubilized brain membranes also was detected on nitrocellulose blots by the method of Bhullar and Haslam (Biochem J. 245:617, 1987). Acetyl-farnesyl-cysteine (AFC), a selective competitive inhibitor of "CAAX" box methylation (Volker, et al., Methods, 1:283, 1990), inhibited [^3H]methyl group incorporation in the 25 kD protein from brain in a concentration dependent manner. AFC also blocked potentiation of NE-stimulated cyclic AMP production by SAM in a similar concentration-dependent manner. These data suggest that a small G-protein containing a "CAAX" box in the carboxyl terminus might be involved in modulation of cyclic AMP production by SAM.

Supported by NIMH grant #MH41819.

241.7

CANNABINOID RECEPTOR CHARACTERISTICS IN RAT CEREBELLAR GRANULE CELLS AND NG108-15 CELLS. M.A. Pacheco, S.R. Childers, and S.J. Ward, Dept. Physiol./Pharm., Bowman Gray Sch. Med., Winston-Salem, NC 27103; Dept. Neuroscience, Univ. of Florida, Gainesville, FL.; Sterling Drug Inc., Rensselaer, NY.

Both cannabinoid analogs (Cn) and aminoalkylindoles (AAI) bind to G-protein coupled Cn receptors. Cn receptors were assayed in membranes by binding of the AAI agonist ^3H -WIN 55212 (^3H -212) and, in intact cells by inhibition of forskolin-stimulated cAMP formation by Cn and AAI analogs. ^3H -212 binding sites and Cn-inhibited cAMP were detected in cerebellar granule (CG) cells after 12 days in culture. ^3H -212 binding was inhibited by GTP in CG membranes. In CG cells levonantradol (LN) and WIN 212 inhibited cAMP in a dose-dependent manner. An AAI antagonist blocked both LN and WIN 212 inhibited cAMP in CG cells. The AAI antagonist alone had no effect on cAMP. Pertussis toxin blocked LN and WIN 212 inhibited cAMP in CG cells. These data suggest that Cns and AAls are working through the same inhibitory G-protein coupled receptor in CG cells.

The levels of Cn receptors were similar in NG108-15 and CG cell membranes but only 20% the level in adult rat cerebellar membranes. Although LN and WIN 212 were equipotent in displacing the ^3H -212 binding to cerebellar membranes, LN was much less potent than WIN 212 in displacing binding to NG108-15 cell membranes. These data suggest that CG and NG108-15 cells may differ in their sensitivity to various Cn analogs.

Supported by PHS grant DA-06784 from NIDA.

ESTROGEN UNCOUPLES β -ADRENERGIC RECEPTORS FROM ADENYLATE CYCLASE IN FEMALE RAT HYPOTHALAMUS. S. Ungar and A.M. Etgen, Depts. Psychiat. & Neurosci., Albert Einstein Coll. Med., Bronx, NY 10461.

Previous work from this laboratory demonstrated that estrogen desensitizes β -adrenergic receptor stimulation of cAMP accumulation in female rat hypothalamic and preoptic area slices without modifying either receptor number or antagonist binding affinity. The current experiments compared β -adrenoceptor activation of adenylate cyclase (AC) in membranes prepared from combined hypothalamus-preoptic area of ovariectomized (OVX) and OVX, estrogen-primed rats. OVX rats received oil vehicle or 2 μg of estradiol benzoate (EB) 48 and 24 hr prior to sacrifice. Stimulation of AC by the β agonist isoproterenol (10^{-8} - 10^{-4}M) and by forskolin (10^{-8} - 10^{-6}M), a receptor-independent activator of AC, were assayed. Membranes from OVX animals displayed a concentration-dependent stimulation of AC when incubated with isoproterenol, with enzyme activity maximally increased by approximately 60% above basal levels at 10^{-6}M . In contrast, membranes from EB-treated animals showed no isoproterenol-dependent elevation in AC activity. EB administration had no measurable effect on basal or forskolin-stimulated AC activity. These data suggest that estrogen promotes a stable uncoupling of β -adrenergic receptors from AC in the hypothalamus and preoptic area either at the level of receptor coupling to G protein or G protein coupling to AC.

FUNCTIONAL INTERACTIONS OF STRIATAL D_1 AND D_2 DOPAMINE RECEPTORS: EFFECTS OF TISSUE PREPARATION AND LESIONS.

L.L. Cook, D.M. Mottola, J.M. Petitto, M.H. Lewis, R.B. Mailman, Brain and Development Research Center, Univ. of North Carolina, Chapel Hill, NC 27599.

These studies examined functional D_1/D_2 interactions of dopamine receptors in rat striatum. Molecular or biochemical studies have shown that D_1 (and " D_5 ") receptors can be positively coupled to adenylate cyclase (AC), whereas D_2 (" D_3 " and " D_4 ") receptors are negatively coupled. As reported previously, dopamine (100 μM) increased cAMP efflux in slices of rat striatum, an effect blocked by SCH23390. The relative potency and efficacy of D_1 agonists to increase cAMP synthesis in slices was similar to that seen in striatal homogenates. As expected, the addition of a selective D_2 antagonist (sulpiride, domperidone or spiperone) resulted in an enhanced efflux of cAMP in slices, presumably due to blockade of inhibitory D_2 receptors. Conversely, in homogenates, D_2 antagonists (domperidone, remoxipride, and sulpiride) did not increase cAMP synthesis. Since this functional interaction between D_1 and D_2 receptors is eliminated following gentle homogenization, two possibilities are suggested. One is that the biochemical coupling of D_2 receptors to G proteins is more sensitive to disruption compared to D_1 receptors in this tissue preparation. Alternately, this biochemical interaction may require intact cellular architecture, consistent with the hypothesis that these receptor classes are located on different cells.

The D_2 interaction with D_1 -coupled AC was assessed in slices from rats with unilateral 6-OHDA substantia nigra lesions. Such lesions are known to increase the density of D_2 receptors, to increase (in homogenates) the potency of dopamine in the AC assay, and to abolish behavioral D_1/D_2 interactions. Striatal slices were prepared from sham controls, and from each striatum of the 6-OHDA-lesioned rats. In slices from the lesioned side, there was a 58% increase in cAMP efflux compared to sham controls and a 47% increase compared to the unlesioned side. Sulpiride (30 μM) produced a 32% increase in cAMP efflux in control slices, a 73% increase on the lesioned side and a 77% increase on the contralateral side. These results demonstrate that after deafferentation this functional interaction between D_1 and D_2 receptors remained intact, and appears to be potentiated, consistent with up-regulation of D_2 receptors. IN VIVO ASSESSMENT OF D_1 RECEPTOR ACTIVATION IN RAT PREFRONTAL CORTEX. W. A. Clark and R.H. Roth, Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

The medial prefrontal cortex (PFC) receives dopaminergic input from cells originating in the ventral tegmental area. This mesoprefrontal dopamine system exhibits exquisite sensitivity to mild stressors and to a class of benzodiazepine receptor inverse agonists, the anxiogenic β -carbolines. Both D_1 and D_2 receptors are found in this dopaminergic terminal field. In order to evaluate postsynaptic responses to changes in presynaptic dopamine turnover, we have evaluated extracellular (EC) cAMP, recovered by *in vivo* microdialysis, as a biochemical index of postsynaptic D_1 receptor activity (c.f. Egawa et al., *Brain Research* 458:303-308, 1988).

We utilize commercially available RIA materials to quantify cAMP to a lower limit of 0.5fmol. This high sensitivity assay eliminates the requirement for IBMX or other phosphodiesterase inhibitors in the perfusion buffer and allows measurement of basal EC cAMP.

All drugs are administered through a microdialysis probe located in the PFC of the anesthetized rat. Basal EC cAMP levels are insensitive to GTPyS (1 μM to 250 μM) suggesting that cAMP is generated within and transported from intact cells. While perfusion of the D_1 selective agonist SKF38393 (up to 100 μM) results in a dose-dependent increase in EC cAMP, this effect is TTX- and EGTA-insensitive (2 μM and 4mM, respectively) indicating that the cAMP is formed from direct D_1 receptor-mediated stimulation of adenylate cyclase.

Our data suggest that EC cAMP is a useful index of *in vivo* activation of D_1 receptors in the PFC (c.f. Hutson & Suman-Chauhan, *Neuropharmacology* 29:11: 1011-1016, 1990).

DEVELOPMENTAL CHANGES IN CYCLIC AMP-DEPENDENT PROTEIN KINASE ASSOCIATED WITH RESPONSE TO PROTHORACICOTROPIC HORMONE. A.H. Varghese*, K.J. Lou*, and W.A. Smith. Dept. of Biology, Northeastern University, Boston, MA 02115.

Prothoracicotrophic hormone (PTTH) is an insect cerebral neuropeptide which stimulates ecdysteroid secretion by the prothoracic glands. PTTH has previously been shown to activate glandular cAMP-dependent protein kinase in Manduca sexta, particularly during the mid-portion of the final larval stage. At this time, glandular response to PTTH is maximal with regard to steroidogenic output. We have further characterized glandular kinase, and have noted a predominance of the type II (54-55 kD) regulatory subunit. Further, a protein co-migrating with this subunit on 2-dimensional gels is a prominent substrate for thiophosphorylation in the presence of [³²S]ATP. Exposure to PTTH enhanced regulatory subunit occupancy by cAMP, primarily in the cytosol at this stage of development, though substrate phosphorylation occurred in plasma-membrane and microsomal cell fractions. Thiophosphorylation permitted us to examine regulatory subunit content independent of subunit occupancy by endogenous cAMP. Putative RII examined in this manner increased dramatically during the period of ecdysteroid secretion occurring between days 3 and 5 of the last larval stage. Increased RII content was also suggested during the prepupal ecdysteroid peak on day 8. Thus a strong correlation exists between PTTH responsiveness, secretory capacity, and RII subunit content, which we hypothesize may all be regulated by enhanced glandular levels of cAMP. SUBCELLULAR DISTRIBUTION OF THE CALMODULIN-DEPENDENT CYCLIC NUCLEOTIDE PHOSPHODIESTERASE IN THE RAT BRAIN. V. Burmeister*, N. Ludvig, P.C. Jobe and R.L. Kincaid. Depts. of Basic Sciences and Pathology, University of Illinois College of Medicine at Peoria, Peoria, IL 61656 and Section on Immunology, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

In this study the subcellular localization of the calmodulin-dependent cyclic nucleotide phosphodiesterase (CaM-dependent PDE) in cerebral cortex, hippocampus and inferior colliculus of rat brain was analyzed by electron microscopic immunocytochemical methods. Affinity purified antibodies were used. The immunoreactivity was found exclusively within neurons whereas glial cells were unstained. Preabsorption of antibody with phosphodiesterase eliminated this reactivity demonstrating the specificity of immunostaining. In the neuronal perikarya, deposits of immunoreaction product occurred as sparse patches, and were often associated with organelles such as mitochondria and endoplasmic reticulum. Nuclei, however, were free from immunoreaction product. In the neuronal processes, immunoreactivity was found within dendrites and dendritic spines, whereas the myelinated axons and axon terminals were immunonegative. The post-synaptic densities of asymmetric synapses were associated with especially high concentrations of immunoreaction product. The immunopositive profiles appeared to be quite selective; they comprised only a small percentage of the total number of synapses in the examined areas.

These data indicate that the CaM-dependent PDE is localized predominantly at postsynaptic sites in the rat brain. This supports other morphological evidence indicating a principal involvement of the cyclic nucleotide second messenger system in postsynaptic and not presynaptic functions in brain. Furthermore, CaM-dependent PDE may play an important role in the post-synaptic integration of Ca²⁺-mediated neuronal inputs.

241.13

LOCALIZATION OF PUTATIVE PI LINKED G PROTEINS BY *IN SITU* HYBRIDIZATION. C.E. Glatt and S.H. Snyder. Dept. of Neuroscience, Johns Hopkins University, Baltimore, MD 21205.

PI turnover is a major second messenger system. Several G proteins have recently been identified which can stimulate PI turnover (Moriarty, (1990) *Nature* 343,79 and Smrcka, (1991) *Science* 251,804). These G proteins include G₀ and the G_q/G₁₁ family. It remains unclear, however, which neurotransmitter systems stimulate PI turnover through which G proteins in the CNS. Detailed mapping of these putative PI linked G proteins by *in situ* hybridization may help determine which receptors couple to which G proteins by co-localization.

Complementary cDNA oligonucleotide probes have been synthesized against G₀, G_q, and G₁₁. These probes recognize unique sequences from each respective G protein. Northern analysis shows that each probe recognizes a single band of the appropriate size for each message. *In situ* hybridization histochemistry shows high levels of expression for G₀ in the Purkinje cell layer of the cerebellum, cortex and hippocampus, particularly the dentate gyrus and CA4 regions. G₁₁ labels the cortex, granule cell layer of cerebellum, superior and inferior colliculi, olfactory bulb and all regions of the hippocampus. G_q shows similar distribution but lower levels in all regions particularly the olfactory bulb and colliculi.

MECHANISMS UNDERLYING THE DIFFERENTIAL MODULATION OF GLYCINE CURRENT BY CYCLIC AMP DEPENDENT PROTEIN KINASE IN ACUTELY DISSOCIATED VENTROMEDIAL HYPOTHALAMIC NEURONS. N. Agopyan, N. Tokutomi* and N. Akaike. Dept. of Neurophysiology, Tohoku Univ. Sch. of Med., Sendai 980, Japan.

We recently reported that in acutely dissociated ventromedial hypothalamic (VMH) neurons cyclic AMP (cAMP) reduces the amplitude of 100 μM glycine (Gly)-induced chloride current (I_{Cl}) without affecting that induced by Gly concentrations up to 10 μM (Proc. of third IBRO World Congress of Neuroscience 1991, Montreal). Such a specific action of cAMP on >10 μM Gly-induced I_{Cl} may reflect the presence of either two different Gly receptor subunits or different conductance states of a single Cl channel (Hamill et al. 1983, *Nature* 305:805-808) with different sensitivities to cAMP dependent phosphorylation. To differentiate between these possibilities we studied the effect of cAMP (20 μM - 1 mM) on the inactivation kinetics of I_{Cl} induced by Gly (3 - 100 μM). Whole cell currents from acutely dissociated VMH neurons, held at -20 mV in symmetrical [Cl] (120 mM), were recorded at room temperature by patch-pipettes filled with internal solution containing 4 mM ATP and 1 mM GTP.

Under control conditions the amplitudes of I_{Cl} evoked by <10 μM Gly do not desensitize while that evoked by >10 μM Gly decrease to a steady-state level upon prolonged Gly application. Internal perfusion with cAMP induced a transient enhancement and the desensitization of 10 μM Gly-evoked I_{Cl} without significantly affecting the inactivation kinetics of that evoked by 30 and 100 μM Gly. H-8 (10 μM), a cyclic nucleotide-dependent kinase inhibitor (Hidaka et al. 1984, *Biochem.* 23:5036-5041), blocked the effect of cAMP, indicating the involvement of protein kinase A. Presently we are investigating the effects of cAMP on single channels to further elucidate the mechanism underlying Gly receptor modulation. Our preliminary data favours the presence of two different Gly receptor subunits in the VMH neurons.

ISOLATION AND CHARACTERIZATION OF A cDNA WHICH IDENTIFIES BOTH NEURAL-SPECIFIC AND UBIQUITOUSLY EXPRESSED NOVEL G_α mRNAs. B.A. Habecker, J.M. Martin, and N.M. Nathanson. Dept. of Pharmacology, Univ. of Washington Sch. of Med., Seattle, WA 98195.

A clone has been isolated from a 1321N1 human astrocytoma cDNA library which is identical to G_α-1 except for a novel 460 bp of 5' sequence, thus implying that the mRNA results from the use of an alternative promoter and alternative splicing of the G_α gene. Polymerase chain reaction confirmed the presence of an mRNA corresponding to this cDNA in astrocytoma cells. Northern blot analyses indicate that two mRNAs containing this novel sequence are present in rat, a 2.0 Kb RNA found primarily in neural and neuroendocrine tissues, and a 1.8 Kb mRNA expressed in many tissues.

The novel sequence does not contribute an in-frame ATG, which may be due to the presence of 160 bp of aliphoid satellite DNA at the 3' portion of this novel sequence. Insertion of this aliphoid DNA (which ordinarily is centromeric and not transcribed) into the transcription unit of this G_α variant results in an mRNA encoding a truncated form of G_α, probably translated from the first in-frame ATG in exon 2 as seen in G_α-5 (Ishikawa et al., 1990). Studies are currently underway to determine whether this aliphoid insertion is only found in astrocytoma cells, or if it is also present in G_α related mRNA found in other neural cell lines and in normal brain tissue.

CHARACTERIZATION OF G-PROTEINS IN XENOPUS MELANOCYTES. S. Karne*, C. K. Jayawickreme*, T.P. Nguyen*, M.L. Anderson and M. R. Lerner. Howard Hughes Medical Inst., Depts. of Internal Medicine, Pharm. & Neuroscience, Yale University School of Medicine, New Haven, CT. 06510

Xenopus Melanocytes translocate their pigment granules in response to a variety of stimuli, including light, melatonin, melanocyte stimulating hormone, norepinephrine, and serotonin. These ligands are believed to stimulate G-protein coupled receptors. Using the polymerase chain reaction and degenerate oligonucleotides to the conserved regions of known G-proteins, thirteen different PCR generated fragments for the G-proteins in these cells have been isolated and sequenced. Comparison of these sequences to the known G-proteins reveals that these cells contain all known members of the G-protein superfamily, save for transducin which is coupled to rhodospin in rods and cones. There are six different G_s-like, one G_i-1, one G_i-2, one G_o, and three G_p-like proteins in these cells.

241.15

MOLECULAR CLONING AND SEQUENCING OF A G-PROTEIN α_1 -LIKE SUBUNIT FROM THE LOBSTER OLFACTORY ORGAN. A.P. Byrnes*, T.S. McClintock and M.R. Lerner. Section of Molecular Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510.

The polymerase chain reaction (PCR) was used to amplify DNA sequences encoding G-protein α subunits from lobster olfactory organ cDNA. Sequencing of two cloned PCR fragments revealed homology with α_1 and α_2 subunits of G-proteins. One cloned PCR fragment was used to probe an olfactory organ cDNA library. A clone with a 1.4 kb insert containing the entire coding region was isolated and sequenced. This clone's predicted amino acid sequence has 77% - 82% identity to α_1 subunits, 66% - 68% to α_2 subunits, 62% - 65% to transducins, and 44% - 45% to α_3 subunits according to a search of the Genbank and EMBL databases. A Northern blot probed with this clone revealed a single 8 kb message in lobster olfactory organ, brain, eyestalk, leg, and tail muscle.

CA²⁺ / CALMODULIN AUGMENTS CHRONIC ANTIDEPRESSANTS' EFFECT ON THE COUPLING OF G PROTEIN (Gs) TO ADENYLATE CYCLASE H. Ozawa, N. Katamura, H. Kamada, H. Ikeda, N. Takahata, and T. Saito Dept. of Neuropsychiatry, Sapporo Medical College, Sapporo 060 Japan.

Our previous studies have shown that enhanced adenylylase (AC) activity after chronic treatment with antidepressants is attributable to changes in the nature of the stimulatory GTP-binding protein (Gs) or increased coupling between Gs and the catalytic unit of AC. Thus, the molecular locus of action of antidepressants may reside at Gs. Recently it has been reported that although AC appears to bind calmodulin, the regulation of enzyme activity by that compound is complicated and likely to involve G proteins. The present study examines the modulation of antidepressants' effect on the coupling of G protein to adenylylase by Ca²⁺/calmodulin. Male Sprague-Dawley rats (150-200g) were injected (intraperitoneal) once daily for 21 days (chronic) with amitriptyline, iprindole (10mg/kg) or saline (as control) and cerebral cortex membranes were prepared and assayed for AC. When membranes were assayed under conditions in the absence of 1 mM EGTA, chronic treatment with antidepressant increased basal AC activity but not in the presence of EGTA. Enhancement of GppNHP stimulated AC activity by antidepressants, however it was not affected by EGTA. Ca²⁺ dependent AC activity was enhanced in membranes from chronic antidepressant treatment by the addition of 1 μ M calmodulin. In the absence of calmodulin, however, Ca²⁺ dependent AC activity was not altered by chronic antidepressant treatment. Ca²⁺ dependent AC activity stimulated by GppNHP was increased in membranes from rats treated by chronic antidepressant with or without calmodulin. These results suggest that increased sensitivity of Ca²⁺/calmodulin by chronic antidepressant treatment on the AC system may be attributed to enhanced coupling between Gs and the catalytic unit of AC.

EXPRESSION OF MAMMALIAN MUSCARINIC RECEPTORS AND TRIMERIC G-PROTEINS IN THE YEAST SACCHAROMYCES CEREVISIAE.

P. Pavette, M. Caron, E. Leberer and M. Dennis National Research Council of Canada, Biotechnology Research Institute, Montreal, CANADA, H4P 2R2

It is now well known that yeast cells possess a G-protein signal transduction pathway similar to mammalian cells. This signalling pathway is used by the pheromone receptor (STE2 or STE3) in haploid cells to activate the mating response. In the resulting diploid cell the production of the signalling pathway components is repressed. We have expressed in diploid cells, trimeric mammalian G-proteins ($\alpha_1\beta\gamma$ or $\alpha_2\beta\gamma$) and either the human muscarinic receptor subtype 1 (Hm1) or subtype 2 (Hm2) using different expression vectors. We have assessed the production of the G-protein subunits by western blot and have tested the ability of pertussis toxin to ADP-ribosylate the associated trimer. Binding displacement experiments with agonists were also performed to verify if a high affinity state is conferred to the receptor by the active trimer.

It appears that G_s is produced in greater quantity than G_i, and pertussis toxin labels only the complete trimer and not alpha alone. Agonist binding profiles are now being investigated, and preliminary experiments demonstrate no change for Hm1 binding whereas Hm2 shows a slight difference (i.e. High affinity state in low proportion) when in the presence of the G_s-protein trimer.

241.16

EFFECT OF MASTOPARAN, A WASP VENOM TOXIN, ON GTP-BINDING PROTEINS THAT REGULATE RAT CORTICAL ADENYLATE CYCLASE. S. Hatta, H. Ozawa*, and H. Ohshika. Departments of Pharmacology and *Neuropsychiatry, Sapporo Medical College, Sapporo 060, Japan.

Mastoparan, a wasp venom toxin, has been shown to be a potent stimulator of exocytosis for several mammalian cells. Mastoparan (MP) has recently been suggested to interact with G_o and/or G_i protein directly in the reconstituted system, and to inhibit an IAP-insensitive putative G-protein which activates phospholipase C in 1321N1 human astrocytoma cells. In this study, we examined the effect of MP on the function of G-proteins which regulate adenylylase (AC) in rat cerebral cortex (CCX). MP (10⁻⁴ M) potentiated GppNHP-stimulated AC activity and lowered the EC₅₀ value of AC activation for GppNHP in CCX membrane. Furthermore, GppNHP-stimulated AC activity in the membranes that preincubated with GppNHP was augmented by MP. On the other hand, there was no significant effect of MP either on isoproterenol-stimulated AC activity or on GppNHP inhibition of forskolin (100 μ M)-stimulated AC activity. AC activation with MnCl₂ (20 mM) was not different in the membranes incubated with or without MP. From these results, it appears that MP potentiates the G_s protein function in the rat cortical AC system. However, no significant effect of MP on the G_i protein function was observed in rat CCX membranes.

G_o ACTIVATES A CONDUCTANCE IN RAT HIPPOCAMPAL NEURONS SIMILAR TO THAT INDUCED BY SEROTONIN. R. D. Blitzer, O. D. Gil, D. Carty*, M. DeVivo*, R. Iyengar* and E. M. Landau. Depts. of Psychiatry and Pharmacology, Bronx VAMC and Mt. Sinai Med. Center, New York, NY 10029.

Serotonin hyperpolarizes hippocampal neurons by activating a K⁺ conductance. This effect is sensitive to pertussis toxin, suggesting that either G_o or G_i transduces the 5HT response. We are investigating the properties of activated G-proteins on these neurons, and report that activated G_o (G_o^{*}) induces a membrane conductance which is similar, and possibly identical, to the 5HT-activated conductance.

CA1 pyramidal cells were voltage clamped in slices (500 μ m thick) obtained from either immature or adult rats, using whole-cell patch methods. In control cells, 5HT (10 μ M) evoked an outward current of 140 \pm 23 pA at V_h = -60 mV, with a reversal potential of -80 \pm 1 mV (n=12). In other cells, the pipette solution included 30 nM G_o^{*}. 4/6 of these cells exhibited a slowly-developing steady outward current, peaking at 105 \pm 28 pA and with a reversal potential of -78 \pm 5 mV. The G_o^{*}-induced current did not occlude the response to 5HT, indicating that G_o^{*} and 5HT may activate different types of K⁺ channel. An alternative explanation is that the receptor-mediated response may be transduced by G_o, but that either (1) the maximal agonist response is not limited by the number of available channels, or (2) the channels activated by the introduced G_o^{*} are spatially distinct from those activated by 5HT. We are presently exploring these possibilities. (Supported by the VA Merit Program and NIH-NIA AG02219).

EFFECTS OF COCAINE SENSITIZATION ON G-PROTEIN RIBOSYLATION. C.D. Striplin and P.W. Kalivas. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

Sensitization is a behavioral and neurochemical process that results from repeated administration of psychostimulants. Neurochemically sensitization has been correlated with an increase in dopamine (DA) transmission in nuclei of the mesolimbic system. Biochemically, the reason for this augmented DA release is not well understood; however, it is known that the G-protein second messenger system is involved. Recently, Nestler et al. (J. Neurochem., 55:1079-1083, 1990) demonstrated that chronic cocaine (30 mg/kg) causes a decrease in pertussis toxin (PTX) labelling of G_i and G_o proteins in several mesolimbic nuclei. However, since both high and low doses of cocaine cause sensitization, it is important to determine if changes are a general phenomena of sensitization or a toxic effect of the dosage regimen. To investigate this question, rats were sensitized for five days with different doses of cocaine (0, 15, and 30 mg/kg, ip). On the fifth day, animals were sacrificed at 1, 6, or 24 h after their last injection. The ventral tegmental area (VTA) and nucleus accumbens (NA) were dissected over ice, and *in vitro* PTX activated ³²P-ADP-ribosylations were performed. Ribosylated proteins were separated by SDS-PAGE and analyzed by densitometry following autoradiography. After the last cocaine injection in both dosage regimes, a slight decrease in the ribosylation of G-proteins was observed in the VTA at 1 h but not at 24 h. No change was apparent in the NA. The short term decrease in G-protein ribosylation produced by cocaine argues that G-proteins are not involved in the longer expression of behavioral sensitization to cocaine.

241.21

MODULATION OF SIGNAL TRANSDUCTION PATHWAYS BY ELECTROCONVULSIVE SHOCK (ECS). **H. Manji, G. Chen*, J. Bitran*, M. Masana, and W. Z. Potter*** Section on Clinical Pharmacology, ETB, NIMH, Bethesda, MD 20982

Electroconvulsive therapy (ECT) is an effective treatment for depression, catatonic states, and even Parkinson's disease. Despite extensive research, the molecular mechanisms underlying its efficacy in these clinical conditions remains to be elucidated. We have recently investigated signal transduction pathways as putative targets for electroconvulsive shock (ECS). 10 male sprague-dawley rats were administered a series of 10 electroconvulsive shocks (alternate day) via ear-clip electrodes. Sham-treated animals were handled similarly without electric current being administered. 24 hours following the last shock, the animals were decapitated, and frontal cortex (CORT), hippocampus (HIPP), accumbens (ACC), and striatum (STR) were dissected.

Chronic ECS did not have any effect on the amount of $\alpha_s, \alpha_{11-3}, \alpha_o$, as assessed by western blotting. In contrast, ECS produced a significant increase in the cholera toxin [32 P] ADP-ribosylation of Gs in striatum, in the absence of any changes in the pertussis toxin [32 P]ADP-ribosylation of Gi/Go. ECS also produced a selective decrease in the levels of PKC γ in the HIPP, without altering PKC α or PKC β . These findings may have relevance for both the therapeutic (mood-elevating and motoric) and deleterious (memory-impairing) effects of ECT.

REGULATION OF DOPAMINE RECEPTORS

242.1

FURTHER STUDIES OF AGONIST- AND ANTAGONIST-INDUCED REGULATION OF mRNA OF MUSCARINIC CHOLINERGIC RECEPTORS IN CEREBELLAR GRANULE CELLS. **E. Fukamauchi, C. Hough, and D.-M. Chuang.** Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

We have previously demonstrated that cerebellar granule cells express mRNA of m2- and m3-muscarinic acetylcholine receptors (mAChRs) and that their mRNA contents are up- and down-regulated by exposure to the receptor antagonist atropine and agonist carbachol, respectively. In this study, we investigated some pharmacological details involved in m2- and m3-mAChR mRNA regulation. Exposure of cells to 1 μ M atropine induced a differential up-regulation of m2- and m3-mAChR mRNA with a maximal increase at 24 and 8 hr for m2- and m3-mAChR mRNA respectively. Treatment of cells for 2 hr with 10 μ M AF-DX 116, a selective m2-mAChR antagonist, significantly increased m2-mAChR mRNA. The copresence of AF-DX 116 with 100 μ M carbachol blocked carbachol-induced m2-mAChR mRNA down-regulation. On the other hand, treatment for 8 hr with 10 μ M 4-DAMP, a selective m3-mAChR antagonist, resulted in a marked increase in m3-mAChR mRNA content. Moreover, 4-DAMP completely blocked m3-mAChR mRNA down-regulation induced by 8 hr stimulation with 100 μ M carbachol. The level of m3-mAChR mRNA was decreased by 20, 40 and 43% after 8 hr treatment with 10, 100 and 1000 μ M carbachol. Under these conditions, m2-mAChR mRNA was decreased by less than 20%. Exposure of cells to 500 nM PDBu and 50 μ M H7 for 2 hr did not affect m2- and m3-mAChR mRNA contents. These results provide further evidence for differential regulation of levels of m2- and m3-mAChR mRNA by the receptor agonists and antagonists. Moreover, agonist-induced mAChR mRNA down-regulation appears to be independent of a change in protein kinase C activity.

242.3

CHRONIC SUBSTANCE P INCREASES MUSCARINIC RECEPTOR BINDING IN RAT CORPUS STRIATUM BUT NOT IN FRONTAL CORTEX. **NW Pedigo, JS Fu*, MA Rice*, and JK Rowlett*** Depts Pharmacology, Anesthesiology and Physiology, Univ. of Kentucky Med. Ctr., Lexington, KY 40536.

The neuropeptide substance P (SP) is widely distributed in mammalian brain, including corpus striatum (CS), where it provides a major excitatory output pathway, and frontal cortex (FC), where it may coexist with acetylcholine. The purpose of this study was to evaluate possible neuromodulation by SP of postsynaptic muscarinic receptors or function. *In vitro* SP (final concentration = 0.1 μ M) did not directly alter binding of 3 H-quinuclidinyl benzilate (3 H-QNB) or carbachol-stimulated phosphoinositide (PI) hydrolysis in rat FC. *In vivo* treatment of rats with repeated intracerebroventricular (icv) injections of SP (50 ng/2 μ l, 2X/day for 10 days) did not alter muscarinic receptor binding or function in FC. However, chronic icv SP did elevate 3 H-QNB binding density (B_{max}) in CS (2095 \pm 54 vs 1730 \pm 55 fmol/mg protein for SP- and vehicle-treated rats, respectively; $p < .001$). No change in receptor affinity was noted (K_d 's = 46 vs 50 pM). This effect may be due to SP actions within CS or due to SP activation of dopaminergic nigrostriatal neurons which, in turn, inhibit cholinergic neurons in CS. Subsequent decreased cholinergic activity could lead to muscarinic receptor up-regulation.

242.2

CHRONIC NICOTINE ADMINISTRATION DOES NOT AFFECT MESOLIMBIC NICOTINIC RECEPTOR BINDING OR FUNCTION. **Peter P. Rowell and Laurence A. Carr,** Dept. of Pharmacology, Univ. of Louisville Sch. of Med., Louisville, KY 40292.

It has generally been found that chronic nicotine administration to rodents leads to an increase in the number of nicotine binding sites in most brain areas which have been investigated. The explanation for this effect is that chronic nicotine causes receptor desensitization resulting in a consequent upregulation. Many of nicotine's effects are thought to result from the nicotine-induced stimulation of mesolimbic dopaminergic neurons, particularly those terminating in the nucleus accumbens; however, the effects of chronic nicotine on the density of nicotine binding sites in this tissue have not been investigated. In this study, rats were administered nicotine (3 mg/kg/day) for two weeks via osmotic minipumps, after which [3 H]-methylcarbamylcholine binding in the nucleus accumbens and amygdala was determined. The ability of 10 μ M nicotine to release [3 H]-dopamine from these brain areas was also investigated using *in vitro* superfusion. It was found that there were no differences between control and nicotine-treated animals with respect to the B_{max} for [3 H]-MCC binding in either tissue, nor were there differences in nicotine-evoked dopamine release. These results indicate that chronic nicotine treatment does not induce receptor upregulation nor does it alter dopamine release in the mesolimbic system as it does in some other brain areas. This supports evidence that tolerance to the reinforcing properties of nicotine, thought to be mediated in part via mesolimbic neurons, may not develop with chronic nicotine use. (Supported by a grant from the Tobacco and Health Research Institute.)

242.4

Effect of chronic neuroleptic treatment on central nervous system muscarinic receptors. **T.A. Cawley, Jr. and G.R. Luthin,** Dept. of Physiology and Biophysics and Institute for Neuroscience, Hahnemann University, Philadelphia PA 19102.

Clozapine is an atypical neuroleptic agent that has a much-decreased frequency of motor side effects when compared to typical neuroleptics. Clozapine has a high potency to inhibit both muscarinic and dopamine receptor activity in binding studies. This is consistent with clinical observations that motor side effects, due to chronic treatment with typical neuroleptics, may be reduced by co-administration of anticholinergic drugs. Administration of anticholinergic drugs generally produces increases in muscarinic receptor levels in brain. Therefore, we hypothesize that the decrease in motor side effects during chronic clozapine treatment is due to its ability to act as an antagonist to modulate muscarinic receptor levels. It was the general purpose of this study to measure levels and distribution of muscarinic receptor subtypes following chronic administration of typical and atypical neuroleptics and anti-cholinergic agents in rats. Animal treatment groups consist of the following: clozapine (20 mg/kg), atropine (20 mg/kg), fluphenazine (12.5 mg/kg), fluphenazine/atropine or saline (0.5 ml). All animals were chronically treated for 14 days. Striata were dissected from the brains and immediately frozen in liquid nitrogen and stored at -80°C. Receptors were solubilized using a digitonin/cholelate method. Antibodies to muscarinic receptor subtypes were used in immunoprecipitation assays to assess the effect of the treatments to modulate the levels of the different subtypes. Binding assays demonstrated the expected increase in the total muscarinic receptor density in the atropine and fluphenazine/atropine groups but no increase in the clozapine group. The increases due to atropine treatment could be accounted for by increases in the m1 receptor subtype. No alterations in subtype levels were seen with clozapine. This study suggests that the clinical profile of clozapine activity may not be related to its anti-cholinergic activity.

CHRONIC ESTRADIOL TREATMENT INCREASES ANTERIOR PITUITARY BUT NOT STRIATAL D-2 DOPAMINE RECEPTOR mRNA LEVELS IN RATS. D. Lévesque¹, E. Gagné², N. Barden², and T. Di Paolo¹, ¹Dept. Mol. Endocrinol., CHUL Research Centre and School of Pharmacy, Laval University, Québec, G1K 7P4, and ²Dept. Molecular Psychogenetics, CHUL Research Centre, Laval University, Québec, Canada, G1V 4G2.

Much evidence suggests that estrogens modulate central dopaminergic system activity and the most interesting aspect of this interaction is the effect of estrogens on dopamine (DA) receptors. However, the mechanism underlying this interaction is yet to be fully understood. In this report, we investigated the effect of chronic 17 β -estradiol (E2) treatment (10 μ g, b.i.d., for 2 weeks) on D-2 DA receptor mRNA levels in striatum and anterior pituitary tissues. We used ³²P-labeled probes specific for D-2 receptor and β -actin mRNAs in Northern blot analysis. We observed that the ratio of D-2 DA receptor mRNA/ β -actin mRNA level was increased in anterior pituitary tissue of E2-treated rats compared to vehicle-treated animals (70% increase, $p < 0.01$). Anterior pituitary weight and protein content were also increased in E2-treated animals, but β -actin mRNA levels remained constant. The D-2 DA receptor mRNA/ β -actin mRNA ratio in the striatum was not affected by E2 treatment. However, the medial striatum showed a significantly lower ratio compared to the lateral striatum ($p < 0.01$) in both vehicle- and E2-treated rats. Thus, E2 effects on anterior pituitary D-2 receptors may implicate transcriptional regulation, while these results support the hypothesis of an alternative mechanism of action for E2 in the striatum, and which may implicate synaptic membrane components. This work was supported by the MRC of Canada.

D1 AND D2 RECEPTORS DO NOT UP-REGULATE IN RESPONSE TO NEONATAL INTRASTRIATAL 6-HYDROXYDOPAMINE (6-OHDA) LESIONS. B.S. Neal and J.N. Joyce. Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

In adult rats, extensive lesions of DA neurons produce profound behavioral impairments which mimic changes observed in Parkinson's disease. This syndrome is not seen following neonatal lesions. Adult-lesioned rats are supersensitive to D2 agonists and antagonists, whereas neonatally-lesioned rats are supersensitive to D1 agonists and subsensitive to antagonists (Neal and Joyce, *Devl. Brain Res.*, in press). Therefore, differential receptor regulation following adult vs. neonatal lesions would be expected. Adult lesions cause an increase in D2 receptor density, with either no change or a decrease in D1 density (Joyce, *Expt. Neurol.*, in press). No clear-cut results have been forthcoming with neonatal lesions. Conflicting findings have been reported for both D1 and D2 binding depending upon the degree of DA depletion and the age at lesioning. To determine what effect the extent of DA depletion had on receptor regulation, we administered a range of 6-OHDA doses (0-20 μ g/striatum) bilaterally into the striatum on day of birth or postnatal day 1. Quantitative receptor autoradiography revealed a dose-dependent loss of DA uptake sites (³H-mazindol) and μ -opioid receptor patches (³H-naloxone) in adult striatum, as a consequence of neonatal 6-OHDA lesions. Doses of 2-16 μ g of 6-OHDA caused an approximate 10% loss of D1 binding (³H-SCH23390) in the central and medial portions of the striatum; 20 μ g caused a greater loss (up to 24% in the central striatum). D2 binding (¹²⁵I-epidepride) did not increase, in fact, there was a slight decrease (5-10%) in the central and medial striatum, which was not dose-dependent. These results suggest that D1 and D2 receptors are affected differently by DA depletion during development or in adulthood. Supported by grants from the Tourette Syndrome Association and USPHS (MH09888 and HD26979).

EFFECT OF LONG-TERM HALOPERIDOL TREATMENT ON DOPAMINE-INDUCED INOSITOL PHOSPHATE FORMATION IN RAT BRAIN SLICES. B. Li*, L.L. Wing, R.J. Wyatt, D.G. Kirch and D.-M. Chuang. Neuropsychiatry Branch, NIMH, Neuroscience Center at St. Elizabeths, Washington, D.C. 20032 and Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

Although it is firmly established that haloperidol blocks dopamine receptors, the actual mechanism of its antipsychotic action remains unclear. Previous studies have shown that in vitro stimulation of dopamine D1 receptors can enhance phosphoinositide (PI) turnover in the brain. We examined dopamine receptor-mediated PI turnover in rats treated with saline or haloperidol (1.5mg/kg/day, IM) for 6 weeks. Basal and dopamine stimulated PI hydrolyses were assayed by lithium-dependent accumulation of ³H-inositol monophosphate (IP₁) in rat brain slices pre-labeled with ³H-myo-inositol. Our results showed that: (1) basal PI turnover was unchanged after haloperidol treatment; (2) dopamine stimulation in vitro significantly increased PI hydrolysis in striatum, hippocampus and frontal cortex; (3) long-term haloperidol treatment significantly attenuated dopamine-induced ³H-IP₁ accumulation in striatum and frontal cortex ($P < 0.05$) and to a lesser extent in hippocampus. The relationship between dopaminergic receptors and PI turnover will be discussed.

DOPAMINE D1 AND D2 RECEPTORS IN ADULT RAT BRAIN AFTER NEONATAL 6-OHDA TREATMENT: AN AUTORADIOGRAPHIC STUDY. F. Radja*, K.M. Dewar, T.A. Reader and L. Descarries. Centre de recherche en sciences neurologiques (Départements de physiologie et de psychiatrie), Université de Montréal, Montréal (Québec), CANADA H3C 3J7.

A membrane binding study has already demonstrated an increased number of dopamine (DA) D2 but not D1 receptors in the neostriatum of adult rats subjected to neonatal destruction of the nigrostriatal DA system by intraventricular 6-OHDA (Dewar et al., *Brain Res.*, 536:287, 1990). In the present study, the regional distribution of D1 and D2 receptor binding was investigated by quantitative autoradiography, 3 and 6 months after the neonatal 6-OHDA lesion. The selective antagonists [³H]SCH23390 and [³H]raclopride were used as radioligands for the D1 and the D2 receptors, respectively. In all lesioned rats, the DA content of the neostriatum was reduced by more than 90% of control values. Three months after the lesion, the density of [³H]raclopride binding was increased by approximately 30% over controls in both the rostral and the caudal neostriatum. A similar increase in D2 receptors was found at 6 months post lesion. In the substantia nigra examined at 6 months, there was an obvious reduction of D2 receptor density. In contrast, there were no apparent changes in D1 receptor density in either the neostriatum nor the substantia nigra, as observed after 3 months. These results confirm the up-regulation of D2 receptor binding previously described in the rostral neostriatum, 3 months after the neonatal, nigrostriatal DA lesion. They also indicate that this up-regulation takes place in the caudal as well as the rostral neostriatum and suggest that it is a permanent phenomenon. The reduction in nigral [³H]raclopride binding is consistent with a somato-dendritic localization of the D2 receptors on the DA neurons in this part of the brain. (Supported by MRC grants MT-3544 and MT-6967).

MECHANISMS UNDERLYING THE DEVELOPMENT OF DA RECEPTORS SUPERSENSITIVITY: ROLE OF G-PROTEINS. C. Ventra, T. Florio, S. Talia*, F. Cocozza*, A. Avallone*, G. Schettini. Dept. of Pharmacology, II School of Med., Naples, Italy.

We have shown an enhanced response of striatal adenylate cyclase activity (AC) to GTP in up-regulated D1 and D2 receptors, suggesting the involvement of G-proteins in the development of DA receptors supersensitivity. Here, we used NaF, an agent activating AC via G_s, that, unlike GTP, stimulated striatal AC by the same extent in saline and 21 days neuroleptic-treated rats. To evaluate whether the increased response to GTP is due to an enhanced expression or functioning of G-proteins, we tested the effect of 21 days Haloperidol and SCH 23390 on striatal mRNA encoding G_s and Gi α subunits. Unexpectedly, the only difference observed, so far, was in the levels of Gi1 mRNA following SCH treatment, while no changes in G_s mRNA levels were observed. [³H]-GTP binding studies are in progress to detect possible modifications in the GTP-binding activity of supersensitive DA receptors. Finally, no changes in AC-stimulated by MnCl₂ or forskolin were detected, thus excluding the involvement of the catalyst in the development of DA receptors supersensitivity.

D₂ DOPAMINE RECEPTOR REGULATION IN THE INTERMEDIATE LOBE OF THE RAT PITUITARY. Daniel S. Dickerson*, Belinda S. Pratt*, William R. Millington and Bibie M. Chronwall. University of Missouri-Kansas City, School of Basic Life Sciences, Kansas City, MO 64108.

Peptide secretion from the rat intermediate lobe is regulated by D₂ dopamine receptors. This study demonstrates the change in D₂ dopamine receptor kinetics in conjunction with changes in D₂ mRNA level in the intermediate lobe of the rat pituitary following chronic treatment (2mg/kg/d, 12d) with the D₂ receptor antagonist haloperidol and agonist bromocriptine. Receptor autoradiography using emulsion coated coverslips apposed to slide-mounted tissue sections was employed to assay the effects of haloperidol and bromocriptine on the D₂ receptor population. ³H-Spiperone (0.04 nM to 0.4 nM) was used as the D₂ binding ligand and butaclamol (3.0 nM) as the D₂ competitive ligand. Analysis of the D₂ receptor kinetics indicates that haloperidol treatment leads to a statistically significant increase in B_{max} (from 5.63 \pm 0.68 fmol/ μ m² to 10.12 \pm 1.12 fmol/ μ m²) and an increase in K_d (from 525 \pm 134 to 839 \pm 140) as compared to control values. Bromocriptine treated animals show no change in B_{max} (6.16 \pm 0.46 fmol/ μ m²) or K_d (591 \pm 71).

Radioactive and non-radioactive *in situ* hybridization of D₂ receptor mRNA levels indicate that D₂ mRNA levels increase 50% following chronic haloperidol treatment with no change following chronic bromocriptine treatment. This parallel change in receptor concentration and affinity as well as mRNA levels follows the classic paradigm by which a cell, in response to an antagonist, up-regulates the receptor population.

AMYGDALA KINDLING ALTERS STRIATAL AND EXTRASTRIATAL DOPAMINE D2 RECEPTOR REGULATION UNILATERALLY.

A. Janowsky, K.A. Neve, L.A. O'Toole*, J.K. Belknap, and C.D. Applegate, VAMC and Oregon Health Sci. Univ., Portland, OR., and Univ. of Rochester Sch. of Med., NY

Previous reports indicate that hippocampal and (or) amygdala kindling alters dopamine D2 receptor density in the nucleus accumbens. We now report that amygdala kindling produces long-term unilateral changes in dopamine D2 receptor regulation in striatum. Extrastriatal brain regions that contain a very low density of neurotransmitter binding sites were also examined. Electrodes were implanted into the left amygdala and rats were kindled to 6 consecutive stage 5 seizures. Animals were sacrificed 30 days after the last seizure, and 16µm sections from frozen brain were incubated with [¹²⁵I]epidepride (40 to 76 pM) in the presence and absence of spiperone (1 µM) for autoradiographic determination of dopamine D2 receptor density. Analysis of tissue sections indicates that there is a 20% to 50% increase in specific radioligand binding on the side ipsilateral to the kindled site, as compared to the contralateral side. Changes were most obvious in lateral neostriatum. Binding to nucleus accumbens, hippocampus, cortex, hypothalamus, amygdala, and other extrastriatal regions is being analyzed. The long term effects of kindling suggest the involvement of altered genetic expression, and experiments concerning the temporal aspects of, and the molecular mechanisms involved in the receptor changes are now in progress. Supported by NIMH, NIAAA, and VA Merit Reviews.

PREVENTION AND REVERSAL OF DOPAMINE RECEPTOR (DAR) SUPERSENSITIVITY (SS) BY CYCLO(LEU-GLY) (CLG)

GE Drucker, RF Ritzmann², LJ Wichlinski, JH Gordon & JZ Fields. Res Svce 151, VA Hospital, Hines IL 60141; Dept Pharm, Loyola U Med Sch, Maywood IL; ²Psych Svce, VA Med Ctr, Sepulveda CA

Chronic administration (21 d) of haloperidol (HAL) (IP, 1.0 mg/kg/d) induced a behavioral SS to dopamine (DA) agonists (stereotypic sniffing) and up-regulation of striatal and limbic D2 DAR. Co-administration of CLG (8 mg/kg, SC, every third day, every other day, or every day) with HAL attenuated the behavioral SS except for CLG every day. D2 DAR binding assays showed CLG-induced changes parallel to these behavioral changes, suggesting that CLG's ability to prevent behavioral SS to DA agonists involves a decrease in the total number (Bmax) of D2 binding sites. DAR binding changes also suggest that the biphasic behavioral dose response curve involves a failure of CLG at the highest cumulative doses to reverse the elevated density of D2 DAR. CLG was also able to reverse an already established DAR up-regulation, since a similar down-regulating effect of CLG on behavior and binding was observed when CLG was injected daily (8 mg/kg, SC) for 4 days during the period of withdrawal from HAL. Chronic CLG by itself had no significant effects on behavior or binding. These data suggest that CLG may be useful, within a therapeutic window, in disorders that are thought to involve up-regulated striatal or limbic DAR including tardive dyskinesia, L-DOPA induced dyskinesias, and schizophrenia. 242.12

NEUROCHEMICAL BASIS FOR THE ABSENCE OF OVERT STEREOTYPED BEHAVIORS IN RATS WITH UP-REGULATED STRIATAL D2 DOPAMINE RECEPTORS (DAR).

JZ Fields, GE Drucker, L Wichlinski & JH Gordon. Res Svce, VA Hosp, Hines IL 60141; Dept Pharm, Loyola U Med Sch.

Because of substantial evidence for the hyperdopaminergic hypothesis of tardive dyskinesia (TD), animal models, especially rats, treated chronically with neuroleptics are used to study this disorder. The rat model has been criticized because, unlike TD, there is an apparent lack of spontaneous abnormal movements even when striatal D2 DAR density is increased. Our data suggest a mechanism by which rats suppress these abnormal movements normally associated with elevated DAR. We correlated neurochemical with behavioral changes using several animal models, including non-neuroleptic ones, which elicit varied levels of DAR upregulation. There was (as expected) a significant robust, positive correlation between striatal DAR density and apomorphine-induced stereotypy. In contrast, there was a significant negative correlation between increased DAR and synthesis capacity for striatal DA (Vmax for tyrosine hydroxylase). We conclude that this decrease in Vmax is compensation by the nigrostriatal DA tract for the increased DAR density induced in our animal models. Our data suggest that an observed increase in receptor density does not necessarily predict a functional change (spontaneous behavior, neuropathology) because compensatory mechanisms exist. In TD this compensation may fail, leading to spontaneous abnormal behaviors. (Supported by VA Med Res & RoINS26449)

CROSS-SENSITIZATION BETWEEN D1 AND D2 DOPAMINE AGONISTS: EFFECT OF A SINGLE INTRA-ACCUMBENS INJECTION ON SUBSEQUENT LOCOMOTOR ACTIVITY IN MICE.

C. Messier, O. Mrabet*, and C. Destrade. Laboratoire de Psychophysiology, URA CNRS n°339, Université de Bordeaux I, 33405 Talence Cédex, France. *Département de Biologie, Faculté des Sciences, BP 20, ElJadida, Morocco

We tested the effect of a single unilateral injection of a specific D1 agonist into the nucleus accumbens on the behavioral response to a subsequent unilateral intra-accumbens injection of a selective D2 agonist ten days later. The effect of the inverse order of presentation (D2 agonist followed ten days later by a D1 agonist) was also tested. No significant differences between the locomotor effects of the intra-accumbens injection of either SKF-38393 (3.5 µg) or LY-171555 (10 µg) were observed during the first test. Ten days later, during the second test, intra-accumbens injection of both the LY-171555 and SKF-38393 increased the percentage of contralateral rotations relative to the first test while LY-171555 also increased the total number of rotations. Control injections showed that these effects of LY-171555 and SKF-38393 were not due to a conditioning process. Rather, the results suggested that the locomotor changes observed during the second test were the result of behavioral sensitization due to the initial acute injection of the agonists.

CARDIOVASCULAR REGULATION: BRAINSTEM MECHANISMS I

PROJECTIONS FROM THE PERIAQUEDUCTAL GRAY (PAG) TO THE PERIAMBIGUAL AREA: RELATION TO VAGAL OUTPUT NEURONS.

M. Ennis, T.A. Rizvi, M.T. Shiplev, M.M. Behbehani, D. Smith, E.J. Van Bockstaele, P. Luppi and G. Aston-Jones. Univ. Cinti. Coll. Med.; Hahnemann Univ.

Activation of PAG elicits selective pressor and depressor responses. PAG projections to the rostral ventrolateral medulla sympathoexcitatory zone is a likely substrate for PAG-evoked pressor responses. Circuits mediating PAG-evoked depressor responses are less clear. Here, we report PAG projections to nucleus ambiguus (NA) and the periambigual area (pNA) in rat.

WGA-HRP and PHA-L injections into lateral and ventrolateral PAG labeled a rostrocaudally oriented, longitudinal fiber plexus surrounding, and occasionally within, NA. Labeled fibers increase along the rostral to caudal axis of pNA. These injections also labeled neurons in pNA and, less frequently, in NA. Injections into dorsomedial, dorsolateral, or ventromedial PAG produced only sparse fiber labeling in NA and pNA. WGA-HRP injections into the vagus nerve retrogradely labeled longitudinally organized columns of neurons in NA and pNA. The distribution of pNA cells labeled after vagus nerve injections appeared to substantially overlap with the fibers anterogradely labeled from PAG.

These results indicate that PAG has reciprocal connections with NA and pNA. pNA contains preganglionic parasympathetic neurons that project to the heart (Bieger and Hopkins, 1987). Experiments in progress will determine if PAG innervates identified vagocardiac neurons and if this pathway mediates PAG-evoked depressor responses. (Support: PHS Grants HL08097, NS20463 and NS24698).

243.2

HEMODYNAMIC RESPONSES PRODUCED BY MICROINJECTION OF [D-ala²-met⁵]ENKEPHALINAMIDE (DAME) IN ROSTRAL MEDULLA OF SPONTANEOUSLY HYPERTENSIVE RATS (SHR).

L. R. Portis and R. L. Tackett. Department of Pharmacology and Toxicology, Cardiovascular Pharmacodynamics Laboratory, College of Pharmacy, University of Georgia, Athens, GA 30602.

Previous studies have shown that stimulation of opiate receptors in rostral ventrolateral medulla (RVLM) by an enkephalin analogue produces hypotension and bradycardia in normotensive rats. The present study was designed to determine what, if any, hemodynamic changes are produced by microinjection of the enkephalin analogue [D-ala²-met⁵]enkephalinamide (DAME) into RVLM of genetically hypertensive animals. Experiments were performed on pentobarbital anesthetized spontaneously hypertensive (SH) rats instrumented for measuring arterial pressure and heart rate and ventilated artificially. A pulsed doppler flowprobe was placed on the abdominal aorta for measurement of hindlimb blood flow. The RVLM was identified by bilateral microinjection of L-glutamate (300 ng/side). Bilateral injection of DAME (100 ng/side) in RVLM produced a decrease in arterial pressure (-41 ± 9 mmHg). No significant change in heart rate was observed. Hindlimb vascular resistance was decreased 19% from baseline. These data suggest that in SH rats bilateral microinjection of the enkephalin analogue DAME produces a decrease in arterial pressure and hindlimb vascular resistance.

243.3

EVIDENCE THAT STIMULATION OF OXYGEN SENSORS IN VENTRAL MEDULLA INITIATES THE CEREBRAL ISCHEMIC RESPONSE. M.-K. Sun and D.J. Reis. Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

Brief (<5 sec) ischemia of the brainstem elevates arterial pressure (AP) secondary to excitation of sympathoexcitatory reticulo-spinal neurons of the rostral ventrolateral medulla (RVL-SE neurons), and elicits bradycardia and apnea: the cerebral ischemic response (CIR). The adequate stimulus for the CIR is unknown. Here we investigated whether it could be hypoxia. In anesthetized paralyzed rats the activity of RVL-SE neurons was recorded extracellularly. In sino-denervated rats, systemic hypoxia ($pO_2=27.3\pm 1.8$ mmHg) excited RVL-SE neurons (by $122.5\pm 18.4\%$ increase in firing rate from 19.3 ± 3.1 spikes/s, $n=7$). In contrast, hypercarbia ($pCO_2=54$ mmHg, $pH=7.11$) or extracellular iontophoresis of hydrogen ions did not produce a comparable change of RVL-SE neuron activity nor AP. H^+ however attenuated the GABA-mediated baroreceptor inhibition of these neurons. Iontophoresis of cyanide (CN) or sulfide onto RVL-SE neurons elicited a dose-dependent, site specific, rapid (<2 sec), reversible increase in neuronal activity (2-fold increase, $n=29$). Microinjections of cyanide increased AP and reduced phrenic nerve discharge. Adjacent respiratory neurons were inhibited by CN. We conclude that hypoxia, but not acidosis or hypercarbia, may be the main stimulus for the sympathoexcitatory component of the CIR. RVL-SE neurons themselves may be O_2 sensors.

243.5

ARTERIAL BARORECEPTORS AND CNS HISTAMINE CONTRIBUTE TO THE BRADYCARDIA DURING PERIPHERAL HYPEROSMOLALITY. M. J. Kenney and S.L. Bealer. Rhodes College and University of Tennessee, Memphis, TN 38112.

Peripheral hyperosmolality produced by infusion of 2.5M NaCl (10 μ l/100g/min) hypertonic saline (HTS) increases mean arterial pressure (MAP) and reduces heart rate (HR). The current study tested the hypothesis that decreases in HR observed during HTS infusion in conscious rats are dependent on afferent baroreceptor mechanisms and involve central histamine. HTS infusion increased MAP (26 \pm 3 mmHg) and reduced HR (54 \pm 10 mmHg) in rats ($n=5$) with intact arterial baroreceptors whereas in sino-aortic denervated rats ($n=5$), HR remained unchanged despite a similar increase in MAP. After the central (icv) administration of cimetidine (specific H_2 antagonist) in intact rats, HTS infusion increased MAP (20 \pm 3 mmHg), however, the reduction in HR (18 \pm 6 mmHg) was significantly attenuated. In contrast, central cimetidine did not alter the HR responses to peripheral phenylephrine and nitroprusside. These results suggest that the bradycardia accompanying HTS infusion is mediated through the arterial baroreceptor reflex and involves a selective histaminergic pathway.

243.7

UNEQUAL EFFECT OF CHEMORECEPTOR ACTIVATION ON THE CAROTID SINUS BAROREFLEX IN RABBITS. Long Qu and S.L. Stuesse. Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

Carotid sinus baroreceptors influence various components of the carotid sinus baroreflex unequally when carotid sinus pressure (CSP) is increased. We examined the effect of chemoreceptor activation on the unequal control. In rabbits anesthetized with urethane, the aortic depressor nerves and vagus nerves were cut, and isolated carotid sinuses were bilaterally perfused with physiological saline. CSP was increased in steps from 50 to 200 mmHg while heart rate (HR), cardiac contractile force, renal nerve activity (RNA), and hindlimb perfusion pressure (HPP) were recorded. Stimulus-response curves were constructed for control (95% O_2 - 5% CO_2) and 6% CO_2 perfusates, and the slopes of the curves were calculated. In controls, the sum of the gains of the reflex changes is maximal (1.62) when CSP is 90 mmHg. HR and HPP were very sensitive to changes in CSP. In high CO_2 , the total baroreflex activity was attenuated at middle and high CSP levels (> 80 mmHg) as indicated from the sum of the reflex gains (1.3). However, the gains of HR and RNA were increased. This suggests that hypercapnia influences the regulatory mechanism of baroreceptors on cardiovascular components in a nonlinear fashion. Supported by a grant from the American Heart Association.

CENTRAL RESETTING OF THE ARTERIAL BAROREFLEX IN RENAL HYPERTENSIVE RATS. M. Hay, L. E. Hayward, J. A. Smith and R. B. Felder. Cardiovascular Center, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

Previous studies have shown impairment of baroreflex control of arterial pressure (MAP), heart rate (HR), and sympathetic nerve activity in animals with some forms of experimentally induced hypertension. The present study was designed to determine the effect of Grollman hypertension on the central regulation of baroreflex function. MAP and HR responses to aortic depressor nerve (ADN) stimulation were compared in anesthetized, age-matched control and 21 day post figure-8 Grollman hypertensive Sprague Dawley rats. Renal hypertension resulted in a shift in the baroreflex mediated MAP and HR responses upward and to the right. In control rats ($n=4$), resting MAP and HR were 106.2 ± 9 mmHg and 372.3 ± 27 beats/min, respectively. Stimulation of the ADN (8.0 V, 2.0 msec, 1.0 min) at 2, 5, and 25 Hz resulted in a 30, 44 and 82 beat/min. decrease in HR and a 24, 39 and 49% decrease in MAP. Resting MAP and HR in the renal hypertensive rats ($n=3$) were 121.7 ± 6 mmHg and 332 ± 49 beats/min, respectively. The ADN stimulation resulted in an upward parallel shift of the MAP response as well as a significant attenuation of the HR response as compared to the control animals. ADN stimulation at 2, 5, and 25 Hz resulted in only a 3, 10 and 28 beat/min decrease in HR and a 4, 29 and 44% decrease in MAP. These results suggest that the central regulation of baroreflex function is impaired in chronic renal hypertensive rats. (Supported by HL29302)

243.6

THE ROLE OF REFLEX HYPOTENSION IN ACUTE RESETTING OF THE CAROTID BAROREFLEX IN RABBITS. L. Hayward, M. Hay and R.B. Felder. Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Previous work has shown that carotid sinus baroreflex control of arterial pressure is acutely reset by electrical stimulation of the aortic baroreceptors (FASEB J. 5,1033, 1991). The present study examined the role of reflex hypotension associated with this resetting protocol. Reflex changes in mean arterial pressure (MAP) and renal sympathetic nerve activity (RSNA) were recorded during unilateral ramp increases (0-200 mmHg) in carotid sinus pressure (CSP) in anesthetized, vagotomized rabbits with bilaterally isolated carotid sinuses. Acute resetting was induced by 5 minutes of electrical stimulation of both aortic depressor nerves (ADN) cut distal to the stimulating electrodes (25 Hz, 10 V, 0.2 ms). In the same animal, reflex characteristics were compared: 1) before and after acute resetting alone and; 2) before and after acute resetting with resting MAP maintained during ADN stimulation with phenylephrine (PE) infusion (15 μ g/ml over the first 4 min. of ADN stimulation). Resetting protocols were separated by 40-60 minutes. In 4 animals, 1 minute following ADN stimulation alone, the curve relating MAP to CSP was shifted upward and to the right. This shift was characterized by significant increases ($p<0.05$) in the resting MAP (79 ± 7 to 91 ± 8 mmHg; mean \pm SE; control vs reset), mid-range CSP (116 ± 7 to 124 ± 9 mmHg CSP), and minimum MAP (39 ± 6 to 47 ± 10 mmHg); there was also a decrease in the resting RSNA (92 ± 14 to 63 ± 5 imp/sec). All values returned to control in 10 minutes. There were no significant differences between these "reset" reflex characteristics and those induced by ADN stimulation with PE maintained pressure, demonstrating that reflex hypotension does not significantly influence acute resetting of the carotid sinus baroreflex. These findings also provide further support for the concept of a central change in the processing of baroreflex information during acute resetting. (Support: HL29302, HL44546).

PARAVENTRICULAR EFFERENTS INFLUENCE AREA POSTREMA NEURONS. P. Smith* and A.V. Ferguson. Dept. of Physiology, Queen's University, Kingston ONT. Canada K7L 3N6.

The rat area postrema (AP) is a midline circumventricular organ (CVO) situated at the level of the obex on the floor of the fourth ventricle. Previous electrophysiological studies from our laboratory have demonstrated AP neurons to be influenced by changes in blood pressure, circulating peptides such as angiotensin, endothelin, and vasopressin, and parabrachial nucleus stimulation. Anatomical tracing studies have demonstrated that a major afferent input to the AP is provided by the paraventricular nucleus (PVN).

In order to investigate the functional nature of such neural connections sodium pentobarbital anesthetized male Sprague Dawley rats were fitted with femoral arterial and venous catheters and endotracheal tubes. A bipolar stimulating electrode was positioned in PVN using stereotaxic coordinates and fixed into position using dental cement. The AP was exposed by a midline incision dorsal to the medulla and a glass recording electrode (tip diameter <1 μ m, resistance 10 - 30 M Ω) was placed on the surface using a micromanipulator. Extracellular single unit recordings were obtained from AP cells and peristimulus histograms were used to determine the effects of PVN stimulation on these neurons. Of the 13 AP cells tested 38.5% were excited by PVN stimulation while the remainder were unaffected. In animals that had stimulation sites outside of PVN 12.5% of AP cells tested were inhibited by such stimulation while the remaining 87.5% were unaffected.

These data demonstrate that activation of PVN neurons elicit excitatory effects on cells in the AP. They thus further emphasize the potential significance of descending hypothalamic inputs in controlling neuronal activity in this CVO.

RENAL AFFERENT INPUT TO THE VENTROLATERAL MEDULLA OF THE CAT. M.A. Vizzard, A. Standish, and W.S. Ammons. Department of Physiology, Thomas Jefferson University, Philadelphia, PA 19107.

Experiments were performed to determine the effect of renal nerve stimulation on neurons within the rostral ventrolateral medulla. Extracellular action potentials were recorded from 91 cells within the rostral ventrolateral medulla of alpha-chloralose anesthetized cats. Cells were tested for responses to electrical stimulation of both left and right renal nerves. Renal nerve stimulation excited eighty-nine cells (97.8%) and inhibited two (2.2%). Forty cells (43.9%) responded to both left and right renal nerve stimulation. Forty-six cells (50.5%) responded to electrical stimulation of renal nerves on the opposite side and five cells (5.5%) responded to electrical stimulation of renal nerves on the same side. For cells which received bilateral excitatory renal nerve input, a conditioning-test paradigm revealed that a stimulus to renal nerves on one side decreased the response elicited by a stimulus applied to the renal nerves on the opposite side for at least 300 msec. All cells had somatic receptive fields that included the forelimbs, hindlimbs, abdomen and flank. Twenty-four cells with short latency responses to renal nerve stimulation required stimulus intensities greater than the A-delta volley threshold but less than the C-fiber volley threshold of the compound action potential recorded from the least splanchnic nerve. Fourteen cells exhibited both early and late responses to electrical renal nerve stimulation. The threshold of the late response was always greater than the threshold for the C-fiber volley in the compound action potential. Thus it was concluded that C-fibers mediate the late responses to renal nerve stimulation. Twenty-one cells (26.7%) responded to activation of renal mechanoreceptors or chemoreceptors. Occlusion of the renal vein or ureter increased the activity of nine cells from 21.4 ± 7.8 imp/s to 47.6 ± 12.8 imp/s and decreased the activity of eight cells from 14.8 ± 2.6 imp/s to 4.9 ± 1.4 imp/s. Renal artery occlusion increased the activity of twelve cells from 17.8 ± 7.8 imp/s to 40.8 ± 11.6 imp/s. These studies demonstrate that the rostral ventrolateral medulla is a supraspinal site to which information from both kidneys projects and that cells receiving renal input also receive convergent input from somatic structures. Furthermore, the demonstration that mechanical stimulation of renal receptors elicits responses from cells within the rostral ventrolateral medulla suggests a functional significance to this renal afferent input. The existence of a functional afferent connection between the kidneys and the ventrolateral medulla suggests that the rostral ventrolateral medulla may play a role in supraspinal reflexes of renal origin. GLUTAMATE - IMMUNOREACTIVE TERMINALS IN THE NUCLEUS TRACTUS SOLITARIUS: ULTRASTRUCTURAL IMMUNOGOLD STUDY. T.F.C. Batten* and S. Saha*. (SPON: European Neuroscience Association). Cardiovascular Studies and Physiology, The University, Leeds LS2 9JT, U.K.

Glutamate has been implicated as a neurotransmitter at the site of synaptic termination of vagal afferent fibres in the nucleus tractus solitarius (NTS), but little morphological evidence is available to support this hypothesis. Vibratome or cryo-sections of rat and cat brain stem and nodose ganglia, perfused fixed with 2% formaldehyde/ 2% glutaraldehyde, were incubated with anti-glutamate antibodies (Arnel and Incstar), and bound antibody was visualized by a biotin-avidin-peroxidase method for light microscopy (LM). Tissue was also processed for electron microscopy (EM), and ultrathin resin sections were incubated in anti-glutamate, followed by colloidal gold labelled IgG conjugate. Immunoreactive (IR) cell bodies of vagal afferent neurons were found in the nodose ganglion. At EM level the gold particles were at highest density over the smaller ganglion cells. Intense glutamate-IR cells were found in many brain stem nuclei, but not the NTS, which had a moderately dense matrix of fibre varicosities. Under EM, gold particles were associated with terminals forming mainly asymmetrical synapses on NTS neurons, and containing round synaptic vesicles. A combined neuronal tracing and EM immunogold study is underway to confirm the identity of glutamate-IR terminals in the NTS as vagal afferents.

CHRONIC SINO-AORTIC DENERVATION ELIMINATES INCREASES IN VASOPRESSIN AND MEAN ARTERIAL PRESSURE INDUCED BY NUCLEUS TRACTUS SOLITARIUS LESIONS IN RAT. A.M. McDonald and A.F. Svadlow. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

We previously reported (Neurosci. Abst. 98:12, 1990) that the pressor response elicited by bilateral microinjection of the GABA_A agonist muscimol into the nucleus tractus solitarius (NTS) in chloralose-anesthetized, ventilated rats was absent following chronic sino-aortic denervation (SAD). Those results suggested that, upon removal of arterial baroreceptor afferents by SAD, NTS neurons involved in cardiovascular control are no longer tonically activated. To further investigate this phenomenon the present study examined the effects of prior SAD on the typical responses of increased plasma vasopressin (VP) and hypertension that occur following bilateral electrolytic NTS lesion in conscious rats. One week following SAD or sham-denervation, baroreceptor reflexes (phenylephrine-induced bradycardia and nitroprusside-induced tachycardia) were tested in conscious, cannulated rats and were totally absent in SAD rats. One hour following reflex testing a baseline blood sample was collected to assess plasma levels of VP. Rats were then anesthetized with halothane and bilateral electrolytic lesions (1mA, 10sec) were placed in the NTS. Mean arterial pressure (MAP) and heart rate were recorded one hour later while rats were totally conscious. A second blood sample was then collected and completeness of lesion was confirmed by the absence of hypotension in response to bolus i.v. injections of phenylbiguanide (50µg/kg). In sham-denervated rats NTS lesions markedly increased MAP and VP levels ($p < 0.01$), but NTS lesions did not significantly alter MAP or VP levels in SAD rats.

	MAP (mmHg)		VP (pg/ml)	
	Pre	Post	Pre	Post
Control (n=7)	117±3	165±6	9±2	100±27
SAD (n=8)	123±3	108±6	13±5	27±7

These results are consistent with our previous data and lend additional support to the hypothesis that in chronic SAD rats NTS neurons modulating cardiovascular function are no longer tonically activated. Further, these data are inconsistent with the notion that remaining cardiopulmonary baroreceptor afferents are responsible for the restoration of normal average resting MAP in SAD rats.

MYELINATED AND NONMYELINATED VAGAL AFFERENTS PROJECTION TO THE INSULAR CORTEX IN RATS. S.Ito, Dept. Physiol., Kumamoto Univ. Med. Sch., Kumamoto 860, Japan.

I have shown the projection of vagal C-afferent to the rostral insular cortex. Further analysis on A-afferent are presented here. SD rats anesthetized with sodium amobarbital or alpha-chloralose were used. Microelectrodes were placed at the solitary tract nucleus (NTS) and the cortex to record field potentials (FPs) evoked by cervical vagus nerve stimulation. Under chloralose anesthesia, A-afferent activation resulted in surface-recorded positive-negative FPs with the latency around 40ms in the granular insular cortex (GI). Barbitol diminished this response. Irrespective of the anesthetics, A-afferent activation produced FPs with 4-8ms latency at NTS, and stimulation of NTS produced positive-negative FPs in GI with 10-20ms latency. The latency of vagally evoked cortical FPs was longer than a simple sum of those of vagus-NTS response and NTS-GI response. These results indicate that vagal myelinated afferent projects to the cerebral cortex probably by way of thalamic relay nucleus and that this ascending system has certain structure at NTS extremely susceptible to barbitol which is absent from C-afferent projection system. HEMODYNAMIC EFFECTS OF NMDA ± MK-801 INFUSED INTO EITHER THE AREA POSTREMA OR THE NTS IN RATS. D.K. Hartle and B. Tian, Department of Pharmacology and Toxicology, College of Pharmacy, University of Georgia, Athens, GA 30602.

The hemodynamic effects of microinfusing NMDA (10 ng/min x 3 min) into either the area postrema (AP) or unilaterally into the medial nucleus of the solitary tract (NTS) was tested in 8 Pb-anesthetized SD rats. NMDA infusion reduced mean blood pressure (MBP) 28% at area postrema and 31% at NTS. Analysis of regional hemodynamics in renal, mesenteric and iliac vascular beds revealed that while no significant changes in vascular resistance occurred during NMDA infusion into either AP or NTS, blood flow decreased significantly in the renal bed, but not in the mesenteric and iliac beds. MK-801 (1 nmol/50 nl/min) did not alter MBP, HR or regional hemodynamics by itself. This dose of MK-801 effectively blocked all the hemodynamic effects of NMDA at AP/NTS. In separate experiments, this dose and site of administration of MK-801 was shown to also significantly attenuate reflex bradycardia during pressor events elicited by intravenous phenylephrine. Conclusion: MK-801 infused into the AP/NTS of Pb-anesthetized rats produced no blood pressure or heart rate changes alone, but effectively blocked the cardiovascular effects of subsequent NMDA administration at this site. THE HYPOTENSIVE EFFECT OF PURINES IN THE NUCLEUS OF THE SOLITARY TRACT IS ASSOCIATED WITH SELECTIVE GLUTAMATE RELEASE. R. Mosqueda-Garcia, M. Appalsamy* and D. Robertson. Department of Pharmacology, Vanderbilt University, Nashville TN 37232.

We have previously reported that microinjection of purinergic substances into the nucleus of the solitary tract (NTS) evokes excitatory cardiovascular effects. These effects were blocked only by specific adenosine and/or excitatory amino acid receptor antagonists. In the present study we addressed whether perfusion of adenosine in the NTS affects cardiovascular function and the release of glutamate (GLU), glycine (GLY) or taurine (TAU) in the NTS.

New Zealand white rabbits (2.5-3.0 kg) were anesthetized with urethane and cannulated for direct recording of blood pressure (BP) and heart rate (HR). A microdialysis probe (1 mm membrane tip, 240 µm o.d.) was implanted in the right NTS. Artificial cerebrospinal fluid (CSF) was perfused at a rate of 1 µl/min. After implantation of the probe, a stabilization period was followed by perfusion over 60 min with CSF containing either no adenosine or adenosine in concentrations of 10^{-6} or 10^{-3} M. Samples were analyzed for their GLU, GLY and TAU content using a HPLC system. After placement of the microdialysis probe in the NTS, a period of 120 min was allowed for stabilization.

Basal BP, HR and glutamate concentrations during CSF perfusion were 86 ± 3 mmHg, 258 ± 26 bpm, and 16 ± 3 µmol/L, respectively (n=6). Perfusion of 10^{-6} M of ADO through the probe only slightly increased GLU levels by 31%. In contrast, 10^{-3} M adenosine increased GLU levels by 694%, decreased BP by 21 ± 10 mmHg and HR by 15 ± 8 bpm. No significant changes were observed in GLY or TAU levels. These results indicate that local release of glutamate is one mechanism by which purinergic substances in the NTS exert cardiovascular control.

INTRINSIC PROPERTIES OF MEDIAL NTS NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS. S.M. Johnson and R.B. Felder. Cardiovascular Center, Univ. of Iowa Coll. of Med., Iowa City, IA 52242.

Previous work has shown that spontaneously hypertensive (SH) rats have a central abnormality in the baroreflex control of arterial pressure. We tested the hypothesis that the intrinsic properties of neurons in the medial portion of the nucleus tractus solitarius (NTS) might be altered in hypertensive SH rats. An *in vitro* brainstem slice preparation was used to record intracellularly from 15 neurons in 5 month old SH rats and 25 neurons in 3-5 month old, non-hypertensive Fischer 344 (F344) rats. Comparison of SH and F344 medial NTS cells showed that there were no differences in resting membrane potential (-55 ± 4.0 , -58 ± 7.5 mV [mean \pm std.dev.]), action potential amplitude (85 ± 7.5 , 79 ± 7.9 mV), action potential undershoot (7.0 ± 2.1 , 9.8 ± 3.4 mV), and action potential duration ($.93 \pm .25$, $.78 \pm .13$ ms). The input resistance, however, was significantly greater for SH cells than for F344 cells (125 ± 70 , 81 ± 38 M Ω). SH cells with a high input resistance had a nearly flat steady-state current-voltage relationship (-40 to -100 mV). In addition, more action potentials were expressed for the same amount of positive current injection. Spike frequency adaptation did not differ in SH and F344 cells, suggesting that the defect reported in superior cervical ganglion cells is not present at the medial NTS level. SH and F344 NTS cells similarly expressed post-tetanic hyperpolarization ($>90\%$ of the cells), delayed excitation ($\approx 50\%$ of the cells), and post-inhibitory rebound ($<10\%$ of the cells).

We conclude that SH rats have a larger proportion of medial NTS neurons with a high input resistance, which may affect the post-synaptic responsiveness of these neurons to central and peripheral inputs. (Supported by AHA 89-1017, AHA 85-235)

THE CARDIOVASCULAR EFFECTS OF 5-HT IN THE NUCLEUS TRACTUS SOLITARIUS. M.E. Hall*, R.A. Greer* & J.M. Stewart, Dept. of Biochem. & Neuroscience Training Program, University of Colorado School of Medicine, Denver, CO 80262

The role of 5-HT in regulating baroreceptor reflex function in the Nucleus Tractus Solitarius (NTS) is unclear. Previous studies have shown that intra-NTS injections of 5-HT can alter blood pressure and heart rate. However, some studies report a depressor effect while others describe a pressor effect.

We now report that the effects of 5-HT are biphasic and dose-dependent. Following intra-NTS injection, 5-HT has a depressor effect at picomole doses but a pressor effect at nanomole doses. Similar effects are seen when p-chloroamphetamine is injected into the NTS to release 5-HT from endogenous stores. We also observed that, while the pressor effect of 5-HT is often of short duration, there is a prolonged inhibition of responses to subsequent injections of 5-HT.

The pressor and depressor effects of 5-HT appear to be mediated by different receptor subtypes. 5-HT₂ antagonists effectively block the depressor response to picomole amounts of 5-HT, but not the pressor response to nanomole amounts. In contrast, the 5-HT_{1A} agonist buspirone can reproduce the pressor effects of nanomole amounts of 5-HT.

These and other findings indicate that within the NTS, 5-HT may function as an important modulator of baroreceptor reflex function.

Central 5-HT-induced pattern of cardiovascular regulation. R.L. Davison & A.K. Johnson. Dept. of Psychology and Pharmacology, Univ. of Iowa, Iowa City, IA 52242.

Evidence exists to support either a facilitative or inhibitory influence of centrally administered serotonin (5-HT) on sympathetic outflow and cardiovascular functions. Recent results from our laboratory indicate that central 5-HT induces a bradycardia, hypotension, and natriuresis which is dependent on renal nerves. The present study examined the central 5-HT-induced pattern of sympathetic outflow mediating hemodynamic regulation.

We examined the effect of ICV injection of vehicle or 5-HT (20 μ g) on blood pressure, heart rate, and regional vascular resistances in anesthetized Sprague Dawley rats. Central 5-HT produced a brief pressor response and sustained bradycardia. Hindquarter resistance was elevated above baseline, and reached maximum levels by 10 min post-injection. Renal vascular resistance was significantly reduced below baseline by 10 min post-injection. Mesenteric resistance remained unchanged. These results indicate a pattern of sympathetic outflow that is under differential control by central 5-HT mechanisms.

TIME COURSE OF HEMORRHAGE-INDUCED C-FOS EXPRESSION IN BRAIN STEM CARDIOVASCULAR NUCLEI. R.K.W. Chan and P.E. Sawchenko, The Salk Institute, La Jolla, CA 92037.

In situ histochemical localization of c-fos immunoreactivity (IR) and mRNA was carried out in brain stems harvested from rats sacrificed at varying intervals following an hemorrhagic stress, in order to clarify the sequence and extent of functional activation in cell groups targeted by, and presumably involved in adaptive responses to, reduced blood volume. Hemorrhage was carried out in conscious animals by withdrawing 10 ml/kg blood via indwelling jugular catheters at a rate of 0.5 ml/min, and resulted in a transient 50% reduction in mean arterial pressure. A progressive increase in the number of cells displaying nuclear c-fos-IR was seen predominantly in tyrosine hydroxylase (TH)-IR neurons in the caudal nucleus of the solitary tract (NTS), and in the A1 and C1 cell groups of the ventrolateral medulla from 0.5-1.5 hr after hemorrhage. Using concurrent retrograde tracing methods, some fos-expressing C1 and NTS cells were found to project to the spinal cord. Recruitment of cells in the locus coeruleus and the A5 cell group became evident at about 1.5 hr, and in the parabrachial nucleus at 2 hr after hemorrhage. A massive activation of cells in the area postrema occurred at 2 hr after the challenge. Expression of c-fos-IR at all of these loci diminished beginning at about 2.5 hr, and was indistinguishable from control levels at 4 hr after hemorrhage. Analyses of c-fos mRNA in this paradigm revealed a similar pattern of results, which preceded alterations in c-fos-IR. These data emphasize the importance of medullary catecholamine neurons in orchestrating integrated neuroendocrine and autonomic responses to cardiovascular challenge, and are compatible with an hierarchical organization in which aminergic neurons in the caudal NTS and the ventrolateral medulla play important roles.

243.18

DIFFERENTIAL AUTONOMIC AND CARDIOVASCULAR EFFECTS OF SEROTONIN AND A SEROTONIN 5-HT_{1A} RECEPTOR AGONIST. A. Dedeoğlu* and L.A. Fisher. Department of Pharmacology, College of Medicine, University of Arizona Health Sciences Center, Tucson, AZ 85724.

Different subtypes of serotonin (5-HT) receptors within the central nervous system (CNS) mediate varying effects on autonomic outflow, arterial pressure (AP) and heart rate (HR). The present studies compared the mechanisms underlying the cardiovascular effects of 5-HT and the selective 5-HT_{1A} receptor agonist, 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) in conscious rats. Intracerebroventricular (icv) administration of 5-HT (100 nmol) elevated AP (15 mm Hg), plasma epinephrine (E) levels (10-fold), plasma norepinephrine (NE) levels (2-fold), and reduced HR (50 beats/min) at 5 min post-injection. Prior bilateral adrenalectomy (ADX) abolished the AP and plasma E responses but did not modify the HR and plasma NE responses. Prior intravenous (iv) injection of propranolol (PROP) doubled the AP increase without altering the HR response. Prior iv injection of methylatropine (ATR) blunted the HR decrease by 40% but did not alter the AP response. Icv injection of 8-OH-DPAT (100 nmol) did not change AP at 5 min post-injection but elevated plasma E (30-fold) and NE (3-fold) levels and reduced HR (60 beats/min). ADX blocked the E response, did not alter the NE response, unmasked a small decrease in AP (5 mm Hg), and slightly enhanced the HR response (75 beats/min). Iv injection of PROP unmasked a large increase in AP (22 mm Hg) but did not change the HR response. Iv injection of ATR abolished the acute HR response but did not modify the acute AP response. The depressor response (13 mm Hg) to 8-OH-DPAT at 30 min post-injection was not modified by ADX, but was enhanced and attenuated by ATR and PROP, respectively. These results suggest that 5-HT and 8-OH-DPAT stimulate adrenal E release but have differential effects on sympathetic and vagal activity.

EFFECTS OF ANESTHESIA ON BLOOD PRESSURE CHANGES MEDIATED BY KAINIC ACID STIMULATION OF THE FASTIGIAL NUCLEUS. T.J. Parry and J.G. McElligott. Dept. of Pharmacology, Temple Univ. Sch. of Med., Phila., PA 19140

Microdialysis administration of kainic acid (KA) into the rostral fastigial nucleus (RFN) of awake rats produces tonic and phasic increases (pressor response) in mean arterial pressure (MAP) [Parry and McElligott, Soc. Neurosci. Abst. #233.17, 1990]. In contrast, other studies (Chida et al., Brain Res. 370: 378-382, 1986) have shown that local injection of KA into the RFN of α -chloralose anesthetized rats produces a tonic decrease in MAP (depressor response). In order to determine if this difference was due to the method of KA administration (microdialysis vs. injection) or due to anesthesia, we injected KA (5 nmole) into the RFN of either awake (n = 4) or anesthetized (α -chloralose, 55 mg/kg i.p., n=4) rats. Initially, the blood pressure modulatory site within the RFN was localized by electrical stimulation in head restrained awake animals. Probe placement was also confirmed by histological verification following the experiment. Half of the animals were anesthetized and half were kept unanesthetized. After approximately 40 minutes, a vehicle injection into the RFN was made producing no change in MAP in either awake or anesthetized rats. KA was then injected into the same site producing within 2 minutes a tonic depressor response ($\Delta = 23 \pm 2$ mmHg) in anesthetized rats and a tonic pressor response ($\Delta = 36 \pm 2$ mmHg) in awake animals. In awake rats, phasic increases in MAP also appeared within 1 hour of injection which are similar to those in our previous microdialysis studies. Phasic increases also appeared in the α -chloralose treated group only upon recovery from anesthesia. KA treated rats (including those which had recovered from anesthesia) also exhibited severe disturbances in postural tonus seen in previous studies. These results show that injection of KA into the RFN of awake rats produces a pressor response by stimulation of local RFN neurons. The use of α -chloralose anesthesia not only inhibits this increase in MAP but converts it to a depressor response. (Supported by a grant from the American Heart Assoc., Southeastern PA Chapter)

EXCITATORY AMINO ACIDS MAY MEDIATE NUCLEUS TRACTUS SOLITARIUS EXCITATORY INPUT TO RAT PARABRACHIAL NEURONS. J.H. Jhamandas & K.H. Harris, Dept. of Medicine (Neurology) & Div. of Neuroscience, University of Alberta, Edmonton, Alberta, Canada T6G 2B7.

The pontine parabrachial nucleus (PBN) is a recipient of predominantly excitatory input from the nucleus of the solitary tract (NTS). Recently the presence of glutamate-like immunoreactivity in these brainstem nuclei suggests a role for excitatory amino acids (EAAs) in neurotransmission within this projection. We characterized electrophysiologically *in vivo* the NTS-evoked excitation of PBN neurons by blocking the synaptic input with locally applied EAA antagonists. Extracellular recordings in urethane-anesthetized rats were obtained from 64 PBN neurons following electrical stimulation (50-300 μ A, 200 μ sec current pulses at 0.5 Hz) applied through bipolar electrodes implanted in the NTS. Non-selective EAA antagonist kynurenic acid (KYN), the selective N-methyl-D-aspartate (NMDA) antagonist DL-2-amino-5-phosphonovalerate (APV) and non-NMDA blocker 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) were applied by iontophoresis and pressure ejection from multi-barreled micropipette attached to the recording electrode. Post-stimulus histogram data revealed that NTS-evoked excitation could be reversibly blocked by KYN, APV, and CNQX in 15 of 36, 7 of 15 and 6 of 13 cells respectively. These data suggests a role for both NMDA and non-NMDA receptors in mediating the excitatory input from NTS to PBN.

LATERAL PARABRACHIAL AREA (LPB) UNITS WHICH RESPOND TO CARDIOVASCULAR STIMULI DO NOT REACT TO GUSTATORY STIMULI. J.A. Lovell and S.L. Stuesse, Neurobiology Dept., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272

The parabrachial region (PB) receives visceral sensory information from the nucleus tractus solitarius (NTS). Subnuclei within the NTS project to discrete subregions of the PB. In general, the medial PB receives gustatory information while cardiovascular information is believed to terminate more laterally. However, previous studies have indicated electrical stimulation of widespread areas of the PB elicits cardiovascular responses. We tested units in the lateral PB (LPB) for convergence of inputs from these two modalities. Multiple unit activity (MUA) and arterial pressure were monitored in the LPB of anesthetized male Sprague-Dawley rats (200-250 gm) before, during, and after the presentation of the following stimuli: 1) phenylephrine-induced hypertension (0.2 mg, i.v.), 2) nitroprusside-induced hypotension (0.75 mg, i.v.), 3) saline washing of oral cavity (0.5 M), 4) sucrose washing of oral cavity (0.1 M), 5) acid washing of oral cavity (0.01 N HCl), 6) distilled water washing of oral cavity. Units were first tested for their responsiveness to blood pressure changes. LPB units responded in a vigorous excitatory fashion to hypotension; they displayed no change or a decrease in spontaneous activity in response to hypertension. When the blood pressure-responsive units were then tested with the gustatory stimuli, none were found which responded to gustatory stimuli. These results show that the segregation of visceral information in the NTS is maintained in the LPB.

243.22

DORSAL RAPHE NUCLEUS (DRN) NEURONS PROJECT SIMULTANEOUSLY TO THE RAT PARAVENTRICULAR NUCLEUS (PVN) AND THE LATERAL PARABRACHIAL NUCLEUS (LPB). T.Petrov, T.L.Krukoff and J.H.Jhamandas, Depts. of Anatomy & Cell Biol. and Medicine (Neurology), Univ. of Alberta, Edmonton, Alberta T6G 2H7.

The DRN is known to project to LPB and PVN, sites involved in autonomic and neuroendocrine regulation. The chemical anatomy of these pathways is unclear, but serotonin (5-HT) is the most abundant transmitter in DRN perikarya. This retrograde tracer investigation was designed to study the presence of 5-HT DRN neurons, projecting both to the LPB and PVN. Rhodamine and fluorescein labelled latex microspheres were stereotaxically injected in the LPB and the PVN areas, respectively. After 4-5 days, fixed and sectioned tissues were processed for immunocytochemical detection of 5-HT.

Thirty five percent of all the labelled neurons within the DRN contained both tracers indicating the presence of collateral branching to the PVN and LPB. Double labelled cells were predominantly observed close to the aqueductal wall within the caudal portion of the DRN, but were located more ventrally at rostral levels of the nucleus. Less than 5% of the double labelled cells demonstrated 5-HT immunoreactivity.

These data suggest that mainly non-5-HT DRN neurons are capable of influencing simultaneously, through collateral input, the activity of LPB and PVN for the control of autonomic functions.

FOS IMMUNOREACTIVITY IN RAT BRAIN ELICITED BY ELECTRICAL STIMULATION OF THE PARABRACHIAL COMPLEX. K.H. Harris, J.H. Jhamandas, and T.L. Krukoff, Depts. of Medicine (Neurology), and Anatomy & Cell Biology, Univ. of Alberta, Edmonton, Canada T6G 2E1.

To further study the role of the pontine parabrachial complex (PBN) in autonomic regulation, Fos-immunoreactivity (Fos-ir) was examined as a marker of neuronal activity after electrical stimulation of the PBN. In urethane-anesthetized rats, the PBN was unilaterally stimulated (7-25 V, 10 sec pulsed trains, 20 Hz, 100 usec duration) for 1-2 h so that arterial pressure (AP) was elevated 20-35 mm Hg. Controls included rats with (1) stimulation of PBN below threshold for AP changes, (2) placement of electrode but no current passed, or (3) stimulation of non-PBN area (cerebellum) with equal current. In controls, Fos-ir was found in the n. tractus solitarius, ventrolateral medulla, lateral PBN, ventral supraoptic nucleus (SON), and central n. of the amygdala. PBN stimulation also led to induction of Fos-ir in the ipsilateral SON, piriform cortex, and insular cortex. No changes in Fos-ir could be attributed to elevation of AP. Results support a role for PBN modulation of autonomic function in the forebrain and show that increases in Fos-ir observed are due to stimulation-evoked activation of PBN efferents and not to changes in AP.

Supported by the Medical Research Council of Canada.

CARDIOVASCULAR REGULATION: HYPERTENSION AND ENDOTHELINS

244.1

ATROPINE BLOCKADE OF CENTRAL ENDOTHELIN'S PRESSOR EFFECT. T. LaHann and G. Daniell, College of Pharmacy, Idaho State University, Pocatello, ID 83209

Endothelin-1 (ET-1) binding sites exist in brain and ET-1 has been found in CNS neurons. We report here that ET-1 applied to the ventral surface of rat medulla oblongata elicits dose-dependent increases in systemic blood pressure and that this effect can be antagonized by i.v. pretreatment with atropine sulfate, but not by i.v. pretreatment with atropine methyl nitrate. Although ET-1 is a potent vasoconstrictor, the pressor effect of topically applied ET-1 was not duplicated by application of the vasoconstrictor drug clonidine. Bilateral vagotomy not only did not eliminate the pressor effect of ET-1, it seemed to enhance it. Sinoartical denervation reduced ET-1's pressor effect by about half. Our results suggest that 1) ET-1 acts within the central nervous system to increase systemic blood pressure, 2) this action is, at least in part, the result of a direct, specific effect on neurons lying on or near the ventral surface of the medulla oblongata and 3) this pressor action is mediated through a central, atropine-sensitive mechanism.

ENDOTHELIN-1 MICROINJECTED INTO NUCLEUS TRACTUS SOLITARIUS OF RAT BLOCKS ARTERIAL BAROREFLEXES. C.C. Lee, H. Ohta, and W.T. Talman, Dept. of Neurology and CV Center, VAMC and University of Iowa, Iowa City, IA, USA 52242.

Injection of endothelin-3 into the cisterna magna attenuates baroreflexes and increases arterial pressure (AP). We have sought to determine whether endothelin acts at the nucleus tractus solitarius (NTS) to modulate AP, heart rate (HR), and arterial baroreflexes. Endothelin-1 (Et-1) was microinjected bilaterally into NTS of rats anesthetized with chloralose. The baroreflex was assessed by means of a sigmoidal curve fitting analysis applied to reflex changes in HR when AP was increased or decreased by i.v. injection of phenylephrine or nitroprusside respectively. A high dose (10 pmol) of Et-1, but not low doses (1 and 2 pmol), elicited prolonged increases in AP and HR (42.5 \pm 4.2 mmHg and 38.8 \pm 7.1 bpm respectively) and decreases in respiratory rate. There was a dose-related decrease of the slope of the baroreflex curve (slope=-1.5 before and -0.1 after ET-1 after a 10 pmol dose, p<.05). Unilateral microinjection of Et-1 completely blocked decreases in AP and HR elicited by microinjection of N-methyl-D-aspartate (1 pmol), glutamate (250 pmol) or acetylcholine (300 pmol) at the same site. This study suggests that Et-1 abolishes baroreflexes by nonselectively blocking neurotransmission in NTS. Support: VA Merit Review and NIH HL-32205, HL-14388, and NS-24621. CENTRAL REGULATION OF BLOOD PRESSURE INDUCED BY VASOPRESSIN AND ENDOTHELIN IN RATS. N. Ono, M. Kaneko*, S. Etoh* and H. Kamiya*, Dept. of Pharmacol., Fac. of Pharmaceut. Sci., Fukuoka Univ., Fukuoka, 814-01, Japan.

Comparative study on central regulation of blood pressure induced by vasopressin and endothelin (ET-3) found recently the presence in the CNS carried out using urethane-anesthetized rats. Vasopressin (1-10 nmol) and ET-3 (30-60 pmol) administered intracerebroventricularly (i.c.v.) elicited dose-relatedly the pressor and positive chronotropic effects with long duration. These pressor actions of vasopressin and ET-3 were inhibited by the intravenous pretreatment with pentolinium and phentolamine. The pressor action of vasopressin was inhibited by the i.c.v. pretreatment with α -agonists, norepinephrine, phenylephrine, methoxamine and V1-antagonist, but not clonidine, α -blocker, β -blocker and aspirin. On the other hand, ET-3 was inhibited by the i.c.v. pretreatment with aspirin, indomethacin, and propranolol and ICI 118,551, but not metoprolol and naloxone. Also prostaglandin F₂ α , which elicited a pressor action by i.c.v. treatment, produced similar manner to the mode of ET-3 action. These results suggest that these peptides may have a different mechanism in cardiovascular regulation through the activation of sympathetic nervous system, all involving in the CNS. It appears that vasopressin participates in the α -1 subsystem and ET-3 mediates prostaglandin system of the CNS.

EFFECT OF EXCITATORY AMINO ACID (EAA) RECEPTOR BLOCKADE ON CENTRALLY MEDIATED CARDIOVASCULAR RESPONSES OF ENDOTHELIN-1 (ET). M. A. Hashim and A. S. Tadepalli, Division of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

We have previously shown that ET (1-3 pmol) applied to the IV ventricle of anesthetized, ventilated rats decreases mean arterial pressure (MAP) and renal blood flow (RBF). These responses occur in two phases, with immediate *phase I* decreases of short duration (5 min) followed by long-lasting (90 min) *phase II* decreases. ET or glutamate elicited similar depressor responses when microinjected into the same, discrete cardiovascular sites (dorsal strip, commissural subnucleus) within the solitary complex. Microinjections of NMDA or quisqualate at these sites, or application to the IV ventricle, also evoked depressor responses (blocked by aminophosphonovaleric acid (APV) or 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), respectively), while kainate produced a pressor effect (blocked by kynurenic acid). Therefore, in the present study, we examined the role of EAAs in the central ET-induced cardiovascular effects. Prior application of a combination of APV (2-5 μ mol) and CNQX (100-300 nmol) to the IV ventricle significantly attenuated *phase I* decreases in MAP and RBF by ET (3 pmol). Thus, peak *phase I* decreases to ET were (% change, pretreated vs. untreated rats): MAP=-8 \pm 7 vs. -26 \pm 4; RBF=1 \pm 6 vs. -16 \pm 4. Peak *phase II* decreases due to ET (3 pmol) were also reduced, but not significantly: MAP=-22 \pm 6 vs. -34 \pm 4; RBF=-13 \pm 6 vs. -29 \pm 7. Pretreatment with a combination of MK-801 and CNQX produced similar results. These data suggest that the centrally induced hemodynamic responses of ET are mediated, in part, indirectly via release of an endogenous EAA which probably activates NMDA and/or AMPA receptors.

L-N^G-NITRO ARGININE (LNA) PRODUCES AN EXAGGERATED HYPERTENSION IN ANESTHETIZED SPONTANEOUSLY HYPERTENSIVE RATS (SHR). A.K. Johnson, P.J. Lacolley, M.J. Brody and S.J. Lewis, Depts. Psychol. and Pharmacol., & Cardiovasc. Ctr., Univ. Iowa, Iowa City, IA 52242.

In vitro studies suggest that endothelium-dependent vascular relaxation is impaired in various hypertensive rat models including the SHR. The aim of these studies was to examine the effects of i.v. injection of the nitric oxide (NO)-synthesis inhibitor LNA on mean arterial pressure (MAP) and heart rate (HR) of urethane-anesthetized 16 week old Sprague-Dawley (SD), Wistar-Kyoto (WKY) and SHR rats. The resting MAPs (mmHg) were SD (116 \pm 4) > SHR (103 \pm 3) > WKY (92 \pm 3). The resting HRs (bpm) were SD (389 \pm 12) = WKY (354 \pm 8) = SHR (351 \pm 16). There were no differences in the baroreceptor reflex activity (bpm/mmHg) of the SD (-1.8 \pm 0.2), SHR (-1.4 \pm 0.3) and WKY (-2.0 \pm 0.2). The two cumulative i.v. doses of LNA (0.005 mmol/kg) given 30 min apart produced dose-dependent hypertension in the three strains. The LNA-induced hypertension was most marked in the SHR (+89 \pm 8%, post-2nd dose of LNA) whereas the increases in MAP were equal in the two normotensive strains, i.e., SD (+40 \pm 7%) = WKY (+52 \pm 4%). These data suggest that the synthesis/release or biological activity of NO may actually be augmented in the SHR and that this vasodilator may modulate the expression of the hypertension in this strain. (Supported by HL-14388)

CENTRALLY MEDIATED HEMODYNAMIC RESPONSES OF PROENDOTHELIN-1: EVIDENCE FOR THE PRESENCE OF AN ENDOTHELIN-CONVERTING ENZYME IN RAT BRAIN. A. S. Tadepalli and M. A. Hashim, Division of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Previously, we reported that central application of endothelin-1 (ET) produces long-lasting decreases in mean arterial pressure (MAP), renal blood flow (RBF) and heart rate (HR). ET is produced from its precursor, big endothelin-1 or proendothelin-1 (PET) by an endothelin-converting enzyme (ECE). The aim of the present study was to determine the presence of an ECE in rat brain. Application of ET (1-10 pmol) or PET (30-100 pmol) to the IV ventricle of anesthetized, ventilated rats, evoked similar dose-dependent, falls in MAP, RBF and HR lasting 90-120 min. The latency of the responses was longer with PET (3 \pm 0.8 min) than with ET (1 \pm 0.2 min). Compared to ET, approximately 10 times higher doses of PET were required to produce similar effects, and doses of PET lower than 30 pmol were ineffective. Thus, falls in cardiovascular parameters evoked by 10 pmol of ET were: MAP=-48 \pm 4%; RBF=-46 \pm 7%; HR=-19 \pm 3%, while those elicited by 100 pmol of PET were: MAP=-43 \pm 3%; RBF=-37 \pm 10%; and HR=-10 \pm 2%. Application of phosphoramidon (PRD; 90 nmol), a metalloproteinase inhibitor, to the IV ventricle, 15 min prior to PET, inhibited the hemodynamic responses to PET. Thus, after PRD pretreatment, peak falls produced by PET (100 pmol) were: MAP=-9 \pm 2%; RBF=-6 \pm 2%; HR=-6 \pm 1%. PRD pretreatment failed to significantly affect the ET-induced responses from the IV ventricle (MAP=-43 \pm 3%; RBF=-32 \pm 5%; HR=-15 \pm 2%). Intravenous administration of the same low doses of PET or ET did not produce any cardiovascular effects. Saline (vehicle) applied to the IV ventricle was also without effect. These data indicate the presence of a phosphoramidon-sensitive ECE in rat brain and suggest a physiological role for endothelin in the central nervous system.

244.6

L-N^G-NITRO ARGININE (LNA) MARKEDLY REDUCES ARTERIAL PRESSURE LABILITY (APL) IN CONSCIOUS SINOARTIAL BARORECEPTOR DENERVATED (SAD) RATS. R.A. Shaffer*, A.K. Johnson, W.W. Kaelber and S.J. Lewis, Depts. Pharmacol., Psychol. and Anatomy, & Cardiovasc. Ctr., Univ. Iowa, Iowa City, IA 52242

Our laboratory has shown that (1) the marked APL in conscious SAD rats is dependent upon increased sympathetic neurogenic drive to the vasculature and (2) the generation of the vascular endothelium-derived relaxing factor nitric oxide (NO) is also dependent upon sympathetic drive. This study examined whether the generation of vascular NO is involved in the APL in conscious SAD. In these experiments, the effects of the NO-synthesis inhibitor LNA (0.02 mmol/kg, i.v.) and equipressor infusions of the α ₁-adrenoceptor agonist phenylephrine (\approx 4 μ g/kg/min) on the mean arterial pressure (MAP) and APL of conscious SAD rats (n=10) were examined. The injection of LNA increased MAP (pre vs post, 108 \pm 6 vs 162 \pm 7 mmHg, +50 \pm 7%, p<0.05) and decreased APL (pre vs post, 13.4 \pm 1.7 vs 2.4 \pm 0.8 mmHg, -82 \pm 7%, p<0.05). The infusion of phenylephrine produced a hypertension (pre vs post, 104 \pm 3 vs 159 \pm 8, +49 \pm 6%, p<0.05) of equal magnitude to that produced by LNA but in contrast potentiated APL (pre vs post, 12.1 \pm 2.3 vs 19.6 \pm 3.8 mmHg, +62 \pm 17%, p<0.05). These findings strongly suggest that vascular NO is involved in the generation of APL in SAD rats. (Supported by HL-14388)

ARGININE-VASOPRESSIN (AVP) IMMUNOREACTIVITY IN CENTRAL AND PERIPHERAL NEURONAL TISSUES OF DOCA-SALT HYPERTENSIVE RATS. J.S. Simon, S.J. Lewis, B.G. Kasson* and A.K. Johnson, Depts. Pharmacol. & Psychol. & Cardiovasc. Ctr., Univ. Iowa, Iowa City, IA 52242

We have shown previously that AVP is present and may be synthesized within peripheral blood vessels of both rat and cow. However, AVP synthesis and storage within peripheral afferents has not been studied. Since the development of DOCA-salt hypertension (DOCA) is an AVP-dependent process, the aims of this study were to examine whether (1) AVP is stored within vagal afferent perikarya in the nodose ganglion (NG) and (2) DOCA alters AVP levels in pituitary (PIT), hypothalamus, hippocampus, medulla/pons, NG and efferent perikarya of the superior cervical ganglion (SCG). Neural tissues were removed from DOCA and sham rats, homogenized in 1M HCl and centrifuged at 25,000 x g. Supernatants were collected and assayed in radioimmunoassay for AVP using a specific antiserum. Both the NG and SCG contained significant amounts of AVP immunoreactivity (\approx 25 ng/gm tissue) which were unaltered in DOCA rats. AVP levels in the PIT (\approx 20 μ g/g) of DOCA rats were markedly reduced in comparison to levels in sham rats (\approx 135 μ g/g). AVP levels in other brain tissues were unchanged. These studies indicate that peripheral afferent and efferent neuronal tissue contain AVP immunoreactivity and PIT stores of AVP are markedly depleted in DOCA rats. (Supported by HL-44546)

Hypertension and Longevity in Rapp-Dahl Rats: Influence of Repeated Stress and Food Intake. R.J. Servatius, J.E. Ottenweller, S.D. Drastal, M.T. Bergen, and B.H. Natelson. University of Medicine and Dentistry of New Jersey; Neurobehavioral Unit (127A), V.A. Medical Center, E. Orange, NJ, 07019

We have studied the effects of repeated stress on the development, course, and outcome of hypertension in salt-sensitive Rapp-Dahl spontaneously hypertensive rats. In Experiment 1, rats were habituated for 3 weeks to the blood pressure apparatus, matched for blood pressure and body weight, and then randomly assigned to the stress group or to the non-stressed control group. Stress consisted of supine 4-limb restraint (2 hr sessions, 5 days a week, every other week, for 4 weeks). Blood pressure was measured on weeks between stress, then monthly thereafter. Stressed animals exhibited a delayed rise in blood pressure and lived significantly longer than non-stressed controls. The stressed rats lost weight during stress weeks, gained weight during non-stress weeks, but never attained the weight of the nonstressed group. Because reduced food intake with its consequent reduction in salt ingestion might have explained these results, we undertook Experiment 2. All procedures were identical to Experiment 1, except that stressed and non-stressed rats were food-yoked. The development of hypertension and life-span were equivalent in the two groups in this experiment. The results closely resembled those from the stressed rats in Experiment 1. These data do not support the hypothesis that repeated stress exacerbates the hypertensive process and indicate that control of food intake is a critical variable for further research into the effects of stress on blood pressure. BRAINSTEM AND PERIPHERAL ENDOTHELIN RECEPTORS IN THE CAT: A ROLE FOR ENDOTHELIN IN BARORECEPTOR AND CHEMORECEPTOR REFLEXES.

R.M. Sykes*, M.R. Dashwood*, D.S. McQueen*¹, M.de B. Daly* and K.M. Spyer. Dept. of Physiology, Royal Free Hospital School of Medicine, London and Dept. of Pharmacology, University of Edinburgh Medical School*¹, United Kingdom.

Endothelin (ET), a powerful vasoconstrictor peptide, is present within certain regions of the central nervous system. Using autoradiography [¹²⁵I] ET binding sites have been identified in the medulla oblongata involving the nucleus tractus solitarius, dorsal vagal nucleus and rostro-ventrolateral medulla. Dense binding was also observed in the carotid body and at the level of the carotid bifurcation. Injection of ET into the common carotid artery caused a dose-related fall in baroreceptor discharge but had little effect on chemoreceptor activity. Chemoexcitation evoked by acetylcholine or sodium cyanide injected during ventilation with 11% O₂ was markedly potentiated following ET. These changes together with its localised CNS binding suggest that ET has a potent influence on reflex control of circulation and respiration.

ACUTE AUTONOMIC RESPONSES IN A HYPERTENSIVE RAT STROKE MODEL. K.S. Butcher, V.C. Machinski and D.F. Cechetto, Roberts Research Institute, University of Western Ontario, London, Ontario, Canada N6A 5K8.

Acute increases in sympathetic activity, and frequency of myocardial damage, occur following middle cerebral artery occlusion (MCAO) in Wistar rats (Cechetto, et. al., 1989). Hypertension is a major risk factor for stroke. The autonomic responses to MCAO in the spontaneously hypertensive (SHR) and Wistar-Kyoto (WKY) rats were therefore investigated. Arterial pressure (AP), heart rate (HR), renal sympathetic nerve discharge (SND), and ECG were measured in 16 SHR and 16 WKY male rats, which were subjected to either MCAO or sham MCAO. Infarct size did not differ between SHR and WKY rats, as shown by tetrazolium staining. Initial AP and SND were significantly ($p \leq 0.05$) higher in SHR (96.2 ± 4.4 mmHg; 18.3 ± 4.1 μ v-s) than in WKY (70.9 ± 1.3 mmHg; 9.1 ± 1.3 μ v-s). No significant differences in initial HR were observed between SHR and WKY. By 6 hours after MCAO, AP and SND in SHR significantly decreased (69.4 ± 9.9 mmHg; 8.0 ± 2.3 μ v-s), while HR showed a significant increase (352.8 ± 11.1 bpm). The decrease in AP and SND may be associated with damage to the insular cortex. AP, SND and HR in the WKY were not significantly affected by MCAO. These responses contrast with previous findings in Wistar rats. Differences may arise from the relative amounts of baseline sympathetic activity in the three strains.

CARDIOVASCULAR REGULATION: SPINAL MECHANISMS

245.1

SYNAPSES ON AXONS OF SYMPATHETIC PREGANGLIONIC NEURONS IN RAT AND RABBIT SPINAL CORD. I.J. Llewellyn-Smith, P.M. Pilowsky, J.B. Minson* and J.P. Chalmers*. Centre for Neuroscience and Department of Medicine, Flinders University, Bedford Park, SA 5042 Australia.

In searching for a retrograde tracer that would allow us to visualize distal dendrites of sympathetic preganglionic neurons (SPN), we have managed to reveal their axons and have examined them for the presence of synapses. Cholera toxin B subunit (CTB) was injected into the superior cervical ganglion of rats and rabbits, into the stellate ganglion of rabbits or into the adrenal medulla of rats. After perfusion with fixatives suitable for both light and electron microscopy, CTB-immunoreactivity was found in the axons of sympathetic preganglionic neurons as well as in their cell bodies and dendrites. At the light microscope level, most SPN axons ran through the ventral horn near its lateral border with the white matter, although some ran more medially. A small proportion of axons were branched. At the ultrastructural level, synapses were found on the proximal parts of the SPN axons and in one case on an axonal branch immediately after it diverged from the main axon. These axoaxonic synapses are likely to be an important part of the neuronal circuitry that regulates the activity of SPN. This work was supported by grants from the National Health and Medical Research Council of Australia and the National Heart Foundation of Australia.

245.2

NEURONS IN CERVICAL SPINAL CORD PROJECT TO THE INTERMEDIOLATERAL CELL COLUMN (IML) IN THE RAT. M.A. Haxhiu and C.J. Helke*. Case Western Reserve Univ., Cleveland, OH and Uniformed Services University, Bethesda, MD 20814.

Neurons in the dorsolateral funiculus (DLF) of cervical spinal cord can affect sympathetic outflow (Schramm and Livingstone, 1987). To provide direct anatomic evidence for this effect, we evaluated cervical cord for the retrograde transport of rhodamine-labeled microspheres (50-60 nl) or 4% Fluoro-Gold from the T₃ IML. Control injections were made into surrounding areas. Five to 10 days later the rats were perfused fixed and cryostat-cut sections (20 μ m) of cervical and thoracic spinal cords were prepared. The site and spread of IML injections were determined. Following restricted IML injections, retrogradely-labeled cells were found in the nuclei of the DLF (Giesler and Elde, 1985) of C₂-C₃ both ipsilateral [7 ± 3 (mean \pm SD) cells/section] and contralateral [3 ± 2 cells/section] to the IML injection. The cells were oval, triangular or spindle-shaped. Numerous tracer-labeled cells were also found in laminae IV, V, and VII, whereas only a few labeled cells were observed in laminae X. In addition, retrogradely-labeled neurons were found in the ventral horn of upper thoracic segments. This study provides anatomic evidence for intraspinal projections to the IML from neurons in the cervical DLF, and from regions of the cervical gray and thoracic ventral horn. (USUHS grant R075A2; NIH grants NS24876 and HL38701).

EFFECT OF RENAL NERVES ON RENAL AND CARDIOVASCULAR FUNCTION IN CHRONIC SPINAL RATS. K.A. Trostel* and J.W. Osborn. Dept. of Vet Biol., U. of MN, St. Paul, MN 55108.

Previous studies have demonstrated that renal nerve activity has acute effects on renal function in rats with cervical spinal cord transection (CST). The present study addressed the question: **Do renal nerves have chronic effects on renal and cardiovascular function in CST rats?** Three groups of conscious Sprague-Dawley rats were studied: renal denervated + CST (RDNX+CST), sham-RDNX + CST (SHAM+CST), and sham-RDNX + sham-CST (INTACT). CST or sham-CST surgeries were performed 8 days after RDNX or sham-RDNX. Sodium and water intake were fixed by i.v. infusion. Mean arterial pressure (MAP) and plasma renin activity (PRA) were measured before and for 9 days after CST/sham-CST. In addition, urine flow, urinary sodium excretion, and urine pH were measured in the two groups of CST rats. One day after CST, MAP had fallen 25 mm Hg in both RDNX+CST and SHAM+CST groups. PRA was lower in RDNX rats compared with sham-RDNX rats before CST/sham-CST (1.2 ± 0.3 vs 2.1 ± 0.2 ng Al/ml*hr). One day after CST, PRA had fallen to 0.7 ± 0.1 ng Al/ml*hr and was not different between CST groups. MAP and PRA remained depressed throughout the study. There was no difference between SHAM+CST and RDNX+CST rats in any of the renal or cardiovascular variables measured after CST. In summary, we found no evidence for a chronic effect of renal nerves on renal or cardiovascular function in CST rats. NIH grant HL 39619

Renal and adrenal sympathetic preganglionic neurons in rabbit spinal cord and presumed premotor neurons in brain: tracing with Herpes Simplex Virus. Y.-W. Li, Z.-Q. Ding*, S. L. Wessling* and W. W. Blessing. Centre for Neuroscience, Flinders University of S.A., Bedford Park, SA 5042.

We studied the location of renal and adrenal sympathetic preganglionic neurons in the spinal cord, and premotor neurons in the brain, using Herpes Simplex Virus type 1 (HSV1) as a transneuronal retrograde tracer. NZW rabbits (n = 28) were anesthetized and a clinical isolate of HSV1 was injected into the left renal nerve or the left adrenal gland, or Dil was injected into the adrenal gland and HSV1 into the renal nerve, or both tracers were injected into the adrenal gland. After 3 - 8 days rabbits were anesthetized, the spinal cord and brain perfused and sectioned, and HSV1 was localized using the immunofluorescence or the avidin-biotin-peroxidase procedure. Five days after renal injection, virus labeled neurons were observed in spinal segments T7 - L2, with 95% in the ipsilateral intermediolateral column (IML). Three days after adrenal injection, virus labeled neurons were seen ipsilaterally in segments T4 - T12, with 91% in the IML. In rabbits with renal injection of virus and adrenal injection of Dil, surviving 4 - 7 days after viral injection, 5 - 12% of Dil labeled neurons were HSV1-positive. In rabbits with both Dil and HSV1 injection into the adrenal gland, 50% of Dil labeled neurons were HSV1-positive. In rabbits surviving 7 days after renal injection and 5 days after adrenal injection, virus labeled neurons appeared in restricted brain regions, including the rostral ventrolateral medulla, parapyramidal area, A5 area and paraventricular nucleus. In the rostral ventrolateral medulla a proportion of labeled neurons (61% after adrenal and 40% after renal injection) contained tyrosine hydroxylase, identifying them as C1 catecholamine neurons. Results suggest that most renal and adrenal sympathetic preganglionic neurons belong to separate neuronal populations. The presumed premotor neurons in the brain were located in similar regions after injection of virus into either the adrenal gland or the renal nerve.

245.7

CARDIAC RESPONSES TO INJECTIONS OF ADRENERGIC RECEPTOR AGONISTS INTO THE INTERMEDIOLATERAL COLUMN (IML) OF THE SPINAL CORD IN THE RAT.

Y. Malhotra, A. Kachroo, A.J. Krieger & H.N. Sapru, Section of Neurosurgery & Pharmacology, UMDNJ-New Jersey Medical School, Newark, NJ 07103.

In pentobarbital-anesthetized, artificially ventilated Wistar rats, injections (20 nl) of L-glutamate (1.77 nmole) into the right IML at T1-T3 increased (30%) heart rate (HR). Different doses (0.001-0.1 pmoles (pm) in 20 nl) of agonists [phenylephrine (alpha-1), dobutamine (beta-1), clonidine (alpha-2) & terbutaline (beta-2)] and antagonists [prazosin (alpha-1), metoprolol (beta-1), idazoxan (alpha-2) & butoxamine (beta-2)] were injected into the IML. The following changes in HR were observed: activation of alpha-1 and beta-1 receptors increased (10-20%) HR, alpha-2 decreased (15-20%) it and beta-2 produced no change. The response to each agonist was blocked by its specific antagonist. Microinjections (20 nl) of Epi in lower doses (0.001-0.8 pm) increased (10-20%) while higher doses (2000-3200 pm) decreased (5-10%) HR. Excitatory actions of Epi were blocked by injections of prazosin & metoprolol (0.1 pm/20 nl each) while the inhibitory action was blocked by idazoxan. These results suggest that in the IML at T1-T3 the receptors mediating the actions of Epi are: (1) alpha-1 and beta-1 for excitatory action and (2) alpha-2 receptors for inhibitory action.

Support: NIH (HL24347) and Am. Heart Assoc. (NJ).

SOURCES OF SYMPATHETIC PREGANGLIONIC CONTROL OF RENAL, SPLENIC AND MESENTERIC NERVES IN RATS. R. B. Taylor*, M.M. Robinson and L.C. Weaver. John P. Roberts Research Inst. and Dept. of Physiol., Univ. of Western Ontario, London, Canada.

The locations of sympathetic preganglionic neurons (SPNs) controlling renal, splenic, and mesenteric nerves were studied in anesthetized rats. SPNs were excited by injecting D,L-homocysteic acid (DLH, 3 nM, 0.16 M) into the thoracolumbar gray matter (T4-L4) while recording sympathetic firing. Responses of the three nerves could be elicited from overlapping spinal segments extending from T4 to T13, demonstrating no discrete topography of SPNs controlling these organs. Increases in renal nerve discharge were greatest after ipsilateral injections into T8-T12 (12 rats); the largest change (+58±10%) occurred at T10. Increases in splenic (8 rats) and mesenteric (12 rats) nerve discharge were produced from either side of the cord uniformly in segments T4-T12 and T4-L3, respectively. Their largest increases of 20±5% (T5, splenic) and 33±13% (T13, mesenteric) were smaller than those of renal nerves. The larger renal nerve responses demonstrate that sympathetic output can be differentiated at the level of the spinal cord. Further experiments were done to determine if tonic afferent input to the cord contributed to the excitation of renal nerves. In 6 rats, dorsal root rhizotomy from T7-L2 caused no significant change in renal nerve firing (+4±12%) and did not alter responses to DLH injections. In contrast, in 10 acute spinal rats, this rhizotomy decreased firing by 29±10%. No predominant contribution of rootlets from any segment or side of the cord was detected. This suggests that afferent excitation of renal nerves may become important after loss of bulbospinal drive. (Support: MRC Canada)

CNS NEURONS INFECTED BY RENAL INJECTION OF PSEUDORABIES VIRUS. L.P. Schramm, A.M. Strack, K.B. Platt*, and A.D. Loewy. The Johns Hopkins School of Medicine, Baltimore, MD 21205, The Washington University School of Medicine, St. Louis, MO 63110, and Iowa State University, Ames, IA 50011.

The purpose of these experiments was to delineate the CNS neurons regulating renal circulation and function. Others have located the renal postganglionic neurons (RPN) using conventional retrograde tracers. However, these tracers did not cross synapses and, therefore, did not demonstrate the synaptic antecedents of the RPN. Studies indicate that pseudorabies virus (PRV) is transported centrally across synapses (Br. Res. 491:274, 1989; J. Neurosci. 10:2139, 1990). Under anesthesia, we injected kidneys of Sprague-Dawley rats with PRV. Rats were sacrificed 48 to 96 hours later. Brains, spinal cords, and most sympathetic ganglia were removed, sectioned, and reacted immunohistochemically for the presence of virus. Rats exhibited a wide range of severity of CNS infection. In lightly infected rats, most infected spinal neurons were in the intermediolateral column between T7 and T13, and their morphology suggested that they were sympathetic preganglionic neurons (SPN). Infected neurons were also observed in the rostral ventrolateral medulla (RVLM), A5 cell group, and the paraventricular nucleus of the hypothalamus (PVN). However, none were detected in rostral thoracic or cervical spinal cord. Rats in which the infection involved more medial, thoracic, interneurons exhibited infected neurons in the dorsolateral funiculus of the rostral cervical spinal cord. We conclude that several brain stem regions, including the RVLM, A5 group and PVN, may affect renal function via direct projections to SPN. Cervical spinal neurons also may be involved in regulating renal circulation or tubular function. Their effects, however, are mediated via spinal interneurons rather than by direct synapses on SPN. Supported by NIH grants HL16315 and HL25449.

DIFFERENTIAL RELATIONSHIPS AMONG DISCHARGES OF POSTGANGLIONIC SYMPATHETIC NERVES. S. Zhong, M.J. Kenney, S.M. Barman, and G.L. Gebber. Dept. of Pharmacol. & Toxicol., Mich. State Univ., E. Lansing, MI 48824.

The relationships among the simultaneously recorded discharges of as many as four postganglionic sympathetic nerves were studied with coherence and phase spectral analyses in baroreceptor-denervated cats. Activity was recorded from the inferior cardiac (CN), vertebral (VN), and renal (RN) nerves. Most of the power in sympathetic nerve discharge (SND) was below 6 Hz, and the discharges of any two nerves cohered at frequencies between 0 and 15 Hz. Our most significant findings are as follows: 1) Coherence values were significantly higher in chloralose-anesthetized than in unanesthetized-decerebrate cats. 2) Coherence values were higher for near ipsilateral nerves (e.g., CN and VN) than for widely-separated ipsilateral nerves (e.g., CN and RN). 3) Coherence values for most pairs were higher when the nerves were located on the same side (ipsilateral nerves) rather than opposite sides (contralateral nerves) of the body. 4) Coherence values were higher for some functionally complementary nerves (e.g., CN and RN) than for noncomplementary nerves (e.g., VN and RN). Functionally complementary nerves are those whose discharges change in the same direction (increase or decrease) during affective behaviors, whereas the discharges of noncomplementary nerves usually change in opposite directions. 5) As revealed by phase spectral analysis, the interval between the discharges of two nerves was constant within the coherent frequency band at a time when the interval was frequency-dependent for other nerve pairs. These results indicate that both the anatomy of spinal sympathetic outflow and the functional diversity of postganglionic nerves are reflected in the coupling of central circuits responsible for SND. (Supported by NIH grants HL-13187 and HL-33266.)

245.9

CARDIOVASCULAR EFFECTS OF SEROTONIN_{1C/2} (5-HT_{1C/2}) AGONISTS IN THE THORACIC SPINAL CORD OF THE RAT. E.T. Phillips and C.J. Helke. Dept. of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

Recent receptor autoradiographic studies demonstrated the discrete and preferential localization of 5-HT_{1C/2} binding sites to the intermediolateral cell column of the thoracic spinal cord (Thor et al., this meeting). To determine the mean arterial pressure (MAP) and heart rate (HR) effects of the activation of 5-HT_{1C/2} receptors in spinal cord, the 5-HT_{1C/2} agonists dimethoxyiodophenyl-aminopropane (DOI) and α methyl serotonin (α M-5HT) were intrathecally (i.t.) administered to anesthetized, artificially-respired rats. DOI (1-100 μ g) caused initial decreases followed by increases in MAP and HR whereas α M-5HT (1-30 μ g) only decreased MAP and HR. Studies with i.t. administration of ¹²⁵I-DOI, and studies with peripheral administration of a 5-HT₂ antagonist (LY53857) prior to i.t. DOI, showed that the pressor effects of i.t. DOI were due to peripheral leakage and that the depressor effects were due to a spinal cord site of action. The depressor effects of DOI were prevented by peripheral administration of phentolamine. Pretreatment with i.t. administration of 5-HT₂ antagonists (LY53857 and ketanserin) was inconsistent in blocking the depressor effects of i.t. administration of DOI or α M-5HT. These data suggest that activation of spinal 5-HT_{1C/2} receptors decreases MAP by reducing sympathetic outflow to the vasculature. Whether the receptor activated is an atypical 5-HT₂ site or a 5-HT_{1C} site remains to be determined. [Supported by NIH grant NS24876]

PHYSIOLOGICAL AND ANATOMICAL EVIDENCE FOR A MONOSYNAPTIC PATHWAY BETWEEN A CARDIOVASCULAR REGULATORY SITE IN THE ANTERIOR CINGULATE CORTEX AND THE THORACIC SPINAL CORD IN THE RAT S.J. Bacon and A.D. Smith Department of Pharmacology, South Parks Road, Oxford OX1 3QT UK

In 42 anaesthetised rats, blood pressure was recorded from the femoral artery and a double-barrelled glass micropipette positioned stereotaxically in the cingulate cortex. One barrel contained a solution to stimulate neurons (0.1 M glutamate or 25 mM KCl), and the other contained the anterogradely transported tracer *Phaseolus vulgaris* leucoagglutinin (PHAL). Extracellular injections of 100-150 nl of stimulant were made by pressure until a change in blood pressure was recorded. PHAL was then injected iontophoretically at the same site. Immunohistochemistry was used to reveal the PHAL containing cells, and light and electron microscopy (LM and EM) used to study their targets. In all 42 rats injections of stimulant elicited a depressor response. Blood pressure fell by 15.0 \pm 8.3 mm Hg (mean \pm SD) from a resting value of 92.4 \pm 14.6. Injections of artificial cerebrospinal fluid or saline had no effect. PHAL injection sites consisted of a few hundred labelled somata and their associated dendrites and axons. The vast majority of somata were confined to the Cg3 region of the anterior cingulate cortex. LM showed PHAL labelled axons and varicosities in the cervical and thoracic spinal cord. 10 varicosities from the central autonomic region of the thoracic spinal cord were serially sectioned and examined in the EM. All varicosities formed asymmetric synaptic specialisations with small dendritic profiles or spine-like processes. These results demonstrate the existence of a monosynaptic pathway between cells from a region of the anterior cingulate cortex shown to be involved in cardiovascular regulation and regions of the spinal cord with known autonomic function.

LABELLED BULBOSPINAL NEURONS FROM NEONATAL RAT IN CULTURE. P.G. Wagner and M.S. Dekin. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506-0225.

Intrinsic membrane properties of bulbospinal neurons from the dorsal respiratory group have been well characterized using an *in vitro* brainstem slice preparation (Dekin et al., *J. Neurophysiol.*, 58: 195, 1987). These studies, however, were limited to macroscopic current measurements. Analysis of single channel properties would allow a more quantitative description of these currents and provide direct observation of how putative neurotransmitters/modulators affect channel kinetics. Although the whole-cell patch clamp technique has been applied to the slice, the quality of the patch seals is often not sufficient for resolution of single channel currents. We have, therefore, combined the technique of primary cell culture which allows direct visualization and access to the cell surface with the use of fluorescent retrograde tracers. Tracers were used to circumvent the loss of functional/anatomical identity usually associated with cell culture. Discrete pressure-injections of rhodamine filled latex beads (Lumofluor, Inc.) were made in the ventrolateral regions of cervical spinal cord (C4-C6) in 3-4 day old rats. After 24 hrs, brainstems were removed and transverse slices just caudal to the obex extending 1 mm rostral were made. The slices were subdivided into dorsal and ventral portions and cultured separately. Cells extended both dendrites and axons. Labeled neurons were observed in both ventral and dorsal cultures. The numbers of labeled neurons in both cultures were relatively low. This is consistent with reports on the numbers of respiratory bulbospinal neurons (Berger et al., *J. Comp. Neurol.*, 224:60, 1984). Neurons had resting membrane potentials in the range of -70 to -55 mV and conducted action potentials in the whole-cell current clamp mode. Calcium channels were observed in both cell-attached and inside-out patches in which 110 mM BaCl₂ (pipette) was used as the charge carrier. (Supported by NIH Grants HL40369, HL02314 and RR07114).

245.10

RESPONSES OF RAT LOWER THORACIC AND LUMBAR SYMPATHETIC PREGANGLIONIC NEURONES TO IONTOPHORESED MET-ENKEPHALIN. M.P. Gilbey and S.Y. Zhou* Department of Physiology, Royal Free Hospital School of Medicine, London NW3 2PF, England.

Recent studies have shown enkephalin immunoreactive neuronal projections from the medulla to the intermediolateral cell column (Sasek C.A. and Helke, C.J., *J. Comp. Neurol.*, 287: 484, 1989). Furthermore, endogenous opioid systems appear to decrease the cardiovascular response to stress (Morris, M. et al., *Psychoneuroendocrinology* 15:185, 1990). Consequently, in this investigation the responses of lower thoracic and upper lumbar sympathetic preganglionic neurones (SPNs) to iontophoresed met-enkephalin were examined.

Twenty eight SPNs were studied in chloralose anaesthetized rats. Twenty one SPNs had their activity decreased by met-enkephalin, 2 had their activity increased and the remainder were unaffected. Naloxone given either intravenously or iontophoretically was observed to antagonize the decrease in sympathetic preganglionic neuronal discharge (n=2).

These results indicate that endogenous opioids may act directly on SPNs to modulate cardiovascular responses to stress.

246.2

IN VIVO AND IN VITRO RESPONSES OF VENTROLATERAL MEDULLARY NEURONS TO HYPOXIA. P.C. Nolan* and T.G. Waldrop. Dept. of Physiology & Biophysics, College of Medicine, Univ. of Illinois, Urbana, IL 61801.

Previous studies from this laboratory have shown that ventrolateral medullary (VLM) neurons modulate the respiratory response to hypoxia and that hypoxia increases the discharge rate of VLM neurons. The purposes of the present study were to determine if hypoxia can stimulate VLM neurons in the absence of peripheral chemoreceptors and if the stimulation is dependent upon synaptic input from other brain areas. In a first set of experiments, the extracellular responses to hypoxia of VLM neurons were examined in anesthetized rats after transection of peripheral chemoreceptor and baroreceptor afferents. Inhalation of a hypoxic gas (10% O₂/90% N₂) elicited increases in the discharge frequency of 67% of the neurons studied in these peripherally-chemodenervated rats. Most of these neurons had a basal discharge related to the cardiac and/or respiratory cycle. Additional experiments were performed *in vitro* with 400 μ m brain slices containing the medulla from 3-6 week old rats. The slices were maintained in an interface chamber perfused with nutrient media and bubbled with 95% O₂/5% CO₂. VLM neurons increased their discharge frequency during perfusion of the chamber with anoxic (5% CO₂/95% N₂) and hypoxic (10% O₂/5% CO₂/85% N₂) gas; cells increased their discharge in a dose-related manner. These results suggest that neurons in an area of the medulla known to be involved in cardiorespiratory regulation are excited by hypoxic stimulation (Supported by NIH 38726; American Heart Association).

246.3

PHRENIC AND SYMPATHETIC NERVE RESPONSES TO INTRAMEDULLARY NaCN MICROINJECTION IN CAT J. Mitra, N.B. Dev*, J.R. Romaniuk*, R. Trivedi* and N.S. Cherniack. Case Western Reserve University, Dept. of Medicine, Cleveland, Ohio 44106.

We showed that intravertebral artery injection of either sodium cyanide (NaCN) or hypoxic saline solution in normoxic cats depresses breathing and stimulates sympathetic nerve activity. To investigate the site(s) of action of NaCN in the brainstem, we microinjected NaCN (100nl of 100 µg/ml sol.) into the ventral medulla 1-12mm caudal to foramen caecum (FC) and 2-5mm lateral, to a depth of 1mm from the surface, in anesthetized, paralyzed and ventilated cats and recorded from phrenic and cervical sympathetic nerves. Following observations were made: (a) phrenic excitation ($8.0 \pm 2.0\%$) without changing sympathetic activity at 1-4mm caudal (Area1). (b) Phrenic depression ($37.5 \pm 9.4\%$) and simultaneous excitation of sympathetic ($26.0 \pm 9.2\%$) at 5-8mm caudal (Area2) ($P < 0.05$). (c) Variable effect on sympathetic nerve response without significant change in phrenic amplitude at 9-12mm caudal (Area3). NaCN did not alter breathing frequency at any injection site.

Our results suggest that both respiratory excitation and depression can be elicited by NaCN. However, significant respiratory depression along with sympathetic excitation obtained only from Area2. We conclude that the neural substrates underlying Area2 may be involved in intravertebral NaCN responses.

SIMULATION OF RESPIRATORY NEURAL NETWORKS. U. J. Balis*, K. F. Morris, J. Koleski* and B. G. Lindsey. Dept. Physiol. & Biophysics, Univ. South Florida Med. Ctr., Tampa, FL 33612.

We tested whether synaptic relationships among respiratory neurons of the ventrolateral medulla inferred from spike train cross-correlation (J. Neurophysiol. 57:1101; 61:1185) were sufficient to generate discharge patterns similar to those of bulbospinal I neurons. Neurons with accommodation, but no "bursting" properties, were simulated with SYSTM11 (MacGregor, Academic Press, 1987). Five populations were connected using a symbolic network editor running under X Windows. Terminals from each population were randomly distributed on each specified target population. Firing patterns were similar to those previously described for I/EI, I-AUG, I-DEC, E-AUG, and E-DEC neurons. For example, I/EI neurons became active during the second half of the E-phase as E-DEC inhibition declined; some E-AUG neurons discharged transiently prior to their ramp activity coincident with the onset of E-DEC neuron firing. Inhibition of E-DEC and I-DEC neurons decreased the duration of their respective phases and increased respiratory rate; reduced I-DEC activity also increased the slope of the inspiratory ramp. "Apneustic" patterns were generated by varying the balance of tonic excitatory and inhibitory inputs to the network. Inhibition of some E-AUG neurons by other E-AUG cells increased respiratory rate. The results: (a) show that our network schemes are sufficient to generate normal and abnormal respiratory phase durations and discharge patterns similar to those observed in anesthetized vagotomized adult *in vivo* preparations, (b) predict consequences of modulating specific synapses, and (c) provide a foundation for addressing the scaling of network parameters and roles of various membrane conductances. Supported by NS19814.

MICROINJECTION OF MORPHINE INTO THE MEDIAL PONTINE RETICULAR FORMATION (MPRF) CAUSES INCREASED NUMBER OF APNEIC EPISODES. J. Keifer*, H.A. Baghdoyan, R. Lydic (Spon: J.F. Biebuyck) Dept. of Anesthesia, The Penn State University, College of Medicine, Hershey, Pa 17033

Morphine, a potent analgesic and respiratory depressant, decreases rapid eye movement (REM) sleep. The mPRF is a cholinergic area which is involved in REM sleep generation and is believed to mediate sleep-dependent changes in ventilation (*Neurosci. Lett.* 102:211, 1989). Since several lines of evidence point to an interaction between cholinergic systems and narcotic receptors, we are testing the hypothesis that the mPRF is a site which mediates morphine's effect on states of consciousness and ventilation. To date we have injected normal saline (0.25µl) and morphine sulphate (15.2µg/0.25µl) into the mPRF in 4 intact cats chronically instrumented for measuring sleep and ventilation (saline control = 12 trials, morphine = 8 trials). The mean (\pm SD) number of apneic episodes in a two hour period following microinjection was significantly greater ($p < .05$) after morphine (9.3 ± 5.9) than after saline (3.8 ± 2.4). These preliminary results suggest that the mPRF, a cholinergic region containing no known clusters of respiratory neurons, can mediate some of the respiratory effects of morphine.

246.4

EFFECTS OF SMALL VOLUME INJECTION OF GABA AGONISTS AND ANTAGONISTS ON MEDULLARY RESPIRATORY NEURONAL DISCHARGE DURING OPOSSUM DEVELOPMENT. J. P. Farber and S. R. Barker*. Dept. Physiol.; Univ. Okla. HSC; OKC, OK; 73190

Changes in breathing pattern between immature and adult animals could be due in part to changing post-synaptic sensitivity to particular neurotransmitters and/or to the fate of these neurotransmitters after release. We examined inhibition of extracellularly recorded action potentials from medullary respiratory neurons after localized pressure injection of GABA (~25 pl) using multibarrel pipettes in Inactin-anesthetized adult and suckling opossums down to about 20 days of age (1.8 g). Injection volumes were estimated by droplet diameter of injections both before and after the pipette was inserted into the medulla. GABA concentrations were 0.5 and 10 mM (balance NaCl; total conc. = 150 mM; pH=7.4). Effects were assessed as the interval between time of injection and resumption of action potentials. Results showed longer intervals of inhibition (approx. 3 fold on average) with the higher concentration of GABA. Using the higher concentration of GABA, where the results would be less influenced by breathing pattern because of the relatively longer duration of inhibition, average time of inhibition was 9.8 ± 0.7 sec SE (n=33) among adult animals. For animals approx. 60 days of age to weaning, 40-60 days, and 20-30 days, the times of inhibition were, 6.4 ± 0.4 (n=36), 5.1 ± 0.4 (n=38), and 7.4 ± 0.80 (n=8) sec, respectively. Similarly, the GABA_A receptor antagonist, bicuculline (2 mM; 25 pl), increased the discharge of some respiratory units at all ages. Some aspects of GABAergic systems appear to be functional in young opossums; clearance of exogenous GABA is effective despite incomplete glia proliferation in the young animal. (Supported by HL-37318 and Presbyterian Health Foundation).

ALTERATION OF BREATHING BY NON-NMDA RECEPTOR BLOCKADE IN PRE-BÖTZINGER REGION OF ADULT CATS AND RATS. C.A. Connelly, J.D. Hernandez*, E.G. Finlon, M.R. Otto-Smith*, & J.L. Feldman. Systems Neurobiology Lab., Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1527.

The pre-Bötzinger complex (pre-BötC), a region of the ventral respiratory group (VRG) located immediately caudal to expiratory Bötzingers (BötC) neurons, is hypothesized to contain neurons responsible for the rhythmic drive underlying breathing in mammals (Feldman et al., *Eur J. Neurosci. Suppl.* 3: 171, '90). The discharge patterns and distribution of cell types found in the pre-BötC were examined in adult rats and cats. Results in both spontaneously breathing (vagi intact) rats and anesthetized, paralyzed, artificially ventilated cats and rats indicate a heterogeneous mixture of inspiratory (I), expiratory (E) and phase-spanning respiratory neurons. Pre-I neurons (discharge in late E and continue into mid to late I) in the pre-BötC of the adult rat were excited by iontophoresis of L-glutamate and DL-homocysteic acid. To determine if blockade of non-NMDA receptors in pre-BötC alters breathing, CNQX (1 mM in saline, 20-100 pmoles) was microinjected in subregions of the pre-BötC; decreased breathing frequency was observed in both species following unilateral microinjections. Control injections of CNQX in adjacent respiratory regions, including VRG, BötC, and subregions of the pre-BötC did not alter respiratory frequency or amplitude. CHOLINERGIC RETICULAR MECHANISMS PRODUCE STATE-DEPENDENT DECREASES IN PARABRACHIAL RESPIRATORY NEURON DISCHARGE. K.A. Gilbert and R. Lydic. Department of Anesthesia, Pennsylvania State University, College of Medicine, Hershey, PA 17033.

Pontine respiratory group (PRG) discharge decreases during sleep, but the mechanisms which cause these state-dependent changes in firing rate are poorly understood. Since microinjection of carbachol into the medial pontine reticular formation (mPRF) of intact, unanesthetized cats produces a rapid eye movement (REM) sleep-like state (DCarb) and respiratory depression (*Neurosci. Letts.* 102:211, 1989), the current study is using the DCarb model to test the hypothesis that cholinergic reticular mechanisms can also cause state-dependent decreases in PRG neuron discharge. These studies recently reported that parabrachial REM-on and REM-off cells recorded during REM sleep had similar state-related discharge during DCarb (Gilbert & Lydic, *Neurosci. Letts.* 120:241, 1990). PRG neurons have now been recorded in the cat and these cells decrease discharge during DCarb similar to decreases observed during REM. Average discharge during DCarb compared to waking (W) revealed a 42% decrease in inspiration (I) and a 76% decrease in expiration (E). This carbachol-induced decrease was blocked by mPRF pretreatment with the muscarinic antagonist pirenzepine. During the REM sleep-like state produced by mPRF microinjection of neostigmine, PRG neuron discharge also decreased during E (-26.7%). These results demonstrate that cholinergic reticular mechanisms can causally mediate state-dependent decreases in PRG neuron discharge.

MEDIUM FREQUENCY OSCILLATIONS (MFO) OF PHRENIC UNIT DISCHARGES IN THE COURSE OF INSPIRATION (I). W.-X. Huang*, S. Lahiri*, W.R. Seg., R. Barnhardt* and M.I. Cohen, Univ. of Penna. School of Med., Phila., PA 19104 and Albert Einstein Col. of Med., Bronx, NY 10461.

In 11 pentobarbital-anesthetized, paralyzed and vagotomized cats, we studied the activities of single phrenic fibers using spectral analysis. Of 34 units recorded, 20 were early-I (onset delay ≤ 80 ms) and 14 were late-I. Out of a total of 43 pairs of phrenic fibers, 12 pairs were early-I. The autospectra of unit discharges, based on activity in the whole inspiratory phase, always showed a prominent frequency peak between 10 and 50 Hz (MFO), followed by several harmonic peaks, indicating the rhythmicity of the discharge. For all units, the frequency of the main peak was lower during the first half of I than during the second half (19.7 ± 1.2 Hz vs 32.0 ± 1.9 Hz). This is a characteristic of MFO rhythms (Christakos et al., FASEB J. 2: A510, 1988). A statistically significant coherence between activities of members of a pair near their autospectral MFO frequencies was found for 16/43 pairs (range of coherence values 0.04 to 0.35). This incidence was predominantly due to the activity of early-I pairs in the first half of I; 12/12 pairs showed such coherences in the first half whereas only 2 had a significant MFO coherence during the second half. This contrasts with previously reported results (Christakos et al., *ibid.*) that unit-(whole phrenic) MFO coherences were rare and weak in unanesthetized decerebrate cats. (Supported by NIH Grants NS-21068 and HL-27300.)

POST-INHIBITORY EFFECTS OF LUNG INFLATION (LI) ON EXPIRATORY PHASE (E) IN DOGS. T.E. Dick, J.R. Romaniuk*, M.R. Bachoo*, N.S. Cherniack, G. Supinski*, A. DiMarco*, MetroHealth Med. Ctr., Case West. Res. Univ., Cleve., OH.

We have previously shown that LI during E inhibits chest wall expiratory muscle EMG, inhibits cervical sympathetic activity (CS) and prolongs E. Release of LI is followed by a return of expiratory EMG prior to the next inspiration. In anesthetized, spontaneously breathing dogs (n=11), we further characterized the return of expiratory activity (EA) by varying the duration and magnitude of LI. We also studied the effects of electrical vagal stimulation on EA in vagotomized, artificially ventilated dogs with open chest. We recorded triangularis sterni (TS) EMG and phrenic (Phr) and CS nerve activity as activities modulated by the central pattern generator for respiration (CPG). The duration of EA after release of LI was inversely proportional to the duration of LI and to the train duration of vagal stimulation and unrelated to blood gas tensions. Increasing amplitude of LI decreased TS activity during LI and increased the duration of EA after release of LI. Release of LI caused excitation of CS which correlated with the degree of decrease in Phr and T_E prolongation of the next breath. These results suggest that LI applied during expiration resets the CPG rather than promoting the expiratory phase. Supported by PHS 25830 and HL34143.

246.13

SDH ACTIVITY OF FIBER SUBTYPES ACROSS RESPIRATORY MUSCLES. J.F. Watchko*, W.Z. Zhan, Y.H. Fang*, M.J. Daood*, B.S. Brozanski*, R.D. Guthrie* and G.C. Sieck, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213, and Mayo Clinic, Rochester, MN 55905.

Fibers classified histochemically as type IIB in the rat diaphragm (DIA) express primarily a 2X myosin heavy chain (MHC) isoform, whereas IIB fibers in the external oblique (EO) muscle express a 2B MHC isoform. To indirectly compare the oxidative capacity of different respiratory muscle fiber subtypes, we quantified SDH activity of histochemically classified fibers in the DIA and EO muscles in adult rats using a microdensitometric procedure. SDH activity was expressed as mmol fumarate/l/min.

	Type I	Type IIA	Type IIB
DIA % fibers	35 \pm 2	24 \pm 8	41 \pm 8
SDH	5.95 \pm 1.25	6.72 \pm 1.31	4.82 \pm 1.32
EO % fibers	16 \pm 2	14 \pm 3	70 \pm 2
SDH	3.67 \pm 0.63	3.94 \pm 0.53	1.58 \pm 0.49

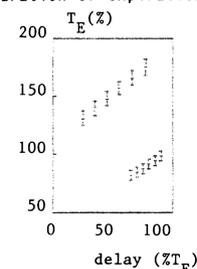

SDH activity was lower in all EO fiber types compared to the DIA. The SDH activity of IIB fibers in the EO was disproportionately lower than IIB fibers in the DIA. We conclude that the oxidative capacity of a specific fiber type can vary markedly between respiratory muscles and that this reflects differences in activation history between the DIA and EO muscles. We also conclude that the SDH activity of fibers expressing MHC 2X is intermediate to those expressing MHC 2B and MHC 2A isoforms.

SHORTENING OF THE EXPIRATORY PHASE BY LUNG INFLATION (LI) IN DOGS. J.R. Romaniuk*, T.E. Dick, E. Bruce*, G. Supinski*, A.F. DiMarco*, MetroHealth Medical Center, Case Western Reserve University, Cleveland, OH.

It has been reported that LI during the last 30% of expiration (E) does not change the duration of expiration (T_E). However, we noted that expiratory motor activity could be terminated by LI (50% of V_T , 1 sec. duration) when applied in late E. In the present study, we reassessed the effect of pulse LI applied in E on T_E . We recorded airway pressure (P) and EMG activities of triangularis sterni (TS) and parasternal intercostal muscles in spontaneously breathing, anesthetized dogs (n = 11). T_E was correlated with the delay (normalized as percent of E, 100% control) at which pulse LI was applied in expiration (See Fig. 1). When LI is applied late in E, vagal input can randomly either prolong or shorten T_E according to two separate linear functions. This bifurcation of the response of T_E to LI suggest the existence of long-lasting central after-effects of LI, becoming evident during repeated stimulation. Supported by HL34143.

DYNAMICAL ANALYSIS OF NONLINEAR RESPIRATORY SYSTEMS BY RECURRENCE PLOTS AND ENTROPY CALCULATIONS. Charles L. Webber, Jr. and Joseph P. Zbilut*, Department of Physiology, Loyola University of Chicago, Maywood, IL 60153 and Departments of OR/Surgical Nursing and Physiology, Rush Medical College, Chicago, IL 60612.

Recurrence plots are becoming an important graphical tool for the analysis of nonlinear dynamical systems. Careful examination of contour maps reveals subtle time (or spacial) correlation information as distinguished from stochastic behaviors (noise) and system transients (drifts). Deterministic structures appear as linear segments in a field of rarified or clustered points. To quantify the amount of determinism present, recurrent linear segments are distributed into length histograms. From these binned segments, Shannon entropy values (information content) are computed as complexity measures. To obtain a composite profile of any dynamic ranging from local to global scales, recurrence plot calculations are repeated for step increases in a normalized cutoff parameter. For low cutoff values (local dynamic), entropy values differentiate between aperiodic random and aperiodic deterministic time series. Applying this analysis to respiratory data from spontaneously breathing, unanesthetized rats shows deterministic (rule-obeying), non-random structuring of the local dynamic both in terms of breathing periods and pressure amplitudes. As experience is gained in their interpretation, it is envisaged that recurrence plots will accrue respect for utility in analyzing nonlinear dynamical systems.

MATURATION OF THE VAGAL NERVE IN FETAL LAMB. S.U. Hasan, H.B. Sarnat*, R. Auer and A. Rigaux*, University of Calgary, Departments of Paediatrics and Pathology, Reproductive Medicine Research Group, Calgary, Alberta, CANADA T2N 4N1.

Lung distension and oxygenation induce arousal and continuous fetal breathing movements (FBM) in sheep. These breathing and behavioral responses are critically dependent on intact vagal nerves and fetal maturity; almost always occurring after 136 days of gestation (term = 147 days). The objective of this study was to delineate the vagal myelination and axonal maturation at various gestational ages, ranging from 79 to 147 days (n=18). Also, comparison was made with neonatal (n=3) and adult (n=6) vagal nerves. Methods included transmission electron microscopy and computer-assisted analyses of ratios of small, medium sized and large myelinated nerve fibres and axonal diameters in semi-thin plastic embedded sections, stained with toluidine blue. Scattered myelinated fibres are already evident by 92 days gestation. Unmyelinated fibres and lightly myelinated fibres show numerous microtubules in their axoplasm, but more heavily myelinated nerves have relatively fewer microtubules and more neurofilaments. The axoplasm in even the youngest animals examined showed mature neurofilaments with short perpendicular branches; elongated mitochondria with well formed cristae also were observed. Degenerative and abnormal proliferative changes were not observed at any age. During the phase of myelination, chromatin of Schwann cells becomes finely dispersed, while completely myelinated fibres are enclosed by Schwann cells. There is a progressive increase in the number of myelinated nerve fibres in the last third of gestation and adult level of vagal maturation is achieved by 138 days of gestation. We speculate that the lack of fetal breathing and behavioral responses prior to 136 days might be due to vagal immaturity.

247.1

ENRICHMENT OF GLUTAMATE-LIKE IMMUNOREACTIVITY IN CERVICOTHALAMIC AND ROUND LARGE TYPE TERMINALS IN THE VENTRAL POSTEROLATERAL NUCLEUS OF THE CAT THALAMUS. J. Broman and O.P. Ottersen. Dept. Cell Biol., Fac. Health Sci., Univ. Linköping, Sweden (JB) and Dept. Anatomy, Inst. Basic Med. Sci., Univ. Oslo, Norway (OPO).

The distribution of glutamate-like immunoreactivity (Glu-LI) in the ventral posterolateral nucleus (VPL) was quantitatively evaluated with the electron microscopic immunogold technique. Cervicothalamic tract (CTT) terminals were identified through the presence of peroxidase activity following injections of WGA-HRP into the lateral cervical nucleus (LCN). Three sections from each of 3 cats were analyzed.

Figure 1 shows the results expressed in percent of the mean gold particle density for all structures analyzed in each of the sections. Enrichment of Glu-LI was evident in RS (round small) terminals of probable cortical origin and also in CTT terminals and RL (round large) terminals, the latter probably originating from the dorsal column nuclei and/or the LCN.

The present findings suggest that glutamate is a neurotransmitter in ascending somatosensory afferents to the VPL.

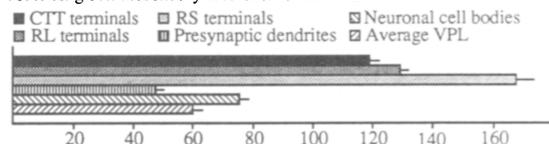

Fig. 1. Normalized mean values of gold particle density (%)

POST-SYNAPTIC EFFECTS FROM THE DORSAL COLUMN NUCLEI IN THALAMIC VL NEURONS. R. Mackel and E. Miyashita*. The Rockefeller University, New York, NY 10021.

To reinvestigate of whether dorsal column (DC) information may reach motor cortex via the ventrolateral (VL) nucleus of the thalamus, we recorded intracellularly from VL neurons while stimulating the DC nuclei. Experiments were performed in cats anesthetized with chloralose. Recordings were obtained with glass micropipettes filled with 2 M K-acetate saturated with fast green. VL neurons were identified by their direct input from the cerebellum and, if possible, antidromic activation from motor cortex. Recording sites were marked by dye injection, stimulation sites by electrolytic lesions.

80/105 (76%) neurons (20 fully identified as projection neurons), located throughout VL, including the border area with VPL, responded with excitation or inhibition to DC stimulation. One EPSP occurred at a latency of 2 ms, did not display temporal facilitation and may have been monosynaptic. The remaining EPSPs had latencies of 3-20 ms (median 10 ms) and showed temporal facilitation, consistent with polysynaptic transmission. Increasing the stimulus intensity did not shorten the EPSPs, mitigating the possibility of restricting stimulation sites. Results show that DC input can reach motor cortex polysynaptically via VL. However, no evidence was obtained for a direct, short latency route via VL to motor cortex.

Supported by NS 26288.

EFFECTS OF NEONATAL INFRAORBITAL NERVE DAMAGE UPON THE MORPHOLOGY AND RESPONSE PROPERTIES OF CELLS IN VENTRAL POSTEROMEDIAL NUCLEUS OF THE RAT. N.L. Chiaia, W.H. Bauer, S. Zhang* and T.D. King*. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Infraorbital nerve (ION) damage in neonatal rodents alters the somatotopic organization of the ventral posteromedial thalamic nucleus (VPM). This investigation utilized intracellular recording and HRP injection techniques to assay the effects of such lesions upon the morphology and response properties of individual VPM neurons. In normal adult rats (N=148 cells), 82% of VPM cells respond only to vibrissa deflection and the average number of vibrissae in a receptive field is 1.4. Only 3% of the VPM neurons recorded in normal rats are unresponsive. In nerve damaged rats (N=409 cells), only 23% of the neurons responded to vibrissa deflection and the average receptive field 'size' was 2.0 vibrissae; 21% of the vibrissa-sensitive cells also had other tactile inputs. Thirty five percent of the VPM cells in the nerve damaged rats were unresponsive. VPM cells recovered from normal rats (N=34) had an average total dendritic length of 4,476 μm and an average cross-sectional area of 34,764 μm^2 . The average values for the 30 VPM cells recovered from nerve damaged rats were 4,799 μm and 48,011 μm^2 , respectively. There were no significant correlations between receptive field size or type and measures of dendritic morphology for the recovered neurons. These data thus indicate that neonatal ION lesions render many VPM cells unresponsive to peripheral stimulation and increase the receptive field sizes of many other neurons. Both of these functional changes are associated with an increase in the extent, but a reduction in the density, of the dendritic arbors of these cells. DE 07734, DE 08971

AN ULTRASTRUCTURAL ANALYSIS OF CALCITONIN GENE-RELATED PEPTIDE IMMUNOREACTIVE (CGRP-IR) SYNAPTIC CONTACTS IN THE THALAMUS OF THE RAT. A.M. Williamson and H.J. Ralston, III. Dept. of Anatomy, UCSF, San Francisco, CA 94143. USA.

Several recent studies have shown a large CGRP-ir projection from the medial and ventral lateral parabrachial nuclei to the ventroposterior nucleus (Vpcc) of the thalamus and to the cortex in the rat. The function of CGRP in this system is not known, but may be linked to somatic or visceral central pathways including those mediating nociception.

We used standard immunohistochemical and electron microscopic techniques to examine the nature of the CGRP-ir synaptic contacts in Vpcc.

Our initial analysis of 300 synaptic contacts in Vpcc (3 rats) showed both symmetric and asymmetric types in roughly equal numbers. We saw only 4 contacts on cell bodies. We did not observe synaptic contacts onto presynaptic elements, or onto CGRP-ir dendritic elements. CGRP-ir fibers were primarily small and unmyelinated, but several myelinated fibers were also seen. The postsynaptic element varied in size sufficiently to conclude that CGRP-ir input occurs on all calibers of dendrites.

We suggest that the dual forms of synaptic contacts, symmetric and asymmetric, made by CGRP-ir axons may represent different types of synaptic function.

DIFFERENTIAL SYNAPTIC ORGANIZATION OF THE TRIGEMINAL PRINCIPALIS AND INTERPOLARIS PROJECTIONS TO THALAMIC BARRELOIDS. M.N. Williams, D.S. Zahm, & M.F. Jacquin. Anatomy & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Most thalamic VPM cells in rodents have single vibrissa receptive fields (RFs) that establish similar RFs in layer IV of barrel cortex. However, it is not clear how VPM RFs are synthesized. Multiple lines of evidence indicate that extensive inputs from trigeminal nucleus principalis (PrV), where single whisker RFs are prevalent, play a major role. A less robust projection to VPM arises from subnucleus interparialis (SpVi), yet these multi-whisker inputs are only expressed after PrV lesions. To account for the differential effectiveness of these 2 parallel pathways in activating VPM cells, Rhoades et al. (*J. Neurophysiol.* 57, '87) hypothesized that SpVi fibers end on more distal portions of VPM dendrites than those from PrV. As a first step in testing this hypothesis in adult rats, HRP transport to VPM from left (L) SpVi and right (R) PrV in the same cases was processed for TMB reaction product and electron microscopy. Analysis of all labeled terminals in matching L and R barreloids (N=2), as well as the majority of labeled terminals in all of the L and R VPM (N=3), indicated that PrV terminals contacted VPM dendrites with a mean (\pm SD) diameter of $1.51 \pm 10 \mu\text{m}$. SpVi contacts were on VPM dendrites with a mean diameter of $1.27 \pm 07 \mu\text{m}$. This difference was statistically reliable ($F=11.6$, $df=1,4$, $p<.05$). PrV endings were also more likely to contact VPM somata ($11.0 \pm 4.2\%$) than those from SpVi ($3.0 \pm 1.0\%$, $p<.05$). Insofar as primary dendrites are thicker than distal dendrites in VPM (e.g. Harris, *JCN* 251, '86), these data suggest a differential distribution of V inputs onto VPM cells that may account for the different roles of PrV and SpVi in VPM RF synthesis. FRactal Dimensions of Neurons Located in the Cat's Thalamic Ventrobasal Complex (VB) and Its Ventral Periphery (VB_{vp}). K.-D. Kniffki(1), D. Chialvo(2), C. Vahle-Hinz(1) and A.V. Apkarian(2). (1)Physiologisches Institut, Universität Würzburg, D-8700 Würzburg, Germany; (2)Depts. of Neurosurg. and Pharmacol., SUNY Health Science Center, Syracuse, N.Y. 13210, U.S.A.

The complex dendritic branching pattern of neurons is thought to result from local environmental as well as from genetic influences. Which mechanisms underlie the formation of these branching patterns during development is an unresolved question. Recently, the shapes of retinal neurons were found to have a fractal dimension of $D=1.68 \pm 0.15$ (Caserta et al., *Physical Rev. Lett.* 64: 95-98, 1991). The authors proposed an explanation of certain stages of neuronal shape development in terms of a diffusion-limited-aggregation model which predicts $D=1.70 \pm 0.10$.

In the present study we examined the fractal dimension of Golgi-stained neurons located in VB and VB_{vp} using 2-dimensional drawings. Two different protocols were employed to determine D. Hausdorff (D_h) dimensions were determined by the box-counting protocol. For a new protocol (D_s) a Sholl analysis (Sholl, *J. Anat.* 87: 387-406, 1953) with a grid of concentric circles was used. D_s was determined by the slope of the log-log plots of the cumulative number of intersections of the dendrites with the grid versus the radius of the circles. Corrections were made for differences in the thickness of the dendrites.

In general, D_s (range 1.39-1.81) was larger than D_h (range 1.27-1.49). There seems to be a tendency, however, for both D_s and D_h to be larger for neurons within the core of both nuclei as compared to those located near the ventral border of the VB_{vp}. The fractal dimension might be a useful parameter to characterize the morphology of neurons.

MAPS WITHIN THE CAT'S SOMATOSENSORY THALAMUS.

J.W. Crabtree. Department of Human Anatomy, University of Oxford, U.K.

The rabbit's visual thalamus contains precise maps of the visual field both within the main thalamic relay nucleus and the thalamic reticular nucleus (TRN). In the present study of the cat's somatosensory thalamus, injections of HRP and/or [3H]proline were made into somatosensory cortical areas S1 and S2. The cortical representation of the chorda tympani nerve (CT) was also injected. The resultant anterograde labelling in the thalamus was analyzed. The thalamus was also processed for immunoreactivity to monoclonal antibody Cat-301.

The cat's main thalamic somatosensory relay, the ventrobasal complex (VB), is immunoreactive to Cat-301. Three major reactive regions are distinct, which laterally to medially appear to correspond to the electrophysiologically defined hindlimb, forelimb, and head representations, respectively. The patterns of labelling within VB following tracer injections into focal regions of S1 confirm this correspondence. The somatosensory sector of the TRN is also immunoreactive to Cat-301, revealing distinct regions of strong and weak reactivity that correspond to the sector's outer and inner aspects, respectively.

Single injections of a tracer into S1 result in single zones of terminal label within the TRN. Each zone lies within the plane of the nucleus, occupies only a fraction of its thickness, and is broadly distributed in the dorsoventral and oblique rostrocaudal dimensions. Injections into the three major body representations of S1 (hindlimb, forelimb, and head, respectively) progressively produce labelling in lateral to medial zones within the region of the TRN that is strongly Cat-301 reactive. Injections of S2 produce labelling that overlaps that resulting from S1 injections. Injections of CT (cortical taste representation) produce labelling that lies adjacent to and inside the zone of the head representation, demarcating the innermost aspect of the strong Cat-301 reactive region.

The present results indicate that there is a precise map within the somatosensory sector of the cat's TRN, the spatial organization of which mimics the map within VB. Precise maps within the TRN provide evidence for a specific functional role for the nucleus. (Supported by the MRC, Grant No. G8720770N)

PRIMARY PROJECTION TARGETS OF THERMORECEPTIVE LAMINA I TRIGEMINOTHALAMIC AND SPINOTHALAMIC CELLS IN THE CAT. J.O. Dostrovsky and A.D. Craig. Dept. of Physiology, Univ. of Toronto, Toronto, Canada M5S-1A8 and Div. of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Preceding anatomical (PHA-L) studies indicated that lamina I trigeminothalamic (TrT) and spinothalamic (STT) cells terminate in n. submedialis (Sm), the dorsomedial aspect of the ventral posterior medial n. (dmVPM), the ventral aspect of the basal part of the ventral medial n. (vVMb), and other sites. We are using antidromic activation from a roving array of 8 electrodes to identify the projections of single thermoreceptive-specific (cold sensitive) lamina I TrT and STT cells. We have previously demonstrated that all "cold" lamina I cells that project to Sm also project to vVMb and dmVPM. In the present experiments, the array was initially positioned to select for lamina I cells that projected to dmVPM rather than Sm. Antidromic maps with 0.25 mm vertical and 0.5-1.0 mm horizontal resolution were made for 9 lamina I TrT and 7 lamina I STT (L7) "cold" cells recorded with tungsten microelectrodes in 16 barbiturate-anesthetized cats. The preliminary histological analyses indicate that 6 of the 16 cells did not project to Sm, although all projected to vVMb. Thus, dmVPM and vVMb, but not Sm, appear to be the primary projection targets for thermoreceptive lamina I TrT and STT cells. These data support the possibility that dmVPM, where Landgren ('60) first identified cold-specific activity, may be an important thalamic site for thermoreception. (supported by NIH grants to J.O. Dostrovsky and A.D. Craig)

ANALYSIS OF DENDRITES FROM INTRACELLULARLY FILLED THALAMO-CORTICAL PROJECTION (TCP) NEURONS IN THE SOMATOSENSORY THALAMUS OF THE PRIMATE. L.A. Havton and P.T. Ohara. Dept of Anatomy, UCSF, San Francisco, CA 94143. USA.

Quantitative analysis of physiologically characterized, intracellularly filled TCP neurons in the primate somatosensory thalamus reveals the neurons to form a homogenous population with a stereotyped morphology. In order to determine whether individual dendrites of the labelled neurons also have a stereotyped morphology we have examined the dendrites from all labelled neurons as a single group.

98 dendrites from 13 neurons were fully reconstructed and quantitatively analysed at the light microscopic level. Dendrites range in total surface area from 1418 μm^2 to 6848 μm^2 with a mean of 2393 μm^2 (S.D. 1372).

There is a positive correlation between primary dendritic size and total dendrite size. The mean segment length increases with increasing segment order for preterminal segments, whereas the mean segment length of end segments decreases with increasing segment order. Analysis of dendritic branching reveals a consistent pattern of fairly asymmetrical distribution of dendritic end segments at branch points. (PSAD=0.60, S.D. 0.19).

There is considerable variation in the morphology of individual dendrites indicating that the more stereotyped structure of individual TCP neurons results from a combination of dendrites with different features.

247.8

THE ROLE OF THE RETICULAR THALAMIC NUCLEUS IN THE PROCESSING OF SOMATOSENSORY INFORMATION IN THE VENTROPOSTERIOR LATERAL THALAMIC NUCLEUS OF THE CAT. R.A. Warren and E.G. Jones. Dept. of Anatomy and Neurobiol., University of California, Irvine, CA 92717.

In the cat ventroposterior lateral thalamic nucleus (VPL), GABAergic inhibition originates both from local acting interneurons and from the GABAergic projections from the reticular thalamic nucleus (RTN). We used an inactivating paradigm in order to evaluate the contribution of the RTN to the inhibition observed in the VPL. Pressure ejected cobaltous chloride was used to inactivate the somatosensory part of RTN while recording single VPL neurons responding to mechanical stimulation of their receptive field.

Fourteen VPL neurons from 6 cats were studied. The neuronal activity of certain neurons was enhanced during and/or just after the ejection of the cobalt solution in RTN. In a few cases the inactivation of RTN appeared to produce a transient inhibition of neuronal activity while in the remaining cases no change in neuronal activity could be detected.

While the excitation is consistent with the hypothesis that the cell under study is under the direct influence of RTN inhibition, the inhibitory effects resulting from the inactivation also suggest an indirect projection via inhibitory interneurons. These two hypothesis are currently under investigation. Supported by NIH grant NS22317 and FRSQ of Canada.

247.10

ANALYSIS OF INTRACELLULARLY FILLED THALAMO-CORTICAL PROJECTION (TCP) NEURONS IN THE SOMATOSENSORY THALAMUS OF THE PRIMATE. P.T. Ohara and L.A. Havton. Dept of Anatomy, UCSF, San Francisco, CA 94143. USA.

Standard techniques were used to record receptive fields and label TCP neurons in sodium pentobarbital anaesthetized primates using glass micropipettes containing 4% HRP or 2% Neurobiotin. The animals were perfused with aldehyde fixatives and 50 μm coronal sections through the thalamus were cut, processed and mounted for light microscopy. The filled cells were located in VPM or VPL and responded to the normal range of non-nociceptive stimuli.

Somata and all dendrites of 13 cells were fully reconstructed using a light microscope with camera lucida attachment. The reconstructed neurons have between 7 and 10 dendrites (mean=7.5; SD=1.2) and range in total surface area from 33,000 μm^2 to 73,600 μm^2 . Most dendritic branching occurs in close proximity to the soma resulting in short preterminal segments while terminal segments are long, comprising 88.5% (SD=2.2) of the total dendritic length. Analysis reveals that dendritic nodes are unevenly distributed in the perisomatic space and the majority of neurons have a different but preferred orientation of dendrites.

Analysis of all the measured parameters suggests that non-nociceptive somatosensory TCP neurons form a homogeneous population and have a stereotyped morphology.

THE ORGANIZATION OF CHOLINERGIC PROJECTIONS FROM THE NUCLEUS BASALIS OF MEYNERT TO SENSORY-MOTOR CORTICES. **K. A. Baskerville*, P. Herron, and H. T. Chang.** Dept. of Anatomy and Neurobiology, The Univ. of Tennessee, Memphis, Col. of Medicine, Memphis, TN 38163

The purpose of this study was to determine in rats 1) the topography of cholinergic neurons in nucleus basalis of Meynert (NBM) of the basal forebrain that project to the somatosensory and motor cortices, and 2) the percentage of retrogradely-labeled neurons that are cholinergic.

Double-labeling experiments were done using fluorescent retrograde tracers and choline acetyltransferase (ChAT) immunocytochemistry. Tracers were injected in electrophysiologically-identified sites of sensory-motor cortices. Following survival periods of 24 to 48 hrs, animals were perfused with 4% paraformaldehyde in phosphate buffer, the brains were sectioned, and the tissue reacted for ChAT immunocytochemistry.

The results show that a medial-to-lateral distribution of injections in the somatosensory cortex labeled a rostral to caudal sequence of neurons in the NBM. Injections in homotopic regions in somatosensory and motor cortices labeled different groups of NBM neurons. Seventy to 96% of retrogradely-labeled NBM neurons were also labeled by ChAT immunofluorescence.

These results suggest that most afferents from NBM to the sensory-motor cortices are ChAT-positive and that these afferents are topographically organized. Moreover, cholinergic input to homotopic regions of sensory-motor cortices arise from separate populations of NBM neurons. (Supported by NIH grant AG05944, Alzheimer's Association, and The Center for Neuroscience of The Univ. of Tennessee, Memphis).

MORPHOLOGY OF INDIVIDUAL THALAMOCORTICAL AFFERENTS IN THE PRENATAL RAT NEOCORTEX **S. Catalano*, R. T. Robertson and H. P. Killackey,** Depts of Psychobiology and of Anatomy and Neurobiology, University of California, Irvine, CA 92717

Dawson and Killackey ('85, Dev. Brain Res. 17:309) reported that on the day of birth, topography within the thalamocortical projection to rat somatosensory cortex is similar to that of the adult. On the other hand, Naegele et al ('88, J.Comp.Neurol. 277:593) reported that geniculocortical topography within the neonatal hamster visual cortex is progressively refined during postnatal development; these authors attribute this refinement to loss of multiple short collaterals from individual afferents within the intermediate zone. In this context we examined the morphology of thalamic afferents in the somatosensory cortex of rats aged embryonic day 16 (E 16) through 21 (the day of birth). Afferents were labeled with DiI, photoconverted and drawn using a camera lucida. On E 17, fibers run parallel to the pial surface within the intermediate zone without branching, and turn at the lower border of layer VIB. These fibers course obliquely through layer VIB to reach the bottom of the cortical plate where they terminate in a complex growth cone. At later ages fibers begin to form obliquely oriented branches within the lower cortical layers. At any age examined, only a very small proportion of fibers within the intermediate zone give rise to radially oriented collaterals. These observations suggest that topographic cortical maps may develop differently in different areas of cortex or different species of rodent. Supported by NSF grant BNS90-22168.

248.5

DIFFERENTIAL LAMINAR DISTRIBUTION OF CORTICOTHALAMIC PROJECTION NEURONS IN RAT PRIMARY SOMATOSENSORY CORTEX. **K. E. Good* and H. P. Killackey,** Department of Psychobiology, University of California, Irvine, CA 92717.

Several previous studies have reported that corticothalamic projection neurons arise from layers V and VI of rat primary somatosensory cortex (Wise & Jones 1977; Chmielowska et al., 1989). These studies, however, did not differentiate between two potential targets of such projections in the rat thalamus, namely, the ventral posterior nucleus (VP) and the medial division of the posterior complex of nuclei (POM). The present study was undertaken to assay the differences, if any, between the cortical projection to these two thalamic cell groups.

Stereotaxic pressure injections of rhodamine or fluorescein conjugated microspheres were made into either VP or POM. In most cases, an individual injection of a tracer was confined to one of the two targets on a given side of the thalamus although in some cases dual injections were made into the same side of the thalamus. Forty eight hours after the injections the rats were euthanized, perfused and their brains removed. The brains were sectioned in the coronal plane and processed for examination by epifluorescent microscopy.

The dual injections revealed that few, if any, cortical neurons projected to both thalamic targets. Further, both the dual and individual injections revealed that projection neurons which project to VP and POM have a differential laminar distribution. Cortico-VP projection neurons were distributed in a single dense band which was largely confined to the upper portion of layer VI. Cortico-POM projection neurons, on the other hand, were distributed in a bilaminar fashion consisting of a dense band of labeled neurons in the lower portion of layer VI, and a more superficial and sparse band in layer V. This differential distribution of corticothalamic projection neurons is presumably related to differences in the functional properties of the two thalamic targets.

THALAMOCORTICAL CONNECTIVITY PATTERNS IN AN OLD WORLD PRIMATE, *Erythrocebus patas*. **S. Warren and J. E. Taylor*** Univ. of Mississippi Medical Center, Dept of Anatomy, 2500 N. State St., Jackson, MS. 39216-4505.

The topographic organization of cutaneous inputs within the primary somatosensory (SI) cortex of the Old World primate, *Erythrocebus patas* (Warren and Carlson, '87) has been examined electrophysiologically. However, patterns of thalamocortical connectivity between the ventral posterior (VP) nuclei and SI cortex in *E. patas* have not been described. Consequently, these connections were studied in five animals by placement of separate, discrete injections of different retrograde tracers into physiologically identified, SI body, hand and/or face recipient areas. Similar to other Old World anthropoids, neurons retrogradely labeled from injections confined to areas 3b and 1 form somatotopically arranged lamellae with lower extremity laterally placed in ventral posterior lateral (VPL) nucleus, the hand medial, and the face in ventral posterior medial (VPM) nucleus. There is a tendency for lamellae resulting from digit injections to be located in the rostral half of the nucleus, while lamellae resulting from injections of palm and hand dorsum appear restricted to more caudal portions of nucleus. Injections into SI digit areas responding to both cutaneous and joint stimulation of the same digit produce an intermingling of labeled neurons of differing submodalities within individual digit lamellae. In addition, labeled neurons are seen within the posterior (Po) group. To contrast with other monkeys, some injections confined to SI cortex, also label an additional separate population of neurons confined to a location medial and dorsal to the labeled lamellae within the confines of VP. This particular pattern suggests a possible connection between intralaminar nuclei and/or ventral lateral nucleus and SI cortex in this species. Thus, while displaying patterns of thalamocortical connectivity similar to other species, fine details of these patterns in *E. patas* suggest additional species specific connections. Supported in part by BRSR #2S0RR5386 and NIH #NS29776.

Volume Rendering of Mouse Barrel Components Labeled in Fixed Tissue with Lipophilic Dyes **S. L. Senft and J. J. Christensen,** Department of Neurology and Neurosurgery, Washington University School of Medicine, Saint Louis, MO. 63110.

Elements of the developing mouse trigeminal pathway were labeled in fixed tissue using crystals and solutions of a variety of lipophilic dyes, including DiA, DiI, and DiQ (Molecular Probes). Serial confocal optical sections were acquired using a Laser Scan Microscope (LSM, Carl Zeiss), and transferred across an IEEE interface into an imaging workstation (Silicon Graphics). Three-dimensional views of thalamocortical afferents and intrinsic cortical cells were obtained, as volume renderings of the scanned data, using commercially available software (Vital Images). The spatial interrelationships of labeled ingrowing axons and cortical dendrites, with each other and with the developing barrel septa, are clearly evident in stereo pairs and film loops of the volume reconstructions. They support the view that these neurites are selectively remodeled to match (and form) emerging barrel boundaries. Attempts are currently being made to analytically extract the three-dimensional boundaries of the labeled material for structural analysis, electrical modeling and simulation of interacting neurite outgrowth in a synthetic population of cells. Supported by NIH grants NS 17763 and NS 07057.

248.6

COMBINED INJECTIONS OF IBOTENIC ACID AND HORSERADISH PEROXIDASE (HRP) FOR STUDYING RECIPROCAL CONNECTIONS. **E.L. WHITE and D. CZEIGER,** DEPT OF MORPHOLOGY, BEN-GURION UNIV. BEER SHEVA, ISRAEL.

Reciprocal pathways are particularly prominent in the cerebral cortex where they link cortical areas with each other and with specific thalamic nuclei. Previously, we have examined reciprocal thalamocortical (TC) relationships by combining injections of HRP into mouse thalamus to label corticothalamic neurons, with electrolytic lesioning of the injection site, one day later, to label synapses made in cortex by TC afferents. Here we describe a simplified approach: thalamic lesions and HRP labeling are effected by a single injection of a 40% solution of HRP containing 1.0% ibotenic acid.

The axon terminals of chemically lesioned TC afferents to layer IV of the SI barrel field form approximately 20% of the asymmetrical synapses within barrel hollows. At 4 days post-injection, all affected terminals are in medium/late stages of degeneration; about 80% synapse onto spines. The retrograde labeling of corticothalamic cells by HRP is unaffected by the presence of ibotenic acid; the local axon collaterals of these cells form asymmetrical synapses mainly onto dendritic shafts. These are precisely the same results obtained when HRP injections are followed by electrolytic lesions. We conclude that combined HRP/ibotenic acid injections represent an efficient alternative to HRP injection/electrolytic lesioning, since with the former, the lesion is placed easily and accurately at the site of the HRP injection. NIH 20149 and BSF 89000-52.

DISTRIBUTION OF GABA-IMMUNOREACTIVE NEURONS IN CAT SI CORTEX. J. Li* and H.D. Schwark. Department of Biological Sciences, University of North Texas, Denton, TX 76201.

Rapidly- (RA) and slowly-adapting (SA) submodality-specific regions have been described in area 3b of the cat primary somatosensory (SI) cortex (Sretavan & Dykes '83). Compared to SA regions, a higher proportion of neurons located in RA regions are sensitive to locally applied bicuculline (Dykes et al. '84), suggesting differences in the organization of GABAergic systems between these two regions.

In the present study, we have plotted the distribution of GABA-immunoreactive cells in 16 um parasagittal sections through SI in order to determine if differences in GABA cell densities might correlate with the segregation of submodalities. In each section, all GABA-positive profiles throughout SI were plotted in a Cartesian plane. Heterogeneities in GABA-immunoreactive cell densities were assessed by visual inspecting cell plots and by counting the number of GABA-immunoreactive cells in a grid of 100 um x 100 um bins. Reliability of detected patterns was determined by analyzing series containing 4-6 alternate sections.

We have analyzed three cortical hemispheres. The distribution of GABA neurons in area 3b was somewhat patchy, but the patterns were not uniform across a series of sections, suggesting that the differences in densities are not related to the interdigitating band pattern described by Sretavan and Dykes ('83). GABA-immunoreactive cells are more densely distributed in superficial than in deep cortical layers in all areas. The middle layers of area 3b contain higher densities of GABA neurons than the same layers in area 2. We are presently quantifying total cell numbers to determine the percentages of GABA-immunoreactive cells in SI. Supported by NIH grant NS25729.

THE DISTRIBUTION OF LOCAL CIRCUIT NEURONS AND GABAergic BOUTONS WITHIN THE GUINEA PIG THALAMUS. C. Asanuma. Laboratory of Neurophysiology, NIMH, NIH Animal Center, Poolesville, MD 20837.

There is considerable variation in the relative proportions of GABAergic local circuit neurons within thalamic relay nuclei among mammals. For example, GABAergic neurons may account for as much as 30% of the relay nuclei neuronal population in cats, while local circuit neurons are essentially absent from many nuclei in rats and mice, as well as in opossums (LGN, MGN, and LP excepted).

To determine if the striking paucity of local circuit neurons is seen as well in guinea pig thalamic nuclei, frontal or horizontal sections of guinea pig brains were stained with GABA or GAD. As in all species examined thus far, GABA(+) neurons occur within the LGN, MGN and LP of guinea pigs. In addition to these nuclei, GABA(+) neurons are prevalent also within the guinea pig VB. This contrasts with the virtual absence of interneurons well documented in the VB of other phylogenetically primitive mammals. The GABA(+) VB neurons in the present material are, in general, smaller (ca. 10-15 um in diameter) than nearby GABA(-) neurons (ca. 20-25 um in diameter). GABA(+) neurons account for ~10 % of the neurons in this nucleus; this is somewhat less than the proportion seen in LGN, MGN, and LP. The rest of the guinea pig dorsal thalamus contains only occasional GABA(+) neurons.

While GABA(+) neurons are found only in a few select relay nuclei within the guinea pig thalamus, small GABA(-) or GAD(-) puncta, possibly corresponding to GABAergic axonal boutons, occur virtually throughout. The distribution of the labeled puncta, however, is not uniform, and their densities are significantly higher within those nuclei containing appreciable numbers of local circuit neurons.

Thus, there is considerable variation in the presence and distribution of local circuit neurons and GABAergic puncta among thalami in different species - such variation can be marked even within a single order of mammals. The differential distribution of the GABAergic elements within the guinea pig thalamus described here may be of relevance for studies of thalamic function in this species.

CHEMICAL COMPARTMENTS IN VPL NUCLEUS OF MONKEY THALAMUS. E. Rausell¹, C.S. Bae¹, C.G. Cusick², E.G. Jones¹. ¹Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717 and ²Dept. of Anatomy, Tulane University Medical Center, New Orleans, LA 70112.

The ventral posterior lateral nucleus (VPL) of the monkey thalamus is the relay for medial lemniscal and spinothalamic pathways to somatosensory cortex (SI). Two different classes of thalamo-cortical relay cells in VPL can be distinguished by differential immunoreactivity (IR) for the calcium binding proteins parvalbumin and 28Kd-calbindin (Jones and Hendry, Eur.J.Neurosci., 1:222, 1989). In the associated ventral posterior medial nucleus (VPM) parvalbumin and calbindin-IR neurons form separate compartments, which relay principal and spinal inputs respectively to different layers of SI (Rausell and Jones, J.Neurosci., 11:226, 1991). In this study, we investigated the distribution, and connective relationships of parvalbumin and calbindin neurons in VPL by combining immunohistochemical, histochemical, and fluorescent tracing techniques in normal monkeys and in monkeys subjected to chronic dorsal rhizotomy. a) Parvalbumin-IR neurons are concentrated in cytochrome-oxidase (CO) rich patches that form discontinuous lamellae oriented anteroposteriorly in VPL. These neurons project to deep layers of SI. b) Calbindin-IR neurons are distributed in CO poor spaces that intervene between the parvalbumin patches, form a shell around the nucleus, and project to superficial layers of SI. c) The calbindin domain of VPL is the recipient of spinothalamic terminals and the parvalbumin domain of lemniscal terminals. d) Chronic dorsal rhizotomy results in enhanced calbindin immunostaining, and decreased parvalbumin immunostaining in the regions of the VPL deprived of afferent activity. These results indicate that lemniscal and spinothalamic inputs are relayed to different layers of SI by separate VPL neuronal populations. The two populations show differential responses when the balance of afferent activity is perturbed. Supported by USPHS grants NS 21377 and NS 22317.

ONTOGENY OF EXCITATORY AMINO ACID RECEPTORS IN BARREL FIELD CORTEX OF IMMATURE RAT. M.E. Blue, J.W. McDonald and M.V. Johnston. Kennedy Research Institute, Dept. of Neurology, Johns Hopkins Univ. Sch. of Med. Baltimore MD, 21205.

The ontogeny of quisqualate (QUIS) and *N*-methyl-D-aspartate (NMDA) receptors in barrel field cortex was studied in rats between postnatal days 1 and 21 (P1-P21). The pattern of QUIS and NMDA sites was examined in flattened sections of cortex using QUIS-sensitive and NMDA-sensitive [³H]-glutamate binding. No distinct pattern of QUIS labeling is observed at birth (P1), but by P5, dense patches of QUIS sites are localized in discrete barrel centers, forming a vibrissa-related map. After P14, the pattern becomes less distinct and by P21, QUIS sites no longer form a vibrissa-related map. In contrast, NMDA binding shows a complementary pattern with fewer sites in barrel centers at ages P7-P10. With time (P14-P21), the density of NMDA sites increases in barrel centers, yet the number of NMDA sites remains low in barrel septa. These results show a differential ontogeny of NMDA and QUIS sites in the barrel field of the immature rat. The developmental expression of QUIS sites follows that of thalamocortical and serotonergic axons, which are distributed over barrel centers by P3 (Blue et al., 1990). Unlike the thalamocortical axons, the expression of QUIS sites in a vibrissa-like pattern is transient. The initial appearance of QUIS labeling in barrels most closely coincides with the onset of barrel formation, suggesting that the ontogenetic pattern of these postsynaptic receptors may reflect the cytologic differentiation of barrels. The period of rise in the density of NMDA sites occurs after that of QUIS sites suggesting that NMDA sites may influence later stages in barrel development. Supported by NIH grant NS28208.

SIMULTANEOUS EM-IMMUNOCYTOCHEMICAL IDENTIFICATION OF SEROTONIN TERMINALS AND GABA PROCESSES IN CAT VPL THALAMIC NUCLEUS. X.-B. Liu, J. DeFelipe and E.G. Jones. Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Only 7-10% of monoaminergic terminals make conventional synaptic contacts in the VPL thalamic nucleus. The majority however form close membrane appositions that may represent atypical synaptic sites. (X.-B. Liu and E.G. Jones, Exp. Brain Res., in press). In the present study, preembedding immunoperoxidase (for serotonin) and postembedding immunogold labeling (for GABA) were combined to demonstrate light and electron microscopically the neuronal targets of serotonergic afferents.

Adult cats were perfused with 4% paraformaldehyde or 2% paraformaldehyde plus 0.2-0.5% glutaraldehyde in 0.1M phosphate buffer. Vibratome sections through VPL were processed for serotonin immunocytochemistry by ABC peroxidase and embedded in Araldite. Thin sections were collected on Formvar-coated single slot nickel grids and postembedding immunogold staining for GABA was carried out on the grids.

5-HT immunoreactive fibers and terminal varicosities surround both relay cells and GABA positive interneurons. Ultrastructurally, the majority of serotonin terminals make close contact without membrane specializations with GABAergic axon terminals (F1 type) or GABAergic presynaptic dendrites (PSD) and some contact GABAergic somata, but few conventional synapses are detectable. A small number of 5-HT terminals contact GABA negative dendritic shafts of relay cells and form typical asymmetric synaptic contacts. These findings suggest a dual innervation pattern in VPL. Supported by USPHS grant no. NS 22317.

FUNCTIONAL ASYMMETRIES IN THE RODENT BARREL CORTEX. J.S. McCasland, G.E. Carvell, D.J. Simons and T.A. Woolsey. Dept. Neurosurgery, Washington University, St. Louis MO 63110, and Dept. Physical Therapy and Dept of Physiology, University of Pittsburgh, Pittsburgh PA 15261.

Asymmetries in the functional organization of rodent whisker-barrel cortex have been demonstrated by previous 2-deoxyglucose (2DG) and neurophysiological studies. We examined the possibility that the activity gradients observed in metabolic studies can be attributed to subtle rostral/caudal and dorsal/ventral asymmetries in physiologically measured surround or cross-whisker inhibition by comparing 2DG results with predictions generated from quantitative single-cell receptive field data. Despite differences in the two experimental approaches there is remarkable agreement between them. 1) The density of 2DG labeling declines across the barrel cortex of the behaving animal from anteromedial to posterolateral barrels in a manner qualitatively and quantitatively similar to the values predicted from neurophysiology. 2) The strength of surround inhibition in barrel neurons predicts the two-fold increase in activation of the C3 barrel following acute trimming of adjacent whiskers. And, 3) within a cortical column the decrease in metabolic activity associated with adjacent whisker stimulation is greatest in layer IV and least in the infragranular layers, a finding qualitatively similar to the laminar distribution of inhibitory interactions observed physiologically.

SUPPLEMENTARY SENSORY AREA VERSUS THE PARIETAL OPERCULUM: WHICH IS THE REAL SECOND SOMATOSENSORY AREA? Richard J. Caselli, M.D., Department of Neurology, Mayo Clinic, Scottsdale, Arizona 85259

Isolated lesions of the parietal operculum, currently regarded as the second somatosensory area (SII) and supplementary sensory area (SSA) are rare, but two patients are presented to contrast the striking differences resulting from selective damage to each somatosensory area. Damage to SII causes a subtle, non-disabling disturbance of somesthetically mediated object recognition (tactile agnosia), which cognitively may represent dysfunction of the "first" cortical somatosensory system at a very distal point of processing, analogous to other agnosic disturbances. Damage to SSA, in contrast, causes much greater somesthetic impairment. Despite normal elemental somesthetic sensibility (touch, vibration, proprioception, superficial pain), other basic (2-point discrimination), intermediate (barognosis), and tactile object recognition functions were significantly impaired. This patient also had profound apraxia, probably due to concurrent, but less extensive damage to the supplementary motor area (SMA). Following SSA and SMA infarction, both somesthetic and motor deficits resolved within a year, in contrast to tactile agnosia following SII infarction which was found four years following infarction. Initial severity followed by dramatic resolution is consistent with the notion of a "second" system that can function in parallel to the "first", and such is known to be the pattern following damage to the second motor area (MII), or SMA. Historical considerations aside, the greater known anatomical and physiological parallels of SSA than parietal operculum with SMA, and the pattern of deficits following SSA infarction suggest that SSA, and not SII should be considered the true second somatosensory area.

MINICOLUMNAR ORGANIZATION OF SI SEGREGATES.

O.V. Favorov and D.G. Kelly*. Depts of Physiology, Endodontics, Mathematics, Univ. of N. Carolina, Chapel Hill, NC 27599. Recent evidence suggests that SI is organized as a mosaic of discrete column-shaped topographic entities - "segregates" - 0.3-0.5 mm in dia. A segregate consists of 40-80 minicolumns (MCs) - radial cords of cells ca. 45 µm in dia. Whereas receptive fields (RFs) of neurons in the same MC are very similar, RFs of neighboring MCs have much less overlap. Moving across a segregate from one MC to the next, RFs jump back and forth on the skin, but with no appreciable drift (Favorov & Diamond 1990 J Comp Neurol 298:97-112). To study how RFs of a segregate might be arranged on the skin, we implemented a single-segregate model with 61 MCs. Each MC was represented by an input "spiny-stellate" cell (distributor of thalamic input to all other cells of the same MC and, to some degree, to other MCs); an intrinsic "double-bouquet" cell (inhibitor of neighboring MCs); and an output "pyramidal" cell. Connections from thalamus to spiny-stellates were made Hebbian. The network was stimulated with a random series of point "skin" stimuli until its connections settled into a dynamic equilibrium. In this "matured" state, MC RFs formed a regularly permuted arrangement, consistent with experimental observations. A majority of MCs showed a degree of orientation selectivity in response to elongated stimuli and directional selectivity in response to moving stimuli. As in the visual cortex, 1) preferred orientation changed gradually across the segregate with all angles represented, and 2) MCs in the center of the segregate lacked orientation tuning. These results demonstrate the power of Mountcastle's concept of the minicolumn as the basic functional unit of cortical organization. Supported by NIDR DE07509.

MULTINEURONAL RESPONSES IN THE SI AND MI CORTEX DURING LEARNING OF A STIMULUS CUED MOTOR TASK. J.K. Chapin and R.T. Mariano*, Dept. Physiology, Hahnemann Univ., Phila, PA 19102

Our aim is to define the neuronal network mechanisms by which the cortex processes sensory stimuli to trigger motor responses. For this we trained rats in a task in which they were required to hold their forepaw on a bar and to move the bar immediately after a vibratory cue. Ensembles of neurons were recorded simultaneously through microwire electrodes chronically implanted in the MI cortical forelimb area, and in the SI cortical forepaw-forelimb area, including the granular zone (GZ, homologous with area 3b) and the caudally adjacent perigranular zone (PGZ, homologous with areas 1-2). The GZ neurons had cutaneous receptive fields (RFs) on the forepaw, and PGZ neurons had deep/proprioceptive RFs in the forelimb. In one rat, 22 microwires were implanted, of which 16 recorded discriminable neurons. 100Hz vibratory stimuli produced responses in both GZ and PGZ neurons during rest, but only in GZ neurons during and just before forelimb movement. 50Hz stimuli produced strong excitatory responses in the GZ at 10 msec latency, and weak excitatory or inhibitory responses in the PGZ at 15-20 msec latency. Initially, the MI neurons had no RFs, and did not respond to the 50Hz cue (though one did respond to 100Hz). However, after the animal learned to move the bar immediately after the cue, the MI neurons did respond to the cue, at 20-30 msec latency. Cross-correlating the activity of the simultaneously recorded neurons revealed serial functional connections between neurons within the GZ and PGZ, but not between the PGZ and MI, which nevertheless are known to be neuroanatomically connected. However, after learning the task such serial connections between the PGZ and the MI began to be observed, suggesting a learning related enhancement of the pathway for transmission of cue related sensory information to the MI cortex. Supported by grants AFOSR-90-0266, NS23722, and AA06965 to JKC.

STIMULUS-EVOKED 2DG LABELLING IN SI: IN VIVO AND IN VITRO STUDIES.

M. Tommerdahl, C.-J. Lee, and B. Whitsel. Physiol, UNC, Chapel Hill, NC 27599.

C14-2-deoxyglucose (2DG) labelling in somatosensory cortex (SI) of monkeys and cats was quantitatively characterized. Repetitive stimuli were used to evoke the labelling patterns. In regions of SI corresponding to the stimulated skin field the first-order distribution of C14-2DG concentration values was multimodal, and most frequently, trimodal. For regions outside the SI representational field, and for all of SI in animals receiving no skin stimuli, the distribution was unimodal. A trimodal distribution is predicted by a recently proposed model of stimulus-driven pericolumnar lateral inhibitory interactions (Whitsel, et al, 1990). Additional evidence was obtained in 2DG studies which employed pharmacological or neurosurgical manipulations. These studies showed that the first-order distribution of C14 concentration values in SI is modified in a predictable manner in subjects in which the cortical (1) GABAergic inhibitory neurotransmission was blocked by bicuculline, (2) NMDA receptor system was antagonized by either PCP or APV, and (3) input was interrupted by spinal dorsal column lesion. The 2DG method was adapted for use with the cortical slice. The advantages it offers are considerable: (1) input drive to a cortical network can be precisely controlled and applied at a known locus, and (2) agents (2DG and/or neuroactive drugs) can be administered easily at known concentration and for precisely defined time periods. The characteristics of stimulus-evoked 2DG labelling in cortical slices are consistent with the idea that a dynamic process involving NMDA receptor supported GABAergic pericolumnar lateral inhibitory interactions is triggered into activity by repetitive extrinsic excitatory drive. Collectively, these observations suggest that SI should be regarded as a dynamic network possessing short- and long- term mechanisms enabling it to respond to input in a manner that reflects the prior history of sensory experience. INTRACORTICAL ORGANIZATION OF PROJECTIONS TO INDIVIDUAL MODULES IN SI CORTEX. R.J. Weinberg and O.V. Favorov, Dept. of Cell Biology & Anatomy, Dept. of Physiology, and Dept. of Endodontics, U. of North Carolina, Chapel Hill, NC 27599.

Receptive field mapping studies of primary somatosensory cortex (SI) have demonstrated that the body surface is represented as a mosaic of discrete place-defined cortical columns, or "segregates," approximately 0.3-0.5 mm in diameter. The intracortical organization of these modules has been studied in cats and rats. Small injections of retrograde tracers, especially gold-labeled wheat germ agglutinin conjugated to apo-horseradish peroxidase were made in individual physiologically-identified SI segregates in anesthetized rats and cats. After 12-48h survival, animals were reanesthetized and perfused with mixed aldehyde fixative. Vibratome and frozen sections processed with silver intensifier (Janssen IntenSE BL) were mounted on slides and examined under darkfield and polarization optics.

Large numbers of labeled neurons were found in the ipsilateral cortex, even after very small and confined injections. Labeled neurons tended to cluster into vertical patches whose dimensions corresponded to typical segregates. Labeling was also observed in diffusely scattered neurons, whose frequency declined with distance from the injection center. Work is now in progress to test whether the patches of retrograde labeling coincide with electrophysiologically-defined segregates functionally related to the injected area. Portions of this work were supported by NIH awards #NS-16264 and DE-07509.

EFFECTS OF CIRCUIT OSCILLATIONS AND NOREPINEPHRINE-LIKE MODULATION IN A NEURONAL NETWORK MODEL OF THE SOMATOSENSORY SYSTEM. J.P. Utz, B.D. Waterhouse and J.K. Chapin. Department of Physiology, Hahnemann University School of Medicine, Philadelphia, PA, 19102-1192.

In order to investigate the effects of oscillations and norepinephrine (NE) in simple neuronal networks within the somatosensory system, a computer simulation was used. The simulation consisted of layers of "neurons" (30x30 2-D arrays) representing the ventral basal thalamus (VB), cerebral cortex (CTX) and nucleus reticularis thalami (nRT). Each neuron incorporates a membrane potential (Vm) calculated from membrane conductances and Nernst potentials for Na⁺, K⁺, and Cl⁻. State variables (eg, conductances and Vm) are re-calculated every ms of simulation time. The VB is driven by a 30x30 array of randomly-timed input fibres, with a bar of increased activity serving as a focal stimulus. VB excites nRT and CTX, CTX excites VB and nRT, and nRT inhibits VB. Each connection fans out in a 5x5 array. In this model, spatiotemporal oscillations are observed throughout the network under certain conditions. During increased oscillatory behavior stimulus discrimination by the network decreases. Effects of NE were modeled by increasing synaptic efficacies. When NE is set to increase all synaptic efficacies by up to 30%, the observed spatiotemporal oscillations and discrimination by the network decreases. When NE increases all synaptic efficacies by 30%, except the CTX to VB feedback, the ability of the network to discriminate a stimulus increases without increasing the oscillatory behavior of the network. This simulation demonstrates that NE's cellular modulatory actions can increase stimulus discrimination by sensory neuronal network, and that control of oscillations is important for discrimination by the somatosensory system. Supported by grants NS23722, AA06965 & AFOSR-90-0266 to JKC.

MODELING THE CIRCUIT CHARACTERISTICS WHICH MAY UNDERLIE OSCILLATORY PROPERTIES OF THALAMOCORTICAL NETWORKS. T. Fisher, A. Gupta, M.A.L. Nicolelis, and J.K. Chapin. Dept. Physiology/Biophysics, Hahnemann Univ., Phila, PA 19102

In simultaneous recordings of single neurons in multiple regions of the somatosensory thalamus and cortex in chronically implanted rats we have observed strong oscillatory firing under conditions of drowsiness, slow wave sleep, and pentobarbital anesthesia. Several findings suggest that purely circuit characteristics of this system may be extremely important for such oscillations: 1) Cross-correlation studies showed that the neurons oscillated synchronously, but at different phase angles. 2) The oscillations exhibited well known characteristics of nonlinear dynamical systems, such as sudden frequency bifurcations, and low-dimensional chaos. We have used computer modeling techniques to investigate the characteristics of neuronal circuits which may support such oscillatory functions. Several types of simple and complex circuits have been modeled, culminating in models which incorporate the major circuits of the somatosensory system. From these we have determined that, to support oscillations, a circuit must incorporate both positive and negative feedback of sufficient strength and non-zero delay, nonlinear (e.g. sigmoid) neuronal activation functions, and some initial activation of at least one of the neurons. If the synaptic strength of the excitatory feedback, or slope of the sigmoid activation curve are initially set to low levels, oscillation will develop suddenly as one of these parameters is incrementally increased above a certain threshold. The frequency of oscillation is determined complexly by the synaptic delays, time constants of decay of neuronal activation, and the relative strength of the inhibitory feedback. If multiple feedback systems exist within the network, complex frequencies can be produced. Long loop feedbacks can support chaotic properties. Strong afferent inputs to such networks can abolish the oscillations. After cessation of the afferent input, the oscillations resume in a phase reset fashion. Conversely, strong continuous oscillations tended to suppress network responses to weak afferent inputs. Thus, in situations where two dynamic processes were competing for control of the network (e.g. afferents vs. endogenous circuit oscillation) the stronger process tended to dominate, and suppress the weaker process. Supported by grants AFOSR-90-0266, NS23722, and AA06965.

APPLYING MULTI-SINGLE UNIT RECORDING TECHNIQUES TO THE STUDY OF PLASTICITY AT MULTIPLE LEVELS OF THE RAT TRIGEMINAL PATHWAY. M. A. L. Nicolelis, R. C. S. Lin, and J. K. Chapin. Department of Physiology and Biophysics, Hahnemann University, Philadelphia, PA 19102-1192, USA.

Peripheral sensory deprivation induces a reorganization of cortical receptive fields (RFs). Whether this cortical phenomenon is influenced or not by a reorganization of subcortical structures is still unclear. Here, we approached this issue by mapping the cutaneous RFs of neurons in the ventral posterior complex (VP) of the thalamus in anesthetized rats which were subject to an unilateral removal of their facial whiskers at the day of birth. These experiments revealed that thalamic neurons undergo extensive reorganization of RFs. Typically, larger facial RFs and the coexistence of continuous face-body RFs were observed in the VP of these rats. Although these results point to the existence of thalamic rearrangements which may parallel the cortical reorganization, they do not provide a definitive link between the processes and endow little insight in what happen in the awake rat. To approach these issues we have developed new methods for chronic multi-single unit recordings in awake, freely behaving rats. Thus, up to 48 50 μm teflon-coated stainless steel microwires are simultaneously implanted in the trigeminal nuclei, dorsal thalamus and somatosensory cortex of adult animals, as well as wires for recording facial muscle activity (EMG). Single units are studied in behaving rats in terms of their waveforms, receptive fields, tuning curves and correlation to the EMG. Principal components analysis is used for a quantitative spike classification, providing criteria for following single spikes in chronic recordings. Single trigeminal, thalamic, and cortical units are then chronically recorded during different whisking behavior paradigms in order to study networks of neurons located at different levels of the trigeminal pathway. Sponsored by grants NS26722 and FAPESP 88/4044-9.

SUBCORTICAL VISUAL PATHWAYS: LGN

249.1

REORGANIZATION OF RETINO-GENICULATE PROJECTIONS FOLLOWING EXCISION OF AREAS 17 AND 18 IN NEWBORN AND ADULT CATS. S.G. Lomber, B.R. Payne, P. Cornwell* and H.E. Pearson. Department of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA 02118.

The purpose of the present study was to evaluate the pattern of retinal projections to the dorsal lateral geniculate nucleus (dLGN) at least six months after ablation of primary visual areas 17 & 18 in the newborn kitten and adult cat. The terminations of retinal projections to the degenerated dLGNs in both groups of cats were studied following the injection of tritiated amino acids into one eye. In the dLGN of adult lesioned animals there is substantial neuron death in both laminae A & A1 and moderate neuron loss in the C-laminae. Quantification of the retinal projections show their density and distribution to be very similar to those in the intact cats. However, in cats which had areas 17 & 18 removed on the day of birth both the configuration and cytoarchitecture of dLGN and retinal projections to the nucleus are abnormal. The entire nucleus failed to rotate so that its orientation is close to its initial vertical position. Laminae A & A1 have collapsed completely and virtually all surviving neurons are in the C-laminae. Retinal projections to dLGN terminate almost exclusively in the C-laminae with only a hint of projections to laminae A & A1. These results show substantial retraction of retinal projections from laminae A & A1 following ablation of areas 17 & 18 on the day of birth and provide little evidence for retraction of retinal projections from the degenerated layers of dLGN following equivalent ablation in adulthood. These data show that immature retinal projections are plastic and can change in response to ablation of areas 17 & 18. (Supported by MH44647 and Whitaker Health Sciences Fund.)

249.3

THE PROJECTION OF PRETECTAL AXONS TO THE LATERAL GENICULATE NUCLEUS (LGN). D.J. Uhlich and K.A. Manning. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

The midbrain pretectal region contains distinct cell groups that are involved in vision. Within this region is a column of cells, mostly in the nucleus of the optic tract (NOT), that projects to the LGN. Because the NOT is involved with optokinetic nystagmus, this projection may coordinate the sensory and motor aspects of eye movements.

Little is known about the projection from the NOT to the LGN at the single cell level. Therefore, we labeled pretectal axons with iontophoretic injections of the anterograde tracer, *Phaseolus vulgaris* leucoagglutinin, targeting the NOT. We find labeled fibers in all laminae of the LGN as well as in adjacent visual nuclei. The terminal fibers contain boutons, mostly *en passant*, that are larger (1.8 μm \pm 0.6 μm) than the boutons of other extraretinal fibers that innervate the LGN. Serial reconstructions of portions of labeled pretectal axons indicate that they freely cross laminar borders in the LGN. Preliminary results show that pretectal terminal arbors are asymmetrical. They are relatively flat in the rostral-caudal dimension (i.e., visual field elevation in the LGN retinotopic map), but they can encompass one third of the medial-lateral extent of the LGN (i.e., visual field azimuth). These terminal fields are consistent with observations that the pretectum is well organized retinotopically for visual field elevation, but not for azimuth. It is also consistent with observations that NOT cells respond best to large visual stimuli that are drifting along the horizontal plane.

Supported by NIH grant EY-06610.

249.2

DEGENERATION OF MEDIUM-SIZED RETINAL GANGLION CELLS IN RESPONSE TO LOSS OF POSTSYNAPTIC NEURONS IN THE DORSAL LATERAL GENICULATE NUCLEUS OF THE ADULT CAT. H.E. Pearson and D.J. Stoffler*. Dept. of Anat. and Cell Biol., Temple Univ. Sch. of Med., Philadelphia, PA 19140.

We have demonstrated previously that postsynaptic targets are essential for the survival of mature retinal ganglion cells. In the absence of normal targets, ganglion cells will first retract their axon terminals and then degenerate. We have now expanded this study to determine whether this degeneration is confined to a specific ganglion cell population. Kainic acid (3 nmol/ μl) was injected at multiple sites within the dLGN of adult cats. Following survivals of 2, 4 and 6 months, the cats received multiple injections of HRP into the dLGN. After a further 72 hr, the retinae were reacted for the presence of HRP and counterstained with cresyl violet. Adjacent brain sections were processed for thionin staining and HRP histochemistry. At each survival, counts of retinal ganglion cells were made at comparable locations in peripheral nasal retina, at a site corresponding retinotopically to regions of degeneration within the dLGN. Cell densities were determined separately for cells labelled retrogradely with HRP and for unlabelled cells stained for Nissl. Separate analyses of small, medium and large ganglion cells revealed that only medium sized cells were lost at 2 months, whereas both medium and large cells were lost at 4 and 6 months. By 6 months, 92% of medium cells and 65% of large cells had degenerated. These results show that the dependence of mature retinal ganglion cells on target integrity varies with ganglion cell type, being greatest among those with medium-sized cell bodies and least among the small cells. Supported by NS25196.

QUANTITATIVE IMMUNOGOLD EVIDENCE FOR HIGH LEVELS OF GLUTAMATE BUT NOT ASPARTATE IN SYNAPTIC TERMINALS OF RETINO-GENICULATE, CORTICO-GENICULATE AND GENICULO-CORTICAL AXONS IN THE CAT. V.M. Montero and R.J. Wenthold. Dept. of Neurophysiology, Univ. of Wisconsin, Madison, WI 53705, and Lab. Molecular Otolaryngology, NIDCD, NIH, Bethesda, MD 20892

In a previous study, high Glu immunogold reactivity (IGR) was found in synaptic terminals of retinal and cortical afferents to LGN, and of geniculo-cortical axons in the cat (Montero, *Visual Neurosci* 4:437-443, 1990). However, several pharmacological and uptake-release studies in cats that indicate excitatory amino acids (EAA) as neurotransmitters in these retino-geniculo-cortical synapses leave still open the possibility that Asp may be a neurotransmitter in these pathways: Asp and Glu act on the same type of EAA receptors (although with slight different preferences) and are taken up by the same mechanisms; NMDA and non-NMDA receptors are known to be involved in retino-geniculate transmission. It was of interest, therefore, to compare the IGR intensity to an Asp antibody in the retino-geniculo-cortical synapses with that in GABAergic terminals in LGN, in order to detect any relative enrichment of Asp in these synapses (and to compare these results with those obtained with a Glu antibody). The results showed that Glu-IGR in ultrastructurally identifiable synaptic terminals from retinal (R) and cortical (C) axons in LGN, and from geniculo-cortical (G-C) axons in the perigeniculate nucleus was 1.6 - 2.1-fold that seen in GABAergic F terminals, confirming the previous results. By contrast, the intensity of Asp-IGR in C, R and G-C terminals was similar or less than that seen in F terminals. These immunocytochemical results support the notion that Glu but not Asp is the neurotransmitter in the retino-geniculo-cortical pathways. Supported by NIH grants EY02877 and HD03352.

CALBINDIN ANTIBODIES LABEL SPECIFIC CELL CLASSES IN THE CAT LATERAL GENICULATE NUCLEUS. Francis Barrio and Banney Mize, Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, TN 38163.

Calbindin 28Kd, a calcium binding protein, is important in the regulation of calcium and may be associated with calcium spiking neurons in some regions of the CNS. We have localized calbindin (CaBP) in the cat dorsal lateral geniculate nucleus (dLGN) using antibody immunocytochemistry to determine if it labels specific cell classes in this nucleus. Anti-CaBP labeled neurons were found in all layers of the dLGN. Anti-CaBP cells in layers A, A1, and the magnocellular and parvocellular C layers were mostly small to medium sized cells with a mean area of 139.3 μm^2 . Labeled cells in the interlaminar zones were larger (range 250-677 μm^2). By contrast, most unlabeled neurons in the main layers were large neurons (mean area 270.9 μm^2). Labeled neurons in the A layers had round or ovoid soma morphologies. Over 75% of these neurons had vertically distributed dendrites whose orientation was 45° or more from the longitudinal axis of the lamina. The labeled neurons constituted 60-75% of neurons in the A layers. Labeled neurons in the C layers had similar soma morphologies, but over 50% of these neurons had horizontally distributed dendrites whose orientation was within 45° of the longitudinal axis of the laminae. Labeled neurons were more than 75% of the total neuron population in the C layers, and included virtually all neurons in the parvocellular C laminae. At the electron microscope level, we found label in F2 presynaptic dendrites within the retinal glomeruli, and in conventional dendrites and myelinated axons. Some neurons with cytoplasmic laminated bodies were also labeled by CaBP antibodies. Double labeling studies showed that CaBP was colocalized with GABA in a subset of neurons in both the A and C layers. We conclude on the basis of cell size and ratio data that all X and W cells, and GABAergic interneurons are labeled while Y neurons are not labeled by CaBP in the cat LGN. Supported by NEI EY-02973.

NAAG DEPOLARIZES NEURONS IN SLICES OF RAT LGN.

D.G. Tieman, N. Hori*, D.O. Carpenter and S.B. Tieman.

Neurobiology Research Ctr and School of Public Health, SUNY, Albany NY 12222 and Wadsworth Labs, NYS Health Dept, Albany NY 12201.

N-Acetylaspartylglutamate (NAAG) is an endogenous brain dipeptide satisfying many of the criteria for a neurotransmitter. In particular, it is found in retinal ganglion cells and their terminals in rat and cat, and is released from those terminals in a calcium-dependent manner following electrical stimulation of the optic nerve. Further, NAAG activates glutamate receptors, and glutamate receptors have been implicated in retinogeniculate transmission. We have therefore investigated the effects of NAAG on the target cells of the retinal pathway using intracellular recordings from slices of rat lateral geniculate nucleus (LGN), iontophoretic application of agonists, and bath application of antagonists. Synthetic NAAG (10 mM in 150mM NaCl, pH 7.0-7.5) was iontophoresed by passing negative current for 1 sec intervals with 30 sec in between. During the inter-stimulus intervals a small retention current was applied. Under these conditions NAAG depolarized cells in LGN. This depolarization was largely, but not completely, blocked by bath application of 50 μM APV or CPP, and could be enhanced by perfusion with Mg^{2+} -free Ringers, suggesting that NAAG activates NMDA channels. The response could also sometimes be decreased by bath application of 10 μM CNQX, suggesting a kainate or quisqualate component. The pharmacology of these responses is similar to those for electrical stimulation of the optic tract, but not identical in that they imply a greater dependence on the NMDA channel. These results are consistent with a role for NAAG in retinogeniculate transmission. (Supported by NSF grant BNS 811039 to SBT and PHS grant NS 2380705 to DOC.)

SYNAPTIC RESPONSES TO STIMULATION OF THE VISUAL CORTEX PROJECTION TO THE FERRET LATERAL GENICULATE NUCLEUS IN VITRO. M. Eguerra and M. Sur, Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139

Corticofugal afferents were activated by electrical stimulation of the optic radiations in isolated slices of adult ferret lateral geniculate nucleus (LGN). Optic radiation stimulation elicited both excitatory and inhibitory postsynaptic responses in the LGN. The excitatory responses (EPSPs; $n = 17$) were monosynaptic and appeared to be similar to optic tract-evoked postsynaptic potentials in amplitude and duration. In contrast to retinogeniculate EPSPs, optic radiation-evoked responses could be divided into "fast" and "slow" types based on the EPSP latency-to-peak and EPSP rise time. Most corticogeniculate EPSPs were attenuated by blockade of NMDA receptors; one EPSP was observed only in low-magnesium medium, and was blocked completely by normal levels of extracellular magnesium.

Optic radiation stimulation also led to purely inhibitory synaptic events ($n = 2$) which did not include any sign of depolarizing or excitatory components at resting potentials. This pure inhibition may represent direct stimulation of axons arising in the perigeniculate nucleus of the thalamic reticular complex. In 2 cells optic radiation stimulation elicited mixed excitatory and inhibitory responses characterized by a short excitatory component followed by a longer duration inhibitory component (IPSP). These most likely represent direct excitatory input from corticofugal afferents paired with disynaptic feed-forward inhibition by intrinsic geniculate interneurons.

We propose that a possible role of the corticofugal projection is to produce local dendritic depolarizations that can modulate nearby sites of retinogeniculate input.

THE DISTRIBUTION OF SOME PROTEINS IN CLASS 3 CELLS IN THE CAT LATERAL GENICULATE NUCLEUS A.J. Schectz and Mark Wm. Dubin.

Department of MCD Biology, University of Colorado, Boulder CO 80309.

The cytoarchitecture of the cat lateral geniculate nucleus (LGN) has been characterized to the point that the origin and connectivity of a given synaptic profile can be determined based on synaptic relationships. Because of this, we have been able to study the distribution of proteins within specific cell classes in the LGN using electron microscopic immunocytochemistry. We examined the distribution of some proteins normally associated with either dendrites or axons in LGN class 3 cells. These cells had normal axons but their dendrites were capable of interacting as pre- and postsynaptic partners. We examined whether some proteins that are normally associated with dendrites are present in these atypical dendrites, and if some proteins that are normally associated with axons are included in class 3 cell dendrites. We examined both adult and neonatal (3 week) LGN tissue that had been stained with various antisera. We were unable to detect any form of spectrin or fodrin in class 3 cell dendrites and their terminals (F2 terminals). This is probably due to the activation of calcium dependent proteases specific to spectrins during the tissue preparation. Calcium and calmodulin dependent protein kinase II (CAM II) staining was seen in class 3 cell dendrites and their terminals where it was associated with postsynaptic densities and microtubules. Synapsin I was found in F2 terminals. Map-2 staining was absent from class 3 cell dendrites and F2 terminals. Tau was seen in all axons but was excluded from F2 terminals. We found that class 3 cell dendrites have cytochemical compositions that differ from other axons and dendrites. This confers special functional capabilities to these synapses. CAM II is incapable of phosphorylating Map-2 in class 3 cell dendrites and F2 terminals. These terminals are the only place in the cat LGN where CAM II can phosphorylate synapsin I. We conclude that class 3 cell dendrites have atypical distributions of some proteins which may reflect certain functional differences between class 3 cell synapses and other synapses in the LGN. Such differences may be a ubiquitous feature of presynaptic dendrites in general. Supported by EY04629 to MWD

THE MODULATION OF TRANSMITTER RELEASE BY PRESYNAPTIC GABA_B RECEPTORS IN THE DORSAL LATERAL GENICULATE NUCLEUS (dLGN). Vincenzo Crunelli, Katalin Toth, Zsuzsa Emri and Ivan Soltesz, Dept. of Visual Science, Inst. of Ophthalmology, London, U.K.

A wealth of experimental evidence suggests that GABA can decrease its own release as well as that of glutamate via presynaptic GABA_B receptors (Bowery et al, Nature, 1980; Dolphin & Scott, J.Physiol., 1987; Deisz & Prince, J.Physiol., 1989). In the dLGN similar evidence has been lacking, though it is well established that both GABA_A and GABA_B IPSPs evoked by electrical stimulation of the optic tract (OT) show a decline in amplitude with increasing frequencies of stimulation (Crunelli et al, J.Physiol., 1988). Here we tested the hypotheses that this frequency-dependent decrease in the amplitude of GABA IPSPs in the dLGN might be due to presynaptic GABA_B receptors.

2-OH-Saclofen (0.4mM), which abolished the postsynaptic GABA_B responses, greatly reduced the frequency-dependent decrease in the amplitude of GABA_A IPSPs. Phaclofen (1mM) had no effect on the frequency-dependent decrease of GABA_A IPSPs, suggesting that this antagonist is less potent than 2-OH-saclofen on presynaptic GABA_B receptors, at least in the dLGN. The GABA_B agonist baclofen (10 μM), in the presence of Ba^{2+} (1-2mM) which blocks the postsynaptic, K^{+} dependent GABA_B receptors, decreased the amplitude of the OT evoked EPSPs. Thus in addition to the regulation taking place through interneurone-interneurone and perigeniculate neuron-interneurone synapses, dLGN interneurons are capable of controlling GABA release by negative feedback mechanisms through presynaptic GABA_B receptors. Moreover, GABA_B receptors on the OT terminals might regulate glutamate release. This negative control of glutamate and GABA release by presynaptic GABA_B receptors will be of major importance during visual processing *in vivo* owing to the high firing rate of retinal afferents.

VISUALLY EVOKED BURST DISCHARGES IN CAT LGN CELLS: SPATIAL AND TEMPORAL TUNING. S.M. Sherman, S.-M. Lu, and W. Guido, Dept. of Neurobiology, SUNY, Stony Brook, NY 11794-5230.

LGN cells display voltage-dependent, low threshold (LT) spikes, which are large depolarizations due to an increased Ca^{2+} conductance. Typically riding the crest of each is a burst of 2-7 action potentials. *In vitro* studies show that, once initiated, LT spikes may continue spontaneously at roughly 6 Hz, signaling a *burst discharge mode* that may interfere with retinogeniculate transmission. This differs from the *tonic discharge mode*, during which LT spikes are inactivated. We now extend our preliminary *in vivo* observations that LT spikes do not necessarily interrupt retinogeniculate transmission. From intracellular recording, we found that bursts of action potentials with interspike intervals ≤ 4 msec occur only during LT spikes, so we could recognize these events extracellularly. We thus recorded extracellular responses from cat LGN cells to drifting, sinewave gratings that varied in spatial frequency, temporal frequency, and contrast. We separately resolved the total responses into those due to more tonic responses and those limited to bursts. Among our sample, burst responses represented a variable proportion of the total response, from practically zero for some cells to the majority of the response for others. Y cells tended to display more visually-evoked bursts than did X cells. The spatial and temporal tuning functions were indistinguishable between tonic and burst responses, indicating that bursts clearly can be stimulus-evoked. No differential temporal tuning existed between the burst and tonic responses, suggesting that any rhythmic firing due to LT spiking does not contribute noticeably to these responses. We also found no difference between tonic and burst discharges in contrast response functions. We conclude that LT spikes are visually-evoked and may be a component of useful retinogeniculate transmission that helps to amplify signals while a cell is relatively hyperpolarized. FEEDBACK FROM V1 IMPROVES THE ABILITY OF MONKEY LGN NEURONS TO DISCRIMINATE AMONG PICTURES. J. W. McClurkin, L. M. Optican, B. J. Richmond. Laboratory of Sensorimotor Research, National Eye Institute, and Laboratory of Neuropsychology, National Institute of Mental Health, Bethesda, Maryland 20892.

Cooling the striate cortex (V1) altered the magnitude and temporal properties of the responses of lateral geniculate (LGN) neurons. Cooling V1 also reduced the average information transmitted by LGN neurons about 16 black-and-white pictures presented at each of 9 luminance pairs. We related the change in the responses to the change in transmitted information to elucidate the influence of cortical feedback on the LGN.

The responses of LGN neurons are multivariate and can be represented as points in a 3-D space. Neuronal codes for the picture parameters of pattern and luminance can be represented by 2-D planes fit to sets of points lying in this space. The variance of the points from the planes represents the noise in the code.

Transmitted information would be reduced if either the noise in the codes increased or the difference between the codes decreased. If cooling V1 increased the noise in LGN codes, we would expect the planes representing heavily affected parameters to fit the data less well than planes representing unaffected parameters. However, there was no relationship between the fits of the planes and changes in transmitted information. Rather, cooling changed the orientations of the planes representing the affected parameters.

We hypothesize that the role feedback from V1 is to improve the ability of LGN neurons to discriminate among pictures by increasing the difference between their temporal codes. The basis for this increased differentiation may be visual information from neighboring retinal locations that is fed back to LGN neurons from V1.

SPATIAL FREQUENCY AND ORIENTATION DOMAIN SUBSTRUCTURE TO THE FEEDBACK FROM THE VISUAL CORTEX TO THE LATERAL GENICULATE NUCLEUS. J. Cuddeiro*, A. M. Sillito & P. C. Murphy. Dept. of Visual Science, Institute of Ophthalmology, London.

The dorsal lateral geniculate nucleus (dLGN) in the cat receives a major projection from layer VI cells in the visual cortex. This projection can enhance inhibitory interactions in dLGN cell fields (Murphy and Sillito 1987, Nature 329: 727-729) and hence provides the potential for an orientation sensitive influence on mechanisms in the dLGN. Utilising a visual stimulus (drifting grating) subdivided into an inner window located over the receptive field centre and an outer window, we have examined the effect of varying the orientation alignment and spatial frequency of the two components on dLGN cell responses. The orientation and spatial frequency of the inner and outer stimuli were varied independently and when in alignment they appeared as a grating moving over the field.

For non-endstopped cortical cells tested with this stimulus, the orientation aligned condition produced the largest responses. In dLGN cells, the converse applied, when the stimulus was in alignment the smallest responses were observed. For any given dLGN cell the sensitivity to the aligned condition appeared to apply for any given orientation of the whole stimulus. Effects of orientation alignment were greatest when spatial frequencies in the inner and outer windows matched and were in the range 0.1 - 0.5 cycles/degree. These data match the effects that would be predicted from the action of the stimuli used on layer VI cell responses. They suggest the feedback may serve to enhance the sensitivity of the dLGN field to discontinuity between stimulus components moving over centre and surround mechanisms.

EFFECTS OF STIMULUS ORIENTATION ON SIGNAL TRANSMISSION THROUGH THE LGN. Y. Chino, E.L. Smith III, H. Cheng*, and A. Langston*. College of Optometry, University of Houston, Houston, TX 77204-6054.

The mammalian lateral geniculate nucleus (LGN) regulates signal transmission from the retina to the visual cortex in a highly complex manner. Besides the non-specific effects associated with an animal's arousal level, local mechanisms appear to gate visual information in a stimulus-dependent manner. Because the majority of LGN neurons exhibit a substantial orientation bias, we investigated the effects of stimulus orientation on LGN signal transmission. We recorded extracellular action potentials from single LGN neurons and their S-potentials (their retinal inputs) in anesthetized and paralyzed cats. Responses were measured for drifting sinusoidal gratings that varied in spatial frequency and/or orientation. We found that the transmission ratio, defined as the firing rate of an LGN relay cell divided by that of its S-potential, was highest at the optimal stimulus orientation. Furthermore, the transmission ratio at all orientations was directly related to the firing rate of the LGN neuron. Therefore, our results provide additional evidence for the hypothesis that LGN relay cells can act as non-linear spatio-temporal filters. Supported by NIH R01-EY08128, R01-EY03611 and P30-EY07551.

CONTRIBUTION OF GENICULATE MECHANISMS TO THE GENERATION OF LENGTH TUNING IN THE VISUAL CORTEX. H.E. Jones & A.M. Sillito. Dept. of Visual Science, Inst. of Ophthalmology, Judd St, London WC1H 9QS, UK.

Although length tuning is conventionally regarded as a higher order cortical property, some reports have indicated that dLGN cells also exhibit length tuning. To explore this issue, we examined the responses of cat dLGN cells to stimuli routinely used to assess cortical length tuning. The majority of dLGN cells were highly length tuned (mean 71%, n = 186) with many cells showing a degree of length tuning that matched or surpassed that seen in tightly tuned cortical hypercomplex cells. These data suggest that cortical length tuning may merely reflect the dLGN input, and that interactions in the dLGN play a major role in generating length tuning in the visual cortex.

A component of dLGN length tuning arises from centre-surround interactions in the retina and from the enhanced surround generated in the dLGN through GABAergic inhibitory mechanisms. However, our data indicate that strength of surround antagonism and length tuning are not always correlated. It seems that a significant component of dLGN length tuning derives from a corticofugal drive to geniculate inhibitory interneurons, which could be mediated via intrinsic dLGN or PGN interneurons. The interneurons might be expected to show rapid spatial summation for lengths over which the decline in relay cell responses occur, to be non-endstopped and to be strongly driven by their corticofugal input. To dissect out whether PGN cells are involved, we have compared their length tuning curves in the presence and absence of corticofugal feedback. While the tuning profiles of many PGN cells appear suited to generating dLGN length tuning, removal of the cortex did not provoke any obvious change in these profiles. Thus while PGN cells may well play a role in the subcortical generation of dLGN length tuning, they are unlikely to mediate the corticofugal component which is therefore most likely to be mediated via intrinsic inhibitory interneurons.

249.14

INHIBITORY AND EXCITATORY COMPONENTS TO THE SUBCORTICAL AND CORTICAL INFLUENCE OF LAYER VI CELLS IN THE CAT VISUAL CORTEX. K.L. Grieve*, P.C. Murphy & A.M. Sillito. Dept. of Visual Science, Inst. of Ophthalmology, Judd St, London WC1H 9QS. U.K.

Layer VI cells in the visual cortex provide a major corticofugal contribution to the synaptic input to the dLGN and send collaterals up to layer IV. Recent anatomical evidence suggests that the distribution of the corticofugal terminals from layer VI is biased towards the processes of inhibitory interneurons whilst the cortical terminals are biased to those of excitatory interneurons. We have explored the functional influence of layer VI cells at these two locations.

Pharmacological blockade of layer VI (iontophoretic application of GABA or muscimol) produced shifts in the properties of cells recorded in the overlying layer IV. These were commensurate with a reduction in an excitatory drive. In particular we noticed a selective decrease of responses to short stimuli in end-stopped layer IV cells. We were unable to detect any reduction in inhibitory influences underlying layer IV cell fields. Conversely, in the dLGN, elimination of the corticofugal influence reduced the response attenuation normally elicited when the length of a moving bar was increased so that it encroached on the receptive field surround. In the presence of corticofugal feedback attenuation of responses to a bipartite drifting bar were sensitive to the orientation alignment of the components crossing centre and surround, reinforcing the view that a component of the inhibitory drive derives from effects mediated via the cortical influence. Thus layer VI cells seem to exert a spatially organised influence on the translation of visual information into the cortex via a facilitatory mechanism in layer IV and an enhancement of inhibitory mechanisms in the dLGN.

249.16

THE INFLUENCES OF EYE POSITION ON THE RESPONSES OF X AND Y CELLS IN THE DORSAL LATERAL GENICULATE NUCLEUS OF THE AWAKE, BEHAVING CAT. S. Lehmkuhle and J.A. Baro. School of Optometry, University of Missouri-St. Louis, St. Louis, MO 63121

Recent work on the synaptic circuitry of cells in the dorsal lateral geniculate nucleus (dLGN) clearly demonstrates that information from retinal ganglion cells can be modulated in several ways. To begin to elucidate the modulatory functions of these neural circuits, we have measured the responses of cells in dLGN as a function of eye position in awake, behaving cats.

Cats were trained to fixate LED targets situated in front of a CRT display on which grating stimuli were presented. Scleral search coils recorded eye position. The eye position signal from the coil, via a sample and hold circuit, was used to displace the entire display horizontally and vertically on the CRT in concert with the movement of the eyes. Stimulus position was updated according to eye position at the 200-Hz frame rate of the display. Because the eyes were relatively stable due to fixation, and the 200-msec duration stimulus was stabilized on the retina, the phase of the grating within a receptive field could be precisely controlled. From these data, we classified cells as X or Y and quantified the effects of eye position on a variety of response measures. Response amplitudes and latencies of both X and Y cells varied with eye position.

LATERAL GENICULATE NUCLEUS (LGN) RESPONSE TO FLASH: CURRENT SOURCE DENSITY (CSD) AND PRINCIPAL COMPONENTS (PCA) ANALYSES. C.E.Tenke and C.E.Schroeder, Dept. Biopsych./ Psychophysiol., NYS. Psych.Inst., NY, NY and Dept. Neurosci., A.Einstein Coll.Med., Bronx, NY

The surface flash-VEP of the awake monkey arises largely from the activation of cortical regions. However, An early negativity (N25) may be traced from the frontolateral surface to the LGN, where it abruptly inverts in polarity within lamina 6. This inversion occurs in association with a sink/source configuration in the derived CSD profile. Although the superficial laminae of LGN appear to be crucial for the production of N25, multielectrode recordings through LGN indicate considerable concurrent activity in deeper laminae, much of which is not discernable above the LGN. Cancellation of this activity may occur locally, from closed field generators which are detectable only within a lamina. Alternatively, each LGN lamina may act as an open field generator whose contribution is largely cancelled by activity of opposite sign in superficial laminae. We explored these alternatives using two CSD methods: 1) CSD estimates computed directly from field potential profiles using a range of differentiation grids; 2) quasistationary CSD estimates computed from waveforms extracted by a PCA. Although considerable cancellation was seen within laminae using high resolution CSD profiles, the use of wider differentiation grids revealed regions of source and sink which summate across laminae without evidence of closed field artifacts. At the latency of the N25 peak, an effective sink extends throughout laminae 3-5, in association with a source in magnocellular laminae; a corresponding PCA factor showed the same pattern. Additional peaks, including oscillatory activity, also build within the parvocellular laminae. These findings support the second alternative, and extend the applicability of VEP techniques to the study of LGN physiology. (Supported by MH36295 and MH06723)

AUDITORY AND VESTIBULAR HAIR CELLS: ULTRASTRUCTURE, REGENERATION AND TUNING

250.1

SIMILAR FREQUENCY RESPONSES FROM FIBERS INNERVATING MORPHOLOGICALLY DIFFERENT PARTS OF THE LATERAL LINE SYSTEM IN AN ANTARCTIC FISH. S. Coombs and J.C. Montgomery*, Parml Hearing Institute, Loyola Univ., Chicago, IL. 60626 and Dept. of Zoology, University of Auckland, Auckland, NZ.

Extracellularly-recorded responses to a sinusoidally vibrating sphere (6 mm in diameter) were obtained from both anterior and posterior lateral line nerve fibers innervating different canals on the head and trunk of the antarctic nototheniid fish, *Trematomus bernacchii*. Despite large regional variations in anatomical dimensions known to affect the biomechanics of the system, fibers innervating different regions showed remarkably similar frequency responses. In response to stimuli of equal pk-pk acceleration levels, all fibers had (1) maximum responsiveness in the range between 10 and 45 Hz that was nearly flat and independent of frequency and (2) a decline in responsiveness that began around 45 Hz and continued at the rate of around 18 dB/octave. Attempts to model the filtering effects of the different sized canals and cupulae indicate that all morphologies predict the flat, low frequency portion of the neural response function, but quite a wide range of high frequency cut-offs that are well above those measured from single fibers. These results suggest that (1) there may be considerable variability in the morphology with little consequence for function and (2) there are additional filters between the cupula and primary afferent fibers.

250.3

IMMUNOHISTOCHEMICAL LOCALIZATION OF CALCIUM BINDING PROTEINS IN AUDITORY HAIR CELLS OF THE BARN OWL AND THE CHICKEN. C. Hue and C. E. Carr, Univ. Maryland, Dept. Zoology, College Park, MD 20742

Calbindin-28kD has been found in the chick cochlea (Oberholtzer et al, 1988) and calbindin-28kD and calmodulin have been localized to bull frog hair cells (Shepherd et al, 1989). These studies have characterized the calcium binding proteins from isolated hair cells and stereocilia. We describe the distribution of calcium binding proteins over the basilar papilla. The avian basilar papilla has two hair cell types, tall hair cells and short hair cells (Smith et al, 1985). Short hair cells are thought to receive primarily efferent innervation, while tall hair cells are innervated mainly by afferent fibers.

Immunohistochemical techniques were used on tissue sections as well as whole basilar papillae to determine if calcium binding proteins were differentially distributed in the different hair cell types. Both monoclonal and polyclonal antibodies against calbindin and calretinin, parvalbumin and S-100 were used.

Calbindin-like immunoreactivity labels both short and tall hair cell bundles and cuticular plates. The antibodies also labelled some ganglion cells, nerve terminals and axons, but did not stain supporting cells.

Parvalbumin-like immunoreactivity reveals a gradient of label across the basilar papilla. The hair cell bundles and cuticular plates of the short hair cells were more darkly stained than those of the tall hair cells. Some nerve terminals, ganglion cells and axons were also immunoreactive.

Thus short hair cells may be differentiated from tall hair cells on the basis of calcium binding protein immunoreactivity.

250.2

ULTRASTRUCTURAL COMPARISON OF STRIOLAR AND EXTRA-STRIOLAR HAIR CELLS OF FISH UTRICLE, J. Chang* and A. N. Popper, Dept. of Zoology, Univ. of Md., College Park, MD 20742.

Different types of vestibular hair cells have been characterized from striolar region and extra-striolar region of fish utricle using EM 3D computer reconstruction technique.

The results showed that fish inner ears have type I like and type II like hair cells. Type I hair cells (striolar cells) restrict to the striolar region while type II hair cell (extra-striolar cells) locate in extra-striolar regions. Its ultrastructural difference correlates to our recent finding on calcium binding protein immunoreactivity, trigger zone like membrane activity, and gentamycin toxicity. This study suggests that the two types of hair cells as transducers may produce different types of information by releasing presynaptic vesicles at different frequencies. They may have different intracellular mechanisms involved in intracellular calcium activity as well.

In addition, the ultrastructural characteristics of the two types of cells resemble the type I and type II hair cells in mammals. These findings suggest that the two types of hair cells evolved as early as in piscine species.

COMPARTMENTAL MODELS OF CURRENT FLOW IN RAT VESTIBULAR CALYCEAL AND NERVE BRANCH PROCESSES USING 3-DIMENSIONAL RECONSTRUCTIONS FROM ELECTRON MICROGRAPHS OF SERIAL SECTIONS.

T.C. Chimento, D.G. Doshay*, and M.D. Ross*. NASA, Ames Research Center, Mountain View, CA 94035

As the first stage in the development of computational models of the rat vestibular macula, current flow within single primary afferents is being simulated. This work is focused on the flow of current within collateral-like processes of calyces and nerve fiber branches that are either pre- or postsynaptic to type II hair cells. Detailed morphometrics and synaptic areas of processes are obtained from electron micrographs of serial sections cut at 20 nm. The models simulate current flow with both passive and active membranes using NEURON, generously provided by Michael Hines, Duke U. Med. Center. We are testing the hypothesis that small changes in morphology produce significant changes in the current at the base of afferent processes, with corresponding changes in the total current reaching the spike initiation zone. Similarly, the hypothesis is that morphological variations in efferent-type processes determine whether transmitter release will occur for a given depolarization of the calyx. For example, resistance is so high in some small diameter stems that the heads are effectively decoupled from the calyx or nerve branch, indicating that local processing could occur in the network. These results demonstrate that morphometric details that can be resolved only at the EM level have large effects on the current at the output end of the process and thus upon simulations of the functioning network. This work was supported by NASA and the National Research Council.

HAIR CELL REGENERATION IN THE LATERAL LINE: IDENTIFICATION OF PROGENITOR CELLS AND LINEAGE RELATIONSHIPS. J.E. Jones and J.T. Corwin. Dept. of Neuroscience and Dept. of Otolaryngology-HNS, University of Virginia Sch. of Medicine, Charlottesville, VA 22908 USA.

As a step toward understanding mechanisms that underlie the regeneration of sensory hair cells in the ear, we have used lateral line hair cell epithelia as models for determining the lineage relationships of the cells that give rise to replacement hair cells. Two types of injury to the system were used in anesthetized salamanders, *Ambystoma mexicanum*. The responses evoked by each were observed during nearly continuous time-lapse video microscopy until hair cells had been regenerated, usually over the course of one week.

In the first experiments, amputation of a segment of the tail that contained lateral line neuromasts stimulated macrophage activity and a dramatic increase in proliferation of mantle-type supporting cells at the posteroventral edge of the posterior-most neuromast of the tail stump. The new cells continued to divide and migrated posteriorly as the regenerative placode. Their progeny ultimately differentiated to form replacement neuromasts.

In a second series of experiments, a UV laser microbeam was used to individually kill all pre-existing hair cells in one neuromast, leaving a sensory epithelium that contained only supporting cells. Replacement hair cells were regenerated during time-lapse recording in the week following the laser treatment. In some cases replacement cells differentiated directly from cells that were present in the epithelia immediately after the laser treatment. In other cases, cells went through one or two divisions prior to the differentiation of one daughter as a hair cell. These results suggest that cell differentiation during replacement of sensory hair cells in the lateral line depends both on cell lineage and on cellular response to environmental or positional cues.

CURRENT-CLAMP RESPONSES OF VESTIBULAR HAIR CELLS. A.J. Ricci¹, C.H. Norris, P.S. Guth Departments of Otolaryngology, Pharmacology and the Neuroscience Training Program, Tulane University, New Orleans, LA 70112

The whole-cell patch configuration was used to record from frog semicircular canal hair cells. A current-clamp protocol was used that stepped in both positive and negative directions from the zero-current level, in an attempt to measure the cell's physiologic voltage responses to a variety of stimuli. Three types of hair cell voltage responses were observed. The first type responded in a relatively ohmic fashion to both depolarizing and hyperpolarizing steps. The second type showed large voltage shifts in the hyperpolarizing direction that tended to relax with time. The depolarizing direction was ohmic with small voltage changes. The third type of cell produced major non-linear voltage changes in both depolarizing and hyperpolarizing directions. Both responses tended to relax with time. These results suggest that vestibular hair cells have different proportions of channel types. They also suggest that an active conductance is present at rest. A comparison and characterization of voltage-clamp responses will be given. This work was supported by PHS grant DC303.

250.6

REGENERATIVE CELL PROLIFERATION IN ORGAN CULTURES OF THE MATURE AVIAN COCHLEA. M.E. Warchol, C. Laverack^{*}, and J.T. Corwin. Dept. of Otolaryngology-HNS and Dept. of Neuroscience, University of Virginia School of Medicine, Charlottesville VA 22908 USA.

Sensory hair cells in the avian cochlea are regenerated after acoustic trauma or aminoglycoside toxicity *in vivo*. Regeneration appears to result from renewed proliferation in an otherwise mitotically quiescent cell population within or near the sensory epithelium. We are attempting to conclusively identify the progenitor cells and the signals that lead to this renewed mitosis by experimentation in an organ culture preparation of the avian cochlea.

The chick cochlea is anatomically mature at hatching. Cochleae from 7- to 14-day-old chicks are removed to Hank's balanced saline under sterile conditions. The tegmentum vasculosum and lagena are dissected away and the remaining sensory epithelium is transferred to a collagen coated culture well containing 50 μ l of medium (80% Medium-199, 20% fetal bovine serum). The well is sealed in a Rose chamber to allow microscopic visualization of the sensory epithelium. Normal hair cell morphology can be maintained under these conditions at 37° C for at least five days.

Approximately 50 adjoining hair cells near the distal tip of the cochlea are individually lesioned using a UV laser microbeam. Immediately following lesioning, ³H-thymidine (1 μ Ci/ml) is added to the culture medium. After 24 hr of incubation with ³H-thymidine, specimens are fixed for autoradiography. Near the lesion sites labeled supporting cells are found within the sensory epithelium. A lesser number of labeled supporting cells are found at locations away from the lesions. Labeling is also common among cells located just outside the inferior edge of the sensory epithelium. The onset time of the proliferative response following lesioning is currently being determined.

(Supported by an NRS to M.E.W. and NIDCD and DRF grants to J.T.C.)

250.8

RECOVERY OF THE MAMMALIAN ORGAN OF CORTI AFTER LASER MICROBEAM ABLATION OF EMBRYONIC HAIR CELLS. M.W. Kelley, C.M. Laverack^{*}, and J.T. Corwin. Dept. of Otolaryngology - HNS and Dept. of Neuroscience, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Loss of hair cells from the adult mammalian cochlea results in the formation of epithelial scars that are believed to be permanent. It has been suggested that recovery of the organ of Corti following hair cell loss may be constrained by its complex cytoarchitecture. In light of this, we felt that at earlier stages in development more complete recovery might occur.

To test this hypothesis, cochleae were dissected from embryonic (E15 - E20) or neonatal (P0 - P3) mice and maintained *in vitro* using a modification of the Sobkowicz technique. Individual hair cells were ablated using an ultraviolet laser microbeam. The response to ablation of different numbers of hair cells was assessed through DIC microscopy, phalloidin staining of filamentous actin, and tritiated thymidine labelling of proliferative cells.

After lesioning of hair cells in neonatal (P0 - P3) cochleae, cells migrated into the lesion sites from the greater epithelial ridge (GER). Proliferative cells were observed adjacent to some lesion sites and in several cases were located in or near the sensory epithelium, but recovery was also observed without proliferation. In control regions, no proliferative cells were observed in either the GER or the sensory epithelium. Preliminary data from E16 cochleae indicate that hair cell lesions made at this stage are completely repaired in 24 to 48 hours. No proliferation was observed during these repairs.

Prior to maturation of cytoarchitecture, the organ of Corti is capable of self-repair. In addition, the observed replacement of ablated hair cells suggests that differentiation of cells as hair cells is a function of the cell's response to environmental cues rather than an autonomous determination of cell fate.

250.10

FREQUENCY SELECTIVITY AND ITS DEPENDENCE ON SOURCE LOCATION IN THE FROG. T.D. White¹, B. Schmitz^{2*}, and P.M. Narins¹. ¹Dept. of Biology, Univ. of California, Los Angeles, CA 90024 and ²Fakultät für Biologie, Universität Konstanz, Postfach 5560, D-7750 Konstanz 1, FRG.

The directional characteristics of hearing in the leopard frog (*Rana pipiens*) were investigated by obtaining frequency threshold curves (FTCs) from nerve fibers of cranial nerve VIII. Three populations of neurons were identified: low-frequency sensitive (LFS, 63-500 Hz), mid-frequency sensitive (MFS, 720-1199 Hz), and high-frequency sensitive (HFS, 1404-2177 Hz). In LFS neurons, the characteristic frequency (CF) did not vary significantly with speaker azimuth but thresholds at the CF were least sensitive when obtained from the anterior field and most sensitive from the posterior field. For MFS neurons, the posterior field produced FTCs with CFs significantly higher (0.16 octave) than the anterior field. CFs obtained from HFS neurons with ipsilateral stimulation were significantly lower (-0.29 octave) than those from the anterior field. Differences in frequency selectivity were attributed to acoustic transmission through extratympanic pathways. NIH #DC00222 to PMN.

DOWN-REGULATION OF CELL PROLIFERATION IN THE AVIAN VESTIBULAR EPITHELIUM. P. Weisleder and E.W. Rubel. Hearing Devel. Labs., RL-30, U. of Washington, Seattle, WA 98195.

A low, ongoing level of cell proliferation and hair cell differentiation has been described in the intact vestibular epithelium of postnatal chicks and adult budgerigars. Recent studies in our laboratory have demonstrated that the rate of proliferation increases following streptomycin toxicity. In the present study we sought to determine if VIIIth-nerve activity blockade influences the amount of cell proliferation following aminoglycoside damage.

Ten, two-week old chicks received daily injections of streptomycin for 5 days. On the sixth day, five animals had a tetrodotoxin-impregnated (TTX) Elvax (a plastic polymer) -bead placed in the oval window of one ear. The other five animals were implanted with beads not containing TTX. Beginning two hours later, the animals received four bi-hourly injections of the cell proliferation marker, bromodeoxyuridine (BrdU). Following the last BrdU injection, the animals were sacrificed; the cristae ampullaris were dissected, embedded in plastic, and every fourth section was processed for BrdU-immunocytochemistry.

A ratio, derived by dividing the number of labeled cells by the number of sections analyzed, was obtained for each organ. The tissue obtained from ears that were not exposed to TTX consistently had 30% more BrdU-positive nuclei than tissue exposed to TTX. These results suggest that silencing the VIIIth-nerve reduces the pace at which the damaged avian vestibular epithelium replaces lost elements. Supported by DC00395 and Cora M. Poncin Foundation.

ELECTRON MICROSCOPIC LOCALIZATION OF ACETYLCHOLINESTERASE ACTIVITY IN THE RAINBOW TROUT INNER EAR. K.M. Khan¹, J.S. Hatfield², M.J. Drescher¹, and D.G. Drescher¹. ¹Laboratory of Bio-otology, Wayne State University School of Medicine, Detroit, MI 48201, and ²V.A. Medical Center, Allen Park, MI 48101.

The hair cells of the trout inner ear are morphologically similar to type II hair cells of the avian and mammalian vestibule. These cells are innervated by two kinds of nerve terminals. The nonvesiculated terminals are considered to be afferent, while the efferent endings contain numerous clear, round vesicles and a few that are dense-cored. Morphological features of the vesiculated terminals are similar to those of cholinergic endings present in the avian and mammalian inner ear. The aim of the present study was to characterize the efferent terminals in the rainbow trout inner ear sensory epithelia at the electron microscopic level, by histochemical localization of acetylcholinesterase (AChE) activity. Tissues were fixed in 2% paraformaldehyde and 2.5% glutaraldehyde in 10⁻¹ M phosphate buffer, pH 7.2 for 2 h. All procedures were carried out at 2-4 °C. After a brief rinse in buffer, specimens were incubated according to the method of Karnovsky and Roots (J. Histochem. Cytochem. 12: 219, 1964). Eserine sulfate (an inhibitor of AChE and pseudocholinesterase) was added to the medium as control for nonspecific staining. Vesiculated endings in the cristae ampullares, and saccular and utricular maculae exhibited AChE activity. The reaction product was present on or adjacent to the plasma membranes of the efferent terminals. Nonvesiculated endings did not show any reaction product, except at presumed axodendritic synapses. No staining was observed in control specimens. In some instances the reaction product was not intense, perhaps caused by limited penetration of the incubation medium through the dense connective tissue associated with the basal surface of the sensory epithelia. These results suggest that the vesiculated nerve endings in the trout inner ear contain cholinergic elements. Supported by NIH grant DC 00156.

INFLUENCE OF ATP ON THE SEMICIRCULAR CANAL (SCC) OF THE FROG. A. Aubert^{*1}, C.H. Norris^{1,2} and P. S. Guth^{1,2}. Depts. of Pharmacology¹ and Otolaryngology². Tulane University, New Orleans, LA 70112

Ashmore and Ohmori (1990) and Shigemoto and Ohmori (1990) have shown that ATP induced an alteration of calcium processing in the cochlear outer hair cells. In an attempt to determine the possible role of ATP as a neuromodulator in the SCC, we have investigated the dose-responsive influence of disodium-ATP on the bioelectrical activities of the isolated SCC of the frog. At a concentration of 10⁻¹² M, disodium-ATP induced an increase of the spontaneous afferent activity while the evoked afferent activity was decreased. ATP caused a depolarization followed by a hyperpolarization of the transepithelial D.C. potential. The nerve direct current at rest and its variation during mechanical stimulation were decreased. These data imply the existence of ATP receptors in the SCC. The possible role of ATP and its receptors in the physiology of the SCC will be discussed. (Supported by USPHS grant # DC-00303)

ORGANIC Ca²⁺ CHANNEL BLOCKERS HAVE HIGHER POTENCY THAN K⁺ CHANNEL BLOCKERS IN BLOCKING K⁺ CONDUCTANCE IN THE ISOLATED OHCs OF GUINEA PIG. X. Lin^{*1}, R.I. Hume², A.L. Nuttall¹. Kresge Hearing Research Institute¹ and Department of Biology², University of Michigan, Ann Arbor, MI, 48109.

Many types of voltage-gated membrane conductances have been studied in the isolated outer hair cells (OHCs) of guinea pig. Under whole cell voltage-clamp, the dominant ionic current at depolarizing voltages is an outward K⁺ current. In this work, the potency of a variety of K⁺ and Ca²⁺ channel blockers in blocking this K⁺ conductance was investigated.

The whole cell voltage-clamp technique was used to study the voltage-dependent currents in isolated outer hair cells (OHCs) maintained in short-term culture. The pipette internal solution contained (in mM): KCl 134, MgCl₂ 2, NaCl 4, BAPTA 10, Hepes 10, Glucose 10, pH 7.4. The external solution had: NaCl 134, MgCl₂ 2, KCl 4, EGTA 1, Hepes 12.5, Glucose 10, pH 7.4. Ion channel blockers were applied by pressure ejection from a fine glass pipette (tip size 3µm) located near the OHC. The typical whole-cell current to clamped depolarizing voltages was an outward current which showed little inactivation at the end of a 200ms test pulse. The reversal potential and ion substitution tests both indicated that most of the current was carried by K⁺ ions. Pharmacological tests showed this current was reversibly suppressed by a variety of conventional K⁺ channel blockers. Surprisingly, organic Ca²⁺ channel blockers also blocked the K⁺ current, with even higher potency. The order of potency of these channel blockers was (estimated half maximum blocking concentration listed in the parentheses): nimodipine(10µM) > verapamil=D600(20µM) > nifedipine(100µM) > 4-AP(150µM) > quinidine(700µM) > TEA(5mM).

The ionic composition and strong Ca²⁺ buffers used in this experiment suggested that it is unlikely the effect of these organic Ca²⁺ channel blockers on the K⁺ current was mediated by a Ca²⁺ dependent K⁺ current. (supported by NIH DC00141)

THE DEVELOPMENT OF THE INNER EAR EFFERENTS IN MICE: A Dil AND AChE STUDY. B. Fritzsche and D.H. Nichols, Creighton Univ., Div. of Anat., Omaha, NE 68178

Three populations of cells in the brainstem provide efferent innervation to the vestibule, the outer, and the inner hair cells of the cochlea, respectively. We employed Dil in fixed tissue and AChE-histochemistry to analyze the time course of arrival of efferents at the ear, the segregation of fibers at the target and of the cells in the brainstem during development. At E11% we could label efferents retrogradely from the ear and we anterogradely labelled their fibers from the brainstem to the ear. At E 12% we could fill efferent fibers from one ear to the other ear where they reached all future sensory epithelia. AChE-histochemistry showed a continuous band of cells from the ventricle to the meninges between E 11% and E12% suggesting migration at that time. At E 14 the distribution of olivocochlear efferents as revealed with Dil gave no indication of a segregation into the two adult subsystems but the numbers of retrogradely labelled cells were already approaching known adult values and distribution of all olivocochlear efferents (Campbell, J.P. & Henson, M.M., Her. Res. 35 (1988) 271). These data suggest that (1) the efferents reach the future sensory epithelia at the same time as afferents and around the time hair cells are born, i.e. much earlier than suggested using other techniques, (2) peripheral segregation may precede onset of migration of olivocochlear neurons, and (3) the sorting of the two subpopulations of olivocochlear neurons (LSO and MSO) is a late ontogenetic event.

GLUTAMATE DECARBOXYLASE AND GABA-TRANSAMINASE LOCALIZATION IN THE GUINEA PIG VESTIBULE. IMMUNOCYTOCHEMICAL SUPPORT FOR AN AFFERENT GABAERGIC NEUROTRANSMISSION.

*I. LOPEZ(1), J.-Y. WU(2) and G. MEZA(1). Dept. of Neurosci. IFC UNAM, México., 04510(1) and Dept. of Physiol and Cell Biol. The Univ of Kansas, Lawrence KS, USA(2)

In a recent report a GABA-like immunoreaction in the guinea pig vestibular hair cell and adjacent fibers was demonstrated(1). In order to investigate the source and fate of this GABA pool, pre and postembedding techniques were used to study the localization and distribution of glutamate decarboxylase (GAD) and GABA-Transaminase (GABA-T) (enzyme of synthesis and degradation of GABA respectively) in the guinea pig vestibule. Animals were perfused with a mixture of aldehydes, the vestibular organs were dissected, dehydrated and embedded in paraffin. Vestibular cristae sections were incubated with either GAD or GABA-T antisera and processed for pre and postembedding immunoperoxidase staining. GAD-like immunoreactivity was found in both type I and II hair cell cytoplasm, whereas GABA-T-like immunoreactivity closely followed GABA distribution being found in the calyx, some nerve fibers and ganglionic cells. These results show that GABA is synthesized in the hair cell cytoplasm and after its release and action upon its receptor is degraded by the afferent fiber, thus strongly supporting its afferent neurotransmitter role in the vestibule. 1.- López, I. et al (1990) Brain Res. 170-175.

CHOLINERGIC AND PURINERGIC RECEPTORS ARE NOT CO-LOCALIZED ON OUTER HAIR CELLS ISOLATED FROM THE GUINEA-PIG ORGAN OF CORTI. G.D. Housley¹ and J.F. Ashmore² Depts. of Physiology, ¹University of Auckland, New Zealand & ²University of Bristol, England.

It has been suggested that adenosine-5'-triphosphate (ATP) may act as a neuro-modulator of the cholinergic olivo-cochlear innervation to the outer hair cells (OHCs) of the mammalian cochlea (Nakagawa et al., J. Neurophysiol. 63:1068-1074, 1990). Using the whole-cell patch-clamp technique we have shown that acetylcholine (ACh) elicits a rapidly inactivating outward potassium current when applied by pressure injection from a fine glass pipette to a region around the basal pole of isolated OHCs (Housley & Ashmore, Proc. R. Soc. Lond. B. 1991, *in press*). These responses were highly variable (<+10pA to +678pA at a holding potential of -50mV, using 100µM ACh) and limited to cells shorter than 65µm. We have now used this procedure to study the effect of ATP and ACh on the same cell.

Our evidence suggests that purinergic receptors (P2) which produce an inward cationic current in OHCs are not co-localized with the nicotinic-like cholinergic receptors around the basal pole of OHCs. ATP (0.1 - 100µM) produced the largest inward currents with minimum onset latencies when applied to the apical region of all OHCs tested (n = 60), irrespective of cell length (19µm - 87µm). Using double-barrelled ejection pipettes, application (0.5 - 2s) of ACh (50µM) + ATP (10µM) to the base of the cells voltage-clamped to -60mV yielded outward current responses no different from using ACh (50µM) alone. This contrasted with the application of ACh + ATP to the apical region of these cells where an inward current (ATP response) was produced, ACh alone had no effect when applied here (n=4). There was no difference between the minimum onset latencies of ATP and ACh responses (approximately 30-60ms). VESTIBULAR OTOCONIAL MATRIX OF YOUNG CHICKS (*Gallus domesticus*). C.D. Ferrin and D. Martin. Dept. of Pathology, Tulane University Medical School. New Orleans, LA 70112-2699.

Otoconia or statoconia are microscopy calcite crystals (1-10 µm) located over the sensory epithelia of the inner ear organs that respond to gravitational forces. High resolution transmission electron microscopy, histochemical and biochemical assays demonstrated that the hexagonal crystals of the chick inner ear vestibular organs could be made up of intercalating fibrillar arrays that conform to mature crystal shape. Usually the crystals of hatchlings have angle of 115° and short face sides of >1 µm. Crystals treated with sodium hypochlorite and ultrasonic vibrations yielded submicroscopy subunits with similar angle value but <100 nm short face sides, indicating that each large crystal could be made up of interconnecting subunits. Previous work from this lab has shown that early in development, these crystals may be made up mostly of organic substances, including glycosaminoglycans. Potassium pyroantimonate staining, indicated that calcium is probably gradually added between the fibrils of the organic matrix. It is possible that after a certain critical period of development the organic components of the matrix are aligned in register with the calcic components in such a way that perfect hexagonal subunit crystals can be formed. Whether otoconia is recycled or not is still a mystery despite numerous works in several species. A permanent organic template (e.g. glycosaminoglycans and glycoproteins) could be selectively inactivated and also reactivated if necessary providing sufficient flexibility for crystal recycling and/or maintenance. Because of the exquisite homeostatic control of the endomyphatic environment where crystals reside this idea deserves further analysis. Regulation of Differentiation of Cultured Human Olfactory Neuroblasts. Trey Sunderland, B. B. Zheng*, H. Coon*, B. L. Wolozin. Lab. of Clinical Science, NIMH and Lab. of Genetics, NCI, Bethesda, MD 20892.

We are studying the regulation of differentiation of human olfactory neuroblasts grown in cell culture. We now report that TPA stimulation at 200 ng/ml for 24 hrs or 33 ng/ml for 48 hrs results in the extension of multiple long narrow processes. Immunocytochemical and immunoblotting experiments indicate a corresponding increase in the density of neurofilament and olfactory marker protein OMP staining. Immunoblots of tau protein however, shows no TPA induced increase. db-cAMP and IBMX (0.5 mM each) also promote process outgrowth though over a somewhat longer time course, requiring 24-48 hrs. This paradigm, however, did not elicit any increase in neurofilament or OMP immunoreactivity seen by immunocytochemistry. Immunoblots indicate that db-cAMP + IBMX elicits a small decrease in neurofilament and larger decrease in OMP reactivity. Because cAMP is implicated in the odorant transduction pathway, this reduction in neuronal immunoreactivity may represent a general down-regulation event. Growth factors, such as EGF and NGF, however, act via a cascade that includes protein kinase C. Hence, the TPA induced upregulation of neuroreactivity may mimic the stimulation of neuronal differentiation or axonal outgrowth by endogenous factors *in vivo* resulting in an upregulation of these elements.

VOMEROMODULIN, A NOVEL GLYCOPROTEIN OF LATERAL NASAL GLAND: A PUTATIVE PHEROMONE TRANSPORTER. M. Grillo¹, Y.S. Khew-Goodall², M. Geitchell³, W. Danho⁴, T. Geitchell², F.L. Margolis¹. ¹Dept. of Neurosciences, Roche Inst. of Molec. Biol., Nutley, NJ 07110. ²The Hansen Ctr. for Cancer Res., Adelaide, Australia. ³Dept. of Surgery & Sanders-Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY 40536. ⁴Peptide Res. Dept., Hoffmann-La Roche, Inc., Nutley, NJ 07110. ⁵Dept. of Physiol. & Biophys., Univ. of Kentucky, Lexington, KY 40536

Vomeromodulin, a novel glycoprotein of the lateral nasal gland, has been cloned by differential hybridization of a cDNA library from nasal/olfactory tissue. The 2.2kb mRNA directs the *in vitro* synthesis of a 60 kD primary translation product in reticulocyte lysates. Differential sensitivity to endoglycosidases indicates that vomeromodulin is post-translationally modified *in vivo* by N-glycosylation to form a 70 kD glycoprotein of the complex type. Immunocytochemical localization with two different antisera demonstrated that vomeromodulin is abundant in the lateral nasal glands and is also present in the posterior septal and vomeronasal glands. Most striking is the observation that it is highly concentrated in the mucus of the vomeronasal organ but is not detectable in the mucus of the main olfactory neuroepithelium. Evaluation of mRNA and protein distribution by Northern and Western analyses indicated that vomeromodulin is absent from 15 other tissues. The glandular and mucosal distribution of this glycoprotein implies a transport function that may be related to the mechanism by which pheromone molecules of low volatility gain access to their receptors in the vomeronasal organ. We propose that vomeromodulin participates in perireceptor events.

251.2

FINE-STRUCTURAL LOCALIZATION OF THE OLFACTORY TRANSDUCTION APPARATUS. B. Ph. M. Menco. Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208.

We localized important components of the olfactory transduction apparatus in chemosensory receptor cells and of some mucus regulating factors in olfactory supporting cells in the rat's olfactory epithelium. For most of the work we used rapid-freeze, freeze-substitution and post-embedding (in Lowicryl K11M) gold-label electron microscopic immunocytochemistry. G-proteins and adenylate cyclase act, together with among others cyclic nucleotide-gated channels, to transduce the olfactory signal. We used antibodies to Go_{1α} (Jones & Reed, *Science*, 244:790 (1989)), G_{sα} (Mania-Farnell & Farbman, *Devl. Brain Res.*, 51:103 (1990)) and Type III olfactory adenylate cyclase (Bakalyar & Reed, *Science*, 250:1403 (1990)). All three antibodies co-localized in majority in the same cellular compartment, i.e., antigens were mainly found in the long distal parts of rat olfactory cilia, suggesting that these regions are specifically modified to transduce, and most likely also receive, the olfactory message. Apical regions of olfactory supporting cells share several properties with apical regions of cells of transporting epithelia, in particular those of kidney collecting tubules (Brown, *Am. J. Physiol.*, 25:F1 (1989); Brown et al., *Am. J. Physiol.*, 25:F366 (1989); Tousson et al., *J. Cell Sci.*, 93:349 (1989)). Supporting cell microvilli labeled with antibodies to amiloride-sensitive sodium channels and, with light microscopy, their apices seemed also to bind antibodies to a proton pump. This suggests that these cells play a role in the maintenance of the mucous pH and sodium concentration around receptor cell cilia. Drs. Heather Bakalyar, Dale Benos, Steve Gluck, David Jones, and Randy Reed and their colleagues are thanked for sharing their antibodies. Supported by NSF grant BNS-809839.

251.4

DIFFUSION AND TRANSPORT OF ODORANTS AND TRACERS IN THE OLFACTORY MUCUS LAYERS OF THREE SPECIES OF SALAMANDERS. P. A. Moore, M. N. Friedemann, T. E. Finger +, G. A. Gerhardt. Departments of Pharmacology and Psychiatry, + Dept. of Cellular and Structural Biology, University of Colorado Health Science Center, Denver, CO 80262

Perireceptor events are important aspects of chemoreception. These include the movement of chemicals by turbulence and diffusion, the binding of odorants to transporter proteins and diffusion to receptor sites. In terrestrial olfaction, odor molecules must diffuse through a mucus layer before binding with receptor proteins and subsequently back through the mucus layer to be removed from the olfactory epithelium. Thus, the diffusion properties of molecules in mucus have remained relatively unknown. Using high speed *in vivo* electrochemical recordings coupled with local chemical application techniques, we have determined the apparent diffusion coefficients of dopamine (tracer) and several odorants, including vanillin, eugenol, and safrole, in the mucus layer covering the olfactory epithelium of the tiger salamander (*Ambystoma tigrinum*). In addition, diffusion coefficients were determined for both the marbled (*Ambystoma opacum*) and spotted salamanders (*Ambystoma maculatum*). Diffusion coefficients in the mucus (0.2 x 10⁻⁶ cm/s) were significantly slower than in solution (0.6 x 10⁻⁶ cm/s). In addition, these values were at least an order of magnitude slower than those previously used in theories and models. These studies are needed to understand the role that diffusion and transporter proteins play in determining the structure of chemical signals as they arrive at receptor cells.

Support by USPHS (AG00441) and NSF 2534920 to GAG.

251.5

EXPRESSION OF RAT OLFACTORY RECEPTORS IN XENOPUS OOCYTES. N. Dahmen*¹, H. Wang¹, T.V. Getchel², F.L. Margolis¹. ¹Dept. of Neurosciences, Roche Inst. of Molec. Biol., Nutley, NJ 07110. ²Dept. of Physiol. & Biophys., Univ. of Kentucky, Lexington, KY 40536

We demonstrate that ligand specific olfactory receptors are expressed by Xenopus oocytes following the injection of mRNA isolated from rat olfactory epithelium. Application of appropriate ligands activates stimulus-dependent transmembrane currents in the oocytes, measured under two-electrode voltage clamp recording, that reverse direction at the chloride equilibrium potential. The currents show characteristic secondary oscillations, that are assumed to reflect the underlying Ca²⁺ oscillations. Similar ligand activated membrane currents induced in oocytes after injection of other mRNAs have been shown to be due to Ca²⁺ dependent chloride channels. These are dependent on an intracellular rise of free Ca²⁺ that is released from intracellular stores by inositoltriphosphate. Mammalian olfactory signals therefore appear to be capable of being coupled not only through the well-established cAMP pathway, but also through the Ca²⁺/IP₃ pathway. Currently, we are using the Xenopus oocyte *in vitro* expression system as a tool for the identification of ligand specificity profiles of olfactory receptor molecules and for the expression cloning of these receptors.

Molecular Modelling of the Receptor-like Binding Sites in Monoclonal Antibodies to Intense Sweet Taste Ligands. Jerry M. Anchin and D. Scott Linthicum, Dept. Vet. Pathobiol., College of Veterinary Medicine, Texas A&M University, College Station, TX 77843-4467, USA

Knowledge-based computer-assisted molecular modelling of monoclonal antibodies is now feasible using a modelling protocol involving "canonical structures" from known crystallographic coordinates of empirically solved myeloma proteins and monoclonal antibodies. Modelling and energy minimization techniques permits the construction of interactive residues involved in ligand binding. In our study we examined the binding sites of monoclonal antibodies directed against intense sweet taste compounds derived from guanidines. The high potency of these sweeteners is useful for the identification of sweet taste epitopes which bind the antibody. These epitopes are probably important in sweetener-receptor interactions and molecular modelling of the antibody binding sites can reveal structural features and chemical interactions which may be similar to those postulated for the receptor site model. The use of antibody binding sites as a paradigm for taste receptor binding sites is an important concept in our understanding of ligand-receptor interactions. Detailed structure-activity relationships and molecular modelling studies of sweet taste ligands and receptors are important tools if valid comparisons are to be made. Supported by the Nutrasweet Co. Gig'em Aggies!

LOCALIZATION OF N-CAM AND N-CADHERIN IN THE FETAL HUMAN PRIMARY OLFACTORY PATHWAY. M.I. Chuah and C. Au*. Dept. of Anatomy, Chinese University of Hong Kong, Shatin, Hong Kong.

The cell adhesion molecule N-CAM has been shown to be present in the adult mouse primary olfactory pathway. Results from recent *in vitro* studies indicate that N-CAM, in addition to N-cadherin, mediates neurite extension from olfactory neurons cultured on astrocyte monolayers (Chuah et al. Developmental Brain Research, In press, 1991). In the light of this functional role, we have examined human olfactory epithelium and bulb for the presence of N-CAM and N-cadherin during a stage when there is extensive growth of olfactory axons into the bulb. Immunofluorescence staining was performed on olfactory tissues from fetuses of 17 1/2 to 21 weeks of gestation. Moderate staining for N-CAM on olfactory neurons and basal cells was observed while the most intense staining was present in the nerve bundles in the lamina propria. Immunoreactivity for N-CAM was slightly reduced as the nerve bundles approached the olfactory bulb. All layers of the olfactory bulb showed labeling for N-CAM although increased staining was generally found in the olfactory nerve and glomerular layers. For N-cadherin, the most intense labeling was found in the olfactory epithelium. The olfactory nerve axons also showed immunopositivity but the labeling decreased progressively as they reached their termination in the glomerular layer of the bulb. Some staining for N-cadherin was also found in the other layers of the bulb.

251.6

EXPRESSION OF CATFISH L-AMINO ACID OLFACTORY RECEPTORS IN XENOPUS OOCYTES INJECTED WITH *IN VITRO* TRANSCRIBED RNA. H. Wang¹, N. Dahmen*¹, K. Kodukula*¹, N. Yan*¹, J. Teeter² and F.L. Margolis¹. ¹Dept. of Neurosciences, Roche Inst. of Molec. Biol., Nutley, NJ 07110. ²Monell Chemical Senses Center, Philadelphia, PA 19104

We report the functional expression of catfish olfactory receptors in Xenopus oocytes injected with either isolated mRNA or with *in vitro* transcribed RNA. Catfish olfactory tissue contains high-affinity receptors for L-alanine (A) and L-arginine (R), which are odor stimuli for catfish. These L-amino acid olfactory receptors are coupled to phosphatidylinositol (PI) turnover through G proteins. Two electrode voltage-clamp recording of RNA-injected oocytes is being used to clone olfactory L-amino acid receptors. Oocytes injected with mRNA purified from catfish olfactory tissue were monitored by two electrode voltage clamp recordings. Superfusion of mRNA injected oocytes with A or R resulted in oscillating and outward rectifying membrane currents. A and R activated currents reversed direction at about the Cl⁻ equilibrium potential. This result is consistent with the hypothesis that A and R evoked Ca⁺⁺-dependent Cl⁻ currents of the oocytes by activating the endogenous IP₃-Ca⁺⁺ second messenger system. A cDNA library was constructed using the mRNA preparation responsible for expression of A and R receptors in the oocytes. RNA transcribed from a subpool of the cDNA library was injected into the oocytes. A and R stereospecifically evoked Ca⁺⁺-dependent Cl⁻ currents in these oocytes. Stepwise fractionation of this cDNA library subpool is in progress to isolate individual cDNA clones encoding the L-amino acid olfactory receptors.

251.8

ANATOMIC AND SPECIES DISTRIBUTION OF THE N-CAM GLYCOFORM RECOGNIZED BY MONOCLONAL ANTIBODY 1D9. M.J. Crowe & S.K. Pixley. Dept. of Anatomy & Cell Biology, Univ. of Cincinnati, Cincinnati, OH 45267.

We report here on the anatomic distribution of the antigen recognized by the monoclonal antibody (MAb) 1D9 in the olfactory epithelia (OE) of several species. The preparation and initial characterization of MAb 1D9 has been described (Neurosci. Abst. #466.13, 1988 & #364.10, 1990). The N-CAM character of the antigen was reported by Key & Akeson (Neuron, 6:381-396, 1991). Using coronal sections of E19 and P7 rat heads, we see a varied antigen distribution. In E19 tissues, 1D9 immunoreactivity (IR) is strongest in neuron-like cells in the vomeronasal organ and in taste buds. Both of these tissues have receptors sensitive to non-volatile compounds borne primarily within a fluid medium. No 1D9 IR is seen in the E19 main OE. In P7 rat OE, a subset of neurons within the main olfactory region is labeled. We examined an amphibian, Ambystoma tigrinum, to see if any differences between OE located at a tissue/air interface versus a tissue/fluid interface could be observed. The flat sheet of OE comprising the main part of the olfactory sac in the post-metamorphosed land phase (air-breathing) animal is labeled with MAb 1D9 specifically in a subset of cells with processes. The remnants of water phase OE, which are present in land phase animals, are completely labeled by 1D9. We then tested OE from the pre-metamorphosed water phase (gill breathing) A. tigrinum. In this animal, the main part of the olfactory sac is composed of folds of water phase OE with a small portion of the OE being flat and sheet-like. Again, a subset of olfactory cells is immunolabeled with MAb 1D9 in the flat OE, while all cells in the folds of water phase OE are strongly 1D9-reactive. In rat and A. tigrinum, MAb 1D9 appears to differentially label those sensory epitheliums dependent upon a tissue/air interface and those dependent upon a tissue/fluid interface. Supported by NIH DC00342 and DC00347.

THE GROWTH OF OLFACTORY NERVES IN EXPLANT CULTURES IS NOT INHIBITED BY CNS MYELIN. Albert I. Farbman and Judith A. Buchholz, Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208.

Transplantation experiments have shown that the olfactory nerve is unique in its ability to grow in all kinds of environments within the CNS (Morrison & Graziadei, 1983, Brain Res., 279:241). The CNS is not permissive for the growth of several other types of neuron, both central and peripheral, apparently because of the presence in CNS myelin of 2 proteins not present in PNS myelin (Caroni & Schwab, 1988, J. Cell Biol., 106:1281). We have made fresh frozen sections of adult rat cerebrum and cerebellum and placed them on polyornithine (PORN)-coated glass cover slips. Explant cultures of fetal rat olfactory sensory epithelium were grown on these cover slips, both on and off the sections. After 2-5 days *in vitro*, there was little difference in the amount of axonal outgrowth from explants in contact with the white matter, the grey matter, or the PORN substrate. The results suggest that olfactory neurons do not have the receptors that respond to the growth inhibitory proteins of CNS myelin.

Supported by NIH Grant # DC 00347.

GLOSSOPHARYNGEAL NERVE SECTION DOES NOT IMPAIR SALT TASTE DISCRIMINATION IN RATS. A. C. Spector and H. J. Grill, Dept. of Psychology, University of Florida, Gainesville, FL 32611 and Dept. of Psychology, University of Pennsylvania, Philadelphia, PA 19104.

Recent behavioral and electrophysiological findings suggest that the peripheral coding of taste qualities may, to some extent, be topographically organized. We have previously shown that rats trained to discriminate potassium chloride (KCl) from sodium chloride (NaCl) across a concentration range show severe performance deficits at this task following deafferentation of the anterior tongue by section of the chorda tympani nerve (removes 15% of the total taste buds). The present study demonstrates unequivocally that the glossopharyngeal nerve (Gln), which innervates the posterior tongue (65% of the total oral taste buds), is not necessary to maintain performance in the KCl vs NaCl discrimination task. Eight water-deprived Sprague-Dawley rats were trained in a specially-designed gustometer to maintain licking during brief presentations (5 sec) of one taste stimulus (S-) and to avoid licking a second tastant (S+). Rats were trained (counterbalanced) to respond one way to KCl (0.05, 0.10, 0.20 M) and another way to NaCl (0.05, 0.10, 0.20 M). On S+ trials, if the rat did not suppress licking during the latter 3 sec of the 5 sec trial it received a brief footshock. On S- trials, if the rat suppressed licking during the latter 3 sec of the trial, the rat received a 30 sec time-out further delaying the next fluid trial. Stimuli were presented randomly during 60 min sessions. Rats easily learned this discrimination. Next, half of the rats received bilateral sections of the Gln and the other half served as full surgical controls. Postsurgical assessment of their discrimination performance revealed no deficit. These findings suggest that different oral receptive fields provide differential contributions to the peripheral signals characterizing various chemical stimuli. OLFACTORY FUNCTION FOLLOWING PERIPHERAL OLFACTORY LESIONS. S.L. Youngentob and J.E. Schwob, Departments of Physiology, Anatomy and Cell Biology, and the Clinical Olfactory Research Center, SUNY Health Science Center, Syracuse NY 13210.

Several investigators have demonstrated that the olfactory epithelium has a remarkable capacity to recover anatomically following experimentally induced lesions. However, there is a paucity of information regarding the degree of functional recovery. Therefore, the present study was undertaken to assess functional recovery, as defined by psychophysical techniques, following lesions that induce the cycle of neuronal degeneration, epithelial reconstitution and axonal reconnection with the bulb. Long-Evans rats were trained to criterion (>90% correct) on a five odorant identification task and then lesioned by intranasal infusion with ZnSO₄ or by exposing them to 330 ppm MeBr gas for 6 hrs. Animals were randomly allocated into either the 3 day survival or full behavioral recovery group. For each animal the anatomical state of the olfactory epithelium was evaluated relative to behavioral performance on the odorant identification task (see also Schwob and Youngentob, this meeting). The results of this study demonstrated for the first time that the reconstituted olfactory epithelium preserves the coding of odorant quality. Furthermore, restoration of behavioral function is supported by less than complete anatomical recovery. Supported by NIH DC00220.

GNRH IMMUNOREACTIVE SOMATA IN THE PERIPHERAL AND CENTRAL OLFACTORY SYSTEM OF ATLANTIC SALMON (*SALMO SALAR*): A LIFE HISTORY ANALYSIS. G.A. Nevitt, M.S. Grober and A. Bass. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York, 14853.

Salmon are known for their ability to imprint and home to the stream in which they were spawned in order to reproduce. Behavioral studies have demonstrated an olfactory basis for home stream recognition (Scholz, *et al.*, 1976). Changes in olfactory receptor cell sensitivity have also been linked to behavioral imprinting (Nevitt and Moody, 1989). However, the potential role that hormones play in establishing these changes is unknown. The present study is the first in a series designed to identify possible sites of hormone modulation in the peripheral olfactory system of salmonids. Because of its established localization to the terminal nerve ganglion and putative involvement with olfaction, initial studies have focused on gonadotropin releasing hormone (GnRH).

Using a monoclonal antibody to salmon GnRH, GnRH-like immunoreactive somata were identified within four regions of the olfactory system of early life stage animals (fingerlings, parr and smolts): 1) the medial component of the olfactory nerve as it immediately arises from the olfactory epithelium, 2) the entire rostro-caudal extent of the olfactory nerve, 3) the peripheral layers of the olfactory bulb, and 4) the lateral preoptic area. Prior to this study, GnRH positive somata have not been reported anterior to the olfactory bulb in salmonids. Preliminary analysis suggests a similar distribution of these cells between all three life stages, and studies will continue as fish mature into adults. These data provide new morphological evidence for the potential role of GnRH in modulating olfactory receptor cell function at multiple life history stages. RECONSTITUTION OF THE OLFACTORY EPITHELIUM AND RE-INNervation OF THE OLFACTORY BULB AFTER METHYL BROMIDE LESIONS. J.E. Schwob and S.L. Youngentob, Depts. of Anatomy and Cell Biology, Physiology, and the Clinical Olfactory Research Center, SUNY Health Sci. Ctr., Syracuse, NY 13210.

In adult animals, the olfactory epithelium has some capacity to recover from direct injury by generating a new population of sensory neurons. However, the timing and degree of neuronal recovery is poorly characterized. We have been examining the reconstitution of the epithelium of adult rats following lesions induced by a single inhalation exposure to methyl bromide gas (330 ppm X 6 hr). A variety of immunohistochemical markers for immature (e.g., anti-GAP-43) and mature (e.g., anti-OMP) olfactory neurons and their axons have been used. In addition, the status of the axonal projection of the newly born neurons onto the bulb was assessed (1) by anterograde transport of WGA-HRP, to identify when the bulb had been re-innervated, and (2) by immunohistochemical staining with the monoclonal antibody RB-8, to selectively mark axons that derive from the ventrolateral olfactory epithelium. We find that the epithelium recovers in thickness by 2 weeks after lesion, but at this time it contains mostly immature neurons. The normal balance between immature and mature olfactory neurons is not struck until 6 weeks post exposure. By comparison, reinnervation of the bulb begins as soon as 1 week after MeBr, and is largely complete by 4 weeks. The newly formed axonal projection recapitulates the restricted spatial distribution revealed by the RB-8 antibody in normal rats. That is, after recovery, axons from the ventrolateral epithelium reinnervate the ventrolateral bulb. In conclusion, the adult primary olfactory projection has the capacity for virtually complete anatomical recovery after MeBr lesions. Supported by DC 00467 and DC 00220.

CONVERGENCE IN THE VOMERONASAL AND MAIN OLFACTORY SYSTEM OF NEONATAL AND MATURE MAMMALS AND ITS RELATION TO SENSITIVITY. Essie Meisami, Physiol. Dept., Univ. of Illinois, Urbana, IL 61801.

The high convergence of receptor neurons to central relay cells in the olfactory system is believed to be a basis for high olfactory sensitivity. To compare sensitivity between the main olfactory and vomeronasal systems and to predict postnatal changes in sensitivity in the two systems, we determined the number of receptor neurons in the olfactory epithelium and vomeronasal organ and the number of mitral cells in main and accessory olfactory bulbs of newborns and neurologically mature weanlings of rat, hamster and rabbit. From these numbers we obtained the convergence ratios at each age and for the various animals. In the main olfactory system of all three species, the convergence ratio was found to increase postnatally by 5 to 10 folds, mainly due to increase in the number of receptor neurons, reaching maximum values of 1000:1. Compared to the main olfactory system, the adult's vomeronasal convergence ratios were markedly lower. However, like the main olfactory system, the vomeronasal convergence ratio also increased postnatally, although less markedly. The results suggest two general conclusions: one, the main olfactory system is much more sensitive than the vomeronasal system; two, sensitivity is likely to increase postnatally in both the main and vomeronasal system. NEURAL GUSTATORY RESPONSES IN TWO INBRED STRAINS OF MICE DIFFERING IN NaCl PREFERENCE. K. S. Gannon and R. J. Contreras. Florida State University, Department of Psychology, Tallahassee, FL 32306-1051.

When allowed to self-select between water and a taste solution, inbred strains of mice display unique fluid preferences. For example, 129/J mice exhibit remarkably strong preferences for NaCl compared to the inbred strain, C57BL/6J (Beauchamp, *ACHemS Abstr.*, 1990). No data exist on the underlying mechanism(s) of this strain difference in NaCl preference. It is generally accepted that taste plays an important role in the control of NaCl ingestion. The present study examined possible underlying neural gustatory mechanisms of NaCl preference in 129/J and C57BL/6J mice. We found that 129/J mice exhibited a significantly greater preference for 0.08 and 0.3 M NaCl compared to C57BL/6J mice. Peak and tonic response amplitudes of the whole chorda tympani nerve to NaCl and KCl were similar in the two strains. However, neural studies of salt-sensitive neurons may reveal strain differences not evident at a whole nerve level of analysis. Furthermore, behavioral, membrane-transport, and electrophysiological studies indicate that the initial step of NaCl taste transduction involves specific sodium channels on the plasma membrane of taste receptor cells. Use of the reversible sodium transport blocker, amiloride, may produce differential neural response inhibition to NaCl stimulation among 129/J and C57BL/6J mice. (Supported by NIH grant HL38630).

THE DEVELOPMENT OF SEXUAL BEHAVIOR AND PARTNER PREFERENCE IN MALE RATS AFTER REMOVAL OF THE VOMERONASAL ORGAN. C. Tardivel, A. N. Clancy and D. A. Edwards. Department of Psychology, Emory University, Atlanta, Georgia 30322.

Recent reports suggest the importance of the vomeronasal organ (VNO) for rodent social behavior. We studied the effect of removing the VNO on the development of copulation and partner-preference in sexually naive male rats. Sexually inexperienced Long-Evans male rats about 70 days old were randomly divided into two groups. We removed the VNO from individuals in one group (VNX); individuals in the other group were sham-operated. Beginning about two weeks after surgery, males were tested in an arena where the male could choose to spend time with (and mate with) a sexually receptive female, a nonreceptive female, or be in a neutral compartment. Males were tested a total of 6 times over a period of about 1 month.

Seven of 8 control males mated to ejaculation. Five of 9 VNX males mated and the sexual performance of these males was comparable, and in some respects superior to, that of controls. Four VNX males never ejaculated, but 3 of these did mount receptive females. Non-ejaculating VNX males showed many episodes of anogenital investigation, the majority of which were directed at the receptive female. While the VNO may be important for sexual arousal in some males, the development of sexual competence in many others is not compromised by the absence of this chemosensory organ. Control and VNX males (maters and nonmaters) developed a strong preference for receptive females. Since all VNX males who mounted showed a strong preference for a receptive female over a nonreceptive female the VNO is apparently not crucial to the process by which males recognize, and become attracted to, sexually receptive females. CHEMICAL SENSES: CENTRAL PATHWAYS I

252.1

TASTE RESPONSES TO PERITHRESHOLD STIMULI IN THE PARABRACHIAL PONTS OF THE RAT. P.M. Di Lorenzo, G.S. Hecht, and S. Monoge. Dept. of Psychology, SUNY at Binghamton, Binghamton, NY 13902.

In the study of the neural code for gustation, it has been argued that there are 4 basic taste qualities and that these qualities are encoded by separate subsets of units. If this were true, then it can be predicted that, although taste-responsive neural elements are generally broadly tuned across taste qualities, at concentrations that are just identifiable, i.e. at threshold, there should be 4 separate groups of units that each respond to only one quality. To test this prediction, electrophysiological responses to prototypes of the 4 basic qualities were recorded in the parabrachial nucleus of the pons (PbN). Single units were tested initially with gustatory stimuli presented at concentrations that evoked generally robust responses. Next, progressively lower concentrations of each stimulus were presented until no response was apparent. Test stimuli were rapid solutions of NaCl (.1 M, .01 M, .001 M, .0001 M), HCl (.01 M, .005 M, .001 M, .0001 M), quinine-HCl (.01 M, .005 M, .001 M, .0001 M) and sucrose (.5 M, .1 M, .01 M, .001 M, .0001 M). Threshold concentrations of all stimuli were considered to be .001 M based on previous reports of the threshold of the chorda tympani whole-nerve response. At present, taste responses from 19 PbN units have been recorded. At the highest concentration of each stimulus tested, 9 units (47%) responded to all 4 taste stimuli and 9 units (47%) responded to 3 of the 4 taste stimuli. Only one unit (5%) was stimulus-specific. At threshold concentrations, 12 units (63%) responded to at least one tastant; 8 of these 12 units (67%) responded to at least 2 of the 4 prototypical taste stimuli. Because it appears that the majority of taste-responsive units are multisensitive at threshold concentrations of taste stimuli, it is possible to suggest that the neural code for gustation in the PbN may rely on the across unit pattern of responses to encode quality, rather than on the responses from a subset of taste-responsive elements.

MULTIPLE SINGLE UNIT RECORDING FROM OLFACTORY BULB OF AWAKE BEHAVING RATS. U.S. Bhalla and J.M. Bower. Division of Biology, Caltech, Pasadena, CA 91125

The coding of information in the olfactory system has become a major focus of our laboratory's efforts. Here we describe the results of experiments in which activity from multiple single olfactory bulb neurons has been recorded simultaneously in behaving rats using chronic recording techniques. This data is crucial to our continuing efforts to develop realistic network models of the system.

The current experiments are based on a microdrive we have developed that weighs less than 6 gm and allows 8 stereo electrodes to be independently positioned. This device is also used to monitor respiration and EEG rhythms. Implanted rats have been exposed to odors in both passive and behavioral contexts while activity from multiple bulb neurons, presumably mitral cells, is recorded. In the passive situation the implanted rat is placed in an air stream with odorants added at defined times. The behavioral paradigm requires the rat to identify an odor and select one of two paddles for a water reward.

Using these procedures we have investigated temporal and spatial patterns in bulb responses, and their relation to the behavioral context. We have found that most neurons do not show a simple change in firing rate in response to the presence of odors, although many neurons show phasic responses correlated to the respiratory and EEG cycles. In some cells we have detected a modulation of these phase relationships in the presence of specific odors.

WHOLE CELL PATCH AND OPTICAL RECORDINGS OF SYNAPTIC RESPONSES IN SALAMANDER OLFACTORY BULB. D.P. Wellis and J.S. Kauer Neurosci. Program, Tufts-New England Med. Center, Boston, MA 02111.

To further understand the synaptic mechanisms underlying odor coding in the olfactory bulb (OB), we have applied patch clamp and pharmacologic techniques to an *in vitro* tiger salamander hemibrain preparation. Here we describe both spontaneous and olfactory nerve-driven synaptic currents in a population of 37 OB neurons, many identified as mitral/tufted cells with biocytin filling. Input impedances of OB output cells averaged about 700M Ω and resting potentials averaged -60 mV. Under symmetric Cl⁻ conditions and V_h = -70 mV, spontaneous inward currents ranged in size from <10 pA to >100 pA, peaked in a few ms, and decayed over periods up to 100 ms. These currents were evoked at a greater frequency for up to 3 s following olfactory nerve stimulation. The sensitivities of these currents to changes in external and internal Cl⁻, to bicuculline and picrotoxin, and to transmembrane voltage suggest that this activity is associated with activation of GABA_A receptors. These results thus suggest that output neurons are under a low level of tonic inhibition which is further increased by nerve stimulation. The response to olfactory nerve stimulation also included an early bicuculline-insensitive inward current. Latencies to the onset of this component (23 ms) and to the onset of the bicuculline-sensitive component (70 ms) were similar to the onsets of depolarization and hyperpolarization, respectively, in OB neurons *in vivo* (Hamilton and Kauer 1988). We are further investigating the pharmacologic nature of the early current, which underlies the direct depolarization by olfactory receptor axons. We have also begun to obtain simultaneous optical recordings from the same preparation. Preliminary results show that changes in RH414 (kindly provided by A. Grinvald) fluorescence correlate well with the single cell physiology and that the dye does not appear to have a detrimental effect on neuronal function.

TASTE RESPONSES IN THE NUCLEUS OF THE SOLITARY TRACT OF AWAKE RATS: AN EXTENDED STIMULUS ARRAY K. Nakamura and R. Norgren Dept. of Behavioral Science, Col. of Medicine, Pennsylvania State University, Hershey, PA 17033.

Forty taste neurons were isolated in the nucleus of the solitary tract (NST) and tested with 15 rapid chemicals delivered via an intraoral cannula. Each trial consisted of an infusion of 50 μ l of water, followed by a similar amount of rapid solution, and then a water rinse. Although the range was large, on average, NST neurons responded well to NaCl, sucrose, monosodium L-glutamate (MSG), NaNO₂, and glycine (\bar{X} = 8.9-12.0 spikes/sec). Mean responses to KCl, NH₄Cl, HCl, malic acid, and quinine HCl (QHCl) were low (\bar{X} = 0.4-2.3). The average responses to the other stimuli (citric acid, MgCl₂, fructose, maltose, and polycose) fell between these extremes (\bar{X} = 4.3-5.6). Based on the largest response to the 4 standard stimuli, the neurons were classified as follows: 11 NaCl-best, 15 sucrose-best, 12 citric acid-best, and 2 QHCl-best. Sodium-best neurons responded robustly and nearly equally to the 3 sodium salts (\bar{X} = 19.5-24.9) and much less to non-sodium, Cl salts (\bar{X} = 0.5-4.7). Sucrose-best neurons also responded strongly to glycine and MSG (\bar{X} = 18.2 & 14.4, respectively), but only moderately to other, normally preferred chemicals (fructose, maltose, and polycose, \bar{X} = 8.7, 9.5, & 9.6). Citric acid-best neurons responded moderately to citric and malic acid (\bar{X} = 9.4 & 5.1), but only weakly to HCl (\bar{X} = 1.5). The 2 QHCl-best neurons responded moderately to QHCl and MgCl₂ (\bar{X} = 12.0 & 9.5), but weakly or not at all to the other stimuli. Supported by PHS grants DC 00240, MH 43787, and MH 00653.

THE INFLUENCE OF SUBSTANCE P ON CELLS IN THE GUSTATORY PORTION OF THE HAMSTER SOLITARY NUCLEUS: AN *IN VITRO* STUDY. H. Liu*, M. M. Behbehani and D. V. Smith. Univ. Cincinnati Coll. Med., Cincinnati, OH 45267.

Gustatory afferent fibers from the Vllth and IXth nerves project into the rostral portion of the nucleus of the solitary tract (NST), ending primarily within the rostral central (RC) and rostral lateral (RL) subdivisions. Fibers containing substance P (SP) are closely associated with taste buds in the periphery and project centrally into all subdivisions of the NST. We recorded extracellularly from cells in the rostral NST from an *in vitro* slice preparation of the hamster medulla. Sixty neurons were isolated within the NST at the level of the dorsal cochlear nucleus, their activity recorded with 6-8 M Ω micropipettes, and their locations marked with pontamine. Of these 60 neurons, 41 were located within the gustatory projection zone (RL and RC) and the remaining 19 were within the medial or ventral subdivisions. Cells were classified according to characteristics of their spontaneous discharge: 1) 70% slow firing (0.03 - 5 Hz), 2) 20% fast (6 - 40 Hz), 3) 3% bursting, or 4) 7% irregular. Of the 41 cells within the RL and RC, 27 were slow firing, 9 fast, 2 bursting and 3 irregular. SP excited 20 of these cells, inhibited 9, and had no effect on 12 cells. Of the 19 cells within the medial and ventral subdivisions, areas that do not receive gustatory afferent input, 15 were slow, 3 were fast, and 1 was irregular. Within these subdivisions, SP excited 17 of the 19 cells and had no effect on 2. Thirty of the excited cells were tested with SP + the SP antagonist, [D-Pro², D-Trp^{7,8}]-Substance P (DPDT); the response to SP was effectively blocked in 27 cells. Seven of the inhibited cells were similarly tested with DPDT; responses were blocked in 6 cells. These results suggest that SP, which is associated peripherally with taste receptors, may play some role in the central processing of gustatory information. 252.7

IMMUNOCYTOCHEMICAL EVIDENCE FOR DOPAMINERGIC CELLS IN THE SALAMANDER OLFACTORY BULB. K.A. Hamilton and S.S. Foster. Department of Cellular Biology and Anatomy, LSU Medical Center, Shreveport, LA 71130.

In the salamander olfactory bulb, cells located in the granule cell and external plexiform layers exhibit intense tyrosine hydroxylase immunoreactivity (K.A. Hamilton, *Neurosci. Abstr.*, 16: 128, 1990). The cell bodies give rise to smooth dendrites that branch in the external plexiform and glomerular layers, producing varicose processes. Although cells exhibiting both tyrosine hydroxylase and dopamine-like immunoreactivity exist elsewhere in the salamander brain, olfactory bulb cells that are tyrosine-hydroxylase positive do not stain intensely with dopamine antiserum.

To enhance dopamine-like immunoreactivity in the salamander olfactory bulb, in the present study land phase animals were injected with monoamine oxidase inhibitor either alone or prior to injecting methyl L-DOPA (Wallace *et al.*, *Neurosci. Abstr.*, 16:646, 1990). Intense staining was then observed in a large number of granule-layer cells and a small number of external plexiform-layer cells. Both smooth dendrites and varicose processes were stained in the external plexiform and glomerular layers. Staining was also observed within the glomeruli. The cells resembled granule cells and tufted cells described in previous studies.

The results suggest that a heterogeneous population of dopaminergic cells may exist in the salamander olfactory bulb. The cell bodies occur in the granule cell and external plexiform layers, but not in the glomerular layer. The presence of dopamine-like immunoreactivity within the glomeruli, however, suggests that, regardless of soma location, the putative dopaminergic cells might modulate afferent input to the olfactory bulb at an early synaptic level.

OMP mRNA IS TRANSPORTED TO THE AXON TERMINALS OF OLFACTORY RECEPTOR CELLS. C.H. Wensley, J.S. Kauer, F.L. Margolis¹ and D.M. Chikaraishi (SPON: D.M. Chikaraishi) Neuroscience Program, Tufts Univ. School of Med., Boston, MA 02111 and ¹Roche Institute of Mol. Bio., Nutley, NJ 07110

Until recently, neuronal mRNA has been thought to be restricted to the cell body and dendritic portions of the cell. By *in situ* hybridization and RNAase protection, we have studied the distribution of olfactory marker protein (OMP) mRNA in the receptor cells of the rat olfactory epithelium. We found that this mRNA is located not only in the perikaryon but also in the axons as they approach and synapse in the olfactory bulb. To verify that this signal was in the receptor cell axons, we performed unilateral axotomies on the olfactory nerve of one month old rats. The axotomized animals were sacrificed 10-14 days after surgery. *In situ* hybridization on this tissue showed that the OMP mRNA disappeared from the axotomized side while remaining intact on the control side. Similar results were obtained using mice which had undergone intranasal irrigation with 0.17M ZnSO₄ to destroy inputs to the olfactory bulb. Tissue from these animals sacrificed 7 days after lavage revealed no OMP message in either the perinuclear region in the olfactory epithelium or the terminal axon field in the olfactory bulb.

252.6

CO-LOCALIZATION OF SUBSTANCE P, TYROSINE HYDROXYLASE AND GABA IMMUNOREACTIVITIES IN THE HAMSTER OLFACTORY BULBS. T.Jang, R.M.Kream*, and F.Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545, Tufts University Schools of Medicine, Boston, MA 02111.

Postnatal development of substance P (SP), tyrosine hydroxylase (TH) and GABA expression were studied with single and double immunofluorescence techniques. TH- and GABA-positive neurons were present in the main olfactory bulb (MOB) on the 1st postnatal day. Their dendrites arborized in the glomerular layer (GL). SP-positive perikarya were not seen in the olfactory bulbs until the 2nd week; however, prominent SP-positive centrifugal fibers entered the granule cell layer (GRL) of both the MOB and accessory bulb (AOB) in 1-day old pups. By the 2nd week, the distributions on SP-, TH-, and GABA-positive perikarya were like those in adult hamsters.

Neurons co-expressing GABA and TH immunoreactivities were evident in the GL on the 1st postnatal day. Their somal sizes and location indicated that they were periglomerular (PG) cells. During the 2nd week, virtually all the SP-positive neurons in the MOB were also TH-positive, and had the morphological features of external tufted cells. The proportion of such double-labeled cells then declined with age. Some SP and GABA double-labeled cells were seen in the GL by the second week, but these were relatively rare at all ages. These observations suggest multi-subclasses of PG and external tufted cells.

252.8

SPATIAL CODING AND CELLULAR TUNING OF FATTY ACID ODORS IN RABBIT OLFACTORY BULB. K.Mori, N.Mataga* & K.Imamura. Dept. of Neuroscience, Osaka Bioscience Institute, Furuedai, Suita, Osaka 565 Japan.

To examine spatial representation of odors in the brain, odor-evoked oscillatory (40Hz) local field potential (OLFP) was recorded in the external plexiform layer of extensive regions of the main olfactory bulb in urethane anesthetized rabbits. Stimulation of olfactory epithelium with normal (n)-fatty acids elicited large OLFPs within a region at the rostro-dorso-medial part of the bulb.

Single unit recordings from bulbar neurons revealed that in the region of the bulb, about 80% of mitral cells showed excitatory spike responses to fatty acids. Each mitral cell showed tuning to one to four n-fatty acids with hydrocarbon chain of similar length. In addition to n-fatty acids, a group of mitral cells responded to iso-fatty acids. These results indicate that mitral cells responsive to fatty acid odors are grouped together in the region at the rostro-dorso-medial part of the bulb. Above results also suggests that chemical structures of odorants are spatially coded in the main olfactory bulb and that each mitral cell in the bulb is tuned to specific structural features of odorants.

252.10

DIFFERENTIAL DISTRIBUTION OF SYNAPSIN ISOFORMS IN THE MAIN OLFACTORY BULB OF THE RAT. M.R.Dino, E. Mugnaini, A. Czernick¹, and P.Greengard¹ Neuro morphology Lab, U-154, Univ. of Conn., Storrs, CT. 06269 and ¹Lab. of Molecular and Cellular Neuroscience, Rockefeller University, 1230 York Ave. Box 296, New York, N.Y. 10021

Synapsins, of which four isoforms have been uncovered, are a class of molecules involved in the mechanism of neurotransmitter exocytosis. By immunocytochemistry with antisera specific for the four isoforms, we show that synapsins are unequally distributed in the main olfactory bulb of albino rats. Synapsin-like immunoreactivity is mostly situated in punctate structures interpreted as axonal or dendritic presynaptic profiles. Immunoreactivities to synapsins Ia and Ib are present throughout the bulb and are particularly enriched in the external plexiform layer (EPL); in the granular layer (GRL) immunoreactivity for synapsin Ia is relatively lower than that for synapsin Ib. Immunoreactivity to synapsin IIa is strikingly enriched in the glomeruli; in the remaining layers, its distribution resembles that of synapsin Ia and Ib. Synapsin IIb immunoreactivity is localized mostly in the GRL and in a band of immunoreactive puncta at the border between the glomerular layer (GL) and EPL, and it is nearly absent within the glomeruli; it is found only in scattered puncta in the interglomerular neuropil and in the EPL. Severance of the lateral olfactory tract leads to conspicuous reduction of synapsins Ia, Ib, and IIa in the GRL, but produces little change of the respective immunoreactivities in the GL and EPL. This indicates that these isoforms are situated in presynaptic elements belonging to centrifugal afferents as well as to olfactory nerve terminals and intrinsic profiles. The same lesion removes some immunoreactivity to synapsin IIb, indicating that this isoform is localized mostly in centrifugal afferent terminals and in some short axon cells.

252.11

VALPROATE DISTRIBUTION IN THE MOUSE BRAIN AFTER INTRANASAL ZINC SULPHATE. Thomas J. Hoepfner. Department of Neurological Sciences, Rush Medical College, Chicago, IL 60612

Intravenously injected radiolabeled valproate (VPA) concentrates in the olfactory bulb of mice and rats with highest levels in the medial and dorsal glomerular layer as seen with contact autoradiography. The glomerular layer contains processes of four types of neurons: olfactory nerve terminals, periglomerular cells, mitral and tufted cell dendrites. As a preliminary step to determine if the VPA is contained in a single neuronal population the olfactory epithelium and consequently the olfactory nerve were destroyed by intranasal application of zinc sulphate in mice. Subsequent behavioral testing showed the mice to be anosmic. On intravenous injection of a tracer dose of carbon-14 labeled VPA 4-10 days after the zinc sulphate, autoradiography showed the same distribution and concentration of VPA in zinc sulphate treated mice and control mice that did not receive zinc sulphate. These preliminary findings suggest that VPA does not concentrate in olfactory nerve terminals.

MORPHOLOGICAL PROPERTIES OF THE SENSORY NEURON IN THE COCKROACH TACTILE SPINE.

A.S. French, A.R. Klimaszewski* and L.L. Stockbridge*. Department of Physiology, University of Alberta, Edmonton, Alberta T6G 2H7, Canada.

The cockroach femoral tactile spine contains a single mechanosensory neuron. The neuronal soma is within the spine lumen, and a sensory dendrite passes through the spine wall. Intracellular recordings from the neuron produce a wide range of action potential amplitudes and thresholds, suggesting that the soma and dendrite are electrically passive and the site of action potential initiation is variably distant from the soma.

Tactile spine sensory neuron morphology was reconstructed using 1 μ m thick serial sections. Spines were fixed, dehydrated, and embedded before sectioning. Stained sections were photographed and then the outlines of the spine cuticle, the sensory neuron, and the spine trachea were digitized directly from enlarged negatives with a digital graphics tablet. Sections were aligned, reconstructed, and displayed using custom software. The results indicate that the shape, size and position of the dendrite and soma are significantly variable, probably accounting for the electrical observations.

Supported by the Medical Research Council of Canada.

253.3

AN EXTENDED MAP OF SENSE ORGANS OF THE COCKROACH LEG OBTAINED BY APPLYING Dil TO FIXED TISSUES. D. L. MacFarland*, S. F. Frazier*, S.E. Fish and S. N. Zill. Dept. Anat., Marshall Univ. Sch. Med., Huntington, WV 25755.

As a prelude to studies evaluating the functions of proprioceptive sense organs in cockroach walking, running and escape turning, we have mapped the locations of receptors in the legs using the carbocyanine dye, Dil. Animals were anesthetized, decapitated and placed in formalin fixative for 1-2 days. Dil crystals were then positioned at the cut ends of nerve 5 (the main leg nerve) or its branches or nerve 3B. Cockroaches were incubated at 37°C for 10 days to 2 weeks, then returned to room temperature for 1-6 months. Legs were bisected, placed in a clearing solution (Conray) and viewed as whole mounts or sections under both epifluorescent and transmitted light illumination. This technique allows for both the visualization of sensory neuron somata and the cuticular structures which they innervate. We have confirmed the presence of many of the identifiable groups of sense organs previously described including chordotonal organs, campaniform sensilla and hair plates. In addition, we have characterized a number of receptors of the tibia and tarsus that have not previously been mapped. These include new groups of campaniform sensilla and numerous multiply innervated chemoreceptors. In addition, we have also found large sensory neurons in the tarsal segments which resemble "pore" receptors previously described in locusts. These morphological studies will form the basis for future physiological experiments to evaluate the roles of these afferents in behavior.

Supported by a grant from the Whitehall Foundation.

PROPRIOCEPTIVE INPUTS AND INHERENT MUSCLE TENSIONS CONTRIBUTE TO LOAD COMPENSATORY REACTIONS IN LOCUSTS. S. N. Zill and S. F. Frazier*. Dept. Anat., Marshall Univ. Sch. Med., Huntington, WV 25755.

Load compensatory reactions adapt postures to changes in the environment. We have previously shown that locusts show such reactions when they are placed in a chamber which is repeatedly swayed. Discrete, phase linked bursts of motor activities occur in flexor and levator muscles of the legs but not in the antagonist extensors and depressors when animals stand upon the side of the chamber. In order to evaluate the contributions of proprioceptive inputs to these reactions we have now 1) recorded the changes in joint angle that occur during these responses (by videotaping locusts that had miniature light emitting diodes attached to the leg) and 2) stressed the system (by attaching weights to animals and varying the velocity of swaying). These studies have shown that 1) phase linked changes in angle of the femoro-tibial joint occur during compensatory reactions (increasing during the phase in which the substrate is pulled away from the animal); 2) the onset of muscle bursting is significantly correlated with a decrease in the rate of change of joint angle; and 3) stressing the system by increasing weight of the animal induces reciprocal bursting in muscles that are normally silent. We conclude that both proprioceptive inputs monitoring joint angles and modulators of inherent muscle tensions can contribute to load compensatory reactions in these animals.

SPIKING LOCAL INTERNEURONES: CORRELATION BETWEEN INTERNEURONE MORPHOLOGY AND PHYSIOLOGY AND TACTILE AFFERENT PROJECTIONS IN THE LOCUST. F.L. Newland and M. Burrows, Dept. of Zool., Univ. of Cambridge, Cambridge, England.

In the locust, spiking local interneurons that process mechanosensory information have distinct patterns of central arborizations, and receptive fields consisting of groups of receptors on the leg. We have analysed the relationship between the morphology and the receptive fields of these interneurons by relating them to the central projections of afferents from tactile hairs on a hind leg.

Each hair is innervated by a single sensory neurone that projects to the ipsilateral half of the metathoracic ganglion. The central projections of these afferents form a map of a hind leg in the central nervous system such that the spatial position of hairs on a leg is represented in 3 dimensions in the ganglion.

Interneurons that process mechanosensory information from hairs on the leg have receptive fields formed by direct input from the tactile afferents. There is a strong correlation between the branching patterns of spiking local interneurons, their receptive fields, and the projection patterns of the sensory afferents from which they receive inputs. Interneurons with extensive ventral branching covering most of the afferent map have large receptive fields on the leg. Interneurons with small receptive fields, however, have branching patterns overlapping with small and specific areas of the afferent map.

REPRESENTATION OF WIND STIMULUS INFORMATION BY THE RECEPTOR ARRAY OF THE CRICKET CERCAL SENSORY SYSTEM. Michael A. Landolfi and Gwen A. Jacobs. Graduate Group in Neurobiology, University of California, Berkeley, CA 94720.

A combination of morphological and electrophysiological studies were performed to assess the representation of stimulus information by the filiform hair mechanoreceptors of the cricket (*Acheta domestica*) cercal sensory system. Individual receptors give characteristic responses which depend on the direction and velocity of the stimulus. The receptor response adapts to continued stimulation, and the degree of adaptation depends on the stimulus velocity and frequency.

The filiform receptor synaptic terminals form a topographic map of wind stimulus direction within the cercal glomerulus, where they make excitatory synapses onto specific identified interneurons (INs). We have made a 3-D morphological reconstruction of this map from stained afferents representing all receptor directions on the cercus. The directionally selective identified INs which receive input from the receptor afferents were also stained and reconstructed, and the morphological overlaps between the INs and each type of afferent were calculated. We then predicted the directional receptive fields of several different INs by scaling and summing the directional tuning curves of the afferent types which showed anatomical overlap with the dendritic arbors of the INs. The afferent tuning curves were scaled according to: 1) their relative amounts of overlap with the IN; 2) the electrotonic distance between the IN's dendritic arbors and its spike initiating zone (SIZ); and 3) the relative numbers and distributions of presynaptic receptor types on the cercus. These predicted receptive fields were then compared to the physiologically measured directional sensitivity tuning curves of the INs.

253.9

BEHAVIORAL MEASUREMENT OF DIRECTIONAL RESOLUTION IN THE CRICKET CERCAL ESCAPE SYSTEM. B.M. Olberg and J.P. Miller. Dept. of Molecular and Cell Biology, Univ. of Calif., Berkeley, CA 94720.

In response to a rapidly accelerating air current, crickets turn and run or jump away from the source of disturbance. This behavior is mediated by the cercal escape system, consisting of wind sensitive filiform hairs on the cerci and ascending interneurons which receive input from the filiform receptors and project to the thorax. In order to assess the minimum directional resolution of this system we videotaped escape responses of adult crickets (*Acheta domestica*). We analyzed the escape tracks by digitizing the positions of the head and posterior tip of the abdomen in each of 4 frames (133 msec) after stimulus onset.

To isolate the cercal contribution to the escape behavior, we removed the antennae and painted the eyes. We removed the metathoracic (jumping) legs. Two stimuli were used: 1) a rectangular styrofoam block moving downward, stopping just short of the substrate, 2 cm from the cricket or (2) the raised edge of rectangular plexiglass flap, released from an angle of 40° to the substrate. Both stimuli were more effective than air puffs at eliciting escape.

We plotted direction of the change in head position in freely moving animals from time 0 to 100 msec. The mean vector of head movement thus obtained was directly away from the stimulus with a standard deviation of 16° for the best individuals. A second method of measurement, based on the leg movements of tethered animals whose legs were in contact with a slippery surface, gave similar results. The initial response (latency ca. 30 msec) was a thrust by the prothoracic leg on the stimulus side of the animal.

A STUDY OF THE STRUCTURE AND FUNCTION OF TRANSPLANTED CAMPANIFORM SENSILLA IN THE CRICKET REVEALS TWO DISTINCT TYPES OF RECEPTOR. K.A. Killian, D.J. Merritt and R.K. Murphey. Neuroscience and Behavior Program, Dept. Zoology, University of Massachusetts, Amherst, MA 01003.

Insect campaniform sensilla can be segregated into two classes based on their site of projection within the CNS. Campaniform sensilla (CS) associated with the filiform hair receptors on the abdominal cerci of the cricket *Acheta domestica* project to a ventral region of neuropil within the terminal abdominal ganglion (Heusslein and Gnatzy, 1987), while CS located on the thoracic legs project to an intermediate neuropil within each thoracic ganglion. We wondered whether this difference in projection sites was due to a property of the sensory neuron or a regional characteristic of the ganglion under study. We show that CS on cerci transplanted to the position of the metathoracic leg regenerate into the CNS and arborize in a ventral area of neuropil within the host ganglion in contrast to the intermediate arborizations of leg CS. We were interested in determining whether these ectopic afferents could form functional connections in their new location. Interneuron 7-1b, which is excited by both the activation of CS on the cerci and the tactile stimulation of the contralateral thoracic legs, seemed a likely candidate to receive ectopic input. 7-1b's soma is located in the terminal abdominal ganglion and its axon ascends towards the brain to arborize profusely in the ventral neuropil of each of the abdominal and thoracic ganglia. We found that activation of ectopic CS produced a barrage of spikes recorded from the soma of this interneuron comparable to that evoked by tactile stimulation of a normal cercus. This result suggests that transplanted CS can recognize both a local region of neuropil within each ganglion of the CNS and synapse with a normal target within this region. 253.8

INFORMATION THEORETIC CALCULATION OF DIRECTIONAL ACCURACY IN THE CRICKET CERCAL SENSORY SYSTEM. ENCODING BY SPIKE PATTERNS AND COVARIANCE.

F.E. Theunissen*, S. N. Gozani* and J.P. Miller. Dept. of Mol. and Cell Biology, University of California, Berkeley, CA 94720.

The activity patterns of primary sensory interneurons in the cricket cercal sensory system encode information about the direction and velocity of air current stimuli in the animal's immediate environment. In previous work the statistical principles of information theory were used to calculate the maximum directional accuracy attainable from the response ensemble of four low velocity interneurons from this system. We found that 1) the system was capable of encoding wind stimulus direction with a high level of resolution, and 2) the width of the directional tuning curves of the cells were optimal in the sense of maximizing the information theoretic measure of directional accuracy.

In this work, the same principles were used to extend the calculation by considering 1) the encoding by the higher order statistics of the spike train patterns and 2) the effect of the covariance in the response. We found that the higher order statistics of the spike trains could enhance the directional resolution to a negligible extent for the low velocity cells of our previous study but to a significant extent for other cells of the system with higher velocity thresholds. Including the covariance in the calculations further increased the directional accuracy. The covariance was particularly large when the wind stimulus velocity was allowed to vary. The high positive covariance found in those cases did not deteriorate the directional accuracy. However, effective encoding in the high positive covariance situations only occurred if the response curves of adjoining cells had opposite slopes. This was the case in the actual array of cells, and represents another way in which the width and separation of the response curves can be considered as being optimized with respect to the task of discriminating stimulus direction.

CEREBRAL AND TRANSCEREBRAL PROJECTIONS OF OPTIC TRACT FIBERS IN THE CRICKET. D. Moore. Dept. of Biological Sciences, E. Tenn. State Univ., Johnson City, TN 37614

Neuronal projections from the optic lobes in the cricket *Teleogryllus commodus* were mapped from whole-mount preparations using silver-intensified nickel fills of optic tract axons cut between the lobula and medulla.

At least five separate tracts project to the contralateral lobula, where the terminal branches form distinct lateral and medial dendritic fields. The largest trans-cerebral tract, however, completely bypasses the lobula and ends in the medulla; its dense terminal branchings form two separate vertical strata. Associated with this tract are cell bodies in the pars intercerebralis and contralateral medulla, as well as extensive arbors descending from its caudal protocerebral traverse into the deuto- and tritocerebrum of both hemispheres.

Cerebral projections include fibers in all three ocellar tracts, an exceptionally dense ipsilateral tract terminating superficially in the frontal protocerebrum, a tract circumventing the pedunculus of the ipsilateral mushroom body & terminating with extensive branches in the caudal protocerebrum, and tracts leading to somata in the frontal deutocerebrum on both sides of the brain.

The results of this study confirm and extend the findings of Honegger & Schürmann (Cell Tiss. Res. 159: 213, 1975) on the cricket *Gryllus campestris*.

253.11

ASYMMETRIC INHIBITORY INTERACTIONS IN THE ANTENNAL LOBES OF HONEYBEES REVEALED BY REAL-TIME OPTICAL IMAGING. E.E. Lieke, Inst. f. Neurobiol., Königin-Luise-Str. 28/30, D-1000 Berlin 33, FRG.

The antennal lobes are known as the primary olfactory neuropiles of honeybees. They consist of sensory input neurons, output neurons, and several classes of local interneurons some of which are known to be inhibitory. Previous experiments demonstrated the feasibility of real-time optical recording in this neuropile using intrinsic signals. Although the nature of the intrinsic signal is not fully understood it is clearly related to neuronal activity.

Using a 4x4 photodiode array, intrinsic optical signals were recorded from a semi-slice preparation of the bee brain. The antennal nerve of the preparation was stimulated by a train of electrical pulses (100 μ Amp, 100Hz). The sizes of the optical signals were different at different locations of the antennal lobes, having largest amplitudes in anterior areas. The slope of the optical signals began with a steep phase followed by a shallow one. After offset of the stimulus the signals returned to their baselines. After treatment with picrotoxine (5 min, 10^{-6} molar) the amplitudes increased in many regions and the time courses became more continuous. However, the increase was not homogeneous - its degree depending on the spatial position of the recorded area. The increase in signal amplitude is consistent with the assumption that GABAergic chloride channels were blocked by picrotoxine. The differences between the optical signals before and after this treatment can therefore be interpreted as the timecourses of the inhibition. The inhibition starts with a 10 msec delay after response onset, and has at least two phases.

Surprisingly, the spatial distribution of this inhibition is extremely inhomogeneous. Areas of large inhibition are in the proximity of areas with less inhibition. Thus inhibitory interactions in the antennal lobes are asymmetric with areas that deliver more inhibition than others and areas that receive more inhibition. Such aspect of general network wiring in this neuropile is completely new and should be taken into account in further investigations.

253.13

RESPONSES OF AN EYE WITHDRAWAL MOTOR NEURON IN THE CRAB. C.E. Diebel*, R.R. Forman, C.I. Abramson*, A.I. Yuan* and R.D. Feinman, SUNY Health Science Center, Brooklyn, NY 11203.

Pavlovian conditioning of eye withdrawal in the crab consists of pairing a puff of air to the eye (which elicits retraction) with an initially ineffective stimulus, vibration of the carapace. After repeated pairings, the withdrawal response is elicited by the vibration. A key question in conditioning is whether the learned response is a new behavior, specifically related to vibration, or whether it is the same motor act caused by air-puff but now brought under the control of the new stimulus. As a first step in answering this question, we studied two nerve tracts, the optic and oculomotor nerves, which contain the axons of the motor neurons controlling eye movement as well as some sensory fibers which mediate this behavior. We performed extracellular recordings from these nerves in a whole animal preparation and measured the responses to air-puff and to vibration of the carapace. Motor output was observed in the optic nerve as rapid, short latency volleys (typically 400 Hz) during 0.5 s air-puffs to the eye. This response (and the withdrawal behavior) was eliminated by section of the oculomotor nerve, suggesting that the afferent fibers mediating air-puff run in this nerve. Consistent with this, activity that correlated with the air-puff stimulus appeared in the oculomotor tract and persisted in the peripheral end of the cut nerve. Motor response to vibration was different from that caused by air-puff and was not affected by section of the oculomotor nerve. The results indicate that pattern of motor activity underlying eye withdrawal depends on the stimulus and suggest the possibility that conditioned responses may be different from unconditioned responses. FINE STRUCTURE OF OLFACTORY-GLOBULAR TRACT AXON TERMINALS IN THE CRAYFISH BRAIN. DeF. Mellon, V. Alones*, and M. D. Lawrence*. Department of Biology, University of Virginia, Charlottesville, VA 22903.

Globuli cells are interneurons of the arthropod olfactory midbrain, constituting the major projection pathway between the deutocerebrum and the protocerebrum. In decapod crustaceans, globuli cells are relatively numerous; for example, there are at least 10^3 globuli cells on each side of the olfactory midbrain in the crayfish, *Procambarus*. Globuli have small, uniform somata 7-8 μ M in diameter, extensive dendritic arbors in the olfactory and accessory lobes, and their bilaterally-branched axons run out the 'optic nerves' in well-defined olfactory-globular tracts (OGT). OGT axons terminate in the hemi-ellipsoid body (HE). We have used a rapid Golgi technique to study OGT axons and their HE terminals. Light microscopy shows each terminal to be a knot-like structure, 5-7 μ M across, consisting of an expanded axon ending that recurves upon and intertwines with itself. Each OGT axon branches several times within the HE, each branch terminating in a separate knot ending. We suggest that these terminals constitute the microglomeruli described in HE by other authors. In gold-toned Golgi sections examined with the electron microscope, the OGT terminals synapse with larger diameter fibers. The contacts occur between OGT terminals and small spines on the postsynaptic neurons. Serial reconstruction of microglomeruli indicates that closely adjacent pairs of spines comprise a frequent configuration targeted by OGT synapses. These data show each OGT axon terminating as several separate microglomeruli and each synaptic focus having many targets. Questions for future physiological analysis include the identity of cells in the HE postsynaptic to the OGT neurons, and the network properties involved with pattern recognition in the identification of complex odorants. MANDUCA OPSIN mRNA IN RELATION TO RETINOIDS AND LIGHT/DARK CYCLE. R. H. White, J. Bard*, and R. R. Bennett, University of Mass/Boston, Boston, Massachusetts.

Opsin synthesis in insects is curtailed by vitamin A deprivation and stimulated when the chromophore is provided. J. Schwemer (Julich conference abst., 1990) has found that opsin message is low in the vitamin A deprived blowfly (*Calliphora*), and increases in response to 11-cis retinal. We have done similar experiments with the tobacco hornworm moth *Manduca sexta*. Northern blots of moth eye extracts using *Drosophila ninaE* (opsin) cDNA (W. Pak, Purdue) as probe revealed a single labelled band. The similarity in molecular weights (the labelled band from moth retinas at 1.8 kb, the *ninaE* message at 1.7 kb) suggests that the probe is binding to the mRNA for one of the moth opsins. Slot blot analysis showed more of this labelled mRNA in the dark phase of the diel cycle than in the light phase, a modulation similar to that found in mouse mRNA (Bowes et al., Exp Eye Res 47:369, 1988). Retinoid deprived photoreceptors, despite low opsin levels, contained similar or larger amounts of the labelled mRNA than did normal cells. Opsin levels and visual function recover slowly when deprived moth photoreceptors are provided with 11-cis retinal. Surprisingly, the labelled mRNA appeared to decrease in these recovering photoreceptors. Thus levels of message appear to be affected by retinoids in both the fly and moth, but in an opposite sense. Supported by NSF grant BNS 8510087.

253.14

RECEPTIVE FIELD ORGANIZATION OF CRAYFISH STATOCYST INTERNEURONS. H. Nakagawa* and M. Hisada Zool. Inst., Fac. Sci., Hokkaido Univ. Sapporo 060 Japan

In crayfish, *Procambarus clarkii*, many statocyst-related interneurons have been identified or characterized in our previous reports. We, however, have known only their responses to simulated body roll. In order to understand how they produce an adaptive equilibrium response, including compensatory eye movement, it is essential to know how their receptive fields are organized. To clarify this point, a group of sensory hairs in different regions of a statocyst was stimulated artificially while activity of an interneuron was recorded using glass microelectrode filled with Lucifer Yellow.

We found two different types of receptive field. Three local spiking interneurons and an identified descending interneuron, C₁, showed either excitatory or inhibitory response to the stimulation of the lateral hairs. On the other hand, two local spiking interneurons showed inhibitory and excitatory response to the anterior and posterior hairs respectively. These observations suggest that the former control the equilibrium responses to roll and the latter control responses to pitch.

253.16

MULTIPLE TARGETS FOR SEROTONIN, PROCTOLIN, & NEUROPEPTIDE F1 ACTING AS NEUROMODULATORS ON THE LOBSTER MUSCLE RECEPTOR ORGAN. V.M. Pasztor, Biology Department, McGill University, Montreal, Canada. H3A 1B1.

The muscle receptor organ (MRO) of the lobster is a complex proprioceptive system lying in parallel with the axial flexor musculature. Two peripherally located sensory neurons, one tonic and one phasic, extend stretch-sensitive dendrites into individual receptor muscle strands (RM1 & RM2 respectively). Variable gain is provided by efferent motor innervation to the receptor muscles and efferent inhibitors synapsing upon the sensory dendrites.

A previous study of the isolated MRO *in vitro* (Pasztor & Macmillan, 1990) has shown that proctolin and serotonin enhance the spiking responses to passive stretches. Using a combination of intracellular and extracellular recording electrodes and tension transducers, the current study shows that 5-HT, proctolin, neuropeptide F1, but not octopamine, are significant modulators acting at multiple loci on the MRO to enhance the gain of this important reflex system. In the presence of 10^{-6} mol l⁻¹ 5-HT or proctolin: the receptor potentials and excitability of both sensory neurons, as well as the motor junctional potentials and nerve evoked contractions of the receptor muscles, were all enhanced. Neuropeptide F1 had powerful effects upon the receptor muscles but did not modulate the sensory neurons at all. Work on the inhibitory accessory fibers is now in progress.

253.17

TRANSMITTER LOCALIZATION IN THE BRAIN OF THE AMERICAN LOBSTER, *HOMARUS AMERICANUS*. L.S. Gammill* and B.S. Beltz. Biology Dept., Wellesley College, Wellesley, MA 02181.

The localization of transmitters in the brain of *Homarus* has never been examined in detail. In this immunocytochemical analysis of the lobster brain, the distributions of staining for serotonin, proctolin, red pigment concentrating hormone (RPCH), FMRFamide, and small cardioactive peptide B (SCPb) are compared. Labelling in synaptic areas such as the accessory lobes (ALs), olfactory lobes (OLs), protocerebral bridge (PB), and central body (CB), as well as in the deutocerebral giant neurons (DGNs), is emphasized.

Immunoreactivity for all five transmitter substances is observed in the OLs, PB, and CB, although the patterns of labelling are distinct. The ALs, which stain for every compound except proctolin, illustrate the diversity of labelling possible within a single region. Serotonin-like immunoreactivity is found in glomeruli throughout the ALs; FMRFamide and SCPb antibodies label only the cortex of the ALs; intense staining for RPCH is localized in glomeruli at the core of the lobe with sparse staining found in glomeruli elsewhere in the lobe. In contrast to this regional localization of transmitters in the ALs, all of the glomeruli in the OLs label with each of the antibodies tested. The intensity and qualitative appearance of the immunoreactivities, however, are distinctive. The DGNs, which innervate the ALs and the OLs, are immunoreactive only for serotonin.

Thus, each transmitter substance has a unique localization pattern throughout the brain. Comparing the distribution of these substances identifies areas of overlap, revealing sites of regional coexistence between two or more substances. Such coexistence suggests areas where transmitters may interact physiologically within a cell or region, providing a framework for future experimentation. BEHAVIORAL DISCRIMINATION OF ODORANT MIXTURES AND THEIR COMPONENTS: EFFECTS OF MIXTURE INTERACTIONS ON QUALITY CODING. J.B. Fine-Levy*, C.D. Derby, and T.J. Bartness. Dept. of Biology, Georgia State Univ., Atlanta, GA 30303.

Elucidation of the mechanisms by which the qualities of chemical stimuli are encoded by the nervous system would be impossible without an understanding of the effects of mixture interactions on the perception of mixture quality. Mixture interactions have been implicated as the source of mismatches between "predicted" and observed physiological responses to mixtures of components whose individual stimulatory capacities are known. Toward examining this question, we tested the abilities of spiny lobsters to behaviorally discriminate between three odorant compounds (AMP, glutamate (glu), and taurine (tau)) and their binary mixtures through the use of a differential aversive associative conditioning paradigm. Based on the results of ANOVA and multidimensional scaling analysis incorporating observed responses to all stimuli and "predicted" responses to the binary mixtures, the following relationships between the perceived qualities of each binary mixture and its constituent components were determined: AMP + glu was different from either component, as well as its predicted value. AMP + tau was intermediate between both components and no different from the predicted value, a finding consistent with results of binding assays which indicate that these compounds are binding to independent receptor sites. Glu + tau was different from both components and there was some indication that glu was acting to suppress the tau in the mixture. Comparisons between these behavioral results and those of our electrophysiological analysis of the effects of mixture interactions on the coding of stimulus quality and intensity are in agreement, thus lending credence to the use of receptor-based models to predict effects of peripherally initiated mixture interactions on behavioral responses to odorant mixtures.

EMBRYONIC AND LARVAL DEVELOPMENT OF THE DEUTOCEREBRUM OF THE LOBSTER *HOMARUS AMERICANUS*. M.L. Buchhoft*, S.M. Helly and B.S. Beltz. Bio. Dept., Wellesley College, Wellesley, MA 02181.

Embryonic and larval development of the brain of the American lobster, *Homarus americanus*, is documented histologically using thin plastic sections stained with toluidine blue. The primary focus is on the development and differentiation of the deutocerebrum, specifically the olfactory lobes (OLs) and the accessory lobes (ALs).

The OLs begin to develop much earlier than the ALs; the primordia of the OLs are already present at 25% embryonic development. The characteristic columnar glomeruli of the OLs also appear relatively early, by 43% development. The small ALs are first seen at 50% embryonic development, when they appear medial to the OLs. By the first larval stage, the OLs and the ALs are approximately equal in size. The characteristic spherical glomeruli of the ALs do not appear until the second larval stage. By the fourth larval stage a distinct cortex has developed in the ALs. From late embryonic through early juvenile development the ALs gradually shift position in the brain from medial to posterior to the OLs, and the two neuronal clusters of globuli cells that innervate the lobes shift from posterior and anterior to the lobes to lateral and medial locations. In juvenile lobster brains, the gross differentiation and rotation within the lateral deutocerebrum have been completed.

The ALs develop from their first appearance in the presence of direct serotonergic input from a pair of giant deutocerebral cells. In future studies we plan to investigate the potential role of serotonin as a morphogen via its depletion during development. Aspects of the protracted growth and differentiation of the ALs, such as their late appearance, post-hatching acquisition of glomeruli, and shift in position will be used as developmental landmarks to identify potential abnormalities in animals where serotonin has been depleted. (Supported by NSF-BNS-8718938, NSF-BNS-8958169, and NIH-NS-25915)

253.20

BIOCHEMICAL CHARACTERIZATION OF OLFACTORY RECEPTORS OF THE SPINY LOBSTER. K. Olson*, H. Trapido-Rosenthal*, and C. Derby. ¹Dept. of Biology, Georgia State University, Atlanta, GA 30303, ²Whitney Laboratory, St. Augustine, FL 32086

This biochemical study has two goals: (1) to characterize biochemically the binding of odorant molecules with their receptors; and (2) to investigate the roles played by these receptor-odorant binding events in the sensory perception of odorant mixtures (e.g., mixture interactions). An olfactory tissue fraction enriched in dendritic membrane from olfactory receptor cells was prepared from aesthetasc sensilla on the lateral filament of the antennules. [³H]-Taurine and [³H]-AMP, known to be potent olfactory stimulants, were used as radioligands for the olfactory membrane in a filtration assay. Results suggest that specific binding sites for [³H]-taurine and [³H]-AMP exist in this olfactory membrane. K_m values for both types of binding sites are approximately 3 μ M, and B_{max} for taurine sites is 532 pmole/ μ g protein. Inhibition studies indicate that AMP and taurine bind to different sites: for [³H]-taurine binding, IC_{50} values for unlabeled taurine and AMP are 4.5 μ M and $>>1$ mM, respectively; for [³H]-AMP binding, IC_{50} values for unlabeled AMP and taurine are 0.7 μ M and 1 mM, respectively. Glutamate, a known olfactory suppressant, was also tested as an inhibitor and its binding site was characterized. The results elucidate the role of receptor binding in mixture interactions. Supported by NSF and NIDCD grants.

REFLEX FUNCTION

254.1

PHASIC VIBRATORY PATELLAR REFLEXIVE RESPONSE OF ABLE-BODIED AND SPASTIC DISABLED ADULTS. N.J. Lambert, Department of Physical Therapy, East Carolina University, Greenville, NC 27858

Assessing the magnitude of a phasic tendon tap reflex during vibration as compared to the magnitude of the tendon tap reflex without vibration may give an indication of the amount of remanent Ia presynaptic inhibition in spinal pathways of spastic disabled adults (Delwaide, 1985). The agonist (AG), antagonist (ANT) and reflexive FORCE response to a patellar tendon tap with (VIB) and without (NORM) quadriceps tendon vibration and ONE and TWO minutes post-vibration were compared in spastic disabled (n = 12; 6 SCI, 6 CP) and able-bodied adults (n = 12). The AG rectus femoris and ANT bicep femoris reflexive responses of the disabled group were significantly greater than those of the able-bodied group (p < .05). AG, ANT and FORCE reflexive responses during the VIB condition were significantly less than during the NORM, ONE and TWO conditions (p < .05). The inhibitory effect of vibration caused a similar absolute decrease in AG, ANT and FORCE response of the patellar tendon tap for both groups, however the relative percent decreases in reflexive response were much greater for the able-bodied group (AG 47%, ANT 40%, FORCE 49%) than the disabled group (AG 21%, ANT 9%, FORCE 20%). This would indicate that the mechanism of inhibitory feedback due to vibration was not necessarily hindered in the disabled group, but that the abnormally large reflexive responses of the disabled subjects were more difficult to suppress. There are mechanisms distinct from a lack of presynaptic inhibition which are also contributing to spasticity.

254.2

REFLEX AND NON-REFLEX MEDIATED STIFFNESS IN THE PLANTAR FLEXORS OF SPASTIC PATIENTS WITH HEMIPARESIS.

T. Sinkjar, K. Larsen*, M. Thomsen*, and I. Magnussen*. Dept. of Medical Informatics and Image Analysis, Aalborg University, Fredrik Bajersvej 7D, DK-9210 Aalborg, and Department of Neuromedicine, Aalborg Hospital, DK-9000, Denmark

It is often proposed that an enhanced stretch reflex in spastic patients contribute to muscular hypertonia, defined as an increased resistance by the muscles to an externally imposed stretch. The objective of this study was to determine how large a fraction of the force increment to an externally imposed stretch is due to intrinsic properties of the contractile apparatus and how large a fraction is due to the stretch reflex.

In this study, 6 spastic patients with hemiparesis were investigated with respect to the mechanical responses to stretch in the plantar flexors around the ankle joint. Each subject sat in a chair, the left foot strapped to a platform. During ongoing voluntary contraction, the platform was rotated around the ankle joint by a motor (Sinkjar et al., J. Neurophysiol. 1988; 60:1110-1121). The stiffness (the torque increment divided by changes in the ankle position), measured during voluntary contraction, evaluated total stiffness. The stiffness measured during electrical stimulation of the tibial nerve, evaluated non-reflex stiffness (intrinsic and passive stiffness). The reflex mediated stiffness was equal to the total stiffness minus non-reflex stiffness. In each subject the stiffness of the spastic joint was compared with the stiffness of the non-spastic joint.

The total stiffness of the spastic joint was on average 3.6 Nm/degrees compared to 2.6 Nm/degrees of the non-spastic joint. The passive stiffness was increased with 162% from 0.63 to 1.65 Nm/degrees. The reflex mediated stiffness amounted to more than 50% of the total stiffness in the spastic and non-spastic leg of the patients, with slightly larger reflex stiffness in the spastic leg.

The higher total stiffness in the spastic leg was primarily caused by a higher non-reflex stiffness. We hypothesize that under the experimental conditions, where hypertonia is usually assessed, the stretch reflex is masked by a simultaneous descending input to the muscle.

HUMAN SPINAL CORD REFLEX VARIABILITY: NOISE VERSUS CHAOS. S.J. Schiff. Dept of Neurosurgery, Children's Nat Med Ctr, Washington, DC 20010.

Spinal cord monosynaptic reflex variability is striking. Previous analyses have assumed that it has a significant random noise-like component. Recent advances in characterizing complex dynamical systems suggests that a re-evaluation of this phenomenon is warranted. Time series of 1000 human H-Reflex responses to identical 1 Hz stimuli were recorded and integrated. The series were embedded in increasingly higher dimensional space and a box counting algorithm used to compute the correlation integral and approximate a correlation dimension. The Kolmogorov entropy was estimated. Pseudo-random number time series were used as control simulations. Fourier power spectral analysis revealed a broad-band pattern. Entropy results suggest that the output of this system is not random, but resolution of an attractor with fractal dimension proved difficult. The complexity of this system, as well as practical constraints on data collection, limit the applicability of these techniques in this setting.

LIP MUSCLE EMG RESPONSES TO MECHANICAL STIMULATION IN A SIMPLE REACTION TIME TASK. M.D. McClean. Audiology and Speech Center, Walter Reed Army Medical Center, Washington, D.C. 20307-5001.

EMG recordings were obtained of upper and lower lip muscle while subjects produced simple speech utterances in response to mechanical stimulation. Subjects were instructed either to produce the syllable "pa" as quickly as possible or not respond when they detected movement of a paddle held between the lips. Stimuli were adequate to elicit reflexes over poststimulus intervals of 15-30 ms (R1) and 30-50 ms (R2). EMG levels were calculated on-line for 240 trials over several poststimulus time intervals. The independent effects of stimulus level, pre-stimulus EMG level, and reaction time on response levels were assessed using multiple regression analysis. R1 and R2 levels were positively correlated with stimulus level, but stimulus level had little modulating effect on intentional responses. Both reflex and intentional response levels were strongly dependent on prestimulus EMG level. Instructional set had significant modulating effects on reflex responses in 9 of 10 subjects, but the nature of these effects varied among subjects. These findings are discussed in relation to similar studies on limb motor systems and lip motor control for speech.

COMPARISON OF THE EFFECT OF CLONIDINE ON REFLEXES RELATED TO URINARY SPHINCTER AND HINDLIMB FUNCTION. G.J. Bjalik* and J.W. Downie. Departments of Pharmacology and Urology, Dalhousie Univ., Halifax, Nova Scotia, B3H 4H7.

We have previously shown that clonidine (CLON) diminishes somatic and viscerosomatic reflexes evoked on the pudendal nerve (JPET 246:352, 1988). In this study we compared this effect of CLON to its effect on typical group I, II, and III somatic reflexes. These reflexes were monitored by recording compound action potentials on peripheral nerves in response to electrical stimulation of appropriate nerves in chloralose anesthetized or decerebrate cats acutely spinalized at T10. CLON (1-100 µg/kg i.v.) decreased the two pudendal reflexes and the group II and III reflexes, but had no effect on the group I reflex. The ID50 of CLON for suppression of the pudendal reflexes was lower than for group II and III reflexes, however CLON was more efficacious on the somatic reflexes (statistically significant only for group II).

Cord dorsum potentials (CDs) associated with pudendal and group II reflexes were unaffected by CLON. There was a dose-dependent increase in the group III CD. The group I CD was maximally increased at the lowest CLON dose tested (1 µg/kg).

Thus it was possible to separate the effect of CLON on pudendal reflexes from its effect on typical group I, II and III somatic reflexes. The suppressive effect of CLON was not likely expressed at the level of the first order interneurons. Based on the CD data, CLON appears to enhance the first order interneuron depolarization. PARTITIONING OF TRIGEMINAL CUTANEOUS AFFERENT REFLEXES BETWEEN FACIAL MUSCLES IN MAN. C.G. Widmer and J.P. Lund. Dental Research Center, Emory University, Atlanta, GA 30322 and Centre de Recherche en Sciences Neurologiques, Univ. of Montréal, Montréal, Canada H3C 3J7.

It has been assumed that all trigeminal cutaneous afferents provide a similar input to facial motoneurons. This study investigated the alternative hypothesis that trigeminal cutaneous afferents have differential reflex effects on various facial motoneuron pools.

In six subjects who gave informed consent, bipolar surface EMG recordings were made from various facial, masticatory and cervical muscles bilaterally and simultaneously for 32 ms prior to and 128 ms after the stimulus (0.2 ms pulse/2 sec). Facial muscles included frontalis, orb. oculi, lev. labii, zyg. major, orb. oris sup., orb. oris inf., and dep. anguli oris; masticatory muscles included masseter and suprahyoids; and cervical muscles included SCM and trapezius. Stimulation sites on the right side of the face included supraorbital, infraorbital, nose, filtrum, upper lip, corner of lip, lower lip, and mental area (all 6 subjects) and intraoral sites (2 subjects) including palate and mucosa over mental nerve. Ten responses were evaluated at non-noxious (4-5T) and at noxious (9-10T) stimulation levels during conditions of relaxation and active muscle contraction.

There were generally four types of responses that were found to be dependent on the site of stimulation: short (13.4 ± 1.4 ms) and long (40.5 ± 2.1 ms) latency excitation in the orb. oculi muscles which was reduced as the stimulus site was moved away from the eye; short latency (14.2 ± 1.5 ms) excitation in the orb. oris with mental nerve stimulation; middle (23.1 ± 3.0 ms) and long (53.1 ± 3.9 ms) latency inhibition in the facial, masticatory and cervical muscles when the stimulus was in the extraoral region; and short (13.1 ± 2.1 ms) and long (51.6 ± 11.3 ms) latency inhibition in the masseter muscles after intraoral stimulation. The excitatory reflexes were elicited at lower (non-noxious) intensities of stimulation while inhibition was more apparent at the noxious stimulation levels.

These findings support the hypothesis of reflex partitioning of trigeminal cutaneous afferents on facial motoneurons

ELECTROMYOGRAPHIC FINDINGS OF LOCAL TWITCH RESPONSES IN THE RABBIT SKELETAL MUSCLES. C.Z. Hong* and Y. Torjose*. Dept. of Physical Medicine & Rehabilitation, and Dept. of Anatomy & Neurobiology, University of California Irvine, Irvine, CA 92717.

Local twitch response (LTR) is a brisk twitching of a bundle of muscle fibers elicited by a sudden mechanical stimulation on the sensitive site along palpable taut band. It is a characteristic response of myofascial trigger point in skeletal muscle fibers. In this report, electromyographic (EMG) study was performed in adult rabbits under light general anesthesia, preserving most central nervous system mediated reflexes. While LTR was elicited by mechanical tap stimulation (solenoid driven) on the most responsive site of a taut band, EMG activity was recorded from the same band. The EMG recordings showed latency (8-15 msec), amplitude (0.3-1.5 mV) and total duration of burst activities (60-100 msec) that are quite different from stretch reflex. After Lidocaine infiltration or transection of the innervating muscle nerve, LTRs were greatly reduced as demonstrated in the decreased EMG activities. These results suggest that the central nervous system is essential for the propagation of LTR, probably via the nociceptive sensory system. Electric stimulation of the most mechanically responsive sites along the taut bands elicited EMG activities that were less than 10% of mechanically induced responses. The above findings are compatible with the data of human studies on LTRs. We conclude that it is possible to use this animal model for investigations of myofascial trigger points. (Supported in part by UCI College of Medicine Faculty Research Grant).

FIELD POTENTIALS PRODUCED BY STIMULATION OF PUDENDAL, SUPERIOR PERINEAL AND PELVIC AFFERENTS IN THE SACRAL SPINAL CORD OF THE CAT. J.W. Downie*, B. Fedirchuk, L. Song* and S.J. Shefchyk. *Dept Pharm, Dalhousie Univ., Halifax NS; Dept of Med. and Physiol, Univ. of Manitoba, Winnipeg, Canada, R3E 0W3.

The location within the lumbosacral spinal cord of neurons activated by sacral afferents was determined by recording the field potentials produced by low threshold electrical stimulation of peripheral nerves. Experiments were conducted on chloralose anaesthetized male cats paralyzed with flaxedil. The sensory branch of the pudendal, the superior perineal cutaneous nerve and branches of the pelvic nerve in close proximity to the bladder were stimulated. Field potentials were recorded within the L7-S3 spinal cord segments using either sodium citrate-filled glass microelectrodes or carbon filament in glass electrodes. Locations of electrode tracks within the spinal cord were histologically confirmed.

Field potentials evoked from both sensory pudendal and superior perineal nerves had a central latency of 0.7-1.1 ms. Fields produced by the sensory pudendal nerve stimulation were maximal at the rostral to mid S1 segment and were in the medial portion of laminae V & VI. Those produced by superior perineal nerve stimulation were maximal at the mid to caudal S1 segment and located more laterally in laminae V & VI than the sensory pudendal fields. Smaller fields from both nerves could be also localized to areas within laminae IV & X depending on the particular segment. Pelvic nerve stimulation (n=2) revealed discrete field potentials located in S2 and caudal S1 spinal segments.

This research was supported by the Canadian National Centres of Excellence (NCE) network for Neural Regeneration and Functional Recovery.

FACTORS CONTRIBUTING TO CYCLICAL MODULATION OF THE SOLEUS H-REFLEX DURING WALKING IN HUMANS. J.F. Yang, Dept. of Physical Therapy and Div. of Neuroscience, University of Alberta, Edmonton, Canada T6G 2S2.

The soleus (SOL) Hoffmann (H) reflex is highly modulated as a function of the time in the walking cycle. The amplitude of the reflex rises and falls with the amplitude of the background EMG from the SOL muscle, suggesting that the reflex amplitude is simply a reflection of the postsynaptic excitability of the SOL motoneuron pool. Do presynaptic mechanisms contribute to this modulation? Human subjects were trained to activate the SOL muscle during the swing phase, when the muscle is normally inactive. The slope of the relationship between the SOL H-reflex amplitude and the background SOL EMG was higher for the stance than the swing phase, suggesting that presynaptic mechanisms may be important in the cyclical modulation of the reflex. Does reciprocal inhibition from the antagonist, the tibialis anterior (TA), contribute to this cyclical modulation? Subjects were trained to keep the TA inactive during walking. The SOL H-reflex continued to be deeply modulated in spite of a lack of TA activity. This suggests that reciprocal inhibition from the antagonist is not essential for the cyclical inhibition of the SOL H-reflex. In summary, both pre and postsynaptic mechanisms appear to contribute to the cyclical modulation of the SOL H-reflex in walking. This modulation is not entirely dependent on the activation of the antagonist muscle.

H-REFLEX IN THE FREELY MOVING RAT: METHODS AND INITIAL DATA. J.R. Wolpaw, X.Y. Chen, and J.S. Carp, Wadsworth Labs, NY St Dept Hlth & SUNY, Albany, NY 12201.

Primates can gradually increase or decrease the spinal stretch reflex or its electrical analog, the H-reflex (HR). Such conditioning changes the spinal cord (Wolpaw & Carp, *TINS* 13:137-142, 1990; and this volume). To develop further this model for defining the substrates of operantly conditioned plasticity, we are studying the HR in freely moving rats.

Male Sprague-Dawley rats (300-400 gm) are chronically implanted with fine-wire EMG electrodes in right ankle extensors, stimulating cuff on right tibial nerve, and bipolar stimulating electrode in left medial forebrain bundle (MFB). Electrodes connect to a head-mounted tether. Monitored and rewarded by computer, each rat learns to keep background EMG in a specified range. At a random time, nerve cuff stim at M response threshold elicits the HR. Under the control mode, reward (60-Hz MFB stim, 20-40 uA, 250 ms) begins 200 ms later. Rats usually perform more than 7,000 trials in 24 hrs.

The HR begins at about 5 ms, lasts about 3 ms, and is of modest size (<1 x background EMG). Its size appears to display a diurnal rhythm different in phase from that of monkeys. Efforts to condition the HR by making reward dependent on HR size are underway. (Supported by NIH NS22189 and Paralyzed Veterans of America Spinal Cord Research Foundation.)

SUMMATION AND COLLISION BETWEEN ACOUSTIC AND ELECTRICAL SIGNALS THAT EVOKE THE STARTLE REFLEX IN THE RETICULAR FORMATION. J.S. Yeomans and K.A. Cochrane*, Dept. Psychology, Univ. Toronto, Toronto, Canada, M5S 1A1.

To measure when and where the acoustic signals that evoke the startle reflex pass, we delivered brief, loud acoustic stimuli (1-5 ms, 106-110 dB) and tested, at various interstimulus intervals (ISI), the currents required to evoke a startle response with a single 0.1 ms cathodal pulse delivered to the pontine or medullary reticular formation in rats. Acoustic stimulation reduced by 20-90% the required current at ISIs from -10 to +10 ms, suggesting strong summation between acoustic and electrical stimuli. When the electrical pulse was presented 1.5-4.5 ms after the end of the acoustic signal, however, the summation was often blocked for about 0.5 ms, suggesting collision between action potentials evoked by the acoustic and electrical stimuli. Hence, acoustic stimulation evokes a synchronous volley of action potentials that passes through the reticular formation, and this volley evokes most of the acoustic startle reflex. These "acoustic-electric collisions" were similar in form to the "electric-electric collisions" obtained by stimulating pairs of sites in pons and medulla (Yeomans et al., *SN Abstr.*, 1990), but occurred at longer ISIs. These tests define the spatial and temporal properties of the axons and synapses that mediate electric and acoustic startle responses.

254.10

DOWNTRAINING OF TRICEPS SURAE H-REFLEXES DURING A BALANCE TASK IN HUMANS. M.H. Trimble* & D.M. Koceja, Motor Control Lab, Indiana University, Bloomington, IN 47405.

Wolpaw and colleagues (1989; 1990) and Meyer-Lohmann et al. (1986) have demonstrated that the spinal stretch reflex is modifiable under various conditions. In the present study, training induced reductions of the triceps surae H-reflex during a balance task have been demonstrated. Subjects were instructed to balance on a single axis balance board. H-reflexes, which served as the perturbation, were elicited when the subject was balanced. Activity of the tibialis anterior and triceps surae muscles were monitored throughout. The findings support the notion of a downtraining effect, as shown below. Further, these findings suggest that the plasticity of the spinal stretch reflex may play a role in task specific adaptations of balance control.

QUANTITATIVE BEHAVIORAL ASSESSMENT OF CAT TAIL HYPERREFLEXIA AFTER SPINAL CORD LESIONS.

R. M. Friedman, C. J. Vierck, Jr., and L. A. Ritz, Departments of Neuroscience and Neurosurgery, University of Florida College of Medicine, Gainesville, FL 32610

Previously we (Friedman et al., 1990) observed that chronic sacrocaudal transection (at Cal) produces in cat tails the following signs of spasticity: (1) shorter response latencies than normal to mechanical cutaneous stimulation, (2) clonus-like oscillations in response to cutaneous stimulation, and (3) tonic deviation of the tail in a ventroflexed position, suggesting an increase in tone of the ventral muscles. Here we report on responses of the tail to electrocutaneous stimulation. Cats with chronic (> 2 years) Cal transections (1) respond with longer durations than normal cats to an electrocutaneous stimulus, (2) and react to trains of electrocutaneous stimulation with a potentiation (summation) of the reflex. We propose that after spinal cord transections, cutaneous reflexes are influenced by abnormally prolonged activity in spinal circuits. Presently, we are studying the development of these signs of spasticity over time after spinal cord lesions. Supported by grant NS27511.

A NEUROMECHANICAL CONTROL MODEL OF THE RABBIT NICTITATING MEMBRANE. G.T. Bartha* and R.F. Thompson, Neurosciences Program, University of Southern California, Los Angeles, CA 90089.

Nictitating membrane (NM) extension is a passive consequence of eyeball retraction in rabbit. The retractor bulbi muscle is the primary effector for eyeball retraction and the accessory abducens nucleus is the main pool of motoneurons innervating the retractor bulbi muscle. Previous studies have recorded from a small number of isolated accessory abducens neurons in order to functionally characterize their role in NM extension. We have adopted a theoretical approach to define more precisely the relation of motoneuron activity to NM responses.

We have built a computer model of the rabbit eye and retractor bulbi muscle that takes patterns of neural activity in the form of action potentials as input and produces movement of the NM as output. The model is based on known physiological and mechanical properties of the eye and muscle. The retractor bulbi muscle was modeled at the motor unit level to permit direct comparison with experimental data and up to 100 motor units were simulated. The model allows us to investigate what behavior is produced by a given pattern of neural signals and what patterns of neural input are required to produce a given behavior.

Although neural activity is highly correlated with behavior, simulations show that there can be significant differences between the shape of histogrammed motoneuron activity and the shape of the NM response. For example, peak NM extension can occur as much as 70 ms after the termination of a 30 ms burst of spikes. The neural input required for the model to generate NM responses is more consistent with single accessory abducens unit recordings from awake rabbits (Quinn, et al., *Soc. Neurosci. Abstr.*, 8:314, 1982) than recordings from anesthetized rabbits (Berthier and Moore, *Brain Res.*, 258:201, 1983). The model also supports the hypothesis that NM retraction is generally passive. STRATEGIES FOR THE SIMPLIFICATION OF SENSORIMOTOR TRANSFORMATIONS IN THE WIPE REFLEX OF THE SPINAL FROG. W. Z. Rymer and J. L. Schotland. Department of Physiology, Physical Medicine & Rehabilitation and Neuroscience Institute, Northwestern University Medical School, Chicago, Illinois 60611.

In the wipe reflex of the spinal frog, propriospinal and cutaneous information concerning orientation of the body and limbs is combined with cutaneous information related to the location of the stimulus, to yield a smooth, coordinated movement of one of the limbs to remove an irritating stimulus located at any point on the body surface. Just how this kind of transformation is managed by the nervous systems has been the subject of considerable debate. We sought to investigate the kinds of spinal cord circuitry that might be predicted to simplify the coordination of sensorimotor transformations in the wipe reflex.

We examined the kinematics of wiping movements in four animals, elicited as a sequence of stimuli was moved progressively over the skin. The 3-D coordinates of the position of the foot over time, and the displacement of hip, knee, and ankle joints, were recorded using a WATSMART infrared emitter-detector system. These data were quantified using principal components analysis to provide a measure of the shape (eigenvalues) and orientation (eigenvector coefficients) of the movement trajectories. If an unique neural circuit were invoked to coordinate the response to each stimulus location, smooth changes in kinematic parameters of the movement would be elicited in response to continuous changes in stimulus location. Instead, we found that the movement of the foot during the initial flexion of the wipe appears to be constrained to motion along a single axis that is quite similar for wipes to widely differing stimulus locations, including movement that use very different strategies for removal of the stimulus. Likewise, foot movement during the rhythmic portion of the wipe appears to be limited to motion along one of the two axes. The organization of neural circuits required for sensorimotor transformations involved in the wipe reflex appears to be constrained to a great degree in comparison to the number of stimulus sites and variations of wiping movements. Supported by POINS17489 to WZR and NIMH MH09566-03 to JLS.

LARYNGEAL MUSCLE RESPONSES TO PERIPHERAL NERVE AND TRANSCRANIAL MAGNETIC STIMULATION. C.L. Ludlow¹, L.G. Cohen², M. Hallett², J. S. Yeh¹ and M. Shibusawa².¹ Voice and Speech Section, VSLB, NIDCD, and ² Human Cortical Physiology Unit, HMCS, MNB, NINDS.

Magnetic stimulation has been used to evaluate the conduction time from the cortex to the laryngeal muscles. Because of the close proximity of the laryngeal nerves during transcranial magnetic stimulation, responses may be due to stimulation of either the cortical pathways or the peripheral nerves. Our purpose was to identify responses obtained during stimulation of the peripheral laryngeal nerves at different locations, and the cortex transcranially, in awake humans. Indwelling hooked wire electrodes were used to record from the intrinsic laryngeal muscles, the right and left thyroarytenoids and cricothyroids, while stimulating with a Cadwell magnetic stimulator on each side. Six stimuli were presented at 11 positions on each side: at the angle of the jaw and at 1 cm intervals progressing up the side of the face and transcranially 6 cms anterior to T3 or T4. Five peripheral responses were identified: an early ipsilateral one at a latency of less than 3 ms seen only at the stimulation points close to the larynx; an ipsilateral response to nerve stimulation at 3-4 ms for the cricothyroid and 6.5-8 ms for the thyroarytenoid; an ipsilateral one at 14 ms in the thyroarytenoid; a bilateral brief response in all four muscles at 23 ms; and late responses around 45 ms in both thyroarytenoids. The only response to transcranial stimulation that was not seen during peripheral stimulation was a contralateral response in either muscle, between 15 and 20 ms in the thyroarytenoid, and around 12 ms in the cricothyroid, indicating a cortical to laryngeal muscle conduction time of approximately 12-15 ms.

REPETITIVE BURSTS OF FLEXOR MUSCLE EMG ACTIVATED BY SINGLE CUTANEOUS NERVE STIMULI IN SPINAL CAT. R.G. Durkovic and S.G. Nord. Depts. of Physiology and Neurology, SUNY Health Science Center, Syracuse, NY 13210.

In order to characterize flexion reflex responses, EMG activity was recorded with indwelling needle electrodes from the tibialis anticus and biceps femoris muscles of acute spinal cats (decerebrate, unanesthetized). Single electrical pulses (0.2ms) were presented to the lateral sural, saphenous or superficial peroneal cutaneous nerves. Recordings were monitored for 200 ms following each stimulus.

Stimulation of each cutaneous nerve at an intensity that activated large myelinated (A α) cutaneous fibers, but just below the threshold of small myelinated (A δ) cutaneous fibers, produced an initial burst of EMG activity in each muscle (latency 8-24 ms). Additional bursts (usually two) of activity with intervening periods of quiescence often followed the initial one. Cutaneous nerve stimuli that activated both A α and A δ cutaneous nerves supramaximally often increased the amplitude and decreased the intervals between EMG bursts. The results demonstrate that cutaneous nerve stimulation can evoke flexion reflexes with multiple EMG bursts in the absence of either supraspinal influences (e.g., startle) or activation of A δ afferent fibers. Supported by NSF Grant 8808495.

VIBRATORY RESPONSES IN SPINAL CORD INJURY SUBJECTS AFTER CUTANEOUS DEAFFERENTATION. A. M. Sherwood, M. R. Dimitrijevic, and P. J. Sharkey*, Div. of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, TX 77030.

Vibration induces a well-defined tonic vibratory response (TVR) in experimental animals which is abolished by spinal cord transection [Matthews, *J. Physiol. (Lond.)* 184:450-472, 1966]. The TVR is also present in relaxed healthy subjects but has different characteristics in paralyzed spinal cord injury (SCI) subjects [Dimitrijevic et al. *Neurol.* 27:1078-1086, 1977]. Many SCI subjects have exaggerated withdrawal reflexes which can also be elicited by vibration along with the vibratory response (VR). The VR is distinguished by its sustained character time-locked to the vibration. We used multi-channel surface EMG to study responses to vibration at 100 Hz and 2-3mm displacement in four SCI subjects. Recordings were made before and after neurectomy of the sensory branches of the femoral nerve for management of spasticity. We found that the VR did not change, although cutaneous stimuli in the area over the quadriceps no longer elicited withdrawal reflexes. We concluded that, while vibration may elicit a withdrawal reflex mediated by cutaneous afferents, cutaneous receptors do not contribute to the VR itself in paralyzed SCI subjects.

SPINAL CORD AND BRAINSTEM: MOTONEURONS

255.1

STRENGTH OF RECURRENT INHIBITORY POSTSYNAPTIC POTENTIALS BETWEEN CLOSELY SPACED HOMONYMOUS AND HETERONYMOUS MOTONEURONS IN THE CAT. M.L. McCurdy and T.M. Hamm. Div. of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013.

The strength of recurrent inhibition within homonymous motoneuron pools is reported to be stronger than between heteronymous motoneuron pools, as estimated by average composite recurrent inhibitory postsynaptic potentials (RIPSPs) (Eccles et al., 1961). Since the distribution of recurrent inhibition produced by stimulating single motor axons in homonymous motoneurons is restricted along the rostrocaudal axis of the spinal cord (Hamm et al., 1987), homonymous-heteronymous differences in the strength of recurrent inhibition may be a result of this topographic distribution and the displacement in the rostrocaudal locations of heteronymous pools. We investigated this possibility by measuring the strength of recurrent inhibition between pairs of closely spaced motoneurons (range= 86-1861 μ m). Pairs of homonymous or heteronymous motoneurons were impaled with glass micropipettes in the seventh lumbar spinal segment of ischaemically decapitated cats. RIPSPs were recorded in one motoneuron in response to stimulation of a nearby motoneuron by injecting brief current pulses. The RIPSP values in homonymous and heteronymous pairs ranged from 0-339 μ V. Preliminary results suggest that motoneurons innervating the anterior-medial biceps femoris produce RIPSPs in nearby homonymous motoneurons that are significantly larger than RIPSPs produced by nearby heteronymous motoneurons. No significant difference was noted between RIPSP amplitude and the distance between motoneurons in a pair over the short range of distances examined. We also examined RIPSP amplitudes in relation to cell size as judged by input resistance and observed a positive correlation ($r=.55$). These results indicate that recurrent inhibitory pathways from individual motoneurons are distributed preferentially to nearby homonymous motoneurons. Supported by USPHS grants NS22454, NS08773 and NS07309.

255.2

EXCITABILITY OF FACIAL MOTONEURONES IS REDUCED DURING THE ATONIA OF ACTIVE SLEEP. P.J. Soja Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC V6T 1Z3, CANADA.

During active sleep (AS), lumbar and trigeminal (jaw-closer) motoneurons are subjected to powerful postsynaptic inhibition (see *Jnt. Rev. Neurobiol.*, 24: 213-258, 1983). Recent studies have demonstrated that the neurotransmitter glycine mediates this inhibitory drive (*J. Neuroscience* 9: 743-751, 1989; *J. Neuroscience*, 1991, in press). Facial muscles also become atonic during AS. However, the neural mechanism(s) underlying the atonia of the facial musculature during AS has not been determined. Accordingly, the excitability of facial motoneurons (MotVII) was examined during wakefulness (W), quiet sleep (QS), the non-rapid eye movement (non-REM) episodes of AS, and the REM episodes of AS.

Three adult cats were prepared for recording MotVII activity utilizing chronic head restraint methodologies developed previously by Chase et al. (*J. Neurophysiol.*, 44: 349-358, 1980). Glass micropipettes filled with 165 mM NaCl were directed stereotaxically toward MotVII. Low intensity stimuli (0.04 ms, 4.5 mA, 1.0 Hz) were delivered to the VII nerve via miniature stainless steel screws which were permanently implanted into the mastoid process; such stimuli induced a twitch in the muscles controlling movement of the pinna, eyelid and vibrissae. The MotVII pools were located between 21.0-22.5 mm below the surface of the cerebellum by recording a characteristic negative going antidromic field potential of 3.0-4.5 mV in response to VII nerve stimulation. The stimulus intensity was adjusted during W so that the amplitude of the antidromic field potential was approximately 75% of maximal. Computerized analyses indicated that the amplitude of the antidromic field potential did not change from W to QS; it was, however, markedly suppressed by 45-67% during non-REM episodes of AS when compared to W or QS. During the phasic REM episodes of AS, the antidromic field potential was further suppressed.

Bevelled glass micropipettes filled with 2M K⁺-citrate were used to record intracellularly from antidromically identified facial motoneurons. Intracellularly recorded membrane potential activity was characterized by the marked presence of large amplitude spontaneous hyperpolarizing potentials influencing these cells during AS when compared to QS or W; a finding which is reminiscent of the spontaneous glycinergic IPSPs which inhibit lumbar motoneurons during AS (*ibid*). The present results suggest that a process of postsynaptic inhibition contributes to the atonia of the facial musculature which occurs during AS. Supported by grants from the British Columbia Health Research Foundation.

SHORT LATENCY SYNAPTIC EXCITATION OF FORELIMB AND PHRENIC MOTONEURONS INDUCED BY STIMULATION OF THE RED NUCLEUS AND CEREBROFUGAL FIBERS IN CATS. Y. Fujito, T. Imai* and M. Aoki*. Department of Physiology, Sapporo Medical College, Sapporo 060, JAPAN

Recent histological studies have provided evidence suggesting direct rubro-motoneuronal connections in distal forelimb motoneurons (Mns) and direct cortico-motoneuronal connections in the phrenic Mns in the cat. In the present electrophysiological experiments, we examined whether there are short latency EPSPs suggesting monosynaptic rubro- and cortico-motoneuronal connections in the cervical spinal segments in cats. Under pentobarbital anesthesia and immobilization with gallamine triethiodide, intracellular recordings were made from forelimb and phrenic Mns following stimulation of the red nucleus (RN) and the cerebral peduncle (CP). Single pulse stimulation of RN produced EPSPs in the majority of forelimb Mns (60/86, 70%). Segmental latencies of RN-EPSPs shorter than 1.2 ms were observed in 16 of 24 forelimb Mns in which RN-EPSPs were detected in the C8-T1 segments, while in 3 of 36 forelimb Mns in the C6-7 segments. This result suggests that rubro-motoneuronal connections are, at least in part, monosynaptic in forelimb Mns innervating distal muscles in particular. By contrast, single shocks to RN and CP rarely produced EPSPs in phrenic Mns (6/24) and forelimb Mns (8/86), respectively. There was no obvious evidence suggesting monosynaptic connections between RN and the phrenic Mns, and between cerebral cortex and forelimb Mns. In the phrenic Mns, CP-EPSPs were produced by single shocks in 10 of 24 Mns and their segmental latencies shorter than 1.2 ms were observed in few cells.

SUMMATION OF EFFECTIVE SYNAPTIC CURRENTS AND FIRING RATE MODULATION IN CAT TRICEPS SURAE MOTONEURONS PRODUCED BY CONCURRENT STIMULATION OF DIFFERENT SYNAPTIC INPUT SYSTEMS. R.K. Powers, F.R. Robinson, M. Konodi* and M.D. Binder. Dept. of Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195.

We have investigated the summation of effective synaptic currents in triceps surae motoneurons of the cat generated by three input systems; the red nucleus, the sural nerve (5xT), and the homonymous Ia afferent fibers. The modified voltage clamp technique (Heckman and Binder, *J. Neurophysiol.* 60: 1988) was used to measure the steady-state effective synaptic currents produced by activation of each of the inputs alone and the net effective synaptic current when two or all three of the inputs were activated concurrently. We then injected sufficient depolarizing current to elicit repetitive firing in the motoneuron, and repeated the activation of one or more of the inputs. In most cases, the net effective current produced by concurrent activation was within 20% of the predicted algebraic sum of the individual currents. Moreover, the change in a motoneuron's firing rate produced by the concurrent activation of two or more input systems could be predicted from the net effective synaptic current that they generated and the slope of the motoneuron's f-I relation. (Supported by NIH grants NS26840, NS25206 and EY07991)

MOTONEURON PHYSIOLOGY AFTER H-REFLEX CHANGE BY OPERANT CONDITIONING. J.S. Carp, X.Y. Chen and J.R. Wolpaw. Wadsworth Labs, NYSDOH/SUNY, Albany, NY 12201.

Monkeys (*Macaca nemestrina*) can slowly increase or decrease the size of the triceps surae (TS) H-reflex (HR), the electrical analog of the monosynaptic stretch reflex. Such conditioning changes the spinal cord (Wolpaw & Carp, *TINS* 13:137-142, 1990). In order to define these spinal cord alterations, we are recording intracellularly from motoneurons (MNs) in naive animals and in animals in which one leg's TS HR has been trained up (HR↑) or trained down (HR↓). Animals are deeply anesthetized throughout and sacrificed by overdose.

We have analyzed 95, 77 and 66 TS MNs in 14 naive, 8 HR↑ and 3 HR↓ animals, respectively. Soleus MNs on the trained side of HR↑ animals appear to have smaller homonymous compound EPSPs, lower input resistances and faster conduction velocities than those from naive animals. The opposite trend is seen in HR↓ animals. Also, AHP appears to be briefer on the trained than the control side of HR↑ animals, and the reverse is seen in HR↓ animals. These effects are less apparent in gastrocnemius MNs. Thus, these limited data suggest that HR conditioning changes MNs and/or their afferent input. The relationship between these effects under anesthesia and the HR changes in awake behaving animals is not yet clear. EFFECTIVE SYNAPTIC CURRENTS AND FIRING RATE MODULATION IN CAT TRICEPS SURAE MOTONEURONS PRODUCED BY STIMULATION OF THE RED NUCLEUS. M.D. Binder, R.K. Powers, F.R. Robinson and M. A. Konodi*. Dept. of Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195.

We have investigated the effects of stimulating the red nucleus on triceps surae motoneurons of the cat both at rest and during repetitive discharge. The modified voltage clamp technique (Heckman and Binder, *J. Neurophysiol.* 60: 1988) was used to measure the steady-state effective synaptic currents produced by 200 Hz stimulation at a fixed site within the contralateral red nucleus. We then injected an amplitude series of depolarizing 1 sec current pulses and repeated the red nucleus stimulation. From these data, we could determine the firing rate-injected current (f-I) relation of each motoneuron and compare the actual effect of stimulating the red nucleus on motoneuron discharge rate with that predicted from the measurements of effective synaptic current and the f-I slope. We have found that the red nucleus generates both net excitatory and net inhibitory steady-state effective synaptic currents, some of which are considerably larger than those produced by other input systems. In most cases, the observed increase or decrease in motoneuron firing rate was matched by the product of the net effective synaptic current and the slope of the motoneuron's f-I relation. (Supported by NIH grants NS26840, NS25206 and EY07991)

STEADY-STATE VS. TRANSIENT SYNAPTIC INPUT FROM THE SURAL AND CONTRALATERAL PERONEAL NERVES IN CAT MOTONEURONS. C.J. Heckman, J.F. Müller and W.Z. Rymer. Dept. of Physiology, Northwestern University and Veterans Administration, Lakeside Hospital, Chicago, IL, 60611.

Recent studies have used steady-state synaptic input as a tool for assessing the distribution of synaptic input within the motoneuron pool (e.g. Heckman and Binder, *J. Neurophysiol.* 60: 1946, 1988). However, it is possible that sustained stimulation may evoke synaptic fatigue, induce plateau potentials, or alter the balance of interneuronal excitability. We investigated the relation between transient and steady-state post-synaptic potentials (PSPs) for the polysynaptic input from the caudal sural and contralateral peroneal nerves. Both inputs often exhibit single, transient PSPs that combine excitation and inhibition.

PSPs were recorded in medial gastrocnemius (MG) motoneurons in the pre-collicular decerebrate preparation. Steady-state PSPs were generated by 1 s of 100-200 Hz electrical stimulation. Steady-state sural PSPs (5 x threshold) were invariably depolarizing even though the transient sural PSPs often included an inhibitory component that was much larger than the short latency excitatory component. Steady-state peroneal PSPs (20 x threshold) were sometimes inhibitory. In addition, both inputs often produced sustained interneuronal afterdischarge or plateau potentials after cessation of stimulation. In our as yet small sample (n = 10), the amplitudes of the steady-state potentials from these inputs showed no systematic relationship with any intrinsic motoneuronal property.

The mechanism by which the depolarizing component of the steady-state sural input comes to dominate the inhibitory component is as yet unknown. However, this phenomenon may relate to recent findings that electrical stimulation of the sural nerve in the decerebrate does not unduly alter recruitment order (Clark and Cope, *Soc. Neurosci. Abstr.* 16:888, 1990).

MOTONEURON MORPHOLOGY IN THE RAT. X.Y. Chen, J.S. Carp, and J.R. Wolpaw. Wadsworth Laboratories, New York State Department of Health and State University of New York, Albany, NY 12201.

In conjunction with work directed at defining physiologic and anatomic substrates of operantly conditioned plasticity in the spinal cord (Wolpaw & Carp, *TINS* 13:137-142, 1990; and this volume), we are studying morphology of motoneurons in the rat lumbar spinal cord that innervate ankle extensor muscles.

Male Sprague-Dawley rats (300-400 gm) are deeply anesthetized with pentobarbital. Motoneurons identified by antidromic stimulation are labelled intracellularly with HRP. Animals are sacrificed by overdose and perfused.

For 12 motoneurons analyzed to date, soma diameter was 34 ± 5 μ m (mean \pm SD), number of primary dendrites was 8 ± 2 , and dendritic spread was 1190 ± 245 μ m rostrocaudal, 1104 ± 206 μ m dorsoventral, and 764 ± 121 μ m mediolateral. Conduction velocity was 43 ± 4 m/s. Additional evaluation of dendritic extent and complexity and correlation of morphologic and physiologic measures are underway.

FIRING RATE AND FORCE MODULATION OF CONCURRENTLY ACTIVE MOTOR UNITS: IMPLICATIONS FOR THE SYNAPTIC ORGANIZATION OF MOTONEURON POOLS. K.E. Tansey and B.R. Botterman. Dept. of Cell Biology and Neuroscience, Univ. of Texas Southwestern Med. Center, Dallas, TX 75235.

The intrinsic properties of motoneurons and the organization of their synaptic inputs strongly influence their recruitment thresholds and their subsequent firing rate modulation. Here we consider the discharge patterns observed in pairs of type-identified motor units of the cat medial gastrocnemius muscle during graded contractions evoked by brainstem stimulation. Motor units in some pairs were reactivated intra-axonally with their previously recorded discharge patterns to estimate their force contribution to the whole muscle contraction.

Parallel firing rate modulation was observed only in pairs of motor units of the same type and of similar recruitment thresholds. In unit pairs of dissimilar type and recruitment thresholds, however, parallel rate modulation was not seen. As whole muscle force increased, low threshold motor units completed their firing rate modulation before higher threshold units were recruited and subsequently rate modulated. We infer from this that the synaptic drive to the motoneuron pool may be uneven and that higher threshold units may receive increases in synaptic drive that are not shared with lower threshold units. Interestingly, pairs of motor units which demonstrated parallel firing rate modulation rarely produced parallel force modulation. The lower threshold unit usually reached the upper end of its frequency-tension curve before the higher threshold unit reached the steep portion of its frequency-tension curve.

We are presently attempting to sample a larger population of concurrently active motor units by using selective EMG recordings to better assess the distribution of synaptic effects onto selected motoneuron pools. Supported by NIH grant NS17863.

MOTONEURON DENDRITIC TREES: DEPENDENCE OF BRANCH DIAMETER ON ORDER PREDICTED BY A SIMPLE MODEL. W. B. Marks and R. E. Burke. Lab of Neural Control, NINDS, Bethesda, MD 20892

Branch diameter has an approximate double exponential dependence on branch order in motoneurons (e.g. Cullheim et al., *J. Comp. Neurol.* 255: 68, 1987). We have been able to fit this dependence by making two simplifying assumptions about dendrites. First, when a dendrite branches, the daughter diameters are random with a mean and standard deviation proportional to the parent diameter. Second, all daughters with diameters greater than a threshold, d_0 , branch again, while all with lower diameters terminate. Let $G(d; \text{mean}, \text{sd})$ be the distribution of daughter diameters, d , whose integral over d equals 1. Then the change in the distribution at order k , $\text{num}(d, k)$, of branch diameters at the next order would be

$$\text{num}(d, k+1) = 2 \int_{d_0}^{\infty} G(d; \text{mean}=m d', \text{sd}=s d') \text{num}(d', k) d' d$$

Along with $\text{num}(d, 0) = 1$ given initial distribution, this is the complete model. Because of the factor 2, at low orders when all diameters are greater than d_0 , the total number of branches doubles at each order. On average, the diameters drop by the factor $m < 1$ at each branch point. As branch order increases, the total branch number peaks and declines because increasing numbers of branches terminate as diameters fall below d_0 . When all the diameters fall below d_0 the process ends. For gastrocnemius α - and γ -motoneurons, $m = .6$, and $s = .2$. Adjusting $d_0 = 1.7 \mu\text{m}$ gave good fits to plots versus order of the total number of branches, average branch diameter and its variance.

255.13

SHORT-LATENCY EPSPs IN LUMBOSACRAL MOTONEURONS PRODUCED BY STIMULATION IN THE MEDIAL LONGITUDINAL FASCICULUS. M. K. Floeter, G. N. Sholomenko and R. E. Burke. Lab. of Neural Control, NINDS, NIH, Bethesda, MD.

As part of a study of the organization of excitatory last-order interneurons in the cat lumbosacral spinal cord (e.g., *Neurosci. Abstr.*, 16:890, 1990), we have studied the short-latency EPSP produced by electrical stimulation of a medial region of the cat brainstem (P7 - P14, L 0.5, 2mm below the floor of the 4th ventricle; corresponding to the ventral portion of the medial longitudinal fasciculus, or MLF) described originally by Grillner and coworkers (*Exp. Brain Res.* 12:457, 1971). The responsible pathway(s) has a narrow range of conduction velocity (~100 m/s) and generates two kinds of short latency EPSPs: (1) clearly **monosynaptic** (segmental latency 0.4 - 1.0 ms [mean 0.6 ms], small amplitude [$< 0.5 \text{ mV}$], with modest or no temporal facilitation during short stimulus trains [interval 3 - 10 ms]); and (2) possibly **disynaptic** (segmental latency 1.0 - 2.0 ms [mode 1.2 ms], generally larger amplitudes [up to 2.5 mV], with usually dramatic temporal facilitation [2-3 fold amplitude increase]). Facilitatory interactions with segmental excitatory reflex pathways have been surprisingly difficult to demonstrate, although a few clear examples have been found. The latter are consistent with attribution of the longer latency EPSPs to disynaptic connection through segmental last-order excitatory interneurons. The nature of the relatively powerful "disynaptic" MLF EPSPs, and their relation to control of excitatory segmental reflex pathways, particularly during fictive locomotion, are being studied.

255.10

IN VITRO ELECTROPHYSIOLOGY OF DEVELOPING NEURONS IN THE VENTRAL HYPOGLOSSAL NUCLEUS OF THE RAT. P.A. Núñez-Abades*, J.M. Spielmann and W.E. Cameron. Depts. of Behavioral Neuroscience and Pediatrics, University of Pittsburgh, Pittsburgh, PA 15260

Active and passive membrane properties of presumptive genioglossal motoneurons were studied in rats during postnatal development. These motoneurons are important in the control of the upper airways. Animals were anesthetized with halothane and transcardially perfused with cold oxygenated sucrose-artificial CSF and brainstem slices were cut at 300-400 μm . Intracellular recordings were made in cells located in the ventral hypoglossal nucleus in an area where intense retrograde labeling was found as a result of a prior dextran-rhodamine injection into the genioglossus. Both current-voltage and current-frequency curves were generated for 24 neurons with spike heights $>60 \text{ mV}$. Mean input resistance (R_{in}) at 1 week ($91.8 \pm 30.0 \text{ M}\Omega$) was significantly greater than that found at any age including five weeks ($32.4 \pm 4.1 \text{ M}\Omega$; $p < 0.02$) while mean rheobase (I_{rh}) at 1 week ($0.10 \pm 0.06 \text{ nA}$) did not become significantly different from older ages until 5 weeks ($0.42 \pm 0.13 \text{ nA}$; $p < 0.01$). The largest change in R_{in} occurred between 1 and 2 weeks while the largest change in I_{rh} was found between 4 and 5 weeks of age. The peak (first interspike interval) and steady state firing frequencies (FF) were measured in response to a variety of currents amplitudes. The slope of the steady state FF as a function of current was relatively constant throughout development (~30 Hz/nA). While the steady state FF demonstrated only a primary firing range, a secondary range of the peak FF was expressed in some cells at 1 week. By two weeks, all neurons exhibited a secondary range of peak FF. These data suggest different time courses for the change in ionic mechanisms underlying the active and passive properties of the motoneuron membrane. Supported by NIH (HD 22703) and Magee Womens Hospital.

255.12

COMPARATIVE STUDIES OF DENDRITIC MORPHOLOGY USING A COMPUTER SIMULATION APPROACH. R. E. Burke, W. B. Marks, and B. Ulfhake. Lab. of Neural Control, NINDS, NIH, Bethesda, MD 20892 and Dept. of Anatomy, Karolinska Institutet, Stockholm, Sweden.

We have developed a stochastic computational model to reproduce the statistical features of completely reconstructed gastrocnemius α -motoneuron dendrites from adult cats (*Neurosci. Abstr.* 16:115, 1990). Parameters that govern the probabilities of branching (**Pbr**) and terminating (**Ptrm**) and the diameters of daughter branches at branching points were derived directly from the morphological data. The only free parameter was rate of branch taper, which was allowed to vary near its observed mean value. In mature gastrocnemius motoneurons, **Pbr** and **Ptrm** were found to be exponentially dependent on local branch diameter, d , and non-linearly (and less strongly) dependent on path distance from the soma, p . The observed distributions of **Pbr**(d,p) and **Ptrm**(d,p) were approximated by algebraic expressions with four parameters each. Simulation of complete dendritic trees with specified stem diameters produced good agreement with a wide variety of morphological attributes of actual motoneuron dendrites. We have extended this approach to examine the dendrites of other species of spinal motoneurons (soleus and lumbosacral γ -motoneurons in adult cats, as well as triceps surae motoneurons obtained from immature kittens). Preliminary observations indicate that the simulation process permits identification of fundamental features that account for the morphological differences between dendrites of different neuronal groups. We assume that the parameter dependencies reflect underlying biological factors that can be studied in detail when identified, giving this approach more than taxonomic interest.

ELECTROPHYSIOLOGICAL CHARACTERISTICS OF GUINEA PIG TRIGEMINAL MOTONEURONS IN VITRO. S.H. Chandler and L.J. Goldberg. Dept. of Kinesiology, Brain Research Institute, and School of Dentistry, UCLA, Los Angeles, CA 90024

The trigeminal motor nucleus contains the motoneurons responsible for the production of masticatory movements. A detailed characterization of the passive and active membrane properties is essential to understanding the output characteristics of these cells in response to phasic and tonic synaptic input. Therefore, an *in vitro* slice preparation was developed to record from trigeminal motoneurons in the guinea pig. Guinea pigs (150-300g) were anesthetized, the brainstem removed and 400-500 μm slices were obtained. Long term intracellular recordings from motoneurons produced average values for membrane potential, action potential amplitude and input resistance of -65mV, 85mV and 13M Ω , respectively. Application of 1 second current pulses produced repetitive firing with a rapid adaptation to a steady-state discharge (SS). In most cells, a plot of instantaneous frequencies of 1st, 3rd, and 5th intervals versus current (F/I) were linear, whereas in some cells distinct primary and secondary range firing rates were observed which approached 300Hz. Steady-state F/I current relationships were linear approaching a plateau level of approximately 10-30Hz. The slopes of 1st and SS F/I intervals ranged from 24-80Hz/nA and 10-30Hz/nA, respectively. Cobalt substituted for Ca^{++} shifted the SS F/I curve to the left. At the same time, slow, long duration AHPs following each action potential in the train were abolished without a change in spike duration or amplitude. This suggests that the long duration AHP and adaptation of repetitive firing are controlled by activation of a Ca^{++} dependent K^{+} conductance. In contrast, 5-10mM TEA application increased spike duration and reduced the slope of the SS F/I curve. In addition, combined bath application of TTX, TEA, and barium revealed Ca^{++} spikes and plateau potentials. The experiments demonstrate that the *in vitro* slice preparation is viable for characterizing passive and active membrane properties and has established a foundation for future connectivity and pharmacological studies on masticatory motoneurons. CHANGE IN EPSP AMPLITUDE MODULATION DURING HIGH FREQUENCY STIMULATION IS CORRELATED WITH CHANGES IN EPSP AMPLITUDE - A BACLOFEN STUDY. K.R.Peshori, W.F.Collins, III and L.M. Mendell, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

Large amplitude EPSPs in low rheobase hindlimb motoneurons (MNs) depress during high frequency stimulation, whereas small amplitude EPSPs in large rheobase MNs tend to facilitate (Collins et al, *J.Neurophysiol*, 52:980,1984). We hypothesize that systematic differences in transmitter release onto different MNs account for this frequency dependent behavior. We have assessed this by modifying presynaptic transmitter release using l(-) Baclofen, a GABA-B receptor agonist, in the anesthetized *in vivo* rat spinal cord. Composite heteronymous EPSPs were recorded intracellularly from gastrocnemius MNs during low frequency stimulation (18Hz) and high frequency (167Hz) 32 shock bursts, before and after Baclofen injection (10mg/kg.i.v.). Baclofen administration reduced the 18Hz EPSP amplitude, with no change in MN input resistance or rheobase. In addition, depending on the initial pattern of modulation, depression of EPSP amplitude during the high frequency burst was diminished (see also Lev-Tov et al, *PNAS* 85:5330, 1988), facilitation was enhanced, or depression was converted to facilitation. This shift to more positive modulation was seen at all connections regardless of initial (pre-drug) EPSP amplitude, and was directly correlated in a given MN with the decrease in 18Hz EPSP amplitude. This change in facilitation/depression behavior at high frequencies by presynaptic manipulation of EPSP amplitude is an important step towards understanding the underlying mechanism(s) of EPSP amplitude modulation. Supported by NIH NS24206 (WFC) and NS16996 and NS14899 (LMM).

255.17

PROPERTIES OF MOTONEURONES, MUSCLE UNITS, AND THEIR RELATIONSHIPS IN RAT HINDLIMB. P.F. Gardiner, Physical Activity Sciences, University of Montréal, Montréal, Québec, H3C 3J7.

These studies extend previous observations (Gardiner and Kernell, *Pflugers Arch.*, 1990) that suggest that motoneuron (MN) membrane properties may be related to muscle unit contractile characteristics in the rat, as they are in cat. Properties of tibial MN (n=123) a subgroup of which innervated gastrocnemius (n=58), were determined in an *in situ* adult rat preparation using standard microelectrode techniques. For motor units, type slow (S) (twitch half relax time > 28 ms, completely fatigue resistant, absence of sag during unfused tetani) always possessed MN afterhyperpolarization half-decay time (AHPdec) > 20 ms, while fast (F) units always possessed values < 20 ms. Among F units, no significant r values above .5 were noted between MN and muscle unit properties. Similarly, when "slow" MN (AHPdec > 20 ms) were excluded from the total sample, no relationships among MN properties were evident. While slow and fast units in rat muscle can be distinguished based on AHPdec and twitch time-course, subgrouping of F units based on MN properties is less clear than in cat.

255.19

TRICEPS BRACHII FORCE OF ABLE-BODIED AND SPINAL CORD INJURED SUBJECTS. J.G. Broton, C.K. Thomas, B. Calancie, The Miami Project to Cure Paralysis and Dept. Neurol. Surg., Univ. of Miami, FL 33136.

Whole muscle and motor unit forces in triceps brachii were compared in able-bodied (A-B) subjects and those with cervical (cephalad to C6) spinal cord injury (SCI). SCI subjects were examined at least one year post-injury. Subjects sat in a dental chair. The test elbow was flexed at 90-100°. The forearm was supinated and stabilized in a support with Velcro straps. A transducer attached to the support near the wrist measured the force generated by isometric triceps contractions. EMG was recorded from the surface of the triceps and biceps brachii muscles. A bipolar needle electrode placed within the triceps muscle recorded single unit activity. Whole muscle force was measured from brief (3-5s) maximum voluntary contractions. Motor unit forces were measured by spike triggered averaging (STA). For STA, subjects were given auditory feedback of unit activity, and were asked to fire the unit at a slow steady rate for 1-2 min. All data were digitized and analyzed off-line with computer assistance.

Three A-B and six SCI triceps muscles have been studied. A-B subjects were much stronger than SCI subjects. During maximum voluntary contractions, triceps forces ranged between 180-550 N and 10-57 N for A-B and SCI subjects respectively. However at comparable firing rates, the forces produced by motor units in SCI muscles were either comparable or stronger than those of A-B subjects. Unit forces ranged from 11 to 789 mN for SCI subjects (mean \pm SD 165 \pm 207 mN; n=25) while those of A-B subjects ranged from 7 to 92 mN (37 \pm 24 mN; n=44). Larger than normal unit forces were measured in each SCI muscle studied. We suggest these strong units are due to denervation and subsequent motor axon sprouting because: 1) many of the unit potentials were polyphasic; 2) averages of triceps surface EMG showed that the same unit could be encountered at distant muscle sites; 3) unit activation was often accompanied by visible muscle contractions; and 4) denervator potentials were sometimes present (Supported by The Miami Project to Cure Paralysis).

QUANTITATIVE ULTRASTRUCTURE OF Ia BOUTONS IN THE VENTRAL HORN: VARIABILITY AND POSITIONAL RELATIONSHIPS. L.P.Pierce and L.M.Mendell, Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

Three MG Ia muscle afferents in the lumbar spinal cord of the cat were physiologically identified and intraaxonally injected with HRP. Serial sections were reacted with DAB, dehydrated, and embedded in EPON. A light level reconstruction of the fiber was generated, and selected regions were excised and serially thin sectioned for ultrastructural examination. High magnification (10,000x) micrographs were taken of every other section through each entire bouton, and provided the basis for quantitative analysis. Thirty-five boutons were characterized in terms of total volume, mitochondrial volume, total vesicle # and density, extent of apposition to the postsynaptic process, active zone area and shape. These features were then related to the position of the bouton within the terminal field and on the collateral arbor, the presence and number of presynaptic inputs and the type of postsynaptic element contacted.

Bouton characteristics varied greatly. Volumes ranged from 0.63 to 38.9 μm^3 with the distribution skewed towards lower values. Total vesicle # varied from 218 to 34700 and was also heavily skewed, with 45% containing fewer than 5000 vesicles. Volume and vesicle # displayed a high level of covariance (correlation: 0.91). Vesicle density ranged from 394 to 1800 vesicles/ μm^3 , and % mitochondrial volume varied from 5.9 to 39%. Total active zone area ranged from 0.19 to 3.6 μm^2 . The extent of variation is almost as great when one examines a group of boutons from the same afferent, contacting the same motoneuron. This suggests that neither the afferent nor the postsynaptic neuron plays an exclusive role in determining these anatomical features. The position of the bouton in the afferent arbor may be related to some bouton features, however. As one moves downstream within an *en passant* chain, the extent of apposition, volume and vesicle # decrease (excluding the terminal bouton, which shows more variability). Supported by NS08239, NS16996 and NS14899.

255.18

SYNAPTIC ORGANIZATION OF A SPINAL MOTOR POOL STUDIED BY COMPUTER SIMULATION. F.A.Dodge, IBM Research, T.J. Watson Center, Yorktown Heights, NY 10598.

By matching the isometric twitch kinetics, the structure of the motoneurons, and parameters of the Renshaw feedback to distribution measured on specific muscles, a mathematical model can be used to estimate how much excitatory synaptic drive projects to motoneurons of different size during simple reflexes. Tension at recruitment was found to be the most sensitive measure of the projection rules. For tonic reflexes, the excitatory interneurons must project with the same number of synapses independent of motoneuron type or size (S or FR). In this case, the largest motor units are recruited at about 40% or T_{max}, at which value about 1/2 the tension can be ascribed to rate modulation. For a soleus muscle, 40% T_{max} requires a maintained excitatory drive of 20 na to each neuron, or the firing of 200,000 synaptic endings per second (assuming all endings have the same efficacy as the Ia afferents). The observed frequency of departure from strict size-dependent recruitment order are found to be consistent with stochastic variation in structure measured in a given animal.

In a vibration reflex, the muscle tremor is generated mostly by the few largest active units, whose mean firing rates are seen as peaks in the observed power spectra. The magnitude of the tremor is smaller than that predicted from independent firing because Renshaw feedback introduces some negative correlation between larger and smaller units.

255.20

CNS MOTOR DRIVE AND MOTOR UNIT FIRING RATES IN TRICEPS BRACHII MUSCLE OF ABLE-BODIED AND SPINAL CORD INJURED SUBJECTS. C.K. Thomas, J.G. Broton and B. Calancie, The Miami Project to Cure Paralysis, Dept. of Neurol. Surg., Univ. of Miami, Miami FL 33136.

CNS motor drive and motor unit firing patterns were examined during voluntary contractions of triceps brachii in individuals with chronic and incomplete cervical spinal cord injury (SCI) involving levels cephalad to C6. Data from able-bodied (A-B) subjects served as controls. The subject sat in a dental chair with the test elbow flexed at 90-100°. The forearm was supinated and stabilized in a support by velcro straps. The isometric force of triceps brachii was measured with a transducer positioned at the wrist. CNS motor drive was assessed by superimposing site: 1) electrical shocks to the radial nerve and; 2) magnetic transcranial cortical stimuli at Cz on submaximum and maximum voluntary contractions (MVCs) of triceps brachii. All A-B subjects were able to activate triceps brachii maximally by voluntary effort. With either method of stimulation, the amplitude of the superimposed twitch decreased with increasing voluntary effort and the twitch disappeared at maximum force. In SCI subjects, the force evoked by radial nerve stimulation was not eliminated during MVCs. In these same subjects, no force could be evoked by magnetic cortical stimulation during MVCs of triceps. Thus, the force increment seen with radial nerve stimulation during MVCs must represent the contribution of motor units paralyzed by loss of central input to triceps motoneurons.

Motor unit potentials were recorded intramuscularly with a bipolar or tungsten needle. In SCI subjects, motor units were recruited at all force levels. However, unit firing rates differed markedly between subjects. In one SCI subject, minimum and maximum motor unit firing rates varied between 7-45 Hz whereas in another SCI subject, motor unit firing rates never exceeded 13 Hz, even during MVCs. The low motor unit firing rates seen in some SCI subjects may reflect how the CNS (and/or muscle) attempts to compensate for SCI and/or may reflect the nature of the injury (Supported by The Miami Project).

256.1

THE ACTIVITY OF FELINE PROXIMAL FORELIMB MUSCLES DURING LOCOMOTION. C.I. PALMER. Inst. of Physiology, Fribourg Univ. Switzerland.

In order to investigate the fine tuning of muscle activity to the varied requirements of overground locomotion the 3 heads of triceps -lateral (LaT), long (LoT) and medial (MT) all proximal forelimb extensors and the proximal forelimb flexors biceps brachii (Bi) and brachialis (Br) were recorded from chronically implanted EMG electrodes in freely moving cats (LaT n3, LoT n4, MT n2, Bi n4, Br n2) during locomotion on a treadmill with unpredictable minor variations in treadmill speed.

The extensor burst duration of LaT (n6,82 to 131 steps) and MT (n3, 82 to 131 steps) had a significant ($P < 0.05$, Pitman's test) positive correlation to step duration. LoT either had a significant positive correlation (n8, 82 steps) or an insignificant correlation either negative or positive to step duration (n3, 82 steps).

The disparate relationship of LoT to step duration is accounted for by 2 strategies to maintain a constant position on the treadmill. 1) LoT decreases in amplitude and duration, MT parallels this decrease in amplitude, LaT increases in amplitude and overlaps Bi and Br during the first part of swing. Br and Bi increase in amplitude and duration. LoT has a burst of EMG in swing which is negatively correlated to LoT extensor activity. 2) LoT, MT, LaT, Bi and Br increase in amplitude. The amplitude of the LoT swing burst is positively correlated to the amplitude of the LoT extensor burst.

FORCE OUTPUT AND EMG ACTIVITY FOLLOWING EXERCISE INDUCED MUSCLE INJURY. J.N. Howell, G. Chleboun*, J. Cummings*, and R. Conatser*. Ohio Univ. Coll. of Osteopathic Med., Athens, OH 45701.

We examined the relation between force output (FO) and EMG activity in human muscle after exercise (EX). Subjects repeatedly lowered with their elbow flexors a heavy load, normalized to their own strength, until they could no longer control the rate of lowering. This typically took 10 repetitions or less and was repeated 3 times. Isometric strength fell to less than 60% of control on the day after the EX and returned only to 80% 14 days later. The relation between FO and EMG activity was linear over a range of submaximal contractions both before and after EX; the slope gave the ratio of FO to EMG. This ratio dropped by 69% immediately after EX, but gradually returned to normal 4 days later, at a time when the maximum FO capability of the muscle was still 30% below pre-exercise values. A similar pattern occurred with maximum contraction, except that the FO/EMG ratio did not return fully to control values. Injured fibers, initially capable of generating action potentials, but little FO, apparently become electrically silent within 4 days after injury. (Supported by the Am. Osteopathic Assn.)

EFFECTS OF IMAGINARY MUSCLE CONTRACTION TRAINING ON STRENGTH OF IMMOBILIZED MUSCLE. G. Yue, S. Wilson, W.G. Darling, W.T.C. Yuh, and K.J. Cole. Dept. Exercise Science and Radiology, University of Iowa, Iowa City, IA 52242.

In a previous study we demonstrated that voluntary strength of a human finger muscle increased with imaginary maximal muscle contraction (IMMC) training, that is, without muscle excitation (Yue, G., Soc Neurosci Abstr, 107.7, 16:244, 1990). However, it is not known if the subjects' activities with the finger outside of the laboratory during the training weeks contributed to the force increases. The purpose of this study was to investigate the effects of the IMMC training on voluntary strength of human abductor digiti minimi (ADM) muscle which was immobilized during the training period.

The subjects' fourth and fifth fingers of the non-dominant hand were immobilized in a plaster cast for 5 weeks in an effort to induce atrophy of the ADM. During this period the subjects were asked to produce 15 IMMCs of the ADM in each training session for a total of 25 sessions. EMG recordings during training indicated that the trained muscle was inactive. Magnetic resonance imaging of the muscle cross-sectional areas exhibited atrophy following immobilization. We found that after immobilization the mean strength of the ADM of the IMMC subjects (N=5) increased 9.2% and that of the control subjects (N=5) whose fingers were also casted showed a 1.4% decrease. The difference between the two groups was statistically significant. Moreover, the integrated surface EMG of the hypothenar muscles increased in both hands in the IMMC group and decreased in both hands in the control group. These results suggest that training which utilizes imaginary muscle contractions is able to maintain or even increase a muscle's strength by strengthening voluntary neural drive to that muscle.

FORCES GENERATED BY CAT MEDIAL GASTROCNEMIUS MOTOR UNITS DURING SIMULATED WALKING. J.L.E. Weytjens and J.A. Hoffer. Dept. of Clinical Neurosciences, U. of Calgary, Calgary AB, CANADA T2N 4N1.

Muscle force depends on both muscle fiber length and its rate of change. In order to study the characteristics of both dependencies during normal locomotion we used a two-pronged approach. First, we recorded muscle length, muscle fiber length, muscle force and electromyograms from the medial gastrocnemius (MG) muscle of chronically implanted cats walking on a treadmill. Second, in terminal acute experiments on the same cats, we replicated chronic conditions, i.e. muscle fiber length and muscle force, by imposing the chronically recorded muscle length changes with a servo-controlled motor and optimizing the stimulus patterns used for distributed stimulation of five small ventral root filaments (L7 and S1). We then ran simulations with (active muscle) and without distributed stimulation (passive muscle), and with and without stimulation of an additional ventral root filament containing up to 6 motor units. The latter filament was also stimulated at different constant muscle lengths, with and without distributed stimulation at constant rates.

When muscle length was adequately replicated, reproduction of muscle fiber length was very good in the active muscle. In the passive muscle, however, it was quite different from the chronically recorded measurement. In the passive muscle, stimulation of the filament under study induced appreciable muscle fiber shortening (up to 2 mm), both during simulated walking and under muscle isometric conditions. The time course of shortening was a mirror-image of the time course of force generation. In contrast, in the active muscle, muscle fiber lengths with and without stimulation of the test filament were often indistinguishable. Specifically, with constant background stimulation, fiber length deviated only slightly from isometricity. During simulated walking the forces generated by the small test filament were much smaller in the active than in the passive muscle. Construction of force-length curves indicated that this result could at least in part be accounted for by the fact that MG, during treadmill locomotion, operated on the ascending limb.

These results show that 1) muscle fiber length, a crucial variable on which forces generated by motor units depend, can be well reproduced in acute experiments, 2) length-dependence of forces generated by motor units cannot reliably be studied in isometric passive muscle, because of appreciable fiber shortening, and 3) when small multi-unit filaments are stimulated, fiber length can be held (quasi-)isometric, in intact muscle, by using constant rate background distributed stimulation. CHRONIC CHANGES IN PROPERTIES OF CAT MEDIAL GASTROCNEMIUS (MG) MUSCLE AFTER FUNCTIONAL ELECTRICAL STIMULATION OR HEMISECTION AND DEAFFERENTATION. V.F. Rafuse, M.C. Pattullo* and T. Gordon. Dept. of Pharmacology, Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada, T6G 2S2.

Neuromuscular activity of the cat MG muscle was either increased by functional electrical stimulation (FES; 20Hz, 50% duty cycle), or reduced by spinal hemisection and unilateral deafferentation, to determine the time course of changes in muscle force, speed and endurance. These changes were monitored weekly by coupling the foot to a force transducer via an external boot, and isometric contractions elicited by stimulation of MG nerve via implanted nerve cuffs. In addition, acute experiments were performed after 6-24 weeks to measure the same parameters at the motor unit level. Chronic recordings showed that whole muscle tetanic force was reduced after only 1 week of FES reaching a minimum of 50% of the initial force by 2-3 weeks, while reduction of activity had no effect on force production even after 20 weeks. With FES, the muscle became fatigue resistant (2-minute test) by 4-6 weeks, contrasting the progressive decrease in endurance seen following spinal hemisection and deafferentation. Decrease in muscle contractile speed was gradual but had slowed significantly after 24 weeks stimulation. By this time, force, contractile speed and endurance of isolated units was the same as the normal slow unit sub-population, but at earlier times (4-10 weeks) these parameters were intermediate between the total unit and slow unit populations of normal muscles. Thus, FES has a rapid and dramatic effect on unit size, in addition to the established effect on endurance and speed, in contrast to the small changes observed after inactivation by spinal hemisection and deafferentation. LIMB IMMOBILIZATION INDUCES NON-UNIFORM ADAPTATIONS IN SOME MOTOR UNIT PROPERTIES IN A CAT HINDLIMB MUSCLE. M.A. Nordstrom¹, R.M. Enoka^{1,2}, R.M. Reinking^{1*}, K.M. Gotthard¹ and D.G. Stuart¹. Depts. of Physiology¹ and Exercise & Sport Sciences², Univ. of Arizona, Tucson AZ 85724.

We have studied cat tibialis posterior (TP) motor units (MUs) after six weeks of immobilization of the right hindlimb by splinting. Physiological properties of single MUs (n=172) in 12 control and 9 splinted cats were examined by stimulating ventral-root filaments. Wet weight of immobilized TP muscle was 87 ± 16% (SD) of contralateral control. Whole-muscle twitch force was unaffected by immobilization but twitch contraction time (CT) was significantly reduced. For all MU types, twitch force, CT and axonal conduction velocity were not significantly different in immobilized TP. Mean tetanic force (TET) was significantly smaller in all MU types (S, 41% of control; FR, 55%; FF 77%). Twitch/tetanus ratio increased significantly in S (173%) and FR (73%) units, but was unchanged in FF units. Both whole-muscle and MU twitch force were unaffected by atrophy despite reduced MU TET and myofibril cross-sectional area (Callister et al., Neurosci. Abstr. 17, 1991). These results are qualitatively similar to those observed following long-term immobilization (17-29 wks; Mayer et al., Neurosci. 6:725, 1981), but differ from those following short-term (3 wks) immobilization (Robinson et al., Muscle & Nerve, 1991, in press). After 3 weeks of immobilization, twitch and tetanic force increased in FF units and there were a large number of units that produced no force. Taken together, these data suggest that the temporal effects of immobilization may differ among the three motor unit types. Supported by USPHS grants NS 20544, HL 07249, NS 25077, NS 07309 and RR 05675. M.A.N. is a C.J. Martin Fellow of the NH&MRC of Australia.

256.7

MORPHOLOGIC CHANGES IN IMMOBILIZED TIBIALIS POSTERIOR CAN ACCOUNT FOR DECREASED PEAK FORCE OF FATIGABLE, BUT NOT FATIGUE-RESISTANT, MOTOR UNITS. R.J. Callister¹, M.A. Nordstrom¹, D.H. Laidlaw², R.M. Enoka^{1,2}, R.M. Reinking^{*1}, and D.G. Stuart¹. Depts. of Physiology¹ and Exercise & Sport Sciences², Univ. of Arizona, Tucson AZ 85724.

Tibialis posterior (TP) muscles of 9 cats were examined following six weeks of immobilization of the right hindlimb by splinting. Transverse sections of right and left TP were stained for myosin ATPase activity (pH 9.4) following preincubation at pH 4.4 - 4.5. Approximately 800 fibers per muscle were classified as type I, IIa or IIb, and fiber-type proportions and cross-sectional areas were assessed from digitized images. Fiber-type proportions were unchanged by immobilization (splinted: I, 28%; IIa, 27%; IIb, 45%; control: I, 29%; IIa, 28%; IIb, 43%). Cross-sectional area was reduced significantly in each fiber type by immobilization (I, 71% of contralateral control; IIa, 77%; IIb, 79%). These changes were compared to MU data obtained from the same animals (Nordstrom *et al.*, *Neurosci. Abstr.* 17, 1991). The reduced cross-sectional area in IIb fibers in immobilized TP matched the smaller tetanic force of the corresponding type FF MUs (77% of control), suggesting that force reduction in these MUs could be explained by the reduction in myofibrillar contractile elements. In contrast, the reduction in type I and IIa fiber areas were insufficient to explain the smaller tetanic force in the S (41% of control) and FR (55% of control) MUs. In the absence of a change in fiber-type proportions in immobilized TP, these data suggest that additional factors, perhaps related to myofibrillar specific tension or force transmission, are involved in the atrophic response of S and FR MUs to immobilization. Supported by USPHS grants NS 20544, HL 07249, NS 25077, NS 07309 and RR 05675. M.A.N. is a C.J. Martin Fellow of the NH&MRC of Australia.

ELECTRICAL STIMULATION OF THE SCIATIC NERVE IN RATS INDUCES *c-fos* PROTEIN EXPRESSION IN HINDLIMB MUSCLE FIBER NUCLEI. B.L. Goldman*, H.H. Ellenberger, R.R. Roy and V.R. Edgerton Dept of Kinesiology and Brain Research Institute University of California Los Angeles, Los Angeles, CA 90024-1527.

The proto-oncogene *c-fos* is thought to encode transcriptional regulatory proteins. Northern blot analyses have demonstrated the presence of *c-fos* protein mRNA in skeletal muscle. In the present study, a muscle-specific selective expression of *c-fos* protein in muscle nuclei was induced via electrical stimulation of the sciatic nerve. Chloral hydrate-anesthetized rats were stimulated for three hours at 5-10 times the threshold needed to elicit muscle contraction. Immediately following stimulation, the rats were perfused with 2% paraformaldehyde, and the soleus and tibialis anterior (TA) muscles were removed and quick frozen in isopentane cooled in liquid nitrogen. Control rats were anesthetized and the sciatic nerve was isolated but not stimulated. Immunohistochemical detection using polyclonal antiserum to the n-terminal region of the *c-fos* protein showed extensive labeling of nuclei in the stimulated, but little or no labeling of nuclei in the non-stimulated soleus. There also appeared to be a greater number of immunoreactive nuclei in the stimulated than in the non-stimulated TA. The proportion of nuclei labeled in the stimulated soleus far exceeded that observed in the stimulated TA. These data are consistent with the hypothesis that myonuclear expression of immediate-early genes such as *c-fos* can play a role in muscle adaptation. CRITICAL DIFFERENCES BETWEEN SLOW OXIDATIVE MUSCLE FIBERS IN HETERO- AND HOMOGENEOUS MUSCLES. L. L. Glenn and P.J. Rebeta, Department of Physiology, Ohio College of Pod. Medicine, Univ. Circle, Cleveland, Ohio 44106.

In order to determine how muscle fibers should be grouped, fibers of slow-oxidative (SO) muscles of uniform type (homogeneous) were compared to SO fibers in muscles of mixed type (heterogeneous). Measures of myosin ATPase activity, NADH dehydrogenase activity, fiber density, and microvasculature were taken in the feline knee extensors. The vastus intermedius (VI) muscle, which is a homogeneous type SO muscle, was compared to those for nine subdivisions in rectus femoris, vastus lateralis (VL), and vastus medialis (VM), which are all heterogeneous muscles. Similarity analysis using Euclidean distances linked VI most closely to the glycolytic subdivisions of VL and VM. The most influential factors in this linkage were capillary density and fiber density. Taken in conjunction with published findings in other muscles, these results indicate that type SO fibers of homogeneous muscles and heterogeneous muscles are of fundamentally different type, and these should not, in general, be classified together.

256.8

DIFFERENTIAL RESPONSE OF CAT MUSCLE FIBERS AND EXTRACELLULAR CONNECTIVE TISSUE TO INCREASED AND DECREASED NEUROMUSCULAR ACTIVITY. B. Liang, G.R. Chalmers, R.R. Roy and V.R. Edgerton. Brain Research Institute and Kinesiology Dept., UCLA, L.A., CA, 90024-1527.

The adaptation of muscle fibers and extracellular connective tissue has been quantified in models of altered neuromuscular activity in cats. The reduced activity models (6 months, soleus) studied were: 1, Spinal Transection (ST) with daily standing (n=4) or no training (n=4); 2, Spinal Isolation (SI) with daily passive hindlimb oscillation (n=5) or no training (n=6). Five normal cats served as controls (S-C). The increased activity model (3 months, plantaris) studied was functional overload (FO, n=6) induced by synergist removal and daily exercise. Six cats served as controls (FO-C). Frozen sections were stained with FITC conjugated lectin (Con A) to identify extracellular space (ES). Mean fiber cross-sectional area (CSA) and ES per fiber, and fiber/ES ratio were calculated. There was no difference between the trained and untrained cats within the ST and SI groups, so these data were combined.

	S-C	ST	SI	FO-C	FO
CSA (pixels/fiber)	5232	3555	1462*	3938	9194*
ES (pixels/fiber)	1084	1103	1028	867	2033*
Fiber/ES	5.2	3.3*	1.6*	5.1	4.9

*differs from control (p<0.05).

In FO, there was a similar increase in CSA and ES per fiber, suggesting that muscle fibers and associated connective tissue adapt to overload proportionately. Fiber size decreased in SI, while ES was unaffected in SI and ST, demonstrating that muscle fiber CSA, but not connective tissue, decreases in response to reduced neuromuscular activity. These data demonstrate that muscle fibers and surrounding connective tissue respond differentially to alterations in neuromuscular activity level.

COMPARISON OF TETRODOTOXIN (TTX)- AND DENERVATION-INDUCED DISUSE ON RAT MYOFIBRILLAR PROTEINS. B.N. Michel, G. Cowper, and H. Falter. School of Human Movement and Dept. of Chemistry, Laurentian University, Sudbury, Ontario, P3E 2C6.

The purpose of this study was to examine the adaptations of myofibrillar proteins to the removal of neural influences using two different conditions: nerve inactivation with the sodium channel blocker TTX and nerve axotomy causing muscle denervation. The left hindlimb of Sprague Dawley rats was inactivated by either chronic sciatic nerve superfusion with TTX using an osmotic pump and cuff delivery system or denervated (DEN) by excision of a segment of the sciatic nerve. After 2 wks of disuse the plantaris from left and sham-operated right hindlimbs of all animals were removed and myofibrillar protein characteristics compared to each other and to an external control group. Plantaris absolute and relative wet weights were lower by 47% after DEN and TTX. Total protein concentrations (mg/g muscle wt) after DEN and TTX were not different from controls. Myofibrillar protein concentrations (mg/g) after DEN were also similar to controls, whereas values for TTX had a tendency (p<0.06) to be 25% lower than controls. Non-specific myofibrillar ATPase activities ($\mu\text{mol Pi/mg/min}$) at different Ca^{2+} concentrations (pCa range of 9.00 to 3.00) were 26% and 22% lower than controls in the TTX and DEN groups, respectively. At high Ca^{2+} concentrations (pCa 4.42 and 3.00) Ca^{2+} -specific myofibrillar ATPase activities were 44% and 19% lower than controls after TTX and DEN, respectively. There were no clear differences in densitometric scans of SDS-PAGE myofibrillar protein patterns between conditions. In conclusion, although DEN and TTX cause a similar loss of muscle mass, their effect on myofibrillar protein quantity and enzymatic function is different.

Supported by NSERC Canada (RNM).

COMPARISON OF THE PATHOGENESIS OF DIABETES MELLITUS IN SLOW VS. FAST TWITCH MUSCLES.

David J. Porta and Kathleen M. Klueber, Department of Anatomical Sciences and Neurobiology, University of Louisville, School of Medicine, Louisville, KY 40292.

One way that diabetes manifests is progressive weakness in the lower limb presumed to be of neurogenic and myogenic origins. The objective of this study was to compare cytoarchitectural changes in the postural soleus (SOL) muscle with the fast twitch extensor digitorum longus (EDL). Female C57Bl/KsJ-*dbm* diabetic and control mice were sacrificed (ages: 5 to 27 weeks; N = 5/age). The muscles were fixed in situ, processed, and analyzed by standard electron microscopic procedures. Muscle degeneration was correlated to the time course of the disease in slow twitch (SOL) muscle and to both the time course of the disease and blood glucose levels in the fast twitch muscle (EDL). The data indicated that the slow twitch muscle offers more resistance to the disease. Funded by: NIDDK 1R29DK41553.

SUSCEPTIBILITY TO NEUROTRANSMISSION FAILURE VARIES ACROSS MUSCLE FIBER TYPES. B.D. Johnson*, M. Fournier and G.C. Sieck. Mayo Clinic and Foundation, Rochester, MN 55905.

The purpose of this study was to examine the susceptibility of rat diaphragm muscle fibers to neurotransmission failure (NF). Susceptibility to NF was assessed by intracellular analysis of evoked end-plate potentials (EPPs) using an *in vitro* nerve/muscle preparation. Failure to evoke an EPP provided evidence of NF. During 10 Hz stimulation, there was no evidence of NF, whereas at 75 Hz, there was a 25% incidence of NF. In a previous EMG study it was suggested that NF may be more prevalent in fast fatigable muscle unit fibers (IIB) compared to fast fatigue resistant (IIA) or slow (I) unit fibers. To evaluate this hypothesis, fiber glycogen depletion patterns were compared after direct muscle and nerve stimulation using an *in vitro* preparation. After direct muscle stimulation at 10 or 75 Hz (1 train/sec at 50% duty cycle for 8 min), the extent of glycogen depletion among fibers varied according to the following rank order: IIB, IIA, I. For all fiber types, the extent of depletion after 75 Hz muscle stimulation was about 30% greater than after 10 Hz. With 10 Hz nerve stimulation, the glycogen depletion pattern among fibers was similar to that observed after direct muscle stimulation. However, after 75 Hz nerve stimulation, the extent of glycogen depletion was less than that observed at 10 Hz, and the rank order of depletion among fiber types was reversed, i.e., I, IIA, IIB. We conclude that at higher stimulation frequencies fast fatigable muscle unit fibers (IIB) are more susceptible to NF than either IIA or I fibers.

CALCIUM-ACTIVATED (Ca²⁺)-MYOSIN ATPase ACTIVITY OF MUSCLE UNIT FIBERS: RELATION TO MUSCLE UNIT FATIGUE RESISTANCE.

C.E. Blanco, M. Fournier, and G.C. Sieck. Department of Anesthesiology and Physiology, The Mayo Clinic and Foundation, Rochester, MN 55905.

Ca²⁺-myosin ATPase and succinic dehydrogenase (SDH) activities of individual muscle unit fibers in the cat diaphragm (DIA) and tibialis posterior (TP) muscles were determined using quantitative histochemical techniques. Muscle units were isolated by ventral root dissection and classified as fast- (type F) or slow-twitch (type S) using standard physiological criteria. Eight of the 10 units (3 DIA and 5 TP) were classified as type F units with fatigue indices ranging from 0.01 to 1.00. Muscle unit fatigue resistance was positively correlated ($p < 0.05$) with the SDH activity of muscle unit fibers in both the DIA and TP ($r = 0.974$ and 0.962 , respectively). In contrast, a negative correlation ($p < 0.05$) was found between muscle unit fatigue resistance and the Ca²⁺-myosin ATPase activity of DIA muscle unit fibers. Such a correlation was not observed among TP muscle units. These results would suggest that: 1) muscle unit fatigue resistance is dependent upon the generation of ATP via oxidative metabolism (i.e., SDH) and, 2) muscle unit fatigue resistance may also be dependent on ATP utilization during contraction (i.e., Ca²⁺-myosin ATPase activity).

This research was supported by NIH grants HL34817 and HL37680.

BIOCHEMICAL CHARACTERISTICS OF CHOLINESTERASES FROM SEA-BASS TISSUES. E. BACQU, M. YASSINE*, H. ALAMI-DURANTE**+. Département de Physiologie animale, INRA, Place Viala, 34060 Montpellier Cedex 1, and + Département d'Hydrobiologie, INRA, St-Pée sur Nivelle, 64310 Ascaïn, France.

Sea-Bass (*Dicentrarchus labrax*) tissues contain two types of cholinesterases (ChE) that differ in molecular forms and in substrate specificity. One type of ChE is a true acetylcholinesterase (AChE). The second type of enzyme, called atypical, hydrolyses both acetylthiocholine and butyrylthiocholine. The distribution of both enzymes is tissue-dependent and occurs mainly in the detergent soluble (DS) fraction. In muscle, most of the high ChE activity is related to the atypical enzyme, and to true AChE. In the Central Nervous System (CNS), a high level of AChE only is detected. Whatever tissues, the atypical ChE occurs only as a form sedimenting under our experimental conditions at 4.5S in the presence of Triton X-100. AChE occurs in muscle as collagen-tailed asymmetric forms sedimenting at 17.5S (A₁₂), 13.5S (A₈) and 8S (A₄); globular forms occur as G₄ (10.5S) and a lighter form sedimenting at 5.5S. In CNS, AChE occurs mainly as G₄ form. The 5.5S globular form, and A₁₂ and A₈ asymmetric forms are also detected.

AChE appears first during development. In muscle, AChE occurs mainly as A forms. In CNS, AChE shows the same pattern as in the adult.

Our data show that the atypical ChE presents intermediate characteristics of AChE and butyrylcholinesterase which suggest that this enzyme originates from a common polymorphic ChE. These results also show that the classification of ChEs as either "true" (E.C. 3.1.1.7.) or "pseudo" (E.C.3.1.1.8.) is inadequate to the atypical enzyme of muscle sea-fishes.

MYOSIN HEAVY CHAIN ISOFORM COMPOSITION OF DEVELOPING INTRAFUSAL FIBERS IN CHICKEN MUSCLE SPINDLES. A. Maier, Dept. of Cell Biology, Univ. of Alabama, Birmingham AL 35294.

Serial cross sections were incubated with three monoclonal antibodies to determine which myosin heavy chain (MHC) isoforms are present in intrafusal fibers (IF) of chicken leg muscles from embryonic day (E) 13 until 8 weeks *ex ovo*. One antibody reacts with atrial MHC (CA-83), one with both atrial and ventricular MHC (CCM-52) (Sweeney et al., *Circ Res.* 61:287-295, 1984), and the third with fast MHC (MY32) (Sigma Chemical Co.). Muscle spindles were first recognized at E13 when they contained at least one large IF. This presumptive primary myotube reacted strongly with CCM-52 and weakly with CA-83. At about E14 one other large myotube with immunohistochemical properties that were reciprocal to that of the initial myotube was recognized. Between E14 and E21 (hatching) small myotubes appeared, reacting strongly with CA-83 and mostly weakly with CCM-52. None of the IF did bind with MY32. The number of IF increased continuously until the time of hatching when the full complement had been generated in most spindles. Postnatally MY32 did still not bind with small IF, but reacted with IF of relatively large diameter that were negative for CA-83 and CCM-52. The same immunohistochemical properties seen postnatally in large and small IF were also noted in presumptive fast and slow extrafusal fibers, respectively, suggesting that in chicken leg muscles factors other than innervation may also influence MHC expression in maturing IF and extrafusal fibers, or that sensory and motor innervation exert similar influences.

MECHANO-LINKAGE OF MYONUCLEI WITH SARCOMERE LENGTH IN ISOLATED RAT SKELETAL MUSCLE FIBERS.

B.S. Tseng*, D.L. Allen*, C.K. Sung*, C.E. Kasper* and V.R. Edgerton. Dept. of Kinesiology and School of Nursing, University of California, L.A., CA 90024.

Since skeletal muscle fibers have similar biochemical properties along their length, there must be some level of coordination of protein expression among the hundreds of myonuclei per fiber. In-vitro (Vandenberg, *Science* 203:265-268, 1979) and in-vivo studies (Sola, *Exp. Neurol.* 41:76-100, 1973) suggest that mechanical activity has a major role in skeletal muscle protein regulation. To evaluate the possibility of a mechano-linkage transduction pathway, the shape of myonuclei were observed during passive and active fiber length changes. Single rat soleus muscle fiber segments (n=6) were isolated, attached to a micromanipulator and individual myonuclei and sarcomeres were observed under Hoffman modulation (500X). Micromanipulation enabled passive stretch, while a bathing solution [pCa=4.8] was used to initiate submaximal active contractions. The myonuclei were stained with DNA specific dyes, Hematoxylin, Hoechst or Acridine Orange.

One discrete myonucleus was monitored during length changes in six fibers. A correlation of 0.90 ± 0.07 [SD] was observed between myonuclei length and sarcomere length by directly observing the same myonucleus on the same muscle fiber as sarcomere lengths were varied passively (1.33 μ m to 4.00 μ m) and actively (3.80 μ m to 1.75 μ m). These data are consistent with the hypothesis that mechanoreceptors, mechanical-biochemical links, and/or stretch-activated nuclear pores are involved in the regulation and coordination of myonuclei within a skeletal muscle cell.

THE LATERAL BASAL OPTIC ROOT IS COMPRISED OF AXONS ORIGINATING FROM GANGLION CELLS IN THE PERIPHERAL RETINA OF FROGS. Z. Li, K.V. Fite and J.A. Corsa. Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

We have previously reported that the nucleus of the basal optic root (nBOR) of anuran amphibians is innervated by the basal optic root (BOR) which includes both lateral (BORl) and medial (BORm) fascicles, and the medial portion of nBOR appears to receive input predominantly from the central retina (Fite, et al, 1988; Li, et al, 1990).

In the present study, rhodamine latex microspheres (RLM) were injected into the lateral portion of nBOR which is innervated by BORl in order to examine the distribution of retrogradely labelled ganglion cells in the retina. Three different sizes of retinal ganglion cells were observed following RLM injection; small cells with soma 7 um in diameter, medium cells with soma 10 um in diameter and large cells with soma 13 um in diameter. Retrogradely labelled ganglion cells were mostly (more than 70%) located in the peripheral retina. Medium sized ganglion cells represent the largest component (approximately 2/3's) of the retinal input to the lateral portion of nBOR. Thus, BORm and BORl originate from different portions of the retina. (Supported by NSF Grant BNS 8819870 to K.V.F.)

NEURAL CIRCUITRY AND IMMUNOCYTOCHEMICAL PROPERTIES OF PRETECTAL INPUT TO THE VISUAL THALAMUS IN A REPTILE. M.B. Pritz and M.E. Stritzel*. Div. Neurol. Surg., Univ. Calif. Irvine Med. Ctr., Orange, CA 92668.

Nucleus rotundus is a prominent nucleus in the dorsal thalamus of reptiles, Caiman crocodilus. It receives retinal input via the optic tectum and projects to a well-defined area of the dorsal ventricular ridge. The present experiments investigated additional connections of nucleus rotundus.

The neural circuitry of pretectal afferents to nucleus rotundus was determined by injections of horseradish peroxidase (HRP) in juvenile Caiman. Retrogradely labeled neurons were observed in the ipsilateral nucleus pretectalis. Furthermore, HRP labeled axons were seen to leave nucleus rotundus, collect on its lateral border, and then course caudal and dorsally to terminate in the ipsilateral nucleus pretectalis. Thus, retrogradely labeled neurons, axons, and terminals were observed together in the same section through nucleus pretectalis. Immunocytochemical experiments used polyclonal antibodies to parvalbumin and calbindin in animals pre-treated with intraventricularly injected colchicine. Neurons immunoreactive to both of these calcium binding proteins were seen in nucleus pretectalis.

These experiments have demonstrated a reciprocal neural circuit between nucleus pretectalis and nucleus rotundus in Caiman. In so doing, additional sources of calcium binding protein immunoreactivity in nucleus rotundus that originated in nucleus pretectalis have been identified. Since classical GABA inhibitory input to nucleus rotundus and the rest of the dorsal thalamus is absent in Caiman, these observations suggest that calcium binding proteins may play an important role in synaptic transmission in the thalamus of these vertebrates.

GLUTAMATERGIC PHARMACOLOGY OF AUDITORY TRANSMISSION IN BARN OWL OPTIC TECTUM. DE Feldman* and EI Knudsen. Dept of Neurobiology, Stanford Medical School, Stanford CA 94305

Hypotheses of N-methyl-D-aspartate (NMDA) receptor involvement in experience-dependent developmental plasticity in many systems led us to investigate the participation of glutamate receptor subtypes in auditory transmission in barn owl optic tectum. Barn owl optic tectum contains an auditory map of space which is calibrated by visual experience during a critical period in early postnatal development. Multi-barrel iontophoresis electrodes with carbon-fiber recording barrels were used to monitor auditory responses of tectal neurons in adult owls during iontophoresis of glutamatergic agonists and antagonists. pH-equivalent solutions were used as controls. All units tested responded strongly and in a dose-dependent manner to glutamate, NMDA, and quisqualate iontophoresis.

Antagonism of auditory responses was measured with ejections of the nonspecific glutamate receptor antagonist kynurenic acid (KYN) and the selective NMDA receptor antagonist 2-amino-5-phosphonopivalic acid (APV) during presentation of dichotic auditory stimuli. KYN blocked auditory responses effectively and dose-dependently in deep and superficial tectum. When calibrated to a dose which blocked responses to applied NMDA but not to quisqualate, APV antagonized 40-80% of the auditory response in the tectum. In contrast, APV antagonized only 0-40% of the auditory response in the inferior colliculus (IC, external nucleus and lateral shell). These results indicate that auditory transmission in the tectum is at least in part glutamatergic, and that NMDA receptors participate in a large proportion of the adult auditory response. NMDA receptors may play a greater role in auditory transmission in the tectum than in the IC.

HYPOTHALAMIC AFFERENTS IN THE TOKAY GECKO. T.J. Neary and L.L. Bruce. Anatomy Division, Creighton Univ., Omaha, NE 68178.

Iontophoretic and needle applications of wheat germ agglutinin/horseradish peroxidase conjugate were made in the medial and lateral hypothalamus of *Gekko gekko*. Applications in either area labelled cells in the preoptic area, posteroventral thalamic nucleus (ventrolateral to nucleus medialis), isthmal raphe, and two populations ventral to nucleus isthmi, tentatively named parabrachial and pedunculopontine nuclei. Applications centered in the ventral medial hypothalamus also labelled cells in the posterior medial dorsal ventricular ridge (core and shell), lateral and medial amygdalar nuclei, and nucleus sphericus. Applications in the lateral hypothalamus labelled cells in the dorsal cortex, stria-amygdalar area, septal nuclei, diagonal band nucleus, ventral tegmental area, and solitary nucleus. Applications which extended into the dorsal medial hypothalamus labelled cells in the dorsal cortex, septal nuclei, and lateral habenula.

Supported by a BRS Grant to Creighton University.

CHOLERA TOXIN MAPPING OF RETINAL PROJECTIONS IN BIRDS. I. Shimizu, L.R.G. Britto, H.J. Karten and K. Cox*. Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093.

Cholera toxin subunit B (CTb) has been recently recognized as a sensitive anterograde and retrograde tracer. We investigated the retinal projections in birds using CTb combined with immunohistochemical techniques. Pigeons (*Columba livia*) were deeply anesthetized and received unilateral intraocular injections of CTb. In the hemisphere contralateral to the injected eye, CTb-immunoreactive fibers and presumptive terminals were found in several known retinorecipient regions: the superficial layers of the optic tectum; ventral lateral geniculate n. (GLv); principal optic n. of the thalamus; n. of the basal optic root (nBOR); suprachiasmatic n. (SCN); and pretectal nuclei. Furthermore, sparse arborizations were seen in several areas which have not been previously described: layers 8-9, and occasionally even deeper portions, of the optic tectum; n. suprarotundus; intergeniculate leaflet (IGL); and the anterior medial preoptic region dorsal to the initial point of attachment of the optic chiasm. This preoptic region appears to be directly comparable to the mammalian SCN. We also found small numbers of fibers and presumptive terminals in the ipsilateral nBOR, GLv, IGL, n. lateralis anterior, area pretectalis, n. pretectalis diffusus, and medial preoptic region. These projections are less likely due to transneuronal transport from the contralateral retinorecipient areas, since even in the contralateral hemisphere no CTb-immunoreactive projections were observed in other areas which receive secondary visual input. These results reveal more widespread retinal projections to the pigeon brain, including the ipsilateral input, than previously reported.

NEURAL AND VOCAL DEVELOPMENT IN BUDGERIGARS. S. E. Brauth, D. C. Zocchi, P. L. Cohen, W. Liang and W. S. Hall. Dept. of Psychology, Univ. of MD., College Park, MD. 20742.

Budgerigar (*Melopsittacus undulatus*) contact call learning was investigated during the first six weeks posthatching. Previous work has shown that budgerigars learn to produce contact calls during this period in reference to the calls of cagemates. At hatching, young animals produce small peeps and alarm calls. By two weeks posthatching, budgerigars produce food begging calls, the mean durations of which tend first to increase and then to decrease from 2-4 weeks posthatching. Virtually all budgerigars fledge and learn to produce individually distinct contact calls by six weeks posthatching.

There is considerable brain growth and differentiation of neural circuits during this six week period. At hatching the budgerigar brain is extremely immature with little differentiation of the anterior telencephalon including the hyperstriatum, archistriatum and paleostriatum. Neuronal proliferation and migration continue past the third week posthatching with the most substantial growth and development of auditory and vocal motor circuits occurring during the first 2 weeks. This includes development of auditory projections to the anteromedial hyperstriatum ventrale and archistriatal projections to midbrain and medullary nuclei. Thus the most striking vocal performance changes involving contact calls occur after basic motor and auditory circuits have differentiated by 2-4 weeks posthatching.

AN ANTEROGRADE STUDY OF CORTICOSTRIATAL PROJECTIONS TO THE BASAL GANGLIA IN PIGEONS. C.L. Veenman and A. Reiner, Dept. of Anatomy & Neurobiol., Univ. of Tennessee, Memphis, TN 38163.

We previously used retrograde labeling methods to clarify the sources of corticostriatal projections in pigeons (Neurosci. Abs., '91). In the present study we used several anterograde markers (PHA-L, TRITC-conjugated dextran amine and biotinylated dextran amine) to examine the extent and distribution of these corticostriatal fibers in the striatum. The anterograde tracers confirmed the observation from the retrograde studies that corticostriatal projections arise from a broad area of the telencephalon, including much of the rostrocaudal extent of dorsolateral telencephalic wall. These areas included the lateral frontal and intermediate neostriatum (NFL, NIL), the temporo-parietal-occipital area (TPO), the dorsolateral corticoid area (CDL), the caudal dorsolateral neostriatum and the somatic archistriatum. Corticostriatal projections from these regions terminated in lateral striatum (including paleostriatum augmentatum, PA, and lateral lobus parolfactorius, LPO). Neostriatum inferior to olfactory cortex and caudal archistriatum were found to project to medial LPO and ventral striatum-olfactory tubercle. Anterogradely labeled axons in PA and ventral striatum showed few ramifications and possessed many boutons en passant, whereas labeled axons in LPO possessed more extensive arborizations with numerous en passant and terminal boutons. Thus, lateralmost LPO/PA differs from medialmost LPO/ventral striatum in its telencephalic input, with input to the former appearing somatic in nature. Supported by NS-19620 (A.R.)

LIMB PRIMARY AFFERENT INPUT TO REGIONS OF CERVICAL AND THORACO-LUMBAR SPINAL CORD CONTAINING NEURONS PROJECTING TO THE CEREBELLUM IN THE PIGEON. J.M. Wild, Dept. of Anatomy, Univ. of Auckland, Auckland, New Zealand.

Injections of cholera toxin B-chain (CTB) conjugated to horseradish peroxidase were made into the radial, median or ulnar nerves of the wing, or the sciatic nerve of the leg, in order to determine the rostrocaudal extent of their central terminations in the spinal grey. Outside the brachial enlargement wing nerve fibers travelled in the dorsal column, both rostrally in the cervical cord as far as the dorsal column nuclei, and caudally in the thoracic and lumbar cord as far as the lumbosacral enlargement. Throughout the entire extent of these cervical and thoracolumbar trajectories, fibers descended from the dorsal column to terminate densely and specifically in medial lamina V, ventrolateral to the apex of the dorsal column. At thoracic levels between the two enlargements, leg nerve fibers terminated in the same location. In order to determine whether cells in medial lamina V were part of a cerebellar projecting system, as has been suggested, injections of CTB were made into Folium Vb from which evoked potentials and multiunit activity of short latency were recorded following either electrical stimulation of the radial nerve, or small displacements of wing feathers. Retrogradely labelled spinal neurons were visualized immunohistochemically and were found in Clarke's nucleus in both enlargements, and in medial lamina V of the cervical and thoracic cord outside the enlargements. Most medial lamina V neurons were located ipsilaterally in the upper five cervical segments. These results suggest the existence of a substantial disynaptic pathway primarily from the wing to the cerebellum in birds, which is possibly involved in the sensorimotor control of flight.

257.11

DISTRIBUTION OF TYROSINE HYDROXYLASE IMMUNOREACTIVE NEURONS IN THE AVIAN FOREBRAIN. D.S. Henshel, J.D. Steeves, and D.M.S. Webster, Department of Zoology and School of Rehabilitation Medicine, University of British Columbia, Vancouver, BC, V6T 1Z4.

The immunocytochemical demonstration of tyrosine hydroxylase (TH), the first rate-limiting enzyme in the catecholamine synthetic pathway, is commonly used as an anatomical indicator of catecholaminergic neurons. We have examined the distribution of TH-immunoreactive neurons in the forebrains of the Great Blue heron (*Ardea herodias*), and chicken (*Gallus gallus*). As previously reported for other species, we found TH-immunoreactive neurons in the olfactory bulbs and pre-optic areas of both chicken and heron. However, we also found relatively sparse populations of TH-immunoreactive neurons in subregions of the heron forebrain including parts of the neostriatum, paleostriatum, archistriatum, the dorsal septal region (rostral to the hippocampus proper), the area corticoidea dorsolateralis (CDL), and the hyperstriatum. This potentially unique species characteristic may be either a "false-positive" due to an unidentified cross-reactive antigen or it may reflect a true species difference.

CONNECTIONS OF THE HOMING PIGEON OLFACTORY CORTEX STUDIED WITH WGA-HRP AND FAST BLUE.

V.P. Bingman, G. Casini, C. Nocjar* and T.J. Jones*, Department of Psychology, Bowling Green State Univ., Bowling Green, OH 43403.

The avian olfactory cortex receives a direct projection from the olfactory bulb and has been implicated as playing a necessary role in the functioning of the homing pigeon navigational map. We have investigated the origins of afferent projections to, and targets of efferent projections from the olfactory cortex in homing pigeons. Telencephalic afferents included projections from the olfactory bulb, prepiriform cortex, anterolateral neostriatum, hyperstriatum dorsale, parahippocampus, dorsal archistriatum, n. taeniae and contralateral olfactory cortex. Subtelencephalic afferents included projections from the dorsomedial n. of the thalamus, n. subrotundus, mamillary region of the hypothalamus, area ventralis of Tsai, locus ceruleus and the medial raphe. Telencephalic efferents included projections to the hyperstriatum dorsale, septum, bed n. stria terminalis, parolfactory lobe, portions of the paleostriatal area, olfactory tubercle, parahippocampus, n. taeniae, and contralateral olfactory cortex. Subtelencephalic efferents included projections to the region of the lateral hypothalamus and n. intercollicularis. Taken together, the results identify a vast network of brain regions that connect with the olfactory cortex. At least part of this network presumably functions in the processing of olfactory information used for navigation.

A MAJOR CLADE WITHIN AVES: EVIDENCE FROM THE SPINAL CORD. C.J. Woodbury, Dept. of Ornithology, American Museum of Natural History, 79th at Central Park West, New York, NY 10024.

Unlike mammals and pigeons, cutaneous nerves in chickens form two non-overlapping somatotopic maps across the dorsal horn (DH) (Woodbury, Neurosci. Abst. 13:1387, 1987), each composed of a distinct subset of primary afferents (Woodbury, Neurosci. Abst. 15:755, 1989). The DH of chickens differs, therefore, from that of all other amniotes described to date, including pigeons, in that lamina III lies medial rather than ventral to lamina II (Brinkman and Martin, Brain Res. 56:43, 1973).

Comparative studies using HRP methods have revealed that this novel "chicken" character actually has a broad superordinal distribution among birds. This character is found in taxa exhibiting extreme ecological and morphological diversity (e.g., hummingbirds, parrots, loons, et al.), which suggests (in conjunction with physiological studies of chicken and pigeon DH) that it has no obvious adaptive significance. Outgroup analyses indicate that this novel character is derived within birds. In light of the conservative DH lamination patterns in non-avian amniotes, the most parsimonious hypothesis is that this character evolved once, and therefore identifies a major clade within Aves. These data shed new light on the phylogenetic relationships of some historically problematic taxa. (Supported by an F.M. Chapman Fellowship.)

IMMUNOHISTOCHEMICAL LOCALIZATION OF CHICKEN GONADOTROPIN-RELEASING HORMONES I and II (cGnRH I and II) IN TURKEY HEN BRAIN. J.R. Millam¹, P.L. Paris², B.K. Hartman², O.M. Youngren³, M.E. El Halawani⁴ and R.E. Phillips³. ¹Dept. Avian Sciences, UC-Davis, CA 95616, ²Depts. of Psychiatry, Div. Neurosci. Res., and ³Ecology, Evolution and Behavior, U of Minnesota, Minneapolis MN 55455 and ⁴Dept. of Animal Science, U of Minnesota, St. Paul MN 55108.

The immunohistochemical (IHC) distribution of cells and fibers positively stained for either chicken GnRH I or cGnRH II was determined in brains of turkey hens. Cell bodies immunoreactive (ir) for cGnRH I were located: along the medial aspect of the lateral ventricles and extending into the area of nucleus accumbens and the bed nucleus of the stria terminalis; ventral to the septomesencephalic tract and extending medially to the third ventricle, caudally into the lateral hypothalamic area and rostrally into lobus parolfactorius; and in a diffuse band extending dorsally and medially from the medial preoptic nucleus to the dorsomedial anterior thalamic nucleus. cGnRH I fibers were evident in these areas in addition to the hippocampus, medial subhabenular nucleus, ventromedial hypothalamic nucleus and median eminence. Two groups of ir-cGnRH II cells were observed: a magnocellular group near the oculomotor nucleus and a parvicellular group lying medial to the nucleus of the basal optic root and extending in to lateral hypothalamic area. ir-cGnRH II fibers were prominent in: piriform cortex, lateral to nucleus taeniae, hippocampus, olfactory tubercle, lateral subhabenular nucleus, septal nuclei, medial edge of lobus parolfactorius, and several hypothalamic nuclei. No fibers containing cGnRH II were evident in the median eminence. These results suggest that cGnRH I and II occur in separate neuronal systems and that although cGnRH II remains implicated in reproduction, it is not a physiological secretagogue for gonadotropins.

CORRELATIONS OF CORPUS CALLOSUM SIZE IN ODONTOCETE CETACEANS. R.J. Tarpley and S.H. Ridgway. Department of Veterinary Anatomy, Texas A&M University, College Station, TX 77843 and Naval Ocean Systems Center, San Diego, CA 92152

The midsagittal surface area of the corpus callosum was determined by computer-assisted morphometry in four odontocete cetacean families (Delphinidae, Monodontidae, Physteridae and Ziphiidae) and correlated with brain weight and cerebral cortical surface area. Absolute callosal areas ranged from 41-829 mm² in 64 brains from neonates, juveniles and adults in 16 species. Species-averaged callosal area was small in relation to brain weight (.10-.24) and cortical surface area (.047-.097) when compared to other mammal groups. There was a tendency for relative corpus callosum size to be smaller in the larger-brained odontocetes, suggesting that increases in brain size were not necessarily linked with increased callosal trafficking. One delphinid, *Tursiops truncatus*, for which the largest single-species sample (n=16) was available, was examined for sex differences in callosal size relative to brain weight. Among 10 males and six females the averaged-ratio was identical between sexes.

257.15

SURFACE FEATURES OF THE CEREBELLUM AND BRAINSTEM OF THE BOWHEAD WHALE, *BALAENA MYSTICETUS*. D.W. Duffield. Louisiana State University, School of Veterinary Medicine, Baton Rouge, LA 70803.

Only recently has information become available on the brain of the bowhead, a very large baleen whale. Concerns over potential industrial effects have prompted long-term morphological studies utilizing specimens from subsistence-harvested animals. Observations were made on 11 brains from whales obtained under International Whaling Commission guidelines. The brain is removed via the large foramen magnum and placed in 10% formalin. The cerebellum accounts for about 1/5 of the brain weight. The primary fissure, appearing as an inverted "V", separates a relatively small rostral lobe from a massive caudal lobe. The hemispheres meet on the midline caudally, covering the caudal vermal lobules (VIII, IX, and X). The flocculonodular lobe is very small. The wedge-shaped ansiform lobule is wide laterally, filling the space between the simple lobule rostrally and the paramedian lobule caudally. The paramedian lobule is a rounded mass near the midline with transversely arranged folia, limited caudally by the parafloccular fissure which continues rostrally to limit the ansiform lobule laterally. The dorsal paraflocculus extends ventrolaterally from the paramedian lobule, turns rostrally, and loops around the intraparafloccular fissure to continue as the smaller ventral paraflocculus on the ventral surface of the hemisphere. Transversely arranged folia lateral to the lingula and central lobule extend as far laterally as those lateral to the culmen.

Brainstem and cranial nerve anatomy is typical for cetaceans. The cerebellum appears similar to that of the right whale, but interpretation and designations of the hemispheric lobules differ from those previously applied to the cetacean cerebellum.

257.17

DISTRIBUTION AND MORPHOLOGY OF IMMUNOREACTIVE GONADOTROPIN-RELEASING HORMONE NEURONS IN *EQUUS CABALLUS*: A SUMMER BREEDING, SEASONALLY-ANOVULATORY MODEL. H.S. Cheramie, P.A. Melrose & K.M. Knigge. LSU School Vet. Med., Baton Rouge, LA 70803 (HC, PM) & Univ. Rochester Med. Center, Rochester, NY 14642 (KM).

Comparative studies on the topography of gonadotropin-releasing hormone (GnRH) neurons may help to improve our understanding of fertile mammalian reproductive cycles. The present study was performed in order to characterize morphology of GnRH neurons in the basal forebrain of *Equus caballus*. Thick vibratome sections from 6 male and 6 female gonadally-intact ponies were stained for immunoreactive (ir)-GnRH, GnRH-associated polypeptide (GAP) or GnRH prohormone (ppGnRH). Projection drawings were then prepared in order to map the distribution of ir-perikarya and fibers as confirmed by microscopic examination. Clusters of ir-perikarya were localized in the OVLT, medial preoptic areas, arcuate nucleus and ventrolateral to the ventromedial nucleus. Most ir-neurons appeared as smooth fusiform cells with beaded axons branching off from proximal dendritic segments. Fewer irregularly-contoured unipolar neurons and occasional multipolar neurons were also present. Further, thin ir-fibers with regularly spaced varicosities were closely applied to all forms of stained perikarya and presumptive dendritic processes. Numerous ir-fibers were also traced into the lateral septum, periventricular areas, perifornical regions and both lateral and medial external median eminence. There were not any obvious differences in cell structure or distribution of ir-neuropeptides with respect to sex or season. Structure of GnRH neurons in *Equus caballus* therefore appears similar to that found in polyestrous species. However, based on current data, this species apparently lacks projections normally localized close to the optic tracts and terminal fields in the median eminence include medial areas. Whether these regional differences are of functional significance requires further study. Grayson-Jockey Club Research Foundation, AVMA, USDA.

257.14

A THREE-DIMENSIONAL RECONSTRUCTION OF THE BRAIN OF A FETAL PYGMY SPERM WHALE, *Kogia breviceps*. E.A. Gastineau, M.S. Jacobs. Maryland Psychiatric Research Center, Univ. of MD, at Baltimore, Catonsville, MD 21228, Glen Arm, MD 21057

A three-dimensional reconstruction of the brain of a fetal pygmy sperm whale, *Kogia breviceps*, was produced from original magnetic resonance images (MRI). A total of 166 images were obtained in 2 sets (head and body) and 4 planes (sagittal, coronal, oblique, and axial). The head was imaged with: 17 sagittal T2 (TR1500 TE20) weighted images acquired in 5mm thicknesses with a field of view (FOV) of 24cm; 24 coronal T2 weighted images with 5mm thicknesses and a FOV of 24cm; and 10 oblique T1 (TR600 TE20) weighted images acquired in 3mm thicknesses with a FOV of 14cm. These images were retrieved from a 16 track tape using an IbeX tape machine and software programs consistent with processing medical images. Images were then transferred to a Macintosh II with a 4 Mb YARC board and processed with LAI Multi Image Registration and Analysis (MIRA) software. Co-planar images were treated as volumetric data sets. These data sets facilitated 3-D reconstruction of the brain and generation of cortical surfaces. Quantification of brain structures were performed using software applications provided with MIRA. The quantifications were enhanced by the ability to digitally reslice these data sets at variable thicknesses and planes.

257.16

ANATOMICAL DISTRIBUTION OF CORTICOTROPIN-RELEASING FACTORS IN *EQUUS CABALLUS*. M.A. Littlefield-Chabaud & P.A. Melrose. Dept. Anatomy, Louisiana State Univ. School of Vet. Med., Baton Rouge, LA 70803.

In horses, exercise-induced increases in corticotropin-releasing hormone (CRH) and vasopressin (VP) secretion are dissociated, suggesting that two or more cell populations are involved in this response. The present experiment was performed in order to examine localization of various corticotropin-releasing factors (CRFs) in the horse as compared to that described in rats and humans. Thick vibratome sections of hypothalamus, amygdala and brainstem were taken from ten horses. Alternate sections were stained for CRH, VP or oxytocin (OXY) and projection drawings were made to map the hypothalamic distribution of immunoreactive (ir) neuropeptides. Ir-CRH-containing perikarya were found in the OVLT, suprachiasmatic preoptic nucleus and bed nucleus of the stria terminalis. Scattered CRH perikarya were also localized in the medial and lateral preoptic areas and the supraoptic nucleus. In the PVN of all animals, ir-CRF perikarya were localized primarily in lateral regions. This cell group included both magnocellular and parvocellular neurons that also stained for OXY and VP, respectively. In two of the animals, a large dorsal medial parvocellular PVN group was also found. All cells in this group expressed VP and a smaller subset appeared to include ir-CRH. Ir-CRFs were also colocalized in the central amygdaloid nucleus, dorsal vagal complex and the nucleus tractus solitarius. Thus, the distribution and coexistence of ir-CRFs in *Equus caballus* appears similar to that in other species. Experiments on the innervation of external median eminence areas and exercise-induced alterations in cellular neuropeptide content may help to improve our understanding of cell groups coordinating endocrine and ANS response to this particular stressor.

257.18

PARASAGITTAL COMPARTMENTS ARE NOT CONSERVED IN THE MAMMALIAN CEREBELLUM: DIFFERENCES AMONG RODENTS, BATS, AND INSECTIVORES. Lannoo, M. J., J. M. Zook, L. Maler and R. Hawkes. Muncie Cent. Med. Ed., Muncie, IN 47306; Dept. Zool., Ohio Univ., Athens, OH 45701; Dept. Anatomy, Ottawa Univ., Ottawa, Ont. K1H 8M5; Dept. Anatomy, Univ. Calgary, Calgary, Alb. T2N 4N1.

The monoclonal antibody anti-zebrin II has previously been shown to recognize discrete populations of Purkinje cells in the cerebellum. Zebrin II populations are arranged into alternating +/- parasagittal compartments. The general mammalian pattern appears to be seven compartments in each hemisphere, as shown by studies on rats, rabbits, guinea pigs, and marsupial opossums. Here we show that zebrin II distinguishes only three compartments in the bats *Eptesicus fuscus* and *Antrozous pallidus*, and at least eleven compartments in the shrew *Blarina brevicauda* and the mole *Parascalops breweri*. In rats and opossums, zebrin II⁺ regions develop by a suppression of initially zebrin II⁺ Purkinje cells. During development, ingrowing afferents remain within zebrin II⁺ or zebrin II⁻ borders. In *Eptesicus*, zebrin II⁻ compartments also form from a suppression of initially zebrin II⁺ Purkinje cells, similar to the rat and the opossum. Therefore, while the mechanism of compartmentation appears to remain constant, compartment numbers vary across species. This variation may extend to regions recognized by ingrowing axons during development.

DETECTION AND CHROMOSOME MAPPING OF GENES AFFECTING BRAIN WEIGHT IN RECOMBINANT (RI) AND NON-RI INBRED MICE. J.K. Belknap, T.J. Phillips and L.A. O'Toole*, Research Service (151W), VA Med. Ctr., and Dept. of Medical Psychology, OHSU, Portland, OR 97201.

A quantitative trait loci (QTL) method was used, which is potentially capable of detecting and mapping gene loci controlling as little as 20% of the genetic variance. The BXD recombinant inbred (RI) series, derived from a cross between C57BL/6J (B6) and DBA/2J (D2) inbred strains, was used as the initial screen to determine associations between brain weight and 360 known marker gene loci. This yielded five candidate chromosome regions, each reflecting a potential locus (QTL) controlling brain weight. The second step was to test as many of these five as possible with a confirmatory analysis based on standard (non-RI) inbred strain data for brain weight previously reported by Storer (1967) and Roderick et al. (1973). Only those strains possessing either the B6 or D2 allele at relevant marker loci were used. Sufficient data to test two of the five candidate QTL were available. Of these, one was unequivocally confirmed—the D7rp2 region of chromosome 7. The genetic correlations between brain weight and body weight were not significant, indicating that these two traits are virtually genetically independent. (Supported by AA08621, NIDA Contr. 271-90-7405, and a VA Merit Rev.)

STEREOTAXIC MAPPING OF RAT BRAIN:

A NEW DIGITAL APPROACH

E.M. Santori, C.B. Kelly*, A.A. Lee*, K.Thomas*, and A.W.Toga

Laboratory of Neuro Imaging, Dept of Neurology, UCLA Los Angeles, CA 90024

Neuroanatomic atlases have relied upon collections of two dimensional serial maps to describe the shape and location of brain structures. We sought to improve upon this traditional format by employing digital imaging to create a truly three-dimensional (3D) map of the rat brain.

The data used to build this map consists of 400 digitized images of the specimen blockface obtained during the cryoplaning of a whole head obtained from a 300 gram rat. The benefits of this data collection method include the following: (1) direct visualization of bony landmarks; (2) elimination at cutting artifact and distortion; (3) perfect image alignment; and (4) anatomic detail in the z-direction nearly equal to the resolution of the original plane of section.

These data were placed into a standard flat skull orientation on the basis of rotational and translational adjustments calculated from the relative positions of the bony landmarks, lambda and bregma. Transformed images were then rendered by resampling along coronal, sagittal, and horizontal planes. This set images form a complete 3D stereotaxic map of the rat brain that can be accessed interactively.

Surface-based models of several brain structures were created from this 3D map and these were morphometrically compared to stereotaxic descriptions provided in previously published atlases. In addition, two dimensional drawings presented in these other studies were subjected to warping algorithms in an attempt to incorporate their anatomical detail into this digital map of the rat brain

NSF (DIR 89-08174) and NIH (RR05956-01) grants supported this work.

A 3D DIGITAL ATLAS OF A GENERIC RAT BRAIN

A.W. TOGA, P.K. BANERJEE* & E.M. SANTORI,
Laboratory of Neuro Imaging, Department of Neurology,
UCLA School of Medicine. Los Angeles, CA. 90024

Recently three dimensional (3D) reconstructions of whole brain anatomy have been applied as atlas models. The goals of these efforts are to provide spatially accurate (in 3 dimensions) volumes of brain anatomy that is visually realistic and digitally interactive. The difficulties have been the use of several animals to compose a single representative atlas and the inability to accommodate intersubject variability. We used an averaging approach to compute a generic atlas in order to circumvent these problems.

Four adult (300 g) Sprague-Dawley rats were sacrificed, and sectioned on a macrotome with the brains still in the cranium. The animals were not perfused so that gray/white differences could be easily detected by a digitizing camera. Four hundred 1 megabyte images (20 μ m) were collected from the blockface of each brain. Acquisition of blockface imagery eliminated the need for alignment. Each complete 3D brain was oriented to the Paxinos and Watson stereotaxic coordinate space following identification of the bony sutures lambda and bregma and the interaural line. The models were then subjected to global and local deformations using techniques described by (Toga, et al, Neurosci Abs. 1990). These warpings placed all four into a common coincident space by weighting the contribution of each of the 4 brains by 25%. The voxels from each of the models were averaged and used to form the generic model of the brain. This model formed the data set for identification of neuroanatomic structures according to Paxinos and Watson.

HUMAN COGNITION: EVENT-RELATED POTENTIALS, ATTENTION, METHODS

ENDOGENOUS ERPS IN MAN FROM FORAMEN OVALE

ELECTRODES. M.D. Rugg, D.D. Potter, R.C. Roberts and C.D. Pickles (SPON: European Brain and Behaviour Society). Wellcome Brain Research Group, Dept. Psychology, Univ. of St Andrews, and Dept. Medicine, Univ. of Dundee, U.K.

ERPs were recorded during auditory and visual 'oddball' tasks from 8 patients in whom bilateral foramen ovale electrodes had been inserted to aid localisation of suspected temporal lobe seizures. Both tasks consisted of a random series (inter-stimulus interval 2 sec) of target ($p = 0.25$) and non-target stimuli, with the requirement to make a prompt motor response to each target. The foramen ovale electrodes were of stainless steel wire, and comprised 4 contacts, spaced 1cm apart. The deepest contact was inserted approximately 5 cm beyond the foramen ovale such that the electrode was subjacent to the medial aspect of the temporal lobe. Recordings were made from all 8 contacts, and from 3 midline scalp electrodes, with reference to a sterno-vertebral electrode pair.

In 6 patients, a target-evoked negative-going wave was consistently present in one or more foramen ovale contacts. This deflection occurred in the same latency range as the scalp P3 and, as with the scalp component, was longer in latency in the visual than the auditory task. Typically, the deflection showed a clear amplitude maximum at a single contact (never the most superficial), and was frequently asymmetric.

The distribution of the target-related deflection along the foramen ovale electrodes is suggestive of a local source. The deflection may reflect the endogenous ERP activity known to be generated in medial temporal structures.

SELECTIVE ATTENTION AND THE SUPRATEMPORAL N1 COMPONENT OF THE AUDITORY EVENT-RELATED POTENTIAL (ERP). W. Teder, R. Näätänen, K. Alho and J. Lavikainen*. University of Helsinki, Department of Psychology, Ritarikatu 5, SF-00170 Helsinki, Finland.

Auditory stimuli (duration 25 ms; 76 dB SPL) of 300 Hz (left ear) and 6000 Hz (right ear) were presented in random sequences to 9 experienced subjects. The interstimulus interval was very short, varying between 60-200 ms. In the Attend condition, their task was to count, in different blocks, infrequent deviant stimuli of 330 Hz in the left, 6600 Hz in the right ear.

It was found that ERPs to attended tones showed a negative displacement (Nd) in relation to the ERPs elicited by unattended tones. This displacement was of the same amplitude for the two tones. In contrast, the exogenous N1 to the low tones was much larger than the N1 to the high tones during a reading condition. Therefore the present data suggest that the Nd, most importantly its early portion, is caused by an endogenous processing negativity (PN) summing to the exogenous N1 component(s).

AUDITORY MAGNETIC EVOKED FIELDS IN RESPONSE TO AN INCONGRUOUS NOTE WITHIN A MUSICAL SEQUENCE IN MUSICIANS AND NON-MUSICIANS.

Lopez L., Mogilner A., Lado F., Ribary U., Llinás R.R.

Center for Neuromagnetism, Department of Physiology & Biophysics, New York University, Medical Center, New York, NY 10016.

We have investigated whether the presence of an incongruity in a musical sequence generates distinct magnetic auditory responses as compared to other notes, and if so, if this response is lateralized differently for musicians and non-musicians. A familiar musical sequence of four notes (S) (250 to 400 Hz) with same duration (50 ms) and intervals (600 ms) was repeated 300 times and a deviant note (D) (one tone above the highest note of the sequence) was randomly placed with 30% incidence. The sequence was delivered binaurally with earphones. Magnetic recordings were made with the Gemini 14-channel system (BT), for a total of 35 sites on each hemisphere.

In musically trained subjects the response to the D note demonstrated a significant difference in amplitude, at 100-130 ms. In addition there appeared a different magnetic component peaking at 150-170 ms. These two differences were clearly lateralized to the right hemisphere.

In musicians the analysis of melody may be similar to the analysis of language, at least in the sense that music cognition, as language, is lateralized. The fact that it involves the right hemisphere may indicate that music analysis is functionally quite different from linguistic analysis. In agreement with this view, in non-musicians the response to D notes had no noticeable lateralization. Moreover, these subjects mentioned that they had difficulty in following the melody, specially when the D note was in position 1.

These results suggest that in musically trained subjects, the recognition of melodic differences occurs earlier than in the controls and the responses to the whole musical sequence are more pronounced on the right hemisphere, in agreement with the view that music has a different connotation to professionals and to listeners.

LESIONS OF FRONTAL CORTEX DIMINISH THE AUDITORY MISMATCH NEGATIVITY IN HUMANS. K. Alho*, D. L. Woods, A.

Algazi*, R. T. Knight, and R. Näätänen**, Dept. of Neurology, U.C. Davis, VAMC, Martinez, CA, 94553; and #Dept. of Psychology, University of Helsinki, Finland.

Deviant auditory stimuli presented in repetitive tone sequences elicit a mismatch negativity (MMN) that is maximal in amplitude over the frontal scalp. We evaluated the role of frontal cortex in MMN generation in 10 patients with unilateral frontal lesions (7 left, mean lesion volume 41.0 cc). Sequences of 1000 Hz tones (standards, probability(p) = 85%) and 1300 Hz tones (deviants, p = 10%) were presented monaurally (ISI 200-400 ms). Patients and matched control subjects ignored the tones, and attended to a visual display to detect occasional targets (p = 5%). ERPs were recorded from 27 electrodes over the scalp. The MMN was isolated by subtracting ERPs to standards from those to corresponding deviant stimuli.

Standard stimuli elicited N1 (120 ms) and P2 (224 ms) deflections that were similar in amplitude, latency, and scalp distribution in patients and controls. In contrast, amplitudes of the MMN were reduced by frontal lesions (from 130-170 ms, $p < 0.05$ at each successive 20 ms interval). The reduction was more marked over the lesioned hemisphere. (Supported by the VARS, the NIDCD, a Fogarty Fellowship, and the Finnish Academy).

VISUAL P3 LATENCY IS PARTIALLY DEPENDENT ON STIMULUS PARAMETERS. J.P. Harris.

Department of Computer and Information Sciences, S.U.N.Y. at Potsdam, Potsdam, N.Y. 13676

Previous studies have shown that the late components of sensory evoked potentials can be enhanced by manipulating the subjective probability of a sensory event, the relevance of the event to an assigned task, and the complexity of the task itself. Most of these studies, and in particular those involving vision, have relied on relatively complex discriminations and/or task requirements to produce such a change.

In this investigation the late components of the visual evoked potential (N2 - P3) were studied in ten subjects using a modification of standard pattern reversal methods.

It was found that i) infrequent and unpredictable changes in contrast evoked a prominent and statistically significant N2 - P3 complex, ii) the temporal and spatial dynamics of the observed enhancement were consistent with the spread of P3 activity from central to more posterior regions of the brain, with the right parietal lobe showing the greatest degree of synchronization with the vertex, and iii) N2 and P3 latencies were dependent, in part, on the nature of the stimulus materials employed.

THE EFFECTS OF TEMPORAL AND PARIETAL LESIONS ON EVENT-RELATED BRAIN POTENTIALS DURING AUDITORY SELECTIVE ATTENTION. D. L. Woods, R. T. Knight, D. Scabini, and Clay C. Clayworth*, Dept. of Neurology, U.C. Davis, VAMC, Martinez, CA, 94553.

We examined the effects of lesions of the inferior parietal lobe (IPL, n=7) and the temporal/parietal junction (T/P, n=9) on event-related brain potentials elicited in an auditory selective attention task. Tones were presented randomly to the two ears through headphones (rate 2.5-4/sec), with 1300 Hz tones presented to one ear and 700 Hz tones to the other. Patients and matched controls selectively attended to tones in one ear and responded to occasional targets while ERPs were recorded from 15 scalp electrodes.

T/P lesions reduced the amplitude of sensory ERPs, initially over the damaged hemisphere (N1a, 70-110 ms) and then bilaterally (N1b and N1c, latencies 110-170 ms). T/P lesions also resulted in reduced sensory ERPs to stimuli contralateral to the lesion. Nd components associated with attentional selection were slightly reduced in the T/P group, whereas target and novel P3s were more markedly diminished. The mismatch negativity was unaffected by either T/P or IPL lesions. The results suggest a critical role of the temporal parietal junction in sensory and cognitive operations that underlie auditory selective attention. (Supported by grants from the VARS and the NIDCD to DLW, and NIH to RTK).

SELECTIVE INHIBITION OF COGNITIVE AEP GENERATION BY THE PHENCYCLIDINE-LIKE NMDA RECEPTOR ANTAGONIST MK-801 D.C.

Javitt, M. Steinschneider, C.E. Schroeder, J.C. Arezzo, H.G. Vaughan, Jr. Albert Einstein College of Medicine, Bronx, NY 10461.

Deviant auditory stimuli elicit a mismatch negativity (MMN) that indexes the operation of a comparator located within the superior temporal plane in the vicinity of primary auditory cortex. In order to investigate the neurochemical substrates of MMN generation, auditory event-related potentials (AEPs) were recorded from two cynomolgus monkeys in response to soft clicks presented either monotonously or as intensity deviants against a background of more frequent loud clicks. Deviant soft stimuli elicited a long-duration frontocentral negativity that overlay the obligatory AEP components during the 30-105 msec latency range. Intracortical recordings from superior temporal plane demonstrated activity within supragranular cortex that was time-locked to the surface MMN. MK-801, a PCP-like N-methyl-D-aspartate (NMDA) channel blocker, selectively inhibited MMN generation following systemic and intracortical injection while having relatively little effect on preceding obligatory AEP components. By contrast, intracortical injection of kynurenic acid, a nonspecific excitatory amino antagonist, inhibited all activity generated in the region of the recording electrode. These findings suggest that NMDA receptor-activation may be selectively involved in mediating MMN and other cognitive as opposed to obligatory AEP components and that NMDA receptor-mediated neurotransmission may be selectively impaired in schizophrenia and other diseases associated with impaired cognitive AEP generation.

EFFECT OF PHARMACOLOGICALLY INDUCED CHANGES IN AROUSAL ON HUMAN VISUAL SEARCH. B. S. Oken and J. Long.

Dept. of Neurology, Oregon Health Sciences University, Portland, OR 97201.

It has been postulated that there are 2 mechanisms underlying visual search: a preattentive, "parallel" mechanism related to processing in earlier visual pathways and a more attention-requiring, "serial" mechanism related to processing in later visual pathways. It was hypothesized that the more difficult, attention-requiring search would be disproportionately affected by changes in arousal. To evaluate this hypothesis, visual search tasks requiring greater and lesser amounts of directed attention were performed by healthy human subjects before and after being given placebo, diphenhydramine and methylphenidate. The visual search task was a 2-choice reaction time paradigm in which the subject was instructed to determine whether or not a given target shape was present on a screen that contained 2, 6, 10, 20 or 30 distractor shapes. Scalp EEG was recorded during performance of the tasks and EEG event-related desynchronization was calculated. As expected, reaction times increased following diphenhydramine and decreased following methylphenidate. However, there was no disproportionate affect on either of the 2 tasks. Additionally, there was no change in the slopes of the number of distractors-reaction time relationship. EEG desynchronization occurred in approximately half the subjects and was not related to either the visual task or the drug condition.

Attentional Processing During Object Identification. S.J. Luck, S. Fan, & S.A. Hillyard. Department of Neurosciences, M-008, University of California, San Diego, La Jolla, CA, 92093-0608.

Previous studies of visual-spatial attention using the event-related potential (ERP) technique have shown that stimuli presented at precued locations produce larger P1 and N1 components than stimuli presented elsewhere. This finding has been interpreted as a facilitation of early visual processing due to advance cuing of target location. The present study investigated whether similar effects could be demonstrated during a visual search / object identification task without any advance cuing of attention.

The stimulus arrays consisted of 16 randomly positioned T's, half of which were inverted. 14 of the items were blue and the remaining 2 items were red and green; subjects were instructed to identify the orientation of either the red item or the green item. A probe stimulus (a white square) was presented 250 or 400 msec after the onset of the target array, and surrounded either the red item or the green item. At the shorter delay, probe stimuli elicited enhanced P1 and N1 components when they occurred at the location of the relevantly colored item, consistent with attentional cuing experiments. This finding indicates that the attentional mechanisms that operate when attention is explicitly precued to a particular location are also used during visual search and object identification. Specifically, the P1-N1 enhancement suggests that early sensory processing is facilitated at task-relevant locations in both of these paradigms.

THE EFFECTS OF STIMULUS POSITION IN THE VISUALLY EVOKED POTENTIAL: ANALYSIS AND LOCALIZATION WITH MRI.

V.P. Clark¹, S. Fan², and S.A. Hillyard¹. ¹Department of Neurosciences, UCSD, La Jolla, CA 92093-0608 ²Academica Sinica, Beijing, China.

Several of the early components of the visually-evoked potential (VEP) arise from activity in occipital cortex, but the exact locations of their neural generators have been disputed. The present study examined changes in component amplitude and surface topography as a function of stimulus position in order to isolate the activity of different cortical regions. VEPs were recorded to a small (1.5° or 2° diameter) circular checkerboard stimulus randomly placed in the left or right visual fields along positions equidistant from fixation (6° or 8°) spanning 141° of polar angle centered about the horizontal meridian (HM). VEPs were averaged across adjacent stimulus positions. The rising phase of the C1 component (measured at 60-75 msec) achieved its maximum negative amplitude at a polar angle of 20° above HM, with maximum positive amplitudes at approximately 60° above and 50° below HM. The C1 reversed its polarity in the lower visual field at 20° to 40° below HM in most subjects, not at HM as has been assumed in previous research. Subsequent negative and positive components (N150 and P220) were seen to increase in amplitude in the lower visual field, reaching a maximum at the lowest point measured. The Brain Electrical Source Analysis (BESA) system was used to localize the component sources. These sources were localized with respect to MRIs for some subjects. The source of the C1 was slightly lateral to the medial surface of the contralateral occipital lobe, near the position of the calcarine fissure, suggesting a source in striate cortex. The tentative positions of the N150 and P220 source locations were in multiple extra-striate regions.

HUMAN INTRACRANIAL POTENTIALS EVOKED BY FACES E.Halgren, K.Marinkovic*, P.Baudena*, B.Devaux*, D.Broqclin*, G.Heit and P.Chauvel* INSERM U97, Paris 75014 France

Electrodes were implanted in over 500 sites in 10 patients to localize the seizure focus prior to surgical treatment. Informed consenting patients judged the emotion and familiarity of faces exposed for 300 ms. The P70/N110 were observed near area 19 and are thought to be generated by geniculate afferents to area 17. The P160 had a more anterior and lateral distribution. The large widespread N210 polarity inverted in medial and lateral posterior inferotemporal cortex, with maximal amplitude in the amygdala. The N210 corresponds to the scalp N200 associated with complex sensory analysis. The N420 was largest in basolateral amygdala with steep voltage gradients medially, but with a widespread distribution, including parietal, prefrontal, limbic and inferotemporal cortices. The N420 appears to be identical to the N400 evoked by words and associated with their contextual integration. Thus, faces evoke sequential potentials in primary, secondary visual and supramodal cortices, ending in the amygdala. The large amygdala N420 suggests that emotional processing of faces may be simultaneous and integrated with their cognitive processing in association cortex. LOCALIZATION OF THE EARLY COMPONENTS OF THE VISUAL ERP DURING SPATIAL-SELECTIVE ATTENTION. C. Gomez, V.P. Clark, S. Fan and S.A. Hillyard. Dept. of Neurosciences, UCSD, La Jolla, CA, 92093-0608.

Visual stimuli elicit a series of event-related potentials (ERP) components over the posterior scalp including a negative deflection in the interval 50-90 msec (N70) followed by a positive wave between 80-130 msec (P105). Previous studies have shown that the P105 (also called P1) is increased in amplitude when attention is focused on the location of the evoking stimulus. The present experiment used current source density (CSD) and dipole localization (BESA) techniques to determine the brain sources of these components during spatial attention. Stimuli consisted of geometric figures presented in random order to the left and right visual fields at ISIs of 650-900 msec. Subjects paid attention to one field at a time, ignoring the opposite field, with the task of responding to occasional target figures that varied slightly from the non-targets. ERPs were recorded from 29 channels over the posterior scalp. The P105 was enlarged in the ERPs to attended versus unattended-location stimuli, while the N70 was unaffected by attention. The CSD and BESA analyses indicated that the N70 wave could be accounted for by a source near the occipital pole contralateral to the field of the stimulus, within primary visual cortex. In contrast, the P105 could be modelled by a source in the contralateral prefrontal cortex and a delayed ipsilateral source attributed to transfer across the corpus callosum. These results suggest that spatial-selective attention acts to modulate visual processing at a level beyond the primary visual cortex.

258.12

RULES OF MULTISENSORY INTEGRATION AND ATTENTION: ERP AND BEHAVIORAL EVIDENCE IN HUMANS. D. Costin*, H.J. Neville, A.M. Meredith#, B.E. Stein#. Salk Inst., La Jolla, CA 92037, #Med. Col. of VA.

The integration of multisensory (auditory and visual) stimuli has been studied at the single-neuron and behavioral levels in animals. These studies report that neuronal responsiveness and behavioral accuracy are enhanced for spatially coincident multisensory stimuli compared to unimodal stimuli. Spatially disparate stimuli also enhance performance and responsiveness but only when they are lateral to the attended target; they depress or do not alter these measures when medial to the attended target. We tested the hypothesis that similar organizing principles govern multisensory integration and attention in humans by measuring behavior and ERPs to attended and unattended unimodal and multisensory stimuli. Stimuli were faint lights either alone or accompanied by broad-band noise bursts that were spatially coincident with or disparate to the light. The sound disparities were either 30° lateral or medial to the light. The Ss fixated straight ahead, and on different runs attended to the lights at left or right 30°. Spatially coincident and laterally disparate stimuli were responded to more quickly and more accurately compared to visual alone, while medially disparate stimuli resulted in little or no change in performance. Additionally, visual ERP components and their modulation by attention were influenced by the simultaneous presence of a sound and a light: spatially coincident and laterally disparate sounds enhanced visual ERP components relative to their amplitudes when lights were presented alone, while medially disparate sounds produced little or no enhancement. Unattended coincident stimuli also showed enhanced ERP components but unattended disparate stimuli did not. These data suggest that the spatial rules of multisensory integration observed in other animals may apply to humans and may operate across many levels of analysis, from the neuron level, to the neuron-systems level, to the behavioral level. BEHAVIORAL AND EVENT RELATED POTENTIAL INDICATORS OF AGING IN WOMEN. C.A. Christensen, R.J. Compton* and K.J. Drake*. Dept. of Psychology, Vassar College, Poughkeepsie, NY 12601.

Women in four age groups (20,40,60, & 75 ± 2 yrs) were tested on a battery of eight tasks which measure speed of processing, including simple and choice reaction time (RT & CRT), the Sternberg memory task (S), digit symbol substitution, critical flicker fusion, figural synthesis, forward and backward masking. The Beck, Hartford-Shipley and portions of the Cornell medical inventories were used for purposes of group matching. Event-related potentials were recorded during the S, RT, and CRT tasks. The data were evaluated to assess 1) the nature of group differences 2) whether correlations among scores support the notion of a common timing mechanism and 3) whether behavioral and ERP measures provide similar or different characterizations of correlated measures. Significant group differences were observed on most measures, including late ERP components, with the most pronounced effects shown as differences between the two older and two younger groups. Significant correlations of moderate magnitude among many, but not all behavioral measures provide some support for the notion of common timing mechanisms, a conclusion which was also supported by examination of intermeasure correlations observed with ERP indicators. The differences between the ERP and behavioral characterizations which were observed will be discussed.

258.15

EFFECTS OF HIPPOCAMPAL LESIONS ON THE HUMAN P300. R.T. Knight, Dept. of Neurology, University of California Davis, VAMC, Martinez, Ca 94553. The P300 is generated during detection and encoding of significant environmental events. Intracranial recordings report large hippocampal field potentials associated with scalp P300 activity. However, anterior hippocampal removal has minimal effects on the scalp P300. We recorded P300s in patients with posterior hippocampal lesions and anterograde memory deficits due to posterior cerebral artery occlusion. Patients (n=4, 65.0 +/- 5.0 yrs, mean lesion volume= 20.5 cc.) had unilateral damage in the posterior hippocampus and adjacent inferior temporal cortex. P300s to target and non-target novel stimuli were recorded in auditory, visual and somatosensory signal detection tasks. Hippocampal lesioned subjects and age matched controls generated comparable target and novel P300s at parietal scalp sites in all sensory modalities with no lateralized P300 reduction over lesioned hemisphere. However, earlier latency frontal P300 activity was reduced in all sensory modalities by hippocampal lesions. The hippocampal and neocortical lesion data indicate that the frontal scalp P300 indexes hippocampal and prefrontal cortex activity generated during detection of unexpected events. The parietal P300 may index an implicit memory system dependent on integrity of cortex in the temporal-parietal junction.

258.17

LOW-DIMENSIONAL CHAOS IN THE HUMAN EVENT-RELATED POTENTIAL: REDUCTION IN THE POINT CORRELATION DIMENSION DURING THE P300 COMPONENT. J.E. Skinner and M. Molnar, Neurophysiology Section, Neurology Dept., Baylor Coll. of Med., Houston, TX 77030.

Low-dimensional chaos may be inherent in noisy-looking signals rather than randomness. We previously analyzed a biological time-series under neural control (heartbeat intervals) and found that a chaotic measure (the point correlation dimension, PD2) was more sensitive to specific changes in the generator (degree of myocardial ischemia) than were stochastic measures (mean and standard deviation, fast-Fourier transform) (Skinner et al., *Circ. Res.*, 1991). We have now analyzed EEG signals, recorded over somatosensory cortex, that were evoked by meaningful stimuli (i.e., counted cutaneous stimuli) and we found that the time-dependent PD2s were transiently reduced during the development of the event-related P300-potential; when the somatosensory stimuli were delivered while the subject was reading, the P300-potential was still present, but reduced, while the PD2-wave was completely abolished. We conclude that, 1) the PD2-measure is more sensitive to specific changes in biological generators than stochastic measures; and 2) the cortex reduces the chaotic dimension of its dynamical process during processing of task-relevant information.

258.19

COMBINING EEG, MEG, PET AND MRI FOR REAL-TIME IMAGING OF CORTICAL ELECTRICAL ACTIVITY. A.M. Dale and M.L. Sereno, Cognitive Science Department, University of California San Diego, La Jolla, CA 92093.

One approach to neuroelectric source localization is to assume a small number of equivalent current dipoles, and then determine their positions, orientations, and strengths using a nonlinear optimization technique (Scherg, 1989). This approach has various problems: 1) the necessary number of "equivalent dipoles" is hard to determine *a priori*, 2) the nonlinear optimization is computationally hard, 3) no general confidence measures exist for the solutions.

The approach we have adopted in a series of model studies is to use MRI data to determine the shape of the cortical sheet, and thus fix the position and orientation of possible current sources (assuming that electric and magnetic fields measured by EEG and MEG are generated by currents flowing perpendicularly to the cortical surface). The problem then reduces to a linear one of finding distributions of current densities on the cortical sheet consistent with the EEG and the MEG data. We find the cortical sheet by shrinking a deformable template onto the MRI images.

To make the linear problem well-posed, it is necessary to add regularization terms (Tikhonov, 1977) in order to obtain a unique pseudo-inverse. Possibilities are terms favoring "minimum norm" and/or "minimum norm of the gradient" solutions. One problem with the "minimum norm" constraint is that it always favors superficial, spread-out, low-amplitude solutions over deep, local, strong ones. However, we have found that it can be combined with other regularization terms to improve localization of deep sources.

An extension of this approach is based on the assumption that foci of activation observed with PET techniques are correlated with electrical activity. Another regularization term can be added which favors solutions also consistent with the PET data for particular experimental conditions. This technique will not disallow solutions with activity outside the PET foci if EEG and MEG data point there, but it biases us toward solutions at PET foci, which may be deep and localized.

A major advantage of the linear approach to the problem is that the general inverse solution matrix has to be computed only once for a given brain geometry and sensor placement. Particular solutions (e.g., time steps) can then be computed rapidly by simple matrix multiplications, making real-time imaging possible.

IS UNIT ACTIVITY IN THE LOCUS COERULEUS RELATED TO P300-LIKE POTENTIALS? D. Swick, J.A. Pineda, and S.L. Foote, Depts. of Neuroscience, Cognitive Science, and Psychiatry, University of California, San Diego, La Jolla, CA 92093.

Event-related potentials and locus coeruleus (LC) unit activity were recorded from three awake, untrained macaques during the presentation of an auditory oddball paradigm. We wished to test the hypothesis that novel auditory stimuli lead to phasic increases in LC cell firing, which may be a necessary condition for the occurrence of P300 potentials. Spontaneous EEG and LC unit activity were also recorded to demonstrate the correlation between behavioral state and LC firing rate. Auditory oddball stimuli resulted in P300-like potentials with largest amplitude at centroparietal sites. Approximately 12 single unit and 4 multiple unit LC recordings were obtained. As previously reported, changes in LC activity precede changes in EEG. Decreased cell firing was associated with periods of synchronized EEG (e.g., during periods of behavioral drowsiness). However, no consistent relationship was found between the presentation of oddball stimuli and LC responses. Post-stimulus time histograms did not indicate a significant increase following stimulus onset. One explanation could be that the oddballs were not significant enough to elicit a shift in attention. The subjects rapidly habituated to the stimuli, which lost their novel or alerting quality. Studies with trained monkeys are in progress and may resolve this issue.

258.18

SIMULATED INTERACTIONS OF ANTERIOR AND POSTERIOR ATTENTION SYSTEMS IN A NETWORK BASED ON CORTICAL-BASAL GANGLIA LOOPS AND CORTICOTHALAMIC LOOPS. D. LaBerge, M. Carter, University of California, Irvine, & V. Brown, University of Texas, Arlington.

Recent results of brain imaging and neurophysiological studies suggest a role for the pulvinar nucleus of the thalamus in selective visual attention. Computer simulations of the corticothalamic circuit produce selective enhancement (of center) and inhibition (of surround) in cortical units when the corresponding thalamocortical units are given a slight advantage in activation, from either afferent or cortical input (LaBerge, Brown, & Carter, *Soc. Neurosci. Abstr.* 16:579). The circuitry here assumed to be involved in visual attention is repeated in other thalamic nuclei as well, suggesting that other nuclei may produce selective enhancement in other cortical areas. Recent data implicate anterior cingulate cortex in tasks which require complex attentional operations such as attention to multiple dimensions of a stimulus (Corbetta et al., *Science* 24:1556-1559). In addition, major inputs to anterior cingulate corticothalamic circuits are inhibitory connections from basal ganglia. It is possible then that attention to a specific task is under control of anterior cingulate via basal ganglia; corticothalamic circuits in anterior cingulate controlling higher-order cognitive procedures may in turn activate specific processes in posterior corticothalamic circuits. A computer simulation of this larger attentional network produces selection of anterior cortical areas via disinhibition by basal ganglia, followed by selection of posterior cortical areas through connections to pulvinar. (ONR N00014-88-K-0088)

A SENSORIMOTOR PHASE TRANSITION IN THE HUMAN BRAIN REVEALED BY MULTIPLE LOW TEMPERATURE SQUIDS. J.A.S. KELSEO, S. BRESSLER, S. BUCHANAN*, G. C. DEGUZMAN*, M. DING*, A. FUCHS*, T. HOLROYD*. Program in Complex Systems and Brain Sciences, Center for Complex Systems, Florida Atlantic Univ., Boca Raton, FL 33431 and *Biomagnetic Technologies Inc., San Diego, CA 92121.

The recent evolution of multisensor SQUID (Superconducting Quantum Interference Device) instruments allows magnetic field measurement of intracellular current flows over large areas of neocortex, thereby providing a window into the brain's spatiotemporal dynamics. A circular 37-SQUID array of diameter 144mm. was centered over left parieto-temporal cortex. Each of the SQUIDS was sampled continuously at 862 Hz (passband = 1 to 200 Hz). The subject's task was to produce a manual response to an auditory stimulus, the frequency of which was increased every 10 cycles in steps of .25 Hz from 1.0 Hz to 3.25 Hz. At a certain critical stimulus frequency behavior switched from a reactive, uncoupled mode of coordination to an anticipatory, synchronized mode (Kelseo, DelColle & Schöner, 1990). Analysis of signal frequency, phase and amplitude revealed: a) the behavioral task induced a coherent state over the whole array i.e., brain signals were frequency and phase-locked to the stimulus; b) at a critical stimulus frequency (- 1.75 Hz), an abrupt qualitative change (phase transition or bifurcation) in signal phase occurred in specific parts of the array; this transition in the brain dynamics coincided with behavioral switching; c) signal power and principal eigenvalues obtained through mode decomposition techniques dropped dramatically across the transition. Coronal, sagittal and axial MR data (contiguous 3mm slices) have been obtained in order to localize the source of these phenomena. Research Supported by NIMH Grant MH42900 and ONR Contract N00014-88-J-1191.

INTERSUBJECT RELIABILITY OF NEUROMAGNETIC MEASUREMENTS ON THE HUMAN SOMATOSENSORY AND AUDITORY SYSTEMS.

T. T. Yang, C. C. Gallen, B. Schwartz, F. E. Bloom.

Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

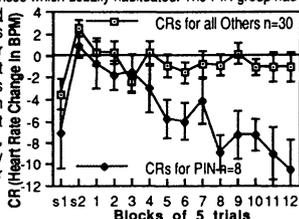

The reliability of neuromagnetic source localization approaches has been demonstrated with intrasubject studies for the auditory and somatosensory systems. An important additional source of localization variability stems from intersubject differences in brain and head morphology. The purpose of this study was to attempt to quantify the intersubject variability of neuromagnetic measurements for the human somatosensory and auditory systems using a BTI 37-channel Neuromagnetometer. In order to quantify the contribution of intersubject variability, we studied the somatosensory area through the repetitive stimulation of the thumb, index, pinky, and cheek. These regions were localized in the human brain using 256 repetitions of a tactile, pressure stimulator upon the respective body regions. We also examined the auditory system using 60 repetitions of four different tones at 500 Hz, 1000 Hz, 2000 Hz, and 4000 Hz, respectively. Dipole localizations were done for these evoked fields on 13 neurologically normal adult subjects. The mean X, Y, Z location for each site was computed. The mean and standard deviations for the point to point variation from the mean for all subjects were also calculated. The variability stemming from the intersubject variables was substantially larger than intrasubject variability. The significance and validity of this variability was further examined using neuromagnetic comparisons with magnetic resonance images (MRI) of the respective subjects. The issue of intersubject variability could stem from the increased error due to problems involved with the neuromagnetic recording techniques and/or due to differences inherent within the subjects themselves.

LEARNING AND MEMORY—ANATOMY IV

259.1

MICROSTIMULATION OF A SPECIFIC REGION OF THE MEDIAL GENICULATE (MG) SERVES AS AN UNCONDITIONED STIMULUS (US) FOR AUTONOMIC FEAR CONDITIONING TO A TONE. Scott J. Cruikshank, Jean-Marc Edeline, and Norman M. Weinberger. *Centr. Neurobiol. Learning and Mem. and Dept. Psychobiol., UC Irvine, CA 92717*

The medial division of the medial geniculate (MGm) and associated posterior intralaminar nucleus (PIN) receive both auditory and somatosensory input, exhibit discharge plasticity with tone/shock pairing, and are necessary for autonomic fear conditioning (cond) to a tone. However, it remains unclear whether critical convergence of somatosensory and auditory information for fear cond. occurs here, or if this area simply provides auditory information to a center of convergence elsewhere. We reasoned that if convergence is in MGm/PIN, microstimulation (stim) of this area would serve as an US for conditioned bradycardia. Adult male Guinea Pigs were subjected to 40-60 trials of Pavlovian cond. following unpaired sensitization control trials. The conditioned stimulus (CS) was a monaural 6s, 70db tone. The US was a .5-1 s train (100-150uA, 50-75Hz, .5ms) delivered at CS offset to the contralateral MG via bipolar stim electrodes implanted 1 week earlier in PIN (n=8), MGm (n=14), ventral MG (n=9), dorsal MG/SG (n=5) or outside MG (n=2). PIN stim. generally elicited bradycardia **Unconditioned Responses**, which were maintained throughout training; stim. of other areas elicited responses which usually habituated. The PIN group had significant bradycardia **Conditioned Responses (CRs)** which developed across cond trials (see blocks 1-12); other placement groups showed no significant CRs, despite similar orienting responses which habituated during sensitization (s1, s2). Thus, stim. of PIN is a sufficient US for cond. bradycardia to a tone CS, supporting that convergence of auditory and somatosensory information for autonomic fear cond. occurs in this area. EQUIPOTENTIALITY OF THALAMO-AMYGDALA AND THALAMO-CORTICO-AMYGDALA CIRCUITS IN AUDITORY FEAR CONDITIONING. L.M. Romanski and J.E. LeDoux. *Center for Neural Science, New York University, NY, NY 10003.*

The lateral nucleus of the amygdala (AL) is essential for the classical conditioning of fear responses to simple auditory stimuli in rats. AL receives projections from both thalamic and cortical areas of the auditory system. The thalamic projection originates in the medial division of the medial geniculate body (MGm) and in the subadjacent posterior intralaminar nucleus (PIN). The cortical projection is from temporal and perirhinal regions, which in turn are the recipients of auditory thalamo-cortical projections. In the present study we examined the sufficiency of thalamo-amygdala and thalamo-cortico-amygdala auditory pathways as conditioned stimulus (CS) transmission systems in fear conditioning.

Rats were given lesions of auditory cortex (ACX, n=6), MGm/PIN (n=7), or both ACX and MGm/PIN (n=7). After 14-21 days recovery time, they were subjected to fear conditioning (30 pairings of a tone CS with footshock). The next day, CS-elicited changes in arterial pressure and freezing behavior were examined. Lesions of either ACX or MGm/PIN failed to interfere with fear conditioning while combined lesions of ACX and MGm/PIN impaired conditioning. Sensory transmission to the amygdala is essential in fear conditioning but either thalamo-amygdala or thalamo-cortico-amygdala pathways are sufficient as sensory transmission routes. LESIONS OF THE AUDITORY THALAMUS BLOCK ACQUISITION AND EXPRESSION OF AVERSIVE CONDITIONING TO AN AUDITORY BUT NOT A VISUAL STIMULUS MEASURED WITH THE FEAR POTENTIATED STARTLE PARADIGM. S. Campeau and M. Davis. *Dept. of Psychology and Psychiatry, Yale Univ. Sch. of Med., 34 Park St., New Haven, Ct 06508.*

Previous research indicated that the auditory thalamus is necessary for the acquisition of auditory fear conditioning (Ledoux et al., *Neurosci.*, 17:615, 1986). To test the generality and specificity of this finding, animals were trained simultaneously with auditory and visual stimuli before or after bilateral lesions of the auditory thalamus, and tested with the fear-potentiated startle paradigm.

Unoperated, sham-operated, and rats sustaining bilateral electrolytic lesions of all the subdivisions of the medial geniculate body, the intralaminar nucleus, and the peripeduncular area, were given 10 pairings each of a 3.7 sec, 70 dB, noise centered at 2 kHz (24 dB/octave attenuation) and a 3.7 sec fluorescent light, each coterminating with a 0.5 sec, 0.4 mA footshock, on each of two consecutive days. All animals were tested 1 day later with 70 startle-eliciting noise-bursts in the presence or absence of the auditory or visual conditioned stimuli. Additional rats, trained as described above, received bilateral electrolytic or sham lesions of the auditory thalamus 24 hrs after the last training session and were tested 10 days later. Bilateral auditory thalamic lesions before or after conditioning nearly completely abolished startle enhancement to the auditory conditioned stimulus. In contrast, the level of visual fear-potentiated startle in lesioned animals was comparable to that of the sham-operated and unoperated rats.

These results suggest that the role of the auditory thalamus in aversive conditioning is specific to auditory stimuli. Experiments investigating the role of subnuclei of the auditory thalamus, as well as other auditory structures, in the mediation of auditory fear-potentiated startle are currently in progress.

DIFFERENT BRAIN SYSTEMS MEDIATE CONTEXTUAL AND EXPLICITLY CUED FEAR CONDITIONING. R.G. Phillips and J.E. LeDoux. *Center for Neural Science, New York University, NY, NY 10003.*

In classical fear conditioning tasks animals develop emotional reactions to a conditioned stimulus (CS) paired with footshock as well as to background or contextual stimuli present during the pairing. In this study we examined whether different brain systems might contribute to the acquisition of conditioned responses to an explicit CS and to contextual stimuli. Lesions were placed in the amygdala (n=8), dorsal hippocampus (n=18) or in the neocortex above hippocampus (n=18). After 10-14 days recovery, blocks of two conditioning trials, consisting of a tone (800 Hz, 80 dB, 20 sec) paired with footshock (0.5 mA, 0.5 sec), were given on three consecutive days. Unoperated controls exhibited freezing during the CS but not prior to it on day 2, whereas on day 3 they exhibited freezing during the pre-CS time and during the CS. Freezing during the CS on day 2 and 3 was used as a measure of conditioning to the CS, whereas freezing during the 20 sec. prior to the CS on day 3 was used as a measure of contextual conditioning. Neocortical lesions had no effect on freezing during the pre-CS time or during the CS. Hippocampal lesions had no effect on freezing during the CS on either day 2 or day 3 but reduced freezing during the pre-CS time on day 3. Amygdala lesions reduced freezing during the CS on both day 2 and 3 and reduced freezing during the pre-CS time on day 3. Thus, the amygdala appears to be involved in the conditioning of fear responses to stimuli explicitly paired with footshock as well as to background or contextual stimuli, whereas the hippocampus only appears to contribute to contextual conditioning. Supported by MH38774.

NMDA LESIONS OF THE LATERAL AND BASOLATERAL NUCLEI OF THE AMYGDALA BLOCK FEAR POTENTIATED STARTLE AND SHOCK SENSITIZATION OF STARTLE. C. B. Sananes & M. Davis, Yale Univ. Sch. of Med., Dept. of Psychiatry, Ribicoff Res. Fac. of the Conn. Mt. Hlth. Cr., 34 Park St., New Haven, CT 06508.

Lesions of the central nucleus of the amygdala block the elevation in startle when this reflex is elicited in the presence of a cue previously paired with shock (fear-potentiated startle). Retrograde and anterograde tracing techniques indicate a direct anatomical connection between the central nucleus of the amygdala and the acoustic startle pathway and lesions at several points along this pathway block the expression of fear-potentiated startle. In addition, lesions of the central nucleus of the amygdala or the pathway between the amygdala and the startle circuit block the elevation in startle that occurs shortly after presentation of a footshock, termed shock sensitization. Finally, electrical stimulation of the amygdala markedly increases the amplitude of the startle reflex using electrical currents and train durations well below those required to produce observable behavioral responses. While these studies strongly implicate the central nucleus of the amygdala in modulating startle, much less is known about the role of other amygdaloid nuclei in fear-potentiated startle.

In the present study, cell bodies in the lateral and basolateral nuclei of the amygdala, but not the central nucleus, were destroyed by local infusion of N-methyl-D-aspartate (NMDA). In Experiment I the lesions were carried out before training and testing, and in Experiment II the lesions were carried out after training but before testing. In both cases the lesions completely blocked fear-potentiated startle. This occurred in each of the 17 animals given NMDA lesions. These lesions also blocked the normal increase in startle observed after a series of footshocks (10, 0.6 mA shocks presented at a rate of 1 shock/sec), but only when the lesion included the ventral aspect of the most anterior part of the basolateral nucleus. We suggest that the lateral and/or basolateral nuclei of the amygdala are involved in relaying visual information to the central nucleus of the amygdala, which is also critical for fear-potentiated startle, and that activation of the anterior part of the basolateral nucleus may be critical for shock sensitization and, perhaps, processing of aversive somatosensory information during fear-conditioning.

EFFECTS OF DEGREE OF TRAINING ON RETENTION OF AVERSIVELY MOTIVATED LEARNING IN RATS WITH NMDA-INDUCED AMYGDALA LESIONS. M.B. Parent, C. Tomaz, E. Yudko* & J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, Univ. California, Irvine, CA 92717.

It is well documented that retention of aversively motivated learning is impaired by lesions of the amygdala. These experiments were undertaken to determine whether the degree of impairment depends upon the amount of training provided before the lesion. Male Sprague-Dawley rats were given either 1 or 10 training trials in a two-compartment straight alley. On each trial they were placed in a darkened compartment and escaped from footshock (0.75mA) by entering the adjoining illuminated compartment. One week following the training, lesions were induced by microinfusing n-Methyl-D-Aspartic acid (NMDA) into the amygdala (10ug/ml, 0.8ul, 4min). Lesions were verified, using light microscope, by observers blind to the behavioral results. Controls were either unoperated (UO) or received sham-lesion surgery (SL). Retention was tested four days after surgery by placing the rats in the illuminated compartment and recording, during a 600 sec period, the latency to enter the dark compartment (where shock was delivered in training), amount of time spent in each compartment, and the number of crossings between compartments. The amount of training given prior to the surgery significantly affected retention. In the UO and SL controls, as well as the amygdala-lesioned groups, the retention performance of animals given 10 training trials was significantly better than that of animals given one training trial. As was expected, the performance of amygdala-lesioned animals that received one training trial was significantly poorer than that of control animals. However, the retention performance of the lesioned animals given 10 trials was comparable to that of controls given one training trial. Thus, these findings indicate that the retention-impairment produced by post-learning amygdala lesions is partially attenuated by increasing the amount of training given prior to the lesion.

ACTIVATION OF AUDITORY CORTEX WITH VISUAL STIMULATION THROUGH SENSORY-SENSORY CONDITIONING. L. Cahill and H. Scheich, Technical University Darmstadt, Institute for Zoology, Schnittspahnstr. 3, D-6100 Darmstadt, Germany.

We have used the 2-deoxyglucose (2DG) metabolic mapping technique to examine changes in brain activity produced through sensory-sensory associative conditioning in the gerbil. Gerbils received 40 training trials, each consisting of a 10 sec presentation of a light followed by a 10 sec presentation of a tone (1KHz). On approximately every third trial a 1 sec mild footshock was given at the end of the tone to maintain arousal in the subjects. Controls received 40 presentations of the light (no tone), with shock given after the light on the same schedule as the first group. One day later, 2DG was injected, and the subjects given repeated presentations of the light alone. The results show a strong activation of the auditory cortex by the light in the light/tone conditioned group compared to the controls, with the most pronounced activation seen in field AAF. It appears that, through conditioning, the light begins to activate sensory regions normally activated by the tone with which it has been associated.

259.6

ANATOMICALLY SELECTIVE BLOCKADE OF PAVLOVIAN FEAR CONDITIONING BY APPLICATION OF AN NMDA ANTAGONIST TO THE AMYGDALA AND PERIAQUEDUCTAL GRAY. M. S. Fanselow, J. J. Kim, & J. Landeira-Fernandez. Psychology Dept, UCLA, Los Angeles, CA 90024-1563.

Previously, we reported that ICV injection of the NMDA antagonist, APV, prior to training eliminates fear conditioning. This experiment assessed the anatomical location of that effect by applying APV to various loci known to be involved in conditional fear. Cannulae were implanted bilaterally into the central (ACE) and basolateral (ABL) nuclei of the amygdala and unilaterally into the ventral (vPAG) and dorsal (dPAG) periaqueductal gray. A total of 5µg APV, or its vehicle, was injected prior to training. Conditioning consisted of placing a rat in an observation chamber and presenting 3 (1 s, 1 mA) shocks spaced 20 s apart. Fear was assessed by observing freezing when the rat was returned to the chamber 24 h later. Fear was virtually eliminated in the rats with ABL and vPAG placements. There was no attenuation of fear in the rats with ACE cannulae. A trend toward a reduction in freezing with dPAG placements was not statistically reliable. These data suggest that both the ABL and vPAG are involved in the NMDA dependent plasticity subserving fear conditioning.

ENHANCEMENT OF RAT VISUAL SYSTEM 2-DEOXYGLUCOSE UPTAKE BY AROUSING FOOTSHOCK IN PATTERNED LIGHT AND DARKNESS. A.R. McIntosh, F. Gonzalez-Lima & R.M. Cooper, Dept Psychol, Univ of Texas - Austin, Austin, TX USA 78712; Dept Psychol, Univ of Calgary, Calgary, AB Canada T2N 1N4.

Autoradiography with [¹⁴C]2-deoxy-D-glucose was used to examine metabolic changes in the visual system of hooded rats exposed to patterned light or to darkness following footshock. Primary retinorecipient structures showed a response to light but not to shock. Higher visual sites showed two different shock effects. First, the intermediate grey layer of the superior colliculus and secondary visual cortex were suppressed by the shock regardless of visual condition. Second, in the lateral posterior nucleus and primary visual cortex, the footshock led to significant enhancement of the metabolic responses to the patterned light. Structural models (McIntosh & Gonzalez-Lima, *Brain Res.*, in press) were constructed using the 2-DG data to quantify changes of the covariance relationships among different visual pathways. The models suggested that patterned light led to an increase in the influence of the geniculocortical path relative to models for groups tested in darkness, and that footshock modified extra-visual influences. The models also demonstrated a significant interaction of geniculocortical and tectocortical paths for the group given footshock with the patterned light display. The findings suggest that footshock-induced arousal has significant modulatory effects on the operations of higher visual pathways of behaving rats.

ELECTROLYTIC LESIONS OF THE ARCULATE NUCLEUS OF THE HYPOTHALAMUS ATTENUATE CONDITIONAL ANALGESIA BUT DO NOT ENHANCE PAVLOVIAN FEAR CONDITIONING. S. L. Young and M. S. Fanselow. Department of Psychology, University of California, Los Angeles, CA, 90024.

In the rat, analgesia is one of many adaptive responses to fearful stimuli. This analgesia has two roles in Pavlovian fear conditioning. First, it serves as a conditional response (CR) to previously neutral stimuli that have been associated with mild footshock. Secondly, during the course of fear conditioning, analgesia as a CR serves to regulate conditioning by reducing the impact of the noxious unconditional stimulus. Reversal of fear-induced analgesia with opioid antagonists suggests opioid mediation. Reversal of the analgesia during training results in enhanced fear conditioning. However, reversal of the analgesia during testing restores responding to a painful stimulus. The µ opioid receptor is critical in the expression of conditional analgesia. β-endorphin (β-EP) has a high affinity for µ receptors and the capacity to produce a profound analgesia. The primary source of brain β-EP is the arcuate nucleus of the hypothalamus (AN). Electrolytic lesions of the AN were used to deplete brain β-EP to test its role in conditional analgesia. Response to a subcutaneous injection of dilute formalin was used to indicate pain reactivity and analgesia. Anterior AN lesions attenuated conditional analgesia and posterior AN lesions had no effect. However, neither reliably enhanced fear conditioning as indexed by freezing. These results suggest that the AN plays a role in fear-induced analgesia.

LEARNED AVERSIVENESS TO A TASTE PAIRED WITH ILLNESS IN RATS LACKING GUSTATORY CORTEX. S.A. Bailey and S.W. Kiefer. Department of Psychology, Kansas State University, Manhattan, KS 66506-5302.

Rats lacking gustatory cortex (GC) and control rats were given four sucrose-illness pairings. Each acquisition trial involved the intra-oral infusion of a sucrose solution while the subjects' taste reactivity was videotaped in a special chamber. Immediately after each infusion, the rats received intubations of lithium chloride (1% body weight of .15 M LiCl). After the training phase, the rats were placed on a schedule of restricted fluid access and tested for sucrose consumption in the home cage. Videotapes of the acquisition trials were scored for orofacial responding, and the two groups' reactivity was compared. Results indicated that while both groups increased aversive responding over the four training trials, the GC animals showed significantly fewer aversive responses than controls. Repeated training trials resulted in reduced ingestive responding for both groups although GC rats' ingestive responses still remained significantly higher than that of control animals. Finally, while the reactivity of the GC rats to sucrose revealed a shift in palatability toward aversiveness, sucrose consumption in the home cage was high. This result indicated that GC rats failed to transfer their learned aversiveness to another context where consumption was used as a dependent measure.

A SIGNALLED BAR-PRESSING PREPARATION FOR STUDY OF THE NEURAL BASES OF APPETITIVE AND AVERSIVE LEARNING IN THE RAT. S.E. Logue, D.P. Miller and J.E. Steinmetz. Program in Neural Science and Department of Psychology, Indiana University, Bloomington, IN 47405.

One interesting aspect of the study of the neural bases of learning and memory is a comparison of how the brain codes appetitive and aversive conditioning situations. Described here is our attempt to develop a rat paradigm that allows for direct comparison of appetitive and aversive learning. We have developed a signalled bar-press conditioning paradigm, in which a bar-press during a 1 sec tone results in either a food reward or the successful avoidance of a footshock. In the appetitive task the rats are shaped to bar-press for food reinforcement and then run on a FR4 partial reinforcement schedule until a high rate of bar-pressing is established. Once baseline bar-pressing is established the rats are given daily sessions of 100, 1 sec tone (2 KHz, 85 dB) presentations. If the rat bar-presses during the tone there is a food reinforcement followed by a 10 sec intertrial interval and a variable pre-CS period (range 1-5 sec). A bar-press during the pre-CS period resets the time interval before tone presentation. This required period of response inhibition increases the distinctiveness of response to the tone. In the aversive task the rats are shaped to bar-press to escape a 0.5 mA footshock and are then run on a Sidman avoidance schedule until a high level of avoidances is established. The tone sessions, using ITI and pre-CS parameters identical to the appetitive preparation, are then begun. The only difference from the appetitive task is that by bar-pressing during the tone the rat successfully avoids a 1 sec 0.5 mA footshock. In addition to describing the neural substrates underlying appetitive and aversive learning using an identical stimulus and response and the same subject, other advantages of this paradigm include the ability to distinguish timed responding from cued responding at a neural level and to distinguish between learning and performance deficits in signalled bar-pressing conditioning. Our initial studies using these tasks have focused on the cerebellum. Early results indicate that large lesions of the deep cerebellar nuclei alter timed responding in the appetitive paradigm through an increase in response preservation but do not affect cued responding. INJECTION OF A PROTEIN SYNTHESIS INHIBITOR INTO GUSTATORY CORTEX IMPAIRS MEMORY OF CONDITIONED TASTE AVERSION IN RAT. K. Rosenblum, N. Meiri and Y. Dudai. Department of Neurobiology, Weizmann Institute of Science, Rehovot 76100, Israel.

In conditioned taste aversion (CTA) organisms learn to avoid a discrete taste if it is followed by poisoning. In contrast to conventional types of associative learning, CTA tolerates a delay of hours between the sensory percept and the explicit reinforcer. The taste representation must hence be stored in the brain over the delay until aversion occurs. CTA can therefore be used to investigate the formation of a lasting central sensory representation and the subsequent association of this stored representation with a reinforcer. We are investigating molecular and cellular mechanisms that subservise taste memory and aversive association in CTA in rat, using saccharin as the gustatory stimulus and LiCl as the aversive agent. In classical and instrumental learning, consolidation of memory requires protein synthesis. We have tested whether protein synthesis is also required for memory of CTA. Acute infusion of the protein synthesis inhibitor anisomycin to the lateral cerebral ventricles of adult rats before, during and after CTA training, at concentrations that were found by us to inhibit water maze navigation learning, led to only a small decrement in the intensity of memory of CTA, when tested in an extinction procedure up to 5 days after training. In this mode of administration, anisomycin was effective in rapidly and reversibly reducing protein synthesis by >90% in some brain areas, e.g. hippocampus and cingulate cortex, but not in others, including the insular cortex which is a candidate for storing taste representations. In contrast, local injection of anisomycin into gustatory cortex shortly before and during CTA training impaired CTA memory without significantly affecting liquid consumption. Our data thus corroborate the notion that gustatory cortex is required for CTA memory and suggest that protein synthesis in this cortical area is involved. (Supported by the Schilling Foundation, Germany).

THE ROLE OF THE AMYGDALA AND PERI-AMYGDALA REGION IN EARLY OLFACTORY ASSOCIATIVE LEARNING. R.M. Sullivan and D.A. Wilson. Developmental Psychobiology Laboratory, Dept. Psychology, University of Oklahoma, Norman, OK

Olfactory associative learning in infant rats is correlated with a modification of olfactory bulb function and structure. However, recent studies have suggested that acquisition and/or expression of olfactory memories in newborns may involve neural circuits in addition to the bulb (e.g., Kucharski & Hall, 1988). The present experiment focused on the role of the amygdala in olfactory learning in infant rats.

Rat pups were cold anesthetized at PN5 and received either bilateral lesions aimed at the amygdala (1 mA, 40 sec) or sham lesions. On PN6, pups were trained in a classical conditioning paradigm in one of 3 groups: PAIRED-ODOR-STROKE (odors were paired with tactile stimulation from a brush), RANDOM-ODOR-STROKE or ODOR only. On PN7 pups were tested for both conditioned behavioral responding and conditioned odor preferences. After the behavioral testing, pups were perfused through the heart and locations of the lesions confirmed histologically. Preliminary results suggest that bilateral lesions in the region of the amygdala impair performance on an olfactory associative learning task in infant rats. LEARNING AND MEMORY—PHYSIOLOGY III

260.1

OSCILLATORY ACTIVITY RELATED TO SHORT-TERM MEMORY IN THE TEMPORAL POLE OF MONKEYS. K. Nakamura, A. Mikami and K. Kubota. Dept. of Neurophysiology., Primate Res. Inst., Kyoto Univ., Inuyama, Aichi 484, Japan.

Neurons in the ventral part of the temporal pole (area TG) of monkeys (*Macaca mulatta*) showed sustained activity during a delay period of a sequential discrimination task with a time delay, while the monkey memorized particular visual stimuli (Nakamura et al. *Soc. Neurosci. Abstr.*, 760, 1990). These activities were not present after the monkey made erroneous responses. Thus, sustained activity is considered to be related to short-term storage of visual information. When auto-correlograms were computed for sustained activity, oscillatory property was detected in 18 out of 21 neurons. The commonest frequency was 3.0 Hz (range, 2.1-20.0 Hz). They also showed oscillation in response to particular stimuli, but the frequency of oscillation during stimulation was higher than that of oscillation during the delay period. It appears that oscillatory activity is involved in short-term storage of visual information. These neurons were located both in the supragranular layers (n=10) and in the infragranular layers (n=8). The data suggest that the oscillatory activity is generated and maintained within the temporal pole.

260.2

FAILURE OF VISUAL IMAGE PAIRINGS TO PRODUCE CORRELATED SINGLE-UNIT RESPONSES IN INFEROTEMPORAL CORTEX OF A MACAQUE. Stanislaw Sobotka and James L. Ringo. Dept. of Physiology, U. of Rochester Med Ctr, Rochester NY, 14642.

In this study we asked if single unit responses to two visual patterns presented separately are made more similar if previously the patterns had often been presented together. During training sessions, 5 pairs of visual patterns were presented (each pair > 1000 times) to a macaque. The monkey distinguished between these 5 pairs and other similarly produced pairs for reward (accuracy > 95%). However, no single member of any pair ever appeared as a member of any other pair. During experimental sessions, responses from 157 well isolated and visually responsive neurons in inferotemporal cortex were recorded to each of the 10 patterns now presented separately. Interlaced sessions continued the pairings training. Spike count analysis as well as a principal components analysis on smoothed response waveforms did not find greater similarity between responses to stimuli presented previously in pairs (compared with responses to stimuli not previously so presented). Interestingly, in response to other stimuli shown in the same sessions, 48 of the 157 cells did show 'recognition' memory (i.e. the response of a cell to an image was significantly altered by previous presentation of that image).

260.3

HIPPOCAMPAL NEURONS IN SHORT-TERM COLOR MEMORY. Joaquín M. Fuster. Department of Psychiatry and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The hippocampus plays a significant role in acquisition and consolidation of memory. In primates, including the human, this role seems to cover a wide range of mnemonic material, whether spatially defined or not. Less understood is the potential involvement of the hippocampus in the retrieval of well-consolidated memory and its temporary retention in short-term working memory. In the course of a study of inferotemporal cortical cells (Fuster, *J. Neurophysiol.*, 64:681,1990), spike records were obtained of 72 hippocampal units from monkeys performing a delayed matching to sample task with familiar compound visual stimuli. On every trial the animal had to attend to a stimulus feature (pattern or color) and retain it for 10-20 sec in order to make a discriminant choice after that delay. Results of statistical spike-frequency analysis can be summarized as follows. Units responsive to the stimulus (sample) were more common in subiculum and CA1-3 than dentate. Latency of response-onset ranged between 120 and 360 ms, mean 217 (SD 62) ms. Responses to color were generally greater when color was relevant (i.e., had to be retained) than when it was not. During the retention period (delay) some cells showed sustained and differential levels of discharge depending on the color to be remembered. These phenomena are similar to those observed in inferotemporal cells of the same animals performing the task. Thus, despite the limited data base, it may be concluded that, in the monkey, at least some hippocampal neurons are part of cortico-limbic circuits that engage in retrieval and short-term memory of nonspatial information.

260.5

AUTOIMMUNITY AND AVOIDANCE LEARNING IN NZB X RF RECOMBINANT INBRED LINES. L.M. Schrott, R.E. Wimer, C. Wimer, G.F. Sherman, G.D. Rosen, A. M. Galaburda and V.H. Denenberg. *Biobeh. Sci. Grad. Prog.*, U.Conn., Storrs, CT 06269; City of Hope National Med. Center, Duarte, CA 91010; and Beth Israel Hospital and Harvard Med. School Boston, MA 02215.

NZB and BXSB mice perform poorly on avoidance conditioning (AC) tasks but well in other behavioral tests. Degree of autoimmunity, especially levels of brain reactive and anti-DNA antibodies influences AC performance (Denenberg et al., submitted; Nandy et al., 1983). To further investigate this relationship, 70 mice from 4 NZB x RF recombinant inbred (RI) lines (Lines 1, 8, 17, and 18) were studied. NZBs are autoimmune and have cortical ectopias, while RFs have neither anomaly. The RI mice received a battery of behavioral tests including two-way AC. Blood was drawn for immune assays and brains were examined. All lines had one or more ectopias. Since in prior studies ectopias have not influenced AC, data were summed across this condition. All lines were poor in AC, and did not differ in avoidance responses. However, Line 18 mice had the slowest escape time ($p < .0001$) and most null responses ($p < .04$). Line 18 also had the greatest degree of immune reactivity. They differed from the other 3 lines on IgM-RF ($p < .004$) and immune complexes ($p < .03$); from Lines 8 and 17 on IgG ($p < .001$) and anti-dsDNA antibody ($p < .01$); and from Line 8 on IgM ($p < .03$). The learning deficit in Line 18 was specific to AC. They performed well in discrimination learning, water escape learning and the Morris maze. Line 18 appears to have received a complement of genes associated with autoimmune disease. Concomitantly, it also has a deficit in some AC parameters. This is the fourth time we have found an association between degree of autoimmunity and AC using 3 different paradigms. This suggests a common mechanism is involved. This work was supported in part by NIH grant HD 20806. We thank Drs. P. Behan and L. Morrison for doing the immune assays.

OVERSHADOWING EFFECTS IN AGED NUCLEUS BASALIS MAGNOCYLLULARIS-LESIONED RATS. A. E. Butt, B. G. Cooper*, D. J. Hardy* & G. K. Hodge. Department of Psychology, University of New Mexico, Albuquerque, NM 87131.

Recovery of function typifies most studies of learning and memory in animals with lesions of the nucleus basalis magnocellularis (nbm). We examined the extent to which behavioral recovery is dependent upon stimulus salience.

The nbm was infused bilaterally with ibotenic acid in rats that were subsequently tested in a bar-press operant discrimination learning task. Although acquisition was initially impaired, enduring behavioral recovery ensued (Butt et al., *Soc. Neurosci. Abstr.*, 1990, 16, 905). Testing was suspended for 11 months. When animals were retested at 18 months post-lesion, operant performance had not changed in either the lesioned or control groups.

The original conditioned stimulus (CS) for food reward consisted of a light accompanied by a "clicking" sound at the light's onset and offset. Overshadowing procedures involved removing the light (CS₁) while retaining the auditory component of the stimulus (CS_A). Although both groups showed less conditioning to CS_A alone than to CS₁ and CS_A in compound, lesioned animals showed significantly poorer conditioning to CS_A compared to controls ($p < .002$).

Results suggest that while nbm-lesioned animals are capable of learning about salient aspects of a given cue, their ability to process relevant cues of lesser salience is dramatically impaired.

CHEMICAL NEURONAL DEATH IN MONKEY HIPPOCAMPUS. T. Ono, E. Tabuchi*, H. Nishijo* and R. Tamura*. Dept. Physiol., Fac. Med., Toyama Med. & Pharmaceu. Univ., Sugitani, Toyama 93001, JAPAN

To investigate effects of transient cerebral ischemia in the monkey, eight monkeys were subjected to temporary occlusion of 8 (bilateral common carotid, internal and external carotid, and vertebral) major arteries. The monkeys were sacrificed by perfusion-fixation 5 days after the operation. Slight increment of glial cells in the striatum and neocortices was the only neuronal change produced by 5 min occlusion. After 10-15 min occlusion, there were ischemic cell changes restricted to the CA1 subfield of the hippocampus. More prominent ischemic neuronal necrosis in the CA1 subfield of the hippocampus was evident after 18 min occlusion. Two other monkeys with ischemic lesion confined to the hippocampus, and which had been well trained pre-operatively, performed a delayed nonmatching to sample (DNMS) task with 60 to 600 sec delays (declarative memory), with scores 10 to 30% below their pre-operative scores until the 10th day of post-operative testing. The monkeys performed object discrimination and motor skill tasks (procedural memories) with their pre-operative scores. The results suggest that the CA1 subfield of the monkey hippocampus is most susceptible to a relatively mild ischemic insult, and transient ischemic insult by 10-15 min occlusion of 8 arteries in the monkey could produce a model comparable to human amnesia.

BRAIN AGING AND AUTOIMMUNITY: ACCELERATED DECLINE OF MEMORY, LEARNING, AND SENSORIMOTOR PROCESSES IN BXS/MPJ, NZB/BINJ, AND C57BL/6N NIA MICE. M. J. Forster and H. Lal. Department of Pharmacology, Texas College of Osteopathic Medicine Fort Worth, TX 76107-2690.

In order to investigate the influence of autoimmunity on functional brain aging, we compared rates of decline in learning, memory and sensorimotor capacities in non-autoimmune C57BL/6N NIA mice and two short-lived autoimmune strains, BXS/MPJ and NZB/BINJ. In accordance with previous studies (Forster & Lal, *Br. Res. Bull.*, 25:503-516, 1990), the autoimmune strains showed a rapid decline in their ability to learn an avoidance task between 2 and 8 months of age, whereas C57BL/6N NIA mice showed no decline until after 12 months. When mice were tested for rates of forgetting under a discriminated escape paradigm (Forster et al., *Drug. Dev. Res.* 11:97, 1987), a clear pattern of accelerated memory decline was observed for NZB/BINJ mice. However, in contrast to the findings with avoidance learning, BXS/MPJ mice failed to show impaired memory for up to 8 months. Both autoimmune strains exhibited an accelerated decline with age in the speed and average duration of spontaneous horizontal locomotion in Digiscan activity chambers. Additionally, the autoimmune genotypes had earlier declines in their capacity to remain on an accelerating rotarod both before and after practice. These findings suggest that brain aging processes involved in memory and sensorimotor functions may be accelerated in genetically autoimmune mice. [Supported by NIH grant AG06182 (MJF)].

IMMEDIATE AND DELAYED MEMORY PROCESSES ARE DIFFERENTIALLY AFFECTED BY AGING. L. Nielsen-Bohlman & R. T. Knight, Neurology Dept, UC Davis, VAMC, 150 Muir Rd, Martinez, CA 94553

We examined long latency ERPs in young (n=9, mean age=22 years) and old (n=6, mean age=70 years) adults in a recognition memory paradigm. Stimuli were line drawings of familiar objects presented in quadrifields (duration 800 msec, ISI 1200 msec). Eighty percent of the images were presented twice and 20% were presented once. The second presentation occurred at 1.2 sec with no intervening images (immediate), or at 4-6, 22-58, or 100-158 sec (delayed). Subjects indicated whether an image had been previously presented by pressing a 'yes' or 'no' button. Older subjects showed enhanced frontal positivity to all stimulus presentations. The first presentation generated a parietal P600 component of comparable amplitude in young (9.3uV) and old (8.7uV) subjects. The P600 generated by immediate stimulus repetition was also comparable in amplitude in young (15.9uV) and old (14.8uV) subjects. Delayed stimulus repetition generated a central negative component at 330 msec in both groups, with reduced amplitude in the elderly (young=5.0uV, old=3.4uV; $p < .05$). The P600 was reduced at all repetition delays in the old group, while the young group showed P600 reduction only beyond 100 sec. These data indicate that while immediate memory processes remain intact, delayed recognition memory is altered by aging.

260.9

ANALYSIS OF MEMORY TESTS AND REGIONAL NEUROPHYSIOLOGY IN DEMENTED PATIENTS USING HMPAO AND XENON SPECT SCANS
 W.R. Shankle*, MS, MD., M. Dick, PhD, E. Fong, BS, J. Mena, MD,
 Dept of Neurology, UC Irvine, CA 92717

Analysis of the relationships between specific psychometric tests, regional cerebral blood flow (rCBF), and regional uptake of HMPAO in patients with various dementias was done to better understand possible psychophysiological differences for different diseases as well as to explore regions of brain that are physiologically related by either rCBF or HMPAO uptake to specific cognitive functions.

Underlying assumptions include: 1) the impairment of a cognitive function is related to the physiological alteration of one or a set of physiologically connected regions; 2) the control of a function does not change loci in the brain as that function deteriorates; 3) the Xenon and HMPAO SPECT methods respectively represent rCBF and regional perfusion of the brain; and 4) a given psychometric test is processed in similar ways by different persons.

We evaluated all patients coming to the UCI Dementia Assessment Program in a similar way. Each received a neurologic and physical exam, a comprehensive battery of psychometric tests that included the CERAD (Consortium for the Evaluation and Research on Alzheimer's Disease), an MRI, an HMPAO and Xenon SPECT scan done at UCLA-Harbor Medical Center by Dr. Ishmael Mena, and a standard set of laboratory tests to exclude dementias other than vascular or Alzheimer's. The regions of interest (ROIs) were selected on axial slices of the HMPAO and Xenon SPECT scans. The psychometrics used for this analysis pertained to memory, and included the CERAD 10 item 3 trial immediate free recall with delayed free recall and recognition, digit span, metacognition, and Mattis nonverbal recognition.

We predict that these tests will have correlations with specific ROIs. We loaded the data onto a massively parallel processing database, the TERADATA DBC, which was then used to select appropriate subsets for statistical analysis. We used BMDP to look for correlations between psychometrics and SPECT measures.

TASTE AVERSION INDUCING EFFECTS OF COCAINE IN SELECTIVELY-BRED TASTE AVERSION PRONE AND RESISTANT RATS R.L. Elkins¹, P.A. Walters¹, T.E. Orr², E.F. Kolbe³, F. Westbrook² and S.H. Hobbs²; ¹VA Medical Center and Medical College of Georgia; ²Augusta College, Augusta, Georgia, USA 30910.

Twenty-two generations of bidirectional selective breeding for efficiency of taste aversion (TA) conditionability have produced markedly different strains of TA prone (TAP) and TA resistant (TAR) rats. Strain selection methodology paired a saccharin flavored conditioned stimulus (CS) with the aversive unconditioned stimulus (US) consequences of a cyclophosphamide injection. The strain difference in TA conditionability is not restricted to the cyclophosphamide US. Other previously identified strain segregating USs include lithium chloride, emetine hydrochloride or ethanol injections and rotationally induced motion sickness. Within the present experiment, a range of cocaine hydrochloride US injections (10, 20 and 30 mg/kg, ip), likewise all produced significant strain differences in conditioned saccharin TAs. A pseudo-conditioning control procedure supported an associative (conditioning) interpretation of the strain differences. The TAP and TAR strains may provide a useful model for studies of biological bases of genetically mediated differences in cocaine reactivity as revealed via the TA conditioning paradigm. PRENATAL MALNUTRITION AND POSTNATAL NUTRITIONAL REHABILITATION EFFECTS ON CA1 HIPPOCAMPAL PYRAMIDAL CELLS IN ADULT RATS. S. Díaz-Cintra, L. Cintra, A. Aguilar*, L. Granados*, T. Kemper* and P.J. Morgane. Inst. Invest. Biomédicas, UNAM, México, D.F.04510, Neurol. Unit. Boston City Hosp. Boston MA, 02118 and Worcester Foundation for Experimental, Biology. Shrewsbury, MA, 01545.

We have previously morphometrically analyzed the effects of prenatal protein malnutrition on the dentate gyrus of the hippocampal formation. We used the same material of previous studies with nutritional rehabilitated animals that were born from mothers that were fed by a 6% casein diet before mating and during gestation. At birth, pups were cross-fostered to normal mothers fed in similar conditions with 25% casein diet. Using the rapid Golgi method we studied the CA1 hippocampal pyramidal cells in rehabilitated rats at 90 and 220 days of age. We found significant reductions in the major axis at both ages in the prenatally malnourished rats. The number of dendritic spines measured in medial and terminal segments showed significant reductions at 90 days while the terminal dendritic spines showed a significant reduction in dendritic spines at 220 days of age. These results indicate a long-term effect of prenatal protein malnutrition on the stratum radiatum and stratum lacunosum-moleculare where fibers from the perforant and Shaffer collaterals synapse on the apical dendrites of CA1 pyramidal neurons. (Supported by NIH Grants HD-22539-04 and HD 23338-03).

260.10

EXPOSURE TO COLD DISRUPTS THE ACQUISITION AND PERFORMANCE OF A FOUR MEMBER RESPONSE CHAIN IN RATS. J. Schrot and J.R. Thomas. Naval Medical Research Institute, Bethesda, MD 20889-5055.

Cold temperature exposure disrupts memory processes. The extent to which this is caused by a failure to acquire tasks in the cold is controversial. This study examined the effect of acute exposure to 2° C air on the acquisition and performance of four member response sequences in rats. Four animals were trained on a four lever, four member repeated acquisition procedure in which each day of the week was associated with a different required sequence of responses. For example, the correct sequence on Monday was 2314 while on Tuesday it was 3241. Each correct response advanced the sequence to the next member and the fourth correct response resulted in the delivery of a food pellet. Incorrect responses resulted in a three second period of timeout. Following the development of baseline stability the animals were exposed to cold air while performing the procedure. Each animal was exposed twice on each day of the week with a minimum of 48 hours between exposures. The procedure was then changed to a performance condition where the required sequence was the same each day. The animals were subsequently exposed to cold twice on this procedure. The results show that cold exposure disrupted both the acquisition and performance of sequences. Accuracy of responding decreased on both the acquisition and performance baselines; however, the magnitude of the change was greater during acquisition. Timeout responding was also disrupted in a similar fashion. The results indicate that cold exposure interferes with the acquisition and memory of response sequences.

260.12

TASTE AVERSION RESISTANT RATS HAVE HIGHER NE AND LOWER 5-HT LEVELS IN BRAIN THAN TASTE AVERSION PRONE RATS T.E. Orr*, R.L. Elkins, P.A. Walters and G.F. Carl; Psychology Research, VA Medical Center and Medical College of Georgia, Augusta, Georgia, USA 30910.

Twenty-two generations of bidirectional selective breeding for taste aversion (TA) conditionability have yielded two strains of rats that show virtually no overlap during behavioral testing of TA conditioning. Following a conditioning pairing of a novel saccharin solution with a cyclophosphamide, ethanol or cocaine hydrochloride i.p. injection, TA prone (TAP) rats prefer water to saccharin, whereas TA resistant (TAR) rats drink the saccharin solution almost exclusively. In an initial study of biological bases the strain differences, whole brains of TAP and TAR rats were analyzed for levels of neurotransmitter amines. The amines were separated by HPLC and measured by electrochemical detection. No strain differences were found with respect to DOPAC, DA or 5-HIAA. However, TAP brains had higher levels of 5-HT and lower levels of NE than TAR brains. Planned studies of regional concentrations and receptor densities as well as the effects of attempted pharmacological and/or dietary manipulations of these and other neurotransmitter systems should clarify the biological bases of TA conditioning. The findings may be applicable to improved treatment and prevention of alcoholism and drug abuse. (Supported by the VA Medical Research Service.)

SLEEP DEPRIVATION IN NORMAL AND MALNOURISHED RATS OF 60 DAYS OF AGE. L. Cintra, A. Galván* and S. Díaz-Cintra. Depto. de Fisiología, Instituto de Investigaciones Biomédicas, UNAM, México, D.F. 04510.

In a previous study we reported significant decreases of REM sleep before and after total sleep deprivation in malnourished rats of 30 days. The objective of the present study was to evaluate the effects of protein malnutrition induced by a 6% casein diet, instituted before mating and continued during gestation and into postnatal life, on the sleep-waking cycle before and after sleep deprivation. A base line-recording day was followed by one day of total sleep deprivation in a continuously rotating cylinder (diam. 32 cm; rotation rate: 1 turn/2.40 min) and three recovery days in normal (25% casein diet) and malnourished rats of 60 days of age. We found a significant increase of SWS in malnourished rats on days 1 and 3 during the activity phase (lights-off) and also during day 3 of the rest phase (lights-on). REM sleep was significantly decreased in the malnourished animals during the rest phase on day 1 and the next 3 recovery days and during the activity phase, these rats showed a significant increase of REM sleep on days 1 and 5. These data reveal a significant delay in the mechanisms that regulate SWS and REM sleep recovery after sleep deprivation as well as a change in the circadian phase shifted in both sleep states. (Supported in part by CONACyT Grant No. P219CCOA 880341. México.)

PRENATAL PROTEIN MALNUTRITION ALTERS VIGILANCE STATE MODULATION OF INHIBITION AND FACILITATION IN THE DENTATE GYRUS. P.J. Morgane, K. Austin, R. Austin-LaFrance, J. Bronzino, J. Tonkiss*, and J.R. Galler*. Worcester Found. for Exp. Biol., Shrewsbury, MA 01545, Trinity College, Hartford, CT 06106 & Boston Univ. Med. School, Boston, MA 02118.

The effects of prenatal protein malnutrition on interneuronally-mediated inhibition and facilitation in the dentate gyrus were examined across several vigilance states using the paired-pulse technique. The paired-pulse index (PPI), computed by dividing the amplitude of the second population spike (p2) by the amplitude of the first population spike (p1), was used as a measure of the net short-term facilitation or inhibition. PPIs were classified on the basis of p1 amplitude to make comparisons between vigilance states and dietary treatment. Testing was performed during slow-wave sleep (SWS), paradoxical sleep (REM), immobile waking (IW) and active waking (AW) using IPIs of 20 - 400 ms. Magnitude and duration of interneuronally-mediated inhibition was significantly increased in rats of the malnourished group. Tests at IPI 20 ms. under high p1 conditions (p1 > median) showed significantly smaller PPIs in malnourished rats regardless of vigilance state. At IPIs > 20 ms. PPIs were consistently smaller in the malnourished group during SWS and IW. No consistent diet-related differences were found during AW or REM at IPIs > 20 ms. No consistent vigilance state effect was observed for either the facilitatory (IPI = 40 - 80 ms.) or late inhibitory (IPI = 400 ms.) periods in either group. Under low p1 conditions (p1 < median) during AW the PPIs at IPI 40 and 50 ms. were smaller than those obtained at IPIs of 30 and 60 ms. This depression interrupts the facilitatory phase and may indicate an interaction between perforant path stimulation and hippocampal theta rhythm which is masked in the high p1 condition. Alterations in interneuronally-mediated inhibition may help to explain the resistance to kindling and inability to maintain LTP previously demonstrated in our malnourished rats. NEUROCHEMICAL EFFECTS OF PRENATAL PROTEIN MALNUTRITION ON HIPPOCAMPAL SEROTONIN ACTIVITY. J.-C. Chen, J. Galler*, J. Tonkiss* and L. Volicer.

Dept. Pharmacology and Ctr. for Behav. Development, Boston U. Med. Sch., Boston, MA 02118.

The effect of prenatal protein malnutrition on central serotonin (5-HT) metabolism was assessed in adult rats. These subjects (6/25 group) were males born to dams fed a 6% casein diet during gestation and fostered at birth to dams fed a control (25% casein) diet. Tissue content of 5-HT, 5-hydroxyindoleacetic acid, 5-hydroxytryptophan, 1-tryptophan and catecholamines in the hippocampal formation was similar to that of well-fed controls (25/25 group). However, a two-fold increase in basal 5-HT efflux from hippocampal slices was observed in 6/25 rats, as compared with 25/25 rats during a 30 min incubation period. [³H] paroxetine binding indicated that there was no alteration of apparent maximal binding and affinity of the 5-HT transporter in the 6/25 rats. In addition, the release rate of pre-taken [³H]5-HT from isolated platelets was similar in the two groups. The results indicate that prenatal protein malnutrition causes selective changes in central 5-HT metabolism. (Supported by NIH Grant HD-22539-04).

PRENATAL PROTEIN MALNUTRITION ALTERS DENTATE GRANULE CELL RESPONSE TO TETANIC STIMULATION. J.D. Bronzino, R.J. Austin-LaFrance and P. J. Morgane. Trinity College, Hartford, CT 06106 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Male rats born to dams fed a 6% casein diet during gestation and fostered at birth to lactating dams fed a control diet (25% casein) were tested at 90 days of age for their ability to establish and maintain LTP of the perforant path/dentate granule cell synapse. Prior to tetanization, input response measures were obtained from each animal to determine the stimulus intensity required to evoke population responses equal to 75% of maximum. Quantification of the population EPSP slope and population spike amplitude (PSA) were used to assess the effects of tetanization on these measures of the evoked field response. The ratio of PSA/EPSP slope was computed to provide a measure of the overall efficacy of neuronal transmission. Following tetanization, 10 evoked waveforms were recorded in response to stimulation at the 75% level at each of 8 time periods ranging from 5 min. - 24 hrs. The percent change in EPSP slope and PSA were determined for each time point with reference to the pre-tetanization measures. Following potentiation, malnourished animals showed an immediate and significant enhancement of EPSP slope which was maintained over the entire 24 period. In contrast, the PSA failed to show significant enhancement until 18 - 24 hrs. post-potentiation. The level of PSA enhancement in the malnourished group remained significantly lower than that of controls across all time points. Ratio measures from the malnourished animals indicated a significant decline in the overall efficacy of neuronal transmission in response to tetanization, whereas controls showed a significant enhancement in this measure. The data suggest that prenatal malnutrition results in enhanced inhibition of granule cell activity, effectively limiting the conversion of potentiated synaptic activation into enhanced cellular discharge. (Supported by NIH Grants HD-22539 & HD-23338 and NSF Grant BCS9010616)

260.16

PRENATAL PROTEIN MALNUTRITION EFFECTS ON THE CHOLINERGIC SYSTEM OF THE RAT HIPPOCAMPAL FORMATION. G.J. Blatt, D.L. Rosene, K.J. Rhodes and A. Virga. Department of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA 02118

Prenatally protein malnourished rats born to dams on a 6% casein diet during pregnancy and cross-fostered at birth to normal females on a 25% casein diet show adult alterations in hippocampally-mediated behaviors and in anatomy, physiology and neurochemistry of the hippocampal formation (HF). Previously we reported a marked decrease in the serotonergic (5-HT) innervation as well as a concomitant decrease in high affinity uptake sites for 5-HT in the HF of adult (day 220) malnourished rats. We report here alterations in the cholinergic system of three matched pairs of adult (day 220) malnourished rats utilizing on-the-slide *in vitro* ligand binding and histochemical techniques. High affinity choline uptake sites (HACU) revealed a 15% decrease in density in the infragranular and granule cell layers in the dentate gyrus (DG) in malnourished rats compared to normals. Histochemical staining using the Tago method for acetylcholinesterase also showed decreased reaction product in the infragranular and granule cell layers in malnourished rats but this marker also showed a decrease in the outer third of the molecular layer of the DG. Using ³H-oxotremorine to assay the muscarinic M2 cholinergic receptor revealed a 20% decrease in malnourished rats in the pyramidal cell layer of CA1-3 and the prosubiculum and subiculum and a 10-15% decrease in the infragranular layer of the DG. In contrast, ³H-pirenzepine labelling of M1 cholinergic receptors revealed no difference in density between normal and malnourished rats. Similar to the 5-HT system, alterations in the cholinergic system were prominent in and around the granule cell layer. This demonstrates that there are corresponding changes in at least two subcortical neurotransmitter afferent systems in the DG of prenatally protein malnourished rats. Such neurochemical changes could effect this first step in the hippocampal 'trisynaptic circuit' and may ultimately underlie some of the observed physiological and behavioral alterations produced by prenatal protein malnutrition. (Supported by NIH HD22539).

260.18

PRENATAL PROTEIN MALNUTRITION AND HIPPOCAMPAL FUNCTION: SPATIAL LEARNING AND LONG-TERM POTENTIATION. R.J. Austin-LaFrance, J. Tonkiss*, J.R. Galler*, J.D. Bronzino and P.J. Morgane. Trinity College, Hartford, CT 06106, Boston Univ. School of Medicine, Boston, MA 02118 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

At 70 days of age, male rats born to dams fed a 6% casein diet during gestation and fostered at birth to lactating dams fed a control diet (25% casein) were assessed for their ability to acquire and retain the location of a submerged, fixed-position platform in the Morris water maze. Twelve trials, four from each of three different start positions, were run on each of two consecutive days. Latency scores over the first day's trials indicated significantly impaired acquisition in these animals compared with well-nourished controls of the same age. Scores recorded during the first three trials of day two revealed a significant deficit in the ability of malnourished animals to maintain the previous day's performance levels. All animals were subsequently tested for their ability to establish and maintain LTP of the perforant path/dentate granule cell synapse over a 24 hr period. Although malnourished animals showed potentiation of the EPSP slope this occurred without the parallel enhancement of population spike amplitude characteristically observed in controls. This suggests that, in the malnourished animals, granule cell activity is under strong inhibitory modulation which serves to limit the translation of synaptic activation (EPSP) to cellular discharge (population spike) resulting in a decrease in the overall efficacy of neuronal transmission. A causal relationship between these behavioral and neurophysiological measures of hippocampal function remains to be determined. (Supported by NIH Grant HD-22539)

260.20

EFFECTS OF RESTRAINT AND ADRENALECTOMY ON BEHAVIORALLY-RELATED SYNAPTIC EFFICACY CHANGES IN RAT FASCIA DENTATA. E. J. Green, P.M. McCabe, and M. A. Nichols*. Department of Psychology, University of Miami, Coral Gables, FL 33124.

The transfer of rats between environments is normally associated with an increase in exploratory behavior and a number of alterations in perforant path - evoked population responses, including a large increase in evoked EPSP slope, and a substantial reduction in both the onset latency and area of the population spike. These response changes have a gradual onset and outlast the exploratory behavior. The present experiments were designed to assess 1) whether the expression of these synaptic efficacy changes requires an animal to move through the environment, and 2) the possible role of peripheral stress hormones in the mediation of these effects.

Chronically implanted rats were subjected to bilateral adrenalectomy (ADX) or sham procedures (SHAM) and maintained on 20 µg/ml corticosterone and 0.9% saline. A sound-attenuating chamber served as the animals home environment. Perforant path - evoked responses, hippocampal EEG, and behavior were sampled from the animals during a baseline period in the chamber. Following the baseline period, animals were either allowed to explore an open field containing junk objects, or they were restrained in the same environment. The animals were then deeply anesthetized with methoxyflurane, and blood was collected for subsequent determination of plasma corticosterone. Baseline responses fluctuated in accordance with the animal's behavioral state at the time of the stimulus. Both ADX and SHAM rats exploring the open field exhibited gradual decreases in the onset latency and area of the evoked population spike, relative to values observed in a similar behavioral state during the baseline period. ADX and SHAM animals also showed robust efficacy changes during and subsequent to restraint. Serum corticosterone levels indicated that bilateral adrenalectomies were complete. The present results indicate that substantial movement through an environment is *not* necessary for the expression of synaptic efficacy changes following environmental transfer. They also indicate that such alterations are not simply a consequence of stress - related adrenal hormone release. Supported by BNS 9021632 to E.J.G.

HUMAN BRAIN ACTIVATION DURING DYSPHORIA

J.V. Pardo, P.J. Pardo and M.E. Raichle, Washington University School of Medicine, St. Louis, MO 63110

Dysphoria describes a negative mood state-- feelings of sadness, anguish, misery, and mental malaise. Dysphoria occurs in normal humans if transient and limited. When severe and persistent, dysphoria is a symptom of psychiatric disease, most notably major depression.

We have used CBF PET to visualize cortical regions activated during dysphoria. Seven right-handed volunteers (4 male & 3 female), who were normal psychiatrically and who did not have first degree relatives afflicted with affective disorder, were studied under two conditions for intrasubject paired subtractions. First, the control state was resting with eyes closed. Second, the experimental condition (dysphoria) was transient self-induced sadness, also with eyes closed. All subjects reported the subjective experience of feeling sad during the mood induction. All three women had visible tearing; two of four men teared to a slight degree.

The major responses occurred in the orbital frontal cortices. Women had bilateral orbitofrontal activation, while men had left orbitofrontal activation.

We conclude that the orbital frontal cortices play an important role in normal emotional cognitive processing.

ABSENCE OF KLÜVER-BUCY SYMPTOMS AFTER NEONATAL LIMBIC LESIONS IN INFANT RHESUS MONKEYS. V. Nalwa and J. Bachevalier. Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

Reactions to familiar vs novel objects were assessed in four monkeys with neonatal amygdalo-hippocampal lesions (AH) and 10 normal controls when the animals were 9 months old. Four of the normal controls were pair-reared with monkeys from Group AH (N/AH) and 6 were pair-reared with each other (N/N). All monkeys saw the same set of 4 familiar and 8 novel objects, presented either one, two, or three objects at a time in a fixed, pseudorandom order for 3 min each at 30-s intervals, in each of 6 daily sessions. All infants looked at and manipulated the familiar stimuli more than the novel and showed displacement activity to the novel stimuli, as indicated by an increase in cage manipulation equivalently in all three groups. However, animals in Group N/AH showed more aggressive responses towards all stimuli than animals in Groups N/N and AH and those in Group AH displayed more temper tantrums and were more passive than the others. It thus appears that early damage to limbic structures does not yield the Klüver-Bucy symptoms of loss of fear and indiscriminate approach to objects, often orally, seen in monkeys with limbic lesions done in adulthood.

261.5

EMG SPECTRAL ANALYSIS DISTINGUISHES SPONTANEOUS FACES FROM FACES TO COMMAND.

M. M. La Cerra and A. J. Fridlund*. Psychophysiology Laboratory, Department of Psychology, University of California, Santa Barbara, CA 93106.

Global differences between faces emitted spontaneously and those emitted to command have been noted in the behavioral neurology literature on pyramidal vs. extrapyramidal lesions, as well as in the neuropsychology literature on cerebral asymmetry. The present study was designed to investigate precise differences in the patterns of muscle fiber contraction between these two types of facial displays. EMG recordings were obtained from facial sites on the cheeks directly over the right and left zygomatic major muscles of subjects while they 1) viewed a comedy video (the spontaneous condition) and 2) responded to commands to emit smiles of varying intensity (the face to command condition). Spectral analyses of these recordings indicated a significant difference in the spectral coherence (degree of synchronization) of right and left cheek muscle recruitment between experimental conditions. These findings suggest an *in vivo* method for parsing pyramidal vs. extrapyramidal influences on facial behavior, and have implications for neurodiagnosis and forensic polygraphy.

261.2

THE NUCLEUS ACCUMBENS IN MONKEYS (MACACA FASCICULARIS): INCENTIVE AND EMOTION.

C.E. Stern and R.E. Passingham. Dept. of Experimental Psychology, Univ. of Oxford, S. Parks Rd., Oxford, England, OX1 4JF. C.E.S. currently at Massachusetts General Hospital NMR Center, 13th St. Bldg. 149, Charlestown, MA 02129.

The nucleus accumbens (NA) receives inputs from the amygdala. In order to better understand the behavioural significance of the NA, studies were undertaken which compared the emotional and motivational behaviour of monkeys with NA lesions with previous studies on amygdala lesioned monkeys (Aggleton and Passingham, 1981, 1982). In addition, results of a button press extinction task and a frustration task are reported.

A comparison was made between 3 unoperated control monkeys and 3 monkeys which received ibotenic acid lesions of the NA. The NA lesioned monkeys maintained normal food preferences between 5 food types and did not show signs of hyperorality in a food vs. non-food discrimination task. There was no significant difference between the food preferences of the two groups pre-operatively ($F(1,4)=1.4$) or post-operatively ($F(1,4)=0.3$). These results contrast with the effects of total amygdala lesions, which result in a flattening of food preferences, a willingness to eat previously aversive foods such as meat, and hyperorality (Aggleton and Passingham, 1981).

The NA lesioned monkeys were capable of working for reinforcement on a button press task (15 presses per nut, 900 presses per session), but they extinguished their behaviour faster than the control monkeys when reinforcement for button pressing was withheld. We suggest that the extinction results may be explained by an increased reaction to frustration in the NA lesioned monkeys. Response to frustration was recorded when peanuts were visible but unobtainable. In this testing situation, as in the extinction task, the NA lesioned monkeys exhibited hyperactive and aggressive behaviors such as pacing, cage rattling, and cage banging. In contrast, it may be significant that lesions which do result in perseveration on button press extinction tasks, such as lesions in the orbitofrontal cortex (Butter, 1969) and amygdala (Weiskrantz, 1956) produce monkeys which exhibit decreased aggressive responses in other testing situations.

261.4

EEG AND STIMULUS SALIENCE IN SCHIZOPHRENIA. G.C. Kessler* and A.S. Kling. Dept. of Psychiatry, 116A-8A, V.A. Med. Center, Sepulveda, CA 91343.

Eighteen unmedicated chronic schizophrenic patients and 13 normal controls were tested in a paradigm designed to examine changes in EEG activity following presentation of emotionally salient auditory stimuli and control tones. Five standard bands of EEG spectral power were examined at bilateral frontal and temporal recording sites. The schizophrenic subjects were assigned to diagnostic subgroups on the basis of DSM-III-R criteria following independent clinical examination by 2 staff psychiatrists. Those subjects who met DSM-III-R criteria for paranoid schizophrenia were assigned to one subgroup (PS subgroup), while those who met DSM-III-R criteria for either residual or undifferentiated schizophrenia were assigned to a second subgroup (R/US subgroup). Analysis of Variance of EEG activity revealed significant diagnosis-related differences at bilateral temporal recording sites (T3 and T4). Post-hoc tests revealed that the R/US subgroup manifested the greatest degree of change following emotionally salient stimuli, including a bilateral decrease in temporal alpha and an increase in temporal beta-2 power. Changes in EEG power following each of 8 categories of emotional stimuli were ranked together, forming a hierarchy of temporal lobe response. Alterations in this response hierarchy were observed in the R/US subgroup. These findings are interpreted as being indicative of subgroup-specific alterations in the processing of emotionally salient information within the schizophrenic spectrum. They suggest that temporal lobe mechanisms may be disturbed in certain forms of schizophrenia.

UNILATERAL POSTERIOR PARIETAL CORTEX LESIONS ALTER EMOTIONALITY IN RATS. Susan E. Maier & Douglas P. Crowne, Dept. Psychology, Univ. Waterloo, Waterloo, Ontario, Canada N2L 3G1

In both human and non-human primates, unilateral injury to the posterior region of parietal cortex (PPC) produces disturbances of spatial ability and affect. In rats however, more is known about PPC effects on spatial ability than emotionality. In this experiment, we asked whether removal of PPC would alter emotionality in the rat and if unilateral lesions would produce a reliable behavioural deficit. We also asked about the influence of infantile stimulation (IS) on emotional behaviour of animals with PPC lesions. Male rats were stimulated in infancy and sustained lesions as adults. Emotionality was measured by ratings of reactivity and the open field. Consistent with human findings, rats receiving unilateral lesions were significantly less emotional than those with an intact PPC, but left lesions produced a larger effect than right lesions. IS changed behaviour consistent with the literature but IS/lesion interactions were not found. We demonstrate the role of PPC in emotionality and confirm that unilateral lesions alter behaviour in rats.

GABA BLOCKADE IN THE REGION OF THE ANTERIOR BASOLATERAL AMYGDALA (BLA) ELICITS "ANXIETY" IN THE ABSENCE OF CARDIOVASCULAR STIMULATION. S.K. Sanders and A. Shekhar. Program in Medical Neurobiol. & Dept. of Psychiatry, Indiana Univ. Sch. of Medicine, Indianapolis, IN 46202.

Intracerebral microinjection of the GABA antagonist, BMI (25 ng/250 nl) into the region of the anterior basolateral amygdala (BLA) elicits significant increases in heart rate (HR) and blood pressure (BP). To study the possibility that this physiological arousal may be part of an "anxiety" response, rats trained in the conflict paradigm were implanted bilaterally with chronic microinjection cannulae for i.c. injections and arterial catheters for direct measurement of HR and BP. Preliminary data show that 1 ng/250 nl BMI microinjected into the BLA enhances punishment-induced suppression, while 5 ng/250 nl BMI generalized the suppression to all responding. Based on the previous study, doses greater than 5 ng BMI were necessary to elicit cardiovascular stimulation. This data suggests that the degree of GABA blockade in the BLA necessary to produce detectable "anxiety" is significantly lower than that which causes minimal cardiovascular stimulation. REPEATED STRESSFUL EXPERIENCES DIFFERENTLY AFFECT INCREASED DOPAMINE RELEASE IN MESOLIMBIC SYSTEM DURING AND FOLLOWING STRESS. A. Imperato, S. Puglisi-Allegra, P. Casolini* and L. Angelucci. Farmacologia Medica 2a, Università di Roma "La Sapienza"; Ist. di Psicobiologia e Psicofarmacologia (CNR), Roma, Italia.

Brain dopamine (DA) release was studied in awake rats during 1h restraint stress and immediately after the animals were freed. Restraint induced a rapid increase in DA release in the nucleus accumbens and in prefrontal cortex, while no changes in the striatum were observed. Forty min after the onset of restraint, DA went gradually back to basal levels, while a pronounced increase of DA release was again evident in both areas as the animals were freed. The effects of repeated stressful experiences (1h restraint once a day for six days) on DA release in the nucleus accumbens were also studied. Starting from the third day no increase in DA release was anymore observed during restraint. On the opposite, the increase of DA release produced by freeing the animal was always present. These findings suggest that increased DA release in mesolimbic and mesocortical areas may be a response to emotional arousal produced by sudden environmental changes, either aversive (restraint) or positive (freeing). Moreover, since increased DA release related to aversive experience undergoes to tolerance while that related to the end of it does not, different adaptation patterns for aversive and positive repeated experiences may be envisaged.

261.8

QUISQUALIC ACID LESIONS OF THE SEPTUM INHIBIT FEAR REACTIONS IN THE ELEVATED PLUS-MAZE AND SHOCK-PROBE BURYING TESTS. C. Pesold and D. Treit. University of Alberta, Canada T6G 2E9.

Recent studies in our laboratory have shown that both electrolytic and kainic acid lesions of the posterior septum inhibit fear reactions in the elevated plus-maze. The purpose of the present experiment was to further characterize the anatomical and behavioral specificity of these lesions, by comparing the behavioral effects of excitotoxic (quisqualic acid) and electrolytic lesions of the posterior septum in the elevated plus-maze and shock-probe burying tests. Following sodium pentobarbital anaesthesia, rats were given either quisqualic acid, electrolytic or sham lesions of the posterior septum and then tested 12-16 days later in the elevated plus-maze and shock-probe burying paradigms. Compared to sham lesions, both electrolytic and quisqualic acid lesions significantly reduced fear reactions (i.e., increased open arm activity in the plus-maze, and decreased burying behavior toward the shock-probe). These results provide further evidence that the posterior regions of septum play an important role in the modulation of anxiety-related behaviors.

261.10

EFFECTS OF REPEATED RESTRAINT ON THE TIME-DEPENDENT RESPONSES OF MESOLIMBIC DOPAMINE SYSTEM TO STRESS Stefano Puglisi-Allegra and Simona Cabib Istituto di Psicobiologia e Psicofarmacologia (C.N.R.), via Reno 1, I-00198 Roma, Italy.

Stressful experiences (restraint or footshock) induce similar biphasic alterations of 3-Methoxytyramine (3-MT) in the nucleus accumbens septi (NAS) of mice. In particular, 3-MT increases dramatically during the first 10 min and then decreases after 30 min (up to 120 min). These data suggest biphasic alteration of dopamine (DA) release during prolonged stress exposure, and are in agreement with *in vivo* microdialysis study in rats which show biphasic changes in DA outflow (increase followed by decrease) produced by restraint. Moreover, they support the hypothesis that biphasic alteration of DA transmission in the mesolimbic system is a general response to stress and suggest that the initial increase DA release represents an arousal response while the subsequent decrease in DA release may be related to coping failure.

Repeated exposure to restraint (5 to 120 min daily for 10 consecutive days) abolishes the increase in 3-MT concentrations induced by 5-10 min restraint in the NAS. By contrast the decrease in 3-MT levels produced by longer exposure to stress is unchanged by repeated exposure to the stressor. These results point to a different effect of repeated stressful experiences on the two phases which characterize the response of the mesolimbic system to stress. While the phase of arousal characterized by increased DA release undergoes tolerance, the phase characterized by decreased DA release does not; thus indicating different adaptation patterns of the two responses possibly depending on their adaptive value.

EXPRESSION OF RHYTHMICITY BY SCN TRANSPLANT IS AFFECTED BY SIZE OF HOST SCN LESION. M. A. Vogelbaum and M. Menaker. Department of Biomedical Engineering and Department of Biology, University of Virginia, Charlottesville, VA 22901.

The circadian oscillators responsible for the temporal control of locomotor activity in mammals are located in the suprachiasmatic nuclei (SCN) of the hypothalamus. While the rhythms expressed by golden hamsters (*Mesocricetus auratus*) normally have periods close to 24 hours, a mutation has been found which in the homozygous form reduces the value of the freerunning period to about 20 hours. Complete lesions of the SCN result in circadian arrhythmicity, and transplants of fetal SCN restore locomotor rhythmicity to fully SCN lesioned, arrhythmic hosts with periods corresponding to those expected from the genotype of the donor.

Partial lesions of the SCN often result in disrupted rhythmic activity patterns with clear circadian components. To investigate the ways in which the locomotor output system would respond to multiple rhythmic inputs, we transplanted fetal SCN tissue from donors of one genotype into adult hosts of a different genotype, bearing partial SCN lesions. By altering the size of the host lesion and the time of transplantation after lesioning, we have attempted to vary the relative amount of host and donor input to the locomotor output system. We have found that individual hamsters with both 24 hour and 20 hour circadian oscillators can express both host and donor circadian rhythms. Consequently, we have referred to these animals as "temporal chimeras".

The results of our experiments show that the response of the locomotor output system to two rhythmic inputs depends upon the size of the partial SCN lesion made in the host. Large lesions reduce the frequency of appearance of host derived rhythms and increase the frequency of expression of donor derived rhythms. Smaller lesions often result in the expression of both. In no case was a donor derived rhythm seen in cases where implants were placed into hosts that had no prior SCN lesion. We believe that an output of the host's circadian oscillators suppresses expression of rhythmicity by oscillators in the transplanted SCN, and vice versa. As a larger portion of the host's SCN is destroyed, the amplitude of this suppression decreases and an increasing percentage of donor derived rhythms are expressed.

RAT-TO-HAMSTER HETEROGRAFTS OF FETAL ANTERIOR HYPOTHALAMIC (AH) TISSUE DO NOT DIFFER FROM MOUSE-TO-HAMSTER HETEROGRAFTS IN THE RESTORATION OF CIRCADIAN PERIOD. P.J. Sollars, S.I. Sollars and G.E. Pickard. Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403 and Depts. of Psychiatry and Anat., Univ. of Penn., Phila., PA 19104.

To determine whether the circadian period restored by fetal AH transplantation is donor-species-typical, we have implanted fetal AH tissue containing the SCN into the third ventricle of arrhythmic SCN-lesioned hamsters, using mouse, rat or hamster donors. The periods restored by hamster homografts (n=6) and mouse heterografts (n=9) were similar to the species-typical period of the intact donor (hamsters, 23.99 ± 0.08 vs 24.07 ± 0.01; and mice, 23.47 ± 0.08 vs 23.62 ± 0.03). However, those restored by rat heterografts (n=17) were significantly different from that of the intact rat (23.60 ± 0.07 vs 24.34 ± 0.04, p<0.001). The results suggest either that the organization of the rat circadian system differs from that of mouse and hamster or, since the rat and mouse heterografts do not differ from one another, that the period of the restored rhythm may be an effect of a host extra-SCN oscillator coupling to the grafted SCN. Supported by GM 07257 (PJS) and NS 21165 (GEP).

TIME-COURSE OF FIBER OUTGROWTH FROM FETAL ANTERIOR HYPOTHALAMIC (AH) HETEROGRAFTS. G.E. Pickard and P.J. Sollars. Depts. of Psychiatry and Anatomy, Univ. of Pennsylvania, Phila., PA 19104 and Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

We have reported that heterografts of fetal AH tissue are capable of restoring circadian rhythmicity to arrhythmic SCN-lesioned hamsters (Soc. Neurosci. 14:49, 1988). We also presented evidence of neuronal outgrowth from the implant into the host brain, demonstrated by the mouse specific anti-M-6 antibody (supplied by Dr. Carl Lagenaur). We have now conducted a time-course study to determine whether this fiber outgrowth precedes the time usually required for the restoration of behavioral rhythmicity (generally more than two weeks for heterografts). Animals were killed at 2, 4, 7, 14, 30 and 45 days after implantation. By 4 days, fibers were observed extending more than 600 μ m into the host brain. By day 14, a dense fiber plexus was observed in the host hypothalamus, which suggests that the restoration of circadian rhythmicity may be mediated by neuronal outgrowth from the graft to the host brain. Supported by NS 21165 and MH 47501 (GEP) and GM 07257 (PJS).

¹⁴C-2-DEOXYGLUCOSE (2DG) UPTAKE REVEALS BILATERAL ASYMMETRY IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF HAMSTERS WITH SPLIT CIRCADIEN ACTIVITY RHYTHMS. S.F. Glotzbach, P.J. Sollars and G.E. Pickard. Dept. of Pediatrics, Stanford Univ., Stanford, CA 94305, Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403, and Depts. of Psychiatry and Anat., Univ. of Pennsylvania, Phila., PA 19104.

Under constant illumination, the circadian activity rhythms of some hamsters split into two components. 2DG uptake in the SCN was used to indicate relative metabolic activity in the nucleus in splitters and non-splitters. 2DG was administered intracardially at circadian times (CT) 2 and 14 to anesthetized hamsters. At 45 minutes post-injection, brains were removed and processed for 2DG autoradiography. Right/left relative optical density (R/L ROD) ratios in the SCN were quantified on a DUMAS image analysis system. Significant differences in R/L ROD ratios were observed between splitters and non-splitters in the caudal half of the SCN at both CT's. The bilateral asymmetry in 2DG uptake in the SCN of split animals suggests that an alteration in the normal pattern of metabolic activity in the SCN may underlie the phenomenon of splitting. Supported by NIH grants NS 21619 (SFG), GM 07257 (PJS) and NS 21165 (GEP).

PATTERNS OF CIRCADIEN BODY TEMPERATURE RHYTHMS IN AGING RATS. H. Li*, M. Price*, and E. Satinoff. Psychology Dept and Neuroscience Program, University of Illinois, Champaign, IL 61820.

Many aging studies use a cross-sectional design, comparing young rats at a particular age with old rats at a particular age. This assumes that old rats are uniform with respect to the variable under investigation. Our strategy is longitudinal: it takes into account that aging proceeds at different rates in separate individuals. Long-Evans rats of both sexes were maintained in a 12:12 light-dark cycle at an ambient temperature of $23 \pm 1^\circ\text{C}$. When they were at least 18 months old, they were anesthetized and implanted intraperitoneally with temperature telemeters and housed individually. Their body temperatures (Tb) were computer-recorded every 10 min until they died. We analyzed changes that occurred during the aging process in 4 variables: 1) daily mean Tb; 2) daily amplitude of the rhythm; 3) acrophase (peak of the rhythm); and 4) mean Tb during light and dark. Old rats of the same chronological age were not homogeneous with respect to their circadian Tb rhythms (CTR). Individual rats showed differences in both their CTR patterns and the way the patterns changed as they aged. Rats younger than 18 months old generally had a high amplitude CTR with little variance in the acrophase. Some rats older than 18 months maintained a fairly good CTR, with clear differences between daily Tb means in the light and the dark, and relatively regular acrophases even at very old ages. Others began to show unstable CTR's, with amplitudes varying over days from flat to ones resembling those of young rats, and greater variance in the phase. These patterns correlate with old rats' ability to maintain Tb during thermal challenges.

SUPRACHIASMATIC NUCLEUS (SCN) LESIONS ABOLISH AND FETAL SCN GRAFTS RESTORE CIRCADIEN GNAWING RHYTHMS IN SCN-LESIONED ADULT HAMSTERS. J. Le Sauter and R. Silver. Dept. Psychol., Barnard College of Columbia Univ., New York, NY 10027.

Lesion studies indicate that the SCN controls daily activity cycles of a number of behavioral and physiological rhythms. Detailed anatomical studies indicate that (at least in rats) rhythms of drinking and eating (Van den Pol & Powley, 1979) and of locomotor activity and drinking (Brown & Nunez, 1986) can be dissociated following SCN lesions (SCN-X). Previous work on restoration of circadian rhythmicity by SCN grafts in SCN-X adult hamsters has shown that the restoration of locomotor rhythmicity and gonadal response to photoperiod can be dissociated (Lehman et al., 1987; Silver et al., 1990). It is not known whether other behavioral rhythms can be restored by fetal tissue grafts, nor whether all responses are restored simultaneously.

Circadian activity of gnawing activity has been demonstrated in adult hamsters (Morin, 1978). We measured both gnawing and wheel running activity in intact, in SCN-X, and in SCN-X hamsters bearing fetal grafts of SCN. Rhythmicity of gnawing activity is abolished by SCN lesions. Fetal SCN transplants into the 3rd ventricle of lesioned hamsters restore locomotor activity and gnawing rhythms simultaneously, suggesting control by a common coupling signal from the SCN. EXAMINATION OF THE PHOTOSENSITIVITY OF THE CIRCADIEN SYSTEM IN AGED *rd/rd* MICE. R.G. Foster, I. Provencio & C.A. Czeisla*. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

We have been investigating the photosensitivity of the circadian system of *rd/rd* mice. This mutation results in the progressive loss of photoreceptor cells; the rods degenerate rapidly while cone degeneration is more protracted. Despite the loss of visual function in *rd/rd* mice at 80 days of age, we have found that the photosensitivity of the circadian system is identical in *rd/rd*, *rd/+* and *+/+* genotypes. While no photoreceptor outer segments have been seen within the *rd/rd* retina at 80 days of age, cone cell perikarya have been identified. It is possible that these cone cell bodies mediate circadian photoreception. Bowes et al. (Exp Eye Res 47: 369-390, 1988) report that all cone perikarya disappear in the *rd/rd* mouse retina between 180 - 360 days of age. We have examined the effect of a half-saturating 15 min. light pulse (515 nm) on phase shifting the circadian rhythm of locomotor behavior in *rd/rd* and *+/+* mice aged between 180 - 700 days. Throughout this age range the magnitude of the phase shift showed no difference between the two genotypes and aged mice showed phase shifts that were not significantly different from animals 80 days of age. At 80 days of age the *rd/rd* eye contains 2% of the rhodopsin chromophore (11-cis retinaldehyde) found in the eyes of *+/+* individuals. The chromophore content of aged *rd/rd* eyes was not significantly different from that of *rd/rd* animals 80 days of age. Chromophore content of the eye does not therefore parallel the decline of cone perikarya. These results suggest that circadian photoreception is not mediated by the "remnant" cone perikarya and that another, as yet unidentified, photoreceptor may mediate circadian light detection within the mammalian eye. (Supported by Jeffress Memorial Trust J-213 to RGF & NSF Grad. Fellowship to IP).

262.8

A PHASE-RESPONSE CURVE FOR THE BENZODIAZEPINE CHLORDIAZEPOXIDE AND THE EFFECT OF GENICULO-HYPOTHALAMIC TRACT ABLATION. E.L. Meyer*, M.E. Harrington and T. Rahmani*. Department of Psychology, Smith College, Northampton, MA 01063.

A phase-response curve (PRC) is used to describe how a particular stimulus can shift the biological clock throughout the circadian cycle. The hamster PRC to light pulses indicates light can phase shift the biological clock during the subjective night, but cannot induce shifts during the subjective day. Dark pulses generate a different PRC in hamsters, with phase-advances during the subjective day and delays during the subjective night. The PRC for the benzodiazepine triazolam is very similar to that for dark-pulses.

The geniculo-hypothalamic tract (GHT) provides a major input to the mammalian circadian pacemaker in the suprachiasmatic nuclei. Lesions of the GHT cause a compression of the phase advance portion of the dark pulse PRC. GHT lesions totally block phase-shifts to the benzodiazepines triazolam and chlordiazepoxide (CDZ) at a few circadian phases. In this study, we measured the complete PRC to CDZ pre- and post- GHT ablation.

Twenty-four male Syrian hamsters (*Mesocricetus auratus*) were housed individually under constant dim red light with continuous access to a running wheel. Intrapertoneal injections of CDZ (100mg/kg dissolved in 0.9% saline) were administered to twelve hamsters at various circadian phases. Other hamsters served as vehicle-injected phase-matched controls. Chlordiazepoxide induced phase-advances during the subjective day, and phase-delays during the early subjective night. Unlike triazolam, during the late subjective night CDZ can induce phase advance shifts. Following GHT ablation, CDZ did not induce phase shifts at any phase tested. The results suggest that the geniculo-hypothalamic tract is a component of the neural mechanism by which CDZ induces phase shifts of circadian rhythms. This work was supported by NIH grant NS26496 to M.E.H. and a grant from the Howard Hughes Medical Institute to E.L.M.

EFFECTS OF THE DOPAMINE AGONIST, BROMOCRIPTINE, ON THE CIRCADIAN CLOCK OF GOLDEN HAMSTERS. C. Wickland and F. W. Turek, Dept. Neurobiol. & Physiol., Northwestern Univ., Evanston, IL 60208.

Administration of dopamine agonists, either systemically or centrally, results in a variety of motor effects in rats and mice. Relatively high doses of dopamine agonists induce a short period of hypoactivity, followed by a longer period of hyperactivity. Since a number of stimuli which result in acute increases in locomotor activity in golden hamsters have been found to induce phase shifts in their circadian rhythms, studies were conducted to determine whether bromocriptine (Br), a dopamine agonist, could induce increases in locomotor activity in this species, and whether this treatment could have an effect on the hamster's circadian clock. Male golden hamsters, 7 to 8 mos. of age were housed in constant light in cages equipped with running wheels. The animals were injected I.P. with 5 or 10 mg/kg Br at either circadian time (CT) 6 or CT 22 (CT 12 = predicted onset of activity). Animals were observed to be awake and actively grooming, eating and pouching for several hours after the injection, and other animals, for which activity was measured by telemetry, showed sustained increases in total activity for up to 20 hours after injection. However, in spite of the general increase in activity, there was usually little or no increase in wheel running at this time. Injections of Br at CT 6 induced phase advances in the wheel running rhythm (mean = +55.0 ± 10.6 min., n=6), while injections given at CT 22 induced phase delays (mean = -27.0 ± 11.4 min., n=5). These results indicate that I.P. injections of Br can induce increases in locomotor activity in golden hamsters, and that these injections also result in phase-dependent shifts in circadian rhythms which are similar in direction to those induced by other agents which are associated with acute increases in locomotor activity. At the present time, it is not known whether the effect of Br on the circadian clock is mediated via dopamine receptors in the SCN region or via the accompanying increased locomotor activity.

CONSTANT ILLUMINATION INCREASES SUSCEPTIBILITY TO ACTIVITY-BASED ANOREXIA. E.Z. Stanley, L.E. Doerries, T.S. Rieg and P.E. Aravich, College of William and Mary, Williamsburg, VA 23185; Christopher Newport College, Newport News, Va 23606; Eastern Virginia Medical School, Norfolk, VA 23501; and Veteran Affairs Medical Center, Hampton, VA 23667.

Circadian rhythms have been implicated in anorexia nervosa and can be disrupted in a variety of species by constant illumination. The purpose of this investigation was to determine the effects of constant illumination on susceptibility to activity-based anorexia. Male and female rats were subjected to activity-based anorexia (ABA) (restricted food intake 1.5hrs/day and voluntary access to a running wheel 22.5hrs/day) and exposed to three different lighting conditions. Two of these conditions involved animals maintained on a 12/12 hour light/dark cycle and fed 1.5 hrs/day at either the midpoint of the dark phase or the midpoint of the light phase. The final circadian condition involved animals fed 1.5 hrs/day under constant illumination, which was utilized to functionally disrupt circadian rhythms. The females required the least number of days to lose 25 ± 1.5 percent of their original body weight in the constant illumination condition (3.1 SE ± 0.1) and the most days in the diurnally fed condition (4.8 SE ± 0.3) with the nocturnally fed condition (3.9 SE ± 0.2) falling in between the two. Analysis of terminal wheel revolution and food intake data revealed no significant differences between any of the conditions regardless of gender. The results suggest that disrupted circadian rhythms increase susceptibility to ABA in female rats. Information regarding the contribution of circadian rhythms to ABA may be useful for the identification of a novel risk factor for anorexia nervosa in humans. Support: Veterans Affairs Merit Award (PFA).

ALKALI METALS CONSOLIDATE CIRCADIAN ACTIVITY RHYTHMS IN SYRIAN HAMSTERS. H. Klemfuss, T.A. Kylvstra, T. T. Bauer, and D.F. Kripke, Veterans Affairs Medical Center, San Diego, CA 92161, Department of Psychiatry, University of California at San Diego, and Universitaet Bonn.

A role for potassium ions in the control of circadian rhythms has been suggested by work in plants, algae, invertebrates, and more recently, mammals. We have previously reported that chronic administration of K⁺ in the diet advances entrained wheel-running rhythms in hamsters and increases the amplitude of phase advances in response to light, while lithium delays entrained rhythms without affecting phase response. In the present studies, we examined effects of dietary K⁺, Li⁺, and rubidium (Rb⁺) on the period (τ) and duration (α) of wheelrunning in hamsters, as estimated by a blind rater.

Adult male Syrian hamsters were housed in running wheel cages in constant darkness. In the first study, hamsters were given either a control diet (171 mmol K⁺/kg diet), the same diet containing 1104 mmol K⁺/kg, or the same diet containing 0.4% Li₂CO₃. Dietary K⁺ supplementation decreased τ from 24.13 ± 0.03 (SEM) to 24.03 ± 0.02 h (N=49 and 54, p < .05 by Newman-Keuls) and shortened α from 12.7 ± 0.26 to 11.8 ± 0.25 h (p < .05). Addition of Li⁺ lengthened τ to 24.27 ± 0.03 h and further shortened α to 11.1 ± 0.25 h (N=70, p < .05). In the second study RbCl (20mM in drinking water), like K⁺ in the diet, shortened τ (from 24.10 ± 0.03 to 23.92 ± 0.03 h, N=22 and 12, p < .001 by t-test) and decreased α (from 12.8 ± 0.38 to 11.3 ± 0.31 h, p < .05).

All three alkali metals significantly shortened the duration of activity. Circadian period was either decreased (K⁺, Rb⁺) or increased (Li⁺). This may suggest that a common ionic mechanism is involved in coupling between oscillators involved in onset and offset of hamster locomotor activity, and that a different ionic mechanism regulates period.

THYMUS VASOPRESSIN CONTENT IN ACTIVITY-BASED ANOREXIA. S. Downing, L.E. Doerries, T.S. Rieg, E. Farrar, A. Johnson & P.F. Aravich, Dept. of Anatomy/Neurobiology, Eastern Virginia Medical School, Norfolk, VA 23501; Department of Psychology, Christopher Newport College, Newport News, VA 23606; Veterans Affairs Medical Center, Hampton, VA 23667.

Anorexia nervosa (AN) is associated with a variety of immunological deficits, including deficiencies in cell-mediated immunity. Unfortunately, it is difficult to distinguish the primary features of AN from the secondary consequences of weight loss. Because of interest in the relationship between exercise and AN, we have been exploring activity-based anorexia (ABA) in the rat (1.5 hr/day access to food; 22.5 hrs/day access to running wheels). ABA is associated with reduced delayed-type hypersensitivity (DTH) skin responses to keyhole limpet hemocyanin (KLH) and reduced relative thymus weights. Both effects are due to the secondary consequence of weight loss (Aravich et al., Neurosci Abs 16:1199, 1990). This investigation determined the effects of ABA on thymus VP, which is synthesized within the gland. Thymi were taken from rats in the DTH study cited above (sacrificed 1-2 days post challenge and 14-15 days post sensitization) and from rats not exposed to KLH. Within each condition there were ABA (defined after a 25% weight loss), weight-matched (BWM) and non-exercised freely fed (ADL) subgroups. The KLH treatment caused an overall increase (p < .04) in thymus VP/mg protein compared to the non-KLH treatment; neither the ABA or BWM groups differed from their respective ADL controls. When thymic VP was expressed per gland wet weight, there was an overall KLH effect with VP/gland weight comparably elevated (p < .01) in the ABA and BWM KLH groups relative to the ADL KLH rats. It is concluded that 1) thymic VP/mg protein is elevated during a DTH reaction irrespective of weight loss and 2) this effect is unrelated to the efficacy of a DTH skin response, which is compromised by weight loss. Support: V. A. Merit Award (PFA).

24-HOUR TIMED-FEEDING SHORTENS THE FREE-RUNNING PERIOD OF THE LIGHT-ENTRAINED CIRCADIAN PACEMAKER IN RATS UNDER LL. J.E. Ottenweller*, W.N. Tapp, S.D. Cook, and B.H. Natelson, Neurobehavioral Unit (127A), VA Medical Center, East Orange, NJ 07019 and Department of Neurosciences, New Jersey Medical School, Newark, NJ 07103.

One circadian pacemaker in rats is entrained by the light-dark cycle (LEP) and another by the time of food availability (FEP). We have shown that phase-shifting the LEP resets the phase of the FEP. In the present study, we examined the influence of the FEP on the LEP by limiting food access to 2 hours a day in constant light (LL). Male rats were housed in running wheels with free access to powdered Purina lab chow. Wheel turns were recorded by computer. Rats were entrained to a 12hr:12hr light:dark (LD) cycle for 27 days and then transferred to LL. After 23 days in LL, food access was limited to 0900-1100h for 20 days. Rats were then returned to ad lib feeding. All rats had large amplitude, well entrained activity rhythms in LD. Spectrum analysis revealed that 15 of 24 rats had significant free-running rhythms in LL with periods ranging from 24.1 to 26.4 hr (mean ± sem = 25.0 ± 0.2 hr). In 22 of 24 rats (including all 9 rats without significant circadian rhythms in the prior LL), timed-feeding induced a 1-3 hr burst of activity before the time of food availability. There was also a very prominent period of inactivity for 4-6 hours before this anticipatory burst. The free-running period of the LEP after timed-feeding was shorter than before by 0.53 ± 0.18 hr (p < 0.01). This change in period made it difficult to determine whether entrainment of the FEP by timed-feeding caused entrainment of the LEP or masking. However, the data do suggest that the LEP was clearly entrained by timed-feeding in 5 rats and clearly not entrained in 3 others. These data suggest that imposing a 24-hour feeding schedule shortens the free-running period of the LEP from 25.0 to 24.5 hr. The coupling between the FEP and LEP may also be such that entrainment of the FEP can produce apparent entrainment of the LEP. Supported by VA Medical Research funds.

DAILY AND CIRCADIAN MODULATION OF THE RAT ACOUSTIC STARTLE RESPONSE. C.C. Chabot*, D.H. Taylor* and R.G. Sherman, Zoology Dept., Miami Univ., Oxford, OH 45056.

When presented with a loud acoustic stimulus, mammals exhibit a stereotyped neuromuscular reflex or "startle". While the acoustic startle response (ASR) of the rat is currently being used in many laboratories to explore questions in pharmacology, toxicology, and reflex and sensory physiology, only one study (Horlington, 1970) has attempted to determine the potential daily modulation of this response. We investigated the daily and circadian modulation of the ASR using female Sprague Dawley rats. The rats (n=12), housed under a 12:12 light:dark (LD) cycle for 2 weeks, were placed into a small cage in a dark anechoic chamber. Ten minutes later they were exposed to bursts (40 msec) of white noise of varying intensity (80, 90, 100, 110, 120 dB; 10 trials each) that were delivered every 20 sec in a semi-random but balanced fashion. This procedure was repeated every 4 h for 24 h. Two weeks later, the ASR of the same rats was measured on the second day of exposure to constant darkness (DD) using the same procedure as above. In LD conditions, dark phase response amplitudes (g) were significantly higher than light phase response amplitudes at stimuli above 90 dB (peak, trough means ± SE; 120 dB: 205 ± 20, 121 ± 11; 110 dB: 166 ± 16, 90 ± 8; 100 dB: 98 ± 15, 42 ± 6). In DD, subjective night response amplitudes were significantly higher than subjective day response amplitudes at 110 dB (145 ± 16, 59 ± 8), 100 dB (78 ± 13, 46 ± 7) and 80 dB (7 ± 1, 4 ± 1). These results clearly demonstrate that the ASR amplitude of the rat is modulated on a daily and circadian basis. Studies are currently underway to determine the sensory or motor nature of this modulation.

STRAIN-DIFFERENCES IN PERIOD OF GROSS CAGE MOVEMENT VS RUNNING WHEEL ACTIVITY IN MICE.

J.R. Hofstetter*, A.R. Mayeda*, and J.I. Nurnberger, Jr. Institute for Psychiatric Research, Indiana University Medical School, and Roudebush Veteran Affairs Medical Center, Indianapolis, IN.

In an earlier study of circadian locomotor activity in mice under constant light (LL), we measured the period of gross cage movement by counting photoelectric beam crossings. For two strains of mice we obtained periods different from those reported for running wheel (Possidente and Hegmann, 1982). We compared running wheel activity and gross cage movement without a wheel in 7 mice of C57BL/6J and BALB/c strains under 200 lux LL. In one protocol, 2 mice of each strain were in each condition for 26 d, then switched for 26 d, and switched back for 10 d. In a second study 3 mice of each strain had running wheels for 18 d then no wheels for 15 d. C57BL mice had clear activity periods in all conditions. The free-running period was greater than 24 hr and similar when measured with either technique. BALB mice had erratic activity patterns and ran less on the wheel. The period for gross cage movement was greater than 24 hr in all BALBs but in 3 the running wheel period was less than 24 hr. There is a clear difference between strains on the running wheel but not in gross movement. This suggests that the two kinds of activities may have both different genetic inputs and different behavioral significance.

EFFECTS OF LIGHT AND MELATONIN ON EXPRESSION OF C-FOS AND NGFI-A IN THE RAT SUPRACHIASMATIC NUCLEUS.

E.L. Sutin and T.S. Kilduff, Sleep Research Center, Department of Psychiatry, Stanford University, Stanford, CA 94305.

Recent studies have demonstrated the expression of the immediate early genes (IEGs), *c-fos* and NGFI-A, in the mammalian suprachiasmatic nucleus (SCN) after photic stimulation at circadian times (CT) which are known to induce phaseshifts of the biological clock. We have previously shown using immunocytochemical methods that the hormone melatonin will induce the Fos protein in the rat SCN at CT 22. The present study intended to evaluate the effects of light and melatonin on expression of *c-fos* and NGFI-A mRNAs in the rat SCN by *in situ* hybridization. Male Sprague-Dawley rats (n=24) housed under LD 12:12 were transferred into darkness for 2 days before being divided into one of four groups. At CT 22, animals were given either a subcutaneous injection of melatonin (100 µg/kg; n=6) or saline vehicle (n=6) and were sacrificed 45 minutes later by decapitation. Another group of animals were given a 30 min pulse of light (n=6) or left in the dark (n=6) for 30 min prior to sacrifice. *In situ* hybridization was performed on alternate sections with either a sense or antisense 35S-labeled riboprobe to murine *c-fos* or similar oligonucleotide probes to NGFI-A. Optical density measurements of the ventral and dorsal regions of the SCN, anterior hypothalamus and optic chiasm were taken from film autoradiograms. Light induced both *c-fos* and NGFI-A mRNA at CT 22 in the ventrolateral SCN but in no other brain region examined. Both IEGs were induced in some animals in the melatonin and vehicle-treated groups, suggesting that non-photic stimuli can also induce IEG expression in the ventrolateral SCN. Supported by a grant from the Upjohn Company.

LOCAL ADMINISTRATION OF CNQX ATTENUATES LIGHT-INDUCED PHASE ADVANCES OF THE CIRCADIAN ACTIVITY RHYTHM AND FOS EXPRESSION IN THE HAMSTER SCN.

M. A. Rea, B. Buckley, A.M. Michel* and L. M. Lutton. Armstrong Laboratory, Brooks AFB, TX.

Male, Syrian hamsters were fitted with guide cannulas stereotaxically aimed at the SCN and were housed in constant darkness. Five minutes prior to photic stimulation (10 min pulse; 20-40 lux) at CT18-18.5, animals received 300 nl injections of either 1 mM CNQX or vehicle into the suprachiasmatic hypothalamus. Light pulses induced phase advances of 81 ± 8 min. Vehicle injections reduced shifts (p<0.01) by 33% to 54 ± 10 min. However, CNQX completely blocked light-induced phase advances in most animals (12 ± 9 min; n=9). Furthermore, CNQX reduced the number of *c-fos* protein (FOS)-immunoreactive cells in the SCN of light-stimulated hamsters by 30% (p<0.05). This effect was most pronounced on the side of the injection (329 ± 63 vs 548 ± 55 cells). Vehicle injections did not affect light-induced *c-fos* expression in the SCN. These results are consistent with the hypothesis that light-induced phase alterations of the SCN circadian pacemaker are mediated by excitatory amino acids and may require the expression of FOS-dependent genes. Supported by AFOSR 2312W6 (MAR).

263.2

DIURNAL AND PHOTIC REGULATION OF C-FOS EXPRESSION IN TRANSGENIC MICE. L. M. Robertson, R. J. Sneyne, D. Luk*, J. I. Morgan, and T. Curran* Departments of Molecular Oncology and Neurosciences, Roche Institute of Molecular Biol., Nutley, NJ 07110

The protooncogenes, *fos* and *jun*, are cellular immediate-early genes that are induced in response to a variety of extracellular stimuli. Their protein products (Fos and Jun) form heterodimers that regulate transcription of a number of target genes. To study the molecular basis of *c-fos* regulation *in vivo*, we developed a transgenic mouse line containing a *c-fos-lacZ* fusion gene. A bacterial β -galactosidase (*lacZ*) gene was fused, in frame, into the carboxyl-terminal region of *c-fos*, without disrupting the known regulatory sequences. The purified fragment was then introduced into mice by microinjection and founder strains were derived and characterized for β -galactosidase (β -gal) activity. In animals sacrificed during the day, basal expression of β -gal activity in the central nervous system (CNS) was restricted to a few discrete areas. In contrast, high basal β -gal activity was observed in many regions of the CNS of animals sacrificed during the night. Northern analysis of mRNA levels in nontransgenic animals revealed a similar temporal pattern of *c-fos* expression. Exposure to a pulse of light in the middle of the night dramatically induced β -gal activity in the suprachiasmatic nucleus of the hypothalamus and in the retina. The regulation of expression of *c-fos-lacZ* in transgenic animals was similar to that of the endogenous *c-fos* gene under a variety of physiological conditions. Future studies will involve the characterization of transgenic mice that contain mutations of different known regulatory elements of the *c-fos-lacZ* gene. This transgenic system should prove useful for the study of *c-fos* regulation by physiological stimuli *in vivo*.

THE NMDA RECEPTOR ANTAGONIST MK-801 INHIBITS LIGHT-INDUCED CHANGES IN FOS-LIKE IMMUNOREACTIVITY IN THE MOUSE SUPRACHIASMATIC NUCLEUS. C.S. Colwell and R. Foster. Dept of Biology, Univ. of VA, Charlottesville, VA 22901.

Recent work has shown that light causes an increase in Fos-like immunoreactivity (Fos-LI) in the suprachiasmatic nucleus (SCN) of rodents. Since antagonists of NMDA receptors are known to block the effects of light on the circadian system, we sought to determine whether the NMDA receptor antagonist, MK-801, could block light's induction of Fos-LI in the SCN of mouse. This experiment consisted of three groups: vehicle plus light, MK-801 alone, and MK-801 plus light. Vehicle plus light led to an increase in Fos-LI compared to vehicle treated controls. MK-801 alone had no obvious effect on Fos-IR. Treatment with MK-801 reduced but did not completely block the light-induction of Fos-IR. Treatment with the optical isomer of MK-801 did not appear to have this effect. The results suggest that NMDA receptors mediate some of the effects of light on Fos-LI in the SCN.

COMPETITIVE NMDA RECEPTOR ANTAGONISTS INHIBIT PHOTIC INDUCTION OF FOS-LIKE PROTEIN IN THE SUPRACHIASMATIC NUCLEUS OF HAMSTERS. H. Abe¹, B. Rusak^{1,3}, and H.A. Robertson². Depts. of ¹Psychology and ²Pharmacology, Dalhousie Univ., Halifax, Nova Scotia, Canada, ³Dept. of Biomedical Sci., Faculty of Health Sci., McMaster Univ., Hamilton, Ontario, Canada.

At some circadian phases, retinal illumination induces expression of several immediate-early genes (including *c-fos*) in cells in the hamster suprachiasmatic nucleus (SCN), a dominant pacemaker in the circadian system. Systemic treatment with non-competitive antagonists affecting the NMDA subtype of excitatory amino acid receptor, MK-801 and ketamine, inhibits photic induction of Fos-like immunoreactivity (Fos-ir) in the hamster SCN (Abe, et al., 1991). Because these drugs block the Ca channel associated with the NMDA receptor, they may also influence the activity of other transmitters acting through Ca channels. To assess the specificity of these effects to the NMDA receptor, we used central injections of a competitive NMDA antagonist, CPP, and of an antagonist of the AMPA/kainate receptor subtype, DNQX, to attempt to block photic induction of Fos-ir in the hamster SCN. Fos-ir was produced in SCN cells of vehicle-injected hamsters by appropriately timed light pulses. Pretreatment with MK-801 (>3 mg/kg), ketamine (>100 mg/kg) or CPP (>1 mM), however, caused a dose-dependent inhibition of light-induced Fos-ir in portions of the SCN. These treatments blocked photic induction of Fos-ir in the rostral SCN and ventrolateral portions of the caudal SCN, but not in a discrete region of the dorsolateral SCN. Pretreatment with DNQX (up to 10 mM) had no effect on light-induced Fos-ir in the SCN. These results indicate that activation of an NMDA-type receptor is critical to the induction of *c-fos* expression in a portion of the SCN, and that blocking the AMPA/kainate receptor does not affect such expression in any region of the hamster SCN.

263.7

INTRACRANIAL NERVE GROWTH FACTOR INJECTIONS PHASE SHIFT ACTIVITY RHYTHMS IN SYRIAN HAMSTERS. K.G. Bina¹ and B. Rusak^{1,2}. ¹Dept. of Psychology, Dalhousie Univ., Halifax, Nova Scotia, and ²Dept. of Biomedical Sciences, McMaster Univ., Hamilton, Ontario, Canada.

The mammalian suprachiasmatic nucleus (SCN) functions as a pacemaker for the generation and photic entrainment of circadian rhythms. In rats, receptors for nerve growth factor (NGF) are found in a region of the SCN which receives photic input, suggesting a potential role for NGF in the circadian entrainment mechanism. We examined whether application of NGF to the SCN region could affect free-running, circadian activity rhythms in hamsters. Hamsters maintained in constant darkness were injected through indwelling cannulae directed at the SCN with either NGF (2µl) or vehicle at circadian times (CT) 6, 14 or 22. In general, NGF produced phase advances of the wheel-running activity rhythm at CT6 (32 ± 10.24 min (mean ± SEM); n=19) and CT22 (44.4 ± 15.2 min; n=21); however, a few animals with very short free-running periods showed phase delays at these times. At CT14, NGF produced small phase delays (17.1 ± 11.96 min; n=12) as well as changes in period which made assessment of shifts difficult. Saline vehicle administration did not produce similar phase shifts at these phases. NGF-induced shifts at these phases were similar to those elicited by the cholinergic agonist, carbachol, suggesting a possible influence of NGF on cholinergic neurons which project to the SCN. Supported by NSERC and MRC of Canada and the US AFOSR.

263.9

PHOTIC REGULATION OF THE PEPTIDES LOCATED IN THE VENTROLATERAL SCN OF RATS. K. Shinohara^{*}, K. Tominaga^{*}, Y. Isobe^{*} & S.T. Inouye. Lab. Integrative Brain Function, Mitsubishi Kasei Inst. Life Sci. Machida 194 Tokyo Japan. The ventrolateral (VL) SCN is characterized by chemically different neurons containing vasoactive intestinal polypeptide (VIP), gastrin releasing peptide (GRP) and neuropeptide-Y (NPY) and also by the terminal arborization of visual afferents. To elucidate the proper function to the VL SCN (photic entrainment), we measured VIP-, GRP- and NPY-like immunoreactivity (LI) in the rat SCN under various lighting conditions.

SCNs were punched out from 1mm section of the brain in a diameter of 400 µm. The tissues were homogenized in acetic acid and lyophilized. Peptides levels of the samples were assayed by enzyme immunoassay.

The present study demonstrates that VIP- and GRP-LI, which are synthesized in the VL SCN, does not show circadian rhythms under constant dark (DD) conditions. Under light dark (LD) conditions, GRP-LI and VIP-LI display a steady rise and fall during light period, respectively and then they gradually recover throughout night. NPY, which is transported from intergeniculate leaflet of lateral geniculate body, shows a circadian rhythm with a peak at CT 12. Apparent circadian rhythms of NPY-LI observed under DD conditions are modulated by light exposure. NPY-LI display a bimodal rhythm with peaks at both the dark-light and light-dark transition periods under LD conditions. Therefore, VIP, GRP and NPY distributed in the VL SCN may be involved in the process of photic entrainment because levels of them are regulated by photic stimulation.

263.6

DNQX AND CPP PREVENT LIGHT-INDUCED PHASE SHIFTS OF THE CIRCADIAN SYSTEM OF THE HAMSTER.

M. Menaker and C.S. Colwell. Biology, Univ. of VA, Charlottesville VA 22901.

We report here the results of experiments designed to evaluate whether the whether the intraventricular administration of EAA receptor antagonists prevent light-induced phase shifts of the circadian rhythm of wheel-running activity in the hamster. Administration of the non-NMDA antagonist 6,7-dinitro-quinoxaline-2,3-dione (DNQX) blocked light-induced phase advances and delays. Similarly, administration of the NMDA receptor antagonist, 3(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) prevented light-induced phase advances. Neither drug, by itself, caused any consistent effect on the phase of the rhythm. These data provide further evidence that EAA receptors mediate the effects of light on the circadian system of the hamster and suggest that both NMDA and non-NMDA receptor types may be involved.

RESPONSE OF HAMSTER SUPRACHIASMATIC NEURONS TO NICOTINIC STIMULI IN VITRO. L.R. Waldman^{*} and C.A. Fuller. University of California, Department of Animal Physiology, Davis, CA 95616-8519.

This study examined the nicotinic cholinergic sensitivity of neurons recorded *in vitro* from the suprachiasmatic nucleus (SCN) of the hamster. Three hundred fifty micron slices were cut and incubated in artificial cerebrospinal fluid. Action potentials recorded were 200 to 800 µvolts in amplitude with durations of 2 to 5 msec. The mean baseline firing rate was 2.0 ± 1.5 Hz.; range, 0.2 to 6.8 Hz. Seventy five cells were given nicotine (30 µmol). Fifty three (71%) showed significant changes in firing rate while 22 (29%) did not. Of those that responded to nicotine, 33 (44%) increased their firing rate while 20 (27%) decreased. The mean absolute value of the change of the responsive group was high (t=7.118, p<0.0001) as compared to the nonresponsive population (t=0.883, n.s.). Eighteen cells recovered from the nicotine and were given mecamylamine (100 µmol) with nicotine (30 µmol). Mecamylamine was effective in blocking the response to nicotine in 15 of the 18 cases. Six showed no significant change in firing rate (t=0.844, n.s.) while 9 responded with changes opposite to those from nicotine (t=6.906, p<0.001). In 3 cases, mecamylamine was not able to block the response to nicotine (t=2.855, p<0.05). Supported in part by the Smokeless Tobacco Research Council Grant #0167.

ELECTRICAL HETEROGENEITY OF SUPRACHIASMATIC NUCLEUS (SCN) NEURONS THAT RECEIVE OPTIC NERVE INPUT. Y.I. Kim and F.E. Dudek. Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

The electrical activity of SCN neurons receiving retinal input is likely to be important in the phase-shifting and entrainment of various circadian rhythms in mammals. To test the hypothesis that the intrinsic electrical properties of SCN neurons are homogeneous, we obtained intracellular recordings (n=30) in parasagittal hypothalamic slice preparations from adult male rats. The action potentials (57 ± 1 mV; measured from threshold) of SCN neurons were very similar in shape; they were short in duration (0.83 ± 0.03 ms; at half amplitude) and followed by pronounced hyperpolarizing afterpotentials (10-25 mV). In most of the neurons, an afterhyperpolarization followed a burst of action potentials evoked by a depolarizing current pulse. However, some intrinsic properties were only observed in a subpopulation of the neurons; low-threshold spikes (LTS) (Llínas & Yarom, J. Physiol., 315:549, 1981) were evident in about 50% of the neurons, and inward rectification was present in 60% of the neurons. Those neurons with inward rectification had a higher spontaneous firing rate than neurons with no rectification or with outward rectification [12.2 ± 2.0 Hz (n=16) vs. 4.2 ± 1.6 Hz (n=11), p<0.01]. In addition, neurons with inward rectification were more excitable; i.e., the slope of the frequency-current (F-I) plot was steeper [418 ± 65 Hz/nA (n=15) vs. 222 ± 33 Hz/nA (n=10), p<0.05]. Neurons with LTS potentials were not significantly different from neurons without LTS potentials in spontaneous firing rate and excitability.

These results suggest that 1) SCN neurons receiving retinal input are not electrically homogeneous, and 2) heterogeneity in certain intrinsic properties is associated with the difference in spontaneous firing rate and/or excitability. Supported by U.S. Air Force Grants 90-0056 to F.E.D.

SIBERIAN HAMSTERS WITH SUPRACHIASMATIC LESIONS EXPRESS TORPOR IN RESPONSE TO FOOD RESTRICTION.N.F. Ruby, Dept. of Psychology, University of California, Berkeley, CA 94720.

The role of the suprachiasmatic nucleus (SCN) in mediating torpor induced by restricted feeding was studied in adult Siberian hamsters housed in a short photoperiod (8 h light/day, ambient temperature = 15°C). Body temperature (T_b) and activity were recorded at 10 min intervals beginning 8 weeks after initial short day exposure. Animals manifesting ≥ 4 torpor bouts ($T_b < 30^\circ\text{C}$) in a 14 day interval received lesions of the SCN (SCNx) or a sham-operation. Expression of torpor was eliminated in 8/11 SCNx animals and unchanged in sham-operated hamsters. Torpor was reestablished in all SCNx hamsters by limiting daily food intake to 75% of normal for 3-7 days. These torpor bouts were temporally random, occurring at all times of day for several weeks even after resumption of *ad libitum* feeding; several animals repeatedly expressed multiple bouts of torpor in a single 24 hour period. Circadian rhythms in T_b and activity were undetectable in 73% and 100% of SCNx hamsters, respectively, as determined by cosinor analysis.

These findings implicate the SCN in timing of torpor bouts. Ablation of the SCN may inhibit torpor by altering hormone secretion, and restricting food intake may reinstate torpor in SCNx hamsters by reversing these hormonal changes.

THE HUMAN SUPRACHIASMATIC NUCLEUS (SCN); DIFFERENCES IN RELATION TO SEXUAL ORIENTATION AND SEASON. D.F.Swaab* and M.A. Hofman*, Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands.

Morphometric analysis of SCN in the human hypothalamus revealed differences between hetero- and homosexual men and seasonal variations in the reference group. The volume of the SCN in homosexual men was 1.7 times as large as that of a reference group of male subjects and contained 2.1 times as many cells. In another hypothalamic nucleus which is isolated in the immediate vicinity of the SCN, the sexually dimorphic nucleus (SDN), no such differences in either volume or cell number were found, indicating the selectivity of this finding (1). The volume and cell number of the SCN appeared also to fluctuate significantly over the year, with the lowest values during the summer and the highest values during the autumn. Again, no such fluctuations were observed in the SDN. Material was obtained from the Netherlands Brain Bank (Coordinator Dr. R. Ravid). (1)/D.F. Swaab and M.A. Hofman, Brain Research 537 (1990) 141-148.

THE RAT RETINOHYPOTHALAMIC PATHWAY REVEALED BY Dil INJECTIONS. D. M. Murakami, I-H. Tang* and C. A. Fuller. Department of Animal Physiology, University of California, Davis, California 95616-8519.

The mammalian retinohypothalamic pathway is critical for mediating the phase-shifting and entrainment effects of light on circadian rhythms. However, little is known about the characteristics of this retinal input. This study examines the general anatomy of the retinal terminal projections to the hypothalamus. Wistar rats were sacrificed and perfused with 10% formalin. The brains were removed and Dil crystals were placed in either the optic nerve or optic chiasm. The brains were kept in 10% formalin for approximately 3 months for transport. Each brain was coronally sectioned at 100 microns on a vibratome and examined for fluorescence. Individual axons and axonal arbors could be distinguished as they projected dorsal from the optic chiasm to the suprachiasmatic nucleus (SCN). Terminals were relatively dense in the ventral SCN, while sparse terminals were found in other areas of the SCN. In addition, retinal axons extended outside the SCN, including the region ventral to the paraventricular nucleus. This research was supported in part by NASA Grant NAGW-2195.

RETINOHYPOTHALAMIC PROJECTIONS IN THE MACAQUE MONKEY. J.C. Speh and R.Y. Moore. Depts. of Psychiatry, Neurology and Behavioral Neuroscience and the Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Recent studies of retinohypothalamic projections in the rat and hamster (Johnson et al, 1988) using cholera toxin-horseradish peroxidase (CT-HRP) have demonstrated extensive projections to the suprachiasmatic nucleus (SCN), anterior hypothalamic area (AHA), lateral hypothalamic area (LHA) and retrochiasmatic area (RCA) with the projection much more extensive in the hamster than in the rat. In the present study the organization of retinohypothalamic projections was analyzed in the macaque monkey using the CT-HRP method. The projection to the SCN is the densest of all projections to hypothalamus. It is particularly dense in the ventral portion of the nucleus in a zone occupied by vasoactive intestinal polypeptide-containing neurons. Labeled fibers are about twice as dense on the side ipsilateral to the eye injection, a pattern differing from rodents where the contralateral projection is most dense. Labeled fibers extend beyond the SCN into the adjacent AHA where they form a sparse plexus. There is also a limited input to the LHA. Labeled fibers extend caudally beyond the SCN into the retrochiasmatic area where they form a dense plexus. This is a restricted pattern of hypothalamic projections similar to that observed in the rat. The pattern of projections to the perigeniculate region (ventral lateral geniculate, intergeniculate leaflet) also will be described. (Supported by a grant from AFOSR).

AN ULTRASTRUCTURAL STUDY OF THE RETINOCORTICAL AND RETINOHYPOTHALAMIC TRACTS OF THE SYRIAN HAMSTER. A.S. Elliott, M.L. Weiss and A.A. Nunez. Dept. of Psych., Neuroscience Program, Michigan State University, East Lansing, MI 48824.

It has been reported that a direct retinal projection exists to the pyriform cortex (PYR; *J. Comp. Neurol.* 1981, 196:155-172; *Brain Res. Bull.* 1991, 26:403-411). The primary aim of this study was to determine if these retinofugal fibers made synaptic contacts with the neurons in that region. Bilateral, intraocular injections of cholera toxin-horseradish peroxidase conjugate were made into Syrian hamsters (*Mesocricetus auratus*), and the animals were allowed to survive for 48 hours. The tissue was then processed for visualization with tetramethylbenzidine (TMB), and the TMB was subsequently stabilized with diaminobenzidine. This procedure allowed both light microscopic and ultrastructural analysis of the labeled fibers. At the light-microscope level, labeled fibers were seen in the superficial layer of the PYR as well as in the suprachiasmatic nuclei (SCN) and other hypothalamic and basal forebrain regions. Ultrastructurally, fibers appeared to make *en passant* synaptic contacts with dendrites in area Ia of the PYR, where no neuronal cell bodies were seen. Post-synaptic densities and vesicles were clearly visible. However, the labeling was too dense to determine the shape of the vesicles. The number of labeled fibers was sparse when compared to the labeling in the SCN, which had numerous fibers containing label that made axo-somatic contacts as well as axo-dendritic. The presence of retinal projections to the PYR may provide a possible mechanism for photoperiodic modulation of chemosensory inputs to the hamster brain. Supported by grants BNS8908576 and BNS8919898 from the NSF, NS 07279 and by Biomedical Research Funds from M.S.U.

SUPRACHIASMATIC NUCLEUS (SCN) GLUCOSE UTILIZATION IN LATE DAY IS NORMALIZED BY SEROTONIN OR cAMP. F. E. Hospod, H. Qi, A. DeMontagnac, K. Grundmann and G. C. Newman. Neurology Service, VAMC at Northport, NY, 11768 and Dept. of Neurology, SUNY at Stony Brook, 11777.

Brain slice glucose utilization (SGU) parallels *in vivo* SCN glucose utilization at every time of day except late subjective day when slice glucose utilization is considerably above that found *in vivo*. We have proposed that this occurs because an inhibitory pathway is removed upon slice isolation. Based on the work of others, we have hypothesized that serotonin (5HT) will inhibit SCN SGU in late subjective day through mechanisms involving cAMP. To test this hypothesis we have measured SGU in the SCN and anterior hypothalamic area (AHA) in early day, late day and at night with 5HT or cAMP analogues.

Brain slices containing the SCN were prepared from male Sprague-Dawley rats (300g) entrained to a 12:12 light:dark cycle (Lights on CT00-CT12). SCN slices were pre-incubated for 75 min, exposed to K-R containing ^{14}C -2DG for 45 min, rinsed for 10 min and frozen. The 2DG incubation midpoints occurred during early day (CT03), late day (CT09) or nighttime (CT21). Cryostat sections were image-analyzed to obtain SGU in $\mu\text{mole}/100\text{g}/\text{min}$ (U).

Serotonin reduces SCN SGU at CT09 from 185 ± 20 U to 94 ± 7 U ($p < .002$). Similarly, cAMP reduces SCN SGU at CT09 to 109 ± 42 U, while forskolin, methylxanthine and the combination reduce SGU at CT09 to a slightly lesser extent. Neither 5HT nor cAMP had any effect on SGU at CT03 or CT21. AHA SGU at CT09 was not affected by 5HT.

These results are consistent with the hypotheses that 1) serotonin inhibits SCN neural activity in late subjective day through a mechanism involving cAMP and 2) the high SCN SGU of late day does reflect loss of an inhibitory pathway, probably from the dorsal raphe, during slice isolation.

TEMPORAL CHANGES IN PROTEIN KINASE A SUBSTRATES IN THE RAT SUPRACHIASMATIC NUCLEUS. L. Faiman and M.U. Gillette. Dept. of Cell and Structural Biology, Univ. of Illinois, Urbana IL 61801

Specific stimulation of cAMP-dependent pathways induces a 4-5 hr advance in the phase of the circadian rhythm of neural activity of the suprachiasmatic nucleus (SCN) *in slice*. Sensitivity is limited to the subjective day of the SCN circadian pacemaker. Additionally, endogenous cAMP levels change *in slice*, peaking late in the day. These results suggest that stimulation of protein kinase A (PKA)-mediated phosphorylation and the level and regulation of PKA itself may be important to the mechanisms underlying time-keeping and phase-shifting.

To address this hypothesis, changes in PKA substrates in SCN maintained *in slice* were examined at hourly intervals. Punches obtained from SCN *in slice* were examined for protein phosphorylation in the presence of exogenous cAMP and EGTA. The resulting phosphorylated proteins of a single punch (~6 μg protein) per circadian time were separated by SDS-PAGE. The identity of these proteins is being established by a) their apparent M.W. and b) by Western blots. Of special interest are the levels of synthesis and phosphorylation of the regulatory and catalytic subunits of PKA across the circadian cycle. (Supported by PHS grant NS22155.)

TEMPORAL CHANGES IN PROTEIN KINASE G SUBSTRATES IN THE RAT SUPRACHIASMATIC NUCLEUS. E.T. Weber and M.U. Gillette. Dept. of Physiology and Biophysics, Dept. of Cell and Structural Biology, Univ. of Illinois, Urbana, IL 61801.

Endogenous cGMP levels in the suprachiasmatic nucleus (SCN) oscillate *in slice* with a circadian period, with a peak around the night-day transition. Additionally, the circadian rhythm of neuronal activity of the SCN *in slice* is subject to 4-5 hr phase advancement with subjective night-time treatment with cGMP analogs, possibly stimulating pathways primed and waiting for the endogenous rise in cGMP levels. This suggests that night-time phase-shifting may involve stimulation of protein kinase G (PKG)-mediated pathways.

Phosphorylation stimulated by exogenous $100\mu\text{M}$ cGMP in low Ca^{++} conditions was examined in lysates of SCN and hypothalamus (HT) micro-punches quick-frozen hourly over the course of a 24 hr cycle *in vitro*. Protein kinase A activity was inhibited with a specific peptide inhibitor. PKG-phosphorylated proteins were identified in single SCN and HT after SDS-PAGE. We are comparing PKG substrate phosphorylation over the course of the day to identify phase-dependent substrates which may underlie circadian rhythm modulation. (Supported by PHS Grant NS22155.)

SEROTONERGIC AGONISTS ADVANCE THE CIRCADIAN RHYTHM OF NEURONAL ACTIVITY IN RAT SCN IN VITRO. M. Medanic and M.U. Gillette. Dept. of Physiol. & Biophys. and Dept. of Cell & Struct. Biol., Univ. of Illinois, Urbana, IL 61801.

Serotonin (5-HT) directly affects the SCN pacemaker *in vitro*. Brief application of 5-HT to ventrolateral (VL) SCN during the subjective day phase-advances (ϕ_A) the time of peak neuronal activity with a maximal shift of 6.9 ± 0.1 hr at CT 7. 5-HT is ineffective at night. This temporal sensitivity matches that for cAMP analogs. To confirm the specificity of 5-HT-induced ϕ_A and to investigate the mechanism by which 5-HT acts on the SCN, the effects of two 5-HT₁ agonists, 5-CT and 8-OH DPAT, were tested.

Hypothalamic brain slices containing the paired SCN were obtained from male Long-Evans rats (8wks old, raised in 12L:12D) and maintained *in vitro*. The slices were treated with 10^{-6}M 5-CT at CT 9 ($n=3$) or 15 ($n=2$), or with 10^{-6}M 8-OH DPAT at CT 9 ($n=3$) on day 1, by a 30 μl drop to the VL-SCN for 5 minutes. The time-of-peak in the rhythm of neuronal activity was accessed the following day.

While treatment of the VL-SCN with 5-CT at CT 15 did not significantly alter the rhythm, exposure at CT 9 resulted in a 6.0 ± 0.1 ϕ_A of the time-of-peak. Similarly, administration of 8-OH DPAT at CT 9 induced a 6.9 ± 0.1 ϕ_A of the peak time. This confirms the specificity of the 5-HT-induced ϕ_A and lends support to the hypothesis that 5-HT may affect the SCN via a 5-HT₁ receptor-linked pathway. (Supported by AFORS grant 90-0205.)

QUANTITATION OF GLUTAMIC ACID DECARBOXYLASE (GAD) AND TYROSINE HYDROXYLASE (TH) IN SINGLE SUPRACHIASMATIC NUCLEI (SCN) ACROSS THE CIRCADIAN CYCLE. D. Richard*, L. Faiman & M.U. Gillette. Dept. of Cell & Struct. Biol., Univ. of Illinois, Urbana, IL 61801

To elucidate the organization of substrates underlying the circadian pacemaker, we are quantitating identifiable proteins in single SCN. The SCN are derived from hypothalamic slices of rat brain maintained in glucose/ NaHCO_3 -supplemented minimal salts, conditions under which the SCN continue the circadian rhythm of neuronal firing observed *in vivo*. At a desired timepoint and after a fixed incubation period, a slice is quick-frozen on dry ice and one SCN (~5 μg protein) punched out. Proteins are separated by SDS-PAGE and identified immunologically by Western blot.

Using this technique, we determined levels of GAD and TH, the biosynthetic enzymes for GABA and dopamine, respectively, throughout the circadian cycle. Since TH is a protein kinase A substrate, we titrated phosphorylatable sites by cAMP-stimulated *in vitro* phosphorylation in the same samples. The level of TH relative to the degree of PKA phosphorylation was compared directly to assess the endogenous TH phosphorylation state.

Levels of GAD and TH were studied to develop the parameters for quantifying other regulatory proteins and their phosphorylation states in single SCN over the circadian cycle.

264.10

THE CIRCADIAN CLOCK IN THE RAT SCN HAS PHASE-DEPENDENT SENSITIVITY TO PROTEIN KINASE INHIBITOR H7. C. Liu & M.U. Gillette. Neurosci. Program, Dept. of Cell & Struct. Biol., Univ. of Ill., Urbana, IL 61801

Both cAMP and cGMP induce a phase advance of the circadian rhythm of neuronal activity of the suprachiasmatic nucleus (SCN) *in vitro*. Sensitivity to cAMP and cGMP is limited to the subjective day and night, respectively. To further elucidate the mechanisms by which these cyclic nucleotides affect the SCN clock, the effect of a nonspecific protein kinase inhibitor, H7, at different circadian times (CT) was examined.

Coronal hypothalamic slices containing the SCN were prepared from 8 wk old female Long Evans rats housed in a 12L:12D cycle. The media in the brain slice chamber was replaced with fresh media containing the H7 for 1 hr at different CTs. All measurements of phase were made on day 2 by monitoring firing rates and determining the time-of-peak of neuronal activity in SCN *in vitro*.

Incubation in H7 at CT 6-7 or 18-19 phase advanced the circadian rhythm. The time-of-peak was advanced by 5-6 hr at $100\mu\text{M}$ and 2 hr at $10\mu\text{M}$. Incubation in $100\mu\text{M}$ H7 at CT 11.5-12.5 had no effect. These results show that the circadian clock has phase-dependent sensitivity to inhibition of activity of protein kinases. We are using relatively specific protein kinase inhibitors to test the possibility that the effect of the H7 during day and night is mediated by different kinases, possibly cGMP and cAMP kinases, respectively. (Supported by NS 22155.)

264.11

CHARACTERIZATION OF REGIONAL NEURONAL ACTIVITY IN THE SUPRACHIASMATIC NUCLEUS USING A CURVE-FITTING TECHNIQUE T.K. Tchong and M.U. Gillette. Neuroscience Program and Department of Cell & Structural Biology, University of Illinois, Urbana, IL 61801.

The rat suprachiasmatic nuclei (SCN) contain an endogenous circadian pacemaker that is expressed in the brain slice as a 24 hr oscillation in ensemble neuronal firing rate (ENFR). We are studying the anatomical distribution of the pacemaker within the SCN by analyzing the ENFR in isolated dorsomedial (DM) and ventrolateral (VL) subregions.

We have previously demonstrated empirical changes in the ENFR of the DM-SCN after surgical isolation. Our current work quantifies these changes and characterizes neuronal activity in the isolated regions. Single unit activities were recorded over >24 hr to examine the circadian pattern of ENFR for each region. A parameterized curve was constructed that describes the 24 hr ENFR of control SCN in an intact slice. Goodness-of-fit for ENFRs from isolated DM- and VL-SCN were calculated after fitting the curve to 24 hr data from control SCN. Significant differences ($p < 0.05$) were found between controls ($N=4$) and isolated DM-SCN ($N=2$) but not isolated VL-SCN ($N=3$). Spectral analysis will be performed on control and experimental data to identify the major periodicities expressed by each group. (Supported by AFOSR grant 90-0205.)

TETRODOTOXIN DOES NOT BLOCK IN VITRO RESETTING OF THE SUPRACHIASMATIC CIRCADIAN PACEMAKER BY QUIPAZINE. J.D. Miller, R.A. Prosser, and H.C. Heller*. Dept. of Biological Sciences, Stanford University, Stanford CA 94305.

The mammalian suprachiasmatic nuclei (SCN) contain a circadian pacemaker that produces a 24 hr rhythm in spontaneous neuronal activity *in vitro*. Previous work shows that this *in vitro* rhythm can be permanently reset by 1 hr applications of the non-specific serotonin (5-HT) agonist Quipazine (Quip; *Brain Res.* 534:336). To begin addressing the issue of whether Quip acts directly on pacemaker cells or on afferents to the clock, we investigated whether blocking Na^+ -dependent action potentials with tetrodotoxin (TTX) prevents Quip-induced phase shifts of the SCN clock.

Brain slices prepared during lights-on from adult male Wistar rats housed in 12:12 LD were maintained *in vitro* under constant perfusion conditions. Slices were treated for 1 hr with TTX (1 μM) alone or TTX + Quip (1 μM) at either CT 6 or 15 during the first day *in vitro*. Neuronal activity was recorded on day 2. TTX treatment by itself at either CT did not affect the phase of the SCN clock. TTX also did not block Quip-induced advances at CT 6 ($X=2.5 \pm 0.6$ hr; $N=2$) or delays at CT 15 ($X=2.5 \pm 0.0$ hr; $N=2$). Therefore, Na^+ -dependent action potentials do not appear to be required for Quip to reset the SCN clock. These results suggest that 5-HT receptors are located on SCN pacemaker cells or on cells that communicate with pacemaker cells by means other than Na^+ -dependent action potentials. (Supported by NIH postdoctoral fellowship NS 08905 and The Upjohn Company)

EFFECT OF NICOTINE AND CARBACHOL ON THE CIRCADIAN RHYTHM OF THE SUPRACHIASMATIC NUCLEI IN VITRO. L. Trachsel*, H.C. Heller*, W.C. Dement, and J.D. Miller. Dept. of Biol. Sciences, Stanford University, Stanford, CA 94305-5020.

Cholinergic drugs have been reported to phase-shift circadian rhythms *in vivo*. However, cholinergic mechanisms in the suprachiasmatic nuclei (SCN) proper have remained unclear. We thus investigated effects of cholinergic compounds on the SCN *in vitro*. SCN brain slices were prepared from adult male Wistar rats housed in 12:12 LD. At a designated circadian time (CT), the slice perfusion medium was replaced for 1 hr with medium supplemented with carbachol (10 μM), or nicotine (10 μM). To determine whether the treatment shifted the SCN clock, the CT of peak neuronal activity in the SCN monitored on day 2 *in vitro* was compared to the control CT 6 (CT 0: lights-on). Nicotine phase-advances the SCN clock: +2.5-3 hrs at CT 9, 12, 15, 21; +1-1.5 hrs at CT 6 and 18. Carbachol had no effect at CT 15 (-1 and +1 hr). The results suggest that nicotine generally accelerates the SCN clock. Nicotine may act on a binding site in or near the SCN that is dissimilar from the classical cholinergic receptor. (Supported by The Upjohn Co. & the Swiss National Foundation.)

264.12

IN VITRO RESETTING OF THE SUPRACHIASMATIC CIRCADIAN PACEMAKER BY SPECIFIC SEROTONERGIC AGONISTS AND ANTAGONISTS. R.A. Prosser, J.D. Miller, and H.C. Heller*. Dept. Biological Sciences, Stanford University, Stanford CA 94305.

The mammalian circadian clock in the suprachiasmatic nuclei (SCN) produces a 24 hr rhythm of spontaneous neuronal activity *in vitro*. We have used the SCN slice to investigate the ability of specific serotonergic (5-HTergic) compounds to reset the SCN circadian clock. In these experiments slices prepared from adult male Wistar rats were maintained *in vitro* under constant perfusion conditions.

We previously found that 1 hr bath application of the nonspecific 5-HT agonist Quipazine (Quip) shifts the SCN clock *in vitro*, inducing phase advances in the day (circadian time (CT) 6 & 9) and phase delays at night (CT 15, 18 & 21) (*Brain Res.* 534:336). These effects are mimicked by 5-HT and blocked by the non-specific 5-HT antagonist metergoline. Here we find that the advances induced at CT 6 are also mimicked by the 5-HT_{1A} agonists 8-OH-DPAT and Buspirone, but not by the 5-HT_{1B} agonist CGS 12066B or the 5-HT_{1C/2} agonist DOB. Also Quip-induced advances were blocked by the 5-HT_{1A} antagonist NAN-190 but not by the 5-HT_{1B} antagonist ICS 205-930. None of the specific 5-HT agonists mimicked the delays induced by Quip at CT 15; neither did the specific antagonists block Quip-induced delays. These results suggest that Quip resets the SCN during the day by stimulating 5-HT_{1A} receptors but acts on undetermined 5-HT receptor type(s) at night to reset the clock. (Supported by NIH postdoctoral fellowship NS 08905 and The Upjohn Co.)

EFFECTS OF CHOLINERGIC AGENTS ON CELLULAR METABOLISM IN CULTURED SUPRACHIASMATIC NUCLEUS. V. Cao*, J. Owicki*, D. Edgar and J.D. Miller. Depts. of Psychiatry, Biology, Stanford Univ., Stanford, CA 94305, and Molecular Devices Corp., Menlo Park, CA 94025.

The suprachiasmatic nucleus (SCN) of the hypothalamus is necessary and sufficient for circadian rhythmicity in mammals. Cholinergic stimulation *in vivo* generates phase shifts in such rhythms, perhaps via a nicotinic receptor. However, high affinity nicotine binding has not been observed in the SCN. We examined the effects of cholinergic agents on cellular metabolism, as measured in a microphysiometer, in cultured SCN cells from two day old Sprague-Dawley rats. The rate of extracellular acidification, following a one min pause in perfusion, was the index of cellular metabolism. Eight cultures underwent a 20 min baseline recording period, followed by three 10 min exposures to either 10 μM carbachol or 10 μM nicotine, in counterbalanced order, with 20 min recovery periods between each drug exposure. Subsequently each culture was exposed to an additional three trials of the other drug. An additional four cultures were exposed to six trials of 5 μM nicotine plus the nicotinic antagonist, mecamylamine (5 μM). Immunohistochemical validation of the cultures was provided by antibodies against VIP, GFAP and MAP2. Carbachol produced no alteration in cellular metabolism whereas nicotine induced a reliable and significant decrease in metabolism compared to baseline (-12.5 \pm 2%). Mecamylamine did not significantly affect the nicotine-induced decrement in cellular metabolism. These results suggest that nicotine's effects in the SCN are probably not mediated by a classical cholinergic receptor.

IN VIVO EVIDENCE FOR A DIURNAL RHYTHM IN SCN SEROTONERGIC ACTIVITY, IN THE SIBERIAN HAMSTER. S.A. Ferreira, W.W. Randolph and J.D. Glass. Dept. Biological Sciences, Kent State University, Kent, OH 44242.

In vivo microdialysis was used to characterize the daily pattern of serotonergic (5-HT) activity in the SCN and to explore the relationship between interstitial 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) in the male Syrian hamster. Freely-behaving animals with a dialysis probe in or near the SCN exhibited an apparent circadian rhythm in 5-HIAA release, with the peak (147 \pm 5% of the daily mean) occurring 2-3 h after lights-off. A direct relationship between 5-HIAA and 5-HT was shown through increased dialysate 5-HIAA (27 \pm 6% of baseline; $p < 0.05$) in response to localized application of 5-HT (3 μM). Tryptophan loading (25 mg/kg i.p.) increased 5-HIAA in SCN dialysates by 42 \pm 6% ($p < 0.05$), and perfusion with high $[\text{K}^+]$ (150 mM) or veratridine (100 μM) decreased 5-HIAA by 62 \pm 5 and 49 \pm 11%, respectively (both $p < 0.05$). The effect of K^+ was not blocked in the presence of Ca^{2+} channel blockers. Localized application of tetrodotoxin (5 μM) significantly decreased 5-HIAA in the dark phase, but had little effect in the light phase (42 \pm 8% vs. 8 \pm 4% suppression, respectively; $p < 0.05$). These results are evidence that synaptic release of 5-HT in the SCN is increased at night and is reflected by a rise in interstitial concentrations of 5-HIAA. (Supported by AFOSR 440785 (J.D.G.).)

NAAG in the Retinohypothalamic Projection System: Metabolism and High Affinity Binding. M. A. Aryan Nambodiri, H. M. Valivullah and John R. Moffett. Molecular Neurobiology Laboratory, Department of Biology, Georgetown University, Washington, DC 20057.

We have recently reported immunohistochemical data indicating that N-acetylaspartylglutamate (NAAG) may act as a transmitter in the retinohypothalamic tract (RHT) in the rat (PNAS 87, 8065-8069, 1990). In the present study, we have investigated uptake, metabolism and high affinity binding of NAAG using hypothalamic preparations containing all the RHT projection areas.

To study uptake and metabolism of NAAG, ³H-glutamate labeled NAAG (50nM, 52Ci/mmol) was incubated with hypothalamic slices in artificial cerebrospinal fluid equilibrated with 95%O₂/5%CO₂ for different duration at 37°C. ³H-NAAG was found to be taken up rapidly, with gradual increase up to 120 min. HPLC analysis (Partisil SAX column, 0.2M potassium phosphate, pH 4.9) of the radioactivity in the tissue showed that about 75% of the ³H-NAAG has been converted to ³H-glutamate at 30 min incubation. To study high affinity binding of NAAG, a hypothalamic membrane preparation (200 ug protein) was incubated (23°C, 5 min and 30 min) with ³H-NAAG (50nM, 52Ci/mmol) in Tris HCl buffer (50 mM, pH 7.4) in a total volume of 100ul, and the bound radioactivity was separated from free by membrane filtration. Nonspecific binding was determined using 50uM nonlabeled NAAG and identity of the bound radioactivity was determined by HPLC analysis. Significant specific binding was detected at both the early (5 min) and late (30 min) incubation times. However, HPLC analysis showed that almost all the bound radioactivity was associated with glutamate at both times. The extraordinarily rapid conversion of NAAG to glutamate in the hypothalamic preparation combined with the high affinity binding of NAAG being exclusively through glutamate suggest that NAAG may act in the RHT system via glutamate by a mechanism that is likely to be specific to NAAG. VIP AND ANGIOTENSIN II BINDING IN RODENT SCN: CIRCADIAN AND DEVELOPMENTAL STUDIES. M. Li and J.L. Fuchs. Dept. Biological Sciences, University of North Texas, Denton TX 76203

VIP and angiotensin II (Ang II) binding are present in high levels in the suprachiasmatic nucleus (SCN) relative to adjacent hypothalamus. Diurnal variation has been reported in the rat SCN for VIP mRNA and for VIP immunoreactivity. In this study, we tested for the presence of diurnal differences in VIP and Ang II receptor levels in 12-17 adult hooded rats at each of two times, mid-L and mid-D (LD 12:12). SCN sections were incubated in [¹²⁵I]-VIP or [¹²⁵I]-Sar¹-Ile⁶-angiotensin II. Autoradiographs revealed no diurnal differences in ratios of binding levels in SCN vs. adjacent hypothalamus. In addition, neither VIP nor Ang II showed evident changes in hamster SCN examined at 3 time points (5-6 animals per group). The results do not support the hypothesis that circadian regulation of these SCN receptors is critical for the generation of rhythmicity.

Rat and hamster SCN had similar levels of VIP binding, with patterns resembling cell distributions in Nissl sections. However, these species showed marked differences in Ang II binding: in rat, label was dense, particularly in ventral SCN except in caudalmost regions, whereas in hamster, levels were considerably lower and did not delineate the SCN.

Developmental studies used 1-3 rats at each age: VIP: E18, E19, P0, P10; Ang II: E16, E17, E18, E20, P1. VIP binding matured early, reaching nearly adult levels in the SCN by E18. In contrast, Ang II levels were very low prenatally and rose substantially from P1 to adulthood. The early appearance of VIP binding suggests that it could be involved in fetal entrainment, while the later development of SCN Ang II binding suggests that this neuropeptide may play a role in postnatal ontogeny of circadian characteristics. ENTRAINMENT OF RAT ACTIVITY RHYTHMS BY MELATONIN DOES NOT DEPEND ON WHEEL-RUNNING ACTIVITY J.R. Redman and C.M. Roberts*, Dept. Psychology, Monash University, Clayton, Vic. 3168, Australia

Daily injections of melatonin (MT) entrain rat activity rhythms free-running in constant dark when the time of MT administration coincides with the time of activity onset (Redman et al. 1983). This circadian phase (activity onset) is also the phase at which hamsters respond to social zeitgebers and it was suggested that the effects of MT on the circadian system may be mediated by some modification of general arousal mechanisms (Mrosovsky 1988). To determine whether entrainment by MT is mediated by alterations in activity levels, we examined the effects of daily injections of MT when wheel-running was prevented. Twenty nine male rats were held in very dim constant light (<0.1Lux) until rhythms in running-wheel activity were established. Rats were injected daily with MT (n=18; 100ug/Kg/2ml 1% ethanolic-saline vehicle) or with vehicle (V) (n=11). On day 37 of the injection regime the running-wheels of 10 MT-injected and 5 V-injected rats were blocked to prevent wheel rotation while still allowing access. Injections were continued for a further 29 days, then wheels were unblocked and wheel-running activity was again monitored. The phase of the rhythm when wheel-running resumed indicated that entrainment to MT persisted even when running-wheel activity was prevented. Further investigations will look at the effects of MT injections on general activity and body temperature.

265.3

NON-PHOTIC ENTRAINMENT IN SUPRACHIASMATIC NUCLEI ABLATED HAMSTERS. Ralph Mistlberger, Psychology, Simon Fraser University, Burnaby, BC Canada.

This study examined the role of the SCN in non-photically entrainment in the hamster. SCN ablated hamsters were recorded in constant dark and under schedules of 2h daily cage changes, restricted food availability and/or light-dark. Some hamster with very large lesions subsuming SCN and local areas exhibited significant but unstable circadian rhythms in DD. Some with similar lesions showed entrained rhythms to daily cage changes. All hamsters showed robust rhythms entrained to a daily feeding schedule, but no hamster entrained to LD cycles. Competent circadian oscillators evidently exist outside of the SCN, at least .5mm or more away, and at least some are non-photically entrainable. Weaker entrainment in animals with larger lesions suggests that non-photically entrainable oscillators also exist within the SCN or its immediate vicinity.

265.2

EFFECT OF LIGHT INTENSITY AND MELATONIN (MEL) ON THE RATE OF REENTRAINMENT OF LOCOMOTOR ACTIVITY IN THE C3H/HeN AND C57BL/6J MOUSE AFTER A PHASE ADVANCE IN THE L/D CYCLE.

J. M. Fang and M.L. Dubocovich, Dept. Pharmacol., Northwestern Univ. Medical School, Chicago, IL 60611.

Melatonin binding sites are found in the SCN of the C3H/HeN and C57BL/6J mice (Eur. J. Pharmacol. 180: 387, 1990). The C57BL/6J does not produce melatonin in the pineal gland, and has a lower threshold for entrainment by light (0.01 lux) than the C3H/HeN mouse (5-10 lux). Mice (4-5 weeks old) were kept on a 12/12 L/D cycle. When illumination during the light period was 45 lux the transitory period to reach reentrainment of activity rhythms after 8 h phase advance of the L/D cycle was significantly longer in the C3H/HeN [6.58 ± 0.36 days (12)] than in the C57BL/6J mouse [4.33 ± 0.31 days, (12), p < 0.05]. Daily injections (12 days) of melatonin (1 mg/kg, i.p.) at the pre-phase shift dark onset decreased the rate of reentrainment in the C3H/HeN mouse [10 ± 0.37 days (11), p < 0.001]. The effect of melatonin was less pronounced in the C57BL/6J mouse [5.25 ± 0.28 days, (12), p < 0.05]. The transitory period was significantly shorter in both the C3H/HeN [3.4 ± 0.4 days, (6)], and C57BL/6J [2.75 ± 0.48 days, (4)] mice, with illumination of 300 lux. Under these conditions melatonin (1 mg/kg, i.p.) significantly decreased the rate of reentrainment in the C3H/HeN mouse [5.38 ± 0.3 (6), p < 0.001]. In the C3H/HeN mouse melatonin and light intensity may partially influence the length of the transitory period.

265.4

THE EFFECTS OF EXOGENOUS MELATONIN OR PINEALECTOMY ON SEVERAL SIMULTANEOUSLY MONITORED CIRCADIAN RHYTHMS. C.W. Coen, M.C. Ruiz de Elvira*, R. Persaud*, R. Stoughton*, D. Suggs* & C. Demaine*. Division of Biomedical Sciences, King's College, London, UK.

Studies designed to test the possibility that melatonin acts as an internal Zeitgeber for circadian rhythms have been undertaken on Long-Evans rats. Four parameters have been monitored every 5 minutes under constant dim red light: wheel-running and drinking (by circuit closure), and core temperature and general locomotor activity (by radiotelemetry, Mini-Mitter Co.). The data were analyzed using Dataquest and Tau software. When daily injections of melatonin coincided with the onset of activity, each of the free-running rhythms was entrained in synchrony: doses of 500, 100 or 50 µg/kg were completely effective, but only 33% of the animals showed entrainment with 10µg/kg, and 17% with 5µg/kg (n=6-8). Each of the parameters remained synchronized during the loss of entrainment associated with the relatively low doses of melatonin. Furthermore, the free-running circadian rhythms failed to show any desynchronization when either pinealectomy (n = 8) or the appropriate sham procedure (n = 8) was carried out at the mid-point of a six-month monitoring period. Thus, although pharmacological doses of melatonin can entrain several rhythms (including that of core temperature which persists in the absence of a rhythm of locomotor activity and even following ablation of suprachiasmatic nuclei), it has not been possible to demonstrate a physiological role for the pineal in the synchronization of the circadian phenomena examined here.

265.5

MELATONIN INJECTION AFFECTS THE CIRCADIAN RHYTHM OF WHEEL RUNNING AND THE PROFILE OF SCN NEURONAL FIRING *IN VITRO* IN PHOTO-NONRESPONSIVE DJUNGARIAN HAMSTERS. B.R. Margraf, P. Zlomanczuk, A. Morissette, and G.R. Lynch. Department of Biology, Wesleyan University, Middletown, CT 06459.

The role of melatonin (MEL) feedback on circadian behavior and SCN function is poorly understood. In this study, we investigated the effects of daily MEL injections on phase angle of entrainment, duration of wheel-running activity, and frequency of SCN neuronal discharge in two phenotypes of the Djungarian hamster, *Phodopus sungorus*. These phenotypes, photo-responsive and photo-nonresponsive, differ in their photoinductive responses to short day (LD 9:15 lights on 0800 h) and in a variety of circadian parameters including phase angle of entrainment, duration of wheel-running activity, and timing of the nocturnal MEL pulse. Further, in this species, these behavioral differences correlate with the daily profile of SCN neuronal activity. Twenty photo-nonresponsive hamsters were identified following 12 weeks of short day exposure and were divided into MEL- and saline-injected groups. Animals from both groups were housed in cages equipped with running wheels, and activity was continuously measured. Following 12-14 weeks of injection (at 2000 h), coronal hypothalamic slices containing the SCN were prepared, and SCN electrical activity from both groups was measured *in vitro* for 24-36 hours (after Margraf et al., 1991, Brain Res 544, 42-48).

MEL-injections transformed formerly photo-nonresponders hamsters into photo-responsive hamsters in that they showed molt, body weight loss, gonadal regression and torpor. Mel-injected hamsters also exhibited an expansion in alpha and an entrainment to lights off, similar to responsive hamsters. Saline-injected animals remained in the nonresponsive state, as characterized by a compressed alpha and delayed activity onset. They did not experience molt, weight loss, gonadal regression or torpor. SCN neuronal activity recorded from MEL-injected animals strongly correlated with behavioral data. In all cases, SCN discharge frequency was high during periods of locomotor suppression. These results demonstrate that MEL induces photoresponsiveness in previously nonresponsive hamsters, that MEL modifies some circadian behaviors to resemble responders, and that MEL affects the daily firing profile of the SCN. Supported by NSF DCB 87-19120.

COMPARISON OF MATERNAL PINEALECTOMY AND MELATONIN-CLAMPS ON PRENATAL TRANSFER OF PHOTOPERIODIC INFORMATION. I.H. Horton, S.L. Ray, R.V. Dorman and M.H. Stetson. Dept. of Biological Sciences, Kent State Univ., Kent, OH 44242 (THH, RVD) and School of Life and Health Sciences, Univ. of Delaware, Newark, DE 19716 (SLR, MHS).

Maternal pinealectomy (PINX) and melatonin-clamps (MEL) alter photoperiodic information transferred from female Siberian hamsters to their fetuses. Female Siberian hamsters were PINX'ed or sham-operated (SHAM), allowed ten days to recover, then received two 7 mm pellets containing beeswax (CONT) or beeswax+melatonin (MEL, 0.13 mg MEL/pellet) and were paired with a male. Females were housed in 16L:8D until parturition when they and their litters were moved to constant light. Male young were sacrificed at 28 days of age to assess the effects of the maternal treatments. MEL altered the effects of PINX, indicating that the young received different prenatal photoperiodic information (ANOVA: Surg x Imp, df 1 / 58, F = 22.81, p < 0.001). Paired testicular weights of young born to SHAM-CONT dams are larger than those born to SHAM-MEL dams (252 mg vs 139 mg, p < 0.001); those of young born to PINX-CONT dams were significantly smaller than those born to PINX-MEL dams (109 mg vs 219 mg, p < 0.001). PINX and MEL alter the prenatal transfer of photoperiodic information through different mechanisms and not simply by obscuring of the day-night difference in serum melatonin levels. (Supported by NSF Grant DCB87-14638 to MHS.)

265.9

AUTORADIOGRAPHIC LOCALIZATION OF MELATONIN RECEPTORS IN RHESUS MONKEY HYPOTHALAMUS. I.H. Stehle, D.R. Weaver, and S.M. Reppert. Laboratory of Developmental Chronobiology, Children's Service, Massachusetts General Hospital, Boston, MA 02114.

Rhesus monkeys housed in a natural lighting environment limit reproductive activity to the fall and early winter. This photoperiodic regulation of reproduction appears to be mediated by the pineal hormone, melatonin (Wilson & Gordon, *J Reprod Fertil* 86:435-444, 1989). In the present work, we used 2 [¹²⁵I]-iodomelatonin (I-MEL, 2000 Ci/mmol, 30-40 pM) to examine the distribution of high-affinity melatonin receptors in the hypothalamus of an adult male rhesus monkey (*Macaca mulatta*). Specific I-MEL binding (defined as I-MEL binding displaced by 1 μM melatonin) was most concentrated in the hypophysial pars tuberalis (PT) and the suprachiasmatic nuclei (SCN). Specific binding was also apparent in low levels throughout the mediobasal hypothalamus. Melatonin potently inhibited I-MEL binding in the PT and SCN, with half-maximal inhibition at melatonin concentrations ca. 1 nM. The PT is the only site of high-affinity I-MEL binding in every photoperiodic species examined to date, and we have suggested that the PT is a prime site of melatonin action in regulating reproduction. The present results are consistent with this hypothesis. It is interesting to note that while I-MEL binding is present in the human SCN (Reppert et al., *Science*, 242:78-81, 1988), I-MEL binding is not readily detected in the human PT. This apparent difference in PT I-MEL binding correlates with the clear photoperiodic influence on reproduction in the rhesus vs. the subtle influence of season on human reproductive function.

MELATONIN DURATION CODES FOR DAYLENGTH IN MALE SYRIAN HAMSTERS. J.D. Karp and J.B. Powers. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

These experiments investigated the response of pinealectomized (PX) male Syrian hamsters to programmed administration of melatonin (MEL). Hamsters were castrated, given s.c. testosterone (T) implants and housed in 8L:16D. After 7 weeks, T was removed and the hamsters were either PX or sham operated. Daily s.c. MEL (250ng) or vehicle infusions began the night after pineal surgery. Infusion durations were long (11 or 12 hours) or short (6 hours) and ended 1 hour before lights-on each night. Measurement of serum luteinizing hormone (LH) after 3 weeks indicated that long duration MEL infusions maintained short photoperiodic conditions, (LH levels were low), but short duration MEL infusions did not (LH levels were elevated). In a second experiment, PX gonadally intact hamsters were housed in 12L:12D and injected s.c. with MEL or vehicle, once daily for 11 weeks. Injections were timed to coincide with a circadian phase reported to be maximally sensitive to the effects of MEL in 12L:12D. Injections 3 or 5 hours after dark did not induce gonadal regression; testes size and serum T levels between the MEL and vehicle treated groups were not different. These results support the hypothesis that the duration of MEL secretion each night is an important variable in conveying daylength information; the circadian phase of MEL availability appears to be less relevant.

265.8

AGE-RELATED DECREASES IN THE DENSITY OF SPECIFIC MELATONIN BINDING SITES IN THE HAMSTER SUPRACHIASMATIC NUCLEI (SCN) AND MEDIAN EMINENCE/PARS TUBERALIS (ME/PT). M.J. Duncan and F.C. Davis. Dept. of Anatomy & Neurobiol., Univ. of Missouri Med. School, Columbia, MO 65212; Dept. of Biology, Northeastern Univ., Boston, MA 02115

In Syrian hamsters, the circadian timing system is very sensitive to melatonin during gestation while the reproductive system is most responsive during adulthood. Specific binding of 2-[¹²⁵I]-iodomelatonin (IMEL; 115 pM) was prominent in the ME/PT at all ages but only in the SCN of fetuses and neonates (Duncan et al, Soc. Neurosci. Abst. 16:773, 1990). Quantitative saturation autoradiography examined if the age-related loss in specific IMEL binding in the SCN represents a change in the affinity (K_d , pM) and/or maximal density (B_{max} , fmoles/mg protein) and if a developmental change also occurs in the ME/PT. In the neonatal SCN, the specific IMEL sites showed $K_d=74.9\pm6.9$ and $B_{max}=0.637\pm0.019$. Very few sections of adult SCN showed specific IMEL binding (<0.35 fmol/mg protein). In the ME/PT, B_{max} decreased significantly (p<0.005) from 6.99±0.76 in neonates to 2.78±0.64 in adults but K_d did not change (neonates: 91.7±17.8; adults: 102.4±16.3). Thus, the density of specific IMEL binding sites in the SCN and the ME/PT decreases during development.

EFFECTS OF PINEALECTOMY ON DAILY PATTERN OF CEREBRAL 2(125I)IODOMELATONIN BINDING IN THE HOUSE SPARROW, *PASSER DOMESTICUS*. LU JUN and VINCENT M. CASSONE. Department of Biology, Texas A&M University, College Station, TX 77843

The pineal gland and its hormone melatonin are important for the generation of circadian rhythms in house sparrows. The application of *in vitro* binding of 2(125I)iodomelatonin (IMEL), and autoradiography have indicated binding is widely distributed in the visual, auditory and limbic systems. This binding is rhythmic: low during subject night and high during subject day. To test the hypothesis that the rhythm is generated via down-regulation by endogenous pineal melatonin rhythms, we have determined the effects of pinealectomy (PINX) on IMEL binding rhythms within the house sparrow brain. 24 house sparrows were maintained in L:D=12:12. 12 birds were pinealectomized and 12 birds received sham operation. After recovery, two pinealectomized and two sham birds were decapitated every four hours, brains were removed, frozen and thaw-mounted on gelatin-coated slides. Brains were sectioned at 20 μM from the rostral to caudal extents. Slides were incubated in 100 pM IMEL exposed to autoradiographic film for 7 days. Binding was measured densitometrically using a computer image analysis system. In sham birds, the binding clearly showed a daily change with maximum at ZT8 and minimum at ZT20. In PINX birds, however, the binding rhythm was not abolished. Its phase was same as that of sham birds. However, the amplitude of rhythm was elevated in all structures 6-20 fold. Characterization of IMEL binding indicated that B_{max} varied significantly but neither the K_i nor Hill coef. of binding were affected by day or PINX. The melatonin binding rhythm is not driven by endogenous melatonin. The source of this rhythmicity is currently under study. Supported by NSF GRANT 88-96225 and AFOSR 90-0244.

2-[¹²⁵I]-IODOMELATONIN BINDING SITES IN THE CHICK BRAIN: DECREASED BINDING IN VISUAL AREAS FOLLOWING UNILATERAL OPTIC NERVE TRANSECTION. D. Krause², J.A. Siuciak¹, and M. Dubocovich, Dept. of Pharmacology, ¹Northwestern University Medical School, Chicago, IL 60611 and ²University of California, Irvine, CA, 92717.

Previous autoradiographic studies have shown wide distribution of ML-1 melatonin receptors throughout the chicken brain, predominantly in areas associated with the visual system (Siuciak et al., J. Neurosci., 1991). The aim of this study was to examine 2-[¹²⁵I]-iodomelatonin binding in discrete visual areas of the chick brain following unilateral transection of the optic nerve.

Chicks were sacrificed 1 or 7 days post transection with all animals 3 weeks old at the time of sacrifice. Quantitative autoradiography was performed in coronal brain sections incubated with 75 pM 2-[¹²⁵I]-iodomelatonin in 150 mM Tris-HCl buffer for 1 h as previously described. Specific binding was defined with 3 uM melatonin.

One day after nerve transection, no significant changes in 2-[¹²⁵I]-iodomelatonin binding were observed. However, seven days following optic nerve transection, significant reductions in specific binding were found contralateral to the lesion in primary retinorecipient areas such as the optic tectum (46%) and the ventrolateral geniculate nucleus (40%). Significant unilateral reductions were also seen in second order sites receiving no direct retinal input, i.e., the N. rotundus (43%) which receives input from the tectum and the Edinger-Westphal nucleus (31%) which receives input from the suprachiasmatic region. The latter finding may reflect trans-synaptic degeneration in visual pathways. No changes in binding were found in the ventral supraoptic decussation (suprachiasmatic area) or in the N. triangularis.

265.13

OVERLAP OF N-ACETYLSPARTYLGLUTAMATE (NAAG)-LIKE IMMUNOREACTIVITY AND 2-[¹²⁵I]-IODOMELATONIN BINDING IN VISUAL AREAS OF THE TURTLE BRAIN. J.R. Moffett¹, J.A. Siuciak², L.J. Larson-Prior³, N.T. Slater³ and M.L. Dubocovich². ¹Dept. Biology, Georgetown Univ., Washington, D.C. 20057, and Dept. of ²Pharmacology and ³Physiology, Northwestern University Medical School, Chicago, IL 60611.

Previous reports suggest a role for both NAAG and melatonin in the visual areas of the vertebrate brain. The aim of this study was to examine the distribution of NAAG and melatonin in discrete brain regions in order to determine areas of overlap.

NAAG was detected immunohistochemically using an antiserum which recognizes carbodiimide-fixed NAAG as previously described (Moffett et al., 1989). 2-[¹²⁵I]-iodomelatonin binding sites were examined using *in vitro* autoradiography. Coronal brain sections were incubated with 75 pM 2-[¹²⁵I]-iodomelatonin in 150 mM Tris-HCl buffer (pH 7.4, 25°C) as described previously (Siuciak et al., 1990, 1991).

2-[¹²⁵I]-iodomelatonin binding and NAAG-like immunoreactivity were widely and unevenly distributed throughout the turtle brain. Overlap was found namely in regions of the brain receiving visual information which include areas of the midbrain: optic tectum, isthmal nuclei, optic nerve, optic tracts, nucleus of the optic tract; the diencephalon: dorsolateral and dorsomedial anterior thalamic areas, geniculate nuclei, habenula; and the telencephalon: striatum, dorsal ventricular ridge, parahippocampal region. These data open the possibility that both NAAG and melatonin may play a role in the processing of visual information in the turtle brain. EFFECTS OF THE TRANSCRIPTION INHIBITOR, 5,6-DICHLORO-1-β-D-RIBOFURANOSYLBENZIMIDAZOLE (DRB), ON THE CIRCADIAN MELATONIN RHYTHM OF CULTURED CHICK PINEAL CELLS. K. Ohi* and J.S. Takahashi*. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

Chick pineal cells contain circadian oscillators that regulate rhythmic melatonin release *in vitro*. Previous work has shown that the protein synthesis inhibitor, anisomycin, can induce phase-shifts of the melatonin rhythm in a phase-dependent manner. Because control of protein synthesis could occur at either transcriptional or post-transcriptional levels, we have investigated the effect of DRB which is a selective and reversible inhibitor of transcription by RNA polymerase-II.

Six-hour pulses of DRB (CT 0-6, 100 uM) produced a phase shift (7.0 ± 0.42 hr) in the melatonin rhythm of pineal cells under constant darkness. Pulses given at 3-hour intervals showed that the effects of DRB were phase-dependent. The phase-shifts were all delays with maximum delays occurring between CT 18 and CT 6. No phase-shifts were detected at CT 9 and CT 12. Treatment with 100 uM DRB between CT 0 and CT 6 inhibited TCA precipitable ³H-uridine incorporation by 75 % and TCA precipitable ³⁵S-methionine incorporation by 25 %. Continuous treatment with several doses of DRB between 5 uM and 50 uM lengthened the period in a dose-dependent manner (29.6 ± 0.62 hr, 50 uM). Treatment with 100 uM DRB blocked both the phase-advancing and delaying effects of light pulses (100 nWatt/cm²).

Our results demonstrate that DRB has three effects on the circadian system in chick pineal cells: 1) phase dependent phase-shifts; 2) lengthening of circadian period; 3) blockade of the resetting effects of light. These results suggest that transcriptional events are involved in the generation and regulation of the circadian oscillator.

265.12

2-[¹²⁵I]-IODOMELATONIN BINDING SITES IN THE CHICK BRAIN: DIURNAL VARIATIONS AND EFFECT OF PINEALECTOMY. J.A. Siuciak, R. Stewart and M.L. Dubocovich, Dept. of Pharmacology, Northwestern University Medical School, Chicago, IL 60611

In the chicken brain, melatonin levels show a diurnal rhythm, with high levels at night. Melatonin receptor sites (ML-1), which are widely distributed throughout the chick brain, are found predominantly in areas associated with the visual system (Siuciak et al., J. Neurosci., 1991). The aim of these studies was to investigate the regulation of melatonin receptor sites by the light/dark cycle and by endogenous melatonin using quantitative autoradiography. Scatchard analysis was performed in coronal brain sections of the optic tectum incubated with 20-300 pM 2-[¹²⁵I]-iodomelatonin. Specific binding was defined with 3 uM melatonin.

For diurnal rhythm studies, chicks were maintained on a 14:10 L:D cycle (light on 0400) until 2 weeks old and sacrificed at 4 hour intervals beginning at 0400 h. Dark phase chicks were sacrificed under dim red light. The density of binding sites follows a diurnal rhythm. B_{MAX} values were 147 and 203 fmol/mg protein at 1200 and 2400 h, respectively.

Pinealectomies (PNX) and shams were performed on two week old chicks sacrificed at 1, 7 or 14 days post surgery. One day after PNX, scatchard plots were linear and indicated a single class of high affinity binding sites: SHAM: K_D = 88.35 ± 2.61 pM, B_{MAX} = 122.51 ± 18.12 fmol/mg protein and PNX: K_D = 91.40 ± 2.13 pM, B_{MAX} = 127.13 ± 15.07 fmol/mg protein. No changes were found in either the affinity or density of binding sites at either 7 or 14 days following PNX. These data suggest that endogenous melatonin may not play a role in the regulation of melatonin receptor site density. Supported by NRSA MH09997 (JAS) and USPHS MH42922 (MLD).

DEVELOPMENTAL RESPONSES OF HAMSTER PINEALS TO NOREPINEPHRINE. C.M. Kaufman and M. Menaker. Department of Biology, University of Virginia, Charlottesville, VA 22901.

The Syrian hamster pineal displays age dependent changes in melatonin output when maintained and measured *in vitro*. Pineal melatonin generation in response to 10uM norepinephrine (NE) increased about 34 fold between 4 and 19 days of age. When incubated with 10uM NE for 6hr in static culture, glands from 11 day old neonates had over 3 times higher serotonin N-acetyltransferase specific activity and produced 20 times more melatonin than did glands from 4 day old animals. Production of melatonin by pineals of one week old hamsters exposed to NE showed a clear dose responsive relationship. The most effective dose was 10uM; the response declined with higher or lower doses. Pineals from 7 day old neonates were perfused *in vitro* and were exposed to four NE cycles consisting 10hr 10uM NE alternating with 14hr 0M NE; their melatonin output followed the imposed NE rhythm with a rising lag-time of approximately 8hr and a falling lag of about 4hr. Pineals from animals of different ages took approximately the same amount of time to rise to half maximal melatonin levels after NE stimulation or to fall to half minimal melatonin level after NE removal. The long lag time between the introduction of NE and the induction of melatonin synthesis is consistent with the idea that transcription events are required.^{1,2} In the absence of exogenous NE, melatonin from most glands dropped to undetectable levels in just over 2 days. However, even after 3 days *in vitro* without exogenous NE, pineals produced high levels of melatonin when NE was added. Our results show that the hamster pineal is capable of producing melatonin as early as 4 days of age. Furthermore, although the gland's response to NE increases with age, the time course of this response to exogenous stimulation does not change throughout postnatal development.

THE EFFECTS OF MELATONIN ON THE ACTIVATION OF PROTEIN KINASE A IN CULTURED OVINE PARS TUBERALIS CELLS.

David G. Hazlerigg*, Peter J. Morgan+, Wilfred Lawson+* and Michael J. Hastings. Department of Anatomy, University of Cambridge, Downing St. CB2 3DY and +The Rowett Research Institute, Bucksburn, Aberdeen AB2 9SB.

The cellular mechanisms which mediate the photoperiodic and circadian actions of melatonin are not known. The ovine *pars tuberalis* contains a very high density of specific, high affinity melatonin binding sites which have been extensively characterized. In this tissue, melatonin acts through a receptor coupled to an inhibitory G-protein to suppress forskolin-induced activation of adenylate cyclase. This study sought to extend this finding by investigating the effect of melatonin upon the effector enzyme of the c-AMP signal transduction pathway, protein kinase A (PKA). Primary cultures of ovine *pars tuberalis* were prepared as described previously (Morgan *et al.* 1989, *J. Mol. End.* 3, R5) and cytosols produced by hypotonic lysis. Photoaffinity labelling of native PKA revealed the presence of both type I and type II isozymes in these cells. The degree of activation of cellular PKA prior to lysis was determined with a phospho-transferase assay in which cytosols were incubated with an acceptor peptide specific to PKA (Kemptide) and γ -³²P-ATP. Enzyme activation was expressed as the ratio (A.R.) of activity within the cytosol in the absence and in the presence of excess amounts of exogenous c-AMP. PKA activation was low in unstimulated cells (A.R. <0.20) and unaffected by incubation with melatonin (10⁻⁶M). Incubation with forskolin produced a rapid (<10 mins) and dose-dependent (10⁻⁷>10⁻⁴M) activation of the enzyme (A.R. 0.70). Coincubation with melatonin (10⁻⁶M) blocked the effect of forskolin and inactivated PKA already stimulated by prior exposure to forskolin. The effects of melatonin were rapid and dose-dependent (EC₅₀ 10⁻⁹M). This study has demonstrated that melatonin has a potent inhibitory influence upon c-AMP dependent signal transduction in the ovine *pars tuberalis*. Suppression of PKA activation suggests that the cellular basis to the actions of melatonin may depend upon altering the phosphorylation state of specific substrate proteins within neuronal and hypophysal target tissues.

IONIC CURRENTS IN ACUTELY ISOLATED CHICK PINEAL CELLS. D. Henderson and S. E. Dryer, Program in Psychobiology and Neuroscience, Department of Biological Science, Florida State University, Tallahassee, FL 32036.

Previous research on cultured chick pineal cells suggests that melatonin production is modulated by Ca^{++} influx via voltage-dependent Ca^{++} channels (Harrison and Zatz, 1989). The possible existence of other channels was investigated using whole-cell recordings from acutely isolated cells at room temperature. Several distinct inward and outward currents were identified. Inward currents included L-type Ca^{++} currents and voltage-dependent TTX-sensitive Na^{+} currents. Sodium currents have not been reported previously in pineal cells. These two inward currents were observed in the majority of cells studied. Considerable heterogeneity was apparent in the amplitude and characteristics of the outward current. Cells expressed several types of voltage-dependent and Ca^{++} -dependent outward currents. Calcium-dependent K^{+} currents were observed with physiological levels of external Ca^{++} . Single channel recordings also revealed several distinct populations of ionic channels. These channels may be important for the modulation of melatonin secretion and circadian rhythmicity.

MONOAMINES AND BEHAVIOR: D₁ AND D₂ MECHANISMS

266.1

BEHAVIORAL EFFECTS OF THE FULL EFFICACY D₁ AGONIST DIHREXIDINE IN MODELS OF DOPAMINE DENERVATION. K.J. Darney, Jr., M.H. Lewis, W.K. Brewster*, D.E. Nichols, S. Southerland* and R.B. Mailman. University of North Carolina, Chapel Hill, NC, 27599, and School of Pharmacy, Purdue University, West Lafayette, IN, 47907.

We have previously shown that dihexidine (DHX; trans-10,11-dihydroxy-5,6,6a,7,8,12b-hexahydrobenzo[a]phenanthridine) has behavioral effects in control rats that may be explained by its properties as a potent, full efficacy D₁ dopamine agonist having some D₂ activity. These characteristics make it useful for testing hypotheses concerning D₁/D₂ dopamine receptor interactions. The present studies investigated how dopamine denervation may cause, as previously reported, a loss of functional D₁/D₂ interactions. We assessed the behavioral effects of systemic DHX (0.1-1.0 mg/kg) in rats with central DA lesions produced by intracerebral administration of the neurotoxicant 6-OHDA (IC). Responses were assessed using an observational method that quantified the modified frequency of multiple behavioral topographies. Unoperated, sham, and IC rats had similar dose response curves for sniffing. There was, however, a significant leftward shift in the dose-response curve for locomotion in the IC vs. sham or untreated rats. Conversely, the dose-response relationship for DHX-induced grooming was absent in IC rats. IC rats showed somewhat elevated baseline grooming, but no increases in grooming at doses of DHX that stimulate grooming in sham or unoperated rats. This effect on grooming may be the result of behavioral competition from the DHX-induced increases in locomotion. We have reported previously that the D₁ antagonist SCH23390 blocks DHX-induced locomotion, grooming, and sniffing (as expected for a D₁ antagonist). Conversely, the D₂ antagonist remoxipride completely blocked only locomotion. We therefore performed preliminary competition studies using these same IC and sham rats. The preliminary data suggest that the pattern of inhibition of DHX-induced behaviors seen in control rats was not significantly altered by the IC lesion. This suggests that a drug like DHX (having both D₁ and D₂ agonist properties) may elicit different functional responses than are seen with receptor selective drugs. Further studies (e.g., in rats with unilateral 6-OHDA lesions, and using drugs like SKF38393 that do not have full D₁ efficacy) will provide important data to understand how lesions affect D₁/D₂ interactions.

266.3

D₁ AND D₂ RECEPTORS IN MPOA DIFFERENTIALLY AFFECT GENITAL REFLEXES IN MALE RATS. E. M. Hull, R. C. Eaton, V. P. Markowski, L. A. Lumley, J. Moses, R. Dua*, and J. A. Loucks*. Department of Psychology, SUNY at Buffalo, Buffalo, NY 14260

D₁ and D₂ receptors in the MPOA differentially control genital reflexes. A D₁ agonist (THP) in the MPOA increased ex copula erections (parasympathetically controlled) and decreased seminal emissions (sympathetically controlled). A D₂ agonist (quineloran, LY-163502) in the MPOA decreased erections and increased seminal emissions. Thus, the D₂ agonist favored sympathetically mediated seminal emission.

A low dose of the mixed (D₁ and D₂) agonist apomorphine in the MPOA increased erections, as had the D₁ agonist. This increase was blocked by a D₁ antagonist (SCH-23390). The low dose of apomorphine did not affect seminal emissions. A high dose of apomorphine increased seminal emissions, as had the D₂ agonist, but did not affect erections. The increase in seminal emissions was blocked by a D₂ antagonist (raclopride). Thus, low doses of the mixed agonist apomorphine may preferentially stimulate erections via D₁ receptors, whereas high doses elicit seminal emission via D₂ receptors.

The differential effects of low and high doses of apomorphine in the MPOA may reflect similar functions of rising levels of dopamine during copulation (Eaton et al., 1991; Pfau, 1990). The smaller increases early in the copulation may enhance erections and penile movements via D₁ receptors. D₁ receptors also may suppress ejaculation early in the bout. However, peak dopamine concentrations observed just prior to ejaculation may switch from parasympathetic erectile processes to sympathetic seminal emission and ejaculation. These observations may explain the progression during copulation from parasympathetic facilitation of erection to sympathetic elicitation of seminal emission and ejaculation.

266.2

ASYMMETRIC ELEVATION OF STRIATAL DOPAMINE D₂ BUT NOT D₁ RECEPTORS IN THE CHAKRAGATI (CIRCLING) MOUSE: AGE DEPENDENCE AND RESPONSE TO QUINPIROLE. L.W. Fitzgerald¹, K.J. Miller¹, A.K. Ratty², S.D. Glick¹, M. Teitler¹, and K.W. Gross^{2*}. ¹Dept. of Pharmacology & Toxicology, Albany Medical College, Albany, NY 12208 and ²Dept. of Molecular & Cellular Biology, Roswell Park Cancer Institute, Buffalo, NY 14263

The Chakragati (Chak) circling mutant displays lateralized circling, postural asymmetry, hyperactivity, and body weight deficits without microcephaly. Previously, we reported that homozygous Chak mice have asymmetric elevations in striatal dopamine D₂ receptors in the absence of presynaptic denervation. To investigate the specificity and permanence of these changes, we measured D₁ and D₂ densities in striatal and extrastriatal regions of mice at postnatal day (PN) 30-40 and PN 180-200 using receptor autoradiography. Chak mice showed characteristic asymmetries in striatal D₂ receptors at PN 30-40; however, these asymmetries were attenuated in older mice. D₁ receptors in striatum, nucleus accumbens, and olfactory tubercle of young Chak mice were neither asymmetric nor elevated compared to heterozygous normal mice; however, D₁ levels in these regions were bilaterally lower in PN 180-200 Chak mice. We examined the functional relevance of striatal D₂ asymmetries by measuring rotation following quinpirole challenge (0.0-2.5 mg/kg, s.c.). Most Chak mice showed dose-related increased rotation, while normal mice never rotated above baseline. Older Chak mice showed a diminished rotational response to quinpirole. The finding that receptor asymmetry and rotational responses to a D₂ agonist show a similar age-related profile suggest that this receptor alteration may underlie the circling phenotype; however, some Chak mice do not respond to quinpirole, suggesting that other transmitter systems may play a role.

266.4

HIPPOCAMPAL MODULATION OF LOCOMOTION: ROLE OF D₁ AND D₂ RECEPTORS. G. Mittleman, P. LeDuc and I.Q. Whishaw. Depts. of Psychology, Memphis State University, Memphis, TN, 38152 and University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

This experiment examined locomotion and stereotyped behavior in mature, male Long Evans rats that had received aspirative lesions of the hippocampus (HPC), control lesions of the overlying parietal cortex, or were unoperated controls. Locomotion, measured as photocell beam breaks, was measured during 2 or 3 hour test sessions. Behavioral stereotypy was simultaneously rated. In agreement with previous results, HPC lesioned rats exhibited a selective enhancement in locomotion following d-amphetamine (0.0-5.6 mg/kg) when compared to animals in the control groups (Whishaw & Mittleman, *Behav. Neural Biol.* in press). Similar results were observed following injections of apomorphine (0.0-0.25 mg/kg), a mixed D₁&D₂ agonist. In order to determine if D₁ or D₂ receptors were involved in this increased locomotion the D₁ agonist SKF 38393 (0.0-15 mg/kg) and the D₂ agonist Quinpirole (0.0-0.5 mg/kg) were tested alone and in combination. HPC-ablated rats showed significantly increased locomotion only in response to Quinpirole, suggesting that these lesion-induced increases were largely mediated by D₂ receptors. When both drugs were administered together, SKF 38393 further enhanced the locomotor stimulating effects of Quinpirole in HPC lesioned rats, indicating a synergistic interaction between D₁ and D₂ receptors in the modulation of locomotion. As the different groups were not distinguishable on the basis of stereotypy, these results provide further evidence of HPC modulation of locomotion and suggest that dopaminergic mechanisms in the nucleus accumbens are involved.

266.5

BEHAVIOURAL SENSITIZATION AND TOLERANCE TO A DOPAMINE D₂ AGONIST IS A FUNCTION OF FREE-RUNNING CIRCADIAN RHYTHMS. M.T. Martin-Iverson and N. Yamada. Neurochemical Research Unit, Dept. of Psychiatry, Univ. of Alberta, Edmonton, Alberta, T6G 2B7, Canada.

Daytime tolerance and nocturnal sensitization occur to the locomotor effects of a direct dopamine D₂ agonist, (+)-4-propyl-9-hydroxynaphthoxazine (PHNO). We investigated whether this phenomenon is a function of the lighting schedule or to the circadian rhythms in locomotor activity, and further investigated interactions between D₂ and D₁ agonists. 48 male Sprague-Dawley rats (300-400 g) were maintained under constant dark (infrared illumination of 2 lux), and an additional 48 rats were maintained under constant light (55 lux) for 5 weeks prior to drug treatments. Groups of rats (n=12) in each experiment were given 14 days of continuous subcutaneous infusions of vehicle (double-distilled water), PHNO (5 µg/h), a direct D₁ agonist (SKF 38393, 336 µg/h) or both PHNO and SKF 38393, using Alzet osmotic minipumps (Model 2ML2). Circadian periodicity under constant lighting averaged 25 h. PHNO was without effect in rats in constant light. Rats in constant dark exhibited behavioural sensitization to the locomotor effects of the D₂ agonist (PHNO) during subjective "night" (3 h peak activity in each 25 h period). On the other hand, the same animals exhibited tolerance to the locomotor stimulant effects of PHNO during their subjective "day" (3 h nadir of activity in each 25 h period). Therefore, it can be concluded that the differential development of daytime tolerance and nocturnal sensitization is dependent upon the circadian rhythms in activity. SKF 38393 was without effect when given alone. When given with PHNO in rats under constant light, the D₁ agonist interacted synergistically with PHNO to increase locomotion. In rats in constant dark, SKF 38393 increased PHNO-induced activity on the first subjective "day" of treatment, but this effect developed tolerance. Under certain conditions, the D₁ agonist blocked the locomotion induced with PHNO. These data indicate that the effects of D₁ and D₂ agonists on behaviour are a function of endogenous activity rhythms and lighting conditions.

266.7

ANATOMICAL LOCALIZATION OF DOPAMINE D₁ RECEPTOR-MEDIATED BEHAVIORS IN RATS USING EEDQ. J.L. Neiswander, A. Ong*, and P. McGonigle. Depts. of Pharmacology and Psychiatry, Univ. of Pennsylvania, Philadelphia, PA 19104.

Systemic injection of the D₁-selective agonist SKF-38393 (SKF) increases grooming. In contrast, direct injection of SKF into brain regions produces neurotoxicity and an increase in locomotion. We have employed an alternative approach for localizing SKF-induced grooming, using the irreversible antagonist EEDQ to inactivate monoamine receptors in discrete brain regions. Either vehicle or EEDQ was injected bilaterally into various brain regions. Forty-eight hr after surgery, the rats were placed into an observation cage for 30 min both before and after injection of SKF (10 mg/kg, SC). Grooming was measured during the last 15 min of each period. EEDQ (1.5 µl/side) injected into the nucleus accumbens did not alter SKF-induced grooming. In contrast, EEDQ (0.15-1.5 µl/side) injected into the lateral caudate-putamen (CPu) dose-dependently decreased SKF-induced grooming. To determine whether this decrease was due to inactivation of D₁ receptors, rats were injected with vehicle or SCH-23390 (3 mg/kg, SC) 15 min prior to injection with EEDQ (1.5 µl/side) into either the medial or lateral CPu. In animals pretreated with SCH-23390 to prevent D₁ receptor inactivation, SKF-induced grooming was not disrupted by EEDQ injected into the lateral CPu. Furthermore, EEDQ injected into the medial CPu did not disrupt SKF-induced grooming. Quantitative autoradiographic analysis confirmed the loss of D₁ receptors in the injected regions of the CPu. We conclude that SKF-induced grooming involves D₁ receptors in the lateral CPu. (Supported by USPHS grant MH 14654 (JLN) and GM 34781 (PM)).

THE EFFECTS OF THE D₂ DOPAMINE RECEPTOR AGONIST, QUINELORANE (LY163502), ON THE SEXUAL BEHAVIOR OF MALE RATS. M.A. Charles*, A.B. Lumia* and M.Y. McGinnis. Dept. of Cell Biology and Anatomy, Mount. Sinai Sch. of Med., New York, NY 10029 and Dept. of Psychology, Skidmore College, Saratoga Springs, NY 12866.

Recent research has demonstrated that dopamine (DA) plays an important role in the mediation of male rat sexual behavior. DA receptor stimulation has varied effects on male rat copulatory behavior due to the presence of three DA receptor subtypes. Quinelorane (LY), a selective D₂ receptor agonist, has produced increases in male rat sexual behavior when given systemically and has been shown to stimulate behavior in sexually inactive male rats.

Two experiments were performed in the first study. The purpose of the first experiment was to determine if the effects seen with systemic LY injections could be reproduced upon intracranial infusion of LY into the medial preoptic area, a brain region implicated in the control of male sexual behavior. Long Evans male rats, which were proven copulators, were castrated and allowed to rest for three weeks. After a post-castration test, noncopulators were implanted with bilateral intracranial cannulae. Following the surgery, all animals received two 10mm Silastic T capsules and were tested twice weekly for the restoration of behavior. Immediately prior to each test, half of the animals were infused with 25µg/kg of LY in 5µl of saline. The results of this experiment showed an acceleration in the onset of behavior with the LY group. In addition, there was a tendency for LY to increase mount latency and post ejaculatory interval, decrease intromission frequencies and increase the hit rate. Using the same paradigm, the second experiment examined whether LY, either alone or in combination with suboptimal T exposure (one 5mm capsule), restores male sexual behavior. The results show that LY alone does not stimulate male rat sexual behavior but requires the presence of T for its effects to be expressed.

A second study examined whether LY injections could stimulate copulation in sexually inactive rats. Intact males received systemic injections of either LY (25µg/kg s.c.) or saline 30 minutes prior to copulatory testing. Our results suggest that LY does not induce high levels of sexual behavior in sexually inactive male rats.

From these results, we conclude that the D₂ receptor is an important mediator of male rat sexual behavior and that its actions require the presence of T.

266.6

OPPOSING EFFECTS OF D₁ AND D₂ RECEPTOR STIMULATION ON LOCOMOTION, SNOOT CONTACT, MOUTHING AND GROOMING. D. Eilan, H. Talangbayan*, K. Clements*, G. Canaran* & H. Szechtman. Dept. Biomedical Sci., McMaster Univ., Hamilton, Ontario, CANADA L8N 3Z5.

The study compares the behavioral profiles induced in rats (N=118) by the D₂-dopaminergic receptor agonist quinpirole (0.03 mg/kg; QLow, and 0.5 mg/kg; QHigh), and the D₁-agonist SKF38393 (1.25 - 40 mg/kg), and both agonists administered together. The amount of locomotion and the frequency of snout contacts were reduced by QLow but increased by QHigh; SKF38393 also reduced these behaviors and attenuated the effect of QHigh. Only QHigh increased the duration of snout contact bouts and the frequency of mouthing; SKF38393 had no effect but in combination with QHigh, it enhanced the performance of these behaviors greatly. The duration of mouthing bouts was not affected by either agonist but was greatly extended when SKF38393 was administered together with QHigh. Grooming was inhibited by both QLow and QHigh, and stimulated by the injection of SKF38393 or its addition to QLow. Spatial distribution of locomotion was transformed from routes that cross the center of the open field under QHigh to travel only along the edge with QHigh+SKF38393 (1.25-2.5 mg/kg). These findings indicate that some behaviors are controlled by modulating the frequency and others by modulating the duration of episodes and that such control can be modelled by an oppositional interaction between D₁ and D₂ receptors.

DOPAMINE D₁ AND D₂ ANTAGONISTS BLOCK L-DOPA-ELICITED AIR-STEPPING IN NEONATAL RATS. A. E. Sickles*, D. J. Stehouwer and C. Van Hartesveldt. Psychology Dept., University of Florida, Gainesville, FL 32611.

Previous studies (Van Hartesveldt et al., 1991) have shown that L-DOPA elicits highly stereotypic coordinated locomotor activity in developing rats if they are fitted into slings and suspended in air. In order to determine the role of dopamine in air-stepping, we attempted to block L-DOPA-induced air-stepping with either SCH 23390, a D₁ antagonist, at doses of 0.25, 0.5, 1, 2, 4, 8, and 16 mg/kg s.c., or with spiperone, a D₂ antagonist, at doses of 0.0625, 0.125, 0.25, and 0.5 mg/kg s.c. Antagonists were administered prior to the injection of 50 mg/kg L-DOPA s.c. in 5-day old rat pups that were suspended in slings. Either antagonist independently inhibited expression of air-stepping in a dose-dependent manner. Therefore, dopamine plays an integral part in air-stepping. However, the additional involvement of numerous other neurotransmitter systems cannot be ruled out.

266.11

RESTORATION OF SELF-STIMULATION BY A COMBINATION OF D1 AND D2 DOPAMINE AGONISTS IN DOPAMINE-DEPLETED RATS. S. Nakajima, C. L. Lau, and X. H. Liu, Dalhousie University, Halifax, Nova Scotia, Canada.

A dopamine antagonist, either D1 or D2, reduces the reinforcing effect of brain stimulation. Recent study in our laboratory suggested that a D2 agonist facilitates brain self-stimulation but a D1 agonist does not (Nakajima & O'Regan). To examine the interaction of D1 and D2 receptors, rats were tested after depleting dopamine in the brain. Rats were implanted with bipolar electrode into the lateral hypothalamus and trained to press a bar for a 0.5 s train of 0.3 ms pulses. The frequency of stimulation was varied from 200 to 12 pulses per s, and a frequency-response curve was plotted. Injection of reserpine (1 mg/kg) was followed by alpha methyl-p-tyrosine 16 hours later. When the animals were tested 4 hours after the second injection, they responded to the highest frequency of stimulation only (shift of the curve to the right). Subsequent injection of either a D1 agonist (SKF 38393, 0.4 mg/kg) alone or a D2 agonist (quinpirole HCl, 1.0 mg/kg) alone did not facilitate self-stimulation. Injection of quinpirole followed by SKF 38393 1 hour later restored self-stimulation to the level prior to reserpine injection. The results suggest that a D2 agonist enhances the reinforcing effect of brain stimulation only when D1 receptors are activated by endogenous dopamine. When dopamine is depleted, an exogenous D1 agonist is necessary to enable the D2 agonist to mediate the reinforcing effect of brain stimulation.

266.13

CLINICAL INVESTIGATION OF THE DOPAMINE HYPOTHESIS OF SELF-INJURIOUS BEHAVIOR IN THE LESCH NYHAN SYNDROME. J. Harris, DF Wong, M. Yaster*, R. Dannals*, W. Nyhan*, S. Hyman*, S. Naidu*, W. Fischer*, C. Piazza*, A. Wilson*, H. Raverty*, H. Wagner, Jr.*, Div Child Psych, Kennedy Inst, Nuclear Med, Johns Hopkins, Baltimore, MD 21205

To investigate the hypothesis that self-injurious behavior in the Lesch Nyhan syndrome is related to dopamine receptor density in the basal ganglia, we have evaluated 6 affected males (ages 4-23) who have received in vivo dopamine receptor PET scan studies (Wong et al, Soc Neuro Sci, 1991). Five of the 6 subjects showed hand and lip biting and had nondetectable levels of HPRT. One case, an adolescent male, has low levels of HPRT activity (1.1%) and has never self-injured. D2 dopamine density (Bmax) was highest in the youngest case (age 4) but D2 density was also high relative to 95% confidence levels in an adolescent male who had never self-injured. Consequently, the significance of the D2 elevation to self-injury remains unclear. The D1 dopamine system has also been implicated in the LN syndrome through an animal model of SIB proposed by Breese (1984). A trial of fluphenazine HCl, a D1/D2 antagonist thought to have adequate D1 blocking effects for a clinical trial, was carried out in two subjects (ages 5, 23). Fluphenazine HCl (Blood level 4.4 ng/ml) showed minimal effects on D1 receptor blockade of 11C SCH23390 in one case, suggesting that it is a poor D1 antagonist in vivo. This was consistent with the clinical trial of fluphenazine HCl (0.3-1 mg/day) where no improvement in self-injury, disruption, or in other LN symptoms was found in a 4-week trial. Future investigations of the self-injury hypothesis in LN syndrome will require utilization of D1 antagonists with greater receptor specificity.

266.15

DIFFERENTIAL EFFECTS OF DIRECT- AND INDIRECT-ACTING DOPAMINE AGONISTS ON GNAWING BEHAVIOR. E. Tirelli and J. M. Witkin, Psychobiology Lab, NIDA Addiction Research Center., P. O. Box 5180, Baltimore, MD, 21224.

Indirect- and direct-acting dopamine agonists were differentiated on the basis of their ability to induce intense gnawing in C57BL/6J mice. Gnawing was assessed by the total damaged surface of a corrugated cardboard floor during a 75-min session. The indirect-agonists, methylphenidate, methamphetamine, cocaine, GBR-12909, nomifensine, amfonelate, and bupropion facilitated gnawing in a dose-dependent manner. In contrast, neither D1 (SKF 38393), D2 (piribedil, RU-24213), D1/D2 (apomorphine), nor selective D2 agonists which stimulate adenylate cyclase (pergolide, (-)-NPA) induced any gnawing even at very high doses. Both the D2 antagonist, eticlopride, and the D1 antagonist, SCH 23390, blocked the gnawing induced by either methylphenidate or cocaine. Non-sedative doses of the GABA-A agonist THIP potentiated gnawing primed by a moderate dose of methylphenidate or methamphetamine as previously reported, but did not potentiate gnawing induced by GBR-12909 or cocaine, suggesting a differential role for GABA in modulating the stimulatory effects of indirect dopamine agonists. THIP did not alter the inefficacy of either apomorphine or RU-24213. These data suggest a rapid *in vivo* screening method for differentiating direct- and indirect-acting dopamine agonists.

266.12

DIFFERENTIAL EFFECTS OF CENTRALLY-ADMINISTERED QUINPIROLE ON LOW AND HIGH BASAL LEVELS OF LOCOMOTION. G.J. Mogenson, and M. Wu* Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Quinpirole, a dopamine D₂ agonist, was injected bilaterally into the nucleus accumbens of rats to investigate D₂ mechanisms in locomotor activity. A comparison was made of the effects of quinpirole (4 µg in 0.2 µl) when basal locomotion (recorded for 30 min in an open field apparatus equipped with lights, photo cells and automated counters) was relatively low and high. A low level of locomotor activity was increased by quinpirole from 203.7±67.5 to 385.9±99.6 (t₁₅=2.40, p<0.05). High levels of locomotor activity resulting from administering amphetamine to the accumbens and from adding novel stimuli to the open field were reduced by quinpirole. Amphetamine-elicited locomotion was reduced from 1057.1±127.6 to 717.2±109.8 (t₁₂=4.16, p<0.002) and novelty-elicited locomotion was reduced from 671.1±60.3 to 400.4±60.1 (t₈=3.07, p<0.02). These observations are consistent with the suggestion that the effects of the D₂ agonist depend on the initial level of locomotion. It appears that quinpirole increases locomotor activity by postsynaptic action and decreases locomotor activity by presynaptic action.

BEHAVIORAL CHARACTERIZATION OF QUINPIROLE AND SKF38393 UNDER VARYING SOCIAL AND ENVIRONMENTAL DEMANDS. J.W. Tidey and K.A. Miczek, Dept. of Psychology, Tufts University, Medford, MA 02155.

D1 and D2 dopamine receptors appear to be of critical importance in mediating motor functions, stress reactions and reinforcement processes. The present experiments examined conditioned and unconditioned behaviors of mice under different demands and reinforcing contingencies. We compared the behavioral effects of the D2 agonist quinpirole and the D1 agonist SKF38393 in mice that were pair-housed with a female for four weeks and received behavioral tests in the home cage versus mice that were singly-housed and examined for motor activities, aggressive behavior and schedule-controlled responses. Singly-housed males tested during a schedule-controlled behavioral session were more motorically active than males housed with females. The singly-housed mice were less sensitive to the suppressive effects of quinpirole and SKF38393 on motor behavior. However, in the presence of an intruder challenge, the different housing and testing conditions did not alter the behavioral effects of quinpirole and SKF38393. Quinpirole decreased the display of aggressive behaviors similarly in both groups of mice, while the singly-housed mice were less sensitive than the pair-housed mice to the suppressive effects of SKF38393 on aggressive behaviors. Finally, following the motor and aggressive behavioral tests, mice completing a schedule-controlled behavioral session were less sensitive to the FR and FI rate-decreasing effects of quinpirole and SKF38393 than they were preceding the motor and aggressive behavioral test. We conclude that mice in resting conditions are more sensitive to the motorically suppressive effects of D1 and D2 receptor agonists than when under intense behavioral demands.

CHANGES IN THE DOPAMINERGIC RECEPTOR SYSTEM AFTER CHRONIC ADMINISTRATION OF COCAINE. M.E. Alburges, M.A. Hunt, N. Narang and J.K. Wamsley. Neuropsychiatric Research Institute, 700 First Avenue South, Fargo, ND 58103.

In order to understand the neurochemical consequences of chronic cocaine administration, groups of rats were injected (15 mg/kg, i.p., b.i.d.) for 1,3,7,14 or 21 days. Binding of [³H]cocaine, [³H]SCH23390 (D₁), [³H]raclopride (D₂) and [³H]BTCP (DA-uptake) in striatal and cortical tissue was compared to controls. [³H]cocaine binding was significantly increased in the striatum and cortex at day 14 and 21, respectively. The binding of [³H]SCH23390 was significantly increased after day 3. In striatal membranes, [³H]BTCP binding was significantly increased after day 7; whereas, binding in cortical membranes was increased from day 1. [³H]Raclopride binding was significantly higher only at day 7 in cortical tissues. These results indicate that repeated exposure to cocaine produces a time-dependent supersensitivity in cortical D₁, D₂, cocaine and DA-uptake receptor sites coupled with an increase in striatal D₁, cocaine and DA-uptake receptor sites; with no changes in striatal D₂ receptor sites.

267.3

EFFECTS OF COCAINE ON THE TRANSPLANT-REINNERVATED STRIATUM. J. Graham, R. Meloni, I. Hanbauer, M. Valchar and K. Gale. Dept. of Pharmacology, Georgetown Univ. Medical Center, Washington, D.C. 20007, and Lab. Chem. Pharmacology, NHLBI, Bethesda, Md. 20892.

Cocaine (COC) (25mg/kg i.p.) elicits asymmetrical locomotor activity in rats with a unilateral 6-hydroxydopamine (6-OHDA) lesion of the dopaminergic (DA) nigrostriatal pathway. This behavior is directed towards the lesioned side (i.e. ipsiversive). As transplants of fetal substantia nigra innervate the lesioned striatum and release DA in an amphetamine (AMPH) sensitive fashion, we were interested in determining the sensitivity of the reinnervated striatum to COC. One month after implantation of solid fetal tissue containing substantia nigra, the ipsiversive rotational behavior induced by COC was significantly reduced, as compared to the pretransplantation baseline. More importantly, a strong contraversive rotational behavior appeared in response to COC in all rats with successful transplants. This behavior, which occurred in several transplant-bearing rats which showed no contraversive rotation with AMPH, was never observed after COC in lesioned rats without transplants. Other DA uptake blockers (GBR 12909, nomifensine) induced the same response as COC, whereas uptake inhibitors for norepinephrine or serotonin were without effect.

Examination of the striatum for ³H-COC binding revealed that the transplant restored a significant amount of the binding lost as a result of the DA lesion. Moreover, the restoration of COC binding sites in the host striatum did not appear to be limited to the region adjacent to the transplant.

These data suggest that the ability of COC to potentiate DA transmission in the transplant reinnervated striatum may be more pronounced than in the contralateral intact striatum. The distribution of cocaine-sensitive DA uptake sites may be a determinant of this action.

Supported by HHS grant #DA02206.

267.5

THE EFFECTS OF CHRONIC COCAINE ON BEHAVIOR, MONOAMINES AND OCCUPATION OF DOPAMINE RECEPTOR SUBTYPES. L.Y. Burger*, G.B. Baker and M.T. Martin-Iverson. Neurochemical Research Unit, Dept. of Psychiatry, University of Alberta, Edmonton, Alberta, Canada T6G 2B7.

The effects of chronic administration of male Sprague-Dawley rats with each of 4 doses of cocaine (0.0 [vehicle], 2.5, 7.5 and 22.5 mg/day) on locomotion, brain regional monoamine levels and striatal binding to selective dopamine D₁ and D₂ antagonists were investigated. Cocaine was administered using Alzet osmotic minipumps (Model 2004), as was the D₁ receptor antagonist, SCH 23390 (80 µg/day) given to some groups. Locomotion in the rats was assessed by counting interruptions of infrared photobeams in hourly blocks throughout the 16 days of drug administration. There was an initial stimulant effect for the middle and high doses of cocaine. Unlike direct D₂ agonists or amphetamine, which produce nocturnal sensitization and daytime tolerance, chronic cocaine administration produced tolerance over successive days and nights. SCH 23390 was found to attenuate cocaine effects at all doses regardless of light or dark cycle. On Day 15, the monoamine receptor inactivator, N-ethoxy-carbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 5 mg/kg) was injected IP. Interestingly, EEDQ produced hyperlocomotion in vehicle controls. Cocaine-treated rats exhibited hyperlocomotion after EEDQ. The D₁ antagonist did not significantly influence the effect of cocaine on EEDQ's actions on locomotion. 24 h post-injection with EEDQ, the rats were killed by guillotine decapitation, and their brains were removed and dissected. Since the degree of receptor inactivation by EEDQ is inversely related to the degree of occupancy of the receptors by drugs and endogenous ligands, the density of binding sites after EEDQ treatment is related to the number of occupied sites. The affinity and B_{max} of sites that bind to [³H]-SCH 23390 and [³H]-spiperone in striatal tissue were determined in all groups. Levels of monoamines and their major acidic metabolites were determined in striatum, nucleus accumbens and olfactory tubercle. It is concluded that chronic cocaine alters the effects of EEDQ on receptors that regulate locomotor activity. Funding by AMHRF, MRC, CPRF and NSERC.

267.2

THE EFFECTS OF COCAINE AND OTHER NEURONAL UPTAKE INHIBITORS ON CULTURED MESENCEPHALIC DOPAMINE NEURONS. BA Bennett and JE Clodfelter*. Dept. of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

Cocaine inhibits the neuronal uptake of dopamine (DA) as do certain other neuronal uptake inhibitors. The purpose of this study was to assess dopaminergic function after chronic exposure to the neuronal uptake inhibitors, cocaine (COC), methamphetamine (METH) and mazindol (MAZ) in a tissue culture model of the ventral mesencephalic area. Previous *in vivo* studies of the effects of these agents on the dopamine uptake system have provided conflicting results. In this study, we utilized a tissue culture model that allows a direct means of drug application to the mesencephalic cells and minimizes peripheral influences.

Brains from fetal rats (19 days gestation) were removed and the mesencephalic area obtained and dispersed into single cells. Neuronal uptake inhibitors, COC and METH, (10⁻⁴, 10⁻³M) or MAZ (10⁻⁶, 10⁻⁷) were added to the cultures on day 2 and fresh daily thereafter. The effect of chronic exposure to the uptake inhibitors on high affinity DA uptake was determined. In addition, cultures were fixed with 5% acrolein and immunohistochemistry for the presence of tyrosine hydroxylase (TH) positive cells. Lactate dehydrogenase (LDH) activity was measured as an indicator of cell death. Preliminary results show that COC (10⁻⁴M) causes a slight, but insignificant, decrease in high affinity DA uptake (18%) while 10⁻³M has no effect. Chronic exposure to METH, on the other hand, decreases DA uptake at both 10⁻⁴ and 10⁻³M (> 50% at 10⁻⁴M). MAZ also decreased high affinity DA uptake, but not as vigorously as METH. These results will be discussed in relation to data obtained from immunocytochemical and neurotoxicological analyses. Supported by grant DA05073 (BAB).

CORRELATION BETWEEN NUCLEUS ACCUMBENS NEURONAL ACTIVITY AND COCAINE SELF-ADMINISTRATION BEHAVIOR IN RATS. J.Y. Chang, S.F. Sawyer, R.-S. Lee and D.J. Woodward, Department of Cell Biology and Neuroscience, University of Texas Southwestern Medical Center & Callier Center, University of Texas at Dallas, Dallas, TX 75235.

The goal of this study was to obtain detailed correlations between neuronal activity in the nucleus accumbens (NAc) and components of behavior that precede lever pressing for cocaine self-administration in rat. Single unit recording was performed in the NAc of freely moving rats using chronically implanted microwires. Rats were trained to self-administer cocaine (0.1 mg/kg, i.v.) by pressing a lever. The animal's behavior during lever pressing was divided into 7 categories in which the animal 1) turns from a corner towards the lever; 2) faces lever with no overt movements; 3) raises head towards lever; 4) rears towards lever; 5) touches and depresses lever with forelimb; 6) moves forelimb from lever to floor; 7) turns away from lever. Some NAc neurons exhibited an increase or decrease in spike activity beginning 5-20 seconds prior to lever pressing. These responses were termed excitatory and inhibitory anticipatory responses, respectively. For neurons that exhibited an excitatory anticipatory response, the increase in spike activity was associated only with categories 3, 4 and 5, i.e., the initiation and completion of movements directly related to lever pressing. Such alterations in neuronal activity were not secondary to movements *per se* since no alterations in unit activity occurred during equivalent rearing behaviors on the other side of the chamber or during treadmill-enforced locomotion. The inhibitory anticipatory response, on the other hand, often began before and persisted throughout the behaviors leading to lever press. The dopamine D₂ antagonist pimozide (0.25 mg/kg, i.p.) failed to block either type of anticipatory response even though it elicited an extinction response. The results of this study provide further evidence that the NAc participates in the expression of reward seeking behaviors through distinct anticipatory responses that are contingently linked to movement. ELECTROPHYSIOLOGICAL EFFECTS OF COCAINE IN AMYGDALA NUCLEI: RELATIONSHIP TO DOPAMINE AND SEROTONIN ACTIONS. P.M. Callahan and K.A. Cunningham, Dept. of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston TX, 77550.

Implicated in psychological processes (mood, emotion) affected by psychoactive drugs, the amygdala may be an important site of action for cocaine, particularly as it is sensitive to cocaine-induced kindling. Cocaine (iv) inhibits and excites the spontaneous activity of amygdala neurons (Cunningham et al., Soc. NS. Abst. 15: 1098, 1989), possibly due to dopamine (DA) and/or serotonin (5-HT) uptake inhibition. In the present study, extracellular recording and microiontophoretic techniques were employed to investigate the direct actions and interactions of cocaine with DA and 5-HT in amygdala neurons of male rats (n=16) anesthetized with urethane (1.5 g/kg). Of the 24 neurons recorded to date, 13 were in the basolateral, 8 in the central, 2 in the medial dorsal and 1 in the lateral amygdala. As observed previously, the spontaneous activity of these neurons was slow (range: 0.1-8.5 Hz) and irregular. The majority of both spontaneously-active and glutamate-driven cells were inhibited by microiontophoretic DA (0.1 M, pH 4) and 5-HT (0.04 M, pH 4); 83% (10/12) and 95% (20/21) of cells tested were inhibited by DA and 5-HT, respectively. Maximal inhibitions (50-70%) occurred with ejection currents between 10-40 nA. Cocaine (0.01 M, pH 4) inhibited 66% of the cells tested (n=4/6); remaining neurons were unaffected by cocaine (5-20 nA). Intravenous cocaine (1 or 2 mg/kg) also potentiated the duration of the inhibitory response to microiontophoretically-applied DA or 5-HT. These data suggest that cocaine has direct actions on a proportion of amygdala neurons which is probably a consequence of DA and 5-HT uptake inhibition. We are currently studying the role of potential "synergistic" actions of DA and 5-HT in mediating the inhibitory effects of cocaine on amygdala neurons (White, PB&B 24: 365, 1986). Support by NARSAD, DA05708, DA06511.

COCAINE-INDUCED BEHAVIORAL SENSITIZATION AND D-1 DOPAMINE RECEPTOR FUNCTION IN RAT NUCLEUS ACCUMBENS AND STRIATUM. R.D. Mayfield*, G. Larson* and N.R. Zahniser. Dept. Pharmacol., Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Repeated cocaine administration produces a persistent sensitization of dopamine (DA)-mediated behaviors. It also produces a persistent enhancement of the electrophysiological sensitivity of D-1 DA receptors in nucleus accumbens (Henry and White, Soc. Neurosci. Abstr. 15:1013, 1989). Our goal was to determine if repeated cocaine administration induces long-lasting increases in D-1 DA receptor density, in agonist (DA) affinity at D-1 receptors and/or in the ability of DA to stimulate D-1 receptor-coupled adenylate cyclase activity. Male Sprague-Dawley rats were treated once daily for 6 days with either 15 mg/kg cocaine-HCl (i.p.) or saline. Locomotor and stereotypic behaviors were rated on treatment days 1 and 6 to confirm that the rats were behaviorally sensitized. Assays were conducted on tissue taken 1 week after the last injection. Quantitative autoradiographic analysis of [³H]-SCH 23390 saturation curves in nucleus accumbens and striatum detected no differences in D-1 receptor density or affinity between control and cocaine-treated rats. Furthermore, competition curves indicated that the affinity of D-1 receptors for DA was similar between brain regions and between treatment groups. Dose-response analysis of DA-stimulated adenylate cyclase activity also revealed no changes induced by repeated cocaine treatment in nucleus accumbens or striatum. While not ruling out changes in other D-1 receptor mediated events, these results indicate that repeated cocaine administration does not produce persistent changes in D-1 DA receptor density, affinity of D-1 receptors for DA or D-1 receptor-stimulated adenylate cyclase activity in nucleus accumbens or striatum. Supported by DA 04216 and AA 07464.

267.9

DEVELOPMENT OF TOLERANCE OR SENSITIZATION TO INHIBITION OF DOPAMINE UPTAKE BY COCAINE IS DEPENDENT ON TREATMENT REGIMEN. B.M. Cox and S. Izenwasser. Dept. of Pharmacology, Uniformed Services University, 4301 Jones Bridge Road, Bethesda, MD 20814.

We have previously shown that repeated daily injections of cocaine (one injection of 15 mg/kg/day for three days, a dose regimen which produces behavioral sensitization) produced a decrease in [³H]dopamine uptake in rat nucleus accumbens but not in striatum (caudate-putamen). Additionally, the potency of cocaine in inhibiting [³H]dopamine uptake in the nucleus accumbens was increased by this treatment. In the present study, male rats were chronically treated with either cocaine (50 mg/kg/day, expressed as free base) or saline (0.9% sodium chloride, 24 µl/day) via subcutaneously implanted osmotic mini-pumps. After 7 days, the effects of cocaine on [³H]dopamine uptake in chopped tissue slices of striatum and nucleus accumbens were examined. Total uptake of [³H]dopamine was not influenced by these treatments in either tissue. However, tolerance to the inhibition of [³H]dopamine uptake by cocaine was observed in both the nucleus accumbens and striatum of cocaine treated rats. Thus, chronic cocaine has different effects than intermittent cocaine on [³H]dopamine uptake. The occurrence of sensitization or tolerance depends on the schedule of administration. (Supported by a grant from NIDA).

CHARACTERIZATION IN VIVO OF THE NEUROCHEMICAL STATE OF THE DOPAMINE NERVE TERMINAL IN THE NUCLEUS ACCUMBENS AFTER CHRONIC COCAINE. J.W. Brock, L.H. Parsons, J.P. Ng and J.B. Justice Jr., Department of Chemistry, Emory University, Atlanta, GA 30322

The effects of repeated administration of cocaine on synthesis and metabolism of dopamine (DA) in the nucleus accumbens after 10 days of abstinence were determined. Male rats were pretreated with cocaine (10 mg/kg i.p.) or saline once daily for 10 days followed by 10 days of abstinence. On the tenth day of abstinence, microdialysis perfusion of NSD 1015 was used to assess DOPA accumulation. Reduced DOPA formation (73% of control) was found in the cocaine-treated animals (N=4/group). Rates of DOPA clearance after synthesis inhibition by an acute AMPT injection (200 mg/kg i.p.) were similar for both groups further suggesting a difference in DOPA production. Prior to NSD 1015 perfusion, DOPAC in dialysate was monitored to determine the effect of repeat cocaine injections on basal extracellular DOPAC. Reduced DOPAC levels (73% of control) were found in the cocaine-treated animals (N=4/group). Previously, using the same paradigm, similar decreases were found after one day of abstinence (Brock et al. Neurosci. Lett. 117, 234-239, 1990). Thus, the effect on synthesis and metabolism persists longer than an increase in maximal uptake and stimulated release seen at day 1 which then relaxes to control values by day 10 (Ng et al., J Neurochem. 56, 1485-1492, 1991). The decreased synthesis rates may contribute to decreased basal extracellular DA levels seen at day 10 (Parsons et al., Synapse, in press, 1991).

DIFFERENCES IN DOPAMINE CLEARANCE/DIFFUSION IN STRIATUM AND NUCLEUS ACCUMBENS FOLLOWING PERIPHERAL COCAINE ADMINISTRATION. W. A. Cass, G. A. Gerhardt, P. Curella and N. R. Zahniser. Depts. of Pharmacology and Psychiatry, Univ. of Colorado Hlth. Sci. Ctr., Denver, CO 80262.

In vivo electrochemistry was used to determine whether or not dopamine (DA) nerve terminals in striatum and nucleus accumbens respond differently to a single, systemic dose of cocaine. Nafion-coated carbon fiber electrodes were positioned in dorsal striatum or nucleus accumbens in urethane anesthetized rats. When a finite amount of DA (25-50 nM, 200 µM barrel concentration) was pressure-ejected every 5 minutes from a micropipette positioned 300 ± 30 µm from the electrode, transient ($t_{1/2}$ = 15-32 sec) and reproducible increases in DA (0.35-2.35 µM) were detected. In response to a 15 mg/kg (i.p.) injection of cocaine-HCl, no change in DA clearance/diffusion was detected in dorsal striatum. In contrast, pressure-ejected DA concentrations increased 57% above baseline in nucleus accumbens indicating significant inhibition of the DA transporter. The time course of the DA increase paralleled the behavioral changes observed in nonanesthetized rats injected with 15 mg/kg cocaine (see R. D. Mayfield, this meeting). Analysis of competition curves (³H-mazindol binding to the DA transporter) revealed that the affinity of the transporter for cocaine did not differ between the striatum and nucleus accumbens. However, similar to previous reports, the density of ³H-mazindol binding sites in the nucleus accumbens was 40% of that in the dorsal striatum. Our results suggest that the greater apparent sensitivity of the nucleus accumbens to cocaine is due to a lesser number of DA transporter molecules for cocaine to inhibit in nucleus accumbens, as compared with dorsal striatum, rather than a higher affinity of the DA transporter for cocaine in the nucleus accumbens. TOLERANCE TO INHIBITORS OF DOPAMINE UPTAKE: DIFFERENTIAL EFFECTS OF CHRONIC COCAINE OR NICOTINE. S. Izenwasser and B.M. Cox. Department of Pharmacology, Uniformed Services University, 4301 Jones Bridge Road, Bethesda, MD 20814-4799.

We have previously shown that nicotine inhibits [³H]dopamine uptake in striatum (caudate-putamen) *in vitro* via a mechanism that appears to differ from that of cocaine. In the present study, male rats were chronically treated with either nicotine (6 mg/kg/day, expressed as free base), cocaine (50 mg/kg/day), or saline (0.9% sodium chloride, 24 µl/day) via subcutaneously implanted osmotic mini-pumps. After 7 days, the effects of nicotine and cocaine on [³H]dopamine uptake in chopped tissue slices of striatum and nucleus accumbens were examined. Chronic nicotine treatment produced tolerance to the inhibition of [³H]dopamine uptake by nicotine and cross-tolerance to cocaine in the striatum. Chronic cocaine, however, produced tolerance only to itself. Nicotine did not inhibit uptake of [³H]dopamine in the nucleus accumbens of saline treated animals. In this tissue, both cocaine and nicotine treatments produced tolerance to cocaine, as in striatum. Neither chronic nicotine nor cocaine led to changes in the total amount of [³H]dopamine accumulated in either brain region. These findings provide further evidence that nicotine and cocaine inhibit dopamine uptake via different mechanisms. (Supported by a grant from NIDA).

ANALYSIS OF ACUTE AND CHRONIC COCAINE EFFECTS ON EXTRACELLULAR DOPAMINE PEAK-TO-BASAL RATIOS. E. Weiss, M. Paulus¹, M.T. Lorang*, and G.E. Koob. Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037 and ¹Department of Psychiatry, University of California, San Diego, CA 92161.

Recent evidence suggests that basal dopamine (DA) activity can predict the behavioral response to psychostimulant treatment. These findings suggested a possible relationship between basal DA release and the magnitude of stimulant-induced increases in extracellular DA. To test this hypothesis basal and peak DA levels in response to an acute injection of cocaine (10 mg/kg; IP) were determined in the nucleus accumbens of anesthetized rats on Days 1, 3, and 7 following a 10-day chronic cocaine (30 mg/kg; IP) or saline pretreatment period. Both basal (10.7 ± 2.55 nM vs. 3.55 ± 0.56 nM) and peak (23.6 ± 4.36 nM vs. 12.61 ± 1.76 nM) extracellular DA concentrations were significantly elevated in chronic cocaine-pretreated rats on Day 1 post cocaine, but decreased to control levels by Day 7. The percent increase in peak levels was inversely related to basal concentrations in both chronic cocaine and saline treatment groups at all postchronic intervals tested. Compared to saline pretreatment, chronic cocaine produced a significant decrease in peak-to-basal ratios on Day 1 suggesting some tolerance. This effect was no longer evident on Day 7. Regression analyses of logarithmically (ln) transformed data revealed the existence of a significant non-linear relationship between basal and peak DA concentrations independent of chronic pretreatments. All regression line slopes (0.58 to 0.73) were significantly less than 1. No statistical differences among slopes of individual treatment groups were found. These results indicate that a) chronic cocaine can increase the absolute levels of basal and peak DA, b) the magnitude of the cocaine-induced increase in extracellular DA decreases proportionally with increasing basal levels, and c) the DA response to cocaine can show tolerance in spite of elevations in absolute DA levels. This work was supported in part by NIDA grant DA 05843.

OPPOSITE EFFECTS OF DOPAMINE D₁ AND D₂ AGONIST PRETREATMENT ON COCAINE SELF-ADMINISTRATION. D.W. Self and L. Stein. Dept. of Pharmacology, College of Medicine, Univ. of California, Irvine, CA 92717.

D₁ and D₂ receptor antagonists both block cocaine reward, but animals will self-administer only D₂ and not D₁ receptor agonists. To further clarify the role of D₁ and D₂ receptors in reward, we pretreated rats with D₁- and D₂-selective agonists 30 min before cocaine self-administration tests. The D₂ agonist N-0923 (0.03, 0.1, and 0.3 mg/kg s.c.) dose-dependently reduced cocaine self-administration rates by lengthening the interinfusion interval between successive self-injections ($p < .001$). The same effect is produced by increasing the self-administered dose of cocaine, suggesting that N-0923 prolongs cocaine's reinforcing efficacy. In contrast, the D₁ agonist SKF 38393 (3 and 10 mg/kg s.c.) increased cocaine self-administration rates by shortening the interinfusion intervals ($p = .001$). This effect resembles decreasing the cocaine dose, suggesting that SKF 38393 reduces the reinforcing efficacy of cocaine. The combination of SKF 38393 and the D₁ antagonist (+)SCH 23390 failed to produce additive increases in cocaine intake; hence, the rate-increasing action of SKF 38393 alone did not result from D₁ receptor antagonism (due to the partial agonist properties of the drug). Opposing effects of D₁ and D₂ receptors on cocaine reward is consistent with their opposing roles in cyclic AMP formation, perhaps implicating cyclic AMP in the regulation of reward.

COCAINE CAN INCREASE EXTRACELLULAR DOPAMINE IN THE NUCLEUS ACCUMBENS IN THE PRESENCE OF GAMMA-BUTYROLACTONE. J.D. Steketee and P.W. Kalivas. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

Acute peripheral injection of cocaine stimulates motor activity in parallel with an increase of extracellular dopamine in the nucleus accumbens, as measured by in vivo microdialysis. We have previously demonstrated that injection of the GABA_B agonist baclofen into the A10 dopamine region blocked the motor-stimulant response to cocaine. However, the cocaine-induced increase of accumbal dopamine was not blocked by baclofen pretreatment. It has been suggested that the cocaine-induced increase in accumbal dopamine is dependent on intact firing activity of dopamine neurons. Baclofen has been reported to inhibit firing of dopamine cells, and thus would be expected to block the cocaine-induced increase of dopamine in the nucleus accumbens. In order to further investigate the role of neuronal impulse activity in the increase of dopamine following cocaine, male rats were injected with gamma-butyrolactone (GBL), a compound which has been reported to inhibit dopamine impulse activity, before acute cocaine treatment. One week after being implanted with guide cannulae for in vivo microdialysis monitoring of dopamine in the nucleus accumbens animals were attached to a dialysis probe. Four 20 min baseline samples were collected before injection of saline or GBL (750 mg/kg). 3 additional samples were collected after which animals were injected with saline or cocaine (15 mg/kg) followed by collection of 9 samples. Preliminary data showed that GBL led to a greater than 50 percent reduction in basal dopamine in the nucleus accumbens. Dopamine returned to baseline levels 20-40 min after injection of cocaine. Similar to saline-pretreated animals, when compared to basal concentrations after GBL-pretreatment, cocaine led to an approximate 100 percent increase of dopamine. These data suggest that cocaine can increase dopamine in the nucleus accumbens independent of intact impulse activity of dopamine neurons.

267.17

INTERACTIONS BETWEEN COCAINE AND THE PRESUMED PREFERENTIAL DOPAMINE AUTORECEPTOR ANTAGONISTS, (+)-AJ 76 AND (+)-UH 232. W.E. Hoffmann, Kjell Svensson(#), P. Calahan(+), K. Cunningham(+), B. Mead*, J.T. Lum, and M.F. Piercey. The Upjohn Co., Kalamazoo, Mi., U. Goteborg, Goteborg, Sweden (#), and U. Texas, Galveston, TX(+).

(+)-AJ 76 and (+)-UH 232 are stimulant dopamine (DA) antagonists that may preferentially act at DA nerve terminal autoreceptors (Svensson et al., 1986, Arch. Pharmacol., 334:234 and Hoffmann et al., 1988, Neurosci. Abs. 14:524). In ventral tegmental area (VTA), both (+)-AJ 76 and (+)-UH 232 antagonized cocaine-induced depressions in firing rates of DA neurons, with (+)-UH 232 being significantly more potent (ED₅₀=22 µg/kg i.v.) compared to (+)-AJ 76 (ED₅₀=1360 µg/kg i.v.). (+)-AJ 76 and (+)-UH 232 moderately increased locomotor activity (LMA) in habituated rats, but antagonized the stronger stimulant effects of cocaine. (+)-AJ 76, but not (+)-UH 232, partially generalized to the cocaine cue in drug discrimination tests. Neither agent blocked the cocaine discriminant cue. In 2-deoxyglucose autoradiography studies, (+)-AJ 76 antagonized cocaine-induced increases in energy metabolism in most brain regions. It is concluded that these preferential autoreceptor antagonists have unique interactions with cocaine that could be useful in treating cocaine abuse.

267.14

MICRODIALYSIS RECOVERY IN VIVO IS ALTERED INDEPENDENTLY OF CONCENTRATION: EFFECTS OF CHRONIC COCAINE L.H. Parsons, A.D. Smith and J.B. Justice, Jr. Dept. Chemistry, Emory Univ., Atlanta, GA 30322.

The basal state of the dopaminergic system was examined during abstinence from chronic cocaine using the quantitative microdialysis method of Lonroth et al. (1987). Rats were treated for ten days with cocaine (20 mg/kg, i.p.) followed by either one or ten days abstinence. After one day of abstinence there was no significant difference in basal extracellular dopamine (DA) levels in the nucleus accumbens (N ACC) between cocaine treated (4.1±0.3 nM) and saline treated (3.9±0.2 nM) groups (mean±SEM; n = 5/grp). There was, however, a significant increase in the in vivo probe recovery of the cocaine treated group (91±4% vs 67±8%; $P < 0.03$). After ten days of abstinence, basal extracellular levels of DA were reduced in cocaine treated animals (2.1±0.3 nM vs. 3.9±0.2 nM; n = 5/grp), while the in vivo recoveries were not significantly different for the cocaine (63±7%) and saline (64±9%) groups. These results suggest not only that basal levels of DA are altered by chronic cocaine, but also that the dynamics of release and uptake are independently altered as well.

To examine the effect of active processes on in vivo recovery, the same experimental procedure was performed to compare the in vivo recovery for DA and the metabolite DOPAC. The in vivo recovery of DA was found to be significantly higher than that of DOPAC (77±10% vs 22±1%; $P < 0.0007$; n = 5/grp). There was no significant difference in the in vivo recoveries for DA or DOPAC. The difference in in vivo recovery is thought to be caused by the active processes of release and uptake associated with DA, but not DOPAC. Rats which displayed 80% DA depletion (caused by unilateral 6-OHDA lesions) had significantly lower in vivo recoveries for DA than control animals (30±3% vs 60±3%, respectively) indicating that reduced numbers of DA nerve terminals result in reduced in vivo recovery. The basal extracellular DA levels between the groups were unchanged by the lesions.

MICRODIALYSIS STUDIES ON MDMA-INDUCED NEUROTRANSMITTER RELEASE. J. F. Nash and J. Brodtkin*. Dept. of Psychiatry and Neuroscience, Case Western Reserve Univ., Cleveland, OH 44106

The effect of the serotonin (5-HT) neurotoxin, MDMA (3,4-methylenedioxy-methamphetamine), on the extracellular concentrations of dopamine (DA) and 5-HT was studied using in vivo microdialysis. Infusion of MDMA (1-1000 µM) directly into the dialysis probe produced a dose-dependent increase in the extracellular concentration of DA in the striatum. Peripheral administration of the DA uptake inhibitors GBR 12909 (10 mg/kg) or mazindol (5 mg/kg) 30 min prior to the infusion of MDMA (10 µM) inhibited MDMA-induced DA release. In contrast, neither the 5-HT uptake inhibitor, fluoxetine (10 mg/kg), nor the 5-HT₂ antagonist, ketanserin (3 mg/kg), affected the increase in DA release produced by the local infusion of MDMA (10 µM). The peripheral administration of MDMA produced a dose-dependent increase in the extracellular concentration of DA and 5-HT. Pretreatment with the tyrosine hydroxylase inhibitor, α-methylparatyrosine (250 mg/kg), partially inhibited the increase in the extracellular concentration of DA produced by MDMA (20 mg/kg). Similarly, infusion of the sodium channel blocker, tetrodotoxin (TTX, 10 µM), attenuated MDMA-induced DA release. Pretreatment with the 5-HT₂ antagonist, piperperone (3 mg/kg), significantly attenuated MDMA-induced DA release whereas the peripheral 5-HT₂ antagonist, xylamide (5 mg/kg), had no effect on MDMA-induced DA release. These data are suggestive that MDMA increases the extracellular concentration of DA in the striatum, in part, via a carrier mediated mechanism which is largely independent of its effects on 5-HT release. However, the ability of TTX to partially antagonize the effect of MDMA coupled with the inability of α-MPT to completely abolish the effects of MDMA is suggestive that MDMA also affects impulse-mediated release of DA, perhaps via a 5-HT₂ receptor mechanism.

DOPAMINE AND DOPAC EFFLUX DURING WITHDRAWAL FROM CHRONIC COCAINE

G. R. King*, E. H. Ellinwood, Jr., and K. S. Sundar, Department of Psychiatry, Box 3870 Duke Univ. Med. Ctr., Durham, NC 27710.

Previous research conducted in this laboratory indicated that subjects receiving chronic subcutaneous injections of cocaine exhibited sensitization to a subsequent challenge dose of cocaine. In contrast, rats implanted with cocaine osmotic minipumps exhibited tolerance to a subsequent challenge dose of cocaine. The present study examines whether tolerance and sensitization under these conditions are correlated with differences in dopamine efflux in slices of the caudate nucleus. On the seventh day of withdrawal from the chronic dosing regimen, the caudate was removed by decapitation, and then rapid dissection using a vibratome. The slices were then perfused with artificial CSF for two hours, at which time baseline samples were collected. At the end of the baseline period, the slices were perfused with either 10, 20, or 40 micromolar cocaine for ten minutes and samples collected every two minutes during drug perfusion. At the end of the perfusion period, the drug was removed, and samples collected for a subsequent 45 min. The samples were assayed for dopamine (DA) and 3,4-dihydroxyphenylacetic acid (DOPAC) using HPLC-EC. The results indicate that the baseline levels of DOPAC are similar across all three dosing regimens. However, the basal levels of DA are depressed in the subjects pretreated with the osmotic minipumps. Dopamine efflux, in the presence of cocaine, in the injection pretreatment group is significantly higher than in the saline control; the dopamine efflux, in the presence of cocaine in the cocaine pump pretreatment group is significantly less than in the saline control groups. Therefore, the present results indicate that the behavioral differences produced by a cocaine challenge are correlated with differences in dopamine efflux in the caudate nucleus. Supported by NIDA DA 05303.

BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF REPEATED COCAINE ADMINISTRATION IN RATS. J. I. Javadi and J. M. Davis. Illinois State Psychiatric Institute, University of Illinois at Chicago, Chicago, IL 60612.

Repeated administration of cocaine causes augmentation in behavioral effects induced by acute administration. Present studies were designed to examine the changes in dopaminergic systems in various areas of rat brain after repeated cocaine administration. Repeated daily injections of cocaine (10 mg/kg, IP) resulted in progressive increases (behavioral sensitization) in locomotor activity and stereotypy scores (repetitive movements, sniffing). The basal levels of DA and its metabolites, DOPAC and HVA in nucleus accumbens and caudate putamen from sensitized rats were not significantly different than control animals. However, DA levels in hippocampus from sensitized rats were significantly higher than controls. ³H-Spiroperidol binding, with butaclamol as a displacer, was decreased in nucleus accumbens but remained unchanged in caudate in sensitized rats. However, with sulpride as a displacer, ³H-spiroperidol binding was decreased in both brain regions. Thus, repeated cocaine administration results in differential effects on dopaminergic systems in different brain areas.

EFFECTS OF AMPHETAMINE AND COCAINE ON EXTRACELLULAR DOPAMINE LEVELS IN THE DORSOLATERAL PREFRONTAL CORTEX AND CAUDATE NUCLEUS IN THE RHEBUS MONKEY: A MICRODIALYSIS STUDY. B.S. Kolachana, R.C. Saunders, and D.R. Weinberger. Clinical Brain Disorders Branch, NIMH, Washington, D.C. 20032.

Extracellular dopamine (DA) levels were measured in the caudate (cd) and dorsolateral prefrontal cortex (pfc) of the Rhesus monkey using *in vivo* microdialysis coupled with HPLC electrochemical detection. Magnetic resonance imaging was used in conjunction with a specialized guide implant to permit accurate probe placement. Dialysis probes with a 5 mm exposed membrane tip were perfused constantly with artificial CSF at a rate of 1 μ l/m. Basal levels of DA were consistently found in the cd 180 fmol/20 μ l and pfc 3.5 fmol/20 μ l. Amphetamine infusion through the dialysis probe (7 ng/ μ l) increased DA 25-40 fold in the cd (2000-8000 fmol/20 μ l) but only a 5 fold increase in the pfc (18-25 fmol/20 μ l). Cocaine infusion (40 ng/ μ l) induced a moderate release of DA in the cd (1500 fmol/20 μ l) and a smaller increase in pfc. In one monkey amphetamine infusion in pfc resulted in marked decrease in cd DA (55 fmol/20 μ l) and later cocaine infusion resulted in total depletion of DA in cd. The results demonstrate that reliable levels of DA can be measured in the monkey pfc and cd, and these levels can be manipulated locally via infusion through the dialysis probe.

DRUGS OF ABUSE--COCAINE: MONOAMINES AND BRAIN STIMULATION

268.1

COMPARATIVE INTERACTIONS OF IBOGAINE WITH OPIATE AND STIMULANT DRUGS: *IN VIVO* MICRODIALYSIS AND MOTOR BEHAVIOR. I.M. Maisonneuve, K.L. Rossman* and S.D. Glick. Department of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208.

Ibogaine, an indolalkylamine, has been claimed to be effective in treating opiate (patent No 4,499,096) and stimulant addiction (patent No 4,587,243). In order to determine if there is a rational basis for these claims, neurochemical and behavioral studies of potential interactions between ibogaine and either morphine, d-amphetamine or cocaine were conducted in rats. When administered 19 hr before a morphine challenge (5 mg/kg, i.p.), ibogaine (40 mg/kg, i.p.) prevented the expected rise in extracellular dopamine levels in the nucleus accumbens. Using photocell activity cages, the same ibogaine pretreatment was found to block the stimulatory motor effects induced by morphine (0.5 to 30 mg/kg, i.p.). In contrast, ibogaine pretreatment enhanced the rise in extracellular dopamine levels induced by d-amphetamine (1.25 mg/kg, i.p.) in the nucleus accumbens and potentiated the motor activity induced by d-amphetamine (0.625 to 5 mg/kg, i.p.). Lastly, ibogaine pretreatment did not appear to modify the increase in dopamine levels normally induced by cocaine (20 mg/kg, i.p.) in the nucleus accumbens; however, effects of cocaine on dopamine metabolite (DOPAC and HVA) levels were enhanced. A small enhancement of cocaine (5 to 40 mg/kg, i.p.) induced motor activity was also observed. In summary, ibogaine induced neurochemical and behavioral changes that could be consistent with its having anti-addictive effects. (Supported by NIDA grant DA03817).

COCAINE'S EFFECT ON DOPAMINERGIC AND SEROTONERGIC ACCUMBENS NEURONS ORIGINATES IN A PRESYNAPTIC MECHANISM FOR RELEASE. P.A. Broderick and F.T. Phelan. Dept. Pharmacol., CUNY Medical School (Rm. J-910), Convent Ave. & W. 138th St., N.Y., N.Y. 10031, U.S.A.

Gamma-butyrolactone (γ BL) is a known impulse flow inhibitor. γ BL increases dopamine (DA) synthesis and predicts a reduced dopamine release; γ BL does not increase serotonin (5-HT) synthesis and its effects on serotonin release are not known (Walters, J.R. and Roth, R.H., *Biochem. Pharmacol.* 21(1972) 2111). Since presynaptic mechanisms for release are dependent on impulse flow, γ BL was used to assess possible DA and 5-HT releasing properties of the psychostimulant, cocaine. *In vivo* voltammetric studies, (semiderivative electroanalysis and stearate working electrodes) provided selective detection of DA and 5-HT in nucleus accumbens of chloral hydrate anesthetized, male, virus free, Sprague-Dawley rats (cf. Broderick, P.A., *Brain Res.* 495 (1989) 115). In the γ BL studies and in the cocaine studies, voltammograms were recorded one hour before and after administration of either γ BL (750 mg/kg ip) or cocaine (20 mg/kg sc). In the γ BL plus cocaine studies, after impulse flow was significantly blocked by γ BL ($p < 0.006$), cocaine (20 mg/kg sc) was administered and synaptic DA and 5-HT concentrations were measured for one hour. The results from time course data show that cocaine's effects on synaptic concentrations of DA were significantly inhibited ($p < 0.002$) and synaptic concentrations of 5-HT were significantly inhibited ($p < 0.0001$) by γ BL. It is concluded that cocaine-induced alterations in synaptic concentrations of DA and 5-HT originate in presynaptic mechanisms for release. (Supported by NIDA, 1 R01-04755-01, and PSC/CUNY 6-61188).

268.2

INTERACTIONS BETWEEN COCAINE AND DOPAMINERGIC OR SEROTONERGIC ANTAGONISTS: EFFECTS ON PATTERNS OF MOTOR ACTIVITY. M.P. Paulus and M.A. Geyer. UCSD Dept Psychiatry, Lab of Bio Dynamics and Theoret Med, CA 92093

Cocaine's effects on geometric patterns of motor activity can be distinguished clearly from patterns observed for amphetamine treated animals. In this investigation, we used a video system to track the movements of animals in an 30.5 x 61 cm rectangular enclosure. Based on other investigations showing that a 5-HT 1B agonist, RU-24969, led to extremely repetitive straight paths of locomotion, we hypothesized that similar path patterns observed after relatively high doses of cocaine may reflect influences on the serotonergic system. In addition, previous results with the D1/2 agonist apomorphine and specific combinations of the D1 agonist, SKF-38393, and the D2 agonist, quinpirole, indicated that the synergistic activation of D1 and D2 receptors may also lead to consecutive straight movements. Thus, the changes of path patterns could also result from specific activation of D1 or D2 receptors. Therefore, we tested the effects on patterns of motor activity of the interaction between 20.0 mg/kg cocaine and 20.0 mg/kg propranolol or 2.0 mg/kg ritanserin, and 5.0 μ g/kg SCH-23390 or 25.0 μ g/kg raclopride, respectively. The animals were injected 10 min prior to exposure to the video-tracker; the behavior was recorded by a video camera; and the movements were reconstructed with a resolution of 0.3 cm in the x and y direction and a sampling frequency of 18 Hz. The patterns of activity were assessed using a previously introduced scaling approach which was augmented by additional calculation of the fluctuation of scaling exponents and the susceptibility of changes of one scaling exponent with respect to another. The results indicate that some components of highly local movements induced by cocaine can be specifically influenced by the 5-HT 1 (and β) antagonist propranolol, suggesting that the behavioral movement patterns observed for cocaine result from a combined activation of dopaminergic and serotonergic systems.

268.3

SELF-ADMINISTERED vs. PASSIVE COCAINE INTAKE: EFFECTS ON MONOAMINE NEUROTRANSMITTERS IN THE RAT BRAIN. J.M. Wilson, J.N. Nobrega, W.A. Corrigan, K. Shannak* and S.J. Kish. Dept. Pharmacology, Univ. Toronto, Clarke Inst. Psychiatry, Addiction Res. Fnd., Toronto, Ont.

Recent evidence suggests the possibility that self-administered and experimenter-given cocaine (COC) have different effects on brain amine systems. To test this hypothesis, one group of adult, male Long-Evans rats (responders, $n = 6$) was allowed to self-administer COC (1 mg/kg i.v./infusion) for 1 h/day, 5 days/week for 4 weeks. Each responder was yoked to a partner which received the same dose of COC at the same time as the responders, but had no control over the drug administration schedule. Mean daily COC intake was 8.6 ± 0.4 mg/kg. Control animals in a third group were sham-operated but received no drug. Four weeks following the last COC session, rats were killed and brains dissected into discrete areas, including striatum, n. accumbens, medial prefrontal cortex and hypothalamus. For both responders and yoked groups, chronic COC exposure failed to alter levels of the monoamines DA, NA and 5-HT or their metabolites HVA, DOPAC, MHPG and 5-HIAA in the brain areas studied as compared with controls ($p > 0.05$). The level of the dopamine metabolite 3-methoxytyramine was elevated in the striatum (+44%, $p < 0.05$) of responders but not of yoked animals. These data suggest that, irrespective of the method of administration, cocaine at the doses employed does not produce permanent degeneration of brain monoaminergic neurones. Self-administration may, however, be associated with long-lasting changes in striatal dopaminergic metabolism and/or activity.

268.5

THE EFFECTS ON COCAINE SELF-ADMINISTRATION OF DIFFERENT DOPAMINE ANTAGONISTS INJECTED INTO THE NUCLEUS ACCUMBENS. R. Maldonado, P. Robledo, A.J. Chover and G.F. Koob. Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

The peripheral administration of D1 and D2 dopamine receptor antagonists has been shown to produce an increase in cocaine self administration. Animals are thought to compensate for decreases in the magnitude of the reinforcer by increasing their self-administration behavior. In response to changes in the injection dose, animals typically show an inverse relationship between dose and number of injections per session, and thus the effect of dopamine antagonism resembles decreasing the dose of cocaine. In this study, the effects of several dopaminergic antagonists injected into the nucleus accumbens on cocaine self administration behavior were tested in rats. Animals were trained to perform operant responses to self administer cocaine (0.75 mg/kg/inj) via an intravenous catheter on a FR5 schedule of reinforcement. Bilateral intra-accumbens injections (1 μ l total) were performed through indwelling cannulae. Fluphenazine, a non specific but preferentially D2 dopamine receptor antagonist, when injected intraperitoneally significantly increased the number of lever presses for cocaine at the dose of 0.03 mg/kg ($p < 0.05$), and decreased them at the dose of 0.1 mg/kg ($p < 0.01$). When fluphenazine was injected into the nucleus accumbens (1 and 2 μ g) no significant effects were observed, but a higher dose (4 μ g) significantly decreased lever presses for cocaine ($p < 0.02$). Haloperidol, another preferential D2 dopamine antagonist, significantly increased the self-administration of cocaine when injected into the nucleus accumbens (1 μ g; $p < 0.05$). Injections of the selective D1 dopaminergic antagonist SCH 23390 into the nucleus accumbens significantly increased response rate for cocaine (1 μ g; $p < 0.01$). These data suggest that both D1 and D2 receptors in the nucleus accumbens are important for the reinforcing actions of cocaine (supported by NIDA Grant number DA 04398).

268.7

EFFECTS OF SELECTIVE DOPAMINE D₁ AND D₂ AGONISTS ON THE DEVELOPMENT OF BEHAVIORAL SENSITIZATION TO APOMORPHINE. B.A. Mattingly, G. Lovell*, S. Fauver*, & G. Johnson*. Dept. of Psych., Morehead State Univ., Morehead, KY 40351

Recent work suggests that behavioral sensitization to amphetamine and apomorphine (APO) develops as a result of repeated D₂ stimulation. In the present study we tested this view by determining the effects of selective dopamine agonists on locomotor activity and subsequent sensitivity to APO. In two experiments, male Wistar albino rats (250-350 g) were injected SC daily with either the D₁ agonist SKF 38393 (SKF; 0-, 4-, 8-, or 16- mg/kg) or the D₂ agonist quinpirole (QUIN; 0-, .3-, or 3.0- mg/kg) and tested for locomotor activity in photocell arenas for ten days. On day 11, all rats were tested with a 1.0 mg/kg dose of APO. Both SKF and QUIN depressed activity when first injected. This inhibition of activity persisted across sessions for SKF but progressively decreased with QUIN. Indeed, rats injected with QUIN were more active than vehicle control rats by day 10. When challenged with APO on day 11, rats pretreated with SKF were more active than control rats. Rats pretreated with QUIN were also more active than control rats, but these rats were less active after APO than they were after the last QUIN injection. These results suggest that although D₁ receptor stimulation may be sufficient to induce behavioral sensitization, D₂ receptors also play a role.

CONDITIONED INCREASES IN MESOLIMBIC DOPAMINE OVERFLOW BY STIMULI ASSOCIATED WITH COCAINE.

D. J. Fontana, R.M. Post, and A. Pert. BPB/NIMH, Bethesda, MD

Stimuli associated with the pharmacological effects of cocaine acquire the ability to elicit actions similar to those produced by the drug itself. The purpose of this study was to evaluate the neurochemical bases underlying such conditioned effects of cocaine — specifically in the mesolimbic dopamine (DA) system. Three groups of rats, implanted with microdialysis guide cannulae aimed for the n. accumbens, were employed in the initial study. On Day 1, the first group (conditioned) was injected with cocaine (40 mg/kg, i.p.) and placed in locomotor activity chambers. One hour following return to their home cages, the rats were injected with saline. The second group (pseudo-conditioned) was treated in a similar fashion but received saline in the activity chambers and cocaine in the home cage. The third group (control) received saline in both environments. On Day 2 microdialysis probes were introduced into the nucleus accumbens. Two hours following insertion, all rats received a low dose of cocaine (10 mg/kg, i.p.) and were placed in the locomotor chamber. Activity counts were recorded at 20-min intervals. Dialysate samples also were collected at the end of each interval and assayed for DA and its metabolites with microbore HPLC-EC procedures. Conditioned rats were significantly more active on Day 2 compared to the pseudoconditioned and control groups (1206 vs. 685 vs. 486 horizontal activity counts at peak effect, respectively). Similarly, extracellular DA levels were also elevated significantly in the conditioned group in comparison to the pseudoconditioned and control groups (218 vs. 176 vs. 162%, respectively). Such elevations in extracellular DA cannot be attributed to increases in locomotor activity per se, however. Systemic administration of MK801, which similarly elevated locomotor activity, had no effect on extracellular DA in the n. accumbens. These findings indicate that conditioned stimuli are capable of altering extracellular DA in the mesolimbic system.

SENSITIZATION TO COCAINE'S REINFORCING AND MOTOR ACTIVATING EFFECTS: DIFFERENT RESPONSE TO QUINPIROLE PREEXPOSURE. B.A. Horgar and S. Schenk. Texas A&M Univ., Dept. Psychol., College Station, TX 77843

We have previously reported more rapid acquisition of cocaine self-administration in rats that had been preexposed to moderate levels of amphetamine, caffeine, cocaine or nicotine. The present study was designed to assess the hypothesis that the sensitized response to cocaine could be attributed to an alteration in the sensitivity of D2 dopamine receptors produced by the pretreatment regimen. Rats received daily injections of the specific D2 agonist quinpirole (1.5 mg/kg) or saline. Although this dose of quinpirole failed to increase motor activity after the first exposure, it reliably elevated activity after 5 daily injections, suggesting that the rats had become sensitized to this behavioral effect of the drug. Cross sensitization to cocaine's motor activating effect (10 mg/kg) was also apparent in that quinpirole exposed rats were more responsive to this dose of cocaine. A separate group of rats was also preexposed to quinpirole or saline, as above, and was then tested for intravenous self-administration of a low dose of cocaine (0.25 mg/kg/infusion). Although quinpirole had sensitized rats to the motor activating effects of cocaine, the same preexposure regimen failed to facilitate the acquisition of cocaine self-administration. These data suggest that (1) sensitization to cocaine's motor activating effect may be related to enhanced sensitivity of D2 dopamine receptors, (2) sensitization to the reinforcing effects of cocaine does not appear to be similarly related to changes in D2 dopamine receptor sensitivity under the same parameters, and (3) the motor activating and reinforcing effects of cocaine may rely on different dopaminergic mechanisms. Supported by DA05548.

SELECTIVE SIGMA LIGANDS BLOCK STIMULANT EFFECTS OF COCAINE J. M. Witkin, M. Menkel, P. Terry, M. Pontecorvo, and J. L. Katz. Psychobiology Lab, NIDA Addiction Res. Center, Box 5180, Baltimore, MD 21224 and Nova Pharmaceutical Corporation, Baltimore, MD 21224

Compounds which bind to sigma receptors are being developed as novel antipsychotic agents which may be devoid of the side-effects associated with dopamine antagonist agents. We evaluated the ability of the sigma ligands BMY 14802 and NPC 16377 to block the locomotor stimulant effects of cocaine in male, SW mice. The effects of haloperidol and (+)-3PPP which have both dopamine and sigma receptor affinity, and the novel non-sigma antipsychotic clozapine were studied for comparison. When given alone, IP, the compounds produced dose-related decreases in activity with a rank order of potency of haloperidol > clozapine > (+)-3PPP > BMY 14802 > NPC 16377. Behaviorally-inactive doses of BMY 14802 (10 mg/kg) and NPC 16377 (40 mg/kg) decreased the locomotor stimulant effects of cocaine and shifted the dose-response curve to the right without reducing maximal effect. In contrast, behaviorally-active doses of haloperidol (0.1 mg/kg) or clozapine (1 mg/kg) were required to dampen the stimulant effects of cocaine; higher doses of (+)-3PPP were still ineffective. These results suggest that behaviorally-inactive doses of some sigma ligands may provide protection against the stimulant effects of cocaine.

EFFECTS OF INDIRECT DOPAMINE AGONISTS ON BRAIN STIMULATION REWARD THRESHOLD AT MULTIPLE CURRENTS. C.S. Maldonado-Irizarry, D. Garity*, J.R. Stellar Dept. Psychology, Northeastern University, Boston, MA 02115.

The rate-frequency curve paradigm of measuring brain stimulation reward thresholds is well accepted in the literature. However, it has been recently discovered that MFB lesions produce different rate-frequency threshold shifts at multiple currents in the same subject. Stellar et al. (Neuroscience Abstracts, 1990) showed that at low currents, LOR was dramatically increased by the lesion, but at higher currents this LOR shift was smaller. If true for pharmacology, this effect would require testing at multiple currents, and could undermine many past results. To address this issue, dopamine indirect agonist like GBR-12909 (5-20 mg/kg), cocaine (5-30mg/kg), and amphetamine (1.0 mg/kg) were administered IP acutely to rats self-stimulating in the rate-frequency paradigm at multiple currents (200-501 uAmps). Results show no systematic variation in drug-induced threshold shift at different currents. (supported by the Whitehall Foundation)

THE EFFECT OF A MIXED $D_2/5-HT_2$ ANTAGONIST, MDL 28133, ON COCAINE-INDUCED DECREASES IN BRAIN STIMULATION REWARD THRESHOLDS. S. Panicker, P. Z. Manderscheid, R. A. Frank, J.H. Kehne, C. J. Schmidt & S. M. Sorensen, Dept. of Psychology, Univ. of Cincinnati, Cincinnati, OH 45221 & Marion Merrell Dow Research Inst., Cincinnati, OH 45215.

Recent neurochemical & electrophysiological studies have shown that the mixed $D_2/5-HT_2$ antagonist MDL 28,133 can modulate stimulant-induced changes in central dopaminergic neurotransmission. The ability of this compound to reverse cocaine-induced decreases in intracranial self-stimulation thresholds was assessed in the present experiment. Cocaine-induced shifts in thresholds were evaluated following 5, 15 and 30 mg/kg cocaine HCl (IP) in ten rats with ventral tegmental area electrodes. The magnitude of cocaine's effects was also assessed following pretreatment (IP) with 5 and 10 mg/kg MDL 28,133. The effects of cocaine and MDL 28,133 were mutually antagonistic, as might have been predicted for the interaction of a neuroleptic and psychomotor stimulant drug. This research was supported by NIDA grant DA04483 to R. A. Frank.

AN ANIMAL MODEL OF COCAINE WITHDRAWAL USING BRAIN STIMULATION REWARD. Michael A. Bozarth & Cindy M. Pudiak. Department of Psychology, University at Buffalo, Buffalo, NY 14260.

An animal model of cocaine withdrawal was developed based on studying the function of the brain system mediating cocaine reinforcement. Measurement of reinforcement from electrical activation of this system was used to examine changes in the system's functional activity following the termination of daily cocaine injections. Male, Long-Evans rats were implanted with monopolar electrodes aimed at the lateral hypothalamic level of the medial forebrain bundle. After 7 days recovery from surgery, rats were trained (during daily 60-min test sessions) to press for monophasic cathodal stimulation pulses using the threshold tracking method.

Subjects were administered daily cocaine injections (40 mg/kg, i.p.) for one week, and their brain stimulation reward thresholds pre- and post-treatment were compared. A marked elevation of brain stimulation reward thresholds was seen following the cocaine injection series. This threshold elevation persisted for 3 days with thresholds gradually returning to pretreatment levels. The decreased efficacy of electrical brain stimulation (demonstrated by an increase in the minimum stimulation frequency necessary to maintain responding) probably corresponds to the diminished dopamine levels seen following intravenous cocaine self-administration. It is also likely that diminished functioning of this important brain reward system may produce subjective experiences of anhedonia, depression, and drug craving in human cocaine users.

EFFECTS OF REPEATED COCAINE ADMINISTRATION ON INTRACRANIAL SELF-STIMULATION (ICSS) THRESHOLDS IN RATS. Athina Markou, Ilham Y. Polis and George F. Koob. Dept. of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

It has been hypothesized that human cocaine users tend to increase their cocaine dose due to the development of tolerance to cocaine's euphorogenic effects. The purpose of the present study was to investigate whether there is tolerance or sensitization to the rewarding effects of cocaine as measured by ICSS current-thresholds. Rats were injected (IP) with 10 mg/kg/8 hr for 10 consecutive days. Thresholds were assessed daily, 10 min after one of the 10 mg/kg injections. The results indicated the development of sensitization to the threshold lowering effect of cocaine. This finding suggests that repeated, intermittent administration of cocaine results in sensitization to the rewarding effects of cocaine. The influence of chronic self-administered (IV) cocaine on ICSS thresholds was also investigated. The effect of self-administered cocaine on thresholds was dose-dependent. Low doses of cocaine (i.e., short intravenous self-administration sessions) lowered thresholds, reflecting cocaine's rewarding effect. However, higher doses of cocaine (i.e., longer self-administration sessions) raised thresholds. These higher thresholds may reflect the post-cocaine anhedonia experienced by human cocaine users during cocaine withdrawal.

WITHDRAWAL FOLLOWING COCAINE SELF-ADMINISTRATION DECREASES REGIONAL METABOLISM IN CRITICAL BRAIN REWARD REGIONS. R.P. Hammer, Jr., W.S. Pires*, D.W. Clow, A. Markou, and G.F. Koob. Dept. Anatomy & Reprod. Biol, Univ. Hawaii Sch. Med., Honolulu, HI 96822, and Dept. Neuropharm., Res. Inst. of Scripps Clinic, La Jolla, CA 92037.

Psychostimulant withdrawal produces biological changes in brain activity which are reflected in elevated intracranial self-stimulation thresholds and reduced local cerebral glucose utilization (LCGU) in the basal forebrain. LCGU was examined at 30 hr after a 3 hr cocaine self-administration session, at either 6 or 72 hr after a 12 hr session, or in drug-naive rats. LCGU was significantly reduced following cocaine self-administration compared to drug-naive animals in the nucleus accumbens (-21-32%), olfactory tubercle (-14-31%), rostral striatum (-15-26%), lateral hypothalamus (-14-22%), amygdala (-16-22%), substantia nigra (-13-17%), ventral tegmental area (-12-15%) and several cortical and brain stem regions. Moreover, a main effect of time was observed in many brain regions, suggesting that cocaine withdrawal produced a sustained reduction of LCGU which is greater at 72 than at 6 hr post-drug. The results indicate that drug experience produces significant metabolic changes even in the absence of a 12 hr drug "binge." In addition, the amount of drug self-administered during the 12 hr session was significantly correlated with LCGU in medial prefrontal cortex, olfactory tubercle, substantia nigra and locus coeruleus at 6, but not 72 hr post-drug. Reduction of regional metabolic activity may represent a biological substrate for the motivational aspects of the cocaine withdrawal syndrome. Supported by USPHS awards DA06645 and HD01161 to RPH, DA05365 to AM, and DA04398 to GFK.

268.14

THE VENTRAL STRIATOPALLIDAL SYSTEM AND CONDITIONED REINFORCEMENT IN RATS. B.J. Everitt, G. Phillips*, J. Le Noury*, T.W. Robbins¹, G. Wolterink* & L. Wolterink*. Depts Anatomy & ¹Experimental Psychology, Cambridge University, Cambridge CB2 3DY, U.K.

We have investigated the interaction between cholecystokinin (CCK) and dopamine (DA) in the ventral striatum (VS), as well as the effects of excitotoxic lesions to the ventral pallidum (VP) and cholinergic nucleus basalis (nbm), on the control over behaviour by conditioned reinforcement (CR). In the training phase, rats received pairings of a light/noise compound stimulus, and 10% sucrose. In the test phase, in the absence of sucrose, a response on one of two novel levers produced the CR, but on the other had no programmed consequences.

Intra-accumbens infusion of d-amphetamine (AMPH) enhanced responding selectively on the CR lever. Co-infusion of CCK8 potentiated the impact of AMPH, and this potentiation was blocked by the CCK-A antagonist, devazepide.

Lesions of the VP induced by ibotenic acid completely prevented the acquisition of a new response with CR and also the effects of intra-accumbens AMPH, but did not affect consumption of sucrose. These lesions were associated with 25% reductions in cortical cholinergic markers. Lesions of the nbm induced by AMPA reduced cortical cholinergic markers by >65%, but spared many VP neurons. These lesions caused a small impairment in the acquisition of a new response with CR independently of the effects of intra-accumbens AMPH. The results will be discussed in terms of the modulation by DA/CCK8 of limbic afferents to the VS and the involvement of VP and/or nbm cholinergic targets of VS outflow in reward-related processes.

COMPARISON OF THE EFFECTS OF AMPHETAMINE WITH NOMIFENSINE ON A BRAIN SELF-STIMULATION REINFORCEMENT THRESHOLD TASK IN RATS. G.J. Schaefer and R.P. Michael, Department of Psychiatry, Emory University, School of Medicine, Georgia Mental Health Institute, 1256 Briarcliff Rd., Atlanta, GA 30306.

Rats (N=12) were implanted with stimulating electrodes in the lateral hypothalamus and trained in the auto-titration brain self-stimulation (ICSS) procedure. After reinforcement thresholds stabilized, animals were administered saline, *d*-amphetamine (0.1, 0.3, 1.0 mg/kg) or nomifensine (1.0, 3.0, 10 mg/kg) and tested in the ICSS procedure. Amphetamine produced a graded decrease in reinforcement thresholds to approximately 30% at the highest dose ($p < 0.01$). All three doses, increased responding by about 25% above baseline levels ($p < 0.01$). Nomifensine also produced a graded decrease in reinforcement thresholds, but the slope was steeper and, at the highest dose, there was a 70% decrease in thresholds ($p < 0.01$). Nomifensine produced no significant increase in rates but, at the highest dose, rates declined to 35% below baseline ($p < 0.01$). We have previously shown that amphetamine lowers reinforcement thresholds in the auto-titration procedure, and we now extend this to a second stimulant, nomifensine. While both drugs lowered the reinforcement threshold, they had opposite effects on rates of responding under these conditions. This provided further evidence that in the auto-titration procedure changes in reinforcement threshold can occur independently of changes in response rates. ANTIPSYCHOTICS I

269.1

TYPICAL VERSUS ATYPICAL NEUROLEPTICS: DIFFERENCES IN REGIONAL CEREBRAL GLUCOSE UTILIZATION IN RATS. N.G. Cascella*, F.I. Tarazi, O. Shirakawa, C.A. Tamminga. Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228

Typical neuroleptics, like haloperidol, are potent antidopaminergic antipsychotic agents. Recently, new atypical neuroleptics have been developed with low extrapyramidal side effects and unique antipsychotic actions. An understanding of the biologic basis of atypical drug action may be informative about the nature of psychosis and may encourage new drug development. We have used regional cerebral glucose metabolism (rCMRglu) to functionally localize the action of several neuroleptic drugs, typical and atypical. Haloperidol (H) (1.0mg/kg), raclopride(R) (1.5mg/kg), and saxoxepine (S) (0.005 mg/kg and 0.5mg/kg) were administered individually to rats just prior to 14C-2DG injection. rCMRglu was measured quantitatively using 2DG autoradiography technique. (H) reduced rCMRglu in neocortical, limbic and extrapyramidal systems. (R) reduced rCMRglu only in limbic and neocortical areas but not in extrapyramidal regions. This suggests that raclopride has little functional effects in motor regions of brain, while exerting a haloperidol-like effects in areas traditionally linked to cognitive and affective behaviors. At a low dose (0.005mg/kg) selective for hippocampal D2 receptors, (S) was found to have functional effects in all three cerebral systems, limbic, neocortex and extrapyramidal. (S) produced (H)-like changes in striatum at doses too low to block postsynaptic D2 striatal receptors, but at doses which nonetheless elevated HVA and DOPAC, two major metabolites of DA in rat striatum (Baumann, P.A. et al. *Psychopharmacology* 96,S-339. 1988). This is consistent with an action of (S) as a D2 autoreceptor antagonist.

269.3

BITANSERIN AND HALOPERIDOL FAIL TO SUBSTITUTE IN CLOZAPINE-TRAINED RATS. J.L. Wiley and J.H. Porter. Department of Psychology, Virginia Commonwealth University, Richmond, VA 23284.

Fifteen naive adult male Sprague-Dawley rats (85% BW) were trained to discriminate clozapine (5.0 mg/kg, i.p.) from vehicle in a two-lever drug discrimination procedure under a FR30 schedule of food reinforcement. Daily session duration was 15 minutes. Following testing for acquisition of the discriminative cue, stimulus generalization tests with clozapine (0, 1.25, 2.5, 5.0, 10.0, & 20.0 mg/kg), haloperidol (0, 0.015, 0.03, & 0.10 mg/kg), and ritanserin (0, 2.5, 5.0, 10.0, & 15.0 mg/kg) were conducted.

Percent drug-lever responding and response rate were calculated for each dose of the test drugs. Linear regression on the linear portion of the clozapine dose-effect curve ($X = \log_{10}$ transformation of the dose and $Y = \% \text{ drug-lever responding}$) revealed that clozapine generalized to the training dose (5 mg/kg) in a dose-dependent manner ($ED_{50} = 1.99 \text{ mg/kg}$). The D2 antagonist, haloperidol, and the 5-HT₂ antagonist, ritanserin, failed to substitute for clozapine at any of the doses tested. These results suggest that the clozapine-cue is not mediated by D2 or 5-HT₂ receptors.

269.2

DIFFERENTIAL EFFECTS OF CLOZAPINE AND HALOPERIDOL ON LIMBIC SYSTEM KINDLING. S. Reeves*, T.B. Borowski*, and L. Kokkinidis. Dept. of Psychology, Univ. of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0.

Kindled seizure activity elicited by repeated intermittent electrical stimulation of limbic structures has shed considerable light on the mechanisms involved in neuronal plasticity and sensitization. Given that limbic system dysfunction is thought to play a significant role in clinical psychopathology, we investigated the effects of clozapine (10.0 mg/kg) and haloperidol (1.0 mg/kg) on the evolution of kindled seizures after stimulation of the central nucleus of the amygdala, and the ventral dentate gyrus of the hippocampus. Neither drug affected the minimum current intensity necessary to elicit an afterdischarge from these limbic structures. However, administration of clozapine 30 min prior to each daily electrical stimulation of the amygdala and ventral hippocampus substantially retarded the development of kindled seizures. Haloperidol treatment did not influence epileptogenesis from either limbic site. Subsequent experiments evaluated the function of the anticholinergic effects of clozapine on its seizure suppressing properties. It was found that pilocarpine administration in doses that did not facilitate kindling genesis (20.0 and 40.0 mg/kg), partially antagonized the clozapine-elicited inhibition of amygdaloid kindling. Injection of this ACh muscarinic receptor agonist together with clozapine induced some catalepsy indicating a synergism on ACh activity. These results suggest that the clinical efficacy of clozapine might involve specific effects on limbic system functioning not shared by the typical neuroleptics.

269.4

FOS IS INDUCED BY THE ANTIPSYCHOTIC DRUG CLOZAPINE IN THE RAT STRIATUM N. Hiroi¹, H. A. Robertson² and A. M. Graybiel¹.

¹Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139, and

²Dept. of Pharmacology, Dalhousie Univ., N.S., Canada B3H 4H7.

The atypical neuroleptic clozapine (CLZ) is a unique antipsychotic drug in that, unlike classical neuroleptics, it alleviates schizophrenic symptoms without causing extrapyramidal side effects. We have investigated the effect of CLZ on Fos-like immunoreactivity (Fos) by immunohistochemistry. Rats (n=4 for each group) were treated with vehicle or CLZ (5.0, 10.0, 20.0, and 40.0 mg/kg, i.p.), and patterns of Fos induction were studied in relation to immunostaining for calbindin D28k (calbindin), a marker for the extrasomal matrix and the core of the nucleus accumbens (NA). Fos was induced in the caudoputamen (CP) and NA of CLZ-treated animals in a dose-dependent manner. At 10 mg/kg, Fos was induced in the medial CP and medial NA anteriorly; caudally, the CP and NA were devoid of Fos. As doses of CLZ increased (20 and 40 mg/kg), Fos induction spread laterally in the anterior CP and, in the middle CP, extended dorsally from medial to lateral in a curving marginal band. Interestingly, Fos induction in the center of the CP tended to be clustered in striosomes, identified as calbindin-poor zones. More caudally, Fos induction was mainly distributed in the dorsomedial corner of the CP. In the NA, abundant Fos was present in the rostral pole, and more caudally, Fos was mainly confined to the shell of the NA; both zones are calbindin-poor. Thus, there was an inverse relation between Fos induction and calbindin immunoreactivity in the NA and, to some extent, in the CP. Fos was also induced, *intra alia*, in parts of the prefrontal cortex, septum, VTA and medial substantia nigra pars compacta. (Supported by the Human Frontier Science Program and Javits Award NS 25529).

269.5

EFFECTS OF AMFONELIC ACID AND GBR 12909 ON THE CLOZAPINE- AND HALOPERIDOL-INDUCED STIMULATION OF STRIATAL DOPAMINE SYNTHESIS, METABOLISM AND RELEASE. G.A. Gudelsky, E. Nwajeri and J.F. Nash, Dept. of Psychiatry, Case Western Reserve Univ., Cleveland, OH

It has been shown that amfonelic acid (AFA) potentiates the increase in striatal DOPAC concentrations induced by haloperidol (HLD), but attenuates that induced by clozapine (CLZ). In the present study, the stimulation of dopamine (DA) synthesis, metabolism and release induced by HLD and CLZ were examined in rats treated with AFA or the dopamine uptake inhibitor GBR 12909. DA metabolism was assessed from the concentrations of DOPAC in post mortem tissue. DA synthesis was evaluated from the in vivo accumulation of DOPA after decarboxylase inhibition. DA release was assessed by quantitation of its extracellular concentration using in vivo microdialysis. Whereas treatment with AFA potentiated the HLD-induced increase in DOPAC in the striatum and n. accumbens, the CLZ-induced increase was markedly attenuated. The CLZ-induced increase in striatal DOPAC also was prevented by treatment with GBR 12909. Although AFA did not alter the HLD-induced increase in DOPA accumulation in the striatum or n. accumbens, it attenuated the CLZ-induced increase in both brain regions. In contrast, the CLZ-induced increase in DA synthesis in the median eminence was not altered by AFA. Both HLD and CLZ increased the extracellular concentration of DA and DOPAC in the striatum. Results from the microdialysis studies with AFA were consistent with those from the post mortem experiments. It is suggested that inadequate blockade of DA autoreceptors by CLZ may account for the suppression of CLZ-stimulated DA synthesis and metabolism by DA reuptake blockers.

269.7

EVALUATING THE PAW TEST AS A PARADIGM FOR DIFFERENTIATING BETWEEN CLASSICAL AND ATYPICAL NEUROLEPTICS. A.T. Shropshire and K.L. Marquis, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

The paw test, originally developed as a motor assay (Vrijmoed-deVries *et al.* Psychopharmacology 92:73-77, 1987), was proposed by Ellenbroek *et al.* (Psychopharmacology 93:343-348, 1987) as a behavioral paradigm for differentiating between classical and atypical neuroleptics. While classical neuroleptics were reported to be equipotent in prolonging both the forelimb (FRT) and hind-limb retraction time (HRT) in rats, atypical neuroleptics were more potent in prolonging HRT than FRT. These data suggested that FRT may reflect parkinsonian side-effect potential with classical neuroleptics, while HRT predicts the antipsychotic effect of both classical and atypical neuroleptics. In the present study, we attempted to replicate these data using the paw test to differentiate between classical and atypical neuroleptics. Moreover, we determined whether drugs which produced false positives in the conditioned avoidance test also appeared as false positives in the paw test.

The classical neuroleptics, haloperidol (1, .5, 1 & 5 mg/kg ip) and chlorpromazine (1, 2.5, 5, 7.5 & 10 mg/kg ip) significantly prolonged HRT and only marginally affected FRT. The atypical neuroleptics, thioridazine (7.5, 15, 30 & 60 mg/kg ip), clozapine (1, 10, 20 & 50 mg/kg ip) and gevotroline (5, 10 & 20 mg/kg ip), significantly prolonged HRT and had no effect on FRT. Other drugs which produced false positives, B-HT 920 (5, 10 & 20 mg/kg ip), clonidine (.06, .125 & .25 mg/kg ip) and prazosin (10 mg/kg ip), in the conditioned avoidance test, also appeared as false positives in the rat paw test. These results failed to support the conclusions drawn by Ellenbroek *et al.* concerning the utility of this test. Moreover, using HRT as an index of antipsychotic activity, the paw test offers no distinct advantage over the conditioned avoidance test which is highly predictive of clinical efficacy in this therapeutic area.

269.9

EFFECTS OF CLOZAPINE ON GLUTAMATERGIC TRANSMISSION. T.I. Lidsky, E. Alter, S.P. Banerjee, Inst. for Basic Research, Staten Island, NY 10314

Clozapine (C), an atypical antipsychotic, differs from conventional neuroleptics in having no appreciable liability for significant extrapyramidal side effects including tardive dyskinesia. The present study is the first in a series from this laboratory investigating the bases of C's unique action.

Both C and haloperidol (H) attenuate glutamatergically mediated electrophysiological responses in the striatum. H's action is dependent on the presence of dopamine: lesions of the nigrostriatal tract abolish H's inhibitory effect. In contrast, C continues to attenuate striatal responses after nigrostriatal lesions. To evaluate the possibility of a more direct influence, C and H were compared with regard to displacement of [³H] MK-801 binding to glutamate receptors in the striatum. C was approximately 3x more effective than H in this regard; at clinical doses, C would be about 600x more potent. Taken together, the electrophysiological and binding data indicate that C is an effective glutamate blocker.

269.6

EFFECT OF AMPEROZIDE UPON DOPAMINE (DA) RELEASE IN VITRO FROM THE CORPUS STRIATUM (CS) & OLFACTORY TUBERCLE (OT) OF MALE RATS. J.L. McDermott and H.Y. Meltzer, Depts. of Geriatrics and Psychiatry, Case Western Reserve University, Cleveland, Ohio 44106

Amperozide, a novel atypical antipsychotic agent, has been shown to block uptake and increase basal release of [³H] DA both in striatal and limbic rat tissue (Eriksson and Christensson, Pharmacol & Toxicol. Suppl. 1:45, 1990). Utilizing *in vitro* superfusion the effect of direct infusion of 10 uM amperozide upon endogenous DA release from CS tissue slices was examined. DA release was significantly increased in response to amperozide infusion (areas under stimulated curves = 26.5 ± 6.4 ng/40 min, N=7) as compared to Krebs-Ringer-Phosphate (KRP) superfused control CS (AUC 8.1 ± 2.5 ng/40 min, N=6). We next examined amphetamine (AMPH - 10 uM)-stimulated DA release from the CS and OT in the presence or absence of 10 uM amperozide in KRP. In the presence of amperozide, AMPH-stimulated DA release from the CS was significantly (P < .05) decreased (AUC 164 ± 35.6, N=9 vs 313.7 ± 53.4 pg/40 min, N=8) whereas there was no effect in the OT (AUC 260.9 ± 59.3, N=7 vs 231.5 ± 76.3, N=6). These results are, in main, consistent with the results of *in vivo* microdialysis techniques (Ichikawa and Meltzer, submitted). However, amperozide did inhibit amphetamine-stimulated DA release in the nucleus accumbens using *in vivo* microdialysis. Further study of possible differences of the effect of amperozide on amphetamine-stimulated DA release in different limbic areas is required.

269.8

DOES THE ATYPICAL ANTIPSYCHOTIC CLOZAPINE BLOCK THE REWARDING PROPERTIES OF AMPHETAMINE? D.C. Hoffman and H. Donovan, Neurogen Corp., Branford, CT 06405.

It has been suggested that the antipsychotic efficacy of clozapine is due to its blockade of dopamine (DA) receptors within the mesocorticolimbic system. Thus, one might expect clozapine to be effective in blocking the rewarding properties of amphetamine which are mediated by an increase in DA levels within the nucleus accumbens, one target area of the mesocorticolimbic DA neurons. The present study investigated this prediction using the conditioned place preference paradigm. Male Sprague-Dawley rats received amphetamine (2.0 mg/kg IP) paired with one side of a two-compartment box and saline paired with the other compartment. During these pairings, locomotor activity was measured by photocell beam breaks. On the test day, the amount of time drug-free rats spent in each compartment was measured. Rats trained with amphetamine alone showed a significant increase in time spent on the drug-paired side from pre- to post-conditioning, indicating a place preference. When rats were injected with clozapine (1, 5, 10 mg/kg SC) 30 min prior to the amphetamine pairings, a dose-dependent decrease in locomotion was observed, but only the highest dose of clozapine blocked the establishment of place conditioning. The typical antipsychotic haloperidol prevented place conditioning at a dose of 0.1 mg/kg. These data suggest that acute injections of clozapine may not possess potent DA antagonist actions within the nucleus accumbens.

REGIONALLY SELECTIVE EFFECT OF CHRONIC CLOZAPINE ON EXTRACELLULAR DOPAMINE LEVELS. K.D. Youngren, R.H. Roth, B.S. Bunney, and B. Moghaddam, Neuroscience Program and Depts. of Pharmacology and Psychiatry, Yale Univ. School of Medicine, New Haven, CT 06510, and West Haven VA Medical Center, West Haven, CT 06516.

Previous studies in this laboratory have suggested that preferential activation of dopamine (DA) release in the medial prefrontal cortex (mPFC) occurs following acute clozapine administration. In order to investigate this preferential effect of clozapine on the mesocortical DA system further, microdialysis was used to measure the extracellular level of DA after chronic administration of clozapine. Dialysis measurements were performed in mPFC, striatum, and nucleus accumbens of the rat. Chronic clozapine administration (20 mg/kg in drinking water) had no effect on basal levels of DA in striatum. However, it did produce a significant increase in the basal levels of DA in mPFC in comparison to control. Upon injection of a challenge dose (20 mg/kg i.p.) of clozapine, a significant tolerance effect in mPFC was observed, while no tolerance was seen in striatum. Study of the effect of chronic clozapine on DA release in nucleus accumbens is ongoing. These results provide additional support to the hypothesis that the clinical profile of atypical antipsychotic drugs like clozapine may relate to a regional specificity of action.

THE EFFECTS OF THE PUTATIVE ATYPICAL ANTIPSYCHOTIC AMPEROZIDE ON EXTRACELLULAR DOPAMINE LEVELS IN THE RAT MEDIAL PREFRONTAL CORTEX. E.A. Pehek, H.Y. Meltzer and B.K. Yamamoto. Dept. of Psychiatry, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

Others have shown that the atypical neuroleptic clozapine, but not the typical neuroleptic haloperidol, has a greater effect on extracellular dopamine (DA) in the medial prefrontal cortex (MPFC) relative to the caudate-putamen (CP). The present study compared these effects to those of amperozide, a novel agent that may have antipsychotic efficacy with few extrapyramidal side effects. *In vivo* microdialysis coupled with HPLC/EC was used to measure DA and its metabolite DOPAC in the freely-moving rat. Each rat was implanted with a guide cannula aimed at the MPFC. Two days later, a 4 mm concentrically designed probe was inserted through this cannula into the MPFC. A modified Ringer's medium was perfused through the system at a rate of 2.0 μ l/minute. Samples were collected every 30 min and immediately injected onto the HPLC for analysis by electrochemical detection. Amperozide (10 mg/kg) increased extracellular levels of DA and DOPAC. These effects were greater in the MPFC (mean DA = 551.71% of basal levels) relative to the CP (mean DA = 202.68%). In contrast, administration of haloperidol (0.5 mg/kg) produced a smaller increase in cortical DA (mean = 169.04%) that was not greater than that observed in the CP (mean = 225.93%). These results suggest that a common property of atypical antipsychotics may be their ability to preferentially increase cortical DA.

269.13

CLOZAPINE DISSOCIATES COGNITION AND PSYCHIATRIC SYMPTOMS IN PATIENTS WITH SCHIZOPHRENIA. T.E. Goldberg, R.D. Greenberg*, S.J. Griffin*, J.M. Gold*, J.E. Kleinman, D. Pickar*, S.C. Schulz*, D.R. Weinberger. Clinical Brain Disorders Branch, NIMH Neuroscience Center at St. Elizabeths, Washington, D.C. 20032

Neuropsychological deficits in schizophrenia, while frequently reported, are often thought to be an epiphenomenon of psychopathology and as such not a valid indicator of reduced cognitive capacities. In the present study, we attempted to "dissect" psychiatric symptoms and cognition in schizophrenia with the atypical neuroleptic clozapine. Assessments of psychiatric symptoms and cognition were made in 14 patients with schizophrenia and one patient with psychosis not otherwise specified while they received a conventional neuroleptic medication and then again after an average of 15 months treatment with clozapine. Despite impressive improvements in psychiatric symptoms, cognitive function in such areas as attention, memory, and higher level problem solving remained impaired and essentially unchanged. This suggests that certain cognitive deficits are relatively independent of psychotic symptoms in schizophrenia and are probably central and enduring features of the disorder. In fact, cognitive disability appeared to have been rate limiting in the sample's rehabilitation as patients' social and vocational adjustment remained marginal during the course of the study. We also observed that clozapine treatment was associated with a decline in some memory functions; the potent anticholinergic properties of the drug may have been responsible.

269.15

REGULATION OF CELLULAR IMMEDIATE-EARLY GENES BY TYPICAL AND ATYPICAL ANTIPSYCHOTIC DRUGS. B. M. Cohen, T.V. Nguyen*, R. Birnbaum* & S. E. Hyman, Mailman Research Center, McLean Hospital, Belmont, MA 02178, and Massachusetts General Hospital, Boston, MA 02214

Cellular immediate-early genes (IEG's) have been studied as sensitive indicators of cellular activation and as potential third messengers involved in long-term changes in neural function. The slow onset of therapeutic effectiveness of antipsychotic drugs suggests that slowly developing neural plasticity, perhaps involving changes in gene expression, is critical to their mechanism of action. We report that, as determined by Northern analysis, expression of mRNA for the cellular IEG's *c-fos* and *zif/268* was increased 2-4 fold in rat striatum after a single dose of the typical antipsychotic drug, haloperidol, or the psychostimulant, amphetamine. These effects were rapid, transient, and dose-dependent. In contrast, the atypical antipsychotic drug, clozapine, induced *zif/268* mRNA but not *c-fos*. With chronic (2 weeks) administration the IEG responses to haloperidol, clozapine, and amphetamine were partly desensitized. The apparent paradox that both a dopamine antagonist (haloperidol) and an indirect agonist (amphetamine) activated striatal *c-fos* expression prompted us to perform an immunohistochemical analysis with an antibody specific for *c-fos* protein. This revealed marked differences in the pattern of *c-fos* expression. A single dose of haloperidol preferentially induced expression in cells in the dorso-lateral striatum while amphetamine increased expression in cells in the ventro-medial region.

RATIO OF POTENCY OF ANTIPSYCHOTIC DRUGS (APD) IN DISPLACING DA-2 AND 5HT-2 RECEPTOR BINDING IN VIVO DISCRIMINATES BETWEEN TYPICAL AND ATYPICAL ANTIPSYCHOTIC DRUGS. C.A. Stockmeier, J.J. DiCarlo*, Y. Zhang* and H.Y. Meltzer. Depts. of Psychiatry, Neuroscience and Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

Atypical APD, as opposed to typical APD, have higher *in vitro* ratios of the pK_i values for 5HT-2 binding in cortex divided by the pK_i values for DA-2 binding in striatum (JPET 254:238, 1989). We sought to determine if this *in vitro* distinction between atypical and typical APD could also be obtained *in vivo* in rat brain. Rats were pre-treated with increasing doses of APD followed by 3 H-n-methyl-spiperone (3 H-NMSP), and killed 60 min later. Cinanserin, cyproheptadine and ritanserin, but not pindolol, blocked *in vivo* binding only in frontal cortex; raclopride potently blocked *in vivo* binding only in striatum and olfactory tubercle. The putative atypical APD clozapine, melperone, amperozide, tiospirone, HP 370, fluperlapine, risperidone, perlapine, FG 5803 and RMI 81,582 were all more potent against 5HT-2 than DA-2 binding sites. Atypical APD were slightly but significantly more potent at olfactory tubercle than striatal DA-2 receptors. The ratios of 5HT-2 (cortex)/DA-2 (striatum or olfactory tubercle) pED_{50} values were significantly greater for atypical than typical APD. It appears that the ratio of the potency at 5HT-2 to DA-2 binding sites rather than the absolute potency is crucial in a drug being classified as an atypical APD. 269.14

THE EFFECT OF AMPEROZIDE (AMP) ON BASAL AND AMPHETAMINE (AMPHET)-STIMULATED DOPAMINE (DA) RELEASE IN RAT STRIATUM (STR) AND NUCLEUS ACCUMBENS (NA) \downarrow Ichikawa* and H.Y. Meltzer, Dept. of Psychiatry, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

Amperozide, a piperazine carboxamide, is a putative atypical antipsychotic drug with strong serotonin (5-HT)₂ and no apparent DA₂ or DA₁ antagonist properties *in vivo*. It is a potent DA uptake blocker. Its ability to modulate the availability of DA *in vivo* was studied by means of *in vivo* microdialysis using awake, freely-moving rats. AMP (2.5-10 mg/kg, s.c.) significantly increased extracellular DA levels in both regions (maximum levels 145% of basal value), whereas AMP (1-5 mg/kg, s.c.) dose-dependently decreased D-AMPHET- (1.0 mg/kg, s.c.)-induced DA release (maximum increase 43-fold) in both regions. AMP alone had only a slight effect on extracellular DOPAC levels. AMP had no effect on the AMPHET-induced decrease (70% of basal) DOPAC levels in either region. The results suggest that amperozide acts on a carrier-mediated mechanism to block the effect of AMPHET on DA release. Chronic administration of AMP (2 mg/kg/day) in drinking water for 21 days followed by a 3 day washout increased basal extracellular DA in the STR but decreased it in the NA. It enhanced the D-AMPHET-induced DA release in the STR but inhibited it in the NA. The effect of AMP to inhibit DA release in the NA may be related to its antipsychotic action.

269.16

COMPARISON OF THE EFFECTS OF STANDARD NEUROLEPTICS ON THE REFLEX RESPONSES TO BILATERAL CAROTID OCCLUSION: A MODEL OF ORTHOSTATIC STRESS. C.M. Detig*, S.E. Aschoff*, D.M. Howard*, J.W. Hubbard, P.L. Wood, A.J. Gorman*. Department of Biological Research, Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ, 08876

It has been clinically recognized that a prominent side-effect of neuroleptic treatment is orthostatic hypotension due to an inhibition of compensatory circulatory mechanisms. The present study utilizes a chloralose-anesthetized dog model of orthostatic stress and compares the relative potency of risperidone (RIS), clozapine (CLOZ), and haloperidol (HAL) on cardiovascular reflex responses to bilateral carotid occlusion (BCO). Each agent was administered intraduodenally at 1x and 4-5x the oral ED₅₀ value for inhibition of pole climb avoidance in rats. RIS (0.5 mg/kg; 1x ED₅₀) attenuated reflex increases in mean arterial pressure (MAP), total peripheral resistance (TPR), and cardiac output (CO) by -84%, -72%, and -100%, respectively. At 5x ED₅₀, CLOZ (60 mg/kg) elicited similar inhibitory effects on reflex responses to BCO (MAP: -66%; TPR: -73%; CO: -100%). In fact, CO decreased by 48% and 44% during BCO after RIS and CLOZ, respectively. Less of an inhibitory influence on BCO-mediated responses was exhibited by HAL at 2 mg/kg, 4x ED₅₀ (MAP: -34%; TPR: -65%; CO: -83%). Therefore, the relative potency of the standard neuroleptics for inhibiting circulatory reflex responses to BCO is RIS > CLOZ > HAL. This model may be useful for preclinical assessment of the relative potential of neuroleptic agents to produce orthostatic hypotension.

270.1

THE REVERSAL OF EXTRAPYRAMIDAL SIDE EFFECTS (EPS) WITH SCH 39166, A D1 ANTAGONIST, IN HALOPERIDOL-SENSITIZED MONKEYS. D.T. McHugh*, A. Barnett and V.L. Coffin. Schering-Plough Research, Bloomfield, NJ, 07003.

Cebus monkeys (female n=5), with a history of haloperidol administration (daily for 28 wks), produced EPS when given either haloperidol or SCH 39166 acutely. EPS was characterized by limb extensions, facial grimacing, chewing and/or tongue protrusions. In agreement with prior work these monkeys are sensitized. This sensitization does not fade with time. Even after 100 drug free days, both dopamine antagonists given acutely still could produce EPS in these monkeys. However, if SCH 39166 is given repeatedly, the EPS observed lessened and then completely disappeared within 5 days. The sedation observed with SCH 39166 was still present after repeated administration, thus tolerance did not develop to this central effect.

Cebus monkeys (female n=6) with a history of SCH 39166 administration (daily for 28 wks.), never produced EPS with SCH 39166. Furthermore, SCH 39166 did not sensitize the monkeys to the effects of haloperidol on EPS. SCH 39166 treated monkeys showed significant sedation compared to vehicle treated monkey (n=6) throughout the 28 weeks.

Thus these studies further emphasize the differences between D1 and D2 antagonists with respect to EPS liability.

270.3

NEUROLEPTIC-INDUCED STRIATAL NEURON LOSS: RELATIONSHIP TO AGE. JB Lohr, J. Browning*, and DV Jeste. Department of Psychiatry, UCSD, and Psychiatry Service, VA Medical Center, V-116A, San Diego CA 92161.

Tardive dyskinesia (TD) is a potentially irreversible movement disorder caused by long-term use of neuroleptics. We have previously demonstrated that there is a loss of large neurons in the striatum after 8 months of neuroleptic treatment in rats. Because advanced age is a well-established risk factor for the development of TD, we studied whether age is also a risk factor for striatal neuron loss in rats treated long-term with neuroleptics. **Methods:** We administered fluphenazine decanoate 5 mg/kg or sesame oil every two weeks for four months to three groups of animals; aged 3 months (n=12), 9 months (n=10), and 18 months (n=10). The brains were removed and fixed in formalin and 12 micron thick sections were stained with cresyl violet. Neuron density was calculated in the central striatum using an IBAS 2000 image analysis system. **Results:** There was a loss of both medium-sized and large neurons with age in both treated and control animals, although the loss was greater in the large cells. With fluphenazine treatment there was a significant decrease in large cell density ($t=2.37$, $df=8$, $p<0.05$) in the 9 month old group only. In the 18 month old group, there was no difference between treated and control animals, but there were very few large neurons in either group. **Discussion:** In conclusion, age appears to be a risk factor for neuroleptic-induced neuron loss, and neuroleptics appear to accelerate a process of age-related large cell loss in the striatum. This study was supported by VA Merit Review Grants to JBL and DVJ, and NIMH Grant R29MH45142 to JBL.

INTERACTIVE EFFECT OF HALOPERIDOL, DEXAMETHASONE AND HYPOTHERMIA STRESS ON HALOPERIDOL INDUCED CATALEPSY. H.L. Schreiber and Carole Slotterback Oakes*. Dept. of Psychology, Univ. Texas at Tyler, Tyler, TX, 75701 and Dept. of Behav. Sci., Highlands Univ., Las Vegas, NM 87701.

In a 2X2X2 factorial design, 96 male rats, matched by weight, received dexamethasone, 400 µg/kg or the corn oil vehicle, followed 30 min later by a high dose of haloperidol (3 mg/kg) or saline, which in turn was followed 30 min later by forced cold water immersion (2 min, 3rd) or by being left in their individual home cages (N/cell=12). Three days later, all rats received haloperidol (1mg/kg, IP) one hour prior to holeboard and latency-to-remove-forepaw catalepsy testing. Analyses of variance revealed significant interactions (dexamethasone history by haloperidol history by immersion history) in catalepsy, $F(1,72)=4.22$, $p<.05$, and in locomotion, $F(1,72)=6.13$, $p<.02$. Among saline history rats, catalepsy was significantly increased by a history of dexamethasone treatment, cold water immersion, or both, in relation to control rats. These effects were not seen among haloperidol history rats. Also, a history of dexamethasone administration, cold water immersion or both significantly diminished locomotion among saline history but not haloperidol history rats. These results indicated a discernible effect of adrenocortical perturbations on catalepsy which was abolished by a single haloperidol administration.

ENHANCED PROLACTIN ELEVATION WITH CHRONIC LOW-DOSE HALOPERIDOL IN THE RAT. H.I. Ryer, J. Woo* and M.R. Lynch. Dept. Psychiat. NYU, VAMC, New York, NY 10010 and Depts. Psychiat. and Pathol., SUNY HSC, VAMC, Syracuse, NY 13210

Typical neuroleptics such as haloperidol (H) are antipsychotic by virtue of central D2 receptor blockade. TIDA DA exerts tonic inhibitory regulation over prolactin (PRL) secretion. In the absence of direct receptor measurements, PRL has been used as an index of central DA antagonism. The clinical significance of this measure remains controversial; PRL response may be correlated with clinical variables in certain schizophrenic subpopulations. Moreover, there are reports of both tolerance to PRL elevation and a lack thereof. More dorsal A9 and A10 areas show an enhanced response to chronic H, mimicking delayed-onset clinical effects. The question addressed here was whether PRL elevation shows tolerance or sensitization to chronic H in a therapeutic dose (0.1 mg/kg). N=6-8/group male rats received daily injections of H or vehicle for 21 days. A separate group of N=5 received acute H 90-min prior to PRL assay with a double antibody RIA (NIDDK-r-PRL-RP-3). Acute H increased PRL from 14.9 ± 3.4 to 28.3 ± 3.0 ($\bar{X} \pm SEM$, $p>.05$); the final dose in chronic H animals (day 21) induced an almost two-fold greater stimulation (49.8 ± 6.2 , $p<.01$) which returned to baseline at 48 hr withdrawal. As challenge with 0.07 mg/kg apomorphine failed to reveal evidence for upregulation, the mechanism for this enhanced response remains to be determined.

270.4

BEHAVIORAL SENSITIZATION TO INTERMITTENT COCAINE ADMINISTRATION: EFFECTS OF CHRONIC HALOPERIDOL. P.A. LeDuc and G. Mittleman. Dept. of Psychology, Memphis State Univ., Memphis, TN 38152.

This experiment examined the effects of chronic haloperidol (HAL) treatment on locomotion and stereotyped behavior elicited by intermittent injections of cocaine (CHCL). Female Long Evans rats received injections of HAL (0.2 mg/kg, ip) or vehicle for 6, 12, or 18 days prior to the start of testing with CHCL. Daily injections of HAL were continued throughout CHCL testing. All rats received 4 doses of CHCL (0.0, 3.0, 7.5, or 15.0 mg/kg) in random order with an intervening vehicle day between successive drug days. The 4 dose sequence of CHCL was repeated a total of 4 times. Initial CHCL administration produced dose dependent increases in locomotion and stereotyped behavior. When the 4 dose sequence of CHCL was repeated, differences among treatment groups emerged. Specifically, groups treated with HAL exhibited heightened locomotion in response to CHCL (all doses) in comparison to vehicle treated controls. Additionally, with repeated injections, CHCL-induced locomotion showed a higher rate of sensitization in HAL treated rats. In order to examine the mechanisms underlying the heightened responsiveness to CHCL, locomotion in response to Apomorphine (0.0-250 µg/kg, sc) was determined. Regardless of dose, rats treated with HAL showed significantly more locomotion in response to apomorphine suggesting changes in the sensitivity of pre- and postsynaptic receptors. Overall, these results indicated that chronic treatment with HAL results in heightened responsiveness to acute CHCL as well as more rapid behavioral sensitization to repeated administration. This increased responsiveness is related to apparent autoreceptor down-regulation combined with postsynaptic up-regulation.

270.6

A RAPID COLOR-BASED VIDEOTRACKER FOR BEHAVIORAL STUDIES: APPLICATION TO STUDIES OF TARDIVE DYSKINESIA IN HUMANS. S. ZEIGLER, A. KEYS*, G. ELLISON and W. WIRSCHING*. Department of Psychology, UCLA, 405 Hilgard Ave., Los Angeles, CA 90024

The form of the altered Oral movements (OMs) in rats administered chronic neuroleptics have been successfully measured using computerized spot-detection circuitry involving fluorescent dyes placed on the rat's muzzle. We now report an extension of these procedures to humans using a new rapid color-detection circuit called the "Multitracker".

In these studies small colored spots were placed on the upper and lower lips of human patients receiving chronic neuroleptics. The resulting video records (30/sec) were analyzed by computer using fast-fourier and other analytic methods and the results compared with those of normal controls. This method permits the study of both vertical and lateral components of the altered oral movements observed in tardive dyskinesia without any attached device, permitting minimal disturbance of the patient. In a further refinement of this methodology, two video cameras can be used to record simultaneously oral movements and movements of the hands and feet so that the exact temporal relationship between different body movements can be quantified. This "Multitracker" system is applicable to a wide range of behaviors in humans and animals.

270.7

N-CYCLOHEXYLBENZAMIDES: A NOVEL CLASS OF DOPAMINE AUTORECEPTORS AGONISTS WITH POTENTIAL ANTIPSYCHOTIC ACTIVITY. L.D. Wise, J.C. Jaen*, B.W. Caprahe*, S.J. Smith*, T.A. Pugsley and T.G. Heffner. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor MI 48105.

As part of a project to develop a selective dopamine (DA) autoreceptor agonist as an improved agent for the treatment of schizophrenia, *trans*-N-[4-[4-(2-pyridinyl)-1-piperazinyl]-cyclohexyl]benzamide (PD136515) was identified as a chemical lead. As expected of a DA autoreceptor agonist, this compound was found to have affinity for DA D-2 receptors, to reverse gamma-butyrolactone-stimulated DA synthesis and to inhibit spontaneous locomotor activity in rodents. SAR studies demonstrated that while activity was retained with the *trans*-4-(piperazinylethyl)cyclohexyl analog, the *trans*-piperazinylmethyl and propyl analogs were much less active as were all of the *cis*-isomers. In addition, the pyridinylpiperazine could also be replaced with a phenyltetrahydropyridine group and the benzamide phenyl group with various heterocycles without a loss of activity. PD138276, *trans*-N-[4-(3,6-dihydro-4-phenyl-1(2H)-pyridinyl)-cyclohexyl]-4-fluorobenzamide, based on its overall profile was selected for further studies.

270.9

EFFECTS OF THE NOVEL DOPAMINE AUTORECEPTOR AGONIST PD 135222 IN NEUROPHYSIOLOGICAL, NEUROCHEMICAL AND BEHAVIORAL TESTS IN RODENT AND MONKEY. L.M. Ball, L.W. Cooke, A.E. Corbin, T.A. Pugsley, F.W. Ninteman, L.T. Meltzer, T.G. Heffner and M.D. Davis Dept. of Pharmacology, Parke-Davis Pharm. Research Division, Warner Lambert Co., Ann Arbor, Michigan 48105.

PD 135222, (±)-1-(2-pyridinyl)-4-[4-(2-pyridinyl)-3-cyclohexenyl]-piperazine, is a dopamine (DA) autoreceptor agonist as demonstrated in neurophysiological, neurochemical and behavioral tests. PD 135222 bound selectively to DA D₂ receptors (IC₅₀=100nM). In the gamma-butyrolactone (GBL) model, PD 135222 reversed the GBL-induced increase in striatal DA synthesis with an ED₅₀ of less than 10mg/kg i.p. In neurophysiological tests, PD 135222 (2.5 mg/kg i.p.) produced a 78% inhibition in firing of A9 DA neurons in chloral hydrate-anesthetized rats. Behaviorally, PD 135222 inhibited spontaneous locomotion in mice (ED₅₀=0.9mg/kg i.p.) and rats (ED₅₀=5.8mg/kg p.o.), consistent with presynaptic activation of DA receptors. PD 135222 also inhibited conditioned avoidance responding after oral dosing in squirrel monkeys (*Saimiri sciurea*) (ED₅₀=3.5mg/kg). Intracerebral microdialysis (ICMD) of the striatum/putamen was used to assess changes in extracellular neurotransmitter levels in both anesthetized and awake Sprague Dawley rats, and squirrel monkeys implanted with guide cannula. As measured by HPLC-EC, PD 135222 (3-10 mg/kg p.o. and i.p.) decreased DA overflow 40-60%. In rats, this effect was reversed by the DA antagonist haloperidol. BHT-920, another DA D₂ agonist, also decreased DA overflow to a similar degree. PD 135222 decreased acetylcholine (ACH) levels using ICMD in conscious and anesthetized rats, an effect seen with DA D₂ agonists such as LY171555 (quinpirole), but not with DA antagonists such as remoxipride. These results indicate that PD 135222 is a potent and efficacious DA autoreceptor agonist.

270.11

EFFECT OF SERTINDOLE, CLOZAPINE AND HALOPERIDOL ON THE DISCRIMINATIVE STIMULUS PROPERTIES INDUCED BY D-AMPHETAMINE, D-LSO AND ST 587 IN RATS.

J. Arnt Pharmacological Research, H. Lundbeck A/S, Ottiliavej 9, DK 2500 Valby Copenhagen, Denmark.

Classical neuroleptics induce extrapyramidal side effects (EPS), and have preferential dopamine (DA) antagonistic activity. The atypical neuroleptic clozapine has preferential inhibitory effect on serotonin (5-HT₂) receptors and α₁-adrenoceptors, compared with its weak effect on DA receptors. In this study the relative effects on the stimulus properties induced by AMPH (1 mg/kg, i.p.), the 5-HT₂ agonist d-LSD (0.16 mg/kg, i.p.) and the α₁-adrenoceptor agonist St. 587 (1 mg/kg, i.p.) were studied for haloperidol, clozapine and the putative antipsychotic sertindole (Skarsfeldt & Perregaard, Eur. J. Pharmacol. 182, 1990, 613). For each training drug discrimination vs. saline was acquired in water-deprived rats responding in a FR 32 schedule in 2-lever chambers. Haloperidol (2 h s.c. pretr.) antagonized the effect of AMPH (ED₅₀ 0.3 μmol/kg), but did not block the effect of d-LSD or St 587 in doses increasing reaction times. Clozapine (1 h s.c. pretr., ED₅₀ values in μmol/kg in parentheses) inhibited the effect of AMPH (7.2), d-LSD (6.4) and St 587 (0.78). Sertindole (2 h s.c. pretr.) inhibited the effect of d-LSD (0.17) and St 587 (0.52), but did not antagonize the effect of AMPH in doses up to 23 μmol/kg. Thus neuroleptics differ markedly in their relative in vivo effects on DA, 5-HT₂ and α₁-adrenergic receptors studied by drug discrimination. This may have importance for the different clinical profiles of neuroleptics.

270.8

EFFECTS OF THE DOPAMINE AUTORECEPTOR AGONIST PD 138276 IN BEHAVIORAL, NEUROCHEMICAL AND NEUROPHYSIOLOGICAL TESTS. A.E. Corbin, C. Christoffersen, L.T. Meltzer, S. Whetzel*, T.A. Pugsley, J.N. Wiley*, Y.S. Shih* and T.G. Heffner. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.

The benzamide PD 138276 was found to be a dopamine (DA) autoreceptor agonist in preclinical tests. PD 138276 bound to DA D₂ receptors in vitro (IC₅₀ = 13.8 nM), inhibited the firing of substantia nigra DA neurons and reversed gamma-butyrolactone-stimulated brain DA synthesis in rats. Consistent with activation of brain DA autoreceptors in vivo, PD 138276 reduced locomotor activity in mice (ED₅₀ = 0.2 mg/kg, i.p.). At higher doses, PD 138276 reduced the stimulation of locomotor behaviors in mice caused by the DA releasing agent amphetamine (ED₅₀ = 2 mg/kg, i.p.) and by the direct DA agonist apomorphine (ED₅₀ = 7.4 mg/kg, i.p.), effects that may stem from weak partial agonist properties. Relative selectivity for presynaptic DA receptors was evidenced by the lack of locomotor stimulation and stereotypy at high multiples of the ED₅₀ for locomotor inhibition in rats. Postsynaptic DA agonist effects were revealed in rats only after co-administration of high doses of PD 138276 with a DA D1 agonist. The effects of PD 138276 in rats persisted for up to 12 h after a single oral dose. Collectively, these results indicate that PD 138276 is an orally-active DA autoreceptor agonist with relative selectivity for presynaptic DA receptors.

270.10

GABAERGIC AND DOPAMINERGIC DYSREGULATION IN THE BASAL GANGLIA FOLLOWING CHRONIC HALOPERIDOL TREATMENT: PUTATIVE RELATIONSHIP TO PATHOPHYSIOLOGY OF TARDIVE DYSKINESIA O. Shirakawa, X.M. Gao, F.I. Tarazi, T. Kakigi*, H. Kaneda, C.A. Tamminga. Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD. 21228

Chronic neuroleptic treatment in rats often leads to spontaneous orofacial movement, described as vacuous chewing movements (VCMs). Many characteristics of VCMs are similar to tardive dyskinesia (TD) in humans (Tamminga, C.A. *Psychopharmacol.* 102, 474, 1990). Co-administration of the GABA receptor agonist progabide with haloperidol (H) inhibits the development of VCMs (Shirakawa, O. *Neurosci. Abst.*, 1989). To identify the neurochemical pathophysiology of VCMs, we studied several measures in 6 month H-treated rats: (1) quantitative regional cerebral glucose metabolism; (2) GABA-A and D1 and D2 receptor densities; (3) correlations between regional neurochemical changes and VCMs. H treatment decreases glucose utilization in extrapyramidal areas and nigral efferent structures, except for the caudate-putamen (CP). H treatment increases D2 receptor binding in CP and GABA-A receptor binding in substantia nigra reticulata (SNR), but without a direct correlation with VCMs. However, VCMs show a significant correlation with the ratio of D2/D1 receptor density in CP and GABA-A/D1 receptor density in SNR. These results suggest that chronic H treatment alters D2/D1 receptor sensitivity in striatum, which leads to VCMs by altering GABA release at D1-regulated synapses in SNR. Thus, hypofunction of nigral efferent pathways, occasioned by a cascade of neurochemical changes in extra-pyramidal structures, appears to underlie VCMs, and perhaps TD.

270.12

EFFECT OF CHRONIC TREATMENTS WITH NICOTINE AND HALOPERIDOL ON NICOTINE POTENTIATION OF HALOPERIDOL INDUCED CATALEPSY. M.D. Zanol*, P.R. Sanberg, D.F. Emerich, B.J. McConville*, L.M. Ford and A.B. Norman. University of Cincinnati College of Medicine, and Cellular Transplants, Inc., Providence, Rhode Island 02906.

Nicotine markedly potentiates the locomotor inhibiting effects of neuroleptics such as haloperidol. Furthermore, coadministration of nicotine with haloperidol has been found useful in further reducing tic frequency and severity in patients with Tourette's Syndrome. We investigated whether chronic treatment with haloperidol or nicotine could modify the interaction between these drugs.

Male Sprague-Dawley rats received 21 daily injections of haloperidol (0.8 mg/kg/day i.p.) or saline. One day after the last injection haloperidol and saline treated rats were divided into 4 groups and received saline only, saline + nicotine, haloperidol + saline, or haloperidol + nicotine. Catalepsy was monitored 2 or 4 hours following the last injection. Nicotine alone produced no significant catalepsy in either group. The catalepsy produced by haloperidol was reduced demonstrating tolerance. Although the magnitude of the nicotine potentiation of haloperidol catalepsy was reduced in the chronic haloperidol-treated rats there was a significant potentiation of the haloperidol catalepsy proportionately similar to that observed in control rats. In a separate experiment rats received either nicotine (5 mg/kg/day p.o.) for 28 days via drinking water or water alone. Rats were then divided and treated as in the previous experiment. Nicotine produced no catalepsy in either group. There was no significant potentiation of haloperidol catalepsy in the chronic nicotine treated rats. Continuous administration of nicotine may produce a tolerance to the beneficial effects in Tourette's patients receiving haloperidol. Intermittent administration of nicotine may avoid this.

PARTIAL DOPAMINE AGONIST -3PPP: PHARMACOKINETIC AND PHARMACODYNAMIC CHARACTERISTICS IN MAN. C.A. Tamminga, N. Cascella, R. Lahti, A. Carlsson. Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228 and Department of Pharmacology, University of Göteborg, Göteborg, Sweden

The partial DA agonist -3PPP acts at the D₂ autoreceptor to reduce DA turnover, diminish rat locomotor behavior, and inhibit DA neuronal firing. Based on its antidopaminergic properties, it is being studied as a novel drug treatment for schizophrenia. It has currently been administered to eight schizophrenic patients for safety and preliminary efficacy study, in doses up to 40 mg IM. Kinetic analysis suggests a plasma half life of 2-2.5 hours, with peak plasma levels of 200-500 nmolar after 30 mg IM. Growth hormone (GH) levels increase in a linear fashion through a dose of 30 mg IM, then precipitously fall to basal GH levels with higher -3PPP doses. Additional endocrine response data will be reported. Four schizophrenic subjects without other CNS medication, were given -3PPP doses up to 40 mg/kg. After the highest dose administered, mental status changes were seen in each subject which resembled a "calming" effect. Two of the subjects failed to respond to -3PPP with any specific antipsychotic effect; one subject had a mild antipsychotic effect, while a single subject had a robust antipsychotic response. These data suggest the feasibility of -3PPP use in schizophrenia and are consistent with its potential therapeutic activity.

270.15

PHARMACOLOGICAL PROFILE OF A NOVEL DOPAMINE-FATTY ACID BIOCONJUGATE WITH CNS ACTIVITY. G.W. Hesse and V.E. Shashoua. Ralph Lowell Laboratories, McLean Hospital, Harvard Medical School, Belmont, MA, 02178.

The behavioral pharmacology of a novel bioconjugate of dopamine was investigated. The compound, which consists of a fatty acid amide linked to dopamine, readily crosses the blood-brain barrier of mice and rats. It inhibits the spontaneous locomotor activity of mice with an ED50 dose of about 12 µmol/kg. No evidence of hyperactivity, catatonia, stereotypy or toxicity has been observed at doses up to 100 times the ED50. The effects of the compound are antagonized in a dose dependent manner by sulpiride, but not by domperidone. The compound appears to have little or no post-synaptic dopaminergic activity. It does not reverse reserpine induced depression of spontaneous locomotor activity, and it does not induce rotation in rats unilaterally depleted of dopamine with 6-OHDA. Finally, daily administration for three weeks produced little or no tolerance. This novel dopamine bioconjugate has behavioral effects which are similar to those of dopamine agonists selective for dopamine D2 autoreceptors.

270.14

MEASUREMENT OF DRUGS USED IN PSYCHIATRY BY FREE ZONE CAPILLARY ELECTROPHORESIS WITH UV DETECTION. M.A. Javors, M.S. De Buysere*, T.S. King, and C.L. Bowden. Departments of Psychiatry, Pharmacology, Cellular and Structural Biology, and Biochemistry, University of Texas HSC, San Antonio, TX 78284-7792.

The purpose of this study was to evaluate the use of capillary electrophoresis with UV detection for the separation and quantitation of psychiatric drugs and their metabolites and to make a preliminary evaluation of the usefulness of this method for clinical and research studies in which these drugs would be measured in biological fluids. We used free zone capillary electrophoresis with a capillary tube that was 75 microns in diameter and 50 cm long, UV detection at 214 nm, and 100 mM phosphate buffers at pH's between 7 and 10. Depending on the running buffer, we varied the voltage between 10 and 25 kV so that the current was constant between 200 and 250 µA. All of the compounds we tested were amines. For all compounds tested, the peak area was linear with concentration between 2.5 and 25 µg/ml (25 nl constant sample volume). Peak height was curvilinear with concentration in the same range. Compounds were best separated from their structurally similar metabolites at running buffer pH's near the pKa's of the compounds. Not all compounds could be separated at any given running buffer pH. We successfully quantitated fluoxetine and its metabolite norfluoxetine in plasma and compared our results to measurements made with HPLC and UV detection. A disadvantage of this method in its present form was that absolute identification of the compounds was not possible. However, in patients that were taking only a specific drug, we were able to quantitate the drug and its metabolites. The development of more sensitive methods of detection would permit therapeutic drug monitoring from very small plasma sample volumes.

270.16

EFFECTS OF DOPAMINE (DA) ANTAGONISTS AND AGONISTS ON DENTATE GYRUS FIELD POTENTIALS IN ANESTHETIZED RATS. K.A. Serpa and L.T. Meltzer. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Multiple lines of evidence provide a rationale for studying the hippocampus as a site involved in schizophrenia and the action of antipsychotic agents. Thus, we have begun to evaluate the effect of DA antagonists and agonists on dentate gyrus field potentials (FPs) elicited by electrical stimulation of the perforant path in urethane anesthetized rats. The effects of the D-2 antagonist, haloperidol (HAL), and D-2 agonist, quinpirole (QUIN), on dentate FPs were variable. HAL (100 µg/kg i.v.) increased the population spike (PS; 5 of 8 experiments) but did not effect the EPSP. QUIN (100 µg/kg i.v.) increased the PS (3 of 6 experiments) and produced decreases and increases in the EPSP. Despite the variability, the magnitude of the changes were much greater than occurred during vehicle treatment. It is unclear why both a D-2 antagonist and agonist produce similar effects. In contrast, neither the D-1 agonist, SKF 77434 (10 & 20 mg/kg i.v.; N-allyl analog of SKF-38393), nor the D-1 antagonist, SCH 23390 (100 µg/kg i.v.), had little effect on dentate gyrus field potentials. These initial data suggest that DA D-2 agents but not DA D-1 agents modify dentate FPs.

ALZHEIMER'S DISEASE: NEUROPATHOLOGY II

271.1

MIDLIN THALAMIC PATHOLOGY IN ALZHEIMER'S DISEASE. V.E. May*, W.G. Tourtellotte and G.W. Van Hoesen. Depts. of Anatomy and Neurology, Univ. of Iowa, Iowa City, IA 52242.

The midline thalamic nuclei are known to have direct connections with structures critical for learning and memory such as the hippocampal formation and entorhinal cortex. Damage to the mediodorsal and midline thalamic nuclei has been shown to impair memory in humans and non-human primates. For these reasons, and because memory impairment is a hallmark of Alzheimer's disease (AD), we investigated the integrity of thalamic nuclei in 15 AD cases and 8 age-compatible controls.

Formalin fixed tissue blocks containing the thalamus were cut on a freezing microtome and stained with Thioflavin S, Nissl and Alz-50 (8 cases, 4 controls). The salient findings are as follows: (1) There were numerous neurofibrillary tangles in both the midline medioventral (reuniens) and paraventricular nuclei of the thalamus; (2) Neuritic plaques were observed in these same nuclei in 7 AD cases; (3) There were abundant NFTs and NPs in the mediodorsal nucleus in 6 AD brains, and in anteroventral nucleus of 2 AD brains; (4) Neither NFTs nor NPs were observed to any degree in other thalamic nuclei; and (5) None of the control cases had NFTs or NPs in any thalamic nuclei.

The paraventricular and medioventral nuclei of the thalamus appear to have a selective vulnerability in AD. The NFTs and NPs seen in these nuclei are likely to disrupt the connections that link these structures with the medial temporal region, thus further deafferenting them and compromising the circuits on which memory processing depend. (Supported by NS 14944 and PO NS 19632.)

271.2

MODULAR ORGANIZATION OF THE HUMAN ENTORHINAL CORTEX. Solodkin, A., Kullis, R.O. and Van Hoesen, G.W. Depts. of Anatomy and Neurology, The University of Iowa College of Medicine, Iowa City, IA 52242.

The entorhinal cortex (EC; Brodmann's area 28) that forms the anterior part of the parahippocampal gyrus, is an important connective link between sensory and multimodal neocortices and the hippocampal formation. By gross inspection of the ventromedial temporal lobe, a modular anatomical organization of this area is suggested by the presence on its surface of *warts* or *verrucae*.

We have examined the EC using cyto- and myeloarchitectonic stains, immunolabeling for various neurochemicals (SP, NPY, GAD) and histochemistry for oxidative enzymes (NADPH, AChE) in blocks of human tissue sectioned in the coronal and tangential planes. For the latter, we have used a method to prepare flat mounts of EC that are cut parallel to the pial surface.

Our results reveal that the EC is formed by a mosaic of columnar components whose most conspicuous elements are the islands of cells of layer II and myelinated fibers that form columns around these islands. The impressions of these cell islands and their surrounding neurites constitute the surface *verrucae*. Additional observations showed the presence of cellular bridges interconnecting two adjacent islands. Module-like compartments are also revealed by AChE histochemistry, in contrast to other subpopulations of local circuit cells (NADPH, SP, NPY, GAD).

The unique organization of the EC has several important implications: a) anatomically evident modules are present not only in sensory and motor cortices; b) these modules could be the basis of physiologically distinct operations; c) since EC is the area most affected in Alzheimer's disease, these data provide a basis to study its pathology in the context of modular organization. Supported by NS 14944 and PO NS 19632.

271.3

PARVALBUMIN IMMUNOREACTIVE INTERNEURONS ARE DIFFERENTIALLY LOST IN HIPPOCAMPAL FORMATION OF ALZHEIMER'S DISEASED BRAIN. D.R. Brady and E.J. Mufson. Inst. Biogeront. Res., Sun City, AZ 85351; NIA/NIH, Bethesda, MD 20892; Rush Med. Ctr., Chicago, IL 60612.

Projection neurons of the entorhinal cortex and subiculum/CA1 subfields of the hippocampal formation undergo severe degenerative changes in Alzheimer's disease (AD). However, the fate of interneurons in the hippocampal formation remains unclear. Using a monoclonal antibody against parvalbumin, which distinguishes a subset of fast-firing GABAergic interneurons, we ascertained the topography of PV immunoreactive neurons in postmortem, paraformaldehyde fixed hippocampal formation from normal (X=64 yrs; n=8) and AD (X=81 yrs; n=12) brains. In normal hippocampus, PV interneurons were aspiny and pleomorphic, with extensive dendritic arbors. In dentate gyrus, PV cells, as well as a dense plexus of fibers and puncta, were associated with the granule cell layer. A few cells also occupied the molecular layer. In strata oriens and pyramidale of CA1-CA3 subfields, PV neurons gave rise to dendrites that extended into adjacent strata. Densely stained puncta and beaded fibers occupied stratum pyramidale, with less dense staining in adjacent strata oriens and radiatum. Virtually no PV profiles were observed in stratum lacunosum-moleculare or the alveus. Numerous polymorphic PV neurons and a dense plexus of fibers and puncta characterized the deep layer of the subiculum and the lamina principalis externa of the presubiculum. In AD hippocampus, there was a significant decrease in the number of PV interneurons in the dentate gyrus/hilar subfield (P<.05) and subfields CA1-CA2 (P<.01). In contrast, PV neurons did not appreciable decline in subfields CA3, subiculum or presubiculum in AD brains relative to normals. Staining with thioflavin-S did not reveal any degenerative changes associated with PV stained profiles. These findings indicate that PV interneurons within specific hippocampal subfields are selectively vulnerable in AD. This vulnerability may be related to their differential connectivity. Support: ADCRC, NIH and AHAF.

271.5

PRELIMINARY CHARACTERIZATION OF A NOVEL ALZHEIMER'S DISEASE ASSOCIATED PROTEIN.

D.J. Gunnerson, B.E. Haley, and J.T. Slevin. Departments of Neurology and Biochemistry, University of Kentucky, Lexington, KY 40536.

To characterize some of the biochemical changes in the Alzheimer's Disease (AD) brain, two-dimensional gel electrophoresis was performed. Use of this technique resulted in the observation of a constellation of proteins near the β -tubulin band that appeared in confirmed AD samples only. The constellation consisted of 5-7 proteins with approximate M_r values of 55-56 kDa and a pI ranges of pH 4-5. These proteins were present in 18 of 18 AD cases examined and absent in 11 of 11 age-matched controls (including other neurological diseased controls). Preliminary characterization of this protein constellation has begun. For example, a. the proteins do not react with α -tubulin antibodies in 2-D Westerns, and b. these proteins can be phosphorylated by [γ - 32 P]ATP. Procedures used to purify, characterize, and sequence these proteins will be presented. To determine if the presence of the protein constellation represents a systemic metabolic defect or if the phenomenon is unique to AD brain, fibroblast cell lines were also examined. Initial experiments indicate that the protein constellation is not present in AD fibroblasts. (Supported by NIH Grants GM35766 and PO1AG05199 and the VA Research Service)

271.7

RECIPROCAL PATTERNS OF UBIQUITIN IMMUNOREACTIVITY IN NORMAL AGED AND ALZHEIMER'S DISEASE BRAIN A.E. Singer, N.W. Kowall, A.C. McKee, Harvard Medical School, Boston MA 02114

A wide variety of intracellular inclusions are ubiquitin immunoreactive (imr) including dot-like structures (DLS), an age-related feature of normal brain. We examined ubiquitin imr in the temporal lobes of 10 aged controls and 10 patients with AD. In control brains, ubiquitin imr DLS were found in CA3, CA2, and to a lesser extent, CA4 and white matter. Occasional smaller DLS were present in the dentate gyrus. Scattered punctate and threadlike ubiquitin imr dystrophic neurites (DN) and rare neurofibrillary tangles (NFT), morphologically similar to typical tau positive DN and NFT but distinct from DLS, were found in CA1 and subiculum. DLS were infrequent in these areas. Occasional ubiquitin imr DN were found in layer 2 of lateral and intermediate entorhinal cortex, whereas dense DLS were prominent in layer 2 of medial entorhinal cortex. DLS were evenly and densely deposited in the superficial layers of transentorhinal and temporal neocortex. In all regions, a few diffusely positive neurons were found, often with intensely positive granular nuclear staining. In AD, diffusely imr neurons with intense nuclear staining were frequent in every region. DLS were more prominent in white matter and less evident in cerebral cortex. In CA1 and subiculum, intensely imr DN and occasional NFT were present. Round and threadlike DN and occasional DLS were found in the vicinity of senile plaques. All entorhinal areas, transentorhinal and temporal cortex contained dense deposits of intensely imr DN, occasional NFT and DLS. Ubiquitin imr DN are most likely neuronal in origin given their topographic distribution, whereas DLS are not similarly distributed and may represent aging changes within astrocytes or microglia. DLS are scant in areas prone to the development of DN and NFT, such as CA1, subiculum, lateral entorhinal cortex, and numerous in relatively less affected areas, such as CA2, CA3, and medial entorhinal cortex. The reciprocal relationship between these imr structures suggests topographically specific variations in degeneration.

271.4

DISTRIBUTION OF PATHOLOGICAL NEURITES ACROSS THE SURFACE OF ALZHEIMER'S NASAL EPITHELIUM: A NEW WHOLE-MOUNT IMMUNOCYTOCHEMICAL METHOD. W.H. Feng, J.S. Kauer and B.R. Talamo. Tufts Univ. School of Med., Boston, MA 02111.

Previous immunocytochemical studies of frozen sections of autopsied nasal tissue from Alzheimer's patients showed that normal and abnormal sensory areas were not uniformly distributed across the olfactory epithelium (oe). For the purpose of targeting areas for sampling by biopsy and understanding how neuritic fibers are misdirected into the oe, a whole-mount immunocytochemical technique was developed to reveal the surface distribution of abnormal neuritic patches and degenerating olfactory receptor neurons (ORN) in the oe of patients with Alzheimer's Disease. Antibody to MAP5 (Sigma) or tubulin (J1, A. Frankfurter) is used to stain normal and abnormal neurons; a second antibody is selected that is specific for abnormal somata and neurites (e.g. to phosphorylated neurofilament proteins or to tau). Whole mount tissue can be rehydrated and sectioned and/or retained for further analysis. In dehydrated and cleared whole mounts from neonates, uniformly distributed normal ORNs and their axons are clearly visible. In AD tissue, normal areas may be present while other areas show abnormally stained ORNs and densely matted or complicated swirled neurites and neuron-free islands circumscribed by a thickened border of neuritic fibers which retrace their circular pathway repeatedly. The pattern of abnormal neuritic aggregation suggests that the axons are diverted from their route to the olfactory bulb (thereby failing to make their normal connections), while they have an enhanced affinity for each other and an apparent attraction to the oe. This lack of normal connectivity may lead to altered expression of macromolecules such as tau. This interpretation is consistent with our other experiments in monkeys in which tau is expressed only in ORNs not showing olfactory marker protein (OMP); low levels of OMP are a feature of ORNs that are deprived of their synaptic targets.

271.6

GANGLION CELL LOSS IN RETINAL WHOLE-MOUNTS FROM PATIENTS WITH ALZHEIMER'S DISEASE. J.C. Blanks, Y. Torigoe and R.H.I. Blanks. Doheny Eye Institute, Dept. of Ophthalmology, USC Sch. of Med., Los Angeles, CA 90033, and Dept. of Anatomy and Neurobiology, Univ. of California, Irvine, Irvine, CA 92717.

Previous studies in this laboratory have shown differences in the number of neurons in the ganglion cell layer (GCL) in the macula of patients with Alzheimer's disease (AD) compared with age-matched controls. The object of this study was to examine the extent of neuronal loss across the entire GCL. The remaining portion of the retina was prepared as a whole-mount and counter-stained with toluidine blue. Seven retinas from 7 AD patients (age 69-88) and 11 retinas from 9 age-matched controls (age 64-86) were examined. All neurons in the GCL were drawn with the aid of a camera lucida and digitized; neuronal density maps were generated by sampling the entire retina at 1 mm or 2 mm increments. A total loss of $37 \pm 12\%$ (mean \pm s.d.) of neurons in the GCL of AD patients was observed compared with age-matched controls. The total loss of neurons in the GCL was remarkably constant across the retinas of AD patients (range = 20-58%) and between both eyes from two AD patients: an 82-year-old (right = 22%; left = 26%) and an 85-year-old (right = 48%; left = 44%). Cell loss in the peripheral retina was correlated (correlation coefficient $r = 0.53$) with loss of neurons in the macula of the same patient. Cell loss occurred equally among both large and small diameter neurons in the GCL. These results confirm earlier reports of retinal degeneration in patients with AD and demonstrate that the defect extends across the entire retina.

271.8

LOSS OF BASAL GANGLIA DOPAMINE IN THE LEWY BODY VARIANT OF ALZHEIMER'S DISEASE. P.J. Langlais,^{1,2} L.T. Thal,^{1,2} L. Hansen,¹ D. Galasko,^{1,2} M. Alford,¹ and E. Masliah.¹ ¹Dept. of Neurosciences, UCSD 92093 and ²Neurology Research Services, VA Medical Center, San Diego, CA 92161

A recent study described diffuse cortical and subcortical Lewy bodies (LBs) in a large proportion (13/36) of clinically diagnosed and pathologically confirmed cases of Alzheimer's disease (AD) (Hansen et al. *Neurology* 40:1-8, 1990). These Lewy body variant (LBV) cases did not appear to represent the coexistence of AD and Parkinson's disease (PD) since clinical parkinsonism and neuronal loss in substantia nigra were mild.

The present study compared monoamine levels and choline acetyltransferase (ChAT) activity in cortical regions and basal ganglia from LBV (N=7), pure AD (N=6), and control (N=7) post-mortem brains. Values are expressed as % of control value. Comparable reductions of ChAT activity were observed in caudate (48-51%) and putamen (14-31%) of the LBV and AD cases. However, ChAT was much lower in the LBV compared to AD cases in frontal (19 vs 68%), medial temporal (22 vs 49%) and parietal (14 vs 45%) cortex. These data suggest a greater destruction of cholinergic basal forebrain neurons and/or cortical interneurons in the LBV cases which may contribute to the selective cognitive impairments observed in the LBV cases. Significant reductions of dopamine in caudate (19%) and putamen (5%) and homovanillic acid (HVA) in caudate (40%) and putamen (25%) were observed in the LBV but not the AD cases. These reductions are comparable to those observed in PD and suggest that the LBV biochemically resembles PD. The reason for milder parkinsonism in LBV than in PD is unclear. The effect of reduced nigrostriatal dopamine activity may be mitigated by the basal ganglia cholinergic deficit in LBV, or possibly by damage to other motor areas, e.g., subthalamic nucleus. Supported by funds from Dept. of Veterans Affairs and NIH (#S10RR04754-01).

271.9

ABERRANT LOCALIZATION OF MAP5 IMMUNOREACTIVITY IN THE HIPPOCAMPAL FORMATION IN ALZHEIMER'S DISEASE. I.W. Geddes and K. Lundgren*. Sanders-Brown Center on Aging and Department of Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536.

The cause of the cytoskeletal abnormalities in Alzheimer's disease (AD) is uncertain. One possibility is that some of the alterations may result from an aberrant sprouting response. We have previously observed that sprouting in the rat CNS results in the re-expression of the embryonic form of α -tubulin mRNA and that expression of the corresponding human α -tubulin mRNA is increased in Alzheimer's disease (*Neurosci. Lett.* 109:54, 1990). Hasegawa and colleagues recently reported that antibodies against phosphorylated epitopes of a fetal microtubule-associated protein, MAP5, label plaques, tangles, and curly fibers in AD (*Neuron* 4:909, 1990). We used monoclonal antibodies against non-phosphorylated MAP5 epitopes to examine the hippocampal formation obtained postmortem from four control individuals, six individuals with AD, and two 'transition' cases which did not have a history of dementia but did exhibit significant AD pathology. In both AD and control cases, axonal staining was restricted to the mossy fibers. In control cases, MAP5 immunoreactivity (IR) was observed in the neuronal cytoplasm and the proximal portion of the apical dendrites of pyramidal and granule cells. In AD, numerous CA3 pyramidal neurons and the occasional neuron in CA1 and subiculum were intensely immunostained. Immunoreactivity filled the neuronal perikarya and the apical dendrite. In transition cases, immunostaining was similar to that observed in AD.

The increase and altered distribution of MAP5 IR in AD may reflect an aberrant sprouting response. The prominent staining in CA3, an area that is relatively uninvolved in AD pathology, suggests that many more neurons are affected in AD would be predicted based on neuropathological alterations. The results further suggest that the increased expression of cytoskeletal proteins may be tolerated in some regions such as CA3, but not in others including CA1 where the increased expression appears to precede aberrant phosphorylation, proteolysis, and incorporation of cytoskeletal proteins into AD pathology.

271.11

EXPRESSION OF SULFATED GLYCOPROTEIN-2 (SGP-2) IN HUMAN GLIOMAS, EPILEPTIC FOCI AND RAT BRAIN TISSUES. J.-G. Chabot, M. Danik*, C. Chauvin*, C. Mercier*, A.-L. Benabid*, R. Ouïrion and M. Suh*. Douglas Hospital Research Centre, Department of Psychiatry, McGill University, Verdun and Maisonneuve-Rosemont Hospital Research Centre, Department of Medicine, Montreal University, Montreal, Quebec, Canada.

SGP-2 was first identified as the major secretory protein of rat Sertoli cells. We have isolated the clone pTB16, the human homologue of rat testicular SGP-2. By RNA blot analysis, pTB16 was elevated by 11-fold in gliomas compared to a primitive neuroectodermal tumor. These results were supported by *in situ* hybridization studies. In malignant gliomas, cells expressing pTB16 mRNA were markedly increased as compared to benign tumors. In metastasis to brain (adenocarcinoma of digestive origin), hybridization signal was found only in normal CNS tissue. Heavy but diffuse specific labeling was also observed in neuronal and glial cells from surgical specimens of epileptic foci. However, the pTB16 gene expression is not restricted to pathological brain tissues. We have also found hybridization signals in temporal cortex from normal control as well as in normal and lesioned rat brain tissues. In normal temporal cortex, clusters of silver grains were detected throughout the gray matter. In normal rat brain tissues, a widespread distribution of pTB16 transcripts was observed. The highest level of expression was found in the choroid plexus and ependyma. Prominent labeling was also observed over the pyramidal cell layer of the hippocampus, the granular cell layer of the dentate gyrus and the hippocampal fissure. In kainate-lesioned striatum and hippocampus, hybridization signals were markedly increased. Our studies demonstrate the presence of pTB16 gene expression in normal and pathological brain tissues. In brain tumors and lesioned tissues, SGP-2 may play a role in mediating apoptosis while its location in the hippocampus and choroid plexus raises interesting possibilities in regard to cognition and production of CSF fluids.

271.13

LONG TERM EFFECTS OF ALUMINUM AND ALUMINOSILICATES ON CULTURED NEURONS OF RAT CEREBRAL CORTEX: RELATIONSHIP TO ALZHEIMER'S DISEASE. Masahiro KAWAHARA, Kazuyo MURAMOTO*, Kazuo KOBAYASHI*, Yoichiro KURODA, Dept. of Neurochemistry, Tokyo Metropolitan Institute for Neurosciences, Fuchu-city, Tokyo 183, Japan.

Several reports have suggested that aluminum, an ubiquitous element, has a strong relation to Alzheimer's disease. In particular, aluminosilicate was found to exist in the senile plaques of patients with Alzheimer's disease. Therefore, we investigated the neurotoxicity of aluminum derivatives on dissociated neurons of cerebral cortex derived from fetal rats. After 22 days in culture, neurons which were exposed to 100 μ M of Al(NO₃)₃ showed extensive outgrowth of axon-like processes. Accumulation and fasciculation of neurofilaments with twisted shapes were observed. Similar results were also obtained with application of other aluminum salts. Using a functional assay system for synapse formation between cortical neurons, long term application of aluminum salts, microparticulates of aluminum oxide, silica gel, and aluminosilicates (zeolites) to cultured neurons was found to influence the frequency of spontaneous oscillations of intracellular Ca²⁺ in neurons which was correlated with the numbers of synapses formed in the culture.

This work was supported in part by the Grant-in-Aid for Scientific Research on Priority Areas No. 01658007 from the Ministry of Education, Science and Culture, Japan.

271.10

REGIONAL SYNAPTIC CHANGES IN ALZHEIMER'S DISEASE W.G. Honer, D.W. Dickson, J. Gleeson*, P. Davies*, Albert Einstein College of Medicine, Bronx, NY 10461

Regional aspects of synaptic pathology in Alzheimer's disease (AD) were studied using an antibody (EP10) which recognizes a synaptophysin like antigen. Homogenates of hippocampus, caudate and temporal and occipital cortices were studied from 10 cases of AD and 7 age and sex matched controls using an ELISA. The EP10 antigen was significantly reduced in AD (F_{1,51}=13.05, p=.002), with a 77% decrease in hippocampus (U=3, p=.001) and a 54% decrease in temporal cortex (U=11, p=.009). In temporal cortex, the reductions in the antigen were inversely correlated with the number of neurofibrillary tangles present (rho=.778, p=.007). This relationship was not observed in the hippocampus. Pallor of the outer two-thirds of the molecular layer of the dentate gyrus was observed with EP10 immunocytochemistry in AD. Western blotting studies qualitatively supported the ELISA findings. These results suggest that synaptic loss in AD occurs to a different extent in different brain regions. Synaptic loss in the temporal cortex may be related to local pathology. The disproportionately large loss of a synaptic marker in the hippocampus suggests an additional contribution of deafferentation to the mechanism of loss in this region.

Supported by MRC Canada and the Metropolitan Life Foundation.

SELECTIVE EXPRESSION OF SULFATED GLYCOPROTEIN-2 (SGP-2) BY HIPPOCAMPAL NEURON AND EPENDYMA IN HUMAN BRAIN ENRICHED IN β -AMYLOID SENILE PLAQUES OF THE ALZHEIMER-TYPE. E. Moyses¹, D. Michel^{1*}, N. Choi^{2*}, Y. Robitaille², G. Brun^{1*}, R. Ouïrion³, and J.G. Chabot^{3,1}. E.N.S. of Lyon, France; ²Dept. of Physiol. Chem., Showa Univ., Tokyo, Japan; ³Douglas Hosp. Res. Ctr., Dept. of Psychiatry, McGill Univ., Verdun, Canada. SGP-2 was first recognized as the major secretory protein of rat Sertoli cells. Overexpression of its gene was recently shown in Alzheimer's disease (AD) hippocampus, human gliomas and transformed neuroretina cells. The present study aimed to compare the distribution of SGP-2 and β -amyloid proteins in the forebrain of AD patients (n=8) and normal controls (n=8) using immunohistochemistry on serial sections. Occurrence and density of SGP-2-like immunoreactivity (IR) in hippocampus were correlated with density of β -amyloid-immunostained senile plaques in hippocampus and temporal cortex. However, the distributions of SGP-2 and β -amyloid-IRs were quite different. SGP-2-IR was mainly detected in hippocampal ependymal cells and neurons. The predominant ependymal localization of SGP-2-IR is in keeping with the high density of SGP-2 transcripts observed in rat choroid plexus and ependyma (Chabot et al., this meeting). β -amyloid IR was exclusively found in senile plaques and blood vessel walls. Overproduction of SGP-2 by periventricular elements may play a role in the normal aging process as well as in its pathological acceleration in AD, especially since this protein has been proposed as a marker of cell death.

271.14

CORTICAL DISTRIBUTION OF ABNORMAL MICROVASCULATURE AND VASCULAR HEPARAN SULFATE PROTEOGLYCAN POSITIVE PLAQUES IN ALZHEIMER'S DISEASE (AD). H.M. Fillit^{1,2}, L. Buée^{1,3}, P.R. Hof^{1,2}, A. Delacourte³, and J.H. Morrison^{1,2}. ¹Dept. of Geriatrics and ²Fishberg Res. Ctr. for Neurobiology, Mt Sinai Sch. Med., New York, NY 10029, and ³U156 INSERM, 59045 Lille Cedex, France.

The heparan sulfate proteoglycan of the vascular basement membrane (vHSPG) may play a role in the formation of amyloid deposits in AD. Using a monoclonal antibody specific to the vHSPG protein core, we studied the distribution of microvessels and vHSPG-containing amyloid deposits in the cerebral cortex of AD and age matched control cases. The distribution of vHSPG+ amyloid deposits was similar to that of thioflavin S (TS) staining in layer IV of the primary visual cortex and in the dentate gyrus. However, there was a differential plaque distribution in the temporal and frontal neocortex: a high density of vHSPG+ plaques was found mainly in deep layer VI, whereas the TS+ plaques were mainly observed in layers III and V. The number of shrunken and tortuous vessels was low or absent in control cases, whereas these pathological profiles were commonly observed in AD cases. Also, in these areas, their density was correlated to TS+ structures. These results suggest that severe damage to the cortical microvasculature occurs in AD. In addition, the specific laminar distribution of vHSPG+ plaques may be related to the specific angioarchitecture of a given cortical region. The pathogenesis of vHSPG+ plaques may be different from other plaques that do not share the same immunoreactivity profile, supporting the notion of the existence of a vasculature-derived subgroup of plaques. BINDING OF THE SECRETED FORM OF THE ALZHEIMER BETA AMYLOID PRECURSOR PROTEIN TO HEPARAN SULFATE. L. Buée^{1,4}, J. Anderson², N.K. Robakis^{2,3}, A. Delacourte⁴ and H.M. Fillit^{1,3}. Dept of ¹Geriatrics, ²Psychiatry and ³Neurobiology, Mt Sinai Med. Ctr, New York, NY 10029 and ⁴U156 INSERM, 59045 Lille France.

Glycosaminoglycans (GAGs) are the proteoglycan (PG) moiety shown to be consistently present in all types of amyloid deposits. In Alzheimer's disease, heparan sulfate (HS) is the main GAG found in amyloid deposits. To investigate the potential physiological significance of this colocalization, we are studying the binding of the amyloid precursor protein (APP) to HS. APP containing the Kunitz protease inhibitor (KPI) insert (APP-PNII) was purified from PC12 cell conditioned medium containing NGF. To study the binding of APP-PNII to HS, a 1ml HS-column was made by coupling AH-Sepharose CL-4B gel and 5mg of HS using the carbodiimide technique. For each experiment, APP-PNII was loaded onto the HS-column. A stepwise gradient elution with NaCl released APP-PNII with 0.75N NaCl. APP-PNII was also eluted at approximately the same normality of Na₂SO₄. A linear gradient of dextran sulfate (average MW 5kDa) eluted APP-PNII at a concentration of 7mg/ml. These data indicate a high affinity binding of APP-PNII to HS, supporting the hypothesis that interactions between HS-PG and APP play a role in normal physiological processes and amyloidogenesis. Supported by the Florence J. Gould Foundation and NIH grants AG05138 and AI24876.

ALZHEIMER'S DISEASE: NEUROPATHOLOGY III

272.1

IMMUNOCHEMICAL LOCALIZATION OF HEPARAN SULFATE GLYCOSAMINOGLYCANS IN ALZHEIMER'S DISEASE

J.H. Su, B.J. Cummings and C.W. Cotman. Department of Psychobiology, University of California, Irvine, CA. 92717 USA.

Recent studies have demonstrated that heparan sulfate proteoglycan (HSPG) promotes neuritic outgrowth *in vitro* and has affinity to FGF and APP. In this study, two monoclonal antibodies were used in AD and control brains; one recognizes a glycosaminoglycan epitope present in heparan sulfate (HSGAG) and the other recognizes the core protein of a basement membrane HSPG. Sections of the hippocampal formation, temporal and occipital cortex were examined. Anti-HSPG antibody immunostained only the walls of arterioles and a few neuritic plaques (NPs). Anti-HSGAG also stained arterioles and NPs. In addition, immunoreactivity was medium to strong in neurofibrillary tangles (NFTs), some of which were not co-localized with Tau-1 positive NFTs. The cytoplasm and/or nuclei of pyramidal and non-pyramidal neurons were also stained. Some plaques contained HSGAG-positive neurites and/or were surrounded by HSGAG-positive astrocytes in AD tissue. The number, intensities, and extent of distribution of NFTs, NPs, and positive neurons were variable in different AD brains, but seemed to have a predilection for entorhinal cortex, CA1, and layers III, V and VI of cortex. A few NFTs, NPs, and positive neurons were also demonstrated by anti-HSGAG antibody in control brains, but their numbers were dramatically less than those seen in the AD brains. These results confirm a recent report (Snow, A.D., 1990) and extend these observations. Furthermore, this study suggests that HSGAG is a major component within specific lesions of AD. HSGAGs may play an important role in the pathogenesis of characteristic lesions and could serve as a marker reflecting pathological changes in AD.

272.3

QUANTITATIVE CHEMOARCHITECTONIC ANALYSIS OF THE CINGULATE CORTEX IN ALZHEIMER'S DISEASE (AD). P.R. Hof, P. Hsu*, and J.H. Morrison. Fishberg Research Center for Neurobiology and Dept of Geriatrics, Mount Sinai School of Medicine, New York, NY 10029.

Analyses of chemically-identified neurons in the human prefrontal and temporal cortex have demonstrated that pyramidal cells that contain high levels of nonphosphorylated neurofilament protein (SMI32+) are highly vulnerable in AD, whereas parvalbumin (PV)+ interneurons are resistant to degeneration. Further, in these areas, vulnerability is linked to cell size in that the large (>350 μm²) SMI32+ are particularly vulnerable. SMI32+ cells in cingulate cortex are predominantly small or intermediate in size (150-350 μm²). Variations of the distribution of both SMI32+ and PV+ cells across the cingulate cortex clearly delineate the subareas within both anterior (ACg) and posterior (PCg) cingulate cortex. While PV+ cells are unaffected in the AD cases, SMI32+ cells are decreased in both supra- and infragranular layers (30-40%) in all PCg subfields, whereas these cells remain unaffected in the ACg. Although neurofibrillary tangles (NFT) are present in both ACg and PCg, their density across cases is highly variable and unlike temporal and prefrontal cortex, does not correlate with SMI32+ cell loss. Moreover, both ACg and PCg are less affected in AD than prefrontal and temporal neocortex. The relative vulnerability of PCg as compared to ACg suggests that both the neuron type profile and connectivity of these areas may be fundamentally different. These data further support the hypothesis that specific chemically-identifiable elements of the cortical circuitry are selectively affected in AD. Supported by NIH AG06647, AG05138, N° 2 T35 AM07420, and the Brookdale Foundation.

272.2

THE RELATIONSHIP BETWEEN DENDRITIC EXTENT AND PLAQUES IN THE HIPPOCAMPUS IN ALZHEIMER'S DISEASE (AD). D.G. Flood, Y.G. Lin*, A.M. Kazee*, T.A. Eskin and L.W. Lapham*. Depts. of Neurology, Neurobiology & Anatomy, and Pathology & Laboratory Medicine, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

Recent attention has focused on the ability of amyloid protein (β/A₄) to induce neurite outgrowth *in vitro* after application of synthetic β/A₄ fragments and *in vivo* around plaques. In order to study the possible effect of plaques on the dendritic extent of neurons in the hippocampus, we have undertaken a correlative study of Golgi-stained dendrites and of Bielchowsky-stained plaques. Data have been collected from 22 cases of the Rochester Alzheimer's Disease Project (RADP): 14 cases with AD (age range 59-96 yrs) and 8 normal control cases (age range 51-89 yrs). Total dendritic extent of 15 randomly chosen neurons was quantified for apical trees of dentate gyrus granule cells and basal trees of CA2/3 and CA1 pyramidal cells. Plaques were counted in the dentate molecular layer, hilus, CA3 and CA1. Dendritic extent was positively correlated between pairs of the cell types. Similarly, plaques between pairs of the regions were positively correlated, especially those of the dentate molecular layer and CA1. Plaques of the dentate molecular layer were negatively correlated with dendritic extent of all 3 cell types. Plaques of CA1 correlated negatively with dendrites of only the granule cells. Plaques in the hilus were seen in only a few of the cases but correlated negatively with dendrites of granule cells and CA2/3 pyramids. Plaques in CA3 were also limited and did not correlate with dendritic extent. Dendritic extent of neurons is either unaffected by plaques within the region (CA2/3 and CA1) or is lessened (dentate gyrus). Because dentate molecular layer plaques correlated with dendritic extent of all 3 cell types, it can be suggested that disruption of the initial input to the hippocampus in the dentate gyrus by plaques has the greater influence on dendritic extent of neurons in later processing stations in the hippocampus. Supported by NIH grant AG 03644.

272.4

MOLECULAR AND NEUROPATHOLOGIC STUDIES OF AMYLOID AND CYTOSKELETAL PROTEINS IN THE LEWY BODY VARIANT OF ALZHEIMER'S DISEASE. V.H. Mah¹, P.F. Reyes¹, L.L. Doyle¹, G.A. Higgins². ¹Dept. of Neurology, Thomas Jefferson Univ., Philadelphia PA, 19107 and ²Mol. Neurobiol., NIA, NIH, Baltimore MD 21224

A subset of Alzheimer's Disease (AD) is the Lewy body variant which is pathologically characterized by increased numbers of Lewy bodies in addition to the typical findings of AD. Recently a mutation in the APP gene was described in two kindreds of familial AD. In these cases cortical Lewy bodies were noted by some observers. The question arises as to the relationship between abnormal amyloid expression and deposition and Lewy body formation in AD. Initial studies using conventional histochemical stains suggest increased amyloid deposition in both plaques and blood vessel walls in cerebral cortex in association with Lewy bodies. Lewy bodies tend to be prominent in the nucleus basalis of Meynert (NBM), amygdala and substantia nigra (SN). In these areas, neuronal cell loss appears to be greater with the presence of Lev₁ bodies. The NBM and amygdala show conspicuous amyloid deposition, in contrast to the SN. Current studies are focused on examination of amyloid precursor protein and neuronal cytoskeletal protein expression in areas affected by Lewy body accumulation in AD.

272.5

LOCALIZATION OF THE PROTEASES CHYMASE AND CATHEPSIN G IN ALZHEIMER'S DISEASE BRAIN. M.J. Savage¹, N.M. Schechter², J.Q. Trojanowski³ and B. Siman¹.
¹Cephalon, Inc. West Chester, PA. 19380, ²Dept. of Dermatology, and ³Dept. of Pathology, Univ. of Pennsylvania, Philadelphia, PA. 19104

Amyloid deposition into neuritic and cerebrovascular plaques is a characteristic of Alzheimer's disease (AD), and results from abnormal proteolysis of the amyloid precursor protein (APP) to form β /A4. Indeed, chymotrypsin-like protease activity is significantly elevated in AD parietal cortex (*Soc. Neurosci. Abstr.*, 16:787). At least two proteases contribute to this activity: chymase, found in mast cell granules, and cathepsin G, found in neutrophil granules. The distribution of these enzymes in AD and control temporal cortex was studied using immunohistochemistry. Mast cell secretory granules were stained selectively with anti-chymase. Mast cells were present in both AD and control brains, usually inside blood vessels. Occasional mast cells were lodged within the brain parenchyma, and a few were intimately associated with neuritic plaques. Neutrophils, containing secretory granules stained by anti-cathepsin G, were plentiful in the brain and are located inside blood vessels. Both types of granulocytes, containing chymotrypsin-like proteases potentially important for β /A4 liberation from APP, are present in brain, and could contribute to pathological deposition of β /A4, especially within the vasculature. Whether an imbalance exists in the numbers of these cells in AD brains is currently being examined.

272.7

ALZHEIMER NEUROPATHOLOGY IN THE BRAINSTEM TEGMENTUM PARALLELS SUBSTANCE P INNERVATION. J.M. Lee*, N. Kowall, and E.T. Hedley-Whyte. Departments of Neuropathology and Neurology, Massachusetts General Hospital, Boston, MA 02114.

Neuronal loss and globose neurofibrillary tangles (NFT) are found in the noradrenergic locus coeruleus (LC) in Alzheimer's disease (AD). Previously, we found a decrease in the number of 5-HT neurons in the dorsal raphe (DR) (-23%) and B9 raphe (-31%) but not in the median raphe (MR) nuclei (JNEN, 1990). Tau antibodies recognized globose NFT's and neuritic changes in the DR and B9 nuclei, the dorsal and ventral but not the middle part of the MR, and the lateral parabrachial nuclei.

Yankner et al. (*Science* 1990; 250:279-82) have shown that B-amyloid (1-40) which is abnormally deposited in the neuropil in AD is neurotoxic. The active moiety is B-amyloid (25-35) which has a structural homology to the human tachykinin, substance P (SP), and therefore may mediate its effect through a SP receptor. We investigated the SP fiber distribution in five human brainstem tegmentums as a possible marker for post-synaptic SP receptor localization. Immunocytochemical staining of SP revealed a dense fiber innervation in the dorsal aspects of the tegmentum, including the dorsal raphe, LC, dorsal to the medial lemniscus in the region of the B9 nuclei, and in the lateral parabrachial nucleus. Fibers were sparse in the MR. Therefore, the SP fiber distribution in the human brainstem parallels the distribution of tau immunoreactive NFT's and cell loss in AD. Receptor binding studies will be necessary to confirm the presence of as well as the ability for B-amyloid to bind to SP receptors in the tegmentum.

272.9

LYSOSOMAL HYDROLASE DISTRIBUTIONS IN BRAINS OF PATIENTS WITH ALZHEIMER DISEASE AND DOWN SYNDROME. A.M. Cataldo, P.A. Paskevich, D.A. Mann, R.A. Nixon. McLean Hospital, Harvard Medical School Belmont, MA, and Department of Pathology, University of Manchester, U.K.

Our previous studies, showing an abnormal extracellular localization of lysosomal hydrolases with β -amyloid deposits in senile plaques (SP) of Alzheimer brains, support a mechanism involving neuronal degeneration and consequent dysregulation of lysosomal mechanism(s) leading to the altered breakdown of amyloid precursor protein. In this study we have localized selected lysosomal hydrolases in 25 brains from individuals with Down Syndrome (DS) (age 31-71). Neocortical sections were analyzed immunocytochemically at the light and EM levels with antisera to cathepsin D (CD), cathepsin B (CB), α -galactosidase (GAL) and β -hexosaminidase-A (HEX). SP were identified with Bielschowsky silver stain and thioflavin histofluorescence. CD, CB, HEX and GAL were abundant within SP of DS brains. Certain neurons were intensely labeled with these hydrolase antisera and many were associated with SP. By EM, immunoreactivity in SP was predominantly in lipofuscin granules of abnormal types and dense bodies of degenerating neurites. Immunoreactive SP in DS were not limited to specific cortical layers, as in AD, but instead were observed in all laminae. All immunoreactive SP contained thioflavin histofluorescence. In DS, as in AD, therefore, a strong relationship exists between prominent amyloid deposition and high extracellular concentrations of lysosomal hydrolases. Neurons appear to be a principal source of these enzymes. The variations observed in the laminar distribution of hydrolase-positive SP in DS and AD brains may reflect differences between these disorders in rates of neurodegeneration.

272.6

THE FIRST APPEARANCE OF AMYLOID PLAQUES IS IN THE NEOCORTEX, NOT IN LIMBIC AREAS. J.L. Price and J.C. Morris, Depts. of Anat./Neurobiol. and Neurology, and the Alzheimer's Disease Research Center, Washington Univ. Sch. Med., St. Louis, MO 63110

The borderline between healthy aging and the early stages of Alzheimer's Disease is being studied in a series of very well characterized cases. Cognitive status was determined by clinical evaluation and psychometric testing before death, or by a structured retrospective interview with a close relative, and a Clinical Dementia Rating was assigned to each case. Fifteen nondemented (CDR=0), six very mildly demented (CDR=0.5) and eleven more severely demented (CDR=1-3) cases were studied.

As reported previously, all of the CDR=0.5 cases had large numbers of plaques in the neocortex as well as in the hippocampus and amygdala, most of which were primitive in type. It is apparent that the earliest development of plaques must be in non-demented cases. Of the non-demented cases, no plaques were found in the seven cases younger than 75, with either the Bielschowsky stain or antibody staining for β -amyloid. In the eight older cases (75-89), plaques were found in only five. Two of these had a single area of primitive plaques restricted to a small part of the temporal cortex, without any plaques in limbic structures. One had more widespread clusters of primitive plaques, although these were also restricted to the neocortex. These plaques were distributed through the grey matter, without any relation to blood vessels. The last two cases had plaques in limbic areas, but the highest density of plaques was in the neocortex. One of these resembled the CDR=0.5 cases with some mature as well as primitive plaques, although the overall plaque density was lower. These observations suggest that β -amyloid deposits first develop as primitive plaques in the neocortex, in contrast to tangles, which are first seen in limbic structures. (Supported by NIH grants AG03991 and AG05681.)

NEURONS DISPLAY PROMINENT LYSOSOMAL ABNORMALITIES IN ALZHEIMER'S DISEASE AND DOWN'S SYNDROME. R. A. Nixon and A. M. Cataldo. McLean Hospital, Harvard Medical School, Belmont, MA 02178

Lysosomes are a major site of intracellular protein metabolism and membrane turnover. Many types of hydrolytic enzymes, including over a dozen proteases of wide-ranging specificity, reside in these vesicular organelles. Using immunocytochemistry and histochemistry on sections of neocortex and hippocampus from mouse brain and postmortem human brain, we found neurons to be the richest source for 7 of 8 acid hydrolases examined. Hydrolase contents and lysosomes were particularly high in neuronal perikarya and proximal dendrites. Certain of the hydrolases (e.g., cathepsin B and α -hexosaminidase) were barely detectable in glia; the others were represented to varying degrees. In sections of neocortex from individuals with Alzheimer's disease and Down's syndrome, immunoreactivity to each of the hydrolases was massively increased in neurons displaying degenerative changes. The cell bodies of some neurons were completely filled with darkly immunostained lysosomes. Within "at-risk" neuronal populations of the neocortex and hippocampus, increased levels and altered distributions of acid hydrolases were also seen in many neurons that appeared normal by other criteria. This finding suggests that hydrolase accumulations may be an early marker of metabolic derangements or compensatory responses in these neurons. Apparent transitions were often seen between the degeneration of hydrolase-laden neurons and the appearance of thioflavin-positive senile plaques containing high levels of the same acid hydrolases. The altered patterns of intracellular degradation implied by these findings may be relevant to the abnormal processing of amyloid precursor protein. Neurons appear to be the principal source of the abundant acid hydrolases in senile plaques, which we consider candidate enzymes in the formation of β -amyloid (PNAS 1990; 87:3861-3865). Supported by the NIH.

QUENCHING LIPOFUSCIN AUTOFLUORESCENCE IN AGED AND ALZHEIMER'S BRAIN: A DOUBLE-LABEL FLUORESCENCE METHOD WITH THIOFLAVIN COUNTERSTAIN. Gisele Styrén, W. Harold Civin, and Joseph Rogers. Institute for Biogerontology Research, Sun City, AZ 85372.

Fluorescence sometimes offers advantages over colorimetric detection—especially when two different antigens must be co-localized within the same cellular elements. Unfortunately, in aged nervous (and cardiac) tissues, lipofuscin and other autofluorescent pigments accumulate markedly, frequently obscuring labeling with a specific fluorescence marker. The emission/excitation spectra of these "aging pigments" span those for most commercial fluorophores. Although there may be differences in color between a fluorophore and lipofuscin at a particular wavelength, the differences are subtle (e.g., with a conventional fluorescein filter set lipofuscin appears yellow-green and fluorescein appears lime-green). Moreover, at exposure times appropriate for micrographs of specific fluorophore labeling, lipofuscin autofluorescence in the field will often overexpose the image. We have attempted to surmount this problem by several methods. Custom filter sets were not helpful. Subjecting tissue sections to a strong UV light for several days did not appreciably quench lipofuscin. Fluorophores in the blue range (e.g., AMCA, Vector Laboratories) were successful, but one still needs a higher wavelength marker for double-labeling.

In the course of counterstaining Alzheimer's tissue with thioflavin S, we had previously noted that lipofuscin autofluorescence was greatly diminished. We therefore modified the thioflavin protocol to maximize lipofuscin quenching and to permit fluorescence double-labeling (the complete protocol will be available at the meeting as a handout). The procedure gives excellent results with AMCA, fluorescein, rhodamine, and Texas Red in aged brain. In Alzheimer's tissue, amyloid deposits are counterstained by the thioflavine, providing a triple label.

Supported by NIA AGO 7367 and the State of Arizona.

SOME ALZHEIMER'S PATIENTS SHOW ATROPHIED OPTIC NERVES CLINICALLY. T. Russell Nelson,¹ R. Angel Cruz,^{1,2} S. Arnold Adler,¹ Douglas McNinch,¹ Monique J. Leys,³ and J. Vernon Odom.⁴ ¹ Bay Pines VA Medical Center, Bay Pines, FL; ² Department of Neurology, USF Medical Center, Tampa, FL; ³ Department of Ophthalmology, University Hospital, Ghent, Belgium; ⁴ Department of Ophthalmology, WVU Health Sciences Center, Morgantown, WV.

Eighty percent of patient's with probable Alzheimer's disease (AD) have reduced numbers of optic nerve (ON) fibers (Sadun and Bassi, Ophthalmol 1990; 97:9-17). Therefore, AD patients should show clinical signs of ON atrophy. We photographed the ONs of 13 patients (23 ONs) with probable AD and 10 normal patients (20 ONs) with the same mean age.

An ophthalmologist, masked as to the diagnosis of the patients, reviewed the photographs, measured the cup-to-disc (c/d) ratios and rated the discs as normal, questionably normal with larger than normal cup excavation, questionably normal with arteriosclerosis, or abnormal with ON atrophy.

The c/d ratios were similar in the two groups. Their ratings differed ($\chi^2 = 19.02$, $p < 0.001$). ON atrophy was more prevalent in the AD group (8 eyes in 7 patients) compared to the normal group (1 eye in 1 patient) as was a rating of questionably normal with arteriosclerosis (4 eyes in 4 patients vs 1 eye in 1 patient). Although ON atrophy and sclerotic vessels are not diagnostic of AD, their presence may assist the physician in making a diagnosis.

272.13

CHEMOARCHITECTURE OF THE STRIATUM IN ALZHEIMER'S DISEASE. N. Selden, C. Geula, L. Hersh and M-M. Mesulam, Harvard Medical School, Boston, MA 02215

The neuronal distributions of choline acetyltransferase (ChAT), somatostatin (SOM) and calcium-binding protein (calbindin D28k) were mapped in striatal tissue from Alzheimer's disease (AD) cases and controls using specific antibodies. In controls, ChAT-positive neurons were large (area: 475u²), multipolar in shape, intensely stained and evenly distributed throughout the striatum. ChAT-positive neurons in the dorsal striatum of AD cases were similar in size, morphology and distribution to controls. By contrast, ChAT-positive neurons in the ventral striatum of AD cases were reduced in size to 77% and in density to 24% of control values. SOM-positive neurons were of medium size (230u²), richly stained, with variable perikaryal morphology and more densely distributed in the caudate nucleus than in the putamen or ventral striatum. Calbindin-positive neurons were either medium-sized (100u²), lightly stained neurons distributed most plentifully over medial caudate nucleus or large (165u²), richly stained neurons frequently encountered in the lateral putamen. No significant change was observed in either SOM-positive or calbindin-positive neurons in AD cases as compared with controls. Selective loss and shrinkage of ChAT-positive neurons in the ventral striatum of AD cases is consistent with the preferential involvement of the limbic system in this disease.

Antibodies to somatostatin and calbindin generously provided by Drs. R. Benoit and M. Celio, respectively.

272.15

LASER MICROPROBE MASS ANALYSIS OF ALUMINUM, COPPER AND ZINC IN DIFFERENT NEURODEGENERATIVE DISORDERS. C. Bouras¹, P.R. Hof², P.F. Good², A. Hsu^{2*} and D.P. Perl². ¹Dept of Psychiatry, Univ. of Geneva, Switzerland, and ²Fishberg Research Center for Neurobiology, Mt Sinai Sch. Med., New York, NY 10029.

The aluminum (Al, M/Z 27), copper (Cu, M/Z 63) and zinc (Zn, M/Z 64) content was analyzed in plastic-embedded semithin sections from the brains of 3 Alzheimer's disease (AD), 4 Pick's disease (PD), 1 dementia pugilistica (DP) and 6 control cases using laser microprobe mass analysis (LAMMA). In the hippocampus of AD cases higher levels of Al were detected in neurofibrillary tangles (NFT), in the nuclei of NFT-bearing cells, as well as in the nuclei of non-NFT-containing cells and neuropil as compared to controls. The Al accumulation was highest in the NFT. In the hippocampal hilus and fascia dentata no differences were observed for Cu and Zn between AD and controls, however values for these elements were higher in the CA1 region in the AD cases. Al was present in higher amounts in the nuclei and neuropil of PD cases than in controls. The Pick bodies contained higher Al levels than the nuclei of the affected neurons in the fascia dentata and CA1. Cu and Zn levels were generally higher in PD than in controls, and were comparable to the level of AD cases. In DP, the nuclei of NFT-bearing neurons contained Al, Cu and Zn levels comparable to those observed in AD cases, however higher Al levels were observed in NFT of the DP case as compared to AD. These results demonstrate the abnormal accumulation of Al, Cu and Zn in brain areas that are severely affected in neurodegenerative disorders, and suggest that Al may play a key role in the formation of lesions such as NFT and Pick bodies. Supported by NIH grants AG05138, AG06833 and ES-928.

ACETYLCHOLINESTERASE-RICH PYRAMIDAL NEURONS IN ALZHEIMER'S DISEASE. S. Heckers, C. Geula, M-M. Mesulam. Harvard Medical School, Boston, MA 02215

The distribution of Acetylcholinesterase (AChE)-rich pyramidal neurons was studied in the cortices of six Alzheimer's Disease patients and four normal aged subjects.

Both groups showed a characteristic distribution of these neurons with the highest density in motor and premotor areas, moderate density in association cortices and low density in limbic-paralimbic areas. Three areas (Brodmann areas 6, 22, and 24) were chosen for quantitative analysis. The density of pyramidal AChE-rich neurons in layers III and V was significantly reduced in AD patients, most pronounced in anterior cingulate cortex. Nerve cell density was not significantly different in adjacent Nissl-stained sections. The density of AChE-positive fibers was also decreased in all three areas of the AD patients but was not correlated with the number of AChE-rich neurons. Loss of AChE-rich neurons was more pronounced in cases with high counts for plaques and tangles but was also found in one case with no tangles and low plaque count in the areas of interest.

These findings demonstrate a dramatic loss of AChE-rich cortical neurons in layers III and V in Alzheimer's Disease which can not be attributed to nerve cell loss or loss of cholinergic fibers. It may occur in the early disease stages, perhaps even prior to the formation of plaques and tangles.

272.14

SELECTIVE ACCUMULATION OF ALUMINUM AND IRON IN THE NEUROFIBRILLARY TANGLES OF ALZHEIMER'S DISEASE: A LASER MICROPROBE (LAMMA) STUDY. D.P. Perl^{1,2}, P.F. Good¹, L.M. Bjerer^{2*}, and J. Schmeidler^{2*}. ¹Fishberg Research Center for Neurobiology, ²Dept. of Psychiatry, Mt. Sinai School of Medicine New York, NY 10029

We report the results of an examination of the elemental content of neurofibrillary tangle (NFT)-bearing and NFT-free neurons identified within the hippocampus of 10 Alzheimer's disease cases and 4 clinically and neuropathologically intact age-matched controls. The study employed laser microprobe mass analysis (LAMMA), a technique which provides extremely sensitive multi-element detection in plastic embedded semithin sectioned tissues. Evidence for selective aluminum accumulation within the NFT-bearing neurons was obtained in all ten Alzheimer's disease cases. The site of aluminum deposition within these cells was the NFT itself, and not the "nuclear region" as we previously reported (Science 208:297,1980). Iron accumulation was also detected within NFTs. Evaluation for the accumulation of other elements within the NFT-bearing neurons failed to reveal any other metallic or non-metallic biologically active element as being consistently present. In addition, probe sites directed to neurons identified in snap frozen cryostat sections of two of the Alzheimer's disease cases, revealed similar spectra with prominent aluminum-related peaks, confirming that our findings are not related to exogenous contamination through fixation, embedding or other procedures prior to analysis. This study further confirms the association of aluminum and NFT formation in Alzheimer's disease. Supported by NIH grants AG-5138, AG-6833 and ES-928.

REPEATED MEASURES OF ChAT ACTIVITY ARE HIGHLY CORRELATED WITH COGNITIVE FUNCTION AMONG 23.5mo F-344 RATS. M.D. LINDNER AND T.L. MARTIN. Bristol-Myers Squibb Pharmaceutical Res. Inst., P.O. Box 5100, Wallingford, CT 06492-7660

Animal studies of aged versus young rats (Decker, 1987), and studies of cognitive function among aged rats (Fischer et al., 1989) have failed to replicate the high correlations with ChAT activity reported clinically ($r=.81$, Perry et al., 1978). We correlated cognitive function, using the Morris water task, with measures of hippocampal and cortical ChAT activity in aged rats (23.5mo). There was a large range in both learning ability (from $3.4 \pm 1.3m$ to $35.1 \pm 1.1m$) and in ChAT activity (the rat with the lowest ChAT activity was 40% less than the highest). Both behavioral and neurochemical measures were very reliable as determined by split-half reliability coefficients on the 10 trials in the water maze ($r=.83$), and the 6 measures of ChAT activity in the cortex ($r=.80$) and hippocampus ($r=.62$). Cortical and hippocampal ChAT activities were both correlated with learning ability ($r=.61$ and $.62$ respectively), and the combined ChAT activities were even more highly correlated with learning ability ($r=.75$). However, even though the variability in our ChAT data was no greater than Fonnum (1975), single measures of ChAT activity were not correlated with learning ability ($n=10$, $r=.11$ and $r=.36$) for hippocampus and cortex respectively. Despite the accuracy of Fonnum's (1975) ChAT assay, these results suggest that large correlations with cognitive function are dependent on further reducing measurement error by taking means of repeated measures.

THE EFFECT OF NORMAL AGING AND ALZHEIMER'S DISEASE ON SPATIAL ATTENTION. Patricia M. Mueller, Steven P. Tipper* and Gordon C. Baylis. Dept. of Psychology, U. C. San Diego, CA 92093, and Dept. of Psychology, McMaster University (S.P.T.)

Normal young adults show an action-based attentional system when tested on a task that requires them to reach for a target stimulus. Distractor objects on the action path towards the target cause very much more interference than those located beyond the target (Tipper et al., *Psychonomic Soc. Meeting*, 1990). Data suggest that a process of distractor inhibition is used in order to minimize interference from such distractor objects. This is manifest as an increased reaction time to a target which was at the location of the distractor on the previous trial.

We examine the extent to which normal aging and Alzheimer's Disease affect the ability to make a speeded reach to the correct target. It was found that normal aged people show increased interference from distractor objects, but a pattern of reaction times that broadly mirrors that in young adults. Patients suffering from Alzheimer's Disease, however, show a different pattern of interference that suggests a fundamental disruption in the basic mechanisms of spatial attention.

SELECTIVE AND DIVIDED ATTENTION TO VISUAL FEATURES ARE IMPAIRED IN PATIENTS WITH EARLY DEMENTIA OF THE ALZHEIMER TYPE. I.V. Haxby*, R. Parasuraman, J. Gillette*, K. Raffaele. Lab. of Neurosciences, Natl. Inst. on Aging, Bethesda, MD 20892

Selective and divided attention to visual features was investigated in 8 patients with mild dementia of the Alzheimer type (DAT) and twelve age-matched controls by measuring reaction time (RT) on visual matching tasks with varying attentional demands. Subjects indicated which of two choice stimuli had the same color, shape, or number as a sample stimulus. On a baseline choice RT task, DAT patient RT was 23% slower than that of controls. On the simplest visual matching task, in which all items in a block matched on the same feature and other features did not vary, DAT patient RT was 26% slower than control RT, indicating they had no difficulty discerning these features beyond what could be attributed to general psychomotor slowing. By contrast, DAT patient RTs were disproportionately slower on tests of selective and divided attention. On the selective attention task, in which irrelevant, non-matching features varied creating distraction, DAT patient RT was 40% slower than control RT. On the divided attention task, in which the matching feature changed every item, DAT patient RT was 115% slower than control RT. On a task that examined primed shifts of selective attention, in which changes in matching feature were followed by 2 to 7 items with the same matching feature, DAT patients demonstrated priming that reduced their disproportionate slowing on divided attention to the level of slowing on selective attention. Mean accuracy was greater than 95% on all tasks for both groups. These results indicate that attentional impairment in early DAT involves decreased ability to filter out irrelevant attributes of visual stimuli and marked difficulty dividing attention among different attributes of compound stimuli.

273.2

DELAYED LATE COMPONENT OF VISUAL GLOBAL FIELD POWER IN PROBABLE ALZHEIMER'S DISEASE. K.L. Coburn, J.W. Ashford and M.A. Moreno*. SIU School of Medicine, Springfield, IL 62708.

Late components of flash visual evoked potentials (FVEP's) are delayed in at least some forms of dementia in the elderly. The delay is selective in that earlier components are not affected. Recent work suggests that this selective late component delay may be characteristic of Alzheimer's disease (AD) rather than an inevitable feature of dementia in general. This study uses reference free Global Field Power (GFP) analysis to more objectively define FVEP components and finds that the GFP peak corresponding to the late P2 component is delayed in a probable AD group but not in a demented unlikely AD group, relative to age equivalent normals. The late component delay is again found to be selective in that the GFP peak corresponding to the earlier P1 component does not differ between groups. These findings further strengthen the evidence for electrocortical changes in the visual system of AD patients.

EARLY BEHAVIORAL SYMPTOMS IN ALZHEIMER'S DISEASE: PATHOLOGICAL CORRELATES. J.M. Verheij*, D.M. Freed, and V.W. Henderson. Departments of Psychology and Neurology (Div. of Cognitive Neuroscience & Aging), Univ. of Southern Calif., Los Angeles, CA 90089

Clinical heterogeneity of Alzheimer's disease (AD) is well documented, but the pathological substrate of AD symptoms is poorly understood. We hypothesized that AD patients with early behavioral abnormalities would show particularly severe neuropathological alterations within frontal lobe association areas. We retrospectively studied 60 demented patients followed by the Alzheimer's Disease Research Center at the University of Southern California with autopsy-confirmed "definite" AD. Based on initial symptoms as reported by a subject's primary caregiver on a structured intake interview, AD patients were dichotomized into those with behavioral changes at the onset of their dementia and those without early behavioral abnormalities. Targeted behavioral symptoms were depression, delusions, hallucinations, or paranoid ideation. Twenty-one index AD subjects (35%) were reported to have early behavioral changes, and 39 (65%) comparison subjects did not; index and comparison subjects did not differ significantly with regard to gender or to mean age at the time of symptom onset, age at death, or symptom duration. At autopsy, numbers of neurofibrillary tangles (NFT) and neuritic plaques (NP) were semiquantitatively estimated in the middle frontal gyrus (Brodmann's area 9) and hippocampus. NFTs (χ^2 [1] = 8.90, $P=0.003$) and NPs (χ^2 [1] = 9.22, $P=0.002$) were significantly more abundant in frontal cortex for the index cases than for comparison subjects, whereas the histopathological burden in the hippocampus was similar for the two subgroups. Findings suggest that early behavioral abnormalities in AD are, at least in part, determined by the distribution and severity of the associated pathological changes. [NIA P50-AG05142]

GLUCOSE ENHANCEMENT OF MEMORY IN ALZHEIMER'S PATIENTS. M.E. RAGOZZINO, C.A. MANNING*, W.K.K. LAM, and P.E. GOLD. Department of Psychology, U. Virginia, Charlottesville, VA 22903.

Recent findings indicate that administration of glucose facilitates memory in elderly rodents and humans. In healthy elderly humans who demonstrate normal age-related memory changes, glucose improves performance on secondary verbal memory tasks but does not affect performance on non-memory tasks or on visual memory or implicit memory (stem completion) tests. The present experiment examined the effects of glucose on memory in Alzheimer's patients.

Subjects, aged 61-92 ($n=14$), were tested on two consecutive mornings. Subjects took a series of tests assessing orientation, explicit secondary verbal and visual recall and recognition, and implicit verbal memory after ingesting 75 g of glucose or 32 mg of saccharin. Blood glucose levels were measured at several times during testing. On Day 2, the procedure was repeated with alternate treatments and test forms, permitting within-subject comparisons.

Recall of contextual and noncontextual verbal material was significantly improved after glucose ingestion ($p's < 0.01$) as was recognition of verbal material ($p < 0.005$). In addition, facial recognition was significantly enhanced by glucose ($p < 0.05$). Performance under glucose on these tests was still substantially below that seen in non-demented aged individuals. Scores on the implicit memory task were unaffected by glucose. These findings provide evidence that glucose enhances both verbal and visual explicit memory in Alzheimer's patients. As in healthy elderly subjects, glucose did not enhance implicit memory in Alzheimer's patients. (Supported by ONR N0001489-J-1216, NIA AG 07648, NSF BNS 9012239, and the Virginia Center on Aging. VISUOMOTOR CONTROL IN ALZHEIMER'S DISEASE: RELATION TO PARIETAL ASSOCIATION CORTEX

S. Murakami, M. Fujii*, J. Miyazawa*, N. Nakano*, R. Fukatsu* and N. Takahata*. Dep. of Neuropsychiatry, Sapporo Medical College, Sapporo 060 Japan.

Pathological changes in visual association area and inferior parietal cortex, has been reported in the patients with Alzheimer's Disease (AD) even in early stage, so that the investigation of visuomotor control in the patients was planned to demonstrate behaviorally specified deficit of the visual perceptual function related to SPECT and MRI findings. Gazing, eye movement trajectory and visual field in front of subject during drawing or copying a cube were recorded and analyzed in 10 patients with AD by means of TV camera and Vision Analyzer (TKK939). They showed the reduced uptake of I-123-IMP SPECT and shrinkage MRI in parietal association area. When they drew a cube according to their memory or without visual guidance, drawing was almost successful. But when they copied a cube by using visual guidance a picture became poor. Gazing shift away from the original and copied figures indicated disorder of accurate eye movement towards visual targets. In our quantitative analyses, the distribution of eye movement velocities during copying was diffuse to wide range from slow to fast and had no peak, and the amount of high velocity eye movements which mean back and forth eye movements between a model and a copied figure showed no difference within head fixed and free condition. It is suggested that parietal association cortex is needed to get accurate eye movement and that abnormal one in AD towards visual targets make negative effects to do something.

MAGNETIC AUDITORY STEADY-STATE RESPONSE INCREASES WITH AGING AND IS GREATEST FOR SUBJECTS WITH MILD ALZHEIMER'S DISEASE. S.B. Baumann*, A.C. Papanicolaou*, H.S. Levin, L.A. Bertolino*, R.L. Rogers*, B.E. Masel*, H.M. Eisenberg. MEG Lab, Div. of Neurosurgery, University of Texas Medical Branch and the Transitional Learning Community, Galveston, TX 77550.

As part of a project to determine if magnetoencephalography (MEG) might contribute to improvements in the diagnosis of early Alzheimer's disease, we have used an auditory steady-state paradigm to test three groups of subjects - young normals (n=11, mean age=31), elderly normals (n=4, mean age=77), and elderly subjects with probable, mild, Alzheimer's disease (n=5, mean age=79). A seven-channel Neuromagnetometer was used to make recordings just above the right ear as subjects lay on a padded table within a shielded room. Tone bursts of a 500 Hz carrier, 4 msec rise/fall time and 2 msec plateau time, were delivered to the left ear in 5 Hz intervals at tones of 20-50 Hz. Each average of 500 epochs was Fourier transformed and analyzed for power at frequencies of 20-60 Hz. When power for the resonant frequency was measured (e.g. power measured at 35 Hz for 35 Hz tone bursts), at nearly every stimulus frequency the young subjects had the least power and the mild Alzheimer's subjects had the greatest power. The effect was greatest in the frequency range of 30-45 Hz where the normal elderly subjects had 21%-57% more power than the young subjects (N.S.) and the Alzheimer's subjects had 117%-165% more power than the young subjects (p<.05). This effect is in agreement with recent reports that many disease processes lead to greater periodicity in physiological signals.

273.11

COGNITIVE DEFICITS IN EARLY ALZHEIMER'S DISEASE RELEVANT TO DRIVING SKILLS. L. J. Fitten, C. J. Wilkinson*, M. Burns*, K. Perryman*, S. Ganzell*, and D. Ganzell*. Lab of Cognitive Neurophysiology, VAMC Sepulveda, CA 91343 / UCLA School of Medicine, CA 90024 and Southern California Research Institute, Los Angeles, CA 90066.

In recent preliminary work, we have shown that generally healthy patients with early Alzheimer's disease (AD) perform significantly worse on an actual road test than either age-matched healthy controls or age and Folstein Mini-mental State Exam (MMSE) score-matched, non-stroke diabetics and multi-infarct (MID) patients. We are presently attempting to define which cognitive deficits present in early AD are responsible for such a decrement in driving ability. In the laboratory, we are measuring driving related skills by various tests of attention (e.g., sustained, divided) perception, information processing and decision-making. These include tests for visual search, tracking, divided attention, vigilance, response time, short term memory and visual evoked potentials. Our preliminary findings show a consistent pattern of differential performance as a function of group, the poorest scores originating from the AD patients followed by MID, diabetics and controls. AD patients performed particularly poorly on high demand perceptual and attentional tasks as well as on short-term memory tests. This was true even for AD patients with relatively high MMSE scores (24-26). Cognitive deficits in mild AD appear to include sizable deficits in the early phases of information processing which appear to impact significantly on driving performance.

273.8

SEMANTIC FLUENCY IN PARKINSON'S DISEASE AND ALZHEIMER'S DISEASE: EFFECTS OF CUING. C. Randolph, A.R. Braun, T.E. Goldberg, T.N. Chase, and D.R. Weinberger. Clinical Brain Disorders Branch, NIMH Neuroscience Center, Washington DC 20032

It was hypothesized that poor performance on semantic fluency tasks might be due to either 1) a degradation of semantic memory, in which exemplars are no longer available for retrieval, or 2) an ineffective retrieval strategy. Patients with Parkinson's disease (PD), patients with Alzheimer's disease (AD), and normal controls were compared on two versions of a semantic fluency task. One version consisted of uncued retrieval from a relatively broad semantic category (e.g. animals). In the other version subjects were provided with a retrieval strategy, which consisted of prompting them with subordinate categories in which to search (e.g. household pets, farm animals). Each version was administered to all subjects in a counterbalanced design using two semantic categories. Both PD and AD patients were significantly impaired relative to controls on the uncued version. PD patients improved significantly on the cued version (to control levels), whereas the AD patients exhibited no improvement as a result of cuing. The results suggest that deficits exhibited by PD patients on semantic fluency tasks may be a result of ineffective retrieval strategies, whereas AD patients may perform poorly as a result of semantic memory loss.

CANTAB PARALLEL BATTERY: A SUITABLE TOOL FOR INVESTIGATING DRUG EFFECTS ON COGNITION? J. Semple*, C.G.G. Link* Clinical Pharmacology Dept., and A.J. Hunter Research Programmes, Smithkline Beecham Pharmaceuticals, Coldharbour Road, The Pinnacles, Harlow, Essex, CM19 5AD.

The Cambridge Automated Neuropsychological Test Battery (CANTAB) was devised to assess various aspects of cognition in patients with brain damage, including conditions associated with dementia. CANTAB comprises 3 "clinical" batteries - Working Memory and Planning, Visual Memory and Attention. A further battery based on elements of these is available in 4 parallel forms and was designed for phase I volunteer studies. The tests can be run on an IBM computer and utilise a Touch Sensitive Screen. Forty eight healthy volunteers completed all four versions of the test battery. Results indicated comparable performance on all versions though ceiling effects may be a problem with young volunteer populations.

273.12

CYTOCHROME OXIDASE INHIBITION BY SODIUM AZIDE INFUSION IMPAIRS LEARNING IN THE MORRIS WATER MAZE. M.C. Bennett and G.M. Rose. Department of Pharmacology, C-236, UCHSC, and VAMC, Denver, Colorado

Cytochrome oxidase activity is significantly reduced in blood platelet mitochondria from Alzheimer's disease (AD) patients [Parker *et al.*, *Neurol.*, 40, 1301 (1990)]. Previously, we reported that chronic and selective inhibition of cytochrome oxidase by sodium azide impaired learning on two behavioral tasks and impaired hippocampal plasticity [Bennett *et al.*, *Neurosci. Abst.*, 16, 1346 (1990)]. We now report that sodium azide treatment impairs learning in the Morris water maze.

Adult male Sprague-Dawley rats were implanted with Alzet osmotic minipumps (2ML4) containing 0.9% saline (CONTROL) or 160 mg/ml sodium azide (AZIDE) 7-21 days prior to training. Rats were given 4 daily trials for 7 days in a tank filled with opaque water maintained 24-25° C. Swim time to a hidden platform, which occupied a fixed position relative to extramaze cues, was the performance measure. The AZIDE rats exhibited overall poorer performance across trials [MANOVA main effect: F(1,23) = 16.0; p < 0.001]. First day performances did not differ significantly between groups (t = 0.78, NS), indicating that the deficit was not due to a motor impairment.

These results extend our previous findings and indicate that chronic cytochrome oxidase inhibition produces a generalized learning deficit. The present finding is consistent with the hypothesis that tonic infusion azide in rats models some characteristics of AD.

273.13

BLUE COLOR DEFICIT IN ALZHEIMER'S DISEASE.

A. Cronin-Golomb, R. Sugiura*, S. Corkin, J.H. Growdon. Dept. of Psychology, Boston University, Boston, MA 02215, Dept. of Brain & Cognitive Sciences & Clinical Research Center, MIT, Cambridge, MA 02139, & Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Our findings with the City University Colour Vision Test (Cronin-Golomb et al., *Ann. Neurol.*, 1991, 29, 41-52) suggested that selective color deficits on the blue-yellow axis occur in Alzheimer's disease (AD). We now report a replication and extension of these findings, using two measures of color vision that are more subtle and sensitive than that used in the previous study. The Farnsworth-Munsell D-15 Test and the Lunau-Lanthony New Colour Test require subjects to discriminate hues on color caps and place them in the proper sequence. We tested 29 patients with AD and 25 age-matched control subjects (CS). Of the AD group, 13 consecutive patients had received a complete neuro-ophthalmological examination that ruled out significant disorders of the anterior visual structures. Statistical analyses showed that the AD patients made more tritan (blue) errors than did the CS ($p < .01$ for each test) but not more deutan (green) or protan (red) errors. Within the AD group, there were more tritan than other error types ($p < .05$). The results support the conclusion that there is a deficit in blue hue discrimination in AD. Such a deficit may result from the lesions of extrastriate visual cortex that are known to occur in this disease.

273.15

PERFORMANCE ON ATTENTIONAL TASKS IN PATIENTS WITH DEMENTIA OF THE ALZHEIMER TYPE IMPROVES FOLLOWING ORAL ADMINISTRATION OF THE COGNITIVE ENHANCER BMY-21502. A. Berardi, K.C. Baffaele, S. Asthana*, J.V. Haxby*, B. Shrotriya*, T.T. Soncrant, Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892 and Bristol-Myers Squibb Pharm. Res. Inst., Wallingford, CT 06492-7660.

Studies of BMY-21502 in laboratory animals indicate that it may prevent the disruption of memory, enhance the acquisition of new learning, and improve spatial memory. The objective of this 12 week open trial was to identify a safe and effective dose range for the treatment of symptoms of mild to moderate dementia of the Alzheimer Type (DAT). Nine DAT patients (mean MMS = 21.4 ± 4.03, range = 15-26) received escalating doses of BMY-21502 according to the following schedule: one week at 100 mg once a day, one week at 200 mg once a day, 5 weeks at 300 mg twice daily (300x2), and 5 weeks at 300 mg three times daily (300x3). Baseline psychometrics were administered during two sessions preceding the beginning of the study, and testing on drug was conducted after 1 week at 100 mg once a day, 1 week at 200 mg once a day, and after 1, 3 and 5 weeks at the 300x2 and 300x3 doses. For the 300x2 and 300x3 doses, mean neuropsychological scores were used for analysis. No significant improvements were found at any dose on tests of dementia severity (MMS, $0.05 < p < 0.15$ for doses 300x2 and 300x3) and memory (Buschke Selective Reminding, $0.05 < p < 0.10$ for doses 300x2 and 300x3). Significant improvements were found at the 200, 300x2 and 300x3 doses on tests of attention (Stroop Color Naming: 300x3, mean improvement = 5.9, $t = 4.378$, $p < 0.008$ ($n=6$); Stroop Interference: 200 mg, mean improvement = 4.722, $t = 2.895$, $p < 0.05$ ($n=9$); 300x2, mean improvement = 4.656, $t = 3.135$, $p < 0.02$ ($n=9$); 300x3, mean improvement = 4.017, $t = 5.3$, $p < .004$ ($n=6$)) and short-term memory span (Digit Span: 300x3, mean improvement = .683, $t = 3.555$, $p < 0.02$ ($n=6$)). The present results indicate that BMY-21502 may act as a cognitive enhancer by improving visuomotor speed and by increasing the general level of arousal and attention.

CLASSICAL EYEBLINK CONDITIONING AND THE ASSESSMENT OF MEMORY DISORDERS. R.G. Finkbiner & D.S. Woodruff-Pak. Dept. of Psychology, Temple University & Philadelphia Geriatric Center (PGC), Philadelphia, PA 19141.

We examined the diagnostic utility of eyeblink classical conditioning in differentiating memory disorders of varying etiologies. Patients ($N=38$; Mean age = 76 years) underwent full diagnostic evaluations at the Baer Consultation and Diagnostic Clinic at PGC which included physical, neurological, psychiatric, and radiological examinations, neuropsychological testing, and eyeblink classical conditioning in a delay paradigm (500 msec, 1 KHz, 80 dB tone CS followed 400 msec after its onset by a 100 msec, 5 psi corneal airpuff US). Following audiometric testing, patients received 10 blocks of acquisition training (90 trials). Learning (measured by total percentage CRs) was significantly poorer for patients meeting NINCDS-ADRDA criteria for probable Alzheimer's disease (AD) or Mixed dementia (17.9%) compared to patients with dementia secondary to alcohol abuse (36.5%). In this sample, the two patients with cerebrovascular dementia (CVD) conditioned more poorly (6.7%) than both AD/Mixed patients and personality disordered patients (25.8%). Eyeblink classical conditioning is a useful measure in differentiating memory disorders. *Supported by NIMH CRC 40380 and a grant from the Alzheimer's Association.*

273.14

INTACT PRIMING OF PICTURES IN DIFFERENT ORIENTATIONS IN PATIENTS WITH ALZHEIMER'S DISEASE. S.M. Park*, S.L. Reminger*, D.A. Grosse, R.S. Wilson, and I.D.E. Gabrieli. Rush Alzheimer's Disease Center, Chicago, IL 60612 and Department of Psychology, Northwestern University, Evanston, IL 60208.

In a prior study, we found that patients with early-stage Alzheimer's disease (AD) showed normal priming on a picture-naming task despite their impaired recognition memory of the pictures. In the present study, we sought to discover if the preserved priming capacity extends to pictures shown in different orientations. Thirteen mildly-to-moderately demented AD patients and 12 normal control (NC) subjects participated in this 3-phase study. In Phase I, subjects named 84 pictures of common animals and objects presented in 12 different orientations in 30° increments around the picture plane; naming latencies were recorded. In Phase II, subjects performed a three-choice recognition test with 12 of the pictures named in Phase I. In Phase III, subjects renamed the remaining 72 pictures that were presented in an orientation different from that in Phase I. AD patients named pictures slower and made significantly more naming errors than NC subjects. AD patients were also significantly impaired on the recognition test. AD and NC groups showed similar and significant picture-naming repetition priming as measured by faster naming of Phase III than Phase I pictures. These results replicate our previous finding of preserved picture-naming despite impaired recognition memory of pictures in AD. Moreover, AD patients demonstrated intact priming despite changes in orientation of the pictures. Thus, these results show that picture-naming priming in AD extends to pictures shown in noncanonical positions and across different orientations. (Supported by grants from the Alzheimer Association and Illinois Department of Public Health.)

273.16

EYEBLINK CLASSICAL CONDITIONING AND NEUROPSYCHOLOGICAL TESTS IN DOWN'S SYNDROME ADULTS. M. Papka,^{1,2} E. Rozette,^{3*} J. M. Coffin,^{1,2} D. A. Rappaport,^{3*} E. W. Simon,^{3*} & D. S. Woodruff-Pak.^{1,2} Dept. of Psychology¹, Temple Univ., Philadelphia Geriatric Center², Philadelphia, PA 19141 & Elwyn³, Elwyn, PA 19063.

Virtually all adults with Down's syndrome (DS) develop Alzheimer's-like neuropathology by age 35, but most do not have accompanying behavioral signs of dementia. We demonstrated that eyeblink conditioning discriminates patients with probable AD from controls. Here we used the 400 msec delay paradigm to see if eyeblink conditioning would detect Alzheimer-like changes in DS adults in the absence of behavioral signs of dementia. Data were collected on 20 DS adults, ranging in age from 19 to 64 years. To assess dementia, the Down Syndrome Mental Status Examination (DSMSE) and the Slosson Intelligence Test (SIT) were used. There was a significant difference in CR percentage between DS adults below 35 (CR average = 36.1%) and those 35 or older (CR average = 17.5%; $t = 2.26$; $p < .05$). Analysis based on a sub-group of the DS adults indicated that the DSMSE and the SIT failed to discriminate between older and younger subjects. Eyeblink conditioning may index neuropathological expression of AD in DS adults when other tests are insensitive to the changes. *Supported by an NIH Biomedical Research grant from PGC.*

273.18

TRACE CLASSICAL CONDITIONING IN ALZHEIMER'S DISEASE. J. M. Coffin, M. Papka, & D. S. Woodruff-Pak. Department of Psychology, Temple University and Philadelphia Geriatric Center, Philadelphia, PA 19141.

We have previously reported that patients diagnosed with probable Alzheimer's Disease (AD) condition more poorly in the delay classical conditioning paradigm than do non-demented, age-matched elderly. Our goal is to identify a classical conditioning paradigm that differentiates non-demented elderly from AD patients to an even greater extent than does the 400 msec delay paradigm. The present study was undertaken to explore performance on the 750 msec trace paradigm in patients who met NINCDS-ADRDA criteria for diagnosis of probable AD and normal elderly. Following a brief hearing test, subjects were presented with 90 acquisition trials. Each trial consisted of a 250 msec, 85 dB tone CS, a 500 msec blank period, and a 100 msec, 5 psi corneal airpuff US (750 msec CS-US interval). The probable AD group had a mean age of 86 years and the non-demented control subjects had a mean age of 79 years. Percentage of CRs for probable AD patients were 15.2, and for normal elderly were 34.4. Classical conditioning of the eyeblink response in the trace paradigm reliably discriminates between normal elderly and patients with probable AD. *Supported by a grant from the Alzheimer's Association.*

274.1

PHYSIOLOGIC RESPONSES TO THYROTROPIN-RELEASING HORMONE (TRH) INFUSION IN ALZHEIMER'S DISEASE AND NORMAL AGING.

T.H.Lampe*, **R.C.Veith***, **S.C.Risse***, **S.R.Plymate*** and **M.A.Raskind**. Univ. of Wash. Sch. of Med. and American Lake VA Medical Center, Tacoma WA 98493.

Physiologic responses to TRH in normal man primarily reflect TRH-evoked activation of the sympathetic nervous system (SNS). To clarify possibilities that evoked SNS activity is altered in aging and blunted in Alzheimer's disease (AD), prompt physiologic responses (i.e., maximum increments over baseline in blood pressure [BP], heart rate [HR] and plasma norepinephrine [NE]), occurring over the first 5 minutes after an i.v. bolus of 0.1 mg TRH (protirelin), were assessed in 11 otherwise healthy men with probable AD (age 64.8 ± 6.3; mean ± SD), 10 Old Normal (ON) men (61.4 ± 9.8) and 8 Young Normal (YN) men (27.1 ± 2.9). Methods employed were similar to our previous study which had identified physiologic responses to TRH as relatively blunted in men with advanced AD vs. matched normals (*Psychoneuroendocrinology* 14:311-320, 1989).

Results: In Old Normal compared to YN cohorts, mean HR response to TRH was significantly blunted (9.3 ± 4.5 bpm vs. 17.9 ± 6.4; $p < 0.05$ [ANOVA]) yet mean plasma NE response was elevated (98.0 ± 64.9 pg/ml vs. 36.9 ± 35.6; $p < 0.05$). In AD subjects, physiologic responses (most notably HR) correlated positively with measures of their cognitive performance on established tests (e.g., correlation of HR responses with Folstein MMS scores, $r = 0.75$ [$p < 0.01$]; HR with Boston Naming, $r = 0.70$ [$p < 0.02$]; HR with Mattis' DRS scores, $r = 0.77$ [$p < 0.01$]).

Conclusions: The impact of age on normal subjects' responses (↓HR, ↑NE in ON vs. YN) accords with prior reports of this pattern of SNS-related alterations with advancing age; this reinforces the potential utility of employing TRH to assess human SNS reactivity. Present findings suggest that physiologic responses to TRH may be relatively blunted as a function of dementia severity in AD; the mechanism(s) underlying this phenomenon and its potential utility as a severity-related pathophysiologic biomarker in AD await resolution.

HP 290: A POTENT, ORALLY ACTIVE CHOLINESTERASE INHIBITOR FOR THE TREATMENT OF ALZHEIMER'S DISEASE.

G.M. Bores, F.P. Huger, R.S. Hsu*, S.M. Chesson*, B. Gorney*, K.C. Bradshaw*, R.R.L. Hamer*, E.J. Glamkowski* and V. Haroutunian. Depts. of Biological and Chemical Research, Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ, 08876 and Mt Sinai Medical Center, New York, NY, 10029.

Cholinesterase inhibitors, such as physostigmine have been proposed for the treatment of Alzheimer's disease (AD). HP 290, (3aS-cis)-1,2,3,3a,8,8a-hexahydro-1,3a,8-trimethyl-pyrrolo[2,3-b]indol-5-ol (1,2,3,4-tetrahydroisoquinolinyl) carbamate (ester), is a physostigmine analog with an improved profile. HP 290 was found to be a potent inhibitor of rat brain AChE (IC₅₀ = 0.032 μM) *in vitro*, with selectivity for inhibition of AChE versus BChE (IC₅₀ = 0.88 μM). *In vivo* experiments demonstrated that HP 290 was orally bioavailable, had a longer duration of action and had a more favorable brain-to-plasma ratio than physostigmine. Doses of HP 290 required to produce acute lethality in rats after i.p. administration were much higher than those of physostigmine. HP 290 (0.16 mg/kg) caused significant (+108%), scopolamine-sensitive increase in wave VI of the brainstem auditory-evoked potential in rats. HP 290 significantly enhanced the performance of rats in a passive avoidance task at doses of 0.32 and 0.64 mg/kg and reversed the effect of a memory deficit induced by a lesion of the nBM at a dose of 0.64 mg/kg. Increased stability and duration of action, improved oral bioavailability, good brain penetration and decreased acute lethality make HP 290 an interesting therapeutic candidate for the treatment of AD.

NEW INSIGHTS INTO THE MECHANISM OF ACTION OF ACETYL-L-CARNITINE (ALCAR) IN NEURO-DEGENERATION.

A. Carta¹, M.T. Alderdice², G. Caruso³, A. Marchionni⁴, N. Benedetti¹, M. Calvani¹. ¹Sigma-Tau S.p.A., Pomezia (Rome) Italy; ²Sigma-Tau Pharmaceuticals, Gaithersburg, MD 20878, USA.

Acetyl-L-Carnitine, an endogenous compound with the primary function of assuring the availability of Acetyl-CoA, the key factor of mitochondrial metabolism, is currently under extensive evaluation in patients with Alzheimer's Disease. Animal studies have shown both in aged models of neuronal degeneration and in pathological models of neuronal damage that Acetyl-L-Carnitine prevents neuronal loss and protects cells from oxidative insults. Data on brain microvessels metabolism also yield new insights into a better understanding of the therapeutic activity of the compound.

Basic research data in animal models will be presented, along with discussions to help explain the basic cellular mechanism(s) of Acetyl-L-Carnitine.

274.2

HP 290: A POTENTIAL ALZHEIMER'S THERAPEUTIC AGENT WITH REDUCED CARDIOVASCULAR LIABILITY.

D. Howard*, S. Aschoff*, G. Bores, C. Detig*, C. Errico*, D. Fink*, E. Glamkowski, R. Hamer*, F. Huger, C. Smith, and A. Gorman*. Depts. of Biological and Chemical Research, Hoechst-Roussel Pharmaceuticals, Inc., Somerville, NJ 08876.

HP 290 is a potential agent in the treatment of Alzheimer's disease displaying potent cholinesterase inhibition (IC₅₀: 31 nM), oral bioavailability and a long duration of action. In this report, the cardiovascular profile of HP 290 was evaluated. In anesthetized beagles, HP 290 (0.1 mg/kg/min, iv) elicited increases in mean arterial pressure (MAP: +54%), cardiac output (CO: +40%), and total peripheral resistance (TPR: +61%) with heart rate unchanged. In contrast, heptylphysostigmine (HEP) caused overall cardiovascular depression (MAP: -24%; CO: -28%; HR: -56%; TPR: -19%). During α- and β-adrenergic blockade, HP 290 elicited responses similar to HEP in the intact state, whereas HEP induced pronounced cardiac depression (MAP: -72%; CO: -89%; HR: -56%) with A-V blockade at cumulative doses of 7.6-10.2 mg/kg. Similar degrees of potentiation of HR responses to electrical stimulation of vagal efferent fibers was observed for HEP and HP 290 at cumulative i.v. doses of 1.2 mg/kg and 12.0 mg/kg, respectively. Cumulative doses of HP 290 (8 mg/kg/day x 4 days) in conscious dogs did not result in prohibitive changes in MAP and HR although AChE in RBC's was inhibited by as much as 90-100%. Therefore, HP 290 exhibits a more desirable therapeutic index in the potential symptomatic treatment of Alzheimer's disease in the elderly.

274.4

ACETYL-L-CARNITINE: A NEUROPROTECTIVE THERAPY FOR ALZHEIMER'S DISEASE.

M. Calvani¹, M.T. Alderdice², M. Iannuccelli¹, A. Koverech¹, A. Carta¹. ¹Sigma-Tau S.p.A., Pomezia (Rome) Italy; ²Sigma Tau Pharmaceuticals, Gaithersburg, MD 20878, USA.

Acetyl-L-Carnitine was originally tested as a potential treatment of Alzheimer's Disease (AD) because of its cholinomimetic properties. Interestingly, a series of controlled clinical trials performed in Europe on Alzheimer's patients demonstrated that Acetyl-L-Carnitine, compared to placebo, was able to slow down the progression of the disease. This was demonstrated by the fact that there was less deterioration in cognitive function in the Acetyl-L-Carnitine group during the period of double-blind treatment. This action appears to be in contrast to nootropic compounds which may enhance cognitive function temporarily, while the underlying degenerative disease process continues to progress.

In particular, a one-year multicenter study on 130 AD patients showed a statistically significant "protection" of deterioration in subjects treated with Acetyl-L-Carnitine, compared to placebo, with respect to decline in cognitive function over time. The first controlled data obtained from clinical trials performed in the United States support these encouraging results. Details of results of changes in cognitive function data will be presented.

274.6

A STUDY ASSESSING THE SAFETY AND EFFICACY OF PHOSPHATIDYLSELINE IN PATIENTS WITH MILD TO MODERATE ALZHEIMER'S DISEASE.

M. Miernicki^a, M. Bradshaw^a, W. Petrie^b & T. Crook^c. ^aFIDIA Pharmaceutical Corporation, Washington, DC 20006, ^bVanderbilt University School of Medicine, Nashville, TN 37240 and ^cMemory Assessment Clinics, Inc., Bethesda, MD 20814.

Phosphatidylserine extracted from bovine cortex (BC-PS) has been shown to reduce age-related declines in certain cognitive functions in both animal models and open-label human trials. BC-PS also exerts modulatory influences on several neurochemical parameters that have been implicated in Alzheimer's disease (AD). Here we report the results of a double-blind, placebo-controlled clinical trial conducted to examine the safety and efficacy of BC-PS in patients with AD.

Fifty-one patients meeting the clinical criteria for AD were treated for 12 weeks with either BC-PS (100 mg capsules, t.i.d.) or placebo. BC-PS treated patients showed statistically significant improvement on objective cognitive performance tests and psychiatric rating scales compared to patients treated with placebo. An analysis of various subgroups suggested that patients with less severe cognitive impairments at the beginning of the study responded more favorably to BC-PS than did patients with more severe cognitive impairments.

These results suggest that BC-PS may be a promising candidate for further study in early, and perhaps prophylactic, treatment of AD.

274.7

PERFORMANCE IMPROVEMENTS IN PATIENTS WITH DEMENTIA OF THE ALZHEIMER TYPE FOLLOWING TREATMENT WITH THE MUSCARINIC CHOLINERGIC AGONIST ARECOLINE. K.C. Raffaele, A. Berardi, S. Asthana,* P. Morris,* M.B. Schapiro,* J.V. Haxby,* and T.T. Soncrant. Laboratory of Neurosciences, National Institute on Aging, Bethesda, MD 20892.

Alzheimer's disease (AD) is consistently associated with deficits in cholinergic function. In the current study, 8 patients with probable or possible AD (NINCDS/ADRDA criteria) with mild or moderate dementia (MMSE scores 15-26, ages from 50-81 years) were treated with arecoline (a direct muscarinic cholinergic agonist) in a two part study. First, each patient received a 2-week continuous i.v. infusion of escalating doses of arecoline. Cognitive testing was performed at 5 doses (1, 4, 16, 28, and 40 mg/day). An optimal dose was selected individually for each patient and each patient was then retested in a double-blind crossover manner during 1-week infusions of the optimal dose and placebo. A significant improvement was found in verbal memory (Buschke selective reminding test, $p=0.03$) at low doses during dose-finding. That improvement was replicated for responders during the double-blind study. Improvement in figure-copying ($p=.053$) was also demonstrated during the double-blind study. Thus, improvement of verbal memory and of visuo-spatial function can be demonstrated in DAT patients in response to treatment with the direct cholinergic agonist, arecoline.

274.9

PHYSOSTIGMINE PHARMACOKINETICS FOLLOWING INTRAVENOUS ADMINISTRATION IN PATIENTS WITH DEMENTIA OF ALZHEIMER TYPE. S. Asthana,* L. Hegedus,* N.H. Greig,* H.W. Holloway,* K.C. Raffaele, A. Berardi, M.B. Schapiro,* P. Pietrini, T.T. Soncrant. Lab of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

Physostigmine, a reversible cholinesterase inhibitor, temporarily influences memory in patients with dementia of the Alzheimer type (DAT). As part of a study to evaluate the effects on cognition of physostigmine administered by continuous i.v. infusion, its plasma pharmacokinetics were measured in four patients with DAT (age 63, 66, 72, 83; 2 males, 2 females). Physostigmine 0.025 mg/min was infused i.v. over 45-60 min. Venous blood samples were collected, at several times during and after completion of the infusion, into tubes containing an excess of the cholinesterase inhibitor octylcarbamoyl eseroline. Plasma was separated by centrifugation and assayed for physostigmine, using high pressure liquid chromatography. Plasma physostigmine levels rose to a peak of 11.9 ± 2.8 (S.E.) nM at completion of infusion, then fell monoexponentially with an elimination half-life of 17.9 ± 5.9 min. Thus, steady state plasma levels of physostigmine will be achieved only after at least 90 min. of continuous i.v. infusion of physostigmine.

274.11

COMPARISON OF BRAIN TO PLASMA METABOLIC DISTRIBUTIONS OF TACRINE AND 1-HYDROXYTACRINE IN RAT. W. F. Pool,* S. M. Bjorge,* B. Windsor,* A. Black,* T. Chang,* and T. E. Woolf. Parke-Davis Pharmaceutical Research, Warner-Lambert Co., Ann Arbor, MI, 48106.

Tacrine (THA, Cognex, CI-970) and 1-hydroxytacrine (1-HOTHA) are acetylcholinesterase inhibitors currently under development for treatment of Alzheimer's disease. The following study was designed to assess the CNS penetration capabilities of THA and 1-HOTHA in rats after single equimolar (79 μ mole/kg) oral doses of 14 C-THA or 14 C-1-HOTHA. Animals were sacrificed at 0.5, 2, 4, and 8 hr with brain and plasma collected. Brain homogenates and plasma were analyzed by liquid scintillation spectrometry and profiled by HPLC radioactivity detection. Results clearly demonstrate that THA readily crosses the BBB and concentrates in the CNS. Rapid concentration of THA-derived radioactivity in brain was also observed in autoradiographic studies (McNally et al. this meeting). Brain to plasma THA concentration ratios between 5.2 and 6.4 were observed throughout the study. The major THA metabolite present in plasma, namely 1-HOTHA, was also detected in brain. Concentrations of 1-HOTHA in the CNS were lower than corresponding plasma concentrations throughout the study (0.2 to 0.7). Based on metabolic profiling data, app. 80% of THA-derived radioactivity in brain was comprised of unchanged THA. Brain to plasma 1-HOTHA ratios after 1-HOTHA dosing ranged from 0.3 to 1.1 with nearly 100% of the radioactivity in brain corresponding to unchanged 1-HOTHA. In conclusion, THA concentrations achieved in rat brain were several fold higher than those observed for 1-HOTHA indicating greater CNS penetration capabilities of THA compared to 1-HOTHA.

274.8

CHANGES IN VERBAL MEMORY DURING CHRONIC ARECOLINE INFUSION ARE CORRELATED INVERSELY WITH AGE IN ALZHEIMER'S DISEASE. T.T. Soncrant, K.C. Raffaele, A. Berardi, S. Asthana,* M.B. Schapiro,* J.V. Haxby*. Lab. Neurosci., NIA, NIH, Bethesda, MD 20892.

Preliminary results of a study employing chronic infusion of arecoline, a muscarinic cholinergic agonist, suggest that verbal memory can be improved by this drug in a majority of patients with dementia of the Alzheimer type (DAT). The present analysis was performed to identify predictors of a positive response. Eight patients (5 male, age 50-81, MMSE 15-26) underwent a 2 wk continuous i.v. infusion of arecoline, escalating from 0.2 to 40 mg/day. The dose producing optimal cognitive enhancement on 10 neuropsychological tests was then administered for 5 days in a double-blind, placebo-controlled, crossover design. Long-term recall (LTR), measured with the Buschke Selective Reminding Test, was improved ($P<0.05$) during dose finding in 6 of 8 subjects, with an inverted U-shaped relation to dose. During optimal dose infusion, 5 of 6 responders again improved (mean increase 6.0 ± 1.0 [SFM] words). Change in LTR during optimal dose arecoline infusion was not correlated with MMSE or baseline LTR, but was inversely correlated with age ($r = -0.77$, $P<0.05$). Whether the greater cognitive responses of younger subjects to arecoline is due to differential pathophysiology of DAT by age or to underlying age-dependent changes in cholinergic function (independent of DAT) is unknown.

274.10

Cholinomimetic Activity of RS86, AF102B and L-689,660 in Primates N.M.J. Rupniak,* S.J. Tye* and S.D. Iversen. Merck Sharp and Dohme Research Laboratories, Neuroscience Research Centre, Terlings Park, Eastwick Road, Harlow, Essex, CM20 2QR, U.K.

Failure to demonstrate convincing beneficial effects of RS86 in Alzheimer patients may be attributable to constraints on dose escalation due to adverse cholinergic side-effects, including cardiovascular disturbances mediated via M_2 receptors. Muscarinic partial agonists with functional selectivity for M_1 and M_3 receptors might exhibit an improved therapeutic window but retain central cholinergic efficacy. We now compare the central and peripheral effects of RS86 with the M_1/M_3 partial agonists AF102B and L-689,660 ((-)-3-[2-(6-chloropyrazinyl)-1-azabicyclo[2.2.2]octane] in primates.

Using a visuospatial task in rhesus monkeys, administration of RS86 (1.5-2.25 mg/kg i.m.) partially reversed a scopolamine-induced cognitive impairment. Animals exhibited pallor, tremor, salivation and emesis shortly after treatment with high doses. In squirrel monkeys, centrally mediated hypothermia was induced by 0.05 mg/kg p.o. of RS86; intermittent emesis was the only observable side effect in this species (≥ 0.25 mg/kg p.o.). Unlike RS86, treatment with AF102B (up to 6 mg/kg i.m.) failed to reverse the effects of scopolamine on cognition. Salivation was the most prominent side-effect. The minimum hypothermic dose of AF102B was 7 mg/kg p.o.; emetic episodes were observed at a slightly higher dose (9 mg/kg). In contrast, L-689,660 (0.05-0.3 mg/kg i.m.) caused partial reversal of the effects of scopolamine on cognition. Transient salivation was the most marked side-effect. Hypothermia and emesis respectively, were induced by 0.01 mg/kg and 0.05 mg/kg p.o. of L-689,660.

In conclusion, central cholinomimetic activity comparable to that induced by RS86 may be achieved using the M_1/M_3 partial agonist L-689,660 in primates.

274.12

A COMPARISON OF IN VIVO DISTRIBUTION OF RADIOACTIVITY IN RAT BRAIN FOLLOWING ORAL ADMINISTRATION OF TACRINE OR ITS 1-HYDROXY METABOLITE. W.P. McNally, P. DeHart,* W. Pool,* and T. Chang*. Parke-Davis Pharmaceutical Research, 2800 Plymouth Rd., Ann Arbor, MI 48105

A previous report on the distribution of tacrine (THA) in rat tissues (McNally et al. 1989) showed penetration of radioequivalents into brain with preferential uptake in gray matter, notably cortex, hippocampus, striatum and thalamus. In rats a major metabolite of THA is 1-OH-tacrine (1-HOTHA). However, Pool et al. (this meeting) have shown that following THA or 1-HOTHA dose the primary radioactive species in brain is parent drug. The present study was undertaken to compare, by quantitative autoradiography, regional disposition and relative concentration of 14 C-THA and 14 C-1-HOTHA radioequivalents in brain following equimolar oral dose. The table below provides comparative data (μ g equivalents/g) for blood and several brain regions:

	30 MINUTES		4 HOURS	
	THA	1HOT	THA	1HOT
BLOOD	1.9	6.1	2.7	1.7
CORTEX	3.6	1.4	4.8	1.7
THALAMUS	3.5	1.3	4.5	1.6
STRIATUM	3.1	1.1	4.1	1.7
HIPPOCAMPUS	2.9	1.1	4.7	1.8
BRAIN STEM	2.5	1.1	2.8	0.9

1-HOTHA appeared to be more rapidly absorbed and reached higher blood levels than THA. Following administration of either substance radioactivity penetrated the blood-brain barrier, but levels in THA animals were up to 3 times higher than in those dosed with 1-HOTHA. At 24 hours postdose, no activity could be detected in brains of 1-HOTHA treated animals, while low but quantifiable levels were found in the THA group. No activity remained in brain at 48 hours for either compound, although blood levels were measurable through 96 hours. Tacrine appears to be better able to penetrate into brain tissue and may have a longer effective half-life there than 1-hydroxy tacrine.

274.13

DOES TACRINE BIND TO THE ACTIVE CENTER OF ACETYLCHOLINESTERASE (AChE)? C.J. Moore, V.E. Gregor*, C. Lee* and M.R. Emmerling. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105

The anticholinesterase Tacrine (THA, Cognex®, CI-970) is a potential palliative therapy for Alzheimer's Disease. Tacrine is a reversible, noncompetitive inhibitor of electric eel AChE ($K_i = 17$ nM). The relation of Tacrine binding to the active center of eel AChE was studied using irreversible inhibitors that covalently bind to the catalytically active serine of the enzyme. We observe that Tacrine protects AChE in a dose-dependent manner from inhibition by diisopropyl fluorophosphate (DFP) and paraoxon (diethyl-4-nitrophenylphosphate), but not from the smaller methanesulfonyl fluoride (MSF). An active center inhibitor, N-methylacridinium, which has a structure similar to Tacrine, also protects from DFP, but not MSF. In contrast, the active center inhibitors edrophonium and galanthamine protect against both MSF and DFP in a dose-dependent fashion. Addition of bulk to the saturated ring of Tacrine can increase its protection of AChE from MSF. PD 141078 (1,2,3,4-tetrahydro-1,4-methanoacridin-9-amine) protects from MSF inhibition of AChE in a manner similar to edrophonium and galanthamine. Both N-methylacridinium and Tacrine antagonize PD 141078 protection of AChE from MSF. The data imply that Tacrine binds to the active center of AChE, protecting the enzyme from irreversible inhibitors through steric hindrance. Tacrine binding appears to overlap with that of N-methylacridinium, leaving the serine in the active center accessible to small irreversible inhibitors. The active center binding of Tacrine agrees with results from the circular dichroism studies of Wu and Yang (1990, *Mol. Pharm.*, **35**, 85) and from the enzymological studies of Dr. Harvey Berman at SUNY in Buffalo (personal communication).

274.15

INTERACTIONS BETWEEN NEUROPEPTIDES AND ACETYLCHOLINESTERASE (AChE). R.T. Carroll, T.W. Hepburn* and M.R. Emmerling. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105

A number of neuropeptides from the enkephalin, dynorphin and tachykinin families were tested for their ability to inhibit electric eel AChE activity. Only Big Dynorphin, α -neoendorphin, BAM-22P, and Substance P inhibit AChE activity with IC_{50} s of 100 μ M or less. The effect of the interaction with purified AChE on the neuropeptides was studied by incubating the peptides (30 μ g) with affinity purified eel AChE (5 μ g) at 37°C for up to 24 hrs. Samples were withdrawn from the mixture at various times during the incubation and subjected to reverse-phase high pressure liquid chromatography (HPLC). No detectable effect by AChE on Substance P is seen. Slight digestion of α -neoendorphin is detected only after 24 hrs. Digestion products in the mixture containing Big Dynorphin are present at 4 hrs and complete loss of the parent peptide occurs after 24 hrs. Cleavage products of BAM-22P appear after 1 hr, and parent peptide is lost completely by 24 hrs. Digestion of BAM-22P does not occur spontaneously, and is dependent upon the amount of AChE added and the time of incubation. The turnover rate for BAM-22P is slow, about 0.05 sec⁻¹. Other met-enkephalin containing peptides (Met-enkephalin-RRVG and Peptide E) are also hydrolyzed upon incubation with purified AChE. These results indicate that inhibition of AChE activity by neuropeptides is not predictive of their hydrolysis by the enzyme preparation. Moreover, our studies show that the neuropeptidase activity is not unique to the purified AChE but is also present in abundance in the starting material used for AChE purification. Thus, our data do not exclude the possibility that the digestion of neuropeptides by purified AChE results from contaminating proteases rather than by AChE itself.

274.14

THE EFFECTS OF ALLOSTERIC INHIBITORS ON TACRINE BINDING TO ACETYLCHOLINESTERASE (AChE). M.R. Emmerling, C.J. Moore, V.E. Gregor*, and C. Lee*. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105

Tacrine (THA, Cognex®, CI-970) is an anticholinesterase which is reported to improve the cognitive deficits associated with Alzheimer's Disease. Our previous study (see preceding abstract) suggests that Tacrine binds to the active center of electric eel AChE, based upon its almost complete protection of the enzyme from inhibition by diisopropyl fluorophosphate (DFP). In contrast, the allosteric inhibitors propidium and gallamine, which bind to sites on AChE peripheral to the active center, only partially protect (about 40%) AChE from DFP inhibition under the same assay conditions. Gallamine and propidium, at doses up to 10 mM and 100 μ M, respectively, do not antagonize protection from DFP in the presence of Tacrine, or in the presence of the active center inhibitors edrophonium and galanthamine. This lack of antagonism is consistent with the active center inhibitors binding to sites on AChE different from the site to which the allosteric inhibitors bind. Gallamine and propidium, however, do produce a dose-dependent decrease in the protection of AChE by edrophonium and galanthamine from irreversible inhibition by methanesulfonyl fluoride (MSF). The allosteric inhibitors also antagonize protection from MSF by the Tacrine analog PD 141078 (1,2,3,4-tetrahydro-1,4-methanoacridin-9-amine). Because they have no effect on protection from DFP, it seems unlikely that the allosteric inhibitors antagonize protection from MSF by displacement of PD 141078, edrophonium, or galanthamine from the active center of AChE. Thus, the observed antagonism of MSF protection in the presence of active center inhibitors may result from the allosteric inhibitors changing the conformation of the active center, making the active center serine more accessible to small irreversible inhibitors.

PARKINSON'S DISEASE: ANIMAL STUDIES

275.1

A HISTOCHEMICAL ANALYSIS OF THE BRAINS FROM MPTP-TREATED ANIMALS. J. Harper, R. Philip, J.S. Schneider and F.J. Denaro. Slippery Rock University, Slippery Rock, PA 16057. Dept. of Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Dept. of Neurology, Hahnemann University, Philadelphia, PA 19102.

A battery of histochemical stains were used to analyze the neuropathology of MPTP treatment across species. Mouse (C-57, Swiss-Webber), rat, cat and monkey were studied. Periodic Acid Schiff revealed granular inclusion bodies in some residual neurons in the substantia nigra of the monkey. Hematoxylin and eosin stains revealed variable gliosis in the caudate/putamen and substantia nigra of all animals studied confirming the findings of previous studies using antibodies against glial fibrillary acidic protein (GFAP) (*J. Neuropath. & Exp. Neurol.* Vol. 47, #4, 1988). Chromatolysis and neurophagia were found for some residual neurons of the substantia nigra in the cat and monkey, but not in the mouse or rat. Bielschowsky stain, which provides a sensitive measure of plaques and neurofibrillary tangles, did not reveal any such neurocytological changes in striatal or nigral neurons in any of the species examined. Immunocytochemistry to ubiquitin revealed positively stained neurons in the substantia nigra in the cat and monkey. Occasional ubiquitin positive neurons were also found in the mouse. In all cases ubiquitin immunopositivity was not associated with inclusion bodies. C-fos immunocytochemistry has been examined in the acute mouse model. Animals were treated with MPTP for one week and were sacrificed within 24 hours of their last MPTP injection. Under these conditions, some neurons of the substantia nigra were found to be C-fos positive. The production of C-fos by these nigral neurons may be a response to the loss of their terminal fields due to MPTP.

275.2

EXTENSIVE LOSS OF BRAIN SEROTONIN INDUCED BY MPTP IN THE MARMOSET. J. Del Río, C. Oset*, I. Pérez-Otaño*, M.L. De Ceballos*, M.T. Herrero*, R. Luquin and J.A. Obeso. Departments of Pharmacology and Neurology, University of Navarra, Pamplona and Cajal Institute, CSIC, Madrid, Spain.

The neurotoxic effects of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) on several non-dopaminergic brain neurotransmitter systems are controversial. In the present study, MPTP (1.25-2.5 mg/kg s.c.) was given twice a week for 5 or 10 consecutive months to common marmosets ($n = 6$) and the animals were sacrificed 15 days or 6 months later. Six other marmosets served as controls. At any of the two survival times, MPTP produced a strong depletion of serotonin (5-HT), approximately 90%, in all regions studied: caudate nucleus, putamen, n. accumbens, hypothalamus, septum, amygdala, frontal and cingulate cortex. Fifteen days after the chronic treatment, 5-hydroxyindoleacetic acid (5-HIAA) concentration was also decreased by 90% in the striatum, the depletion being less profound, about 75%, in all other regions. At 6 months, the 5-HIAA decrease was lower, especially in extrastriatal regions. The 5-HIAA/5-HT ratio, an index of 5-HT turnover, was much higher than in control monkeys at this time. The results suggest that a treatment schedule with MPTP involving multiple injections spread out over months may induce lasting serotonergic lesions in the marmoset brain. (Supported by grants from E.E.C., Schering España S.A. and Fundación J.A.L.S.).

275.3

EFFECTS OF MPTP ON SELECTIVE DOPAMINERGIC FIBERS IN THE STRIATUM AND ON NEURONS IN THE PARS COMPACTA. Y. Gohda, D.L. Felten and S.N. Haber. Dept. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642

Systemic injection of MPTP damages the dopaminergic (DA) nigrostriatal system in C57BL/6 mice. Recently it has been demonstrated that there are variations in the extent of DA terminal injury between striatal regions. To determine the relationship between the pattern of TH-immunoreactive (IR) fiber depletion in the striatum and the subset of nigral neurons involved, we injected WGA-HRP after MPTP treatment. MPTP (4x20mg/kg i.p.) was given to young adult C57BL/6 mice at 3 h intervals. Three days after treatment WGA-HRP was injected iontophoretically into the different regions of the striatum, and into control mice. They were sacrificed 2 days after WGA-HRP injection.

As expected, MPTP treatment resulted in the disappearance of TH-IR fibers in the striatum. However, regional pattern of TH-IR fiber depletion was more complex than a simple dorsal-to-ventral gradient. The central portion of the striatum was preferentially affected by MPTP, often leaving the dorsolateral rim rich in TH-IR fibers. After injections of WGA-HRP into this central striatal region in MPTP treated mice, fewer labeled cells were found in the central nigra than in control mice. These observations indicate that the regions within the dorsal striatum may be differentially affected by MPTP and that this may be a reflection of degeneration of a subset of DA neurons within the A9 region of the substantia, pars compacta. Alternatively the lack of labeled cells may be the results of interference with the transport mechanism of the effected cells. Supported by NIH NS22511, NIH AG06060 and the PEW Foundation.

275.5

Kinetics of Elimination of MPP+ in the MPTP-treated Squirrel Monkey. I. Irwin, L.E. De Lanney*, D. D. DiMonte* and J. W. Langston*. California Institute for Medical Research and California Parkinson's Foundation, San Jose, CA 95128.

We have previously reported the behavioral, neurochemical and neuropathological effects of MPTP on a group of squirrel monkeys (Br Rsrch, 1990). Because the effects of MPTP are thought to be mediated by the toxic metabolite MPP+, we undertook the analysis of MPP+ in 18 brain regions and 8 peripheral tissues of these animals. The purpose of this study was to characterize the distribution and kinetics of elimination of MPP+ to detect and evaluate the relationship to toxicity. All animals received a single 2.5 mg/kg, subcutaneous injection of MPTP. Groups of animals (n=3/group) were sacrificed 1, 3 or 5 days after MPTP and MPP+ was assayed using GC/MS. There were striking differences between the patterns of elimination for MPP+, both inside and outside the CNS, with tissues falling into one of two groups. Seventeen of the 24 tissues studied exhibited first order kinetics of elimination, with half-lives being between 16 and 24 hours. In contrast, the caudate, putamen, substantia nigra, globus pallidus, nucleus accumbens, heart and adrenal medulla all showed virtually no elimination of MPP+ between 1 and 5 days. Indeed, the concentration of MPP+ was found to increase in some of these tissues. Analysis of MPTP-induced neurotransmitter changes in certain brain and peripheral catecholaminergic tissues, and the values for peak concentrations, clearance or area under the curve for MPP+, failed to reveal simple relationships between concentration and toxicity.

GM1 GANGLIOSIDE TREATMENT PROMOTES RECOVERY BUT DOES NOT PROTECT FETAL DOPAMINERGIC NEURONS FROM MPP+-INDUCED DAMAGE. N. Stull, L. Jacovitti, L. DiStefano and J.S. Schneider. Dept of Neurology, Hahnemann University, Philadelphia, PA 19102

Exposure of fetal rat dopaminergic neurons to MPP+ causes the death of some neurons and largely irreversible damage to others. The present study was performed to examine whether MPP+-induced damage to such cultures could be reversed or prevented by GM1 ganglioside treatment. The dopaminergic ventral mesencephalon was dissected from E15 rat embryos and plated at a density of 1x10⁶ cells/well. Control cultures were maintained for a total of 9 days in standard media containing heat inactivated fetal calf serum. To assess the reparative effects of GM1, cells were grown for 3 days in standard media before supplementation with MPP+ (100µM) for an additional 3 days. Some cultures served as lesion controls and the toxic media was replaced with standard media for a final 3 day incubation. In others, the toxic media was replaced with standard media supplemented with 100µM GM1. Possible protective effects of GM1 were assessed in cultures pre-incubated in GM1-supplemented media for 2 days prior to incubation with toxin and standard media as described above. All cultures were then fixed and processed for the immunocytochemical localization of tyrosine hydroxylase (TH). Exposure to MPP+ only resulted in a 41% (± 11) loss of TH positive neurons compared to controls. In contrast, the loss of TH neurons was reduced to only 12.5% (± 9.5) in cultures treated with GM1 after MPP+ exposure. Cultures pre-treated with GM1 before MPP+ contained 31% (± 8.5) fewer TH-positive neurons than controls. TH activity (pmol/culture/hr) was greatly decreased in MPP+ cultures (1.87 vs. 4.60 in normal cultures), minimally protected in GM1-pre-treated cultures (2.03) and greatly restored (3.45) in cultures treated with GM1 after MPP+ exposure. Measures of dopamine from these cultures showed a similar pattern. These data suggest that, under the present experimental conditions, pre-treatment of dopaminergic cultures with GM1 has minimal protective effects against MPP+ toxicity. Nonetheless, GM1 ganglioside administered after toxic insult may have significant reparative effects on dopamine neurons. Supported by Fidia Research Laboratories.

SPONTANEOUS RECOVERY OF THE MPTP-DAMAGED CATECHOLAMINE SYSTEM IN GOLDFISH BRAIN AREAS. A. Poli, O. Gandolfi, R. Rimondini*, L. Villani* and O. Barnabei*. Dept. of Biology, University of Bologna, 40126-Bologna, Italy.

We have previously reported that the neurotoxin MPTP (10mg/Kg i.p. for 3 days) causes a marked disappearance of tyrosine hydroxylase immunoreactivity and degeneration of neurons in several areas of the goldfish brain, with concomitant depletion of DA and NA levels. To better assess damage we measured a number of different dopaminergic parameters at 3 days and six weeks following cessation of MPTP administration. At 3 days, a marked fall in high affinity [³H]-dopamine uptake by synaptosomal preparations of telencephalon (50%), diencephalon (68%) and medulla (46%) was observed, together with increase number of postsynaptic D2 receptors labelled by [³H]-spiperone. Surprisingly at six weeks, the MPTP-induced depletion of DA and NA, and the fall in 3H-dopamine uptake were completely reversed in all damaged areas. In addition, no changes were found in B_{max} for [³H]-spiperone as compared to controls. All these results suggest that catecholamine systems in goldfish brain show a remarkable power of recovery after MPTP lesion.

GM1 GANGLIOSIDE THERAPY REVERSES PARKINSONIAN MOTOR DEFICITS IN MPTP-TREATED MACAQUE MONKEYS. Anne Pope and J.S. Schneider. Dept. of Neurology, Hahnemann Univ., Phila., PA. 19102.

GM1 ganglioside has been shown to reverse motor deficits in dopamine lesioned rats and to accelerate functional recovery in cats made parkinsonian by MPTP. Due to certain limitations of the previously mentioned models, the present study was conducted to assess whether GM1 ganglioside might have therapeutic effects on MPTP-induced model of parkinsonism in the macaque monkey. Prior to MPTP administration, five cynomolgus monkeys were rated on a 19 item behavioral/neurological assessment and performed a reward retrieval task (in which the time taken to remove raisins placed in 16 holes on a tray was measured) and an object retrieval task which assessed both motor and cognitive abilities. After collection of normal data, monkeys received MPTP-HCl (0.35 mg/kg, i.v.) until they became severely parkinsonian. Three monkeys were randomly chosen to receive GM1 treatment and two to receive saline blindly in daily injections begun 48 hrs. after the last MPTP dose. All monkeys became severely parkinsonian and needed to be maintained on dopamine D2 agonist therapy to sustain life. GM1-treated monkeys recovered sufficiently to be taken off agonist therapy after 14 days (±4) while control animals needed to be maintained on agonist therapy for 28 days (±4). Behavioral/neurological scores for GM1-treated animals improved consistently over the 8 wk. treatment period and by wk. 3 of the study, these animals appeared significantly different from control animals. GM1-treated monkeys improved significantly on motor task performance and showed no cognitive deficits while control monkeys performed tasks poorly or not at all. Preliminary examination of the striatum by tyrosine hydroxylase immunohistochemistry has shown evidence of a possible sprouting response in GM1-treated animals. These data suggest that GM1 therapy may be effective in reversing parkinsonian symptoms in primates and may stimulate repair of the nigrostriatal dopamine system in this species. The results suggest the potential usefulness of trophic factor therapies for the treatment of degenerative disorders such as Parkinson's disease. EFFECTS OF LONG-TERM MK-801 TREATMENT ON NEUROTOXICITY OF METHAMPHETAMINE AND MPTP IN MICE AND RATS. P.K. Sonsalla, L. Manzino and A. Giovannini. Dept. of Neurol., UMDNJ-RWJ Med. Sch., Piscataway, NJ 08854

Both MPTP and methamphetamine (METH) are neurotoxic to nigrostriatal dopaminergic neurons. We have previously shown that MK-801, an antagonist at N-methyl-D-aspartate receptors, prevents METH- but not MPTP-induced neurotoxicity in mice. However, it has recently been reported that long-term treatment (24 h) of rats with MK-801 prevented nigral cell loss produced by an intranigral infusion of MPP+, the neurotoxic metabolite of MPTP. Possible reasons for the apparent discrepancies of these findings are: 1) an inadequate duration of MK-801 effects in our MPTP mouse studies, 2) different mechanisms responsible for neurotoxicity produced by an intranigral bolus of MPP+ versus systemic MPTP whereby MK-801 exerts some protective effect in the former situation or 3) a rat versus mouse difference in response to MK-801. To test these possibilities, mice received MK-801 (6 injections, 4 h apart) starting just before the first of 4 injections of MPTP at 2 h intervals. This treatment enhanced lethality and only slightly attenuated the neurotoxic effects of MPTP in the survivors (as measured by neostriatal DA levels and tyrosine hydroxylase activity one week later). To determine if rats differed from mice in their response to the protective effect of MK-801 against METH-induced neurotoxicity, rats were treated with MK-801 just prior to each injection of METH (5 injections, 6 h intervals). This treatment with MK-801 protected the rats against the METH-induced loss of neostriatal DA and TH activity. In contrast, long-term MK-801 treatment failed to attenuate nigral or striatal DA loss following intranigral MPP+ (see Giovanni et al., this meeting). Thus, we conclude that MK-801 provides little if any protection against MPTP or MPP+ in mice or rats, although it protects against METH toxicity in both species.

275.9

FAILURE OF MK-801 TREATMENT TO PROTECT AGAINST MPP⁺-INDUCED NEUROTOXICITY IN RATS. A. Giovanni, L. Manzano, G.D. Zeevalk, R.E. Heikkila and P.K. Sonsalla. Dept. of Neurol., UMDNJ-RWJ Med. Sch., Piscataway, NJ 08854

It has recently been reported that long-term MK-801 administration to rats can prevent the loss of dopaminergic neurons in the substantia nigra produced by the intranigral infusion of MPP⁺, the neurotoxic metabolite of MPTP. In this study we have examined the effects of long-term MK-801 treatment on MPP⁺-induced neurotoxicity in both the nigra and the striatum following either an intranigral or an intrastriatal infusion of MPP⁺. One week following an intranigral infusion of MPP⁺, there was a marked decrement in both neostriatal and nigral DA content. MK-801 did not prevent this effect of MPP⁺ in either brain area. In addition, we examined the selectivity of the lesion induced by intranigral MPP⁺ infusion and observed decrements in GABA and serotonin levels in the nigra at one week post infusion, indicating damage to these neurotransmitter systems. Furthermore, MK-801 treatment failed to alter the MPP⁺-induced decrements in serotonin and GABA. Intrastriatal infusion of MPP⁺ via a microdialysis probe (10 mM, 15 min) resulted in a dramatic increase in dopamine efflux (150x basal levels) which could not be repeated upon re-exposure to MPP⁺ the following day. The fact that subsequent exposure to MPP⁺ did not elicit a dramatic rise in dopamine efflux indicated a loss of dopaminergic nerve terminals. MK-801 treatment failed to block both the initial increase in dopamine efflux seen upon exposure to MPP⁺ and the dopaminergic nerve terminal loss assessed by the subsequent re-exposure of the striatum to MPP⁺. We conclude that, under these conditions, MK-801 provides no protection against MPP⁺-induced dopaminergic neurotoxicity in the nigra or the striatum.

METHYLATION OF DOPAMINE BY 1-METHYL-4-PHENYLPYRIDINIUM (MPP⁺) BUT NOT 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP): A POSSIBLE MECHANISM OF ACTION. C. Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

MPTP and MPP⁺ caused Parkinson's disease-like toxicity, but analogs lacking the N-methyl group are essentially devoid of toxicity, which means that the methyl group of the pyridine ring plays a role in the toxicity. This is of interest because S-adenosylmethionine (SAM), which is the endogenous methyl donor and requires a methyl group for its action also caused MPP⁺-like motor deficits. Therefore, the requirement of a methyl group by MPP⁺ for its action suggest that, like SAM, MPP⁺ may serve as a methyl donor. This hypothesis was tested by reacting SAM, MPP⁺ or MPTP with dopamine (DA) in the presence of catechol-O-methyltransferase. The results showed that similar to SAM, MPP⁺ but not MPTP, donated a methyl group to DA to produce 3-methoxytyramine (3-MT). MPP⁺ and SAM at 62.5, 250 and 1000 nmoles/tube increased the 3-MT recovered by 13.9, 50.58, 121.31 and 6.88, 44.55, 129.47 nmoles above controls, respectively. These values are equivalent to 7.3, 28.1, 67.3 and 3.2, 25.1, 72.8 %. DA was proportionately decreased. These findings suggest that the ability to serve as a methyl donor may represent a mechanism of action for MPP⁺, the active metabolite of MPTP. These are additional support for the possible involvement of methylation in parkinsonism.

S-ADENOSYL-METHIONINE (SAM)-INDUCED HYPOKINESIA BLOCKED BY L-DOPA BUT NOT D-DOPA: RELEVANCE TO PARKINSON'S DISEASE (PD). B. Crowell, Jr., S. Spector and C. Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208 and *Dept. of Psychiatry, Vanderbilt University, Nashville, TN 37232

The symptoms of PD include hypokinesia, tremor and rigidity. SAM, when injected into the lateral ventricles of rats caused PD-like symptoms. For the effects of SAM to represent a model for PD, the PD therapeutic agent, L-dopa, should antagonize the effects of SAM. We tested the "SAM induction of PD Model" by studying the ability of L-dopa and D-dopa to block the hypokinetic effects of SAM.

Rats were anesthetized, cannulated and injected, i.p., with L-dopa, D-dopa or saline and challenged, i.v., with hypokinetic doses of SAM or saline. SAM dose-dependently decreased motor activity in the rats. The onset was within 1 min and lasted for about 1.5 hr. At 1 hr 1.0 μmole of SAM decreased the mean distance traveled (TD) and the number of movements by 65 and 75%. SAM at 6.25 nmoles/rat was without effect, whereas 9.38, 50 and 400 nmoles decreased the TD by 65, 80 and 94.9%, respectively. The effects of the 50 nmoles of SAM was 40% blocked and completely reversed by 200mg/kg of L-dopa, given 2 hr and 4 hrs before SAM. At the same pretreatment times 400 mg/kg of L-dopa completely blocked the effect of SAM. D-dopa had no effect.

The study showed that SAM, at low doses can induce hypokinesia, which may represent a model for PD. L-dopa is an effective therapy for PD and also antagonizes the effect of SAM. D-dopa, the inactive stereoisomer, had no effect. The time and dose-dependent effects of l-dopa are probably related to the rate of absorption for achieving the effective brain level. INTERACTION OF R(+)-MK-801 AND COCAINE IN THE ROTATIONAL RESPONSE TO D1 AND D2 AGONISTS BY RATS WITH 6-OHDA LESIONS. P. Curzon and D.R. Britton. Neuroscience Research, 47U, Pharmaceutical Discovery, Abbott Labs., Abbott Park, IL 60064

Rats with 6-OHDA lesions were tested for rotation to various dopamine agonists following pre-treatment with the NMDA non-competitive antagonist, MK-801, or cocaine at doses which, by themselves, produced equivalent ipsilateral rotation. MK-801 at 0.3, but not at 0.1 μmol/kg, sc decreased contralateral rotation to the D2 agonist, LY171555 (0.6 μmol/kg, sc) (p<.05). The rotation response to the D1 agonist, SKF38393 (0.75 μmol/kg, sc) was increased (p<.05) by MK-801 at 0.1 but not at 0.3 μmol/kg, sc. Cocaine (50 μmol/kg, ip) was without effect on the response to either LY171555 or SKF38393. The rotation response to the full D1 agonist, A68930 (0.75 μmol/kg, sc) was enhanced (p<.05) by MK-801 (0.1 μmol/kg, sc). The response to l-dopa (125 μmol/kg, po) which acts through D1 and D2 receptors was not altered by pre-treatment with MK-801. These findings are consistent with those of Morelli and Di Chiarra (1990) and suggest differential effects of MK-801 on D1 and D2 responses in lesioned rats.

275.12

THE INDUCTION OF METHIONINE ADENOSYL TRANSFERASE (MAT) AND CATECHOL-O-METHYLTRANSFERASE (COMT) BY L-DOPA: DEPENDENCE ON FREQUENCY AND DURATION OF ADMINISTRATION. R. Benson, B. Hill*, K. Doonquah* and C. Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

When injected into the lateral ventricles of mice S-adenosylmethionine (SAM), an endogenous methyl donor, causes Parkinson's disease (PD)-like symptoms. Hence, the positive effects of l-dopa therapy may be due to its conversion to dopamine (DA), as well as, the ability of l-dopa and DA to utilize SAM. Protracted exposure to l-dopa may increase the production of MAT and COMT which may relate to the decreased efficacy of chronic l-dopa therapy. As a partial test for this hypothesis, we exposed mice to several schedules of l-dopa treatments and determined the brain activities of MAT and COMT using chromatographic, spectrophotometric and radioenzymatic methods.

L-dopa (200mg/kg) treatments of 1, 2, and 3 times/day for 4 days increased MAT activity by 0.2%, 4.9% (not significant) and 21.3%, respectively. A treatment of 3 times/day for 8 days further increased (28.4%) MAT activity (V_{max}). The L-dopa treatments of 1 and 3 times/day for 4 days increased the COMT activity by 27.9% and 29.1% above that of the pooled controls. These results show that high frequency and chronic l-dopa treatments will induce increases in the activities of MAT and COMT. This may help to explain the decreased efficacy of chronic l-dopa therapy in PD patients. (Supported by: NIH RCMIR #RR3032, NSF RII-8704121 and NSF 871-4805).

STRAIN-DEPENDENT LOSS OF NIGROSTRIATAL DOPAMINE NEURONS AFTER 3-ACETYLPIRIDINE TREATMENT OF RATS. Ann C. Smith¹, Menek Goldstein², and Ariel Y. Deutch¹. ¹Department of Psychiatry, Yale University School of Medicine, New Haven, CT 06510 and ²Department of Psychiatry, NYU Medical Center, NY, NY 10016.

We have previously demonstrated that 3-acetylpyridine (3-AP) treatment of rats results in a loss of the dorsolateral striatal dopamine (DA) innervation, as well as lesioning the cerebellar climbing fiber innervation. However, the number of DA neurons in the substantia nigra (SN) of rats sacrificed 6 weeks after 3-AP treatment is not decreased, despite a 40% decline in DA concentrations in the dorsolateral striatum. In an attempt to determine if the presence of mid-brain DA perikarya in the face of terminal field degeneration represents a slow retrograde degeneration which ultimately involves the perikarya, or alternatively is due to strain differences, we treated Sprague-Dawley (SD) albino rats (in which our previous studies had been conducted) with 3-AP and sacrificed these animals one year later. We also compared the effects of 3-AP administration to SD and Long-Evans (LE; pigmented) rats on the nigrostriatal dopamine system. No appreciable loss of midbrain DA neurons in SD rats was seen one year after 3-AP treatment, although a significant decline in striatal DA was observed. In SD animals examined one week after 3-AP administration there was also no significant loss of DA neurons. In contrast, LE rats sacrificed one week after 3-AP treatment had a marked loss of SN DA neurons, and a decrease in striatal DA concentrations. Supported by the Amer. Park. Dis. Assn. and by the NPF Center at Yale University.

EQUINE NIGROPALLIDAL ENCEPHALOMALACIA (ENE) AND *CENTAUREA SOLSTITIALIS* (CS) : SEARCH FOR CULPABLE NEUROTOXIN(S). D.N. Roy, M. Craig*, L. Blythe*, M. Lefor*, M. Seelig*, R.E. Kayton* and P.S. Spencer. Center for Research on Occupational and Environmental Toxicology, Oregon Health Sciences University, Portland, OR 97201 (DNR, ML, MS, REK, PSS), and School of Veterinary Medicine, Oregon State University, Corvallis, OR 97331 (MC, LB).

The basal ganglia disorder ENE manifests as somnolence, hypokinesia, and impaired mastication after heavy ingestion of the Yellow Star Thistle (CS), a neurotoxic weed native to the western United States. Although cattle are refractory, entry of the neurotoxin(s) into milk consumed by humans is not excluded. To isolate and evaluate the culpable CS agent(s), dried weed was homogenized in 30% ethanol and the supernatant subjected to Dowex-50W-H⁺ column chromatography, with 0.5M ammonia elution. Eluates (designated by pH ranges) were administered to mouse cortex explant cultures to evaluate neurotoxic potential. Crude CS extracts and Fraction VI (pH 8-9) induced edematous vacuolation, chromatin clumping, and dense shrunken neurons, a picture compatible with excitotoxicity. Fraction VI (most active) contains 10-12 ninhydrin-positive spots identified by two-dimensional thin-layer chromatography. While identification of the active neurotoxic principle(s) is in progress, it seems unlikely that this fraction contains the CS sesquiterpene lactones identified by Ying Wang et al. (*Helvetica Chimica Acta* 74: 117, 1991) as toxic for rat fetal brain cultures. [Supported by NS-19611]

THE EFFECT OF ANTI-PARKINSONIAN MEDICATION ON THE ADRENAL MEDULLA OF THE MOUSE. S.L. Stoddard, G.M. Tyce, J.A. Cook, G.J. Merkel*, A.R. Zinsmeister*, and S.W. Carmichael, Depts. of Anatomy and Microbiology, Indiana University School of Medicine, Fort Wayne, IN 46805, and Depts. of Physiology, Biostatistics, and Anatomy, Mayo Clinic, Rochester, MN 55905.

We have previously shown that catecholamines are significantly lower in the adrenal medulla of parkinsonian patients (Stoddard et al., *Exp. Neurol.* 104:22 and 218, 1989). These patients had been taking L-dopa and carbidopa (Sinemet®) for an average of 11 years. To investigate whether chronic drug treatment with Sinemet® could alter adrenal medullary catecholamine levels, we fed male C57Bl mice L-dopa and/or carbidopa at ten times a common clinical dose (on a per weight basis) for up to 4 months (16% of expected life span; equivalent to 11 human years). The animals were sacrificed at monthly intervals; the adrenal glands were removed and analyzed for catecholamines using HPLC with electrochemical detection. Catecholamine levels were expressed as ng/adrenal pair. There were no differences in the content of norepinephrine or epinephrine with any drug treatment at any time. Dopamine content was significantly elevated at 12 weeks in the mice receiving both L-dopa and carbidopa. These results suggest that the decreased medullary catecholamines observed in patients do not result from chronic Sinemet® treatment.

275.19

PHARMACOLOGICAL CHARACTERIZATION OF THE NEW IRREVERSIBLE MAO-B INHIBITORS p-F-DEPRENYL, MDL 72,974-A AND REVERSIBLE INHIBITOR RO 19-6327 IN MOUSE CEREBRUM. I.A. Terleckyj, R.E. Heikkilä and W.J. Nicklas, Dept. of Neurology, UMDNJ-RWJ Med. School, Piscataway, NJ 08854.

Clinical studies evaluating daily administration of l-deprenyl (DEP), a selective and irreversible MAO-B inhibitor, to newly-diagnosed Parkinsonian patients indicate the need for l-dopa therapy can be delayed by one year (DATATOP). However, chronic DEP treatment is associated with inhibition of MAO-A and metabolism to the CNS stimulant amphetamine in animals and humans. The aim of the present study was to evaluate the pharmacological properties of MDL 72,974A (974A), p-F-deprenyl (F-DEP) and RO 19-6327 (RO 19) in mouse cerebrum. RO 19 and 974A are not metabolized into amphetamine. Also, RO 19 is a highly selective reversible inhibitor of MAO-B and should not inhibit MAO-A with time. *In vitro* IC₅₀ values for inhibition of MAO-B and A by DEP, F-DEP, 974A and RO 19 are, respectively, 4.2 nM, 1.3uM; 1.7nM, 2.1uM; 0.49nM, 464nM; and 3.53nM, 210uM. IC₅₀ values for DEP, F-DEP and 974A following a single administration *in vivo* are 1.9, 296 umol/kg; 2.1, 425 umol/kg; and 0.3, 107 umol/kg. These compounds will be useful tools in understanding the possible role of MAO in the neurodegenerative process of Parkinson's Disease and the exact nature of deprenyl's beneficial effects.

DEGENERATION OF NIGRO-STRIATAL NEURONS INDUCED BY FREE IRON. G.J. Sengstock*, C.W. Olanow*, R. Menzies*, A.J. Dunn* and G.W. Arendash*. Depts. of Biology¹, Neurology² and Psychiatry³, University of South Florida, Tampa, FL 33620 and Dept. of Pharmacology⁴, LSU Medical Center, Shreveport, LA 71130.

Oxidation reactions have been implicated in the pathogenesis of Parkinson's Disease (PD). Postmortem PD brains have increased quantities of iron within the substantia nigra (SN). Since iron facilitates oxidation reactions resulting in free radical formation, iron may be a causative factor in the degeneration of nigro-striatal dopaminergic neurons seen in PD. To mimic this spontaneous accumulation of iron in the SN, we infused various amounts of iron (0.63 - 73 nmol) unilaterally into the SN of young adult male rats utilizing two separate surgical protocols (*Double and Side-by-Side Infusions*). The iron was combined in an iso-osmotic, pH-balanced, citrate-bicarbonate-Tris-HCl buffer solution. Animals were sacrificed through two months post-infusion. Histological examination of thionine- and iron- stained (*PERL's + DAB intensification*) brain sections revealed iron diffusion essentially limited to the infused SN and a selective degeneration of neurons within the zona compacta of SN at low/moderate iron amounts; surviving zona compacta neurons stained for increased iron. Consistent with the degree of neuronal loss, striatal dopamine and its catabolites (*DOPAC and HVA*) were significantly reduced in a dose-dependent fashion (by over 80% at the highest iron amounts). Interestingly, animals infused with an iron solution containing excess transferrin did not have decreased striatal dopaminergic markers. Non-dopaminergic markers in striatum were largely unaffected by free iron infusions into SN. In addition, apomorphine-induced rotational behavior was evaluated; animals receiving higher amounts of iron exhibited a 5-fold increase in ipsilateral turning compared with vehicle-infused controls. Furthermore, the number of ipsilateral turns shown by high iron-infused animals were significantly greater at two months than at one month post-infusion. These data indicate that neurons within the SN, particularly those of the zona compacta, are sensitive to free iron-induced degeneration; thus, the data are supportive of iron as an etiologic factor in the pathogenesis of PD.

IRON CHELATION MODIFIES 6-HYDROXYDOPAMINE (6-OHDA) PARKINSONIAN ANIMAL MODEL. J. Hubble, F. Shi, and B. Skikne, and W. Koller. University of Kansas Medical Center, Kansas City, KS 66103.

Iron may play a role in the pathogenesis of Parkinson's disease by participating in the generation of free radicals, ultimately leading to nigral cell death; if this hypothesis is correct, relative depletion of brain iron may protect against nigrostriatal degeneration. To test this concept, we gave the iron chelator desferrioxamine (250mg) via s.c. pump over 7 days to rats (n=8). 6-OHDA was injected into the left substantia nigra on day 4. Apomorphine (.25mg/kg s.c.) was given on day 25 to assess turning behavior (reflecting unilateral dopamine [DA] depletion). Striatal iron and DA content was quantitated. Non-chelated 6-OHDA lesioned rats served as controls. Controls turned more than chelated rats (means: 182 vs 65 turns/10min, p<.065, Student t-test). Striatal iron was less in the chelated group than in controls (mean ugFe/mg protein: left chelated=50, right chelated=52, left control=88, right control=82; p<.05 ANOVA & Newman Keuls post-hoc). Right striatal DA content did not differ between groups; left striatal DA was greater in the chelated vs controls but did not reach significance by ANOVA (mean DA pmole/mg protein: left chelated=182, right chelated=638, left control=65, right control=718). This latter finding may reflect over-chelation in some animals as a positive correlation existed between left striatal DA and iron in chelated rats but a negative correlation was found in controls (Pearson correlation coefficient r=.83 vs r=-.73). In summary, iron chelation appeared to marginally improve functional outcome (turning) in this parkinsonian animal model. Significant sparing of striatal DA was not established; since DA synthesis is iron-dependent, the neuroprotective effects of iron chelation may occur within a relatively narrow range, that is, normal iron stores may participate in neurotoxic cell damage while markedly reduced iron stores may prohibit residual nigrostriatal DA function.

EFFECTS OF DOPAMINE D1 AND D2 RECEPTORS AGONISTS IN A LONG TERM MODEL OF UNILATERALLY MPTP-TREATED *CEBUS APPELLA* MONKEYS. M.E. Emborg, J.A. Colombo and A. Yañez*. Prog. Unidad de Neurobiología Aplicada -Av. Galvan 4102- (1431) Bs.As.-Argentina.

D1 and D2 receptor agonists were evaluated in an hemiparkinsonian model induced by MPTP. Five 13-15 years old *Cebus Apella* monkeys received an intracarotid infusion of 1.2mg/kg MPTP-HCL (SIGMA) in 50 ml of saline, under ketalar-fluothane. After 48-72 hs all animals developed a hemisyndrome contralateral to the side of MPTP administration: postural abnormalities, hypokinesia, bradikinesia, tremor, reduction of prensile strength, circling behaviour ipsilateral to lesion with inversion after apomorphine administration (0.4mg/kg, im). After 8-10 months 6 monkeys (five treated and one normal) received Bromocriptine Mesilate (D2) or CY 208-243 (D1) (0.5-1.0 mg/kg, im) (Sandoz). Animal care and experimental procedures followed W.H.O. regulations. Both drugs affected motor behavior (reduction/elimination of bradi-hypokinesia and postural changes, with an inversion of circling activity). In our conditions, D1 and D2 agonists were effective to reduce the syndrome induced by MPTP, although individual variations were present. Support: CONICET, CEMIC, CIRHA, Petrol. Arg. "S. Jorge".

SYMPOSIUM. DYNAMICAL BEHAVIOR OF NEURAL SYSTEMS. E. Kaplan, Rockefeller Univ. & R.M. Siegel, Rutgers Univ. (Chairpersons); D. Farmer, Los Alamos National Lab.; L. Liebovitch, Columbia Univ.; J. Rinzel, NIH; M.C. Mackey, McGill Univ. & J.G. Milton, Univ. Chicago Hosp.; R. Llinas, NYU Sch. Med.

Technological advances in the electrophysiological recording from neurons are revealing new dynamical behaviors in complex neural systems. These behaviors can be simple oscillations or enigmatic patterns in space and time. Non-linear dynamical theory, colloquially known as chaos theory, may contribute the matching theoretical advances necessary to classify the behavior of such systems and extract essential mechanisms and principles. The objective of the symposium is to present some modest, yet rigorous, examples of the application of chaos theory to questions in Neuroscience at several different levels.

Siegel will review early work and the strengths of the dynamical approach in the analysis of complex neural systems. Farmer will review recent progress in the use of dynamical system theory to analyze data from neural systems. Liebovitch will analyze the kinetics of single ion channels to delimit the differences between stochastic and deterministic mechanisms. The mechanisms underlying rhythmic oscillations of single and pairs of neurons will be explored by Rinzel using phase space analysis. Mackey & Milton will consider the significance of nonlinearities and time delays in generating a diversity of behaviors from simple, yet physiologically realistic models of neural networks. Llinas will describe the spatio-temporal patterns of neuronal ensembles in cerebellar cortex using different mathematical approaches. Kaplan will summarize and discuss directions for future exploration.

All the presentations will be non-technical in nature and will strive to impart an intuitive grasp of the conceptual framework of dynamical system theory and its application to the brain.

SYMPOSIUM. NEURON DOCTRINE 1891-1991. G.M. Shepherd, Yale University (Chairperson); E.G. Jones, UC,Irvine; L.W. Swanson, University of Southern California; Albert Aguayo, Montreal General Hospital; K. Tyler, Harvard Medical School.

This symposium, organized by the Ad Hoc Committee on the History of Neuroscience, commemorates the centenary of the doctrine that forms the foundation of all work on the nervous system. Formulated by Wilhelm Waldeyer in December, 1891, the neuron doctrine stated that the nerve cell is the anatomical, functional, genetic and metabolic unit of the nervous system. It was an affirmation of the cell theory for the nervous system and was based on the work of several prominent neuroanatomists, especially that of Ramón y Cajal. The symposium examines the evidence upon which the neuron doctrine was based; the laws of connection by contact and of dynamic polarization that formed integral parts of it; the controversy between Cajal and Golgi and the confirmation of the theory by later investigations up to the present day. The importance of the theory for the understanding of neural development, behavior and neurological disorders will be highlighted, along with those revisions of the theory that appear necessitated by current research at the cellular and molecular level.

CARDIOVASCULAR REGULATION II

280.1

DIFFERENTIAL EFFECTS OF BRAINSTEM LESIONS ON THE 10-HZ AND 2- TO 6-HZ RHYTHMS IN SYMPATHETIC NERVE DISCHARGE (SND). G.L. Gebber, S.M. Barman, and S. Zhong. Dept. of Pharmacol. & Toxicol., Mich. State Univ., East Lansing, MI 48824.

The discharges of postganglionic sympathetic nerves often contain a mixture of two rapid rhythms (10-Hz and 2- to 6-Hz) in baroreceptor-denervated, unanesthetized-decerebrate cats. The question arises whether these two rhythms are dependent upon the same brainstem regions. We approached this problem by comparing the frequency components in SND, the strength of correlation between the discharges of inferior cardiac (CN) and renal (RN) postganglionic nerves, and the level of blood pressure before and after lesions of the medullary raphe (R), the parabrachial pontine region (PB), or the rostral ventrolateral medulla (RVLM). SND was characterized with autospectral and coherence analyses. Lesions placed in R or PB produced the following effects: 1) elimination of the 10-Hz rhythm in SND and a marked decrease in coherence of CN and RN discharges at this frequency, 2) an increase in sympathetic nerve power between 2 and 6 Hz without a change in CN-RN coherence values at these frequencies, 3) no change in total power (0-100 Hz band) in SND, and 4) a statistically significant decrease in blood pressure. In contrast, RVLM lesions essentially eliminated the power in the 2- to 6-Hz and 10-Hz bands of SND. Blood pressure in these animals fell to a greater extent than in those cats in which the R or PB were lesioned. These results indicate that the brain stem networks responsible for the 10-Hz and 2- to 6-Hz rhythms are not identical, although they may share some of the same components (e.g., RVLM). Furthermore, the results demonstrate that the level of blood pressure is dependent not only on total power in SND, but also on its rhythmic pattern (10-Hz vs 2- to 6-Hz). (Supported by NIH grants HL-33266 and HL-13187.)

280.3

ORGANIZATION OF CENTRAL SOURCES OF RHYTHMIC SYMPATHETIC NERVE DISCHARGE (R-SND): PARTIAL COHERENCES. B. Kocsis. Center for Complex Systems, Florida Atlantic Univ., Boca Raton, FL 33431.

It has been shown earlier that there is a strong correlation between simultaneously recorded R-SNDs. In this study the analysis was extended to three sympathetic nerves with different functions and anatomical locations, i.e. nerves controlling the heart (inf. cardiac nerve), and visceral (renal nerve) and muscle circulation (vertebral nerve). The resting nerve recordings of chloralose-urethane anesthetized cats were taken from earlier studies in which unequal involvement of these nerves in the cerebral ischemic response was indicated. Examination of ordinary coherences of each pair of these nerve triples revealed common and specific sources contributing to the regional R-SND. The results of such analysis, however, in case of three signals may lead to invalid conclusions. To estimate the overlapping sources of three R-SNDs the coherences have to be partialised. This means separation of coherent components in a nerve pair that are contributed by a source common for all three nerves from those that remain after removal of the influence of the third signal. Five different patterns were observed. They appeared with different frequencies in intact and baroreceptor denervated animals and changed during cerebral ischemia. The results point to the flexibility of central sympathetic networks and an important role of the baroreceptor input in organizing the central map of R-SND sources.

280.2

RAPHE AND ROSTRAL VENTROLATERAL MEDULLARY (RVLM) NEURONS WITH ACTIVITY CORRELATED TO THE 10-HZ RHYTHM IN SYMPATHETIC NERVE DISCHARGE (SND). S.M. Barman and G.L. Gebber. Dept. Pharmacol. & Toxicol., Mich. State Univ., East Lansing, MI 48824.

Autospectral analysis shows that in most unanesthetized-decerebrate, baroreceptor-denervated cats the power in SND is distributed in two frequency-bands: in a narrow band surrounding a peak at ~10 Hz ("10-Hz rhythm") and in a wider band at frequencies <6 Hz ("2- to 6-Hz activity"). Medullary neurons that control the 2- to 6-Hz activity have been extensively studied, but those responsible for the 10-Hz rhythm have not been identified. Since the 10-Hz rhythm is eliminated by ablation of the raphe or RVLM (Gebber et al., this volume), we searched for raphe and RVLM neurons with activity correlated to the 10-Hz rhythm in inferior cardiac SND in nine unanesthetized-decerebrate cats. Spike-triggered averaging and coherence analysis showed that the extracellularly recorded activity of 23 of 88 raphe neurons and 8 of 20 RVLM neurons was correlated to the 10-Hz rhythm in SND. The interval between unit spike occurrence and the peak of the 10-Hz inferior cardiac sympathetic nerve slow wave was 50 ± 8 ms for raphe neurons and 64 ± 5 ms for RVLM neurons. These values are significantly shorter than those reported in anesthetized cats for the intervals between raphe or RVLM unit discharges and the peak of the 2- to 6-Hz slow wave in inferior cardiac SND. Raphe and RVLM neurons missed firing during many 10-Hz sympathetic nerve slow waves (firing rates: 2.5 ± 0.3 and 3.6 ± 1.0 spikes/s, respectively). Since the activity of some of these neurons also cohered to the 2- to 6-Hz component of SND, in part a common pool of medullary neurons governs both components of SND. The activity of other raphe and RVLM neurons cohered to only the 10-Hz rhythm in inferior cardiac SND. These data support the view that some elements of the 10-Hz rhythm generator are not the same as those responsible for the 2- to 6-Hz activity. (Supported by NIH grants HL-33266 and HL-13187.)

280.4

EFFECTS ON ARTERIAL BLOOD PRESSURE FOLLOWING MICROINJECTION OF EXCITATORY AMINO ACIDS INTO THE MEDIAL MEDULLARY RETICULAR FORMATION. S. A. Aicher and D. J. Reis. Div. of Neurobiol., Cornell Univ. Med. Coll., NY, NY 10021.

We examined the effects of chemical stimulation of the rostroventromedial medulla (RVM), a region of the reticular formation which extends from the ventral reticular nucleus to the ventral subdivision of the gigantocellular n., in anesthetized, paralyzed rats (urethane = .9 g/kg i.p.; α -chloralose = 45 mg/kg s.c.). This region appears to be topographically distinct from other vasoactive reticular zones such as the RVL and CVL. Microinjections of glutamate (22 mM; 20 nl) into this region consistently produced decreases in mean arterial blood pressure (MAP) (-15.3 ± 2.1 mmHg; n=9) and heart rate (-12.2 ± 3.8 bpm). The rostral portion of this vasodepressor region is localized immediately adjacent to vasopressor regions lying dorsally and laterally, since injections centered laterally or dorsally or in larger volumes (100 nl) elevated MAP. Microinjections into RVM of either ibotenic acid (IBO) or kainic acid (KA) at neurotoxic doses (65 mM; 20 nl) initially elicited depressor responses (-28 and -30 mmHg, respectively). At 30 min following KA injections, MAP was significantly elevated (MAP = 147 ± 10.8 ; n=5). In contrast, at 30 min following IBO, pressure was significantly reduced and remained down for the duration of the 2 hr test period (MAP = 60 ± 6.0 ; n=5). We conclude that the RVM is a distinct medullary sympathoinhibitory region which is functionally and anatomically distinct from RVL and CVL. Further, the RVM may contain heterogeneous populations of neurons which are differentially sensitive to different classes of excitatory amino acids. (Support:NIH #F32HL08251-01)

280.5

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF NEURONS IN THE CAUDAL VENTROLATERAL MEDULLA (CVL) WHICH MAY MEDIATE THE VASODEPRESSOR RESPONSE TO BARORECEPTOR ACTIVATION. I. Jeske, S.F. Morrison*, and D.J. Reis Cornell Univ. Med. Coll., New York, NY 10021 and *Northwestern Univ., Chicago, IL 60611.

The CVL is thought to be an obligatory synapse in the baroreceptor reflex arc, interposed between barosensory neurons in the nucleus tractus solitarius (NTS), and sympathoexcitatory reticulospinal neurons in the rostral ventrolateral medulla (RVL). We sought to identify baroreceptor "interneurons" in the CVL of urethane-anesthetized, paralyzed rats. In 28 experiments, 13 spontaneously active neurons were identified in the CVL which responded antidromically (5 ± 2.5 ms onset latency) to RVL stimulation. All 13 units were orthodromically excited by electrical stimulation of the aortic depressor nerve (ADN), with Group I (n=3) interneurons responding with a mean onset latency of 20.7 ± 3.1 ms, Group II (n=8) at 45.5 ± 5.3 ms, and Group III (n=2) with two excitatory peaks at 20.5 ± 3.5 ms and 43.5 ± 0.7 ms. The spontaneous discharge (1-10 Hz) of neurons within each group was locked to the cardiac cycle, and increased during the pressor response to i.v. phenylephrine. Three CVL baroreceptor interneurons were silent at arterial pressures below 60, 80 and 120 mm Hg. All CVL neurons were localized at the level of obex, distributed dorsoventrally between the parvocellular reticular formation and the lateral reticular nucleus. The findings provide electrophysiological evidence for an NTS-CVL-RVL relay as the intramedullary neural substrate of the baroreceptor reflex arc. Baroreceptor information may be processed by parallel networks of CVL neurons projecting to the RVL.

280.7

TONIC CARDIOVASCULAR CONTROL BY NEURONS IN THE PONTINE RETICULAR FORMATION IN RATS. K. Hayes and L.G. Weaver, The John P. Roberts Research Inst. & Department of Physiology, University of Western Ontario, London, Ontario, Canada.

The search for specific brainstem nuclei responsible for generating sympathetic nerve activity has focused on the rostral ventrolateral medulla (RVLM). However, we explored a new area, the pontine reticular formation (PRF), for regions providing tonic control of arterial pressure (AP), heart rate (HR) and activity of sympathetic nerves. In Saffan-anesthetized rats, discharge of PRF neurons was inhibited by unilateral injections of glycine (.01-1M; 65nl). Thirty-one injections (1M) produced large, brisk (duration 124±14s) decreases in AP (-28±2mmHg), HR (-21±3bpm) and renal (-47±4%) and splenic (-45±4%) nerve activity indicating that PRF neurons are a powerful source of sympathoexcitatory drive. Seven glycine injections in rats with sino-aortic denervation caused cardiovascular and sympathetic responses as brief (132±27s) as those in intact rats. Therefore baroreflex compensation was not responsible for the brief nature of PRF responses. Moreover, the short duration was not due to compensation by contralateral PRF neurons since bilateral glycine injections (3 rats) produced sympathetic responses as short (87±14s) as those following unilateral injections. Responses were not transient because of short actions of glycine since unilateral injections (10mM; 36nl) of the long-lasting GABA agonist muscimol (3 rats) caused responses which recovered as rapidly (70±15s) as those produced by glycine. We conclude that following PRF blockade, another brain area such as the RVLM must compensate for the loss of important excitatory sympathetic drive originating from the PRF. (Support: Ont. Heart & Stroke Fdn).

INFLUENCE OF THE MIDBRAIN CENTRAL GREY ON MEDULLARY SYMPATHOEXCITATORY NEURONS AND THE BAROREFLEX IN THE RAT. P.G. Guyenet and A.J.M. Verberne, Dept. of Pharmacology, Univ. of Virginia, Charlottesville, VA 22908.

The influence of the central grey (CG) on the activity of barosensitive, sympathoexcitatory neurons of the rostral ventrolateral medulla (RVL) and the sympathetic baroreflex was studied in halothane-anesthetized, paralyzed rats. Electrical stimulation (50Hz, 25-75 μ A, 0.3 ms, 10s train) of the CG produced sympathoexcitation and a pattern of hemodynamic responses characteristic of the defence reaction. Splanchnic sympathetic activation produced by CG stimulation exceeded that of the lumbar nerve. CG stimulation produced elevation of the baroreflex gain and baroreflex cut-off pressure. Intermittent stimulation (0.5 Hz, double pulse, 3 ms interval) of the CG produced splanchnic and lumbar sympathoexcitation with latencies of 46 ± 2 and 80 ± 2 ms, respectively. RVL barosensitive neurons were readily activated by train stimulation of the CG (18/19 units tested). Non-barosensitive units were not excited by CG stimulation (5 units tested). Inhibition of neurons within the RVL by microinjection of the GABA-mimetic agent muscimol (10 ng/50 nl) abolished the pressor responses to CG stimulation, while the accompanying sympathetic activation was converted to inhibition. These findings support the hypothesis that sympathoexcitatory responses elicited from the CG are mediated by RVL barosensitive, sympathoexcitatory neurons. (HL 28785)

280.6

DIRECT EFFECTS OF 8-OHDPAT ON SYMPATHETIC NEURONS IN THE LATERAL TEGMENTAL FIELD. M.E. Clement and R.B. McCall, Cardiovascular Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

The lateral tegmental field (LTF) of the cat contains neurons which exhibit a temporal relationship to the 2-6 Hz slow-wave pattern of sympathetic nervous discharge (SND). These neurons can be designated as sympathoexcitatory (SE) or sympathoinhibitory (SI) depending on their response to alterations of blood pressure. It has recently been suggested that these neurons are a source of the basal activity of similarly sympathetically related neurons in the rostral ventrolateral medulla (RVLM), a site critical to the maintenance of sympathetic tone. We recently demonstrated a high degree of correlation between inhibition of RVLM neurons and the sympatholytic action of intravenous 8-OHDPAT. In this study we have shown that LTF-SE neurons are inhibited in a dose dependent manner by intravenous 8-OHDPAT. This decrease in LTF-SE activity is closely correlated to the inhibition of SND. However, unlike RVLM-SE neurons, LTF-SE neurons are also inhibited by direct application of 8-OHDPAT by microiontophoresis. In contrast, LTF-SI neurons are excited by intravenous 8-OHDPAT. In addition, we demonstrated the existence of sympathetically related neurons in the LTF which can be activated by microiontophoretically applied 8-OHDPAT. These data support the hypotheses that the LTF exerts a sympathoexcitatory influence on neurons in the RVLM and suggests that this area is crucial in the sympatholytic action of 8-OHDPAT.

280.8

A5 NORADRENERGIC (NE) NEURON ACTIVITY AND SYMPATHETIC NERVE DISCHARGE (SND) IN RATS. D. Huangfu, N. Koshlyva*, Lie-Ju Hwang* and P. G. Guyenet, Dept. of Pharmacology, Univ. of Virginia, Charlottesville, VA 22908

We sought to determine if A5 NE neurons contribute to the generation of the vasomotor SND in halothane-anesthetized rats. Presumed A5 cells were selected on the following criteria: location in ventrolateral tegmentum rostralateral to facial nucleus, antidromic (AD) activation from thoracic spinal cord and inhibition by i.v. clonidine (<15 μ g/kg). These cells had low discharge rates and slow conduction velocities. AD activation of 7 out of 8 neurons was abolished after intraspinal microinjection of 6-hydroxydopamine (i.sp. 6-OHDA, 4 μ g, 1 hr). AD mapping located the terminal fields of 16 A5 area neurons in the intermediolateral cell column of the spinal cord. Most neurons (37/59) were inhibited by raising arterial pressure and/or by stimulation of the aortic depressor nerve. The discharge of 12 out of 29 cells was correlated to the splanchnic SND and preceded a peak of SND by 69 ± 6 ms. Microinjection of NMDA (0.5 nmol) in A5 area produced excitation of splanchnic and renal SND and slight inhibition of lumbar SND. The excitation of splanchnic SND was reduced by at least 80% 1 hr after i.sp. 6-OHDA, ii) 3 weeks after administration of this drug into the A5 area, or iii) by i.v. prazosin (1 mg/kg). Thus many A5 cells have a visceral vasomotor sympathoexcitatory function. (HL 28785).

PROJECTIONS FROM THE CARDIOVASCULAR RESPONSIVE REGION OF BED NUCLEUS OF THE STRIA TERMINALIS (BST) TO MEDULLARY CATECHOLAMINERGIC CELL GROUPS. S.A. Janssen and J. Ciriello, Department of Physiology, University of Western Ontario, London, Canada, N6G 5C1.

We have previously shown that microinjection of the excitatory amino acid, L- glutamate into a crescent shaped region of BST hugging the anterior commissure on its dorsal, lateral, and ventral surfaces resulted in decreases in both arterial pressure and heart rate. In this study, the efferent pathways that may be involved in mediating these cardiovascular responses were investigated using the anterograde tracer, Phaseolus vulgaris leucoagglutinin (PHA-L). PHA-L was iontophoresed into the cardiovascular responsive region (CRR) of the ventral component of the lateral BST, and after a survival period of 13 days, transverse sections of the brainstem were processed immunohistochemically for the demonstration of PHA-L and/or tyrosine hydroxylase containing fibers, terminals and perikarya. PHA-L labelled fibers and terminals resulting from the injection within the CRR of BST were observed ipsilaterally within the A5 noradrenergic cell group and bilaterally within the dorsal motor nucleus of the vagus (DMV), rostral nucleus of the solitary tract (NTS-C2), caudal NTS (NTS-A2), rostral ventrolateral medulla (VLM-C1) and caudal VLM (VLM-A1). However, only in the caudal VLM and the caudal NTS were BST fibers and terminals, labelled with PHA-L, observed in close apposition to the noradrenergic cells. As both NTS and the caudal VLM function as vasodepressor sites, these data suggest that both medullary regions may be components of the descending pathway that mediates the decreases in blood pressure seen following stimulation of the CRR of BST. (Supported by MRC of Canada and HSFO).

280.11

HYPOTHALAMIC CONNECTIONS OF THE PARAVENTRICULAR THALAMIC NUCLEUS. M. E. Puigbonet and J. Ciriello. Department of Physiology, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

The paraventricular nucleus of the thalamus (PV) has previously been shown to receive afferent projections from brainstem structures involved in visceral and autonomic regulation. However, the efferent projections of PV have not been completely elucidated. In this study, pathways originating from neurons in PV were identified in the rat using the anterograde tracer *Phaseolus vulgaris* leucoagglutinin (PHA-L). PHA-L was iontophoretically injected into PV and after a survival period of 7-13 days, forebrain sections were processed immunohistochemically for the demonstration of PHA-L in fibers and terminals. Within the hypothalamus, PHA-L labelled fibers and terminals were observed bilaterally. The densest projections were observed in the lateral aspects of the lateral hypothalamic nucleus and ventromedial hypothalamic and supraoptic nuclei. Moderate PHA-L labelling was found in the dorsal and medial parvocellular components of paraventricular nucleus of the hypothalamus (PVH), the area of the tuber cinereum, dorsal medial hypothalamic nucleus and the posterior hypothalamic area. Additionally, scattered fiber and terminal PHA-L labelling was also found in and around supraoptic nucleus and the magnocellular component of PVH. These data suggest that PV may function as an important link in the relaying of visceral afferent information to hypothalamic sites involved in behavioural, autonomic, and endocrine integration. (Supported by MRC of Canada and HSFO).

280.12

ALTERED NEURONAL ACTIVITY IN THE POSTERIOR HYPOTHALAMUS OF SPONTANEOUSLY HYPERTENSIVE RATS. C.A. Shonis and T.G. Waldrop. Dept. of Physiology & Biophysics, Univ. of Illinois, Urbana, IL 61801.

Previous studies have shown that GABAergic activity in the posterior hypothalamus (PH) of the spontaneously hypertensive rat (SHR) is decreased compared to normotensive Wistar-Kyoto rats (WKY). The purpose of these experiments was to determine if this loss of inhibition elevates the discharge frequency of neurons in the PH, a known pressor region. Extracellular single unit activity was recorded from the PH of anesthetized, adult SHR (mean systolic pressure= 205±13.3 mmHg) and age-matched WKY (mean systolic pressure= 141±6.8 mmHg). PH neurons in the SHR possessed a higher spontaneous firing rate (3.66±0.55 Hz) compared to the cells in the PH of the WKY (2.11±0.29 Hz). Many of the neurons in the SHR (38%) had a "bursting" discharge; only 16% of the WKY neurons had this discharge pattern. Computer averaging revealed that 87.5% of the neurons from the SHR had a cardiac-related discharge compared to 64% of those in the WKY. The basal firing rate of these neurons with a cardiac-related discharge was higher in the SHR (5.86±1.56 Hz) compared to those from the WKY (2.32±0.38 Hz). SHRs had a blunted heart rate response to baroreceptor stimulation and a smaller percentage of the PH cardiac-related neurons were responsive to baroreceptor stimulation in the SHR (24%) compared to the WKY (66%). This study supports the hypothesis that the SHR has elevated neuronal activity in the posterior hypothalamus, a region involved in modulating cardiovascular activity; this alteration may contribute to the development and/or maintenance of hypertension in this animal model. (Supported by NIH 38726; American Heart Association).

CELL LINEAGE II

ISOLATION OF LEECH HOMEBOX GENES RELATED TO THE SEGMENT-IDENTITY GENES OF *DROSOPHILA*. M. Shankland & D. Nardelli-Haeffliger*. Dept. of Anatomy, Harvard Med. School, Boston, MA 02115.

In both insects and vertebrates, segmental identity is determined in large part by the action of a particular set of homeobox genes, known in *Drosophila* as the homeotic or segment-identity genes. The cellular events which give rise to segmental diversification are especially tractable in embryos of the leech *Helobdella robusta*, and we have therefore chosen to isolate and characterize the homologous leech genes. Candidate homeobox gene sequences were initially isolated by PCR amplification, and the amplified sequences were then used to screen a genomic DNA library to obtain restriction fragments containing the entire homeobox plus portions of the flanking coding region. Sequence analysis suggests that 4 of the leech homeobox genes obtained in this manner -- designated as *Lox5*, *Lox6*, *Lox7* and *Lox2* -- are respectively homologous to the *Drosophila* homeotic genes *Antp*, *Dfd*, *lab* and *Ubx/AbdA*. (The gene *Lox2* has previously been described in another, distantly related leech species, see Wysocka-Diller et al., *Nature* 341:760, 1989). The presence of discrete *Antp* and *Ubx/AbdA* homologues suggests that these particular genes diverged prior to the separation of annelids and arthropods, contrary to some current models of homeotic gene evolution (Akam, *Cell* 57:347, 1989). Oligopeptides were synthesized to correspond to specific regions of each leech homeodomain protein, and antibodies were raised against those peptides in rabbits. These antisera are currently being used to examine the spatiotemporal pattern of gene expression in the developing leech embryo.

281.3

STRUCTURE AND EXPRESSION OF TES-1: A HOMEODOMAIN-CONTAINING GENE THAT IS EXPRESSED IN THE NEUROEPITHELIUM OF THE EMBRYONIC MOUSE VENTRAL FOREBRAIN. J.L.R. Rubenstein*, M.H. Porteus*, A. Bulfone*# and R.D. Ciaranello. Nancy Pritzker Laboratory, B002, Stanford School of Medicine, Stanford, CA 94305. #Present address: Neurogenetics Laboratory, LPPI, Box F, 401 Parnassus, UCSF, San Francisco, CA 94143-0984.

Using subtractive hybridization and screening with homeodomain-encoding probes, we isolated, from an E14.5 mouse telencephalon cDNA library, a 2.1 kb cDNA encoding a novel homeodomain-containing protein called TES-1. The TES-1 homeodomain is identical in 53 out of 61 amino acids with the homeodomain of the *Drosophila distal-less* gene. Unlike other vertebrate homeodomain-containing genes, TES-1 is only expressed in the head. Within the brain of the midgestational embryo, TES-1 is expressed in the ventral forebrain. At E11.5 it is strongly expressed in the ganglionic eminence and in a separate patch of neuroepithelium that is probably in the diencephalon. At E13.5, it is expressed continuously along the floor of the ventral forebrain, as well in a patch of cells in the ventral thalamus. By E18.5, TES-1 expression can also be seen in the developing olfactory bulb, vomeronasal organ and preameloblasts. At this time, TES-1 is also expressed in the dorsal ventricular zone that gives rise to the cerebral cortex. We suspect that TES-1 may be an important transcriptional regulator that controls differentiation of the mammalian forebrain.

281.2

DETERMINANTS OF CELL FATE: CHARACTERIZATION OF *NOTCH*-RELATED MOUSE CDNA CLONES DERIVED FROM EARLY POSTNATAL GRANULE NEURONS ME Ross¹ and N Heintz² Univ. of Minnesota, Minneapolis MN, 55455¹ and Rockefeller Univ., NY NY, 10021²

In *Drosophila*, the neurogenic locus *Notch* (*N*) plays a pivotal role in the differentiation of neuroectodermal cells as they adopt a neuronal or epithelial fate. Its 10.2 kb mRNA encodes a membrane protein with cysteine rich repeated units in the extracellular domain which are homologous to epidermal growth factor (EGF) and to EGF-like repeats in the cell lineage control gene, *lin-12* of *C. elegans*. Other neurodevelopmental genes in *Drosophila* possess EGF-like repeats, including *Delta* (*DI*), *slit* (*slt*) and *Serrate* (*Ser*). At least two, *DI* and *Ser*, may interact with *N*, suggesting that proteins containing EGF-like regions represent a class of developmentally important genes, many working via cell-cell interactions. To identify mammalian members of this gene family and determine their role in CNS development, we have used probes encompassing the EGF-like repeats of *N* to screen a mouse cDNA library (Ross et al., *Soc. Neurosci. Abs.*, 16:151, '90) made in λ gt11 from postnatal day (P) 3 to 5 cerebellar granule neurons. Of 2x10⁶ recombinants screened, 34 plaques were identified on duplicate filters. Sequence data (~500 bp ea) from the first 6 clones reveals that 5 are unique with respect to GenBank. Translation of open reading frames from the 5' ends of at least 3 clones reveal cysteine rich regions. Pustell DNA matrix comparisons (65% minimum score) align these ends within the EGF-like repeats of *N* and its *Xenopus* homolog, *Xoich*. At least three of these mRNAs are developmentally regulated. Computerized image analysis of Northern autoradiograms, normalized to GAPDH, reveal that MN20 (~9.5 kb) is expressed at levels >200 fold higher in P6 than in adult mouse cerebellum, while MN51 (~4 kb) is 6 fold higher and MN22 (~4.5 kb) is 4.8 fold higher in P6 than adult cerebellum. Our data suggest that several *N* related genes are expressed in mouse cerebellar granule neurons. The temporal regulation of MN20, 22, and 51 indicates a role for these genes in mammalian neuronal development.

281.4

THE NESTIN PROMOTER: DNA SEQUENCES FLANKING AN INTERMEDIATE FILAMENT GENE DIRECT HIGH-LEVEL EXPRESSION OF EXOGENOUS GENES TO NEURAL AND MUSCLE PRECURSORS. L.B. Zimmerman*, M.J. Marvin*, A. McMahon*# and R.D.G. McKay. Dept. of Biology, M.I.T., Cambridge MA. 02139; #Roche Inst. of Molec. Biology, Nutley NJ 07110-1199.

The mitotic neuroepithelium and somites transiently express the intermediate filament nestin. Nestin regulation is effected at the RNA level both *in vivo* and in the teratocarcinoma P19, in which expression of nestin transcripts and protein increases in response to retinoic acid treatment. Reporter constructs containing the lacZ or CAT genes flanked by sequences upstream of the nestin translation initiation site are appropriately expressed by nestin-positive and -negative cell lines in transient transfection assays, but do not show high-level, specific expression in transgenic mice. The addition of sequences from nestin's introns downstream of lacZ confers such expression in the transgenic mouse assay. This provides a general strategy for directing the expression of a wide variety of experimental genes to neural precursor cells both *in vitro* and in transgenic animals.

281.5

A Brain-Derived Oligotrophic Factor

Barbara Q. Kreider, Judith B. Grinspan, Lawrence G. Wrabetz and David E. Pleasure

A brain-derived oligotrophic factor (BDOF) with an apparent molecular weight of 50,000 daltons, was prepared from the 100,000 x g pellet from neonatal rat brains by salt extraction, ion exchange and molecular sieve chromatography. Like platelet-derived growth factor (PDGF) and the fibroblast growth factors (FGFs), BDOF is mitogenic for rat O2A oligodendroglial progenitor cells but, unlike PDGF and the FGFs, BDOF also enhances the proliferation of galactocerebroside+ (galC+) oligodendroglia. BDOF is antigenically distinct from PDGF and the FGFs. Its effects on oligodendroglial differentiation are also distinctive. In the presence of BDOF, cultured neonatal rat O2A cells become galC+, A2B5-oligodendroglia, but expression of myelin basic protein (MBP) and MBP mRNA is inhibited. This is in contrast to PDGF, which induces accumulation of MBP+ oligodendroglia in such cultures, and of basic FGF, which drives proliferation of O2A cells but inhibits expression of both galC and MBP. Thus, BDOF has the following unique properties: it is a mitogen for galC+, as well as galC- cells of the oligodendroglial lineage; and it inhibits expression by galC+ oligodendroglia of the MBP gene. Further purification of BDOF will be necessary to determine if a single protein is responsible for both the mitogenic and phenotypic effects on the oligodendroglial lineage, and to learn its site of origin in brain.

THE RAT INSULINOMA CELL LINE, RINm5F, RESPONDS TO NERVE GROWTH FACTOR (NGF) AND LAMININ BY EXTENDING NEUROFILAMENT POSITIVE PROCESSES. M. Polak*, B. Seilheimer, G.S. Eisenbarth*, H. Pottier. Department of Neurobiology and Joslin Diabetes Center, Harvard Medical School, Boston, MA 02115.

Although insulin-secreting cells do not derive from the neural crest, they share with neurons the expression of certain proteins such as glutamic acid decarboxylase, and both possess the surface ganglioside defined by its reactivity with the A2B5 antibody.

We therefore postulated that extracellular matrix components (ECM) and neurotrophic factors could alter the phenotype of a rat insulinoma cell line, RINm5F, in culture. RINm5F cells grown in defined, serum-free medium were plated at low density on laminin or poly-L-lysine (pLI)-coated plastic or glass coverslips (GC) in the presence of NGF (100 ng/ml) or laminin (10 µg/ml). BetaTC3 cells, derived from a transgenic mouse SV40-induced insulinoma and functionally more differentiated than the RIN cells, were also tested. At day 3 the cells were photographed and prepared for immunocytochemistry of the 160 kD neurofilament (NF) and the NGF receptor (NGFR).

RINm5F cells cultured either with NGF (60%) or with laminin (65%) or both (75%) displayed cellular projections (spikes), in contrast to typical small round cells cultured in defined medium on pLI-coated culture dishes. BetaTC3 remained round in the presence of NGF. RINm5F cells, round on pLI-coated GC, stained for NF and NGFR. On laminin or pLI-coated GC, in the presence of NGF, most of the RINm5F cells displayed NF+ spikes and stained for the NGFR. On laminin-coated GC, the betaTC3 cells had NF+ spikes.

In conclusion, the de-differentiated RINm5F cells respond in a similar way as PC 12 cells to ECM and NGF, which has previously been shown to affect neurons or neural-crest derived cells only. By contrast the more differentiated betaTC3 cells are able to respond to ECM with NF+ spikes but not to NGF. This suggests that neuronal survival factors and ECM may play important regulatory roles in the early differentiation and growth of pancreatic beta cells.

BASIC FIBROBLAST GROWTH FACTOR INDUCES RETINAL PIGMENT EPITHELIUM TO GENERATE NEURAL RETINA IN VITRO. Catrin Pittack*, Micheal Jones* and Thomas A. Reh. Dept. of Biological Structure, University of Washington, Seattle, Washington 98115.

During embryogenesis, the cells of the eye primordium are initially capable of giving rise to either neural retina or pigmented epithelium (PE), but become progressively restricted to one of these potential cell fates. However, following surgical removal of the retina in embryonic chicks and larval amphibians, new neural retina is generated by the phenotypic switching, or transdifferentiation, of PE cells into neuronal progenitors. A recent study has shown that basic fibroblast growth factor (bFGF) stimulates neural retinal regeneration in chicks *in vivo*. To further characterize the mechanisms by which this factor regulates the phenotype of retinal tissues, we added bFGF to enzymatically dissociated chick embryo PE cultured as a monolayer. We found that bFGF stimulated proliferation and caused several morphogenic changes in the PE, including loss of pigmentation; however, no transdifferentiation to neuronal phenotypes was observed. By contrast, when small sheets of PE were cultured as aggregates on a shaker device, preventing growth as a monolayer, we found that a large number of retinal progenitor cells were generated from the PE treated with bFGF. The bFGF treated explants proliferated extensively to form large regions of a nonpigmented pseudostratified columnar epithelium that resembled a neuronal epithelium (NE) characteristic of the neural retina. Immunocytochemical analysis of these explants showed positive immunoreactivity for the following neuronal marker; NCAM, NSE and NF-M in the NE. Negative control explants were negative for these markers. These results indicate that bFGF promotes retinal regeneration *in vitro* as well as *in vivo* and suggest that the ability of chick PE to undergo transdifferentiation to neuronal progenitors appears to be dependent on the physical configuration of the cells. NIH R01 NS28308.

LAMININ INDUCES A RAPID PHENOTYPIC AND BIOCHEMICAL DIFFERENTIATION OF EMBRYONIC RODENT BRAIN CELLS. P. Liesi and S. Murtomäki*. Institute of Biotechnology, University of Helsinki, Valimot. 7, Helsinki 38, Finland.

Laminin promotes neurite outgrowth of cultured neurons and localizes in the brain during early development(1). Retinal pigment epithelium and murine brain cells extend processes on laminin substrate(2,3;4). We show that very early rodent brain cells differentiate into postmitotic neurons in less than 12 hrs when plated on laminin. Neuronal phenotype is accompanied by cessation of cell division and expression of the 200 kDa neurofilament protein. The neurite outgrowth domain of laminin(5) has similar differentiating effects whereas fibronectin supports expression of neurofilament light and middle chains without inhibition of cell division. These results indicate that laminin is a differentiation factor for early brain cells and may direct their development into neurons.

TRANSFORMING GROWTH FACTOR BETA-1 AND CHICK EMBRYO EXTRACT DIFFERENTIALLY AFFECT NEURAL CREST CELL NEURONAL DEVELOPMENT *IN-VITRO*. M.J. HOWARD and M.D. GERSHON. Dept. of Anat. & Cell Biol., Columbia University, New York, NY 10032.

Neural crest cells give rise to neurons of the peripheral nervous system. Previous studies showed that transforming growth factor beta-1 (*TGF-β1*) could substitute for chick embryo extract (CEE)-derived factors in supporting catecholaminergic differentiation by some neural crest cells *in-vitro*. The current studies test the possibility that the responsible factor in CEE might be *TGF-β1*. The time-course of the response to *TGF-β1* was studied by analyzing formaldehyde induced fluorescence, (FIF) in neural crest cells plated in medium supplemented with 2% CEE (a non-permissive growth condition for catecholaminergic differentiation) and 3 ng/ml *TGF-β1* from 1 to 4 days. After removing *TGF-β1*, the cells were maintained in the non-permissive condition for the remainder of the 7 day growth period. Exposure to *TGF-β1* for 1-4 days supports expression of FIF in approximately 50% of explants. This finding contrasts with previous results showing that only 12 to 20% of explants maintain the capacity to respond to CEE-derived factors with catecholaminergic differentiation when initially exposed to non-permissive conditions for 1 to 4 days. Even after the 4 day critical period for CEE-derived factors, *TGF-β1* supports catecholaminergic expression, suggesting that CEE and *TGF-β1* may activate different signalling mechanisms. Antibodies to *TGF-β1* block its effect *in-vitro* but do not block CEE-derived factors suggesting that CEE-derived factors and *TGF-β1* are not the same. Persistence of CEE-supported catecholaminergic expression following early exposure to the RNA synthesis inhibitor 5,6-dichlorobenzimidazole riboside suggests that transcriptional regulation is probably not initially required for catecholaminergic phenotypic expression. The possibility that the inhibition observed later is due to effects on protein synthesis can not be ruled out at this time. These studies suggest that the CEE-derived catecholamine-supporting factor is not *TGF-β1* (This work was supported by NS12969).

EPIDERMAL GROWTH FACTOR IS MITOGENIC FOR RAT RETINAL NEUROEPITHELIAL CELLS. Raymond M. Anchan and Thomas A. Reh. Department of Biological Structure, University of Washington, Seattle, Washington 98105.

The factors that regulate the number of neurons and glia during histogenesis of the central nervous system (CNS) are not well understood. We recently reported that EGF and TGFα are mitogens for multipotent retinal neuroepithelial cells in dissociated primary cultures. In addition, EGF and TGFα messages, as well as the EGF receptor, are also present in the developing rat retina (Anchan et al, 1991, *Neuron*, in press). We have now extended our studies to whole retinal cultures. [³H]-thymidine pulse labelling studies of embryonic day 14 rat whole retinas cultured for up to 11 days *in vitro* show a two fold increase in the number of mitotically active neuroepithelial cells when cultured with EGF. In addition, the number of differentiated neurons is concomitantly reduced in the EGF treated cultures; eg. the number of rod photoreceptor cells in the control cultures is approximately that of the appropriate *in vivo* age (postnatal day 1), while only a few rods are present in the EGF treated retinas. Upon removal of the growth factor and continued culture of the whole retinas for another 3 to 4 days, the majority of neuroepithelial cells withdraw from the cell cycle and differentiate into rods. This data suggests that EGF and TGFα normally regulate retinal cell numbers by stimulating the proliferation and suppressing the differentiation of neuroepithelial cells. NIH R01 NS28308.

281.11

CONTROL OF PROLIFERATION OF RETINAL CELLS IN VITRO. L.E. Lillien and C. L. Cepko. Dept. of Genetics, Harvard Medical School, Boston, MA 02115.

As in other parts of the CNS, progenitor cells in the retina divide for a limited period of time before they differentiate. In order to begin to understand how proliferation is controlled in the retina, we have tried to identify factors that alter the proliferation of retinal cells in vitro. We have found that proliferation in explant and monolayer cultures of embryonic and postnatal retinal cells is enhanced by aFGF, bFGF, EGF and TGF α . The dose-dependence of the mitogenic response to aFGF and bFGF, however, changes with age: higher concentrations of the factors are required to elicit maximal responses at later stages. As this change precedes loss of the capacity to divide, this observation suggests that a decline in responsiveness to FGF may be one of the mechanisms that restricts proliferation in the retina.

SUBCORTICAL VISUAL PATHWAYS

MORPHOLOGY OF GANGLION CELLS INNERVATING THE MEDIAL INTERLAMINAR NUCLEUS OF THE LATERAL GENICULATE BODY. M. Pu* and D.M. Berson. Div. Biology & Medicine, Brown Univ., Providence, RI, 02912

Correlations between morphology, physiology and central projections, well established for alpha (Y) and beta (X) cells of the cat retina, are still largely unexplored for W-cells. We have examined the morphology of ganglion cells innervating a major thalamic target of W-cells, the medial interlamina nucleus (MIN) of the LGN. Living MIN-projecting ganglion cells, labeled by retrograde transport of fluorescent beads, were stained *in vitro* by intracellular injection of Lucifer Yellow and biocytin. The intracellular markers were converted to a stable, high-resolution stain using anti-Lucifer Yellow immunohistochemistry and an avidin-biotin procedure. We stained more than 350 cells in the retinas of two cats. These included alpha cells, beta cells and various presumed W-cells. The beta cells (both ON and OFF varieties) were encountered with surprising frequency, making up about a third of our non-alpha sample. Labeled beta cells were widely distributed over the retina even though our bead deposits apparently spared all of the laminar LGN, confirming earlier evidence for some X-cell input to MIN (Dreher & Sefton, JCN '79; Sur and Sherman, Science '82). About half of the stained W-cells formed a relatively homogeneous group with medium-sized somas (18-28 μ m) and huge dendritic fields (400-600 μ m diam. centrally and > 1000 μ m peripherally) reminiscent of the epsilon cells of Leventhal et al. (JCN '80). Involvement of the geniculate wing (to which epsilon cells project) was minimal, but could have accounted for the labeling of some of these cells. The remaining W-cells were extremely diverse morphologically, including small-field cells with fine, densely interwoven processes; medium-field cells with tortuous or crooked spiny dendrites; and some that resembled the delta cell of Boycott and Wässle (J.Physiol. '74).

282.3

EFFECT OF STIMULUS CONTRAST AND SIZE ON NMDA RECEPTOR ACTIVITY IN THE CAT LATERAL GENICULATE NUCLEUS (LGN). Y. H. Kwon, S. B. Nelson, L. J. Toth* and M. Sur. Dept. of Brain and Cognitive Science, MIT, Cambridge, MA 02139.

39 cells from layers A or A1 of cat LGN were recorded with extracellular iontophoretic electrodes, and were classified as X or Y, and lagged or non-lagged based on standard physiological criteria. We displayed a spot of optimal size in order to visually drive the cells, and examined the cell's response to contrast variation before, during and after application of APV. In the same manner, we recorded responses to maximal contrast stimuli presented at sizes smaller and larger than optimal.

The NMDA-dependent (APV-sensitive) component of the response was found to be a linear function of response for most cells studied, regardless of cell type. APV application changed only the gain and saturation response. The actual NMDA contribution, however, varied between cells and cell types. Lagged X cells were found to have a significantly greater NMDA component, as a population. The NMDA fraction of the response decreased with increasing stimulus size, suggesting that surround inhibition can preferentially decrease the NMDA component. These data suggest that while retinal excitatory drive alone does not affect the percentage of NMDA-dependent response, intrageniculate inhibition can modulate that percentage. Frequency Facilitation and Long-Term Potentiation of Retinogeniculate and Corticogeniculate EPSPs of Cat Lateral Geniculate Neurons Recorded in Thalamic Slices. H.E. Scharfman^{1,2}, M.E. Bickford², S-M. Lu², W. Guido², P.R. Adams^{1,2}, and S.M. Sherman². The Howard Hughes Medical Institute¹ and Department of Neurobiology and Behavior², SUNY at Stony Brook, Stony Brook, NY 11794-5230.

We examined the effects of physiologically relevant stimulus frequencies on retinogeniculate and corticogeniculate EPSPs of cat lateral geniculate neurons recorded in thalamic slices. We were particularly interested in the possibility that brief, high frequency afferent stimulation could cause a long lasting enhancement of EPSPs (long-term potentiation; LTP), since NMDA receptors contribute to EPSPs of relay cells, and NMDA receptors appear to be fundamental to LTP in other systems. We found that pairs of stimuli to either optic tract or optic radiations demonstrated strong facilitation, and brief stimulus trains (3-100Hz, 0.5-2sec) to either input produced long lasting increases in EPSP amplitude. When identical stimuli were presented in pairs with short interstimulus intervals (10-50 msec), the response to the second stimulus was a larger EPSP, which often triggered an action potential. At a surprisingly wide range of membrane potentials, when a single stimulus evoked an EPSP, the second stimulus could evoke a LTS. During 3-10Hz trains that lasted 1-2sec, EPSP amplitude increased greatly and triggered action potentials. Following these trains the EPSP amplitude remained elevated for as long as 5 minutes, and then returned to its original amplitude. The response to 100Hz trains was more dramatic. During these trains, cells depolarized and discharged at high frequency, and the train was followed by an afterhyperpolarization. After 3-10 trains the EPSP amplitude often remained elevated (2-5 fold) for long periods (0.5-2 hours). The ability of cat thalamic neurons to increase their responses to retinal or cortical excitation provides a mechanism for enhancement of retinal or cortical input that may occur during normal signal processing. SUBLAMINAR ORGANIZATION OF METABOLIC ACTIVITY IN THE OFF PATHWAY THROUGH CAT LATERAL GENICULATE NUCLEUS (LGN): D,L-2-AMINO-4-PHOSPHONOBUTYRIC ACID (APB) INTRA-OCULAR INJECTION AND 2-DEOXYGLUCOSE (2-DG) AUTORADIOGRAPHY.

G.A. Thurlow, D.B. Bowling and R.M. Cooper. Depts. of Medical Physiology and Psychology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

In the visual system, ON and OFF pathways show a degree of separation that differs with anatomical location and with species. In cat LGN the ON and OFF cells have been reported to form opposing density gradients through the depth of layer A: OFF cells highest at the bottom of the layer, ON cells highest at the top. However, the evidence for this is entirely based on microelectrode recordings which are subject to sampling errors and positional inaccuracies.

To obtain a measure of ON/OFF activity that is independent of microelectrode techniques we eliminated retinal ON responses with intra-ocular injections of APB. Using 2-DG autoradiography, we examined the spatial distribution of the remaining OFF activity in awake and freely-moving cats. Tetrodotoxin injected controls allowed assessment of baseline LGN metabolic activity. The results showed a simple gradient of OFF activity that was highest at the bottom of layer A. Little or no gradient was detected in layer A1.

In addition to the metabolic gradient in the OFF-pathway, previous work has demonstrated that X/Y cell density, response amplitude (Bowling & Wieniawa-Narkiewicz, J. Physiol. 1986; 1987), response latency (Bowling, Vis. Neurosci. 1989), and projections to cortex (Humphrey et al., J. Neurosci. 1985; Bowling, Brain Res. 1989), all exhibit a sublaminal organization within the A layer. Such an organization is beyond that implied solely by X/Y and ON/OFF channels and may contribute to the unique response properties of cortical cells. Supported by MRC (Canada), NSERC and AHFMR.

STIMULATION OF THE BRAINSTEM RETICULAR FORMATION DOES NOT ABOLISH THE LAGGED/NON-LAGGED CELL DISTINCTION IN THE CAT LGN A.L. Humphrey and A.B. Saul. Dept. of Neurobiology, Anatomy and Cell Science, U. of Pittsburgh, Pittsburgh PA

Two groups of X-cells in the cat LGN are distinguished by their responses to flashing spots (Humphrey and Weller, *J.Comp.Neurol.* 268:429). Non-lagged cells (X_N) respond to spot onset with a short latency (30-60ms) excitatory transient followed by a sustained discharge. Lagged cells (X_L) respond with an early dip in firing, due to GABA-mediated inhibition, and a long latency to discharge (70 to >250ms). Uhlrich et al. (*PNAS* 87: 2560) recently reported that X_L -cells could be induced to respond like X_N -cells by stimulating the peribrachial region (PB) of the brainstem reticular formation. We have reinvestigated this issue using a similar paradigm. Spot stimuli flashing at 0.25-2Hz were paired with short trains (1100ms) of electrical pulses delivered to the PB region in cats anesthetized with halothane in nitrous oxide/oxygen.

For 33 X_N -cells, PB stimulation led to a moderate increase in both the transient and sustained portions of the spot-elicited discharge but did not alter the cells' latencies to discharge. For 40 X_L -cells, PB stimulation significantly increased spot-elicited firing rates, as much as 3 times above control levels, and reduced the cells' latencies (mean reduction in latency: 40%; range:10-70%). Despite these shorter latencies, the spot-induced early dip in discharge was still present in most X_L -cells and all of the cells had longer latencies than any X_N -cell (range: 66-250ms). For 3 additional cells (1 X_L and 2 partially lagged) PB stimulation shortened the latencies from the lagged to non-lagged range. Interestingly, none of these 3 cells had an early dip in their control response to spots, suggesting that the inhibition making these cells lagged may have been minimal and readily counteracted by PB activation. In summary, PB stimulation greatly facilitates the responsiveness of X_L - and X_N -cells but, with very few exceptions, these two cell groups remain clearly distinguishable in response timing. (Supported by EY06459)

282.7

EFFECT OF MEMBRANE VOLTAGE AND PARABRACHIAL ACTIVATION ON LAGGED AND NONLAGGED CELLS IN THE CAT LGN. S.-M. Lu, W. Guido, and S.M. Sherman. Dept. of Neurobiology, SUNY Stony Brook, NY 11794

Lagged and nonlagged responses among cat LGN cells represent may different response modes of the same cells rather than different cells *per se*. A factor in this phenomenon may be a voltage-dependent A-current (I_A) due to a K^+ conductance that offsets and retards EPSPs, thus creating the lag. We tested this hypothesis during intracellular recording of LGN cells in cats by measuring responses to flashing spots centered on the receptive field as a function of V_m . Among other parameters, we determined the latency to reach half maximum response following stimulus onset. In support of the I_A hypothesis, depolarization of V_m in LGN cells did reduce this response latency, and this effect was more prominent in lagged than in nonlagged cells. In some lagged cells, the latency declined into the nonlagged range with V_m depolarization from -70 to -50 mV, but in other cells the latency change was less dramatic. We also repeated an earlier observation that electrical activation of the parabrachial region (PBR), which provides a largely cholinergic input to the LGN, converts lagged responses to nonlagged. We thought this might occur because PBR activation depolarizes LGN cells, thereby inactivating I_A . However, depolarization alone due to PBR activation was insufficient to explain the reduction in response latency: comparable depolarization via current injection into the cell produced much less latency reduction. Perhaps PBR activation has indirect effects on LGN cells through its action on local GABAergic circuits, or perhaps ACh has other effects on LGN cells that are not obvious in our recording. We conclude that I_A may well play a role in the lagged/nonlagged response dynamics, but that other factors, presently unknown, also contribute. Furthermore, the ability of PBR input to convert lagged to nonlagged responses is not a simple consequence of its effects on V_m . (Supported by USPHS grants EY03038 and EY06082.)

ELECTROPHYSIOLOGICAL ANALYSES OF SINGLE NEURONS IN THE LATERAL GENICULATE NUCLEUS (LGN) OF SQUIRREL MONKEYS. James R. Wilson, Yerkes Research Center, and Dept. of Anatomy and Cell Biology, Emory Univ., Atlanta, GA 30322.

Over 200 neurons were recorded in the LGNs of squirrel monkeys. All 58 of the parvocellular cells (P-cells) tested had linear responses to grating patterns, and only 3 of 16 magnocellular cells (M-cells) showed a nonlinear or doubling response. No cell gave a response that would be considered of the lagged type. Also, no cells with non-dominant eye inhibition were observed. Of the 64 P-cells tested, 44 had tonic responses (>5 sec) to standing center contrast, while 13 of 18 M-cells had phasic (<1 sec) responses. Qualitatively, very few LGN cells gave strongly differential responses to red, green or blue spots, and some of those were magnocellular cells, in distinct contrast to LGN cells of macaque monkeys. Most ON-center P-cells were located in the outer or dorsal portion of the parvocellular laminae, while most OFF-center P-cells were in the inner or ventral portion. One P-cell interneuron with an OFF center was observed in the most dorsal lamina. Therefore, the squirrel monkey's LGN probably has laminae physiologically separable into ON and OFF response type cells. It is concluded that squirrel monkey LGN neurons are very similar in their response properties to those of the macaque except for the relative lack of wavelength selective P-cells. Supported by NIH Grants EY04976 and RR00165.

282.6

THE EFFECT OF BRAINSTEM PERIBRACHIAL STIMULATION ON THE CONTRAST-RESPONSE PROPERTIES OF CELLS IN THE CAT LATERAL GENICULATE NUCLEUS. E. Hartveit and P. Heggelund. Department of Neurophysiology, University of Oslo, Oslo, Norway.

Most cells in the retina and LGN respond primarily to stimulus contrast. In the LGN, the response can also be strongly influenced by input from the midbrain peribrachial region (PBR). The functional importance of the input from the PBR is not known. To address this question, we have investigated the influence of input from the PBR on the relationship between stimulus contrast and visual response of LGN cells. We recorded the response of single cells to a series of stationary flashing light spots of different contrasts. The spots approximately filled the receptive field center. The response was recorded both with and without electrical stimulation of the PBR. From contrast-response curves we determined response threshold, contrast gain (the slope of the initial part of the curve), contrast giving half-maximal response (C_{50}), and dynamic range (the range of contrasts over which the cell changed its response).

The visual response of most cells increased almost linearly with increasing contrast over a large part of the dynamic range. In this range, an enhancement of the visual response by PBR stimulation could be elicited at all contrasts. On the nonlagged cells the proportional increase of the response at the various contrasts was approximately constant. Accordingly, the effect of the PBR stimulation was mainly an increase of the contrast gain. Response threshold, C_{50} and dynamic range changed little.

The finding that the PBR stimulation primarily enhances the contrast gain suggests that the mechanism of response enhancement on nonlagged cells is a multiplicative one, rather than an additive one, e.g. by an increase in the spontaneous activity. Preliminary results suggest that the contrast-response curves of lagged LGN cells may change in a different manner during PBR stimulation.

282.8

LOW THRESHOLD CALCIUM SPIKES PARTICIPATE IN LAGGED AND NONLAGGED RESPONSES OF CAT LGN CELLS. W. Guido, S.-M. Lu, and S.M. Sherman. Dept. of Neurobiology, SUNY, Stony Brook, NY 11794-5230.

Voltage-dependent low threshold (LT) Ca^{2+} spikes in cat LGN cells are visually-evoked and comprise a large proportion of responses to visual stimuli. Some have suggested that the pattern of LT spiking might be different for lagged and nonlagged cells, and we tested this possibility. In cat LGN cells, we recorded visually evoked activity to a square-wave modulated bright or dark spot of light centered on its receptive field. Roughly 20% of the sample showed a lagged response (≥ 70 msec latency to half-peak of response). During intracellular recording, both lagged and nonlagged cells exhibited stimulus-evoked LT spikes with bursts of action potentials riding their crests. We could recognize these responses extracellularly as action potentials with interspike intervals ≤ 4 msec, and we refer to them as *burst responses*; we define action potentials with longer interspike intervals as part of the *tonic response*. Nearly all cells displayed burst responses. For both lagged and nonlagged cells, the initial response to stimulus onset tended to be dominated by burst responses, which were then followed by more tonic responses. The latency of the first stimulus-evoked burst (or LT spike) was significantly longer and more variable among lagged cells than among nonlagged cells. Nonlagged cells typically showed a period of poor tonic responsiveness following the initial burst response, and this may reflect a refractory period following most LT spikes. Lagged cells may display a similar refractory period, but in the average histograms this is less evident because of more temporal scatter in the burst responses. Finally, for those lagged cells showing the property, the "anomalous off" discharge was dominated by tonic rather than burst responses. Overall, these data do not suggest any dramatically different involvement of LT spikes between lagged and nonlagged cells. (Supported by USPHS grants EY03038 and EY06082.)

282.10

COUPLING OF NEURONAL OSCILLATORS VIA INTRANUCLEAR COLLATERALS IN THE DORSAL LATERAL GENICULATE NUCLEUS (dLGN). Ivan Soltesz and Vincenzo Crunelli. Dept. of Visual Science, Inst. of Ophthalmology, London, U.K.

Recent *in vitro* studies have shown that some, though not all, thalamocortical (TC) neurons are capable of generating TTX-resistant oscillations in the frequency range of the EEG during the deep stages of slow wave sleep, by the periodic activation and inactivation of two inward currents, I_T and I_h (Leresche et al. *Neurosci.Lett.*, 1990 & *J.Physiol.* 1991; McCormick & Pape, *J.Physiol.* 1990; Soltesz et al. *J.Physiol.* 1991). Here we studied the periodic excitatory and inhibitory synaptic interactions taking place between neurons of the cat dLGN *in vitro*.

In TC cells 3 types of rhythmic synaptic events could be observed: 1) EPSPs which were abolished by TTX ($1\mu M$); 2) IPSPs which were blocked by bicuculline ($50\mu M$); 3) complex, TTX-sensitive synaptic potentials consisting of a fast (15-25ms) depolarizing-hyperpolarizing sequence followed by a slower (50-70ms) depolarization. The frequency of these events was insensitive to changes in the membrane potential (-40 to -90mV). Between -65 and -80mV they could rhythmically evoke low-threshold Ca^{2+} spikes while above -50mV the EPSPs and the complex potentials directly gave rise to action potentials. Since all three types of periodic forcing were observed in slices which did not contain the perigeniculate nucleus, it is suggested that the intranuclear collaterals of TC cells might serve as one of the means of thalamic synchronization. Current pulses, injected intracellularly at different phases of the oscillations, designed to mimic EPSPs and reversed IPSPs revealed the existence of weak type 1 as well as strong type 0 phase resettings, and that critically timed (T') exposure to a stimulus of critical strength (S') could drive the oscillator towards its singularity (Winfree, *J.Theor.Biol.*, 1970).

RETINAL GANGLION CELLS THAT PROJECT TO THE PULVINAR NUCLEUS IN MACAQUE MONKEYS. P. Stoerig¹, A. Cowey^{2*}, and M. Bannister^{2*}, Institute of Medical Psychology, LMU, Munich, FRG¹, and Department of Experimental Psychology, Oxford, GB²

To see which of the three classes of ganglion cells project to the pulvinar in primates, we injected HRP iontophoretically into various parts of the inferior, lateral, and medial pulvinar of 3 monkeys (2 injections 0.5mm apart in each hemisphere). We studied the retrogradely labelled cells in retinal wholemounts, disregarding the focus of dLGN-projecting cells seen when the region of uptake involved the caudal tip of the dLGN. Cells labelled from the pulvinar were found at all eccentricities including the parafoveal region. The vast majority were small, with cell bodies within the size range of P β and P γ cells. On the basis of dendritic morphology we could identify well-filled cells as P β or P γ . A small number of large cells, including classifiable P α cells, were also labelled. There was no noticeable difference in the population when the region of uptake included or excluded the brachium. The results show that it is primarily P β and P γ cells that project to the pulvinar. The subpopulation of P β cells that survives transneuronal retrograde degeneration up to 8 yrs. after striate cortical ablation may at least partially correspond to the pulvinar-projecting P β cells. (Supported by DFG, MRC and MacDonell-Pew)

FORM AND LOCATION PROPERTIES OF SINGLE UNITS IN THE PULVINAR OF AWAKE MACAQUE MONKEYS. Port, J. D. and L. A. Benevento. Department of Anatomy, University of Maryland College of Dental Surgery, Baltimore, MD 21201 and Department of Anatomy and Cell Biology University of Illinois, Chicago, IL 60612.

Recent anatomical studies have shown the pulvinar is composed of a mosaic of cell groups which are defined by their specific connections with functionally and anatomically defined cortical and midbrain areas. These cell groups, located within or across traditional pulvinar nuclear boundaries, are thought to form part of the distributed systems involving the occipitotemporal and occipitoparietal cortical visual systems for the analysis of form/color and location/motion respectively. We designed single unit experiments to examine functional correlates of this anatomical model. We recorded from trained rhesus monkeys performing a number of visual tasks. We found units which responded selectively to different forms. Some of these responded preferentially to simple stimuli such as a circle or square, while others responded preferentially to complex stimuli such as hands or stars. These units were located in clusters. Other units responded preferentially to certain non-foveal locations of point stimuli (0.5°) in the visual field. None of these cells responded differentially to different intensities of a visual stimulus (0.25°) indicating that they are not responding to light alone. The cells responded to form or location with either a suppression or excitation.

Attention effects were also found in some cells. The general firing rate seen throughout the intertrial interval (when the animal is expecting a trial) and the trial itself is suppressed or enhanced relative to the background firing seen in the "no task" state (in which the animal is not expecting any trials). During the trial, firing rate could also be further modulated by fixation and manipulanda action.

NERVE GROWTH FACTOR III

283.1

REGULATION OF C-FOS TRANSCRIPTION BY NGF IN CULTURED SENSORY NEURONS. N. Gabellini*, C. Minozzi*, A. Leon and R. Dal Toso. Fidia Research Labs, 35031 Abano Terme, Italy.

To investigate the possible influence of nerve growth factor (NGF) on c-fos expression in peripheral neurons, dorsal root ganglia (DRG) neurons from chicken embryos (E₈-E₁₂) were transfected with plasmids containing the mouse c-fos promoter linked to the chloramphenicol acetyltransferase CAT gene. Transfected DRG neurons expressed high CAT activity which could be enhanced by adding NGF, fetal calf serum or forskolin to the culture medium. After 24hr of NGF and serum deprivation CAT expression decreased to 30%. Readdition of NGF increased c-fos promoter activity linearly, with a two-fold stimulation after 13hr. The NGF EC₅₀ on c-fos transcriptional activation was approximately 40pM suggesting the involvement of high-affinity NGF receptors. Deletion mutagenesis of the c-fos promoter showed the serum response element (SRE) to be relevant for basal and NGF-induced CAT expression. This experimental paradigm represents an appropriate tool for exploring the mechanisms underlying NGF effects in primary neurons, as well as their modulation by pharmacological agents (e.g. GM1).

283.2

EXPRESSION OF NGF *IN VIVO*, FROM A DEFECTIVE HSV-1 VECTOR ALTERS THE RESPONSE TO PERIPHERAL NERVE AXOTOMY. H.J. Federoff, M.D. Geschwind, A.J. Geller and J.A. Kessler. Depts. of Medicine, Neuroscience and Neurology, Albert Einstein Col. Med., Bronx, NY 10461, Div. Cell Growth and Regulation, Dana Farber Cancer Inst., Boston, MA 02115.

In adult rats, sympathetic neurons in the superior cervical ganglion (SCG) depend on target-derived NGF for maintenance of their adrenergic phenotype; one such action is the stimulation of the activity of the catecholamine biosynthetic enzyme, tyrosine hydroxylase (TH). Axotomy of the SCG results in NGF deprivation, causing a decline of TH activity within that ganglion. This effect can be prevented by the local application of NGF to the axotomized SCG. We used this SCG axotomy paradigm to test whether a HSV-1 vector expressing NGF (pHSVngf) could prevent the decline in TH activity that follows axotomy. Adult rats had one SCG exposed and injected with either pHSVngf virus (N=10) or pNFlac virus (N=9) which expresses *E. coli* β -galactosidase gene instead of NGF. Four days later, animals underwent axotomy of the ipsilateral (virus injected) SCG. After another 10 days, all animals were sacrificed and both the injected-axotomized and contralateral-control ganglia were harvested and assayed for TH activity. In animals injected with pNFlac virus, axotomy produced a 50% decline in TH activity relative to the control ganglion (P=0.02). In contrast, animals injected with pHSV ngf virus did not show a decline in TH activity and instead, manifested an 18% increase in TH levels relative to the control ganglion. These data indicate that defective HSV-1 vectors can be used to modify neuronal physiology *in vivo*.

283.3

INTRODUCTION OF NGF INTO CULTURED NEURONS AND NON-NEURONAL CELLS FROM A DEFECTIVE HSV-1 VECTOR. M. D. Geschwind, J.A. Kessler, A.J. Geller, and H.J. Federoff. Depts. of Medicine, Neuroscience and Neurology, Albert Einstein Col. of Med., Bronx, N.Y. 10461 and Div. Growth and Regulation, Dana Farber Cancer Institute, Boston, MA. 02115.

An NGF minigene has been cloned into a defective HSV-1 vector, termed pHSVngf (Science 241:1667, 1988; Proc. Natl. Acad. Sci., 87:1149,1990; Biochem. Pharm. 40: 2189,1990). pHSVngf virus has been tested for its ability to infect neurons and other cells, to produce NGF, and to modify the physiology of neurons. To ascertain whether the virus can cause the production and secretion of functional growth factor, established cell lines were infected, and the amount of NGF secreted into the medium was quantitated by an ELISA. NGF production rates ranged from 1-3 ng/hr. Moreover, the secreted NGF was functional, since media from these infected cell lines supported the survival of cultured rat sympathetic neurons in a dose-dependent manner. Infection of PC12 cells with the virus stimulated neurite outgrowth in the absence of exogenously added NGF. Furthermore, direct infection of cultured neonatal rat sympathetic neurons (which fail to survive in culture without addition of NGF) allowed survival without exogenous growth factor. Finally, infection of cultured striatal or septal neurons increased levels of the cholinergic enzyme, choline acetyl transferase (ChAT). These studies suggest that pHSVngf virus can be used to modify the physiology of neurons in culture and perhaps *in vivo*.

283.4

MOLECULAR CLONING AND DEVELOPMENTAL ANALYSIS OF NEUROTROPHIC FACTORS AND THEIR RECEPTORS IN ZEBRAFISH. S.C. Martin* and G. Heinrich University Hospital and Boston University School of Medicine, Boston, MA 02118

The Zebrafish (*Brachydanio rerio*) has been used as a model system to study neuron process outgrowth, growth cones and guidance mechanisms. We have sought to integrate this background with a molecular genetic analysis of the expression of nerve growth factor (NGF) and its low and high affinity receptors during neurodevelopment. Firstly, we used pools of degenerate oligonucleotide primers and the polymerase chain reaction to clone the Zebrafish homologs of NGF, the low affinity NGF receptor and the high affinity NGF receptor, the *trk* proto-oncogene. It has been found that these genes are closely similar to their mammalian homologs. We have used Northern blot analysis to study the expression of these genes during development. Secondly, we are using *in situ* hybridization techniques to study the temporal and spatial distribution of these mRNAs during Zebrafish neurodevelopment.

283.5

WIDESPREAD INCREASE OF mRNAs FOR NERVE GROWTH FACTOR AND BRAIN DERIVED-NEUROTROPHIC FACTOR DURING KINDLING EPILEPTOGENESIS

Patrik Ernfors¹, Johan Bengzon², Zaal Kokaia², Olle Lindvall² and Håkan Persson¹.

¹Department of Medical Chemistry, Laboratory of Molecular Neurobiology, Karolinska Institute, S-10401 Stockholm, Sweden. ²Restorative Neurology Unit, Department of Neurology, University Hospital, S-22185 Lund, Sweden.

Kindling, induced by repeated subconvulsive electrical or chemical stimulations leads to progressive and permanent amplification of seizure activity, culminating in generalized seizures. Acetylcholine act as a dis-inhibitory neurotransmitter and increased activity facilitates kindling epileptogenesis. Nerve growth factor (NGF) supports survival of, and induce sprouting from, cholinergic neurons of the basal forebrain, and recently, brain-derived neurotrophic factor (BDNF) have been shown to support cholinergic neurons of the basal forebrain.

Two hours after focal seizure, induced by electrical stimulation in the ventral hippocampus, lead to increases of mRNAs for NGF and BDNF in the dentate gyrus granule cells. Generalized seizures led to further increases of BDNF mRNA in the dentate gyrus, and an increase was also seen in the pyramidal layer of the hippocampus, the piriform cortex, the amygdaloid complex and the outer pyramidal layer of the parietal cortex 2 hrs after the last stimulation. Generalized seizures also led to further increases of NGF mRNA in the dentate gyrus granule cells after 2 hrs. At 4 hrs after the last stimulation an increase in NGF mRNA was seen in the piriform cortex and in the outer pyramidal layer of the parietal cortex. The increased expression of NGF and BDNF mRNA was not blocked the NMDA receptor antagonist MK801 but partially blocked by the quisqualate, AMPA receptor antagonist NBQX. The presumed subsequent increase of the trophic factors themselves may be important for kindling-associated plasticity in specific neuronal systems in the hippocampus, which could promote hyperexcitability and contribute to the development of epileptic syndromes.

283.7

NGF BIOACTIVITY: ROLE OF THE AMINO TERMINUS

RAV Taylor*, JF Kerrigan*, FM Longo, M deBoisblanc*, WC Mobley Dept of Neurology and Neuroscience Program, University of California, San Francisco CA 94143

The amino terminal octapeptide of NGF is highly conserved between species suggesting it might contribute important structural information; moreover, it is cleaved in a physiological setting in mouse submandibular gland. We wished to re-investigate whether or not NGF lacking this peptide (des¹⁻⁸NGF) is active.

NGF was prepared from male mouse submandibular glands as previously described (Biochem 15:5543, 1976). Des¹⁻⁸NGF was prepared by addition of β -NGF endopeptidase which cleaves the NH₂-terminus. It was purified by ion-exchange chromatography; SDS-PAGE showed that > 97.5% chains were des¹⁻⁸NGF. Bioactivity was assessed using neurons from the ED8 chick dorsal root ganglion. Dissociated neurons were cultured with NGF for 24 hours and the number of neurite bearing cells counted. NGF activity was also assessed by measuring c-fos kinase activation in intact PC12 cells. (Method of L Taylor and G Landreth, Case Western Reserve University.)

In both assays NGF was significantly more active than des¹⁻⁸NGF. Neurite outgrowth from chick DRG neurons had an ED50 (50% maximum activity) of 80 pg/ml for routinely prepared NGF(35% des¹⁻⁸NGF) whereas for des¹⁻⁸NGF it was 2000 pg/ml. The c-fos kinase assay gave an ED50 of 10 ng/ml for NGF and an ED50 of greater than 400 ng/ml for des¹⁻⁸NGF.

These results contradict earlier data using intact dorsal root ganglia (Biochem 15:5543, 1976) which indicated that removal of the NH₂-terminal octapeptide had no effect on NGF activity. We are examining further the mechanism whereby the octapeptide confers activity - does it facilitate dimer formation, does it contribute directly to binding, or does it influence binding through allosteric effects? On the basis of our results it will be important to characterize NGF preparations for the extent of NH₂-terminal modification.

283.9

Biological activity of NGF is mediated through a novel subclass of high affinity receptors. G.Weskamp* and L.F.Reichardt, Dept. of Physiology an HHMI, UCSF, San Francisco CA 94143.

Trophic factors, such as NGF, regulate survival and differentiation of neurons by binding to specific receptors. Two types of NGF receptors have been identified, which bind NGF with low and high affinity. However, the molecular relationship between both receptors is still unclear. To determine whether the low affinity receptor is necessary for generating a NGF-high affinity receptor complex, a polyclonal antibody to the low affinity NGF receptor was generated using a recombinant extracellular domain of the receptor as an antigen. The antibodies eliminate binding of NGF to the low affinity receptor expressed in L cells. On PC12 cells, these antibodies inhibit binding of NGF to the low affinity receptor as well as to one class of high affinity receptors. Surprisingly, a second subclass of high affinity NGF receptors was not affected by the antibody. In cross-linking experiments, these antibodies precipitated the complex of NGF with the low, but not the high affinity receptor. Furthermore, NGF-dependent survival or neurite outgrowth by rat sensory neurons or PC12 cells was not affected by the antibodies. Our data suggest that one class of high affinity receptors is derived from the low affinity receptor. However, a second, antigenically distinct class of high affinity receptors sufficient for mediating the major biological actions of NGF exist on PC12 cells. Recently, the product of the *trk* proto-oncogene was shown to be a constituent of a high affinity NGF receptor complex which may correspond to the high affinity receptor complex that is not recognized by the anti-low affinity antibodies.

283.6

MECHANISMS OF INTERLEUKIN-1 ACTION IN HIPPOCAMPAL CULTURES W.J. Friedman^{1,3}, N. Altirk², B. Fredholm², and H. Persson¹

¹Lab. of Molecular Neurobiology, and ²Dept. of Pharmacology, Karolinska Institute, Stockholm, Sweden, and ³Dept. of Neuroscience and Cell Biology, UMDNJ/Robert Wood Johnson Med. Sch., Piscataway, N.J.

Regulation of nerve growth factor (NGF) expression in hippocampus has been examined using a dissociated primary culture system. We have previously demonstrated that inflammatory agents such as interleukin-1 (Il-1) and prostaglandin E₂ increase levels of NGF mRNA.

Further work has proceeded to investigate possible second messenger pathways mediating the influence of Il-1 on NGF expression. cAMP does not appear to play a role as treatment of hippocampal cultures with dbcAMP or forskolin elicited no change in NGF mRNA. Moreover, exposure to Il-1 did not cause any change in cAMP levels. Nor did Il-1 alter PI turnover or calcium flux. Exposing cultures to phorbol ester resulted in a large increase in NGF mRNA, however pretreatment with the phorbol ester to desensitize the protein kinase C pathway only partially blocked the subsequent ability of Il-1 to induce NGF mRNA. This suggests that Il-1 may act partly through a PKC-dependent mechanism, but that other second messengers yet to be defined must also be involved.

We are currently investigating the role of other cytokines in regulation of trophic factor expression in the brain.

283.8

A RATE-LIMITING REPRESSOR NUCLEAR PROTEIN SPECIFICALLY REGULATES NGF GENE TRANSCRIPTION. S. R. D'Mello and G. Heinrich. University Hospital and Boston University School of Medicine, Boston, MA 02118

Analyses of the mouse NGF gene promoter using transient expression assays in L929 cell fibroblasts indicate that the region from -250 to -500 contains an element associated with transcriptional repression. Deletion of this region results in an 8-fold increase in NGF promoter activity. Insertion of this region upstream from the mouse metallothionein gene promoter does not affect transcription suggesting that the repressor element is specific for the NGF gene. DNase-1 footprint analysis indicate that the segment from -269 to -296 is bound by L929 nuclear proteins and suggests that the protected segment serves as the transcriptional repressor element. Cotransfection of a NGF promoter construct with a pUC-18 plasmid containing only 4 copies of the footprinted segment results in a 6-fold increase in transcriptional activity supporting this possibility. Additionally, this result suggests that the nuclear protein(s) that binds to this element is present in limiting amounts. Gel retardation assays show that the protein(s) that bind to the repressor-element are less abundant in L929 cells than in NIH 3T3 fibroblasts and B-16 melanoma cells. Since B-16 cells do not express the NGF gene and NIH 3T3 cells express lower amounts of NGF mRNA as compared with L929 cells, this result suggests that the cellular level of repressor protein(s) may in part influence the level of NGF mRNA expressed. The repressor-element lies within a 170 bp region of the NGF gene that has been implicated in glucocorticoid regulation raising the possibility that this element may be involved in both basal and modulated NGF gene expression.

283.10

TRKB: A FUNCTIONAL RECEPTOR FOR BDNF AND NT-3 BUT NOT NGF. S.P. Squinto, T. Siliti, P.S. DiStefano, D.J. Glass, T.H. Aldrich, P. Hantzopoulos, D.M. Valenzuela, S.M. Bianco, P. Masiakowski, C. Badziejewski, S.H. Nye, N. Ip, M.F. Furth, M. Goldfarb and G.D. Yancopoulos. Regeneron Pharmaceuticals, 777 Old Saw Mill River Road, Tarrytown, New York 10591

A variety of findings seem to functionally link brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3), while distinguishing both of these factors from a third member of the neurotrophin gene family, nerve growth factor (NGF). Here we demonstrate that all three of these neuronal survival molecules similarly bind to the low affinity NGF receptor (LNGFR), but that BDNF and NT-3 unlike NGF do not act via the high affinity NGF receptor (HNGFR). However, both BDNF and NT-3, but not NGF bind to full-length and truncated forms of a receptor-like tyrosine kinase, trkB, for which no ligand had previously been identified. In addition to binding BDNF AND NT-3 with relatively high affinity, trkB can also mediate phenotypic responses to these two neurotrophins. For example, BDNF and NT-3 induce neurite outgrowth from trkB-expressing PC12 cells. BDNF and NT-3, but not NGF, can function as both mitogenic and survival-promoting molecules for trkB-expressing NIH 3T3 cells grown in serum-free defined media (growth factor-dependent 3T3 clone). Also, it appears that trkB alone, in the absence of the LNGFR, can serve as a functional receptor for the mitogenic/survival phenotype induced by BDNF and NT-3. Finally, we have detected trkB mRNA in ratE14 DRG and in some human neuronal cell lines and further expression data predicts the existence of additional functional receptors for the neurotrophins.

283.11

STRUCTURE-FUNCTION STUDIES OF NGF AND BDNF: IDENTIFICATION OF ELEMENTS DETERMINING NEUROTROPHIC SPECIFICITY, BIOLOGICAL ACTIVITY, RECEPTOR BINDING AND PROTEIN STABILITY. Carlos F. Ibáñez¹, Ted Ebdanal², Wilma Friedman³, Ira Black³ and Håkan Persson¹.
¹ Department of Medical Chemistry, Laboratory of Molecular Neurobiology, Karolinska Institutet, S-10401 Stockholm, Sweden, ² Department of Developmental Biology, Uppsala University, Uppsala, Sweden and ³ Department of Neuroscience and Cell Biology, UMDNJ, Piscataway, New Jersey.

Using site-directed mutagenesis, chimeric molecules were constructed in which different combinations of sequences from BDNF replaced the corresponding sequences in NGF. The resulting molecules were transiently expressed in COS cells and were assayed for biological activity in explanted chick sympathetic, spinal and nodose ganglia. Our results show that the biological specificities of the two proteins are obtained by specific combinations of a set of sequences that differ between the two molecules. Some of these combinations allowed us to engineer molecules which display multiple neurotrophic activities recruited from both the NGF and BDNF proteins. These molecules promote survival and induce neurotransmitter synthesizing enzymes in neuronal cultures of specific brain regions. Alanine-scanning mutagenesis was applied to a highly conserved hydrophilic region in the rat NGF molecule (residues 25 to 36). The remarkable conservation of this region, together with its hydrophilic character, has led to the speculation that it could be important for biological activity and receptor binding. Our results show that some of these residues, notably those located between Asp30 and Gly33, are important for binding and biological activity. Our approach has also allowed us to identify residues important for production and/or stabilization of the protein, particularly Lys25, Asp30, Gly33 and Val36. Interestingly, these residues are also conserved in the other three members of the NGF family (BDNF, NT-3 and NT-4), indicating that they may contribute to the formation of a structural frame common to all members of the family.

283.12

EVOLUTIONARY STUDIES OF THE NERVE GROWTH FACTOR FAMILY REVEAL A NOVEL MEMBER NAMED NEUROTROPHIN-4 ABUNDANTLY EXPRESSED IN XENOPUS OVARY. F. Hallböök, C. F. Ibáñez and H. Persson. Department of Medical Chemistry, Laboratory of Molecular Neurobiology, Karolinska Institute, Box 60400, S-104 01 Stockholm, Sweden

Evolutionary conservation of members of the NGF family in vertebrates was studied by DNA sequence analysis of PCR fragments for nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) from human, rat, chicken, viper, *Xenopus*, salmon and ray. The results showed that the three factors are highly conserved from fish to mammals. Phylogenetic trees reflecting the evolution and speciation of the members of the NGF family were constructed. In addition, the gene for a fourth member of the family, neurotrophin-4 (NT-4), was isolated from *Xenopus* and viper. The NT-4 gene encodes a precursor protein of 236 amino acids which is processed into a 123 amino acid mature NT-4 protein with 50 to 60 % amino acid identity to NGF, BDNF and NT-3. The evolutionary analysis showed that NT-4 is closer related to BDNF than to NGF or NT-3. The NT-4 protein was shown to interact with the low-affinity NGF receptor and elicited neurite outgrowth from explanted chick dorsal root ganglia with comparable activity as NGF, BDNF and NT-3. Lower activity was seen on nodose ganglia and no activity was seen on sympathetic ganglia. Northern blot analysis of different tissues from adult *Xenopus* showed NT-4 mRNA only in ovary where it was present in more than 100-fold higher levels as NGF mRNA in adult *xenopus* heart.

HYPOTHALAMIC-PITUITARY-GONADAL REGULATION I

284.1

EFFECT OF TIME OF DAY ON LEVELS OF NUCLEAR AND CYTOPLASMIC POMC mRNA IN PROESTRUS AND ESTROUS RATS. K. Scarbrough, M. Jakubowski, N. Levin and J. L. Roberts. Fishberg Research Center for Neurobiology, The Mount Sinai School of Medicine, New York, NY 10029.

Previous studies showed a diurnal rhythm in the level of POMC mRNA in the periaqueductal region of the hypothalamus of proestrous rats. The aim of the present study was to determine whether this rhythm of mRNA results, at least in part, from changes in the level of transcription of the POMC gene. In addition, we wished to determine if the level of primary transcript and/or POMC mRNA differs in rats on estrus compared to proestrus. We examined changes in the level of these nuclear and cytoplasmic RNA species using a solution hybridization/RNase protection assay.

Young rats exhibited at least two consecutive 4-day estrous cycles before they were killed at 0600 and 1300 h on proestrus or estrus. The medial basal hypothalamus (MBH) was dissected, frozen in freon, and stored at -70°C. Two MBH were pooled in each sample (5-8 samples per group), nuclei were pelleted and the cytoplasmic fraction was separated from the nuclear fraction. RNA was isolated from nuclear and cytoplasmic samples and hybridized to an excess of ³²P-labeled riboprobe complementary to a segment of intron A, extending through exon 2 and covering a segment of intron B of the POMC primary transcript. This probe was designed to distinguish between POMC mRNA (spliced), primary transcript (unspliced), as well as processing intermediates. We observed a similar pattern of change in POMC mRNA in the nucleus (expressed per µg DNA) and cytoplasm (expressed per µg cytoplasmic RNA). Levels of nuclear and cytoplasmic POMC mRNA decreased significantly on proestrus between 0600 and 1300 h. By 0600 h on estrus they returned to levels similar to those observed on the morning of proestrus. We were able to visualize a band corresponding to the POMC primary transcript, however, the signal was too low to quantitate reliably. We are currently pooling more animals/sample in order to quantitate changes in the levels of hnRNAs of low abundance. (Supported by HD07170, HD15955)

284.2

SEXUALLY DIMORPHIC EXPRESSION OF DYNORPHINS AND NEUROKININS IN THE RAT MEDIAN EMINENCE. P. Ciofi, D. Croix*, J.C. Beauvillain*, G. Tramu* and M. Mazzuca*. U.156 INSERM, Place de Verdun, 59045 Lille (France) & Laboratoire de Neurocytochimie Fonctionnelle (GT), URA-CNRS 339, Université de Bordeaux I, 33405 Talence (France).

Brain sexual differentiation results in the dimorphic organization of neural circuits controlling reproduction. Few morphological data are available to explain the marked sex differences in the regulation of neuroendocrine functions.

Antisera specific for gonadoliberin (GnRH), α-neo-endorphin, dynorphin A, dynorphin B, substance P or neurokinin A (NKA), cross-reacts fully with neurokinine B) were used in immunocytochemical studies of the rat mediobasal hypothalamus. Antisera to dynorphins and to NKA all visualize a same population of nerve fibers distributed around blood vessels in the arcuate nucleus and in the palisade zone of the median eminence (ME) in normal adult male animals. This prodynorphin/neurokinin (DYN/NK)-containing innervation is codistributed in these areas with the GnRH-containing fiber plexus. Double-staining electron microscopic studies in the ME with preembedding immunoperoxidase DYN/NK labeling and postembedding immunogold GnRH labeling revealed the close apposition of DYN/NK-immunoreactive boutons with either tanyocytes or GnRH-immunoreactive nerve endings. This DYN/NK ME staining pattern was neither observed in normal cycling, lactating or 35-day ovariectomized female rats, nor in 35-day orchidectomized adult males. Implantation of Silastic capsules filled with either testosterone, dihydrotestosterone or estradiol prevented the castration-induced depletion of ME DYN/NK-immunoreactivity in males. During development, the staining pattern typical of adult animals is installed progressively over the week preceding puberty and is also observed in the ME of 22-month old males.

This pronounced sexual dimorphism in the expression of neuropeptides in a circuit with neurohemal projections may be related to the dimorphic pattern of GnRH secretion which is phasic in females and tonic in males. The metabolism of dynorphins and neurokinins in the afore-mentioned circuit appears to be under the dual influence of testosterone and its aromatized metabolite estradiol.

284.3

PITUITARY PRODYNORPHIN mRNA LEVELS ARE SUPPRESSED BY ANDROGEN TREATMENT, BUT NOT BY ESTRADIOL OR PROGESTERONE. Alan H. Kaynard and Michael H. Melner. Divisions of Neuroscience and Reprod. Biology, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Prodynorphin (proDYN)-derived peptides can inhibit hypothalamic GnRH release thereby reducing pituitary gonadotropin secretion. The high levels of proDYN expression and/or peptide content within neurons of the hypothalamus and gonadotropes of the anterior pituitary gland suggest a role for proDYN-derived peptides in the negative feedback regulation of GnRH and gonadotropin secretion. The present study examined whether gonadal steroid hormones, which exert important negative feedback actions on the neuroendocrine axis, are capable of modulating pituitary proDYN expression in intact, immature rats. Steroids were administered via s.c. Silastic implants; rats were killed at 29 days of age. Northern blot analysis of anterior pituitaries using cDNA fragments of the rat proDYN, LHB, FSHB, and common α-subunit genes as probes was used to measure mRNA levels (normalized to 18S ribosomal RNA). Treatment groups (n=6) consisted of control (CNT; empty implants), estradiol (E₂; 8 days @ ~365 pg/ml), E₂+progesterone (E₂/P₄; 8 days @ ~370 pg/ml and 4 day @ ~25 ng/ml, respectively), and dihydrotestosterone (DHT; 8 days @ ~0.95 ng/ml). Pituitary proDYN mRNA was significantly suppressed in only the DHT treated animals (56 ± 12% of CNT, p<0.05) although slight reductions were seen in the E₂ and E₂/P₄ groups (75 ± 8% and 87 ± 9%, respectively). LHB mRNA was suppressed by all steroid treatments (p<0.01), FSHB was lower in only the E₂ group, and α-subunit was reduced in both the E₂/P₄ and DHT groups (p<0.01). Serum LH was suppressed by all steroid treatments but FSH was reduced in only the E₂ and E₂/P₄ groups (p<0.01). Since treatment of rats with continuous high levels of androgens is known to severely reduce endogenous hypothalamic GnRH release, these data suggest that diminished GnRH stimulation of the pituitary reduces proDYN expression. The absence of such an effect in E₂ and E₂/P₄ treated rats may be attributed to stimulatory effects of E₂ either directly on the pituitary or indirectly via alterations in the release of ovarian non-steroidal products (e.g. inhibin). Supported by NIH DK41035, RR00163, HD18185, and ONR N00014-90-J-1122.

284.4

STEREOIDAL MODULATION OF HYPOTHALAMIC PreProNPY mRNA AND *IN VIVO* NPY SECRETION INTO THE ANTERIOR PITUITARY OF MALE RATS. A. Sahu, C. Phelps, J. White, S.P. Kalra, W.R. Crowley and P.S. Kalra. Dept. of OB-Gyn, Univ. of Fla. Gainesville, FL 32610, ¹Univ. So. Fla., Tampa, FL, ²SUNY, Stony Brook, NY, ³Univ. Tenn, Memphis, TN.

Neuropeptide Y (NPY) is an excitatory signal to LHRH and LH secretion. In male rats, castration (CAST) decreased and testosterone (T) replacement restored hypothalamic NPY levels and release *in vitro* in response to KCl (Endo. 124:410, 1989). To test whether androgens enhance NPY neurosecretion (release and synthesis) *in vivo*, we assessed the effects of T replacement on expression of NPY mRNA in the medial basal hypothalamus (MBH) of CAST rats and the effects of CAST on NPY secretion reaching the anterior pituitary (AP) as determined by push-pull cannula (PPC) technique. **Expt. 1:** Male rats received either T-filled or empty Silastic capsules (60mm, 3x20) s.c. immediately after CAST and were killed two weeks later. The content of PreProNPY mRNA was determined from total RNA extracts from the MBH by solution hybridization/RNase protection assay using cRNA probe against NPY. **Expt. 2:** One week after CAST or sham CAST, AP PPC were implanted. One week later, AP was perfused for 4 h (1100-1500 h) with artificial CSF and samples were collected at 10 min intervals for NPY analysis by RIA. Rats showing methylene blue dye penetration within the AP parenchyma at the end of the experiment were used for analysis. The results show that PreProNPY mRNA levels in the MBH were 2-fold higher in CAST, T-replaced as compared to control CAST rats. Further, NPY release in the AP was significantly decreased after CAST (sham: 33 ± 8.8 vs CAST: 10.4 ± 2.5 pg/10 min). These results indicate that gonadal steroids enhance hypothalamic NPY gene expression and secretion, and for the first time show an existence, *in vivo*, of a close relationship between secretion and gene expression of a neuropeptide involved in regulation of gonadotropin release (NIH HD11362, HD13703; NSF BNS9007573; MH46808).

284.5

NEUROPEPTIDE Y (NPY) GENE EXPRESSION IN THE ARCULATE NUCLEUS IS INCREASED DURING PREOVULATORY LH SURGES. A.C. Bauer-Dantoin, J.H. Urban and J.E. Levine. Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208.

NPY infusions have been shown to potentiate LHRH-induced LH surges in proestrous and steroid-treated, OVX rats. Augmented NPY neurosecretion may serve to sensitize the pituitary to the actions of LHRH on proestrous, and thereby act as an important component of the LH surge-generating process. The hypothesis that NPY neurons in the arcuate nucleus may operate in this capacity was tested in the present experiment. *In situ* hybridization was used to measure NPY mRNA levels at 0900h and every 2h from 14-2200h on the day of proestrous. Comparisons between groups showed a clear, stepwise increase in NPY gene expression throughout the day of proestrous. At 1600h, when LH values were significantly greater than 0900h values, NPY mRNA labeling intensities in the arcuate nucleus were significantly greater than 0900h intensities ($p < 0.01$). By 1800h, the time at which the LH surge peaked, NPY mRNA levels also peaked, and were 3-fold greater than levels observed at 0900h ($p < 0.01$). NPY mRNA levels at 2000h and 2200h remained elevated above 0900h levels ($p < 0.01$), but by 2200h had decreased significantly from 1800h levels ($p < 0.05$). No significant changes in NPY mRNA levels were observed in cerebral cortex during the same period. Our results support the hypothesis that NPY neurons participate in the generation of LH surges through increased production of NPY and subsequent potentiation of the release and/or actions of LHRH. NPY Y₁ RECEPTOR MEDIATES THE EFFECTS OF NPY ON LH AND LHRH SECRETION: STRUCTURAL REQUIREMENTS. S.P. Kalra, M. Fuentes, ¹A. Fournier and ²W.R. Crowley. Dept. of OB-Gyn., Univ. Fla. Gainesville, FL 32610, ¹CNRS, Point-Claire, Quebec, ²Dept. Pharm., Univ. Tenn., Memphis, TN 38163

Recent studies show that hypothalamic neuropeptide Y (NPY) is involved in the regulation of pituitary LH secretion. We have now assessed the effects of NPY Y₁ and Y₂ receptor agonists and several COOH- and NH₂-terminal NPY fragments on LH release *in vivo* and hypothalamic LHRH release *in vitro*. Since the *in vivo* excitatory and inhibitory LH responses to intraventricular NPY depended upon ovarian steroidal milieu, the LH response to these agents was evaluated in ovariectomized (ovx) and ovx rats pretreated with estrogen and progesterone (EP) and on the *in vitro* LHRH release from the hypothalami of ovx EP rats. Like NPY, a specific Y₁ receptor agonist, [Leu³¹,Pro³⁴]NPY, inhibited LH release in ovx rats, but it readily stimulated LH release in ovx EP rats. On the other hand, a specific Y₂ receptor agonist, NPY₁₃₋₃₆, was completely ineffective in these two models. Similarly [Leu³¹,Pro³⁴]NPY and not NPY₁₃₋₃₆ stimulated hypothalamic LHRH release. Interestingly, NPY₂₋₃₆ was also active in these three experimental models. However, with the exception of NPY₁₁₋₃₆ which stimulated LH release in ovx EP rats, other COOH-terminal peptides, NPY₅₋₃₆, NPY₁₃₋₃₆, NPY₁₆₋₃₆, NPY₁₈₋₃₆ and the amidated NH₂-terminal fragment, NPY₁₋₂₄, were completely inactive. Thus, a distinct NPY Y₁ receptor mediates the *in vivo* excitatory and inhibitory LH and the *in vitro* excitatory LHRH responses. Further, these central agonistic responses are fully retained only after deletion of a single amino acid residue at the NH₂-terminal. (Supported by NIH grant HD 08634 and HD 13703).

A SUBSET OF LHRH-IMMUNOREACTIVE NEURONS COLOCALIZE TYPE II (GLUCOCORTICOID) RECEPTORS IN THE RAT BRAIN. R.S. Ahima and R.E. Harlan. Dept. Anatomy and Neuroscience Training Program, Tulane University Medical School, New Orleans, LA 70112

Although estrogen and progesterone regulate LHRH release, the mechanism is still debatable, since LHRH neurons do not have estrogen (ER) or progesterone (PR) receptors. Excess glucocorticoids administered peripherally or intracerebroventricularly inhibit gonadal function, presumably by interacting with LHRH neurons. The distribution of Type II corticosteroid receptors (GR) in the CNS overlaps with the LHRH system. This raises the possibility that the effect of glucocorticoids on gonadal function might be mediated via a direct action on LHRH expression and release. Progesterone can bind to GR *in vitro*. Hormone-activated PR and GR bind to the same DNA response element. Activated ER can act synergistically with GR to regulate multiple gene networks. GR may therefore play a major role in mediating the central effects of sex steroids and glucocorticoids on gonadal function.

Using the anti-GR monoclonal antibody BUGR2 and the anti-LHRH antiserum LR1, we have demonstrated, using immunoperoxidase or immunofluorescence double labeling, that about 20% of LHRH neurons in the median and medial preoptic regions colocalize GR. Few double-labeled neurons were observed in the diagonal bands, medial septum or anterior preoptic regions. These regions are also major targets for estrogen and progesterone. We suggest that the subset of LHRH neurons which colocalize GR may play a central role in linking the hypothalamo-hypophysal adrenal axis to gonadal function. Supported by NS-24148.

STEROID DEPENDENCY OF NEUROPEPTIDE Y (NPY) mRNA-CONTAINING CELLS IN THE ARCULATE NUCLEUS OF THE MALE RAT. J.H. Urban, A.C. Bauer-Dantoin, J.E. Levine. Dept. Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208.

We have recently shown that NPY mRNA levels are increased in the arcuate nucleus (ARC) of female rats on the afternoon of proestrous, suggesting a dependency of NPY gene expression on periovulatory, ovarian steroid secretion. To determine whether testicular steroids regulate the expression of the NPY gene in male rats, *in situ* hybridization and quantitative autoradiography were used to measure NPY mRNA levels in the ARC of intact, castrated (2 wks) and castrated male rats treated with low (30mg capsules) and high doses (4x30mg capsules) of testosterone (T). The intensity of labeled cells was measured unilaterally throughout the ARC and compared between groups. Plasma T levels were significantly lower in the castrate group (<0.1 ng/ml) than in the intact (2.1±0.2 ng/ml), low T (1.3±0.1 ng/ml) or high T (5.3±0.4 ng/ml) treated groups. LH levels were inversely related to T values. NPY mRNA levels were significantly reduced in the castrate group (75% of control; $p < 0.05$). Both low and high T treatment restored NPY mRNA levels, but treatment with high T did not significantly enhance NPY gene expression in the ARC beyond control levels. Our observations support previous immunochemical findings and suggest that in the male rat, T may regulate NPY gene expression in the ARC. Studies are continuing to further investigate the role of NPY on reproductive functions in the male. (NIH HD20677 & HD21921)

NEUROANATOMY OF THE NEUROPEPTIDE Y SYSTEM IN THE MONKEY FOREBRAIN. K.K. Thind, J.E. Boggan* and P.C. Goldsmith. Reproductive Endocrinology Center, Univ. Calif., San Francisco, CA 94143.

Neuropeptide Y (NPY), a 36 amino acid peptide, promotes steroid-dependent release of pituitary gonadotropins, as well as gonadotropin-releasing hormone (GnRH) secretion from the medial basal hypothalamus (MBH). To help elucidate direct and indirect neuroendocrine (NEU) NPY systems in primates, we examined NPY neuroanatomy in the forebrain of female cynomolgus monkeys. Neuroendocrine (NEU) neurons were retrogradely labeled by microinjection of tracer into the median eminence. After aldehyde perfusion, series of 40 um frontal vibratome sections at 500 um intervals were collected and immunostained for NPY with PAP. NPY fiber densities were highest in the area olfactoria, medial septal, and ventromedial nuclei; high in the tuberculum olfactorium, MBH, tuber cinereum, and the arcuate, dorsomedial, lateral septal, medial preoptic (MPO), accumbens, and paraventricular (PVN) nuclei; moderate in the vertical portion of the diagonal band of Broca, the anterior and lateral hypothalamic, lateral preoptic, and anterior ventral periventricular areas, as well as the anterior commissural, supraclasmatic, and dorsolateral supraoptic nuclei; and low in the nucleus and horizontal portion of the diagonal band, and in the supraoptic nucleus (SON). NPY neurons were scattered throughout the caudate nucleus, but none were NEU. However, in a sample series of sections, 65% of 133 NPY neurons in the SON, 41% of 112 in the PVN, 32% of 28 in the MPO, 14% of 118 in the MBH, and 55% of 11 in the inferior thalamic peduncle were NEU. We conclude that NEU NPY neurons occur in classical NEU regions, and that numerous NPY neurons contribute to an extensive forebrain fiber network in primates. The extent to which these diffuse and partially coextensive systems interact and regulate GnRH and other NEU systems remains to be determined. (Supported by NIH HD10907).

GABA-OPIOID-ADRENERGIC INTERACTIONS IN THE REGULATION OF GONADOTROPIN SECRETION IN THE FEMALE RAT. D.W. Brann*, P.L. Zamorano*, W.J. Jackson, V.B. Mahesh*. Dept. of Physiol. & Endocrinol. Medical College of Georgia, Augusta, GA 30912

Previous studies in the male rat has demonstrated that GABA acting via GABA_B receptors can abolish naloxone-induced LH secretion (Endocrinology 121:2251-2255). The purpose of the present study was to determine if an analogous situation exists in the female rat. Naloxone administered to ovariectomized (ovx.) immature rats had no effect on LH release. In contrast, naloxone potently stimulated LH release in estrogen-primed ovx. immature rats. Elevation of endogenous brain levels of GABA by administering aminoxyacetic acid, an inhibitor of GABA catabolism, prevented the naloxone-induced release of LH. This effect appeared to be both GABA_A and GABA_B receptor mediated, since exogenous administration of either muscimol (GABA_A agonist) or baclofen (GABA_B agonist) prevented the naloxone-induced release of LH. Neither GABA agonist had any effect on LHRH-induced LH release *in vivo*, suggesting that their effect was specific and achieved at the level of the CNS. GABA has been previously shown to rapidly reduce catecholamine concentration and turnover in the hypothalamus and this effect may explain GABA's ability to prevent naloxone-induced LH release in our studies. Along these lines, naloxone's effect on LH release does appear to involve catecholamine mediation since we found in the present study that administration of an α_1 or an α_2 adrenergic antagonist (prazosin or yohimbine, respectively) potently blocked naloxone's ability to stimulate LH release. In conclusion, these studies, as a whole, demonstrate that activation of either GABA_A or GABA_B receptors can abolish naloxone-stimulated LH release in the female rat. This effect is specific and appears to be achieved at the level of the CNS. Furthermore, naloxone-induced LH release appears to involve catecholamine mediation through α_1 and α_2 adrenergic receptors. Supported by Research Grant HD-16688, NIH.

HORMONAL REGULATION OF [¹²⁵I]IGF-I BINDING IN HYPOTHALAMUS AND PITUITARY OF THE RAT. K.M. Michels, M. Viswanathan, A.M. Seltzer* and J.M. Saavedra. Lab. Clin. Sci., NIMH, Bethesda, MD 20892.

Brain regions shown in autoradiographic studies to exhibit high levels of [¹²⁵I]insulin-like growth factor-I ([¹²⁵I]IGF-I) binding in the adult rat include the pituitary and several areas of the hypothalamus involved in endocrine regulation. In this study we use quantitative autoradiography to investigate the effect of endocrine manipulations on [¹²⁵I]IGF-I binding. In male rats, thyroidectomy decreased the binding of 250 pM [¹²⁵I]IGF-I in the suprachiasmatic nucleus (SCN), medial preoptic area and anterior and posterior pituitary compared to sham operated animals. Continuous infusion of a constant amount of T4 (48µg/kg/day) for 3 weeks restored the binding to sham operated levels. Binding in the median eminence (ME) was not affected by thyroidectomy. In female rats, ovariectomy decreased the level of binding in the SCN, ME and anterior and posterior pituitary compared to animals receiving continuous estradiol replacement. Binding levels in the SCN and ME of males were similar to estrogen-replaced females in the hypothalamus and to ovariectomized females in the pituitary. These results suggest hypothalamic and pituitary [¹²⁵I]IGF-I binding is affected by blood thyroid hormone levels in the male and by estrogen levels in the female.

COMBINATION OF IN SITU HYBRIDIZATION WITH RETROGRADE MARKER TO STUDY HORMONE EFFECT ON OXYTOCIN mRNA-EXPRESSING NEURONS WHICH PROJECT TO SPINAL CORD. Sookja K. Chung, Jaya Haldar and Donald Pfaff, The Rockefeller University, New York, NY 10021.

Ovarian hormones have been reported to increase oxytocin synthesis and release, and in turn this peptide facilitates reproductive and maternal behaviors. Using in situ hybridization we found increased levels of oxytocin mRNA, following estradiol (E), in SON and ACN neurons (J. Comp. Neurol., 307:281-295, 1991). Now we have combined in situ hybridization with retrograde tracer technique to study effects of E on oxytocin mRNA-expressing cells projecting to cord. Fluorogold pellets were applied to high thoracic cord in ovariectomized female rats treated with E (low dose, 1x2µg; or high dose, 2x10µg) or control (sesame oil vehicle). In situ hybridization was performed with a specific oxytocin oligonucleotide probe, end-labelled as previously described. Oxytocin mRNA-containing neurons which project to cord were found predominantly in middle and posterior levels of the paraventricular hypothalamic nucleus of female rats, comprising 12%-14% of the retrograde-labelled cells there. In frequency distributions of grains per oxytocin-labelled cell, it was seen that high but not low doses of E were followed by significantly greater amounts of oxytocin mRNA in a subpopulation of these neurons which project to cord. These results indicate that high E levels can stimulate oxytocin synthesis in a class of paraventricular neurons which might be important for controlling certain behavioral or autonomic functions.

GLUCOCORTICOID AGGRAVATE THE CHOLINERGIC DEFICIT INDUCED BY ETHYLCHOLINE AZIRIDINIUM (AF64A) IN RAT HIPPOCAMPUS. H.Hörtnagl*, M.L.Berger* and O.Hornykiewicz. Institute of Biochem. Pharmacol., Univ.Vienna, A-1090 Vienna, Austria

Glucocorticoids increase the vulnerability of hippocampal neuronal systems to various noxious stimuli (Sapolsky, TINS 10,346, 1987). In the present study we addressed the question whether glucocorticoids influence the extent of a cholinergic lesion in the rat hippocampus induced by ethylcholine aziridinium (AF64A). Male Sprague Dawley rats (300-350g) received bilateral stereotaxic infusions of 1nmol AF64A or vehicle into the lateral ventricle. Glucocorticoid treatment was started 7 days before AF64A and continued until sacrifice, 7 days after AF64A (corticosterone: 10mg daily or dexamethasone: 1mg/kg every second day; in sesame oil s.c.). Treatment with dexamethasone significantly increased the AF64A-induced loss of choline acetyltransferase (CHAT) activity in the hippocampus (dissected into CA1, CA3 and dentate gyrus), but did not affect CHAT activity in vehicle-treated rats. Reduction in CHAT activity in % + SEM of corresponding control group (*p < 0.05; **p < 0.01 v AF64A(sesame oil)

	(n)	CA1	CA3	dentate gyrus
AF64A/sesame oil	(5)	46 ± 2	57 ± 3	45 ± 2
AF64A/dexamethasone	(7)	55 ± 3	74 ± 3**	59 ± 4*

Similar but less pronounced results were obtained with corticosterone (p < 0.05 in CA1). The data indicate that glucocorticoids have the potential to increase the toxicity of AF64A on the septohippocampal cholinergic pathway.

CELL ADHESION MOLECULES IN THE CEREBELLUM: TARGETS OF METHYLMERCURY TOXICITY? L.A. Lagunowich, S. Bhambhani*, R.D. Graff* and K.R. Reuhl*. Neurotoxicology Labs, Rutgers College of Pharmacy, Piscataway, NJ 08855.

Developmental neurotoxicity of methylmercury (MeHg) may be mediated, in part, by interactions of the toxicant with cell adhesion molecules. To test this hypothesis N-CAM and N-cadherin were examined biochemically and immunocytochemically in cerebella of Swiss Webster mice given 3mg/kg/day for 5 days, beginning on PN day 1 and collected on PN6, and in neurons derived from murine embryonal carcinoma cells exposed to 1-3 µM MeHg for 2 hours. Immunoblots reacted with antibodies for N-CAM revealed persistence of high molecular weight N-CAM form in the MeHg treated tissues. Immunoblots reacted with antiserum to N-cadherin revealed no differences between treated and untreated tissues. Results indicate that: 1) MeHg had no observable effect on N-cadherin; 2) MeHg inhibited conversion of N-CAM from a sialic acid-rich embryonic form to a sialic acid-poor adult form and; 3) both cerebellum *in vivo* and cultured neurons show similar patterns of toxic effect on N-CAM. These data suggests that N-CAM may be an important molecular target for MeHg. Supported by NIH grant ES-04976.

285.2

NEUROTOXICITY OF CENTRAL NERVOUS SYSTEM THERAPY FOR CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA. P.J.Mullenix, A. Schunior*, W.J. Kernan*, D.P. Waber*, A. Howes* and N.J. Tarbell*. Dept. of Toxicology, Forsyth Research Inst., Boston, MA 02115.

As part of the treatment for acute lymphoblastic leukemia, children receive central nervous system (CNS) prophylactic therapy to improve long term survival. Neurotoxic side effects, i.e. cognitive impairment, have been associated with this therapy. We studied a rat model to determine which of the agents in CNS therapy, cranial radiation (XRT), methotrexate (MTX) or prednisolone (PDN), was responsible for the neurotoxicity. All experiments included Sprague Dawley rats exposed on postnatal days 17 and/or 18. The number studied was 15-20/treatment/sex, and each treatment group had matched controls given the appropriate sham radiation and/or saline (ip) injections. Spontaneous behavior was tested in the rats at 6 weeks and 4 months of age. A computer pattern recognition system automatically recorded and classified the behavioral acts performed while exploring a novel environment. Behavioral initiations, total time and time structure were compared in the treatment and control groups. We demonstrated (Mullenix et al., Cancer Res. 50:6461-6465, 1990) that exposure to combined therapy including 1000 cGy XRT, 18 mg/kg (ip) PDN and 2 mg/kg (ip) MTX permanently altered behavioral time structure in males. The XRT given alone did not produce the same effect, and the present study shows that MTX and PDN given alone are without significant behavioral impact. In contrast, when XRT is combined with MTX, steroid omitted, significant changes in behavioral time structure (p < 0.04), total time and number of initiations (p < 0.05) appear in females. We conclude that the neurotoxicity induced by CNS therapy is due to an interaction of XRT and MTX, that females are more sensitive to this interaction, and that steroid modulates neurotoxic response, increasing susceptibility in males while decreasing susceptibility in females. Supported by NIH CA53858.

285.4

IMMUNOCYTOCHEMICAL LOCALIZATION OF METALLOTHIONEIN IN HUMAN SPINAL CORD. E. J. Kasarskis, X. Xie*, and W. R. Markesbery. VA and Univ. of Kentucky Med. Ctrs.; Sanders-Brown Aging Ctr.; Lexington KY 40536.

The accumulation of toxic heavy metals, such as mercury, has been detected in amyotrophic lateral sclerosis and Alzheimer's Disease. In non-neural tissues, metallothionein (MT), a cysteine-rich soluble protein, detoxifies heavy metals and contributes to zinc and copper homeostasis. We have studied the localization of MT in human spinal cord to establish if MT could potentially play a similar role in the human CNS.

The distribution of MT was examined in formalin-fixed spinal cords from 10 middle aged persons using a monoclonal antibody to human liver metallothionein-II, a gift of Dr. Ananda Prasad. MT-immunoreactivity was visualized in the cytoplasm of motor neurons at all spinal levels. Immunoreactivity was also detected in astrocytes, capillary endothelia, and arachnoid.

These findings indicate that MT is widely distributed in human spinal cord. Although the function of MT in spinal cord has not been studied, its localization to neuronal cytoplasm suggests that MT could be important for metal homeostasis and detoxification in motor neurons.

285.5

N-METHYL-4-PHENYLPYRIDINIUM (MPP+) POTENTIATES THE KILLING OF CULTURED HEPATOCYTES BY CATECHOLAMINES. J.W. Snyder*, T.N. Ferraro, M.E. Kyle*, J.R. Grothusen*, G.M. Alexander and J.L. Farber*. Departments of Medicine, Neurology, and Pathology, Jefferson Medical College, Philadelphia, PA 19107. Catabolism of catecholamines can lead to oxidative stress predisposing cells to injury not encountered in cells lacking catecholamines. The glutathione reductase inhibitor BCNU accelerated the death of the cells by dopamine (DA) or 6-hydroxydopamine (6-OHDA), while deferoxamine, catalase or superoxide dismutase reduced cell death. Incubation of hepatocytes with combinations of 1-methyl-4-phenylpyridine (MPP+) and either 6-OHDA, DA or norepinephrine (NE) (order of potency: 6-OHDA > DA > NE) accelerated cell death under conditions where MPP+ alone or catecholamines alone did not kill cells. Cultures treated with combinations of rotenone plus 6-OHDA also displayed increased cell death under conditions where rotenone alone or 6-OHDA alone did not kill cells. Pretreatment with deferoxamine, glycine or fructose delayed death of cells treated with catecholamines plus MPP+. Inhibitors of monoamine oxidase had no protective effect. These data suggest: 1) cells containing catecholamines are more vulnerable to site I (NADH dehydrogenase) inhibition; 2) cell vulnerability is catecholamine dependent; 3) the mechanism of death by catecholamines may involve oxidative stress, but does not require MAO-dependent oxidation.

285.7

TOXICITY OF MPTP IN PRIMARY CULTURES OF MOUSE ASTROCYTES. D. Di Monte, E. Y. Wu*, L.E. DeLanney, I. Irwin* and J.W. Langston. California Institute for Medical Research and California Parkinson's Foundation, San Jose, CA 95128.

Astrocytes are likely to be a primary locus for the bioactivation of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to the toxic 1-methyl-4-phenylpyridinium (MPP+) metabolite. However, degeneration of glial cells does not appear to be a neuropathologic feature of MPTP exposure *in vivo*. In order to identify possible protective mechanism(s) that may make glial cells relatively resistant to MPTP injury, biochemical and toxic changes were studied in primary cultures of astrocytes exposed to this compound. MPTP caused a concentration-dependent loss of cell viability assessed as leakage of lactate dehydrogenase in the incubation medium. An early metabolic change following MPTP (250 μ M) exposure was an increase in the rate of utilization of glucose and accumulation of lactate in the culture medium. The ratio between the rates of lactate production (0.37 mM/hour) and glucose consumption (0.2 mM/hour) was 1.85, thus very close to the ratio of 2 expected if all glucose was stoichiometrically converted to lactate. Exposure of astrocyte cultures to MPTP also resulted in a dramatic depletion of ATP which occurred before the onset of cytotoxicity. ATP depletion and loss of cell viability occurred more rapidly in cultures incubated in the absence than in the presence of glucose. Finally, cytotoxicity was prevented when MPTP was washed from the incubation medium even just before the onset of cell death. This is probably due to the fact that, once formed within cells, MPP+ can cross astrocyte membranes toward the extracellular space. Thus, "escape" of MPP+ from glial cells may represent a protective mechanism against irreversible damage following MPTP exposure *in vivo*.

285.9

MPP+ PRODUCES EXCITOTOXIC LESIONS IN RATS. E. Storey, B.T. Hyman, J.M. Miller* and M.F. Beal. Neurology Service, Mass. General Hospital, and Harvard Medical School, Boston, MA 02114.

MPP+ is the active metabolite of MPTP, and is an inhibitor of mitochondrial complex I. Turski et al. (Nature 349, 414) showed that MPP+ nigral lesions were blocked with NMDA antagonists. In the present study we examined whether local striatal injections of MPP+ produce excitotoxic lesions. MPP+ was stereotactically injected into the left striatum. One week after injection animals were sacrificed and the left and right striata dissected. Neuropeptides were measured by radioimmunoassay and GABA and monoamines were measured by HPLC with electrochemical detection. Increasing doses of MPP+ (7.5 - 90 nmol) resulted in dose-dependent reductions of substance P and GABA, with relative sparing of somatostatin and neuropeptide Y. Relative sparing of somatostatin neurons was confirmed by immunocytochemistry. At a dose of 85 nmol of MPP+, substance P and GABA were depleted 50%, dopamine 85% and serotonin 40%. Prior decortication protected significantly against MPP+ neurotoxicity, however the protection was only partial for dopamine. Immunocytochemistry for glial fibrillary acidic protein and Nissl stains confirmed a protective effect with decortication. Freeze-clamp experiments showed that ATP was 2-fold decreased and lactate was increased 4 fold on the injected side at 3, 24 and 48 hr. These experiments show that MPP+ can produce excitotoxic lesions, presumably by lowering membrane potential which relieves the voltage dependent Mg++ block of the NMDA receptor, leading to persistent receptor activation.

285.6

ACUTE EFFECT OF MPTP ON ATP IN MOUSE BRAIN. P. Chan*, L.E. DeLanney, I. Irwin*, J.W. Langston and D. Di Monte. California Institute for Medical Research and California Parkinson's Foundation, San Jose, CA 95128.

The cytotoxic effects of the parkinsonism-inducing neurotoxicant 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) are dependent upon its conversion to the 1-methyl-4-phenylpyridinium (MPP+) metabolite. Then, MPP+ is thought to block mitochondrial respiration at the level of complex I and to cause cell damage by depleting ATP. In this study, ATP levels were measured in mouse brain after rapid fixation of cerebral tissue *in situ* by microwave irradiation. Administration of MPTP (40 mg/kg s.c.) caused a rapid (within 30 min) decrease (approx. 10-20%) in striatal ATP. This decrease was prevented by mazindol, a catecholamine uptake blocker, and was enhanced (ATP levels were approx. 40% lower than in control animals) by pretreatment of mice with 2-deoxyglucose. In mice exposed to MPTP after treatment with 2-deoxyglucose, a gradual recovery of ATP was observed during the following 24 hours. The time course of ATP changes was similar to the time course of MPP+ accumulation and elimination in the striatum, while dopamine depletion seemed to follow these events. These results suggest that ATP depletion plays an important role in MPTP-induced neurotoxicity and support the hypothesis of a defect of mitochondrial function in the MPTP model of parkinsonism.

MK 801 PREVENTS MPTP-INDUCED NIGROSTRIATAL NEURONAL DEATH IN MONKEYS AND MICE. A. Zuddas, E. Vaglini, F. Fornai, F. Fasce, G.U. Corsini. Institute of Pharmacology, University of Pisa, Italy

An anatomical and biochemical lesion similar to that observed in monkeys can be obtained in mice combining MPTP treatment with acetaldehyde (ACE) (Brain Res. 501:1-10, 1989; Eur. J. Neurosci. 3:72-85, 1991). Here we investigated whether excitatory aminoacids may modulate the MPTP-induced dopamine depletion and cell death. In both mice and monkeys, MK 801, a non-competitive antagonist of the NMDA receptor, was systemically administered together with MPTP. The behavioral, biochemical and histological effects were evaluated 7 days after treatment. In C57BL mice, MK 801 (2.5 mg/Kg administered i.p. 30 min before and 90 min after MPTP), completely prevented ACE-induced enhancement of MPTP toxicity. Striatal dopamine content was 75.6 \pm 6.3 and 6.7 \pm 3.1 ng/mg protein in MPTP and ACE+MPTP-treated animals, respectively (controls: 166.5 \pm 13.7). When MK 801 was also administered, striatal dopamine was 89.5 \pm 3.9 and 59.4 \pm 8.5 ng/mg protein in MPTP and ACE+MPTP-treated animals, respectively. Tyrosine hydroxylase immunostaining revealed that the extensive loss of DA neurons observed in the SNc of ACE+MPTP-treated mice was completely prevented by MK 801 administration.

In monkeys (*Macaca fascicularis*), MK 801 (0.010 mg/kg administered i.v. 7 times per day during MPTP treatment), was able to completely prevent the parkinsonian syndrome induced by i.v. administration of MPTP (0.3 mg/kg/die per five days). Catecholamine analysis showed how MK 801 significantly attenuated the MPTP-induced dopamine depletion in the basal ganglia. The protective effect of MK 801 was more evident in the ventral portion of the caudate and putamen than in the dorsal part of these brain regions (DA in Dorsal Caudate: 132.4 \pm 13.3, 0.8 \pm 0.8 and 27.6 \pm 11.8 ng/mg protein in control, MPTP and MK 801+MPTP-treated monkeys, respectively; DA in Ventral Caudate: 84.0 \pm 9.5, 2.1 \pm 1.6, and 75.0 \pm 17.8, respectively). Taken together, these findings indicate that NMDA receptors play a crucial role in MPTP-mediated cell death and suggest that ACE administration make the MPTP toxicity in mice similar to that observed in primates.

285.10

IS AMPHETAMINE (AMP) INDUCED NEUROTOXICITY THE RESULT OF REDUCED NEUROTROPHIC FACTOR PRODUCTION? C.M. Buhrfiend, J.Z. Fields, G.E. Drucker, D.H. Lin, E.S. Lo, L.R. Ptak, and P.M. Carvey. Rush U. and Hines V.A., Chicago, IL.

Using an established AMP neurotoxicity model (3 daily treatments of 9.2 mg/kg AMP + 10 mg/kg imiprindole) we examined the effect of striatal extracts on rostral mesencephalic tegmentum (RMT) culture growth to determine if toxic AMP treatment reduces the production of a striatal-derived neurotrophic factor (SdNTF). At 7 and 14 days following the last treatment, striatal DA content was decreased 23 and 48% respectively by AMP treatment relative to imiprindole treated controls suggesting neurotoxicity. Forty hours after the addition of striatal extracts to E13.5 RMT cultures, the number of viable cells with processes was assessed. Striatal extracts taken from AMP treated animals 7 and 14 days following the last treatment reduced RMT culture growth by 94 and 84% respectively relative to controls. These data suggest that acute neurotoxic doses of AMP reduce the production of SdNTF and that it is therefore possible that the neurotoxicity observed following AMP treatment could result from AMP-induced reductions in SdNTF.

285.11

CARBAMAZEPINE INDUCES NEUROTOXICITY OF CEREBELLAR NEURONS BY A N-METHYL-D-ASPARTATE (NMDA) REVERSIBLE MECHANISM.

X.M. GAO and D.-M. Chuang, Biological Psychiatry Branch, NIMH, Bethesda, MD 20892

Treatment of cerebellar granule cells with carbamazepine (CBZ) in growth medium resulted in a time- and dose-dependent decrease of carbachol-induced phosphoinositide turnover and of muscarinic cholinergic receptor sites. To investigate whether this effect is due to neurotoxicity, we studied long-term effects of CBZ on ^3H -ouabain binding to neuronal Na^+ , K^+ -ATPase, which recently was shown to provide a means to quantify neurons in a mixed culture (Markwell et al, Brain Res 538:1-8, 1991). Exposure of cerebellar granule cells to CBZ for 3 days induced a dose-dependent decrease of ^3H -ouabain binding to intact neurons. The IC_{50} was approximately 40 μM and maximal loss occurred at 100 μM . CBZ's effect was totally blocked by the co-presence of 100 μM NMDA. The EC_{50} of NMDA for reversing CBZ (50 μM)-induced toxicity was approximately 30 μM and this protection was nullified by 200 μM APV. The reversal of CBZ-induced toxicity by NMDA was visible by morphological examination. MK-801, a NMDA antagonist, also displayed a dose-dependent neurotoxicity and its effect was less than additive to that produced by CBZ. Long-term CBZ treatment resulted in significant up-regulation of NMDA-induced phosphoinositide turnover. Our results indicate that CBZ is capable of inducing slow toxicity in cerebellar neurons. Moreover, this effect might be due to a constant blockade of NMDA receptor by CBZ.

EFFECTS OF COCAINE, AMPHETAMINE, AND GBR 12909 ON THE GENE EXPRESSION OF STRIATAL NEUROPEPTIDES. Y.L. Hurd and M. Herkenham. Section on Functional Neuroanatomy, Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892.

Psychomotor stimulants such as cocaine and amphetamine acutely potentiate the overflow of dopamine (DA) from presynaptic terminals in the striatum. The major post-synaptic targets of DA in this region are medium spiny neurons which contain the neuropeptides dynorphin (DYN), substance P (SP), and enkephalin (ENK). Using *in situ* hybridization histochemistry in rats, the effects of a single acute injection (i.p.) of cocaine, amphetamine, or GBR12909 on the gene expression of striatal neuropeptides were investigated 2 hrs (acute) or 2 weeks (delayed) following drug administration. In the dorsal striatum, acute cocaine and GBR 12909 elevated DYN mRNA and SP mRNA levels. The increases were greater in the dorsal than in the ventral striatum. The acute elevations returned close to control values at 2 weeks. A second, challenge injection of the same stimulants, given 2 weeks after the first, re-elevated mRNA levels of the neuropeptides. However, the increase, e.g. of DYN mRNA by cocaine and GBR 12909, was attenuated compared to the response induced by the acute initial exposure to the stimulant, and although amphetamine had the weakest effect in acute and delayed groups, a challenge injection of the drug greatly potentiated DYN mRNA levels. Thus, differential initial as well as long-term consequences of a single injection can be revealed at the genetic level. Differential effects on striatal DYN, SP and ENK gene expression were also found following daily repeated (2 weeks) administration of the stimulants.

GLYCINE-EVOKED RELEASE OF ^3H -ACETYLCHOLINE FROM NUCLEUS TRACTUS SOLITARIUS. W.T. Talman, H. Ohta, and D. Martinez. * Department of Neurology, University of Iowa and VAMC, Iowa City, IA 52242.

Our previous studies have demonstrated that microinjection of glycine (GLY) into nucleus tractus solitarius (NTS) produces depressor and bradycardiac responses that are blocked by strychnine or muscarinic antagonists and prolonged by the cholinesterase inhibitor physostigmine injected into NTS. Our hypothesis that the responses to GLY were mediated through release of acetylcholine (ACh) from NTS was supported by release of ^3H -ACh from NTS tissue punches exposed to GLY. In the current study we have sought to determine (1) whether GLY-mediated release of ^3H -ACh from NTS is Ca^{2+} -dependent and (2) whether GLY acts through strychnine-sensitive receptors to mediate release of ACh. ^3H -ACh release evoked by GLY (1mM) from micropunches of NTS was significantly reduced by removal of Ca^{2+} from Krebs's bicarbonate buffer bathing the tissue (control: 136 ± 38 dpm/5 min. vs. Ca^{2+} -free: 4 ± 24 dpm/5 min., $p < 0.05$). When 10 μM strychnine was added to Ca^{2+} -containing incubation medium prior to and during application of GLY (1mM), the release of ^3H -ACh was inhibited. These results indicate that GLY causes release of ACh from neurotransmitter pools in NTS and release is mediated through activation of strychnine-sensitive GLY receptors. DIFFERENTIAL EFFECTS OF PARTIAL DOPAMINE DEPLETION ON STRIATAL PROENKEPHALIN AND DOPAMINE D2 RECEPTOR mRNA LEVELS IN THE RAT. Jean Lud Cadet¹, Shy-ming Zhu^{*1}, and Jesus A. Angulo². Columbia University, and ²Rockefeller University, New York, New York

Nigrostriatal (NS) dopaminergic (DA) neurons are thought to exert an inhibitory influence on striatal enkephalergic systems through their DA D2 receptors. In order to investigate the effects of partial lesions of the NS DA on striatal proenkephalin (PEK) and D2 receptor mRNAs, animals were divided into *High*, *Intermediate*, and *Low* rotators on the basis of amphetamine-induced rotation observed after intrastratial injections of 6-hydroxydopamine (6-OHDA). There were significant increases in PEK mRNA in all three groups on the ipsilateral side of the lesions; these changes correlated positively with increases in rotation rate. Unexpectedly, there were significant increases in PEK mRNA on the contralateral side as well. On the other hand, only the *High* rotation group showed any increases in D2 receptor mRNA which occurred only on the side of the lesions. These results indicate that partial lesions of NS DA projections are sufficient to cause increases in PEK mRNA but not in D2 receptor mRNA. These data also provide evidence that the two NS DA projections and the systems which they modulate might be interdependent. The present experiments also suggest that the striatal enkephalergic molecular machinery may actually be under a set of controls that are more complex than a simple inhibitory influence by DA acting via its D2 receptors.

BETA ADRENERGIC REGULATION OF EXTRACELLULAR CYCLIC AMP AND ADENOSINE LEVELS IN CEREBRAL CORTEX IN CULTURE. K.K. Petrisson, R.B. Knowles, and P.A. Rosenberg. Dept. of Neurol. and Program in Neuroscience, Children's Hospital and Harvard Med. Sch., Boston, MA 02115.

Stimulation of astrocyte-rich rat cortical cultures with the beta adrenergic agonist isoproterenol (ISO) caused secretion of cyclic AMP into the extracellular medium with an EC_{50} of 70 ± 40 nM [$n = 5$, 29-34 days in culture (DIC)]; peak extracellular concentration of cyclic AMP with maximal stimulation (1-10 μM) was 71 ± 33 nM ($n=9$, 28-67 DIC), determined by radioimmunoassay. In order to characterize the fate of secreted cyclic AMP, high pressure ion pair liquid chromatography, using pre-column chloroacetaldehyde derivatization, was employed to characterize the time course of the appearance of cyclic AMP, AMP, and adenosine in the extracellular medium following ISO stimulation of cultures. A significant increase ($214 \pm 23\%$; $n=3$, 47-61 DIC) in extracellular adenosine was observed within thirty minutes following addition of 1 μM ISO. The concentration of adenosine measured in the medium surrounding control cultures was 32 ± 7 nM. Secretion of cyclic AMP by astrocytes may be a significant source, in cerebral cortex, of extracellular adenosine, which might in turn mediate some of the actions of norepinephrine by a paracrine mechanism. Supported by NIH grant NS 26830.

INTRACISTERNALLY COINJECTED GALANIN AND A 5-HT_{1A} RECEPTOR AGONIST ACT SYNERGISTICALLY TO PRODUCE VASODEPRESSOR RESPONSES IN THE α -CHLORALOSE ANAESTHETIZED MALE RAT. J.A. Aguirre, P. Hedlund*, J.A. Narváez* and K. Fuxe. Dept. of Histology and Neurobiology, Karolinska Institutet, S-104 01 Stockholm, Sweden.

Interactions between the galanin (GAL) and the 5-hydroxytryptamine receptors of the 1A type (5-HT_{1A}) have previously been demonstrated in *in vitro* studies. The present work has been undertaken to evaluate the possible functional implications of such interactions. DPAT (0.1-30 nmol/kg) was given intracisternally (i.c., 10 μ l) in α -chloralose (100 mg/kg i.v.) anaesthetized male Sprague-Dawley rats (200-250 gr). Coinjections of DPAT and the selective 5-HT_{1A} receptor antagonist 1-(2-methoxyphenyl)-4-[4-(2-phthalimido)butyl]piperazine (NAN-190) were carried out. Simultaneous i.c. coinjections of DPAT and GAL were performed to evaluate any interactive effects of GAL and DPAT. Measurements of mean arterial blood pressure (MAP) were made during a 1 h time interval. In receptor autoradiographical experiments coronal 20 μ m thick cryostat sections from the region of the dorsal medulla (bregma -13.8 mm) were incubated with the radioligand [¹²⁵I]GAL (0.4 nM) in the presence or absence of DPAT (10 nM). DPAT given i.c. produced a dose-dependent reduction of MAP, the peak action being 32% at 10 nmol. The vasodepressor action of DPAT could be counteracted by NAN-190. A threshold dose (1 nmol) of GAL given i.c. was shown to enhance the vasodepressor effect both of an ED₅₀ dose and a threshold dose of DPAT. Quantitative receptor autoradiography showed that the IC₅₀ value for GAL was reduced by approximately 40% within the dorsal region of the nucleus of the solitary tract, the area postrema and the raphe pallidus and obscurus nuclei in the presence of DPAT (10 nM). The results give evidence for a synergistic interaction between DPAT and GAL in cardiovascular regulation upon their central administration, possibly related to an ability of DPAT to enhance the affinity of the galanin receptor within cardiovascular regions of the medulla oblongata.

PROJECTIONS OF GABAergic AND CHOLINERGIC BASAL FOREBRAIN NEURONS TO THE POSTEROLATERAL HYPOTHALAMUS. I. Gritti*, L. Mainville, B.E. Jones. Lab. of Neuroanatomy, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4.

GABAergic neurons are intermingled with cholinergic neurons within the basal forebrain and may correspond to the cells that are active during slow wave sleep which are intermingled with those that are active during waking. Putative sleep active basal forebrain neurons could promote sleep by damping the activating system of the brain stem reticular formation and posterior hypothalamus. To assess the potential influence of forebrain GABAergic and cholinergic neurons upon this system, Cholera-Toxin-B (CTB) was injected into the posterolateral hypothalamus and its retrograde transport was examined in combination with immunohistochemistry for GAD (glutamic acid decarboxylase) and ChAT (choline acetyl transferase) in the rat. Of a total large population of retrogradely labeled cells within the basal forebrain, an important contingent (11.5%) were GAD-immunoreactive, whereas only a small portion (0.5%) were ChAT-immunoreactive. At least 25% of the GAD+ whereas less than 5% of the ChAT+ cells within the basal forebrain were found to send descending projections to the posterolateral hypothalamus. The GAD-immunoreactive cells were found intermingled with ChAT-immunoreactive cells within the basal forebrain, and exceeded the ChAT+ cells in a ratio of 3:2. The results suggest that GABAergic neurons of the basal forebrain could promote sleep through a descending projection onto the posterolateral hypothalamus. (Supported by the Canadian MRC)

COMPARISON OF CHOLINERGIC PROJECTIONS TO MESENCEPHALIC DOPAMINERGIC CELL GROUPS: SUBSTANTIA NIGRA (SN) AND VENTRAL TEGMENTAL AREA (VTA). S.A. Oakman, E.H. Overstreet*, C. Cozzari*, P.L. Faris, and B.K. Hartman. Dept. of Psychiatry, Division of Neuroscience Research, University of Minnesota Medical School, Minneapolis, MN 55455.

It has been established that the dopaminergic cells in the mesencephalon are innervated by cells from the pontomesencephalic cholinergic group. This relatively large and diffuse cholinergic group is composed of cells in the lateral dorsal tegmental nucleus, the parabrachial nucleus, and the pedunculopontine nucleus. This study was initiated to determine whether cholinergic projections to two functionally divergent dopaminergic cell groups (SN and VTA) reflect a similar organization within the cholinergic cell group. Stereotaxic injections of retrograde tracer (Fluorogold, 10-20 nl) were administered in rats to the SN and VTA. Choline acetyltransferase was localized using immunohistochemistry (Texas Red fluorochrome) in sections from the midbrain and pons, and locations of double-labelled cells were analyzed at multiple levels through the cholinergic group. Initial results of this analysis are consistent with a functional organization of the cholinergic group. Cells which project to the VTA were concentrated toward the dorsal/caudal parts of the group. Those projecting to the SN were more evenly distributed through the cholinergic group. Supported by NS12311 (BKH), MH47189 (PLF).

INTERACTION OF PRESYNAPTIC HISTAMINE H₃ RECEPTORS WITH PRESYNAPTIC α_2 -AUTORECEPTORS AND NMDA HETERORECEPTORS IN THE BRAIN CORTEX. M. Göthert, E. Schlicker* and K. Fink*. Inst. of Pharmacol. and Toxicol., Univ. of Bonn, D-5300 Bonn 1, Germany.

We have recently shown that presynaptic histamine H₃ receptors mediate inhibition of noradrenaline (NA) release in the rat and mouse brain cortex. The aims of the present study were (1) to determine the effects of α_2 -adrenoceptor ligands on the histamine (H)-induced inhibition of the electrically evoked NA release and (2) to examine whether H also inhibits the NA release in response to activation of the presynaptic NMDA receptor. In superfused rat or mouse brain cortex slices preincubated with tritiated NA, tritium overflow was evoked either electrically (mouse brain slices) or by NMDA 100 μ M (rat brain slices) superfused with Mg²⁺-free medium. The electrically evoked tritium overflow was inhibited by H 1 and 10 μ M. The effect of H 10 μ M was not modified by α_2 -adrenoceptor ligands but decreased by the α_2 -agonist B-HT 920 1 μ M and increased by the α_2 -antagonist rauwolscine 1 μ M. These effects still occurred, when stimulation parameters were adjusted to obtain the same tritium overflow as in the absence of α_2 -adrenoceptor ligands. In slices superfused in the presence of the α_2 -antagonist idazoxan 1 μ M, H 0.1-10 μ M inhibited the NMDA-evoked tritium overflow. This effect was abolished by the H₃ receptor antagonist thioperamide 0.32 μ M, but was not affected by the H₁ and H₂ receptor antagonists dimetindene 32 μ M and ranitidine 320 μ M, respectively. In conclusion, the presynaptic inhibitory H₃ receptor interacts with two further presynaptic receptor systems on the same noradrenergic nerve terminals of the brain cortex. (1) Activation of the α_2 -autoreceptor decreases, whereas its blockade increases, the ability of the H₃ receptor to mediate inhibition of NA release. (2) The NA release in response to activation of the presynaptic excitatory NMDA receptor is inhibited by the stimulation of the H₃ receptor.

MONOSYNAPTIC INPUT TO DOPAMINERGIC NEURONS IN RAT SUBSTANTIA NIGRA AND VENTRAL TEGMENTAL AREA FROM DYNORPHIN-IMMUNOREACTIVE TERMINALS. V.M. Pickel, J. Chan, and S.R. Sesack. Div. of Neurobiology, Dept. of Neurology and Neuroscience, Cornell University Med. Center New York, N.Y. 10021

We sought to determine whether there is a direct synaptic basis for interactions between terminals containing dynorphin-like immunoreactivity (DYN-LI) and tyrosine hydroxylase (TH) containing dopaminergic neurons in the substantia nigra (SN) and ventral tegmental area (VTA). Sections through the adult rat midbrain were immunolabeled using respectively, peroxidase and gold-silver to identify a rabbit anti-dynorphin (1-17) and mouse anti-TH. Terminals containing DYN-LI were numerous in the SN and rarely detected in the VTA. However, in both regions these terminals were characterized by either all small clear vesicles or a mixture of small, clear and intensely labeled large dense core vesicles. The majority of the synapses were symmetric and the targets included both TH-labeled and unlabeled dendrites in both regions. The rarity of the terminals containing DYN-LI in the VTA prevented further quantitative analysis of their cellular associations. However, from 1191 observed terminals containing DYN-LI in SN, 20% formed synapses with TH-labeled and 40% with unlabeled dendrites. Many of these terminals also were in direct apposition to other terminals with or without detected DYN-LI. These findings provide ultrastructural evidence that in both the SN and VTA, dynorphin may elicit changes in locomotor activity, feeding and other behaviors directly through synaptic input to dopaminergic and non-dopaminergic neurons and possibly through presynaptic associations. OLFACTORY RECEPTORS SHARE ANTAGONIST HOMOLOGY WITH OTHER G-PROTEIN COUPLED RECEPTORS. Stuart Firestein and Gordon M. Shepherd. Section of Neurobiology, Yale University School of Medicine, 333 Cedar St., New Haven, CT, 06510

It is generally believed that olfactory transduction is initiated by the interaction of an odor molecule with a membrane bound receptor. The olfactory receptor has been shown to share homology with receptors belonging to a family marked structurally by possessing 7 transmembrane spanning domains and functionally by coupling to G-proteins. These include, among others, muscarinic, adrenergic and serotonergic receptors. We hypothesized that the olfactory receptor might share sufficient homology with these other members of this family that some identified antagonists might also effect olfactory receptors. The muscarinic antagonists atropine, scopolamine and QNB, applied extracellularly in concentrations of 20-200 μ M, acted as reversible antagonists, attenuating the odor elicited current by one-third to one-half. The inhibitory EC₅₀ ranged from 70-100 μ M. Muscarine, at similar concentrations, had no direct effect on the cell but also antagonized the odor response. The β -adrenergic and 5HT₁ receptor antagonist propranolol was more effective, blocking the odor response at a concentration of 80 μ M with an EC₅₀ of 20 μ M. Similar effects were seen with alprenolol. Although these concentrations are higher than those effective in the native systems, no non-specific effects, such as alterations in input resistance, resting potential or voltage gated currents, were observed. Additionally these antagonists had no effect on the current elicited by application of membrane permeable cyclic nucleotides, suggesting that the effects were upstream of the ion channel. The glutamate channel blocker APV had no effect on odor elicited currents. These results provide added evidence that the odor receptor belongs to the family of 7 transmembrane domain, G-protein coupled receptors. Additionally, since there are no known odor antagonists, these neurotransmitter antagonists may play a role in analyzing odor receptor mechanisms, and in classifying odor receptor families. Supported by Office of Naval Research, NINDS and NIDCD.

286.11

ANTAGONISM OF RESPIRATORY DEPRESSION BUT NOT ANALGESIA PRODUCED BY THE SELECTIVE μ -OPIOID AGONIST DERMORPHIN BY THE NON-IMIDAZOLINE α_2 -ADRENOCEPTOR ANTAGONIST, SK&F 86466. A.-L. Sirén, and S. Vonhof, Dept. of Neurology, USUHS, Bethesda, MD 20814.

Picomole doses of the selective μ -opioid agonist dermorphin (DM) produced analgesia and respiratory stimulation after intracerebroventricular (i.c.v.) administration by an μ_1 -opioid receptor mechanism while nanomole doses of DM i.c.v. induced respiratory depression which was related to activation of μ_2 -receptors (Paakkari, P. et al., J. Pharm. Exp. Ther. 252: 235-240, 1990). In the present study the influence of α_2 -adrenoceptor antagonism on the respiratory and antinociceptive effects of DM i.c.v. was examined in conscious male Sprague-Dawley rats (270-350 g, n=48) using SK&F 86466 (6-chloro-N-methyl-2,3,4,5-tetrahydro-1-H-3-benzazepine), a potent and selective non-imidazoline α_2 -adrenoceptor antagonist (Hieble, J.P. et al., J. Pharm. Exp. Ther. 236: 90-96, 1986). Administration of DM at a dose of 3 nmol/rat i.c.v. decreased respiration rate and ventilation minute volume by 38% and 50% of baseline, respectively. SK&F 86466 (1 or 5 mg/kg i.v. 20 min before DM) had no effect on ventilation minute volume but blocked the DM-induced respiratory depression in a dose-related manner. In contrast, SK&F 86466 had no effect on analgesia (increase in tail-flick latency) produced by low doses of DM (30 and 100 pmol/rat i.c.v.). These data suggest that α_2 -adrenoceptors selectively interact with μ_2 -opioid receptor associated effects such as respiratory depression but are not involved in the modulation of supraspinal analgesia mediated by μ_1 -opioid receptors.

SEROTONIN RECEPTORS I

CLONING OF A HUMAN 5-HT_{1D} SEROTONIN RECEPTOR GENE AND ITS RAT HOMOLOG. M.W. Hamblin and M.A. Metcalf. GRECC, Seattle VA Medical Center and the Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 98108.

We have isolated the human gene for a 5-HT_{1D} type serotonin receptor. The gene contains an apparently intronless open reading frame encoding a 377 amino acid polypeptide with the seven hydrophobic domains characteristic of G protein linked receptors. The 5-HT_{1D} receptor deduced amino acid sequence is 88% identical to that for RDC4 (a canine thyroid cDNA encoding a heretofore undetermined member of the G protein linked receptor family) and 43% identical to that for the human 5-HT_{1A} receptor. Expression of the human gene product in transfected cell lines results in the appearance of saturable, high affinity [³H]5-HT binding with 5-HT_{1D} type pharmacological specificity. It has been suggested that the pharmacologically distinct 5-HT_{1B} receptor found in the rat is the homolog of the 5-HT_{1D} receptor expressed in many mammals. We have cloned a homologous rat gene whose nucleotide sequence is approximately 85% identical to that of the human 5-HT_{1D} receptor. Further studies may help clarify several ambiguities in the classification and action of serotonin receptor subtypes.

Supported by the Department of Veterans Affairs.

287.2

EXPRESSION AND CHARACTERIZATION OF A CLONED RAT 5-HT_{1B} RECEPTOR: COMPARISON WITH A CLONED HUMAN 5-HT_{1D} RECEPTOR. T. Branchek, N. Adham, M. Macchi, P. Hartig, and R. Weinschenk. Neurogenetic Corporation, 215 College Road; Paramus, N.J. 07666

The serotonin receptors, 5-HT_{1B} and 5-HT_{1D}, display similarities in their pharmacology, second messenger coupling, and CNS distribution which have led to the proposal that they are species homologs (Hoyer and Middlemiss, 1989). The recent cloning of a 5-HT_{1D} receptor (Branchek et al., 1990) has enabled a direct evaluation of this proposal. To isolate the putative rat homolog of the 5-HT_{1D} gene, a rat library was screened at high stringency using a human 5-HT_{1D} sequence as a probe. A strongly hybridizing signal was selected, subcloned, and transfected into Cos-7 cells for study. [¹²⁵I]iodocyanopindolol was found to bind to membranes derived from the transfected cells with high affinity (K_d = 0.16 nM). In contrast, no specific binding of [¹²⁵I]-CYP was measured using membranes derived from cells transfected with the cloned human 5-HT_{1D} receptor gene. Rauwolscine was essentially inactive (K_i > 10,000 nM) at the rat receptor as was DP-5-CT. The rank order of potencies for the compounds studied was 5-HT > (-) propranolol > 5-methoxytryptamine > tryptamine > DP-5-CT = rauwolscine. Therefore, the rat gene isolated by homology with the human 5-HT_{1D} receptor encodes a protein with pharmacological properties which identify it as a 5-HT_{1B} receptor. Thus, these receptors are species homologs which exhibit significant differences in pharmacology. The rat 5-HT_{1B} receptor messenger RNA was detected in the brain as well as in several peripheral locations including kidney and aorta. Ongoing studies of second messenger coupling will be presented.

287.3

PROMOTER ACTIVITY OF THE 5'-FLANKING REGION OF THE SEROTONIN-1A RECEPTOR GENE. Paul R. Albert, Caroline Saucier, Alain Charest. Dept. of Pharmacology and Therapeutics, McGill University, Montreal, Canada, H3G-1Y6.

The 3-kb Pst I/BamHI fragment of 5' flanking region of the rat receptor gene was investigated for the presence of *cis*-acting transcriptional regulatory elements. Sequential 5' deletion fragments of this region were linked to the firefly luciferase reporter gene; the KS+ plasmid constructs were transiently-infected into P19 embryonic stem cells, and luciferase activity measured. Sequences between -1065/-1 displayed a 10-fold enhancement of basal luciferase activity, and contained 2 TATAA boxes preceded by a CCAAT box, as well as putative SP-1, AP-1, EGF-responsive elements. Fragments from 1258/-1 or -1391/-1, which contained a poly-GT repeat, suppressed the promoter activity of the -1065/-1 fragment to one-third of basal activity. The largest fragment, containing additional promoter elements (eg., CCAAT and TATAA boxes) enhanced luciferase activity by 2-fold basal. Our results indicate that the 5'-flanking region of the rat 5-HT_{1A} receptor contains an alternating array of promoter and repressor elements which control downstream transcriptional rate. A novel GT-repeat element is associated with the transcriptional repression.

5-HT DEPLETION ALTERS THE LEVELS OF 5-HT_{1A} RECEPTOR mRNA. D. Brousseau, S. Wieland, J. Lucki, P. McGonigle, Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

The regulation of mRNA for the 5-HT_{1A} receptor was studied following depletion of serotonin in the CNS. Twenty-four male Sprague-Dawley rats (225-235 g) were injected ICV either with saline or with 10 μ g of the serotonin selective neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) and sacrificed eleven days later. Half of the brains were hemisected along the midline. One half of each hemisected brain was further dissected and used for an assessment of regional serotonin levels. Alternate cryosections from the remaining brains were labelled with [³H]-8-OH-DPAT, a selective 5-HT_{1A} agonist, or with a 183 base ³⁵S-CTP labelled riboprobe selective for the N-terminal of 5-HT_{1A} receptor mRNA. HPLC analysis confirmed that 5,7-DHT produced significant depletion of serotonin throughout the CNS with losses of 75% in the hippocampus, 50% in the neocortex and olfactory area, and 40% in the anterior raphe area. Regional serotonin depletions were associated with changes in mRNA levels as determined by densitometric measurement of autoradiograms. Except for the dorsal raphe, where there was a 40% decrease in 5-HT_{1A} mRNA, increases in mRNA levels were observed in most 5-HT terminal fields which were examined including increases of 20-40% in the entorhinal cortex, dentate gyrus, and CA1 and CA2 fields of the hippocampus. No increases in the density of sites labelled with [³H]-8-OH-DPAT were observed in any of these terminal fields, however a 60% decrease was observed in the dorsal raphe. (Supported by USPHS MH 43821 and GM-07170)

287.5

ALTERATION OF LIGAND BINDING PROFILES OF THE 5-HT_{1A} RECEPTOR WITH A SINGLE POINT MUTATION. X.-M. Guan, B.K. Kobilka* and S.J. Peroutka. Depts of Neurology, Medicine, Molecular and Cellular Physiology, HHMI, Stanford Univ. Sch. of Med., Stanford, CA 94305.

5-HT_{1A} receptor is a member of the G protein-coupled receptor family, which is characterized by the proposed seven transmembrane topology. Previous studies have indicated that the VI and VII transmembrane domains of the adrenergic receptors are important in determining the specificity of antagonist bindings. Certain beta-adrenergic antagonists such as pindolol also bind to 5-HT_{1A} receptors with high affinity. In the present study, a single amino acid residue, Asn₃₈₅, in the VII transmembrane segment of the human 5-HT_{1A} receptor was changed to Val. Both the wild type and mutant receptor genes were expressed in COS-7 cells. Radioligand binding studies are performed by using ³H-5-HT and ³H-8-OH-DPAT. The affinity of the mutant receptor for pindolol is significantly decreased by about 100 fold while its affinities for 5-HT and 8-OH-DPAT are essentially unchanged as compared to the wild type receptor. The data suggest that Asn₃₈₅ plays an important role in the specific interaction between 5-HT_{1A} receptor and pindolol.

287.7

CHARACTERIZATION OF AN ANTIBODY FOR THE 5-HT₂ RECEPTOR. D.A. Molnák, B. Roth, R. Desai*, S. Garlow and R.D. Ciaranello. Nancy Pritzker Laboratory of Developmental & Molecular Neurobiology, Dept. Psychiatry & Behavioral Sciences, Stanford Univ. Sch. of Med., Stanford, CA 94305-5425.

We have raised an antibody to a unique region of the 5-HT₂ receptor, and have used it to immunocytochemically label the receptor protein expressed in a transfected cell line. Rabbits were immunized with a synthetic peptide antigen representing a sequence unique to the amino terminal region of the 5-HT₂ receptor protein, coupled by sulfo-MBS to keyhole limpet hemocyanin. Resulting antibodies were affinity purified against the synthetic peptide. To verify the specificity of the putative 5-HT₂ antibody, the full length cDNA coding for the receptor was cloned into plasmid pSVK3 and verified by restriction enzyme digestion. The DEAE-dextran technique was then used to transfect COS-7 cells, grown directly on poly-lysine-coated slides, with the pSVK3/5-HT₂ clone. Maximum expression of the receptor protein was observed at 60-72 hours, at which time the cells were fixed for 5 min in 4% paraformaldehyde. Following washes in PBS, cells were incubated on the slide with antibody diluted 1:50 to 1:200 in PBS containing 0.3% Triton X-100 and 5% Biotin, for 48 hr at 4 °C. Following incubation in a biotinylated second antibody (1:200, 90 min, 20 °C) and streptavidin-conjugated HRP (1:1500, 90 min, 20 °C), antibody was visualized by the peroxidase reaction, using H₂O₂ with DAB as the chromogen. Approximately 10% of the cells showed a very intense brown reaction product, concentrated along the cell membranes and around, but not in, the nuclei. Control studies, in which no label or only background labelling was observed, included use of pre-immune serum, non-transfected cells, or pre-incubation of the antibody with varying concentrations of the synthetic peptide.

NOVEL REGULATION OF 5-HT_{1C} RECEPTORS. M.R. Franzatelli and J.M. Murthy. Dept. of Neurology, Pediatrics and Pharmacology, The George Washington University, Washington, D.C. 20010

The 5-HT_{1C} receptor shares many features with the 5-HT₂ receptor despite sites is also similar to that of 5-HT₂ sites, at which both agonists and antagonists induce down-regulation, we studied the effects of chronic treatment (10 mg/kg IP for 30 consecutive days) with six 5-HT_{1C/2} drugs of different classes on [³H]mesulergine specific binding (n=5-9). Spinal cord was chosen for its paucity of 5-HT₂ sites and we have previously shown that drug affinities at spinal 5-HT_{1C} sites are highly correlated with cerebral 5-HT_{1C} sites. Adult male Sprague-Dawley rats were sacrificed 24 hours after the last drug injection. Results from various vehicles were pooled because there were no significant differences (n=30): B_{max} = 3.7 ± 0.1 pmol/g, K_D = 2.6 ± 0.1 nM, n_H = 1.0 ± 0.1. The putative 5-HT_{1C/2} agonists m-CPP (-43t) (±DOI(-39t)), and quipazine (-30t) significantly decreased the B_{max} of spinal 5-HT_{1C} sites compared to vehicle treatment. The putative 5-HT_{1C/2} antagonist ritanserin and metergoline (non-selective) eliminated [³H] mesulergine specific binding. The lack of significant changes in K_D or n_H argues against the presence of residual drug in the tissue. All of these drug effects were highly significant (p<0.0001, ANOVA). In contrast, (±)pindolol, with virtually no affinity for 5-HT_{1C} sites in vitro, did not alter receptor binding parameters. B_{max} values correlated with the affinities of the drugs at 5-HT_{1C} sites in vitro (r=0.77). These data demonstrate a pattern for 5-HT_{1C} sites shared with 5-HT₂ receptors of down-regulation by both 5-HT_{1C/2} agonists and antagonists.

CHARACTERIZATION OF THE TRANSCRIPTIONAL PROMOTER FOR THE SEROTONIN 5HT2 RECEPTOR GENE. Mark Heller*, Bryan Roth, and Roland Ciaranello. Nancy Pritzker Laboratory, Department of Psychiatry, Stanford School of Medicine, Stanford University, Stanford, CA, 94305.

Expression of the 5HT2 receptor and its corresponding mRNA is developmentally regulated during ontogeny in the rat brain. We previously showed that the 5HT2 receptor and its mRNA increased 8-fold and 13-fold, respectively, between embryonic day 17 and early postnatal peak levels, before declining to adult expression levels (Roth et al, *Dev. Brain Res.*, 58:51-58, 1991). To further study the molecular regulation of the rat 5HT2 receptor transcription unit, we have isolated overlapping genomic clones which include the transcribed gene, its putative transcriptional promoter, and sequences 5' of the promoter region which might contain cis regulatory elements. The organization of these clones was confirmed by Southern analysis of rat genomic DNA. cDNA proximal to the transcriptional start was obtained by (i) PCR amplification of cortex cDNA using primers derived from genomic sequences which were shown to hybridize to the 5HT2 receptor transcript on Northern blots, and (ii) RACE PCR amplification of 5' sequences of the transcript. A large intron is present in the 5'-untranslated region of the receptor gene.

We are beginning the functional assay of the 5HT2 transcriptional promoter and possible cis regulatory elements by fusions of these gene segments to reporter genes.

REGULATION OF THE 5-HT₂ RECEPTOR LINKED PHOSPHATIDYLINOSITOL BREAKDOWN IN RAT CORTICAL SLICES: EFFECTS OF CHRONIC PRETREATMENT WITH D-FENFLURAMINE OR P-CHLOROAMPHETAMINE. A. Erfurth*, A. Gardier and R.J. Wurtman. M.I.T., E25-604, Cambridge, MA 02139

Serotonin (5-HT) acts via 5-HT₂ receptors to stimulate phosphatidylinositol (PI) breakdown in the rat cerebral cortex. We studied the effects of chronic pretreatment with serotonergic drugs on the increases in PI breakdown caused by subsequently exposing cortical slices to 0.1 μM 5-HT or to 1 μM carbachol, a muscarinic agonist. Male rats were pretreated for 4 consecutive days and decapitated on day 7. Pretreatment with the 5-HT releasing agent and reuptake blocker d-fenfluramine (10mg/kg) diminished the increase in 3H-IP1 formation caused by 5-HT (p<0.05, t-test), but failed to modify the carbachol-induced increase. Unlike d-fenfluramine, the 5-HT neurotoxin p-chloroamphetamine (PCA) (5mg/kg) decreased the stimulation of 3H-IP1 formation caused by both 5-HT and carbachol (p<0.01). Our data suggest that high levels of 5-HT in the synaptic cleft, as obtained by pretreatment with very large doses of d-fenfluramine, lead to down-regulation of the 5-HT₂ receptor linked PI response. The mechanism by which PCA diminishes PI responses to the muscarinic agonist might involve a decrease in the number of structures (e.g. presynaptic 5-HT terminals) on which this agonist acts, or perhaps an enhancement in phospholipase C activity causing basal levels of PI turnover to be elevated.

287.10

[3H]R-ZACOPRIDE BINDS WITH A HIGH AFFINITY TO A NEW SITE IN ADDITION TO 5-HT₃ RECEPTORS. H. Gozlan*, E. Kidd*, I. Bouchelet*, L. Lanfumey, J.C. Levy*† and M. Hamon*. INSERM U. 288, CHU Pitié-Salpêtrière, 75013 Paris; †Delalande Recherche, Rueil Malmaison, France.

5-HT₃ antagonists such as R,S-zacopride exert potent anxiolytic-like effects in relevant test in rats and monkeys, but, the involvement of 5-HT₃ receptors in these effects is open to question. Indeed, R-zacopride is 1000 times more potent than S-zacopride as a potential anxiolytic drug although its affinity for 5-HT₃ receptors is 10 times less than S-zacopride. This discrepancy led us to examine the recognition sites for [3H]R- and [3H]S-zacopride in membranes from the rat entorhinal cortex and NG 108-15 clonal cells. Both ligands label pharmacologically identified 5-HT₃ receptors but [3H]R-zacopride bind to additional high affinity (10 nM) sites in the two membrane preparations. These sites are stereoselectively recognized with a high affinity by various zacopride derivatives (10-50 nM) but not by other benzamides. Prazosin and mianserin bind with a moderate affinity to these sites but 5-HT₃ ligands (S-zacopride, ondansetron, ICS 205-930 etc..) and other anxiolytic drugs (benzodiazepines, buspirone, ipsapirone...) are poorly recognized (10-100 μM). Interestingly, this new site has been identified in the kidney and in other peripheral tissues. The functional role of these new sites needs further investigation.

287.11

5HT₃ RECEPTORS IN POSTMORTEM BRAINS OF NORMAL AND SCHIZOPHRENIC SUBJECTS. A. Abi-Dargham*, M. Laruelle, D. T. Wong, D. W. Robertson, D.B. Weinberger, and J. E. Kleinman. Clinical Brain Disorders Branch, IRP, NIMH Neuroscience Center at St Elizabeths, Washington, D.C. 20032.

5HT₃ receptor antagonists have been reported to modulate dopaminergic transmission in rodents. We studied the binding in human brain of [³H]LY278584, which has been shown to label 5HT₃ receptors in rat cortex (Wong D.T. et al., Eur. J. Pharmacol., 166: 107, 1989). Saturation experiments were performed with increasing concentrations of the labeled ligand (0.1 to 20 nM) and the nonspecific binding was defined with 1 μM MDL72222. Scatchard analysis revealed a saturable binding site in the amygdala (K_d = 3.08 ± 0.66 nM, B_{max} = 7.02 ± 0.84 fm/mgP, n=4) as well as in other striatal and limbic areas such as the caudate, putamen, nucleus accumbens, hippocampus and entorhinal cortex. Specific binding in neocortical areas was negligible. Pharmacological characterization of [³H]LY278584 in the caudate and the amygdala was consistent with the pharmacology of 5HT₃ receptors. We compared the [³H]LY278584 specific binding in the amygdala in postmortem brains of schizophrenic subjects (n=8) and matched normal controls (n=10) and found no significant differences in the K_d (4.82 ± 1.63 nM versus 3.01 ± 0.41 nM) or the B_{max} (13.48 ± 3.08 fm/mgP versus 11.67 ± 1.2 fm/mgP) values between these two groups. 5HT₃ receptors binding appear to be normal in the amygdala of schizophrenics, but other areas remain to be studied.

287.13

DIFFERENTIAL EFFECTS OF SEROTONERGIC (5-HT) AGONISTS ON NEURAL CONTROL OF MICTURITION AND SEXUAL FUNCTION. W.D. Steers, J.B. Tuttle, E. van Asselt and M. Albo* Univ. of Virginia School of Medicine, Charlottesville, VA 22908

Behavioral and electrophysiological methods were used to study the role of 5-HT receptors on bladder and erectile pathways in the male rat. 5-HT_{1A} (PAPP, 5MeODMT) and 5-HT_{1C} (MK212,TFMPP,mCPP) agonists did not alter voiding frequency (VF) in awake rats or affect micturition threshold (0.4 vs. 0.3cc) in anesthetized rats. 5-HT_B agonist (ORG 6997) reduced VF. 5-HT₁ agonists abolished rhythmic reflex bladder contractions by inhibiting pelvic nerve firing. No 5-HT agonist produced firing in bladder nerves or affected pelvic nerve evoked bladder contractions. 5-HT_{1B} and 5-HT_{1C} agonists produced penile erections (2-5/30 min) in awake rats. These drugs also elicited efferent burst firing in cavernous nerves mediated by preganglionics in the pelvic nerve. Neural activity was abolished by 5-HT₁ (pindolol) and 5-HT_{1C/2} (mianserine) antagonists but not by 5-HT₃ antagonist (ICS 205-930). 5-HT_A agonists caused emission and ejaculation with firing in cavernous and vasal nerves via preganglionics in the hypogastric nerve. 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C} agonists did not influence synaptic transmission in the pelvic ganglion. These data support the existence of functional diversity for 5-HT receptor subtypes and suggest clinical use of related agents for genitourinary disorders.

SENSORY PREJUNCTIONAL 5-HT_{1B} RECEPTORS MEDIATE BLOCKADE OF NEUROGENIC PLASMA EXTRAVASATION WITHIN RAT BUT NOT GUINEA PIG DURA MATER. M.A. Moskowitz, T. Matsubara, M.G. Buzzi* Neurosurgery and Neurology, Mass Gen Hospital, Harvard Med Schl, Boston, MA 02114.

Neurogenic inflammation develops within the rodent dura mater after trigeminal ganglion stimulation (5Hz, 5ms, 1.0mA, 5min) by capsaicin-sensitive mechanisms and is presumably mediated by SP and NKA release. We describe the effects of pretreatment with 5-HT₁ receptor agonists on the leakage of ¹²⁵I-albumin within dura mater. Extravasation in the rat was significantly reduced by 5-CT > DHE > sumatriptan > 8-OH-DPAT whereas 5-HT₂ and 5-HT₃ antagonists were inactive. The potency order is most consistent with a 5-HT_{1B}/5-HT_{1D} response among the known 5-HT₁ family of receptors. The drugs did not block SP, or NKA-induced extravasation, however, suggesting prejunctional localization. We recently tested CP-93,129 (140 nmol kg⁻¹; threshold dose), a potent and selective 5-HT_{1B} receptor agonist possessing nmolar and μmolar affinities for the 5-HT_{1B}/5-HT_{1D} binding sites, respectively. CP-93,129 (140 nmol kg⁻¹) blocked extravasation within rat but 1400 nmol kg⁻¹ did not in guinea pig. By contrast, sumatriptan, a drug exhibiting 30-fold higher affinity for 5-HT_{1D} than 5-HT_{1B} recognition sites, blocked extravasation in the guinea pig at 7 nmol kg⁻¹. Taken together, these data are consistent with the presence of 5-HT_{1B} heteroreceptors blocking neurogenic inflammation within rat, whereas the 5-HT_{1D} receptor may be more important in guinea pig. CEREBRAL EDEMA AFTER PERCUSSIVE TRAUMA IN MATURE AND IMMATURE RATS. P. D. Grundl*, K. V. Biagas*, P. M. Kochanek, J. K. Schiding*, and E. M. Nemoto, Deps. of Anesthesia/Critical Care Medicine and Pediatrics, Univ. of Pittsburgh, Pittsburgh, PA 15213.

Studies suggest that children are more likely than adults to show early diffuse cerebral swelling after head trauma (1). Unlike hypoxia or ischemia, the response to cerebral trauma in an immature model is not well characterized. Hypothesis: Reproducible, age-related differences in the time course of traumatic edema formation can be demonstrated in an animal model.

Wistar rats, sexually immature (3.5-4.5 wks) and mature (>9 wks), were anesthetized and ventilated. Injury to the exposed right parietal cortex was produced by weight drop indexed to brain weight. Percent right brain water (%RBW) was measured at 2, 24, 48, and 168 h post-trauma by wet-dry weight. Within group comparisons to respective, normal controls and between group comparisons were made by t-test with Bonferroni correction. N=34 in each age group.

As anticipated, normal %RBW in immatures was higher when compared with mature rats (80.73 ± 0.16 vs. 79.31 ± 0.20, mean ± S.E.M., p<0.01). Survival was 100% in both groups. In immatures, %RBW was increased at 2 h post-trauma (81.29 ± 0.18, p<0.05) and remained elevated for 24 h after trauma (81.51 ± 0.27, p<0.05). In matures, however, %RBW was not elevated until 24 h post-trauma (80.06 ± 0.27, p=0.05). The magnitude of increase in %RBW vs. respective normals was similar in both groups 24 h post-trauma (0.75 ± 0.27 matures and 0.78 ± 0.27 immatures, p=NS). 7 d after trauma, %RBW did not differ significantly from normals in either group.

These results suggest enhanced early edema after traumatic brain injury in the immature. Future studies using this model may provide insight into the mechanisms of this edema formation.

CARBACHOL-STIMULATED INOSITOL PHOSPHATE (IP) PRODUCTION FOLLOWING TRAUMATIC BRAIN INJURY (TBI). S.E. Robinson, G.S. Borrelli*, J.L. Ang*, J.R. Pascua*, K.P. McDowell*, and E.K. Enters. Department of Pharmacology & Toxicology, Medical College of Virginia, Richmond, VA 23298-0613.

Central muscarinic blockade has been found to reduce behavioral deficits observed following TBI (Lyeth et al, Brain Res. 448: 88, 1988; Brain Res., Robinson et al, 511: 141, 1990). In order to determine whether TBI alters the responsiveness of the IP second messenger system to cholinergic agonists, carbachol-stimulated IP production was quantitated following TBI. Male Sprague-Dawley rats (270-320 g) were surgically prepared under Equithesin anesthesia 24 h prior to receiving moderate fluid percussion injury (2.0-2.4 atm) or sham-injury while under methoxyflurane anesthesia. 3 or 24 h later, methoxyflurane-anesthetized rats were decapitated, and the hippocampi removed, sliced into 225 μm cubes, and labelled for 90' with 1 μM [³H]myo-inositol (14 Ci/mmol) in Krebs-Ringer bicarbonate buffer (KRBB) at 37°C under O₂/CO₂. After labeling, the tissue was incubated for 60' with carbachol (final conc.: 0, 20, 50, 200, 2000 μM) in Li⁺KRBB. Lipids and IPs were extracted, and the IPs were separated from myo-inositol on Dowex 1x8 columns (formate form). Carbachol-stimulated IP production was significantly reduced 24 h and slightly, but not significantly, reduced 3 h after TBI, as compared to sham-injured rats. Thus, it appears that TBI leads to a delayed reduction in phosphatidylinositol hydrolysis in response to cholinergic stimulation. Whether this represents a decrease in receptor number or a change in the receptor coupling to this pathway must be elucidated. (Supported by NS24413 and NS7288)

INITIAL INTRAAXONAL ABNORMALITIES ASSOCIATED WITH TRAUMATIC BRAIN INJURY. A.B. Valadka*, A.A. Yaghai*, J. Astruc, and J.T. Povlishock, Div. of Neurosurgery and Dept. of Anatomy, Med. Col. of VA., VA. Commonwealth Univ., Richmond, VA 23298.

Axonal injury has long been a consistent finding in head-injured animals and man. Laboratory studies do not suggest the immediate tearing of axons, but rather suggest that injury initiates a series of intraaxonal changes that lead to disconnection over a 6-24 h period. What is unknown is the initial intraaxonal event which triggers this reactive sequence. To critically assess this, anesthetized rats and cats were subjected to moderate fluid-percussion injury and allowed to survive for 15 min to 4 h. The animals were perfused with aldehydes and their brains blocked to include loci which, with prolonged survival, manifest reactive axonal change. These regions were immunocytochemically processed for the light and electron microscopic visualization of the 68 kD neurofilament (NF) subunit, which has been shown to undergo selective change with injury. Through this approach, traumatic brain injury never resulted in the direct disruption of the axoplasm, axolemma or related myelin. Within 15 min of injury, the axon displayed focal infolding and irregularity associated with detachment from the overlying myelin. By 1 h, these axons displayed regions of densely packed immunoreactive 68 kD NF. Over a 1-4 h course, these immunoreactive NF became disordered, no longer paralleling the axon's long axis. By 4 h such disordered NF were associated with an initial accumulation of organelles, setting the stage for focal axonal swelling and detachment. These studies suggest that direct tearing is not a factor in the genesis of traumatically induced axonal change. Rather, these findings support the concept that stretching triggers cytoskeletal change leading to progressive axonal failure. (Supported by NS 20193)

Normal and Heat-Induced Patterns of Expression of Heme Oxygenase-1 (HSP32) in Rat Brain. J.F. Ewing*, M.D. Maines* and V.G. Laties, Department of Biophysics, University of Rochester Med. Ctr., Rochester, NY 14642

Heme oxygenase (HO) isoenzymes, HO-1 and HO-2, catalyze the rate limiting step in formation of bile pigments possessing potent antioxidant activity. Presently we have identified HO-1 as the only HO isoenzyme responsive to heat shock and defined hyperthermia as the only stimulus reported to date which causes an increase in brain immunoreactive HO-1 protein *in vivo*. Using an HO-1 specific polyclonal rat antibody and HO-1 specific cDNA probe we examined the expression of HO-1 immunoreactive protein and the level of HO-1 mRNA in normal rat brain and in brain 6 h following heat shock. Exposure of rats to 42°C for 20 min caused a marked increase up to 30-fold in brain HO-1 1.8 Kb mRNA within 1 h post-treatment as determined by Northern blot hybridization. In normal brain, HO-1 protein was observed in select neuronal and non-neuronal cell populations in forebrain, diencephalon and cerebellum. Six hours following heat shock an intense increase in HO-1 protein was observed in glia throughout the brain, ependyma lining the ventricles of brain and Purkinje cells of cerebellum. The specificity of HO-1 antibody-antigen complexes immunohistochemically detected in 50 micron coronal brain sections using horseradish peroxidase was established by preadsorption of HO-1 antisera with an excess of HO-1 protein. This study was supported by NIH grants R3704391, ES03968, ES01247 and ES07026.

THE VERY LONG-TERM CONSEQUENCES OF SEVERE CHI ON IQ. R.F. Zec, J. Belman, J. Miller, D. Zellers, J. Matthews, D. Ferneau, S. Vicari, M. Kocis, S. Verhulst, and R. Robbs. SIU Sch. of Med., Springfield, IL 62794.

It is unclear from the published literature to what degree there may be permanent residual impairment in IQ after severe CHI. The subjects in the present study were 32 patients with severe TBI and 42 controls (age, ed., gender did not differ; t-tests). The M length of coma was 65.4 days and time since injury was 10.1 yrs. A comprehensive test series was administered including the WAIS-R. The TBI group displayed significantly poorer performance on every WAIS subtest (t-tests). The degree of impairment for the WAIS-R VIQ was -1.0 SD difference from the control group mean, PIQ was -1.2 SD, and FSIQ was -1.0 SD. Thirty-eight percent of the TBI patients were greater than 2 SD below the control group mean for PIQ and FSIQ (<76), while only 16% were below 2 SD for VIQ. The greatest percentage of impaired subjects (>2 SD) using raw scores were found on block design (59%), followed by digit symbol (53%), object assembly (50%), picture arrangement (41%), picture completion (28%), arithmetic (25%), vocabulary (22%), comprehension (19%), similarities (19%), digit span (6%) and information (6%). Our findings indicate that many years after sustaining a severe TBI, IQ impairment remains mildly impaired on average, although 38% of patients will have severely impaired PIQ & FSIQ.

288.4

REGIONAL CEREBRAL BLOOD FLOW CHANGES AFTER TRAUMATIC BRAIN INJURY IN THE RAT. C.-L. Chou*, B.G. Lyeth, L.W. Jenkins, R.L. Hayes, and J.T. Povlishock. Depts. of Anatomy and Neurological Surgery, Med. Col. of VA, VA. Commonwealth Univ., Richmond, VA 23298.

Numerous investigators utilize rodent models of traumatic brain injury (TBI) to better understand the pathobiology involved. To date, various structural, functional, and behavioral changes have been described following relatively moderate TBI. Although most evidence points to the primary traumatically-related events in the genesis of these abnormalities, the possible contribution of related regional cerebral blood flow (CBF) change has not been fully explored. To address this issue, quantitative autoradiography using [¹⁴C] iodoantipyrine was used to assess CBF in 26 rats subjected to moderate fluid-percussion brain injury. Regional blood flows were assessed at 1 and 6 h postinjury. Sampling for autoradiographic analysis included numerous regions along the rostral-caudal extent of the neuraxis, including neocortex, cingulate gyrus, caudate-putamen, all subsectors of the hippocampus and various brain stem nuclear groups. By 1 h postinjury, a generalized reduction in CBF was seen in all regions sampled. Statistically significant reductions were seen within the rostral neocortex and cingulate gyrus as well as the mid-neocortex and the CA3 and CA4 subsectors of the hippocampus. Importantly, these flow reductions never reached ischemic levels, and all were noted within anatomical loci in which no evidence of hemorrhage or overt structural damage were identified. At 6 h postinjury, all regional CBF values appeared to recover; yet, they did not attain control levels. The results of this investigation demonstrate that moderate TBI in rat results in some regional reduction in CBF following injury which tends to recover over time. Importantly, since these blood flows never reached ischemic levels, primary ischemia is most likely not responsible for the pathobiology associated with this level of TBI. (Supported by NS 20193)

EFFECT OF CNQX AND HIGH CONCENTRATIONS OF DIHYDROPYRIDINES ON TRAUMATIC CORTICAL NEURONAL INJURY IN CULTURE. R.F. Regan and D.W. Choi. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

A traumatic insult to mixed murine neuronal and glial cortical cell cultures was delivered by multiply tearing the cell layer with a syringe. Injury was assessed by measurement of lactate dehydrogenase in the bathing media 20-24 hours later. Consistent with prior observations, neurons adjacent to a tear rapidly developed acute swelling and then went on to degenerate over the next several hours. About half of this cell death was blocked by the NMDA receptor antagonists MK-801 or dextrorphan. 10-100 μM CNQX plus 1 mM glycine was also neuroprotective in concentration-dependent fashion; at 100 μM CNQX, neuronal death was also reduced about half compared with untreated cultures. Nimodipine provided weaker and more variable neuroprotection, with approximately 20% reduction of injury at 10-30 μM. Similar results were noted with 100 μM nifedipine. Addition of nimodipine or nifedipine to MK-801 consistently reduced injury greater than MK-801 alone. Approximately 35% of neuronal death after trauma in the presence of 10 μM MK-801 was prevented by 30 μM nimodipine or 100 μM nifedipine. These results suggest that traumatic-induced neuronal death in this *in vitro* model may be mediated in part by excessive activation of non-NMDA receptors, and by mechanisms sensitive to high concentrations of dihydropyridines.

LONGITUDINAL POWER SPECTRAL ANALYSIS (PSA) FOLLOWING OVERNIGHT SLEEP STUDIES IN MINOR HEAD INJURED (MHI) ADOLESCENTS. L.C. PARSONS, M.PERLIS*, T. KWAN*, M. KHALIFA*, and L.J. CROSBY*. University of Arizona, College of Nursing, Tucson, AZ 85721. The objective of this study is to measure the PSA of overnight sleep/awake cycles of MHI adolescents within 72 hours, 6 weeks, and 12 weeks of injury. Four channels of electroencephalographic (EEG) data were down loaded from FM magnetic tape (IRIG standard) and converted from analog to digital format using metabyte AD board (Dash-16). EEGs were sampled at 128 samples/sec. for each of the sleep recordings. The digitization process was governed by Stellate Cooperation's Rhythm software (Ver 7.10). PSA was performed by Rhythm software for the following bandwidths: Delta (.75-2.5), Theta (2.75-7.25), Alpha-1 (7.5-9.75), Alpha-2 (10.0-11.75), and Sigma (12.0-14.0). EEG data were submitted for PSA in the form of NREM and REM cycles. Prior to PSA analysis, all NREM and REM cycles were visually inspected for perspiration and electromyographic artifacts. Artifacts > 2 sec. were removed. Data were accumulated in terms of power in 4 sec. epochs. Multiple epochs were averaged to yield the average 4 sec. power spectral distribution for each NREM/REM cycle. Preliminary Findings: PSA analysis of 6 overnight sleep studies performed on 2 subjects within 72 hrs, 6 weeks, and 12 weeks of injury indicated significant changes (one-way ANOVA). The p values for temporal NREM derivations were Delta (.000), Alpha 1 (.001), Alpha 2 (.015), Sigma (.05), and Total Power (.01). Temporal REM derivations indicated p values were Delta (.035), Alpha 2 (.05), Sigma (.03) and Total Power (.04). Conclusion: Preliminary findings suggest that the PSA may serve as a sensitive tool for quantifying electrophysiologic changes in vulnerable brain regions such as the temporal lobes. This study is supported by the National Institute on Neurological Disorders and Stroke under grant number 1 R01 NS 24169-01A1.

ELECTRICAL FIELD MAPPING IN THE RAT SPINAL CORD. R.J. Hurlbert and C.H. Tator. 12-423 Playfair Neuroscience Unit, Univ. of Toronto, 399 Bathurst St., Toronto, CANADA M5T 2S8

Direct current (DC) fields have been shown to possess beneficial effects in the treatment of acute spinal cord injury in animal models. However, little is known about the distribution of these fields within the spinal cord. We report results of field mapping in 5 normal rats. Epidural disc electrodes were placed 10 mm apart under the lamina of C6 and T2. Stimulation consisted of a balanced 20 Hz sine wave, current limited by an on-line ammeter. Field strengths were measured with a lock-in differential amplifier and glass microelectrodes inserted directly into the spinal cord. Recordings were made from various positions and depths between the stimulating electrodes.

The relationship between stimulating current and field strength was linear; for a doubling of current there was a proportional doubling of measured voltage. The field strength was highest in close proximity to the stimulating electrodes; 14 μ A of current produced voltages exceeding 1 mV/mm. At midpoint between the electrodes the measured field dropped to < 400 μ V/mm in the spinal cord and < 200 μ V/mm in the paraspinal musculature. These results characterize the field distribution resulting from this type of stimulation in the normal spinal cord, and will help to determine the optimal stimulation parameters necessary to promote recovery following spinal cord injury in the rat.

288.10

SPINAL CORD BLOOD FLOW (SCBF) CHANGES FOLLOWING GRADED CONTUSIVE INJURIES IN THE RAT THORACIC CORD. A. Martinez-Arizala, D. H. Hesse*, A. Marcillo*, The Miami Project, University of Miami School of Medicine, Miami, FL 33136.

In support of ischemia as a secondary mediator of injury in spinal cord trauma, significant reductions in gray matter SCBF have been described after spinal cord injury (SCI). Changes in white matter blood flow have been less consistent as both hyperemia and ischemia have been reported. This study was designed to establish a correlation between severity of SCI and changes in white matter SCBF. Anesthetized female S-D rats underwent a T8 laminectomy and graded spinal SCI by the weight drop method (10 g weight dropped 2.5, 5.0, 7.5, or 10 cm). SCBF was monitored pre- and for one hour post-injury with laser doppler flowmetry by placing the laser probe on the dorsal columns, adjacent to the site of impact. Neurologic function (Tarlov score, inclined plane, sensory score) was assessed at 2, 7, 14, 21, and 28 days post-injury. SCBF decreased within a few minutes following SCI in all but the mild (2.5 cm) injury group, where some animals exhibited a transient hyperemia. All animals in this group had partial recovery of SCBF by one hour (the end of the observation period), but in animals with more severe injuries (≥ 5.0 cm), SCBF remained significantly reduced. At one hour post-injury, SCBF changes from baseline for each group were (mean \pm sem): 2.5 cm: -36.3 \pm 8.2%, 5.0 cm: -64.8 \pm 11.9%, 7.5 cm: -70.2 \pm 8.4%, and 10 cm: -76.8 \pm 4.3%. Greater neurologic deficit was also present at one month in more severe lesions as reflected in the mean Tarlov scores (0 to 5, where 0=plegic and 5=normal): 2.5 cm group: 3.0, 5.0 cm group: 2.6, 7.5 cm group: 1.8, and the 10 cm group: 1.1. In summary, we find that after SCI, the magnitude of neurologic deficit and degree of post-traumatic ischemia increase as the severity of the injury increases. However, it must be emphasized that ischemic levels for the injured spinal cord white matter have not been defined.

288.11

SPINAL CORD INJURY PRODUCED BY DORSAL SPINAL VENOUS OCCLUSION IN THE RAT PW Madsen and A Martinez-Arazila, The Miami Project to Cure Paralysis, Univ. of Miami Sch of Med, Miami, FL

Although mechanical disruption of the vascular system occurs with traumatic spinal cord injury, the effect of the resultant impairment of the venous drainage is undefined. The restriction of venous outflow can contribute to the development of tissue edema and delay its resolution. Histological examination of rodent spinal cord following the occlusion of the dorsal spinal vein demonstrated edema and hemorrhagic infarction of the dorsal columns (Martinez et al. *Neurosci. Abst.* 1990). To investigate the neurological deficits associated with this lesion, 17 anesthetized Sprague-Dawley rats were subjected to T7-T9 laminectomy to expose the dorsal venous system of the spinal cord. In all animals the vein was isolated, focally coagulated with a micro-bipolar cautery and sectioned at the rostral and caudal extent of the laminectomy. Eight animals undergoing this selective cauterization (SO) and an additional nine animals in which the major branches of the dorsal vein were also coagulated (EO), were neurologically evaluated for a one month period postoperatively. Motor function was assessed using a modified Tarlov scoring scale (0-5) while sensory function was assessed grading the response to hindlimb paw pinch. EO animals manifest a marked motor deficit 48 hrs post-injury (2.0 mean Tarlov score), which became maximal (1.3) at 7 days, and then slowly improved over the next three weeks (3.5). The SO animals demonstrated a similar temporal profile with significantly less motor impairment: 3.6 at 48 hrs, 2.9 at 7 days, and 4.5 at 1 month. The sensory scores demonstrated a similar pattern. The results of this preliminary study suggest that the degree of venous obstruction is directly associated with the development of neurological deficits and may contribute to the pathophysiology of spinal cord injury.

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS III

289.1

SYNAPTIC RECEPTOR HETEROGENEITY AT INDIVIDUAL RETINAL SYNAPTIC BOUTONS Charles L. Zucker¹ and Berndt Ehinger². Eye Research Institute and Harvard Medical School¹, Boston, Massachusetts, and Department of Ophthalmology, University of Lund, Sweden².

It is now well established that neurons often contain more than one neuroactive substance, typically a conventional neurotransmitter such as acetylcholine, GABA or glycine and one or more neuropeptides. There is also evidence that a class of retinal amacrine cells contains both acetylcholine and GABA, which are considered excitatory and inhibitory, respectively. It remains unexplained how these neurons utilize their multiple neuroactive substances. In the present study, we have examined the ultrastructural localization of glycine receptors in the turtle retina using a monoclonal antibody directed to the intracellular domain of the strychnine sensitive glycine receptor. We have found that glycine receptors are only localized to 56% of the synapses made by presumed "glycinergic" amacrine cells. The remaining synapses made by these same boutons show no evidence of glycine receptors, even though they may be located within 0.5 μ m of a glycinergic synapse. These data indicate that only a portion of the postsynaptic sites contacted by the glycine-containing neurons are able to respond to glycine. They also suggest that a neuron containing multiple neuroactive substances can selectively affect postsynaptic elements. In light of our findings, we suggest that it is less useful to classify a neuron in its entirety as glycinergic than to define individual synapses as glycinergic. The same argument can be made for all types of neurons and such a "synergic" hypothesis may provide a functional explanation for the rapidly growing number of neurotransmitter colocalizations being reported throughout the central nervous system.

Supported by NIH grant EY07552 to CLZ and grants from the Crafoord Foundation, the T and R Söderberg Foundation, the Swedish Institute and the Swedish Medical Research Council (project 14X-2321).

SORTING OF SODIUM CHANNELS AND GABA RECEPTORS IN POLARIZED CELLS. K.J. Angelides, B. Wible*, J. Velazquez*, and E.H. Joe*, Departments of Molecular Physiology and Biophysics and Neuroscience, Baylor College of Medicine, Houston, TX 77030.

Neurons are characterized by a cell surface organization in which proteins are segregated and maintained in discrete domains. Fluorescence imaging has shown that GABA receptors are distributed in high density on cell bodies and dendrites and sodium channels (NaChs) are localized to axons. In neurons it is not known how specific cell surface domains are created, but recent work with viral proteins expressed in neurons and epithelial cells suggests similar mechanisms for protein sorting.

In order to gain insight into the subunit requirements and signals that target GABA_A to dendrites and cell bodies and NaChs to axons, we examined the sorting of specific combinations of GABA_A α and β subunit subtypes and rat brain NaChs after transfection of their cDNAs into polarized epithelial cells. Digital and confocal microscopy with NaCh specific antibodies and fluorescent neurotoxins show that NaChs are targeted to the apical membrane and distributed in patches. In addition, both ankyrin and spectrin, cytoskeletal proteins that associate with NaChs, accumulate with NaCh patches. Using GABA_A subunit subtype-specific antibodies, defined receptor assemblies composed of α - and β -subunit subtypes are specifically routed to either apical or basolateral membranes. The results indicate that a signal contained in the NaCh primary sequence is sufficient to target NaChs to a specific membrane domain and to induce NaCh-ankyrin assembly, while the assembly of specific subunit subtypes may determine the differential targeting of GABA_A to either dendrites or cell bodies. NIH and NMSS supported.

289.3

STRUCTURAL AND PRECLINICAL STUDIES WITH THE RADIOIODINATED CHOLINERGIC NEURON MARKER (-)-5-IODOBENZOVESAMICOL (5-IBVM). Y.W. Jung*, M.E. Van Dort*, D.L. Gildersleeve*, D.M. Wieland, D.E. Kuhl. University of Michigan Medical Center, Ann Arbor, MI 48109.

Radioiodinated derivatives of benzovesamicol are promising mapping agents for central cholinergic neurons. Structural studies have shown radioiodine incorporation in position 5 or 6 of benzovesamicol does not lower *in vivo* neuronal selectivity; iodine substitution in the 8 position, however, destroys selectivity. Based on rodent screening studies, 5-[¹²³I]IBVM has been chosen for further preclinical testing. Dosimetry analysis in rats with 5-[¹²⁵I]IBVM shows the intestinal tract to be the critical organ. Nearly 60% of the injected dose is excreted in 24 h, 95% in the feces. Radiation dose to the unblocked thyroid is low. The LD₅₀ of 5-IBVM in rabbits is 120-180 µg/kg (University of New York at Buffalo Toxicology Research Center). A no-carrier-added synthesis of 5-[¹²³I]IBVM was accomplished in 94% yield by chloramine-T/radioiodide reaction with the respective (±)-5-tributyltin analog followed by chiral-HPLC purification on a Chiracel OD column; specific activity was greater than 20,000 Ci/mmol. Tomographic brain imaging of 5-[¹²³I]IBVM distribution and kinetics in Alzheimer's disease patients will be undertaken.

SPECT IMAGING OF THE BENZODIAZEPINE RECEPTOR: COMPARISON OF RECEPTOR DENSITY AND RADIOLIGAND DISTRIBUTION. E. Sybirska, M. Al-Tikriti, S. Zoghbi*, R.M. Baldwin*, R.B. Innis. Depts. Psychiatry & Radiology, VA Med. Ctr. and Yale Univ., West Haven, CT 06516.

¹²³I-Ro16-0154 is a SPECT (single photon emission computed tomography) probe for the central benzodiazepine (BZ) receptor. The purpose of this study was to compare the distribution of radioligand in brain following the i.v. administration of ¹²³I-Ro16-0154 measured with *ex vivo* autoradiography with the distribution of receptors measured with *in vitro* autoradiography using ¹²⁵I-Ro16-0154.

¹²³I-Ro16-0154 was administered i.v. to six monkeys, and transaxial images were monitored with SPECT until maximal brain uptake was reached, approximately 100 min post injection. Animals were then euthanized with an overdose of pentobarbital. The planes of the SPECT images were marked on the underlying brain. Tissue blocks 5 mm thick were cut in a mold and then frozen. Cryostat sections 20 µm thick were apposed to film for *ex vivo* autoradiography. After decay of ¹²³I for at least 1 week, sections were incubated with ¹²⁵I-Ro16-0154 using standard *in vitro* receptor autoradiographic techniques. Digitized *ex vivo* and *in vitro* autoradiograms were analyzed relative to calibrated autoradiographic standards.

SPECT images showed high levels of activity in neocortical areas, with greatest activity in the occipital lobe. *Ex vivo* autoradiograms provided a detailed distribution of radioactivity in tissue sections at the level of the light microscope. Tissue radioactivity measured in a gamma counter was highly correlated in 12 regions with that measured in the *ex vivo* autoradiograms ($r=0.93$). The distribution of BZ receptors determined by *in vitro* autoradiography was highly correlated in 16 regions with that determined by *ex vivo* autoradiography ($r=0.89$), although several regions including LGN, pallidus, and putamen showed consistent discrepancies.

These studies demonstrate the feasibility of quantitative *ex vivo* autoradiographic measurements of SPECT radioligands.

RTA Gene Expression in the Rat Cerebellum. Drew D. D'Angelo, Jeffrey K. Harrison, Pamela Woodring, Scott C. Baraban, Ruth L. Stometta and Kevin R. Lynch. Department of Pharmacology, University of Virginia School of Medicine, Charlottesville, VA 22908 USA.

RTA is a 343 amino acid protein that is a member of the seven transmembrane helix superfamily that includes the guanine nucleotide binding protein (G-Protein) interactive receptors. It is most similar to the *mas* oncogene product followed by the complement C5a receptor; the ligand for RTA is not known at present. RTA cDNAs were isolated initially by screening a rat thoracic aorta cDNA library using an oligonucleotide complementary to a conserved region of a M₂ muscarinic acetylcholine receptor. A 2.4 kb RTA RNA species accumulates in tissues that are predominantly smooth muscle (e.g. aorta, uterus, stomach, intestines, vas deferens) or skeletal muscle (e.g. tongue). Several fibroblastic cell lines express the RTA gene also. CNS RTA gene expression is restricted to the cerebellum, where in addition to the 2.4 kb RNA species, there are 3.0 kb and 6.0 kb RNAs. An alternative form of RTA cDNA, which contained a different 5' non-coding region, was isolated from a cerebellar cDNA library. Analysis of the rat RTA gene showed that the point of divergence between the aorta and cerebellum cDNAs is located at an intron/exon boundary. Further analysis of the RTA gene structured showed the existence of multiple introns. The appearance of different forms of RTA RNAs in the cerebellum raises interesting possibilities including the differential expression of alternative RTA RNAs in different cell types. The expression of different forms of RTA RNA in the context of the rat cerebellum are being examined by *in situ* hybridization.

PET IMAGING AND QUANTITATION OF THE CHOLINERGIC PRESYNAPSE WITH FLUORINE-18 ANALOGS OF VESAMICOL. G.A. Rogers, L. Eriksson*, M. Ingvar, S.M. Parsons, S. Stone-Elander* and L. Widen. Neuroscience Res. Inst., UCSB and Karolinska Inst. and Hosp., Stockholm.

The *in vivo* pharmacological properties of three fluorine-18 analogs of vesamicol were examined in both rat and monkey. In rat, 4-fluoromethylvesamicol (FMV) is rapidly transported across the blood brain barrier and binds with high affinity ($k_{diss} = 0.008 \text{ min}^{-1}$) to a saturable site (the vesamicol receptor, VR) and with low affinity ($k_{diss} = 0.12 \text{ min}^{-1}$) to a nonsaturable site (probably the vesamicol binding protein, VBP). A second analog that was designed to bind more specifically to VR, fluoroacetyl-4-aminobenzovesamicol, was metabolically labile (time-dependent rebound of radioactivity in plasma). However, a structural modification that apparently blocks metabolism produced an analog with increased affinity for VR and diminished binding to VBP.

In both rat and monkey, a prior injection of vesamicol prevents the binding of [¹⁸F]FMV to the VR. Reconstructed images of monkey brain taken ca 1 hr postinjection of [¹⁸F]FMV show good contrast with high specific activity in areas expected to be rich in cholinergic neurons. A prior injection of vesamicol greatly reduces tracer binding in these areas. Our results suggest that fluorinated analogs of vesamicol will be useful tools in imaging and quantitating cholinergic neurons *in vivo*.

PRESENCE OF A- AND B-TYPE CCK BINDING SITES IN RAT VAGUS NERVE. E.S. Corp, M. Curcio* and G.P. Smith. Bourne Laboratory, New York Hospital-Cornell University Medical Center, White Plains, NY 10605.

Cholecystokinin (CCK) binds with high affinity (approx. 1 nM) to axonally transported receptor binding sites in afferent fibers of rat vagus nerve. Based on the relative binding potencies of competing agonists, these sites have been characterized as A-type. To analyze subtype composition further, we used two selective CCK antagonists, devazepide (A-type) and L365,260 (gastrin/B-type) in competition for vagal sites occupied by ¹²⁵I-CCK (50 pM). Cervical vagus nerves (n=5) ligated 24 h. prior to extraction were cryostat-cut, slide-mounted and run under equilibrium binding conditions. We employed *in vitro* quantitative autoradiography with computerized image analysis to characterize parameters of binding to the proximal accumulation of sites.

Analysis (LIGAND) of competition data resolved devazepide binding to a single class of sites with a $K_i = 18.4 \pm 6.6 \text{ nM}$ and a $B_{max} = 2.6 \pm 0.27 \text{ fmol/mg}$. Surprisingly, L365,260 was also a potent competitor of vagal ¹²⁵I-CCK binding: $K_i = 37.1 \pm 4.6 \text{ nM}$; $B_{max} = 2.0 \pm 0.5 \text{ fmol/mg}$. These data suggest that afferent vagal fibers contain comparable densities of A-type and gastrin or B-type receptors.

Moran et al. (1990) have shown that vagal afferents project to the brainstem nucleus of the solitary tract (NTS). Hill and Woodruff (1990) report, and we confirm, a medial-lateral heterogeneous distribution of A-type and gastrin/B-type receptors in the NTS. Medially, in the commissural NTS, devazepide competes with high affinity for ¹²⁵I-CCK-occupied sites ($K_i = 13.1 \pm 4.0 \text{ nM}$) and L365,260 is relatively impotent ($K_i > 100 \text{ nM}$). Laterally, L365,260 competes potently ($K_i = 21.8 \pm 6.5$) and devazepide is impotent ($K_i > 1000$). Taken together these studies suggest a topographical distribution of A-type and gastrin or B-type receptors associated with vagal afferents projecting to the NTS.

SEROTONIN INHIBITION OF ASCORBATE-STIMULATED LIPID PEROXIDATION IN PREFRONTAL CORTEX: DIFFERENCES BETWEEN ALZHEIMER'S DISEASE AND CONTROL. Anne C. Andorn and Bryan A. Ballot, Dept. of Psychiat. and Hum. Behav., St. Louis Univ. Schl. of Med. and St. Louis VAMC, St. Louis Mo. 63125.

Unstimulated lipid peroxidation (LP) is increased, and 0.1 mM ascorbate-stimulated LP is decreased in Alzheimer's disease (AD) prefrontal cortex (PFC) as compared to age-matched (AM) controls. We now report that serotonin (5-HT) inhibits ascorbate-stimulated LP in young non-AD, AM non-AD and AD prefrontal cortices. However, 5-HT is less potent as an inhibitor of ascorbate-stimulated LP in AD than in either AM or young non-AD PFC. In the presence of 10 μ M 5-HT, ascorbate stimulated LP is 45.5 \pm 10.8% (N=5) of the ascorbate-stimulated LP in the absence of 5-HT in young PFC; 30.3 \pm 13.3% (N=3) in AM PFC but 66.0 \pm 8.7% (N=3) in AD PFC. There is statistically no significant difference between young and AM non-AD, but there is a significant difference ($p < 0.05$) between AM and AD as determined by Student's t-test. 5-HT itself does not affect unstimulated LP (not shown). We have observed that ketanserin increases ascorbate-stimulated LP in non-AD PFC, with 10 μ M ketanserin stimulating between 151-224% (N=2) of the ascorbate-stimulated LP in young PFC. These observations suggest that antagonists and agonists may have opposite interactions with ascorbate stimulated LP in human PFC. Current investigations should elucidate whether this might be a receptor mediated phenomenon.

290.3

COMPARISON OF NMR AND HPLC TECHNIQUES FOR THE ESTIMATION OF BRAIN METABOLITES IN POSTMORTEM ALZHEIMER'S DISEASE BRAIN. W.E. Klunk, K. Panchalingam, R.J. McClure, D. McKeag, A. Heist, G. Branthoover, and J.W. Pettegrew, Lab. of Neurophysics, Univ. of Pittsburgh, WPIC, Pittsburgh, PA 15261

In vitro and *in vivo* NMR methods have been used to provide relative quantification of brain metabolites in a variety of CNS disease states, including Alzheimer's disease. The noninvasive nature of NMR and its potential for clinical use makes it likely that this technique will gain even more extensive use in the future. More traditionally, metabolites such as amino acids and phosphomonoesters have been measured by HPLC. Since NMR also is being applied to measure levels of these same metabolites in brain, it is important to directly compare the two techniques to determine if they produce equivalent results. We have measured mixtures of phosphoserine, phosphoethanolamine, and glycerophosphoethanolamine by both HPLC of FMOC derivatives and 31 P NMR. Additionally, we have compared the relative amounts of these compounds in perchloric acid (PCA) extracts of Alzheimer's brain by both techniques. Alzheimer's brain PCA extracts and mixtures of glutamate, glutamine, GABA, aspartate, and taurine also have been compared by HPLC and 1 H NMR. In general the two techniques produced similar results. Specific advantages of each technique will be discussed. For example, NMR can measure some additional compounds without different methods of derivatization. These include phosphocholine, glycerophosphocholine and N-acetylaspartate (NAA).

290.5

INCREASED COTRANSLATIONAL ASSOCIATION OF HEAT SHOCK 70 PROTEINS WITH NASCENT POLYPEPTIDES IN ALZHEIMER'S DISEASE. W. Wallace, J. Sugar*, N. Perez*, G. Johnson, L. Bierer, V. Haroutunian, and C. Merrill; Dept. Psychiatry and Center for Neurobiology, Mt. Sinai School of Medicine, New York and Laboratory of Biochemical Genetics, NIMH, Washington. The cellular disruptions that lead to the production of the abnormal proteins present in the AD brain are unknown. We have investigated potential cotranslational disruptions. Chaperonins are proteins that associate with polypeptides as they are being synthesized and mediate their initial processing. AD cortical tissues contained elevated levels of two heat shock proteins which act as chaperonins. The cytoplasmic chaperonin, hsp 72/73 was measured by immunoblots (259 \pm 142 vs 128 \pm 56; n=8/group; p<0.05), while in the endoplasmic reticulum, binding protein (aka grp 78), was measured on two dimensional gels (1.9-fold increase). The elevation showed specificity to the disease in that cerebellar tissues did not exhibit this increase (302 \pm 48 vs 275 \pm 66; n=4/group). AD polysomes were found to synthesize significantly higher levels of hsp 72/73 indicating that they are induced in the AD tissues. Immunoprecipitation of the newly synthesized hsp 72/73 resulted in the coprecipitation of numerous other nascent polypeptides. This binding indicates a long term association of the hsp with newly synthesized proteins, which may account for the presence of the abnormal proteins in the AD brain.

290.2

BRAIN CELL MEMBRANE ABNORMALITIES IN ALZHEIMER'S DISEASE ARE DISTINCT FROM OTHER NEURODEGENERATIVE DISEASES.

R. Nitsch*, J.K. Blusztajn, R.J. Wurtman & J.H. Growdon, Dept. of Neurology, Mass. General Hospital, Boston, MA 02114, Dept. of Pathology, Boston University, Boston, MA 02118, and Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

Nerve cell degeneration in Alzheimer's disease (AD) is associated with abnormalities in membrane phospholipid (PL) metabolism: Glycerophosphocholine (GPC), a water soluble catabolite of membrane PL, is increased in AD brain. To determine if this alteration is specific to AD, we compared levels of GPC in frontal cortex from AD, Huntington's disease (HD), Parkinson's disease (PD), and Down's syndrome (DS) patients with control subjects using HPLC. GPC was increased 2x in AD cortex but was unchanged in HD, PD and DS. These results indicate that increased GPC reflects an abnormality of brain cell PL metabolism that is specific for AD. Accelerated membrane PL turnover may contribute to amyloid deposition by exposing the intramembranous domain of the amyloid precursor protein (APP) to proteolytic cleavage. The formation of amyloidogenic peptides in DS is not related to this metabolic PL abnormality, but probably reflects the increased gene dosage of APP on chromosomes 21.

290.4

1 H NMR IN VITRO STUDY OF AMINO ACIDS IN ALZHEIMER'S DISEASE BRAIN. R.J. McClure, K. Panchalingam, W.E. Klunk, and J.W. Pettegrew, Laboratory of Neurophysics, University of Pittsburgh, WPIC, Pittsburgh, PA 15261

The relative mole % of glutamate, aspartate, GABA, taurine, and N-acetyl-L-aspartate (NAA) in Alzheimer's disease (AD) brain have been evaluated by *in vitro* proton NMR at 500 MHz. Perchloric acid extracts of 9 brains with autopsy-verified AD and 5 age-matched control brains have been studied. We find an increase in mole % glutamate, glutamine, and taurine, little change in aspartate and GABA, and a decrease in NAA in AD as compared to controls. Senile plaque counts of the immediately adjacent histological sections are used to indicate the progression of the AD samples. We find that the decrease in the mole % of the putative neuronal marker, NAA, significantly and inversely correlates with increasing numbers of SP in AD. This finding is consistent with the profound loss of neurons in AD. The mole % of glutamate, glutamine, and taurine increase with increasing numbers of SP. The decrease in NAA and the increase in glutamate in AD suggests an increase of excitatory neurotransmitter per neuron as AD progresses. This may result in excitotoxic damage to the remaining neurons.

SERUM PROTEINS IN NEUROFIBRILLARY PATHOLOGY OF ALZHEIMER'S DISEASE (AD): ANTITHROMBIN III-LIKE IMMUNOREACTIVITY.

R. N. Kalaria and S. N. Kroon*, Dept. of Neurology, Case Western Reserve Univ. Sch. of Medicine, Cleveland, OH 44106.

We and others have previously shown the presence of amyloid P component, a serum α_2 -glycoprotein, in amyloid deposits of AD and other neurodegenerative disorders. Here, we used immunoblotting and immunocytochemical methods to investigate the presence of antithrombin III (AT III), a serum protein of the *serpin* family, in the pathological lesions of AD. Both mono- and polyclonal antibodies to AT III, obtained from various commercial sources, recognized protein(s) of Mr 58 kD on immunoblots of cerebral microvascular proteins. This was verified by electrophoresis of authentic AT III protein run in parallel. Using the ABC immunocytochemical method at the light microscope level, at least three antibodies labelled neurites associated with plaques and neurofibrillary tangles (NFT) in neocortex and hippocampus of all the AD cases examined. The distribution and intensity of staining in NFT were similar to that of thioflavin S staining in serial sections. However, most of the antibodies stained intracortical vessels and capillaries in both AD and aging controls. Our results suggest the presence of AT III-like immunoreactivity or homologous epitopes in the neurofibrillary pathology of AD. Like other amyloid-associated factors e.g. α -ACT, protease nexin I, AT III may play a role in the pathogenesis of NFT and cerebral amyloidosis.

290.7

INCREASED PHOSPHORYLATION OF ELONGATION FACTOR 2 IS RESPONSIBLE FOR REDUCED POLYSOME ACTIVITY IN ALZHEIMER'S DISEASE BRAINS. G. Johnson¹, C. Merrill¹, L. Bierer², V. Haroutunian², J. Sugar², and W. Wallace². ¹Lab. of Biochemical Genetics, NIMH, Washington, D.C. and ²Dept. of Psychiatry/Center for Neurobiology, Mt. Sinai School of Medicine, New York.

We have previously observed that polysomes prepared from Alzheimer's disease (AD)-afflicted brain tissues exhibit reduced ability to synthesize proteins in an in vitro translation system. No differences were found in either levels or translational activities of mRNA or ribosomes purified from AD polysomes. This result indicates that the reduced polysomal activity may be due to associated soluble factors. Based upon a reduced sensitivity of AD polysomes to the protein synthesis inhibitor, emetine, we proposed that the translocation step of elongation is disrupted. Elongation factor 2 (EF2) mediates this translocation in a phosphorylation-dependent manner. Calcium/calmodulin kinase III-mediated phosphorylation of EF2 results in the inhibition of elongation.

We investigated the phosphorylation state of EF2 in AD brain homogenates. EF2 was identified on two-dimensional (2D) gels of brain homogenates with factor-specific antibody. EF2 exhibits four distinct charge variant polypeptides reflecting its phosphorylation state. The phosphorylation state was directly measured as the distribution of the four polypeptides on silver stained 2D gels. The ratio of the phosphorylated (acidic) forms of EF2 to unphosphorylated forms was significantly greater in AD homogenates as compared to controls (1.11±0.37, n=10 vs 0.70±0.19, n=8; p<.001), indicating an increased phosphorylation of the AD EF2. Therefore, decreased AD polysomal function is due, at least in part, to increased phosphorylation of EF2.

290.9

EVIDENCE FOR ALTERED THIAMINE NEUROCHEMISTRY IN ALZHEIMERS DISEASE. M. Héroux, A.-M. Besnard and R.F. Butterworth, Lab. of Neurochemistry, André-Viallet Clin. Res. Center, Hôpital St-Luc (Univ. of Montreal), Montreal, Que., Canada H2X 3J4.

Previous studies reveal decreased activities of thiamine-dependent enzymes in autopsied brain tissue from patients with Alzheimer's Disease. In the present study, thiamine-dependent enzymes were measured in autopsied temporal and frontal cortex samples obtained from 8 patients with neuropathologically confirmed Alzheimer's Disease and from an equal number of age-matched controls free from neurological or psychiatric diseases. Significant reductions were observed of pyruvate dehydrogenase (decreased by 70%, p<0.01), α -ketoglutarate dehydrogenase (decreased by 71%, p<0.01) and transketolase (decreased by 52%, p<0.01). Activities of the presynaptic cholinergic marker enzyme choline acetyltransferase were reduced by 42% (p<0.01); activities of the non-thiamine-dependent enzyme glutamate dehydrogenase were within normal limits. Analysis of thiamine esters by HPLC revealed reductions of 46% (p<0.01) of thiamine pyrophosphate (the enzyme cofactor form of thiamine) in Alzheimer brain tissue. These results suggest that abnormalities of thiamine neurochemistry could be implicated in the pathogenetic mechanisms in Alzheimer's Disease (Supported by MRC Canada)

290.11

PROPERTIES OF DEPHOSPHORYLATED τ _{PHF} PROTEINS. S. G. Greenberg, L. I. Binder and P. Davies*. Pathology Dept., Albert Einstein College of Medicine, Bronx, New York 10461.

This study examines the possibility that the distinct properties of τ _{PHF} results from modifications of normal τ . Hydrofluoric acid (HF) treatment resulted in the loss of SDS-insoluble and soluble PHF by electron microscopy. Therefore, modifications may serve a critical role in determining the structural integrity of PHF. HF-treated τ _{PHF} proteins are also heat and acid stable, soluble in MES buffers and display the same MW, pI, and immunochemical properties as normal τ . Alkaline phosphatase treatment of disassociated PHF resulted in similar, although less extensive changes in the MW and pI of τ _{PHF}. Therefore, the predominant effect of HF is likely to result from dephosphorylation.

Although dephosphorylated τ _{PHF} displays the same biochemical properties as τ _S, the relative abundance of τ isoforms differs in HF-treated PHF and τ _S samples. Therefore, a selective incorporation or exclusion of specific τ isoforms may also contribute to the formation of PHF. Comparison of dephosphorylated τ obtained from PHF or from a baculovirus vector expressing a human τ sequence indicates that the least abundant τ _{PHF} isoform is the 4 repeat form of τ . While ALZ 50 reactivity was not selectively altered by the dephosphorylation conditions tested, the τ -1 epitope could be exposed under conditions that did not significantly change the MW of τ _{PHF} and PHF-1 reactivity was only significantly reduced under conditions which caused a distinct shift in the MW and pI of τ _{PHF}. Therefore, the PHF-1 epitope and not the τ -1 epitope may be associated with the aberrant MW and pI of τ _{PHF}. Although PHF-1 does not exhibit strong reactivity with normal τ _S isolated from human adults, PHF-1 recognizes phosphorylated human adult τ expressed from a baculovirus vector (generous gift of Ken Kosik). Therefore, the high specificity of PHF-1 in human adults for τ _{PHF} appears to be created by phosphorylation of normal τ _S.

290.8

CATION ENTRY/EFFLUX RATIO IN ALZHEIMER'S DISEASE ERYTHROCYTES IS CORRELATED WITH THE DEGREE OF DEMENTIA. J. W. Pettegrew, K. Panchalingam, G. Branthover, A. Heist, Laboratory of Neurophysics, Dept. of Psychiatry, U. of Pittsburgh, Pittsburgh, Pa 15261

Alteration in Alzheimer's Disease (AD) erythrocyte membrane molecular dynamics and cation transport were studied by magnetic resonance spectroscopy techniques. Na⁺ and Li⁺ transport and relaxation parameters were measured. Correlation between the degree of dementia and membrane alteration was investigated in 7 mildly to moderately demented (Blessed = 1.5 to 13, Mattis 92 to 125) males and females (ages 65 and older) with probable AD (NINCDS-ADRDA criteria). Linear regression analysis showed negative correlation (p=0.004, r=0.8) between degree of dementia and cation entry/efflux ratio as measured by Li⁺ transport. No association of Na⁺ or Li⁺ relaxation times with degree of dementia was observed. Comparison of AD patients with age matched controls does not indicate any disease dependent changes in the relaxation times. A shortening of the entry/efflux ratio would suggest either fast entry or slower efflux. This could be due to an alteration in plasma membrane or membrane associated cytoskeleton. The result could potentially explain why Li⁺ has enhanced neurotoxicity in AD patients while is an effective treatment for mania and a prophylactic treatment for depression.

SEROLOGICAL ALPHA-1-ANTICHYMOTRYPSIN MAY NOT BE A MARKER FOR ALZHEIMER'S DISEASE PATHOLOGY. K. Brugge*, R. Katzman, L. A. Hansen*, R. Terry*, and T. Saitoh. Univ. of California, San Diego, Dept. of Neurosciences, 0624, School of Medicine, La Jolla, CA 92093, U.S.A.

Alpha-1-antichymotrypsin (ACT) is a serine protease inhibitor which is markedly elevated in the serum and cerebral spinal fluid of patients with Alzheimer's disease (AD). Patients with Down's syndrome (DS) are known to develop neuropathological changes of AD by age 40 years and many become demented. Thus, in the present study, we obtained plasma ACT levels from DS subjects and non-DS controls and serum ACT levels from postmortem confirmed AD and control subjects. Plasma ACT levels between the DS (388.0±17.5 mg/dl) and age-matched, mentally retarded control (385.7±37.3 mg/dl) and healthy control (341.7±22.3 mg/dl) groups were not found to be significantly different. Furthermore, we failed to observe a positive correlation of ACT levels with age in the DS group, in spite of the age-dependent premature increase in neuropathological changes of AD that are known to occur in DS. A positive correlation between serum ACT levels and the density of plaques or tangles, neuropathological hallmarks of AD, in brains of AD patients also failed to exist. Thus, our results suggest that ACT levels may not serve as a marker for the development of AD in DS or parallel the development of the neuropathological hallmarks of AD.

BRAIN ALPHA-KETOGLUTARATE DEHYDROGENASE ACTIVITY IN ALZHEIMER'S DISEASE. Stephen J. Kish and Frank Mastrogiacomo*. Clarke Institute of Psychiatry and Departments of Psychiatry and Pharmacology, University of Toronto; Toronto, Canada

Circumstantial biochemical evidence has suggested that a failure of one or more energy metabolizing enzymes may be involved in the brain neurodegenerative processes in Alzheimer's disease (AD). Gibson and coworkers (Arch Neurol 45:836, 1988) reported markedly reduced (-75 to -100%) activity of alpha-ketodehydrogenase (KGD) in both degenerated and morphologically normal areas of postmortem brain of AD patients. A failure of this enzyme could lead to neuronal cell death by a variety of mechanisms including excitotoxic damage. We measured the activity of KGD in autopsied frontal and temporal cortex from 8 neuropathologically confirmed AD cases and 6 neurologically normal matched controls. Although enzyme activities in the AD frontal and temporal cortices were reduced, on average, by 57% and 40%, respectively, as compared with the controls, the differences were not statistically significant (p>0.05) due to a large overlap between the AD and control values with 3 of the 8 AD patients having distinctly normal control levels. We conclude that although decreased KGD activity may, in principle, contribute to the brain neurodegeneration in some AD patients, it is not a constant feature of this human brain disorder. DIRECTION SENSITIVITY OF A δ FIBER MECHANORECEPTORS.

M.B. MacIver & D.L. Tanelian. Pain Research Laboratory, Department of Anesthesia, Stanford University School of Medicine, CA 94305.

Structure-function relationships of pain fiber mechanosensitive nerve endings were investigated to determine a physiological basis for directional sensitivity in trigeminal ganglion sensory afferents. Corneas were isolated from albino rabbits and maintained *in vitro* at constant temperature (35°C) and intraocular pressure (18 mmHg). Fluorescence microscopy was used to visualize and digitally reconstruct individual nerve endings. Combined microstimulation and electro-physiological recording of single isolated fibers were used to map terminal field excitability patterns for each nerve ending. Fiber type was determined on the basis of stimulus/response modality and conduction velocity (A δ fibers > 2 M/s). A δ mechanosensitive endings travelled parallel to the epithelial surface at a depth of 15 to 45 μ m for distances of 0.1 to 1.5 mm. Mechanical stimuli which moved parallel to the long axis of these endings produced 5 to 10 fold more action potentials than did stimuli applied perpendicular to this axis. C fiber endings, in contrast, terminated as finger-like projections which were perpendicular to, and approached to within 2 μ m of, the epithelial surface. C fibers were not mechanosensitive. Both A δ and C fiber endings could be electrically activated and their excitability maps closely followed the underlying anatomy. This study is the first to demonstrate distinct terminal patterns for A δ vs. C fiber nociceptors, and to demonstrate that directional sensitivity of mechanoreceptors results from their unique elongated "leash-like" free nerve endings. Supported by NIH grant NS28646-01 A1.

MICRONEUROGRAPHIC AND PSYCHOPHYSICAL STUDIES OF MECHANICAL PAIN AND HYPERALGESIA USING A NEW STIMULATION TECHNIQUE.

M. Koltzenburg* and H.O. Handwerker. Institut für Physiologie, D-8520 Erlangen, F.R.G.

We have developed a new technique for the evaluation of mechanical pain and hyperalgesia. Light metal cylinders (300 mg; 6 mm diameter) were guided and accelerated in a barrel. On impact against the skin they elicit a brief sensation of pain. In 19 psychophysical experiments using magnitude estimation techniques monotonically increasing stimulus response functions were obtained for different acceleration velocities (7.5-22.5 m/s; $r = .84$) with a mean pain threshold of 11.6 ± 0.5 m/s (mean \pm SEM). Using repetitive painful stimulation (9 impacts, 1 Hz) there was a gradual build-up of pain intensity indicating that temporal summation is important for mechanical pain. This stimulus train also resulted in the reliable development of mechanical hyperalgesia as shown by the elevated pain ratings of a constant test stimulus. Hyperalgesia developed within 1-3 minutes and was maintained for up to 20 minutes. Using percutaneous microneurography single primary afferents were recorded from the superficial radial nerve of conscious humans. Low threshold large diameter afferents responded with few impulses and could not encode stimulus intensity. Some slowly adapting afferents became unresponsive for several minutes following a strong impact stimulus. Nociceptive C-fibers were also activated, often at stimulus intensities that were not rated painful by the subjects. However, in contrast to myelinated low threshold mechanoreceptors, C-fibres showed graded responses to suprathreshold stimuli. (Supported by DFG & Marohn Stiftung)

291.5

THE CONTRIBUTION OF G α AND cAMP TO DECREASED MECHANICAL NOCICEPTIVE THRESHOLDS IN STREPTOZOTOCIN-DIABETIC RATS.

S.C. Ahlgren and J.D. Levine*. Dept. of Anatomy, Medicine and Oral Surgery, and Division of Neurosciences, UCSF, Box 0452, San Francisco, CA 94143.

The purpose of this study was to examine the contribution of stimulatory GTP-binding proteins (G α) and of cAMP to the lowered mechanical threshold in the primary afferent nociceptor in streptozotocin-diabetic (STZ-D) rats. The effect of the intradermal (id) injection of test agents on mechanical nociceptive threshold in the hairy skin of the hindpaw of adult male Sprague-Dawley rats, diabetic for 21 to 35 days, was monitored by the Randall-Selitto paw-withdrawal test.

For normal rats, the action of prostaglandin E $_2$ (PGE $_2$) and of A $_2$ -type purinergic agonists, both direct-acting hyperalgesic agents, is mediated via activation of G α . In STZ-D rats, hyperalgesia induced by PGE $_2$ (100 ng, id) was attenuated by GDP β -S (1 μ g) (PGE $_2$ = $-41.9 \pm 5.0\%$, n=6; PGE $_2$ + GDP β -S = $-6.4 \pm 6.0\%$, n=6; p<0.05). However, GDP β -S alone had no significant effect on nociceptive thresholds in the diabetic rat ($-7.48 \pm 4.1\%$, n=6; p>0.05).

While phosphodiesterase (PD; 0.1 unit/2.5 μ l, id) did not effect nociceptive threshold in normal rats ($-2.8 \pm 1.9\%$; p>0.05, n=12), it attenuated the hyperalgesia produced by the intradermal injection of PGE $_2$ (co-injected with indomethacin (10 μ g); PGE $_2$ = $-39.1 \pm 5.8\%$, n=6; PGE $_2$ + PD = $-19.6 \pm 6.3\%$, n=6; p<0.05), confirming a contribution of cAMP to prostaglandin hyperalgesia. In STZ rats, PD produced a $17.0 \pm 5.1\%$ increase in nociceptive threshold compared to vehicle in STZ rats (n=28; p<0.01).

The membrane permeable cAMP analogue, 8-bromo cAMP, which acts on nociceptors to produce hyperalgesia in non-diabetic rats, was more potent in inducing hyperalgesia in the STZ rat, demonstrating a shift to the left in the dose response curve by an order of magnitude compared to normal rats. These results support a contribution of both increased cAMP levels and increased cAMP responsiveness to the hyperalgesia observed in the STZ-diabetic rat. Supported by NIH grant NS21647

291.2

FAST CONDUCTING (GROUP II) SENSORY NERVE FIBERS IN THE CAT'S KNEE JOINT WITH CHEMORECEPTIVE PROPERTIES

K. Meßlinger*, S.K. Hong*, M. Pawlak*, K. Schepelmann*, R.F. Schmidt Inst. of Physiology, University of Würzburg, D-8700 Würzburg, Germany

Articular group II sensory nerve fibers are known to innervate (rapidly and slowly adapting) mechanoreceptive corpuscular nerve endings. These mechanosensors are usually insensitive to chemical stimuli which typically excite slowly conducting (polymodal) afferents. To examine the response properties of articular afferents, recordings were made from filaments of the medial articular nerve in α -chloralose anesthetized cats using mechanical stimulation (passive movements of the knee) and chemical stimuli, applied i.a. as a bolus close to the knee joint. In this study, we searched for fast conducting fibers which were either excited or sensitized by the inflammatory mediators bradykinin and prostaglandin E $_2$ and I $_2$. A total of 36 afferents with conduction velocities of 20.7 up to 61 m/s were tested. Twelve of 28 units responded to bradykinin in a concentration of 0.26-26 μ g/0.3 ml bolus. Six of 20 units, tested with PGE $_2$ or PGI $_2$ in a concentration of 0.3-30 μ g/bolus, were excited and 8 of 15 units were sensitized to movements (decrease of mechanical threshold). Units tested with both bradykinin and prostaglandins showed differential sensitivity to these compounds. The chemosensitive properties were restricted to more or less slowly adapting units, while rapidly adapting mechanosensors were not chemosensitive. The results suggest that some articular group II sensory receptors, which may correspond to Ruffini-like endings without a perineurial capsule, behave like polymodal sensors similar to slowly conducting nerve fibers. Taken together, it seems probable that specific group II sensors are activated in acute arthritic processes, although their role in nociception remains unclear.

291.4

CENTRAL NERVOUS SYSTEM LESIONS AND DEAFFERENTATION BY C5-T2 GANGLIONECTOMIES IN RATS.

J. Ovelmen-Levitt, E. Rossitch, Jr., S-N Hwang*, M. Abdulhak*, M. Levitt and B.S. Nashold, Jr. Div. Neurosurgery, Duke U. Med. Ctr., Durham, N.C. 27710.

A deafferentation syndrome (DS) has been produced in rats by C5-T2 ganglionectomies that is expressed by scratching of partially deafferented areas and/or biting of anesthetic limb regions. The projection to the brainstem from the spinal cord is bilateral in the rat, with a higher percentage to the midbrain than to the sensory thalamus. In addition, the spinothalamic tract has been found to project to and/or make collateral synapses at locations in the brainstem including the midbrain central gray, the parabrachial region, and the intralaminar as well as the ventrobasal thalamus. We have studied the effect of lesions in these regions on the onset, progression and extent of DS after deafferentation. All surgery was performed under aseptic conditions after anesthesia with i.p. Ketamine (90 mg/kg). The brainstem lesions were made using a thermocouple electrode with a Radionics Lesion Generator. The spinal cord lesions were made using a micromechanical technique. Simultaneous lesions of the dorsal horn significantly reduced DS, as did pre- or post-ganglionectomy lesions of the parabrachial region and the medial thalamus when compared to ganglionectomy only controls. Midbrain central gray lesions did not have this effect, however, and could augment DS. The results validate the rat ganglionectomy model of neural injury and indicate that the spinal cord dorsal horn is important in the generation of this type of pain. They also suggest that certain CNS structures are differentially involved in the expression of dysesthetic sensation following neural injury.

291.6

STUDIES WITH PHASIC AND TONIC NOXIOUS STIMULI SUGGEST THAT BOTH CHOLERA- AND PERTUSSIS TOXIN-SENSITIVE MECHANISMS MEDIATE MORPHINE ANTINOCICEPTION IN THE RAT SPINAL CORD.

H. Wheeler-Aceto* and A. Cowan. Department of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140.

A common feature of opioid receptors is their ability to modulate effector function via PTX-sensitive G-proteins. Using noxious stimuli of different intensities and durations, we have previously shown that i.t. PTX antagonizes morphine (M) antinociception against a high intensity phasic endpoint (50°C water tail-dip reflex). A reduction in the potency of M against intermediate intensity (early phase formalin) and, to a lesser extent, low intensity (late phase formalin) stimuli also occurs but, in these cases, maximum efficacy is still achieved [Eur. J. Pharmac. 195: 411, 1991]. However, accumulating evidence suggests that opioid receptors are not exclusively coupled to PTX-sensitive G-proteins. The present study was therefore undertaken to assess the contribution of CTX-sensitive mechanisms to the antinociceptive profile of M. Male S.D. rats (70-90 g) were pretreated i.t. with CTX (0.5 μ g) or saline (5 μ l) at -24 h. M or saline (n=5-10 rats per dose) was given s.c. 20 min before formalin. Critically, since all three endpoints were recorded in the same rat, dose-response profiles against each endpoint were obtained simultaneously. In controls, M was fully efficacious against each stimulus. After CTX, there was a 3x decrease in the A50 of M in the tail-dip test; this is in contrast to PTX which caused a >12x increase in A50. However, in early phase formalin, both CTX and PTX caused an increase in A50 of 5x and 11x, respectively. In both cases, unlike the effect of PTX in the tail-dip test, maximum efficacy was still achieved. A smaller shift in antinociceptive potency (increases of 1.5x and 4x with CTX and PTX, respectively) was observed in the late phase of formalin. These data, in conjunction with our previous findings, suggest that (i) M acts at spinal sites coupled to both PTX- and CTX-sensitive G-proteins, (ii) high intensity phasic stimuli are down-regulated by PTX-sensitive transducers and transmission of these signals can be enhanced by a CTX-sensitive mechanism, (iii) the effect of M depends on a balance of stimulatory and inhibitory actions which can be shifted by pretreatment with PTX or CTX, and (iv) the down-regulation of intermediate and low intensity stimuli is complex and may involve both PTX- and CTX-sensitive mechanisms. (DA 03945 and DA 07237 from NIDA).

291.7

ON THE ROLE OF NK-1 AND NK-2 TACHYKININ RECEPTORS IN MEDIATION OF SPINAL CORD REFLEX EXCITABILITY

X.-J. Xu¹, Z. Wiesenfeld-Hallin¹, C.-J. Dalsgaard^{2*} and C.A. Maggi^{3*}, ¹Dept. Clin. Neurophysiol., Karolinska Institute, 141 86 Huddinge, ²Astra Pain Control, Södertälje, Sweden and ³A. Menarini Pharmaceuticals, Florence, Italy.

We have studied the effects of intrathecal (i.t.) Spantide II (SII, non-selective tachykinin antagonist), CP-96,345 (NK-1 antagonist) and Men10207 (NK-2 antagonist) on the spinal nociceptive flexor reflex (FR) and facilitation of the FR by i.t. substance P (SP), neurokinin A (NKA) and conditioning stimulation (CS, 1 Hz, 20) of C-afferents in cutaneous and muscle nerves.

i.t. CP-96,345 antagonizes FR facilitation induced by i.t. SP, but not NKA, whereas Men10207 antagonizes NKA-induced FR facilitation without influencing SP's effect. SII blocks the effect of both tachykinins. CS of cutaneous and muscle nerve facilitates the FR for a brief or prolonged period, respectively. Both types of facilitation were blocked by SII. Men10207 antagonized muscle, but not cutaneous, nerve CS-induced FR facilitation whereas CP-96,345 blocked the latter. i.t. CP-96,345 does not depress the FR whereas SII and Men10207 do so at high doses.

It is suggested that NK-1 and NK-2 tachykinin receptors have a distinct role in the mediation of spinal cord reflex excitability and nociception.

291.9

GABA-B RECEPTORS MODULATE THE SENSITIVITY OF WIDE DYNAMIC RANGE NEURONS IN RAT SPINAL DORSAL HORN TO INNOCUOUS MECHANICAL STIMULI Y.-X. Yu*, J.-X. Hao, X.-J. Xu, A. Selger and Z. Wiesenfeld-Hallin, Depts. Clin. Neurophysiol. and Geriatric Medicine, Karolinska Institute, 141 86 Huddinge, Sweden.

Transient spinal ischemia in rats is induced by a photochemical reaction, leading to platelet aggregation, when a dye, Erythrosin B, injected i.v., is activated by an argon laser irradiating an exposed vertebra. The ischemia leads to the development of hypersensitivity (allodynia) to innocuous mechanical stimuli in the dermatomes of the irradiated segments (Hao et al., Pain, in press). The activity of single wide dynamic range (WDR) neurons in allodynic rats was recorded to examine the neural mechanisms underlying this sensory abnormality.

The responses of WDR cells to electric shocks or mechanical stimulation with von Frey hairs in their receptive fields was recorded in normal and allodynic rats. In normal rats electrical stimulation evoked a biphasic response corresponding to A and C fiber input. The mechanical threshold in normal WDR cells was 13.8 g. In the majority of allodynic rats the neural response to electrical stimulation was a single prolonged burst and the mechanical threshold was 2.1 g. The response characteristics of the cells in allodynic rats were normalized by systemic GABA-B agonist baclofen (0.1 mg/kg), but not GABA-A agonist muscimol (1 mg/kg).

Transient spinal ischemia leads to a dysfunction of GABAergic inhibitory mechanisms in the dorsal horn, which normally may control sensory input from myelinated afferents.

291.11

INTRACELLULAR RECORDINGS FROM DORSAL HORN NEURONS IN THE FLUOROCARBON-PERFUSED RAT. C.L. Cleland and G.F. Gebhart.

Department of Pharmacology, University of Iowa, Iowa City, IA 52242

The cellular properties of spinal neurons are likely to contribute significantly to the processing of nociceptive and non-nociceptive input from somatic and visceral sensory receptors. Their investigation, however, has been hampered by the difficulties of obtaining long-term stable intracellular recordings and manipulating the extracellular environment in intact, *in vivo* preparations. Consequently, we have developed a fluorocarbon-perfused, whole rat preparation, which combines the advantages of *in vitro* preparations (intracellular recording and solution alteration) and *in vivo* preparations (adult, normothermic and intact CNS/periphery), in order to study the role of cellular properties in sensory processing.

Adult rats were perfused through the ascending aorta using non-pulsatile flow of a fluorocarbon-based artificial blood which contained pentobarbital and pancuronium and was maintained at 37°C. Intracellular recordings were obtained from the lumbar dorsal horn using 50-100 Mohm 3 M KCl filled micropipettes. Viability of the nervous system, as assessed by the presence of a normal EEG, was maintained for up to 12 hours.

To date, we have obtained 8 intracellular recordings from dorsal horn neurons that responded to cutaneous stimulation of the hindlimb; all neurons exhibited pronounced synaptic potentials often accompanied by spontaneous activity. Receptive fields were similar to those seen with extracellular recording *in vivo*, including both noxious and non-noxious input. Based on micropipette depth, recordings were obtained from both superficial and deeper lamina. These results demonstrate the usefulness of the fluorocarbon-perfused preparation for the intracellular recording of dorsal horn neurons.

Supported by NIH Grant NS19912.

291.8

CENTRAL SENSITIZATION AFTER C-FIBER ACTIVATION IS MEDIATED BY NMDA AND SUBSTANCE P RECEPTORS

Z. Wiesenfeld-Hallin¹, X.-J. Xu¹, and C.-J. Dalsgaard^{2*}

¹Dept. of Clin. Neurophysiol., Karolinska Institute, 141 86 Huddinge and ²Astra Pain Control, 151 85 Södertälje, Sweden.

A brief conditioning stimulus (CS) train (20 s, 1 Hz) to C-afferents facilitates spinal flexor reflex excitability for minutes. Evidence has been presented that NMDA (Woolf and Thompson, Pain, 1991, 44, 293-299) and tachykinin (Wiesenfeld-Hallin et al., Brain Res., 1990, 526, 284-290) receptors may have a role in central sensitization. We tested the interaction of the nonpeptide NK-1 antagonist CP-96,345 and the NMDA antagonist MK-801 on sural nerve CS-induced flexor reflex facilitation in decerebrate, spinalized, unanesthetized rats.

CP-96,345 administered i.v. at 1 and 3 mg/kg significantly attenuated the prolonged facilitation of the flexor reflex for up to 3 h. MK-801 (0.5 mg/kg) had a similar effect. When subthreshold doses of both drugs were coadministered (0.1 mg/kg MK-801 plus 0.3 mg/kg CP-96,345), the central sensitizing effect of the sural CS was totally blocked for 1-2 h.

Prolonged reflex facilitation after a brief C-fiber CS may be due to cumulative depolarization of dorsal horn interneurons. The NK-1 agonist substance P produces prolonged depolarization in the dorsal horn. Glutamate and substance P, which coexist in primary afferent terminal vesicles, may be coreleased and interact synergistically to induce central sensitization.

291.10

CHRONIC PAIN-RELATED SYNDROME IN RATS AFTER ISCHEMIC SPINAL CORD LESION: AN ANIMAL MODEL FOR PAIN IN PATIENTS WITH SPINAL CORD INJURY.

J.-X. Hao^{1,2}, X.-J. Xu¹, H. Aldskogius³, A. Selger² and Z. Wiesenfeld-Hallin¹, Karolinska Institute, ¹Depts. of Clin. Neurophysiol., ²Geriatric Medicine, 141 86 Huddinge and ³Anatomy, 141 01 Stockholm, Sweden.

Spinal ischemia in rats is induced by a photochemical reaction, leading to platelet aggregation, when a dye, Erythrosin B, injected i.v., is activated by an argon laser irradiating an exposed vertebra. Various degrees of neurological deficits and morphological damage may be observed after this photochemical lesion, which is correlated with the duration of laser irradiation.

We report here that a chronic pain-like syndrome develops within weeks in some of the irradiated rats. This syndrome includes mechanical allodynia, which is expressed as a clearly painful reaction to light pressure applied to skin at or near the dermatome of the injured spinal segments, and self-mutilation of the hindpaws (autotomy). The allodynia in the majority of rats is not relieved by clonidine, baclofen, muscimol, guanethidine or carbamazepine and is only relieved by morphine at a sedative dose. In contrast, low, non-sedative doses of the local anesthetic tetracaine have a good effect when applied systemically.

We suggest that the present finding may represent an animal model for chronic central pain after spinal cord injury or stroke.

291.12

LOCATIONS OF AXONS OF PHYSIOLOGICALLY CHARACTERIZED SPINOTHALAMIC TRACT (STT) NEURONS IN RATS. R.J. Dado, J.T. Katter and G.J. Giesler, Jr. Dept. of Cell Biol. and Neuroanat., Grad. Prog. in Neurosci., Univ. of Minn., Minneapolis, MN 55455.

Recent anatomical studies have described a projection of STT axons through the contralateral dorsal lateral funiculus. We extended these findings using microantidromic mapping techniques. This allowed determination of both the positions of individual STT axons and the response characteristics of the recorded neurons. We recorded from 41 neurons in the cervical enlargement that were antidromically activated (mean threshold = 16 μ A) from the contralateral posterior thalamus. Recording points were in the superficial dorsal horn (SDH; n=17) and nucleus proprius/lateral reticulated area (NP/LRA; n=23). Approximately 96% of the neurons tested (n=24) responded preferentially or exclusively to noxious mechanical stimuli and 80% tested (n=15) responded to noxious heat. The position of each STT axon was located at one (n=16) or more (n=25) levels of the cervical cord white matter using a second antidromic stimulating microelectrode (mean = 9.3 μ A). The axons of neurons recorded in the SDH were located primarily in the contralateral dorsal lateral funiculus in segments C3-5. In contrast, axons of neurons in NP/LRA were found primarily in the contralateral ventral lateral funiculus in these segments. However, at C2 the axons of both SDH and NP/LRA neurons were found scattered throughout the dorsal and ventral lateral funiculus. These results confirm that many STT axons ascend in the dorsal lateral funiculus. They also indicate that nociceptive STT axons are segregated in mid-cervical cord according to the location of their cell bodies but often shift locations and become intermingled throughout the lateral funiculus at upper cervical levels. Supported by NS25932 and DA07234.

292.1

EFFECTS OF BRIGHT LIGHT ON HUMAN NOCTURNAL PERFORMANCE, MOOD AND SERUM MELATONIN LEVELS

A. B. Dollins*, H. J. Lynch*, M. H. Deng*, R.J. Wurtman and H. R. Lieberman, Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139

We examined the effects of nocturnal exposure to bright light on human behavior, pineal function, oral temperature and cardiovascular status in 23 healthy male volunteers. On three separate occasions, subjects were admitted to a clinical research center in groups of 2 to 4 for a 13.5-hour session (1630 - 0800 h). Each subject sat at an individual work station that was maintained throughout the night at an illumination of approximately 300, 1500, or 3000 lux. (Three hundred lux is a typical indoor level of illumination). On admission, a catheter with a heparin lock was established in a forearm vein for withdrawal of blood samples. Throughout the night subjects were required to complete interactive computer tasks designed to measure auditory and visual reaction time and vigilance, and a questionnaire to assess mood state. The order and timing of test administration were held constant across test nights. Temperature, blood pressure, heart rate, and sleepiness were assessed every hour. Blood samples were taken at 1900, 2100, 2300 and at hourly intervals thereafter until 0800. Serum was assayed for melatonin concentration by radioimmunoassay. The normal nighttime secretion of melatonin was largely suppressed by the brightest light, partially suppressed by the moderate intensity and appeared to be intact at 300 lux. Mood state was also significantly affected by exposure to bright light. It appeared that bright and moderate light exposure throughout the night increased depression without affecting alertness. However, only subtle variations in performance were noted as a function of light exposure.

292.3

TIME-OF-NIGHT EFFECT ON HEART RATE VARIATION IN HUMAN NEONATES. V.L. Schechtman and R.M. Harper. The Brain Research Institute and the Dept. of Anatomy & Cell Biology, UCLA School of Medicine, Los Angeles, CA 90024.

Circadian patterns have been observed in infants as early as the first few postnatal days. We hypothesized that, in each sleep-waking state, heart rate variation in 3 distinct frequency bands would show consistent changes across a night in 1-week old infants. Twelve-hour nighttime recordings of EEG, EOG, ECG, digastric EMG, respiratory movements, and expired CO₂ were obtained from 25 normal full-term infants at 1 week postnatal age. The extents of 3 types of heart rate variation were determined for all epochs of quiet sleep, rapid eye movement sleep, and waking during each 4-hour period of the night. In sleep states, the extent of all three types of heart rate variation decreased over the course of the night; however, 2 of the 3 did not show this time-of-night effect in waking. Heart rate variation at the respiratory frequency showed a time-of-night effect in quiet sleep only, resulting in a significant sleep state effect on the extent of respiratory-related heart rate variation during the evening that disappeared later in the night. Results indicate that time-of-night effects on heart rate variation are not constant across physiological states in neonates, and heart rate variation during waking is particularly unresponsive to circadian influences.

Supported by NIH Grant HD22695. Data acquisition and sleep state classification were performed under the direction of Drs. J. Hodgman & T. Hoppenbrouwers under NIH Contract HD22777.

292.5

PLASMA NOREPINEPHRINE MANIPULATION BY DIETARY SODIUM FAILS TO MODIFY SLEEP PATTERNS IN HEALTHY OLDER MEN. M.V. Vitiello*, R.C. Veith*, D.D. Ralph* and P.N. Prinz. Psychiatry and Medicine, University of Washington, Seattle and American Lake VAMC, Seattle, WA 98195.

We have shown that elevated nighttime plasma norepinephrine (NE) levels following a low sodium diet were associated with disturbed sleep in healthy young men, indicating that increased sympathetic nervous activity (SNS) may adversely affect sleep. To extend this finding we studied the sleep and nighttime NE levels of 7 healthy older men (61.7 ± 1.6) after four days of low (500), normal (2000) and high (5000mg/day) sodium diets presented in counterbalanced order. Sleep ratings and NE assays were made blind to condition. NE was significantly elevated ($p < .02$) in the low relative to the normal condition. No change in NE was seen in the high condition. No significant differences were observed in any measure of sleep or wakefulness across conditions. Although most measures of wakefulness (total wake time, number of wakes, etc.) were higher in the low compared to the normal condition, variability of these measures in the low condition was also higher obscuring possible differences in this small sample. These results fail to extend our findings of the relationship between elevated SNS activity and sleep disturbance to a healthy aged male sample. It is unclear whether this relationship does not exist in the elderly or is masked by the increased variability in physiological measures often seen in this population and specifically present in the low sodium condition.

292.2

DYNAMIC ANALYSIS OF CARDIAC AND RESPIRATORY COUPLING DURING SLEEP IN INFANTS. S.L. Raetz, A. Garfinkel, V.L. Schechtman, D.O. Walter*, and R.M. Harper. Brain Research Institute and Dept of Anatomy & Cell Biology, UCLA, Los Angeles, CA 90024-1763.

During maturation, physiologic systems couple and decouple, therefore measures of the degree of coupling between systems provide useful indices of development. Traditionally, linear measures (correlation, coherence) are used to assess coupling. We developed two nonlinear measures of association between physiologic variables: (1) mutual information, applied to the cross-plot of two variables, and (2) statistical dependency of changes in one variable on changes in the other. When two variables are plotted on an x-y axis, mutual information is a measure of the extent which the value of one variable reduces uncertainty about the value of the other. When differences in one variable are plotted versus differences in another, chi-square procedures can assess the dependency of changes in one variable on changes in another. We assessed the degree of coupling between cardiac rate and respiration in seven infants who subsequently succumbed to sudden infant death syndrome (SIDS) and seven age- and sex-matched controls. We found that coupling changes with maturational age, and that the extent of cardiorespiratory coupling is significantly greater in this group of control infants than in the group of infants who subsequently succumbed to SIDS. EFFECTS OF CORTICOTROPIN-RELEASING FACTOR ON SLEEP AND RESPIRATION DURING SLEEP IN HEALTHY SUBJECTS. K. Mann*, J. Röschke, M. Nink*#, H. Lehnert#, U. Krause*#, J. Aldenhoff, J. Bever*# and O. Benkert*. Dept. of Psychiatry and Dept. of Endocrinology#, University of Mainz, D-6500 Mainz, Germany.

In a single-blind placebo controlled design the effects of corticotropin-releasing factor (CRF) on sleep EEG and respiration parameters during sleep were investigated in up to now 8 healthy male volunteers aged 24 to 30 years. After an adaptation night either 50 ug ovine CRF or placebo was administered intravenously as a bolus in two successive nights every hour from 0.00 h to 6.00 h. Polysomnography was performed between 23.00 h and 7.00 h, respiration was studied by thermistor measuring of nasal and oral air flow, thoracic wall movements and blood oxygen saturation.

Total sleep time and number of awakenings were not altered by CRF. Also, subjective perception of sleep quality was approximately identical following CRF and placebo administration. Sleep analysis according to the criteria of Rechtschaffen and Kales revealed only slight alterations in sleep architecture. REM sleep as well as slow wave sleep, particularly stage IV, showed a tendency to decrease under CRF, whereas light sleep, particularly stage I, tended to increase. Immediately after an injection of CRF mostly a stimulation of respiration could be observed with an increase of tidal volume over a time interval of a few minutes, whereas blood oxygen saturation was not markedly altered.

CIRCADIAN PHASE SHIFTS AND BENZODIAZEPINE-INDUCED LOCOMOTOR HYPERACTIVITY IN SIGHTED AND BLINDED HAMSTERS. T.A. Houpt*, Z. Boulos, M.C. Moore-Edde. Dept. Physiology, Harvard Medical School, and Inst. for Circadian Physiology, 677 Beacon St., Boston, MA 02215.

The benzodiazepines (BZD) may cause phase shifts in hamsters either by transiently attenuating light input to the circadian system, or indirectly by inducing locomotor hyperactivity with feedback effects on the circadian pacemaker. However, there have been few quantitative studies correlating BZD-induced hyperactivity with phase shifts under different lighting conditions. We compared the hyperactivity induced by diazepam (DZP) and triazolam (TRZ) in sighted and blinded hamsters.

Male golden hamsters were housed in running-wheel-equipped tub cages under LL (~200 lux) or after optic enucleation. Individuals were placed in a large tub cage (45cm x 38cm) at either CT5 or CT17. Infrared photocells divided the cage into 10cm x 13cm rectangles and mean distance (m) per 5 min. was reconstructed from the beam breakages. After 1 hr baseline, the hamsters received either 25mg/kg DZP or 0.5mg TRZ i.p., both in 0.25ml DMSO, and activity was recorded for 2 hrs. Six injections were given at each time for each drug and lighting condition. Both DZP and TRZ induced marked hyperactivity compared to baseline or vehicle (6 m/5 min), reaching a plateau ~1 hr post-injection. In LL, DZP induced similar levels of activity (CT6: 24 m/5 min, CT18: 26 m/5 min) and large phase shifts (CT6: 95 min adv., CT18: 171 min del.) at both time points. In blinded hamsters, DZP induced comparable advances at CT6 but delays at CT18 were greatly attenuated (16 min. del.), despite activity levels similar to those in LL. TRZ induced high levels of activity that were not different in LL and in blinded hamsters (CT6: 32 m/5 min, CT18: 43 m/5 min). However, TRZ induced larger phase shifts in LL (CT6: 191 min adv., CT18: 28 min del.) than in blinded hamsters (CT6: 95 min adv., CT18: 4 min del.).

Since optic enucleation attenuated BZD-induced phase shifts without reducing hyperactivity, we suggest that ambient light perception is necessary for maximal BZD phase shifts, particularly during subjective night. The light-modulating mechanism of BZD phase shifts may be independent of activity induction.

DIURNAL RHYTHM OF CORE BODY TEMPERATURE IS PHASE-ADVANCED IN RATS WITH A GENETICALLY UPREGULATED CHOLINERGIC SYSTEM P.J. Shiromani, H. Klemfuss, S. Lucero* and D.H. Overstreet Dept Psychiatry, San Diego VA Medical Center & UCSD, La Jolla, CA 92093

We examined the diurnal rhythm of core body temperature in a strain of rats with an upregulated central muscarinic receptor system. The Flinders Sensitive Line (FSL) were derived by selectively breeding rats for sensitivity to cholinergic agonists and, compared to randomly bred rats, FSL rats have increased density of muscarinic receptors in various brain regions. Previously, we showed that FSL rats have increased REM sleep (*Neuropsychopharmacology* 1:127-133, 1988) and this is in agreement with the cholinergic hypothesis of REM sleep generation. We now report that FSL rats have a phase-advanced temperature rhythm.

Six each male FSL and control rats were implanted with a Mini-Mitter transmitter in the abdominal cavity under Nembutal anesthesia and continuous temperature recordings were made for 30 days. Temperature data collected during the last two weeks of the experiment were analyzed. Under LD 12:12, FSL rats reached peak temperature 2 hrs and 37 minutes earlier compared to control rats. However, the 24 hr mean temperature and amplitude of the temperature rhythm were not different between the groups.

Carbachol, a cholinergic agonist has been shown to phase-shift circadian rhythms. Therefore, the increased muscarinic activity in the FSL rats might be contributing to the phase-advanced temperature rhythm. These findings are also relevant to depression because some patients with some types of depression show phase advances in a number of circadian rhythms, including temperature. These patients also have short REM sleep latency. Our finding of a phase advance in a rodent model with a known upregulated muscarinic receptor system is compatible with both the phase advance and the muscarinic overdrive theories of depression. These findings also further validate the usefulness of the FSL rats in the study of depression.

PROTEIN DIFFERENCES IN TAU MUTANT HAMSTERS: CANDIDATE CLOCK PROTEINS. J.E. Joy¹, G.S. Johnson¹, C.R. Merrill¹ and M. Menaker². ¹Lab. of Biochemical Genetics, NIMH Neurosciences Center, Washington D.C., 20032, ²Dept. Biology, University of Virginia, Charlottesville, VA 22901.

In the tau mutant hamster, the period of the circadian rhythm is shortened from about 24 hours to about 22 hours in heterozygotes and to about 20 hours in homozygotes. The inheritance pattern of the mutation suggests that it has occurred at a single locus. That a single gene is involved in regulating period suggests that its product(s) is close to the mechanism of the circadian pacemaker, and may even be a component of it. We used two-dimensional gel electrophoresis to look for protein differences among the different phenotypes that may provide clues to the molecular mechanisms of the pacemaker.

We found two sets of proteins that differ among the different phenotypes in gels from both SCN and cortical tissue. "Clock Spot 1" (~33 kD; pI 6.5) was found in all gels from wild type and heterozygous animals, but not in gels from homozygous mutant animals. The protein immediately below this was altered in the heterozygote gels. "Clock Spot 2" (~30 kD; pI 4.8) appeared as a chain of spots, which showed a striking difference in pattern between gels from wild type animals and those from mutant animals. These proteins should be useful as new tools to explore the biochemistry of circadian pacemakers.

292.11

PHOTOPERIOD-DEPENDENT DIFFERENCES IN THE FEEDING EFFECTS OF GROWTH HORMONE-RELEASING FACTOR (GRF) ADMINISTERED INTO THE SUPRACHIASMATIC NUCLEUS/MEDIAL PREOPTIC AREA (SCN/MPOA) OF THE HAMSTER F.J. Vaccarino, P. Sovran, M.R. Ralph, Dept. of Psychology, University of Toronto, Toronto, Ont., M5S 1A1

Previous studies from our laboratory have demonstrated that intra-SCN/MPOA injections of GRF stimulate feeding in rats. This effect is found during the light, but not dark photophase. Unlike rats, hamsters feed throughout the light-dark cycle, although they tend to hoard only during the active dark phase. The present study examined the feeding characteristics of GRF in hamsters.

Male golden hamsters with intra-SCN/MPOA cannulae implants were entrained to a 14:10 light:dark cycle and tested with GRF (1.0 picomole) in the dark and light photoperiods. Food intake and related behaviors were monitored for 90 min following injection.

GRF increased food intake and time spent eating in the light, but not dark, photoperiod. There were no significant effects on other behaviors. Together with work indicating that GRF phase advances activity rhythms in the hamster, these results suggest that GRF plays a role in circadian regulation of food intake. Supported by NSERC grants 35036 to F.J.V. and 43304 to H.R.R.

OSCILLATORY PROPERTIES OF BASAL FOREBRAIN NEURONS IN GUINEA PIG BRAIN SLICES. M. Mühlenthaler, A. Khateb, M. Serafin, B.E. Jones and A. Alonso, Dept. of Physiology, CMU, 1211 Geneva 4, Switzerland and *Montreal Neurological Institute, McGill University, Canada H3A 2B4

Although electrophysiological studies of basal forebrain neurons (BFn) have been performed in both in vivo and in vitro preparations, they have revealed little concerning the intrinsic properties of the cell population and particularly of the specific cholinergic and GABAergic neurons that are distributed through the region and project to the cerebral cortex. In the present study, neurons were recorded in guinea pig brain slices through the horizontal limb of the diagonal band and substantia innominata, where choline acetyl transferase (ChAT)- and glutamic acid decarboxylase (GAD)-immunoreactive neurons were localized. The recorded cells were filled with biocytin for subsequent morphological and histochemical study. A majority of the recorded BFn were characterized by the presence of a large afterhyperpolarization (AHP) and a transient rectification due to the presence of a strong A-current. In addition, they exhibited strongly voltage-dependent low threshold calcium spikes. In the hyperpolarized condition, this latter property was a major determinant in the manifestation of slow oscillatory activity. These results indicate that a class of BFn may behave in a manner similar to thalamic or some cortical pyramidal cells by displaying two modes of firing: a tonic mode, when the cells are at or above their resting potential, and an oscillatory mode when the cells are hyperpolarized. Although the chemical identity of the neurons is not yet determined, our data indicate that certain BFn that are functionally as well as anatomically linked to other rhythmic prone systems of the thalamus and limbic and neocortex, also have the intrinsic ability to oscillate. THYROPARATHYROIDECTOMY (TPX) SHORTENS THE FREE-RUNNING CIRCADIAN ACTIVITY PERIODS OF BLINDED MALE AND FEMALE RATS. D.L. McEachron, Department of Psychology, University of Pennsylvania, Philadelphia, PA 19104

Previous experiments have demonstrated that sighted TPX male rats display significantly shorter free-running activity periods in constant dim red light when compared with sham-operated (Sham) controls (Schull, et al., 1988). Intact sighted female rats displayed significantly shorter activity rhythms when compared to intact sighted males, and TPX surgery did not significantly change their free-running periods (Schull, et al., 1989). In both experiments, the masking effects of light appeared enhanced in TPX animals. The objective of this experiment was to determine: 1. if TPX-induced period changes were mediated by altered light sensitivity; and 2. if sex differences in the effects of TPX surgery could be confirmed.

Forty-eight blinded Sprague-Dawley rats were divided into 4 groups: male Sham; male TPX; female Sham; and female TPX. Each rat was individually housed in a metal cage with an attached running wheel. Cages were housed in groups of 6 in light-tight cabinets. Animals were allowed to free-run for 8 weeks, the last 6 of which were used for period estimation. Periods were calculated by raters using computer-generated actograms, and the averages of 2 such estimates were used in the statistical analysis. Analysis showed that TPX rats displayed significantly shorter activity periods ($F=8.35$, $p<0.01$) but that there was no sexual dimorphism in activity periods ($F=0.008$, ns) nor interaction of sex with thyroid state ($F=0.282$, ns). Evidently, TPX surgery does alter central mechanisms involved in circadian activity rhythms but these mechanisms are not sexually dimorphic.

292.12

GRF: A POSSIBLE NEUROCHEMICAL CONNECTION BETWEEN FEEDING AND CIRCADIAN RHYTHMICITY. M. R. Ralph, P. Sovran and F.J. Vaccarino. Dept. of Psychology, Univ. Toronto, Toronto, M5S 1A1, Canada.

Daily rhythms of ingestive behavior are under the influence of a central circadian pacemaker. In turn, schedules of restricted feeding opportunities are effective in entraining freerunning circadian rhythms in rodents. However, neural substrates for this effect have not been identified. We have hypothesized a role for GRF (growth hormone releasing factor) for a number of reasons: (1) GRF increases feeding behavior in rats and hamsters; (2) the effect of GRF depends on the time of day; and (3) the suprachiasmatic nucleus (SCN) is a site of this GRF action.

We tested the hypothesis by asking whether central injection of GRF through cannulae aimed at the SCN would induce either permanent or transient changes in the phase of freerunning locomotor rhythms in hamsters. GRF (1.0 pmole in 1.0 µl saline) induced permanent phase shifts of the locomotor rhythm. Magnitude and direction were circadian phase dependent, and the resulting PRC was similar in shape to other non-photic curves: eg. large phase advances were predominant in the early subjective day. The results suggest a role for GRF in mediating effects of restricted feeding opportunities on the clock. GRF may be involved in a positive feedback loop connecting a specific rhythmic behavior with the control of rhythm generation. Supported by NSERC grants 43304 to MRR and 35036 to FV.

AGONISTIC BEHAVIOR IN JUVENILE AMERICAN LOBSTERS. R. Huber* and E.A. Kravitz. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

A quantitative study of agonistic behavior in juvenile American lobsters (*Homarus americanus*) demonstrates that fighting proceeds according to strict rules of conduct. Detailed analysis of encounters in ten pairs of behaviorally naive individuals, who were closely matched in size and molt state, indicated that six common agonistic behavioral patterns were displayed by all individuals in a highly stereotypical manner. Furthermore, the data revealed a distinct temporal sequence to these behavioral patterns during a fight. Upon first contact the opponents exhibited extensive threat displays, followed by periods of restrained contact and ritualized fighting. If no winner emerged by this point, the fight culminated in a brief period of unrestrained combat. Claws are dangerous weapons in these fights; therefore the observed orderliness of the encounters may be interpreted in evolutionary terms as effectively reducing the potential for damage. The presence of a rigidly structured behavioral system in this species should prove to be a considerable advantage in attempts to relate fighting behavior to the action of neuromodulatory substances like serotonin and octopamine. Preliminary experiments, relating individual differences in fighting behavior to the action, concentration or metabolism of amines, will be presented (Supported by Harvard and NINDS).

293.3

ALPHA2-ADRENOCEPTORS IN THE BRAINS OF CHRONICALLY STRESSED TREE SHREWS. G. Flügge, O. Jöhren, and E. Fuchs. German Primate Center, 3400 Göttingen, FRG.

Male tree shrews (*Tupaia belangeri*) defend their territories vigorously against intruders. When a male lives in the same cage together with another male a persistent dominant-subordinate relationship will be established within a short time. Thus, tree shrews provide a useful model for studying the physiological consequences of chronic psychosocial stress. Dominant (DOM) and subordinate (SUB) individuals can be distinguished by physiological parameters such as body weight, urinary catecholamine concentration and by behavioral parameters. In DOM animals, the activity of the sympathico-adrenomedullary system is clearly increased.

Since we are interested in the central nervous effects of persistent stress we quantified alpha₂-adrenoceptors in the brains of 8 DOM and 8 SUB by *in vitro*-autoradiography with the antagonist ³H-rauwolscine (³H-RAU). Significant differences in numbers of ³H-RAU binding sites were detected in two medullary nuclei: In the nucleus of the solitary tract (SOL) and in the dorsal motor nucleus of the vagus (X). Since SOL and X are both involved in the transfer of peripheral signals like those from the baroreceptors to the brain, the difference in adrenoceptor numbers may be related to changes in blood pressure which can be observed in DOM during confrontation with the male conspecific.

CONDITIONED NOREPINEPHRINE RESPONSE IN THE OLFACTORY BULB OF 7 DAY-OLD RAT PUPS. C.L. Kirstein, F.B. Weihmuller, J.F. Marshall and M. Leon. Dept. of Psychobiology, University of California, Irvine, CA 92717.

Young rat pups learn to prefer an odor which has been paired with tactile stimulation. This tactile stimulation has been shown to activate noradrenergic locus coeruleus neurons, which project heavily to the olfactory bulb. NE input is present and functional in the olfactory bulb as early as the first postnatal week. Moreover, noradrenergic antagonists can block this early learning.

To determine whether tactile stimulation increases NE overflow in the bulbs of naive pups we used *in vivo* microdialysis to monitor extracellular NE. Tactile stimulation to awake 7 day-old pups increased NE, while odor alone had no effect on NE overflow.

To study the subsequent NE response to a learned odor, we trained rat pups from postnatal days 1-6 (P1-6), with odor and stroking presented in either a paired (forward) or unpaired (backward) fashion. On P7, odor presentation in forward-trained pups increased NE overflow, while the backward stimulus experience did not elicit this conditioned response. These results suggest that conditioned neurotransmitter responses may play a role in the expression of the neural and behavioral changes accompanying early olfactory learning.

293.2

DIFFERENTIAL INDOLAMINE AND CATECHOLAMINE ACTIVATION FOLLOWING AGGRESSIVE INTERACTION IN MALE LIZARDS. C.H. Summers* and N. Greenberg. Calif. State Univ. San Marcos, CA 92096 and Graduate Program in Ethology, University of Tennessee, Knoxville, TN 37996.

Reproductively active male *Anolis carolinensis*, were paired, allowed to fight, and set up dominant/subordinate relationships. While combatants cohabited, the losers of the fights displayed darker color, selection of lower sites, and lower body posture. At one hour, one day, one week, and one month after the fight both dominant and subordinate individuals were sacrificed. Each member of a pair was killed at the same time and animals kept isolated were sacrificed as controls. Brains were rapidly removed and dissected on ice, frozen at -70°C, and then hindbrains were analyzed for indolamines and catecholamines by coulchem electrode array HPLC. Rapid activation of the serotonergic system of losing male lizards is evident from depleted 5-HT levels, increased 5-HIAA levels and 5-HIAA/5-HT ratio. Substrate 5-HTP also increases in losing males, suggesting an activation of production as well as turnover. Significant 5-HTP and 5-HIAA/5-HT increases for subordinate males, compared with levels in control and dominant males, were greatest at one hour and diminished with time. This pattern of indolamine activation is consistent with stress-induced psychogenic stimulation of the serotonergic system and with prolonged activation of stress mediation in subordinate animals.

In contrast with serotonin, dopamine systems were progressively activated as time of interaction increased, in both dominant and subordinate males. Early noradrenergic activation, indicated by normetanephrine/norepinephrine ratio, also decreases with time in losing males, except that the systems are again active after one month of cohabitation of paired males. Patterns of MHPG, epinephrine, and metanephrine activity are significantly different from those of NE/normetanephrine. Differences in measures of adrenergic and noradrenergic activation indicate a significant role for central epinephrine in the lizard's accommodation of social stress.

293.4

THE EFFECTS OF NORADRENERGIC NEUROTOXIN, DSP-4, ON WATER MAZE TASK DIFFER BETWEEN YOUNG AND AGED RATS.

J. Sirviö, P. Riekkinen Jr., A. Valjakka* and P.J. Riekkinen. Dept. of Neurology, Univ. of Kuopio, P.O.Box 1627, Kuopio, Finland.

The present study investigated the role of central noradrenergic system in spatial learning/memory. The effects of noradrenergic neurotoxin, DSP-4, on the acquisition of water maze task were investigated in young and aged rats. Young (4-month-old) and aged (22-month-old) male Wistar rats were treated with DSP-4 (N-(2-chloroethyl)-N-ethyl-2-bromo-benzylamine) 50 mg/kg (ip) or saline. Ten days after treatment, rats were trained in a water maze task for 4 days (3 trials/day) using a hidden platform procedure. DSP-4 treatment impaired the acquisition of water maze task (expressed using escape distance) in aged rats ($F(1,235)=10.1, p<.005$), but it slightly improved in young rats ($F(1,252)=7.3, p<.01$). Previously, it has been shown that even almost complete depletions of forebrain noradrenaline do not impair place navigation in normal adult rats. On the other hand, DSP-4 treatment may aggravate muscarinic receptor blockade (scopolamine) induced place navigation impairment. Because spatial navigation deficit may be related, at least partly, to the dysfunction of basal forebrain cholinergic system in aged rats, DSP-4 treatment induced spatial learning/memory deficit in aged rats may be due to aggravation of cholinergic dysfunction in these rats. It is also possible that DSP-4 treatment impaired the use of some learning strategies other than navigation by distal cues which might be important for aged rats in the solving of water maze task.

293.6

EFFECTS OF ISOLATION REARING ON INDICES OF DOPAMINE FUNCTION IN THE RAT. F.S. Hall, L.S. Wilkinson*, D.A. Kendall*1, C.A. Marsden1 and T.W. Robbins. Experimental Psychology, University of Cambridge, Cambridge CB2 3EB. 1Physiology and Pharmacology, University of Nottingham, Nottingham NG7 2UH. U.K.

Rats reared in isolation exhibit a variety of behavioural disturbances. In particular, isolates are spontaneously hyperactive, display increased responding in reward-related situations and show deficits in the expression of schedule-induced behaviours. The present study examined the effects of isolation rearing on pre- and postsynaptic indices of dopamine function in the nucleus accumbens (NAC). In the first experiment male weanlings (21 days postnatal) were divided into isolates and social controls. After 90 days the animals were anaesthetised with halothane and extracellular dopamine monitored using *in vivo* microdialysis. The dose-response curve for d-amphetamine (dose range 0.5-4mg/kg s.c.) was shifted to the left. In the second experiment weanlings were isolated as above and then NAC tissue taken for dopamine receptor linked adenylate cyclase activity measurements. Isolation rearing had no effect on the D1 response but the inhibitory action of D2 receptors on the D1 response was attenuated. These data suggest that isolation rearing can have effects on both pre- and postsynaptic dopamine mechanisms in NAC by increasing dopamine release and down-regulating D2 receptors, respectively.

THE RAT PUP ULTRASONIC CALL PREDICTS ANXIOLYTIC AND ANXIOGENIC EFFECTS OF 5-HT LIGANDS. J.T. Winslow and T.R. Insel. Lab. Clin. Sci., NIMH, Poolesville, MD, 20837

A modulatory role for serotonin has been described for the development and expression of the ultrasonic call of infant rat pups during brief maternal separations. Serotonin reuptake inhibitors selectively reduced the rate of calling following acute administration to 10 day old pups and a serotonin neurotoxin (MDMA) systematically disrupted the development of ultrasonic vocalizations. Acute administration of 5HT_{1A} agonists buspirone and 8-OH-DPAT (\pm)-8-hydroxy-2-(di-N-propylamino)tetralin) reduced the rate of calling at doses which did not affect motor activity or core body temperature. Administration of purported 5HT_{1B} receptor agonists, CGS12066B and TFMPPP increased the rate of calling depending on receptor specificity. d,l-Propranolol, a 5HT₁ receptor antagonist, blocked the effects of both 8-OH-DPAT and TFMPPP. m-CPP and DOI, drugs with putative actions at 5HT_{1C} and 5HT₂ receptor sites both decreased calling but differed according to their effects on motor activity. Ritanserin, a 5HT₂ and 5HT_{1C} antagonist, produced a dose related increase in call rate. A dose of ritanserin with no apparent intrinsic effects effectively antagonized DOI but potentiated the effects of m-CPP. These data confirm a role for serotonin in the expression of rat pup separation calls and further demonstrate that 5HT may increase or decrease calling depending on which receptor subtype is affected. This rat pup separation test appears to have great potential for elucidating the brain mechanisms mediating the development of anxiety-related behavior.

293.9

CIRCANNUAL CHANGES IN 5-HT FUNCTION: AN HYPOTHESIS REGARDING FLUOXETINE-INDUCED SUICIDALITY. T.D. Brewerton. Institute of Psychiatry, Medical Univ. of S.C., Charleston, SC 29425.

Although suicides occur significantly more frequently during the spring season (especially May), the pathophysiology of this phenomenon is unknown. Since serotonin (5-HT) has a major role in suicide/affective illness, it may be relevant that many parameters of 5-HT function in humans appear to exhibit seasonal changes and include hypothalamic 5-HT content, CSF 5-HIAA levels, Vmax of platelet 5-HT uptake and IMI binding, plasma L-TRP levels, and peak delta PRL responses to m-CPP and L-TRP. Taken together, these data suggest that spring is associated with the most rapid rate of increasing 5-HT turnover, which in turn may be associated with the observed spring increase in suicides. Although speculative, new onset suicidality reported to follow artificial enhancement of 5-HT function with fluoxetine (Am J Psych 147:207, 1990) and other antidepressants may mimic these seasonal changes thereby leading to increases in suicidal behavior. The clinical variables which may predispose certain patients toward such 5-HT hypersensitivity will be discussed and include gender, rate of dose increases, polypharmacy, and presence of suicidal ideation.

293.11

PLASMA PROLACTIN AND HOMOVANILLIC ACID AS MARKERS FOR PSYCHOPATHOLOGY AND DYSKINESIA DURING MAINTENANCE HALOPERIDOL TREATMENT IN MALE SCHIZOPHRENICS.

J.W. Newcomer, *S.J. Riney, *S. Vinogradov, *J.G. Csernansky. Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

The use of plasma prolactin concentration (PRL) and plasma homovanillic acid concentration (HVA) as indicators of central dopaminergic activity has been well investigated during acute neuroleptic treatment. We now report clinical symptom and side effect ratings, along with PRL and HVA, in 24 male schizophrenics during maintenance haloperidol treatment; 14 also underwent a placebo-controlled, double-blind 50% dose decrease. At baseline, an inverse correlation was confirmed between PRL and both dyskinesia ($r_s = -0.600$; $p < 0.005$, one-tailed) and "thought disorder" ($r_s = -0.343$; $p < 0.05$, one-tailed). Although positive and negative symptoms were not related, PRL was also correlated with negative symptoms ($r_s = 0.428$; $p < 0.05$, two-tailed). No relationship was found between HVA and any rated symptom at baseline. Twelve patients received an apomorphine challenge (0.02 mg/kg) at baseline, and a significant inverse correlation was also found between dyskinesia and apomorphine-induced decreases in PRL. In the patients who underwent a dose decrease, no relationship was found between PRL or HVA and any clinical variable. These data suggest that PRL, but not HVA, may be a useful marker of central dopamine function during maintenance neuroleptic treatment.

293.8

EFFECTS OF YOHIMBINE ON REGIONAL CEREBRAL BLOOD FLOW IN PANIC DISORDER. S. W. Woods, P. B. Hoffer*, C. J. McDougle, J. H. Krystal, G. R. Heninger, D. S. Charney. Depts. of Psychiatry and Diagnostic Radiology, Yale U. Sch. of Med., New Haven, CT 06508.

Previous work has shown that behavioral and plasma biochemical responses to the alpha-2 adrenergic antagonist yohimbine (YOH) are abnormal in psychiatric patients (PTS) with panic disorder (PD). The present study aimed to evaluate regional cerebral blood flow (rCBF) responses to YOH in PD and healthy subjects (HS) using single photon emission computed tomography (SPECT). **METHOD:** Thirteen drug-free PTS (5M, 8F, age 37±9 yrs) and 11 HS (2M, 9F, 37±15 yrs) underwent IV infusion of YOH 0.4 mg/kg or saline placebo (PLA) in balanced sequence on separate days. The rCBF tracer Tc-99m HMPAO was injected 15 minutes after YOH or PLA, followed by 40 min SPECT acquisitions (Strichman 810X Brain Imager, Medfield, MA). Data from image analysis blind to diagnosis and drug conditions were expressed as the percent change [(YOH - PLA)/PLA x 100%] in the region of supratentorial whole brain rCBF ratio. **RESULTS:** As expected, YOH-induced, PLA-corrected visual analog rating scale increases in anxiety were greater in PTS than in HS (34±26 vs 9±14 mm, $p < .01$). Preliminary analyses suggest that YOH significantly reduced frontal rCBF ratios bilaterally in PTS compared to HS (right, -3.9±1.0 vs -0.5±2.2 %, $p < .001$; left, -1.5±2.5 vs 0.4±1.4 %, $p < .05$). YOH tended to increase cerebellar ratios in both PTS and HS. **DISCUSSION:** The data are consistent with studies showing that frontal cortical rCBF and neuronal activity decrease with noradrenergic neuron stimulation and suggest roles for altered noradrenergic regulation of frontal cortical neuronal or vascular function in the pathophysiology of PD.

293.10

IN VIVO HIPPOCAMPAL NOREPINEPHRINE RELEASE AND LEARNED HELPLESSNESS. F. Petty, G.L. Kramer*, L.A. Speece*, and T. Phillips*. Dept. Psychiat., VA Medical Center, University of Texas Southwestern Medical School, Dallas, TX 75216.

A role for norepinephrine (NE) in the behavioral depression caused by inescapable stress has long been postulated (Weiss, 1981, Brain Res. Rev. 3:167). Since then, hippocampal NE was found necessary for development and maintenance of learned helplessness (LH) and for its reversal by antidepressant drugs (Soubrie et al., 1987, Brain Res. 437:323). We have previously shown micro-injection of NE into HPC to prevent LH. We have applied *in vivo* microdialysis to measuring extracellular NE in HPC in LH. Rats were perfused before inescapable tailshock stress, 1 day after stress, and after shuttlebox testing for LH (Day 3). Also high K⁺ release was performed after the basal release on Day 3. Unstressed controls demonstrated a gradual decrease in basal HPC NE release during the 3 experimental days, presumably due to gliosis. Rats receiving tailshock stress maintained basal release at prestress levels. On Day 3, after testing, there was a significant difference between control, and stressed rats with high escape latencies (LH) in basal release. There was a significant positive correlation between stress-induced NE release and latency on testing, suggesting that greater NE release accompanies the development of LH. K⁺ stimulated NE release was lower in both stressed groups (LH and non-LH) than control, suggesting stress had depleted intraneuronal NE stores. Taken together, these findings support an important role for NE in HPC in the development of LH.

VENTRAL ORIGIN OF A2B5-IMMUNOREACTIVE GLIAL PRECURSOR CELLS IN THE DEVELOPING RAT SPINAL CORD. Juin Fok-Seang and Robert H. Miller, Department of Neurosciences, Case Western Reserve University, School of Medicine, Cleveland, OH 44106.

Cultures of newborn rat spinal cord contain two distinct populations of migratory A2B5-immunoreactive glial precursor cells. One population, which resembles optic nerve O-2A progenitor cells, gives rise to oligodendrocytes and possibly to type-2 astrocytes, while the other, which has been called MARPs (Migratory Astrocyte-Restricted Precursors), gives rise to distinct classes of astrocytes and not to oligodendrocytes. These two precursor populations also differ in their response to certain mitogenic and differentiation factors in tissue culture.

Explant and dissociated cell cultures in combination with immunocytochemical analysis were used to show that at early developmental stages, A2B5+ glial precursors were initially restricted to ventral regions of the spinal cord. Thus, at embryonic day 14 (E14), only ventral and not dorsal spinal cord regions subsequently gave rise to oligodendrocytes and MARP progeny. By E18, A2B5+ glial precursors were present in both the ventral and dorsal regions. The appearance of A2B5+ glial precursors in dorsal regions coincided with the acquisition by dorsal spinal cord of the capacity to give rise to oligodendrocytes and MARP progeny.

These observations suggest that both O-2A progenitor cells, which give rise to oligodendrocytes, and MARPs which give rise to distinct classes of astrocytes, initially develop in ventral spinal cord regions and subsequently colonize dorsal regions by a ventral-to-dorsal migration.

CLONAL ANALYSIS OF GLIOGENESIS IN THE NEONATAL RAT CEREBRAL CORTEX. K.W. McDermott^{*1}, E. Breding^{*1,2} and M.B. Luskin^{1,2}. Departments of Anatomy & Cell Biology¹ and Pediatrics², Emory University School of Medicine, Atlanta, GA 30322.

Previous studies have revealed that neuronal, astroglial and oligodendrocytic lineages have diverged in the developing rat cerebral cortex as early as the onset of cortical neurogenesis. However, it is presently unclear whether glial progenitor cells in the postnatal developing cerebral cortex are bipotential. We have now undertaken an ultrastructural analysis to investigate whether separate progenitor cells give rise to astrocytes and oligodendrocytes throughout gliogenesis.

A retroviral lineage tracer containing the reporter gene β -galactosidase (*lacZ*) from *E. coli* was injected into the cerebral ventricles of rat pups on postnatal day 1. Animals were perfused 1 to 2 weeks later and their brains were serially sectioned at 100 μ m. Sections were stained with X-gal to reveal *lacZ*(+) cells and subsequently processed for electron microscopy. Discrete groups of stained cells (clones) were identified from camera lucida drawings of *lacZ*(+) cells. The size of such groups varied between 2 and 30 cells. According to ultrastructural criteria, some clones appeared to be composed of a single phenotype. For example, some clones in the subventricular zone were composed entirely of immature glia. Other clones contained cells at different stages of differentiation appearing to be of a single phenotype. Further studies with cell-type specific markers should definitively determine the phenotypes of clonally related cells.

GLIOGENESIS AND GLIAL MIGRATION DURING EMBRYONIC FORMATION OF THE INSECT ENTERIC NERVOUS SYSTEM. P.F. Copenhagen, Cell Biology & Anatomy L215, Oregon Health Sciences University, Portland, OR 97201

The formation of the enteric nervous system (ENS) in the moth, *Manduca sexta* involves two distinct programs of neurogenesis: cells of the anterior enteric ganglia are derived from neuronal precursors that emerge from three neurogenic zones in the foregut epithelium, while the neurons of the enteric plexus (which spans the foregut-midgut boundary) are derived from a separate neurogenic placode. In both regions, neuronal differentiation is accompanied by the proliferation of a distinct population of non-neuronal glial cells that contribute to the structural integrity of the enteric ganglia and nerves. We now report that the neurons and glia of the insect ENS share a common developmental origin. Specifically, the neurogenic zones of the anterior enteric ganglia also produce a limited number of glial progenitor cells. Unlike the neuronal precursors from these zones, the glial precursors remain mitotically active during neuronal cell migration and ganglion formation. Labelling the precursors with a thymidine analogue and injecting individual glial progenitors with lineage-tracing dyes has shown that each glial precursor produces a population of cells that becomes progressively distributed along a particular domain of the ENS. Glial progeny become integrated into the enteric ganglia and also disperse along the migratory pathways of the placode-derived neurons. Thus glial migration follows neuronal migration and contributes to the differentiation of the enteric plexus, as well. We are currently investigating the regulatory interactions between neuronal and glial progeny of the ENS with respect to the timing and extent of glial proliferation and migration during development. Supported by NSF # BNS 9010538 and by the Medical Research Foundation of Oregon.

MIGRATION PATTERNS OF RAT SUBVENTRICULAR ZONE CELLS DURING POSTNATAL GLIOGENESIS AS REVEALED BY RETROVIRAL MEDIATED GENE TRANSFER. Steven W. Levison and James E. Goldman, Dept. of Pathology and Center for Neurobiology and Behavior, Columbia University, New York, NY 10032.

To study the migration patterns of glial progenitors, the BAG retrovirus was injected unilaterally into the anterior subventricular zone (SVZ) of P2-3 rats. At 2 days post injection (dpi) greater than 70% of the infected cells (X-gal+) were within the SVZ. Few labeled cells were observed along the needle track. The labeled SVZ cells were approximately 10 μ m in diameter with a single process. During the next 3 weeks labeled cells appeared in overlying white matter, cortex, and adjacent striatum. Labeled cells were not observed in the SVZ after 21 dpi. The apparent direction of migration was medial to lateral since migration along the rostral caudal axis was generally restricted to a few millimeters from the injection site. Labeled cells were rarely observed in the other hemisphere. Radial arrays of labeled cells were common as were clusters. Discrete clustering suggests that glial precursors can divide once they reach their final destinations. Based on morphological criteria, the large majority of labeled cells in white matter were oligodendrocytes. Myelinating oligodendrocytes first appeared 14 dpi. In grey matter satellite oligodendrocytes were observed as well another population of neuroglia. These cells had round perikarya and several processes, often emerging as thick trunks, that branched extensively a distance from their origin. Many of these cells had processes contacting blood vessels. Experiments are in progress to characterize these cells further. Thus in early postnatal development SVZ generates several populations of neuroglia. Supported by NS17125-09 and MH-15174-14.

GLIAL CELL DEVELOPMENT AND REGIONAL SPECIALIZATION IN XENOPUS SPINAL CORD. C.E. Maier and R.H. Miller, Dept. of Neuroscience, Case Western Reserve Univ. Cleveland OH 44106

Glial cell development has been examined in the spinal cord of developing *Xenopus* using antibodies specific for astrocytes and oligodendrocytes. At Nieuwkoop and Faber stages 44/45, labeling of transverse and longitudinal frozen sections of spinal cord with anti-GFAP antibodies demonstrated the presence of radially oriented astrocytes that spanned the entire width of the developing cord. Though radial astrocytes were found in both dorsal and ventral regions at these early stages, the earliest immunoreactive oligodendrocytes were restricted to the ventral white matter. At later stages (54/55) immunoreactive oligodendrocytes were seen ventrally and focally in developing dorsal columns but not laterally. The distribution of oligodendrocytes and myelin was confirmed at this stage by ultrastructural analysis. In the adult, oligodendrocyte labeling was seen throughout the spinal cord white matter. Anti-GFAP labeling of astrocytes remained radially oriented and continuous from the central canal to the pial surface. The labeling of astrocytes by an anti-radial glia antibody, however, was restricted to the white matter, suggesting a regional specialization for astrocytes. These observations imply that: 1) astrocytes develop before oligodendrocytes, 2) during development oligodendrocytes appear in a ventral to dorsal gradient, 3) during development myelination is not associated with changes in radially oriented astrocyte labeling. These observations suggest that, in *Xenopus*, oligodendrocytes are not derived from GFAP positive radial glial cells.

294.6

DEVELOPMENT OF SATELLITE GLIA IN THE RAT SUPERIOR CERVICAL GANGLION. A.K. Hall and S.C. Landis, Dept. Neurosciences, Case Western Reserve Univ. School of Medicine, Cleveland, OH 44106.

Both neurons and glia in peripheral ganglia arise from the neural crest, but little is known about the subsequent maturation of satellite glia in these ganglia. Morphological, immunocytochemical and culture techniques were used to examine the division and migration of glial satellite precursors in the developing rat superior cervical ganglion (SCG). Numerous clusters of non-neuronal cells were present transiently in the ganglion at embryonic day 18. The clustered cells appear to be generated from individual precursor cells with a similar morphology which are observed at E16. At E18, the clustered cells possessed a characteristic appearance and were morphologically distinct from neurons, as well as from endothelial cells and fibroblasts in the ganglion. An antibody to tyrosine hydroxylase (TH) was used to identify the adrenergic neurons in the E18 ganglion, and propidium iodide (PI) counterstaining to visualize all cell nuclei. The E18 ganglion contained doubly stained neurons as well as clustered cells stained with PI which lacked detectable TH immunoreactivity, consistent with their identification as non-neuronal cells. To assess the possibility that cell clusters arose from cell division, BrdU was administered to pregnant mothers between E16 and E18, and cells in the ganglia examined at E18. Numerous non-neuronal cells divided during this period, and could compose clusters, but few neurons were labelled. An antibody against the low affinity NGF receptor, MAb 217c, was used to identify ganglionic glia. Over half of the 217c immunoreactive glia incorporated BrdU in vivo during this labelling period, consistent with a high level of glial division. The non-neuronal cells were no longer in clusters at birth, but instead were associated with neuronal cell bodies and processes. These findings support the notion that, between E16 and E18, after the peak of neurogenesis, glial precursors divide rapidly to form clusters, and their daughter cells subsequently migrate throughout the ganglion to associate with nerve cell bodies and processes.

DEVELOPMENT OF GFAP-POSITIVE CELLS IN THE CA1 REGION OF THE RAT HIPPOCAMPUS. B. E. Nixdorf, D. Albrecht*, U. Heinemann*, Department of Neurophysiology, University of Cologne, 5000 Cologne 41, FRG.

Astrocytes are thought to play a major role in the maintenance of ion homeostasis. Our electrophysiological experiments have shown that the ceiling levels of extracellular potassium concentration ($[K^+]_o$) induced by extensive neuronal activity is higher in young animals than in adults (Albrecht and Heinemann, *Dev. Brain Res.* 48:316, 1989). These differences between young and adult animals may be due to a limited maturation of the potassium buffering via glia cells in young animals. Therefore, we have studied the development of GFAP-positive cells in different laminae of the hippocampus of the rat in animals of 8, 16, 24 days and in adults. The data of a total of 271 slices were compared in a one way analysis of variance using SYSTAT. Our results have shown that in very young animals (8d) the glial cell population is very small and therefore, may be unable to buffer the high $[K^+]_o$ from the extracellular space. The quantitative analysis on the number of GFAP-positive cells reveals a different temporal pattern for the development in the different laminae. The adult value of GFAP-positive cells is reached in Stratum oriens at 16 days, in S. radiatum and S. moleculare at 24 days. However, the high $[K^+]_o$ can also be observed in the age groups of 16 and 24 days where the number of glial cells had reached adult values. The discrepancy between electrophysiology and GFAP ICC may be due to a different time course in the structural and functional maturation of the glial network. Investigations on the connectivity (e.g. via gap junctions) in the glial cell population may give insight to the functional status of the glial network. Supported by the Sander Foundation.

CULTURED MICROGLIAL CELLS AND A SUBPOPULATION OF BONE MARROW DERIVED MACROPHAGES HAVE A DISTINCT PATTERN OF MEMBRANE CHANNELS DIFFERENT FROM BODY MACROPHAGES. D. Hoppe, K. Gottmann*, B. Banati, G. Kreutzberg and H. Kettenmann, *Max-Planck-Institut für Psychiatrie, Am Klopferspitz 18A, 8033 Planegg-Martinsried, Germany.

Microglia are a population of resident macrophages ubiquitously distributed in the central nervous system. Sharing a number of antigenic and morphological characteristics with macrophages from other tissues they cannot be readily distinguished from body macrophages. The patch-clamp technique, however, revealed that microglia express a distinct, different pattern of ion channels. While body macrophages normally have voltage activated outward and inward currents, cultured microglia lack the outward current and express only an inwardly rectifying K^+ current. The reversal potential in different K^+ gradients and the sensitivity of the current to Ba^{2+} , TEA and 4-AP indicates that this current is K^+ selective. In single channel recordings a 30 pS K^+ selective channel was observed which is similar to the classical inward rectifier K^+ channel. Since the origin of microglia is still under discussion we studied cells of the monoclonal phagocyte system, the stem cells of the macrophages. A subpopulation of bone marrow derived macrophage-like cells indeed expresses an inward rectifier K^+ channel similarly to microglia. These results suggest that, firstly, microglial cells form a unique cell population and secondly, may originate from a stem cell population of bone marrow.

DISTRIBUTION AND CHARACTERIZATION OF MICROGLIA IN THE NORMAL HUMAN FETAL BRAIN. L.A. Mattiace, C. Brosnan* and D.W. Dickson, Dept of Pathology, Albert Einstein College of Medicine, Bx, NY 10461.

Fetal brain tissue obtained from 17 week to 24 week abortuses from HIV seronegative mothers, were examined in serial sections, histochemically, with the lectin RCA-1, and immunocytochemically, with antibodies that detect microglia. These markers included FcγRI, EBM/11, KP1 and LN-3. FcγRI appeared to be the most consistent marker for all forms of microglia, immunolabeling the most highly ramified cells, in addition to the less differentiated cells, which include round and amoeboid microglia. In comparison, macrophage markers EBM/11 and KP1, which recognize CD 68, immunolabeled round cells and amoeboid microglia in the subventricular zone, and to a lesser extent microglia with more ramified processes throughout the developing cortical layers and subcortical grey and white matter. LN-3, an antibody to the major histocompatibility complex class II antigen (HLA-DR), was unexpectedly expressed on microglia in the fetus. Morphologically, LN-3-immunoreactive microglia appeared to be either round and more rarely amoeboid cells with few processes. Their distribution was restricted to the subventricular zone and adjacent areas. The absence of HLA-DR on highly ramified cells, which are considered a more differentiated form of microglia, suggests that the phenotypic expression of HLA-DR may be lost with maturation. The characterization of normal microglia and their genesis may have implications for the understanding of the pathogenesis and pathophysiology of AIDS, since microglia are the main cell type that is productively infected by HIV-1 in the CNS, and since HIV-1 gp120 shares homology with HLA-DR, a marker of microglial activation. Supported by USPHS grant MH 47667.

SURVIVAL OF MICROGLIA IN CULTURES DEPENDS ON AUTOCRINE SECRETION OF CSF-1 INDUCED BY LPS. C. Hao, I. Ahmed and S. Fedoroff, Department of Anatomy, College of Medicine, University of Saskatchewan, Saskatoon, Sask. Canada S7N 0W0

Survival, differentiation and function of normal microglia depend on CSF-1 paracrine secretion by astroglia. Microglia themselves normally do not secrete CSF-1, but have receptors for CSF-1 (Hao et al., *J. Neurosci. Res.* 27:364-323, 1990). To determine whether the secretion of CSF-1 in microglia can be induced, we stimulated microglia of C3H/HeJ mice in cultures with bacterial wall lipopolysaccharides (LPS) at a concentration of 10 μ g/ml for 24 h. The microglia released approximately 100 U of CSF-1/ml, i.e., 4-5 times less than astroglia secrete. To determine whether the LPS stimulation of microglia persists, we set up three sets of microglia cultures. The first were grown in regular growth medium to which CSF-1 was added and the second set had only regular growth medium. The microglia in the third set of cultures were stimulated with 10 μ g/ml LPS for 24 hours, the cultures were washed, and regular medium, without CSF-1, was added. The cultures in the first set (with CSF-1) grew and proliferated throughout the experimental period of 3 weeks. Cells in the second set (grown without CSF-1), all died within 8-10 days and the cells in the third set (grown without CSF-1) survived 3 weeks in cultures similar to those of the first set. These results indicate that LPS induces autocrine secretion of CSF-1 in microglia and that the amount of CSF-1 produced is sufficient for their survival but not proliferation.

EXPRESSION OF AN INTERMEDIATE FILAMENT-RELATED ANTIGEN IN A SUBGROUP OF CULTURED TYPE-1 ASTROCYTES AND IN ASTROCYTES OF POSTNATAL AND ADULT SPINAL CORD OF RATS. H.-Y. Yang, N. Lieska*, D. Johnson-Seaton*, D. Shao*, V. Kriho* and G.D. Pappas, Dept. of Anatomy and Cell Biology, University of Illinois at Chicago, Chicago, IL 60612.

Intermediate filament (IF) cytoskeleton is characterized by both IF structural proteins and IF-associated proteins (IFAPs). There is substantial evidence showing that the expression of various IF structural proteins is intimately related to astrocyte development (e.g., vimentin and GFAP in immature and mature astrocytes, respectively). Recently, we have described the differentiation-related expression of IFAP-70/280kD, a vimentin-associated IFAP originally identified in BHK-21 cells, in radial glia and in a subgroup of cultured type-1 astrocytes of rats (*Soc. Neurosci. Abstr.* 16 (1):352).

In the present study, a monoclonal antibody (3-16C5) which reacts with the astrocytic IF cytoskeleton was produced by the hybridoma technique using glial IF-enriched preparations as antigens. The IF preparations were isolated from primary astrocyte cultures obtained from neonatal rat brain. The immunoreactivity of 3-16C5 was studied in normal and colchicine-treated primary cultures of neonatal rat astrocytes by double-labeling immunofluorescence microscopy using 3-16C5 and GFAP. The astrocytes were identified by the GFAP antibody. The results revealed that the 3-16C5 antigen is present in a subgroup of non-stellate (type-1) astrocytes, but not in the stellate (type-2) ones. In addition, the co-distribution of this antigen with GFAP-containing IF cytoskeleton, both in normal and colchicine-treated astrocytes, indicates that it is a glial IF-related antigen.

The ontogeny of the 3-16C5 antigen was also investigated by immunofluorescence microscopy in spinal cord of rats from embryonic day 19 (E19) to postnatal day 12 (P12), as well as adult. The 3-16C5 immunoreactivity is not present in prenatal spinal cord, and is first detected in the peripheral region of newborn rat spinal cord. It is present only in the astrocytes in white matter of the rat spinal cord by P12 and in both white and gray matter of the adult spinal cord. This development-related expression of 3-16C5 antigen suggests a dynamic role in astrocyte maturation and the potential for use of this IF-related antigen as a differentiation marker of astrocytes, both in vitro and in vivo. (Supported by NIH grant NS26396.)

THE DEVELOPMENT OF CUTANEOUS PEPTIDE-CONTAINING NERVES IN MAN. J.M. Polak, M. Sundaresan, *G. Micosco, G. Terenghi, Histochemistry Department, RPMS, Hammersmith Hospital and *Department Morbid Anatomy, King's College School of Medicine, London, UK.

Classical neuroanatomical studies have investigated the skin innervation during foetal development, but little information is available on the development of cutaneous sensory and autonomic neuropeptide-containing nerves. There is evidence that in the foetus the reflex arc is functional at 8 weeks, which is consistent with the detection of sensory neuropeptides CGRP and SP in spinal cord at 10 weeks gestation. In this study we have assessed the developmental pattern and distribution of CGRP, VIP, SP and NPY-immunoreactive nerves, as well as those of the neuronal marker PGP, in various areas of foetal skin. At 6 weeks gestation, thick and club-shaped PGP-immunoreactive nerves were first seen in all skin areas, mainly distributed in the parallel portion of the subepidermal plexus. Only at later ages (10-12 weeks), thin twig-like nerves extend from this plexus to penetrate the epidermis. At 9 weeks, more PGP-immunoreactive nerves were seen in skin of the palm than in the dorsum. Sweat glands were first noted in axillary skin at 17 weeks, accompanied by few PGP-immunoreactive nerves. Occasional small CGRP-immunoreactive fibres were first noticed in the dermis at 7 weeks, but it was at 17 weeks that this neuropeptide is unequivocally present in axillary dermis. Sparse VIP-, SP- and NPY-immunoreactive fibres are not found until 16-17 weeks gestation, when they are seen in the dermis and around small blood vessels. Developing cutaneous innervation shows immunoreactivity for sensory neuropeptides soon after neuronal protein markers are detectable, at a gestational age consistent with the reported reflex movements of the foetus. The results of this study show a close relationship between morphological and functional development of the peripheral nervous system which might compare to the neuronal regeneration processes observed in adult skin.

295.1

REMODELING OF SYNAPTIC EXTRACELLULAR MATRIX DURING NERVE TERMINAL SPROUTING IN LIVING FROG NEUROMUSCULAR JUNCTIONS. L. Chen* & C. P. Ko. Dept of Biol. Sci., Univ. Southern California, Los Angeles, CA 90089.

Remodeling of synaptic extracellular matrix (ECM) and its dynamic relationship with nerve terminal plasticity have been demonstrated in normal frog neuromuscular junctions (NMJs) *in vivo* (Chen et al., J Neurosci 1991, In Press). This work has led to a hypothesis that extension of synaptic ECM may precede nerve terminal growth during synaptic remodeling. To test this hypothesis, the dynamic relationship between synaptic ECM and nerve terminal during active growth of NMJs was examined in muscles in which nerve sprouting was induced. Sartorius muscles were double-stained with rhodamine conjugated peanut agglutinin (PNA) and 4-Di-2-Asp to label synaptic ECM and nerve terminals respectively. The identified NMJs were observed *in vivo* with a SIT camera attached to a fluorescent microscope. Nerve sprouting was then induced by placing segments of the contralateral sciatic nerve on the muscle surface. Two to three months later, the same NMJs were restained and reviewed as above. There were signs of extensive sprouting and growth in more than 50% of NMJs. Among these NMJs, about two thirds showed correlated extension of synaptic ECM and nerve terminals, while almost all of the rest had PNA staining longer than the terminal staining by at least 10 μ m. All of the extended, PNA-stained regions were devoid of cholinesterase staining which makes it unlikely that these regions had been occupied by nerve terminals that had retracted. Thus, these findings are consistent with the hypothesis that synaptic ECM recognized by PNA leads the nerve terminal outgrowth.

DIFFERENTIAL INDUCTION OF SCG-10 AND GAP-43 mRNA IN THE CONTRALATERAL CORTEX FOLLOWING UNILATERAL STRIATAL DEAFFERENTATION. H.W. Cheng, N. Mori and T.H. McNeill. Andrus Gerontology Center, University of Southern California, Los Angeles, CA. 90089

The present study was undertaken to identify molecular markers that characterize axonal outgrowth during reactive synaptogenesis in the striatum following a unilateral lesion of the corticostriatal pathway. Previously, we have reported that homologous axons from the contralateral cortex are induced to sprout paraterminal axons that reinnervate deafferented striatal cells; however, the genomic events that regulate neurite outgrowth after striatal deafferentation are unclear. In order to address this issue, we used northern blot analysis to assess changes in mRNA prevalence for growth associated protein (GAP-43), SCG-10 and P-19 in the contralateral cortex after a unilateral corticostriatal lesion. In addition, the time course for changes in mRNA prevalence was correlated with data from our previous morphological studies.

We found that both SCG-10 and P-19 mRNA in the contralateral cortex were increased by 13 fold at 3 days postlesion, followed by a gradual decline in message that remained elevated above intact controls at 27 days postlesion. This increase in SCG-10 mRNA could be blocked by cutting the corpus callosum. In contrast, the prevalence of GAP-43 mRNA did not significantly change from intact controls at any time after the lesion. These findings suggest that SCG-10 and P-19 are involved in the cellular events that characterized synaptic remodeling of the striatum following neuronal deafferentation. In addition, we hypothesize that during reactive synaptogenesis that SCG-10 and GAP-43 mRNA may differentially regulated in the brain based on the type of axonal outgrowth required at the lesion site (i.e. paraterminal vs collateral sprouting). Supported by PHS grants AG 00300, AG 09793 and the National Parkinson Foundation.

SYMMETRICAL B50/GAP43-IMMUNOREACTIVITY IN THE CAT SPINAL CORD CAUDAL TO A PARTIAL HEMISECTION. W. Nacimiento, A. Mautes*, A.C. Nacimiento, J. Noth, A.B. Oestreicher* and W.H. Gispen. Dept. of Neurology, Alfred Krupp-Hospital, 4300 Essen, F.R.G., Neurosurgical Research Laboratory, Saarland University Medical School, 6650 Homburg, F.R.G., and Division of Molecular Biology, Rudolf Magnus Institute, 3584 CH Utrecht, Netherlands

The neuron-specific phosphoprotein B50/GAP43 is involved in axonal outgrowth and synaptic plasticity during both ontogenesis and regeneration.

Sprouting of dorsal root axons (DRA) in the mature cat spinal cord caudal to a partial hemisection was evaluated by densitometric comparison of the B50/GAP43-immunoreactivity (IR) on both sides of the affected cord. The lesions were performed at the low thoracic level sparing the dorsal column. Thus, supraspinal descending projections to lumbosacral segments were removed leaving the ascending collaterals of DRA intact. The distribution pattern and density of B50/GAP43-IR was symmetrical in all segments below the hemisection at 2, 3, and 8 weeks postoperatively. The present result indicates that under the experimental conditions used functional plasticity in response to removal of descending pathways is not mediated by sprouting DRA reinnervating partially denervated spinal gray areas in adult cats.

295.2

EXOGENOUS CGRP PARTIALLY PREVENTS THE dTC INDUCED INCREASE IN INTRAMUSCULAR NERVE BRANCHING IN EMBRYONIC CHICKEN. Kubke, M.F. and Landmesser, L.T. Dept Physiol & Neurobiol., Univ. Connecticut, Storrs, CT 06269

Blocking neuromuscular activity in chicken embryos during the cell death period by *in ovo* treatment with d-tubocurarine (dTC), results in an increase in intramuscular nerve branching and a parallel increase in the number of synapses formed (Dahm & Landmesser '88,'91). Activity blockade in adult muscle also results in nerve sprouting at the neuromuscular junction. Calcitonin Gene-Related Peptide (CGRP) was previously shown to be present in motoneuronal cell bodies and nerve terminals during the periods of muscle nerve ingrowth and synaptogenesis (New & Mudge,'86). It was also shown to prevent tetrodotoxin induced neuronal sprouting in adult rat muscle (Tsujimoto & Kuno,'88). To test whether CGRP would prevent the inactivity induced increase in nerve branching in embryonic chick muscle, CGRP was applied to the chorioallantoic membrane at a dose of 50 ug/egg/day, simultaneously with 2mg/egg/day of dTC. This treatment resulted in a decrease in the amount of intramuscular nerve branching within the mixed (fast/slow) iliofibularis muscle when compared to treatment with dTC alone. The effects of CGRP were more pronounced in the fast than in the slow region of this muscle. These results suggest that CGRP may normally play a role during the formation of the intramuscular nerve branching pattern in embryonic development. Supported by NIH grant 19640.

UNILATERAL ENTORHINAL CORTEX/FIMBRIA FORNIX LESION (EC/FFL) INDUCES GAP-43 mRNA IN THE CONTRALATERAL HIPPOCAMPUS. McNeill, T.H., Cheng, H.W., Day, J.R. and C.E. Finch. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089.

Unilateral perforant path transection eliminates over 80% of the presynaptic input to the ipsilateral molecular layer of the dentate gyrus. Under these conditions, surviving axons (septohippocampal and C/A projections) are induced to sprout and form new synaptic contacts with deafferented target neurons. In addition, GAP-43 immunostaining in the ipsilateral hippocampus is markedly increased in the inner molecular layer of the dentate gyrus coincident with the time when C/A fibers begin to sprout axon collaterals. However, the increase in GAP-43 immunoreactivity has not been found to be associated with an increase in GAP-43 mRNA in the cells which project to this area.

In order to address this issue the present study was undertaken to determine if an increase in GAP-43 mRNA in commissural projection neurons to the dentate gyrus could be induced by altering the severity and/or neurotransmitter composition of the deafferentation lesion. This was accomplished by combining a unilateral entorhinal cortex lesion with a septohippocampal path transection (EC/FFL). Northern blot analysis of total RNA from the contralateral hippocampus revealed that there was an initial 2-fold decrease in GAP-43 mRNA at 3 and 6 days after the lesion, followed by a 3-fold increase in message at 14 days postlesion compared to unlesioned controls. *In situ* hybridization found that the increase in GAP-43 message was restricted to the CA4 and CA3 commissural projection neurons of the contralateral hippocampus. These results suggest GAP-43 mRNA may be differentially regulated in the hippocampus based on the severity and/or neurotransmitter composition of the deafferentation lesion. Supported by PHS grants AG 00300, AG 09793, AG 07909.

GAP-43 AND SBA IMMUNOLABELING OF AXOTOMIZED FINE PRIMARY AFFERENTS. R.E. Coggeshall¹, M.L. Reynolds², C.L. Woolf¹, A.A. Cameron¹ and C.M. Pover¹, ¹The Marine Biomedical Institute, Dept. of Anatomy and Neurosci. and Dept. of Physio. & Biophy., The Univ. of Texas Medical Branch, Galveston, TX 77550 and ²The Dept of Anatomy and Developmental Biology, Univ. College, London.

Peripheral nerve transection clearly results in changes in central primary afferent axons. Many of these changes result from such things as ganglion cell loss or interruption of axonal transport and are thus degenerative in nature. Regenerative changes are less well studied. Here we report the presence of growth cones immunolabeled by growth associated protein (GAP-43), the possibility that presynaptic terminals of fine primary afferent axons are withdrawing from their presynaptic targets and an areal increase in the distribution of reactivity to the lectin soybean agglutinin (SBA) in the superficial dorsal horn two weeks after sciatic nerve transection in adult rats. These changes are interpreted as regenerative in nature. If so, the indication is that there is regenerative sprouting of fine sensory axons following peripheral axotomy. CELLULAR AND MOLECULAR LOCI OF THE SELECTION OF TRANSMITTER RESPONSES DURING INNERVATION OF AN IDENTIFIED LEECH NEURON.

S. Catarsi*, S. Ching* and P. Drapeau, McGill Univ. Centre for Research in Neuroscience, Montreal, Quebec, Canada H3G 1A4.

Application of 5-HT activates both a Cl and a cationic conductance in the pressure-sensitive (P) neuron. However, the serotonergic Retzius (R) neuron evokes only a synaptic Cl response.

We cultured R and P cells so that their processes overlapped. Localized (~25 µm) application of 5-HT elicited depolarizing responses in untouched P cell bodies, neurites and growth cones. In contrast, the response of P cell neurites contacted by R cells appeared to be greatly reduced.

Cation channels in excised inside-out membrane patches from single P cells were activated in the presence of protein kinase C (PKC). In contrast, channels recorded from contacted P cells, were insensitive to 5-HT and phorbol esters. These results suggest that the cation channels are no longer activated by PKC at sites of neurite overlap. The lack of a synaptic cationic response *in vivo* may be a consequence of the localized contact between processes during development.

UNEQUAL REGENERATION OF TWO AXONS OF AN IDENTIFIED MOLLUSCAN NEURON. P. J. Kruk, R. L. Ridgway and A. G. M. Bulloch. Dept. of Medical Physiology, Univ. of Calgary, Calgary, Alta., Canada, T2N 4N1.

The success of axonal regeneration of an identified buccal ganglion neuron (B4) of the pulmonate pond snail *Helisoma trivolvis* depends on the site of axotomy. This neuron has two axons, one in the ipsilateral and one in the contralateral esophageal trunks (ETs), which together innervate the paired salivary glands. We have previously found (Kruk and Bulloch, Soc. Neurosci. Abstr. 14: 582, 1988) that complete removal of the ipsilateral axon results in failure of regeneration. This axon does regenerate, however, if a proximal stump is retained and/or when the contralateral axon is given a simultaneous distal crush. These results gave rise to two hypotheses: (1) a proximal axon stump is necessary for regeneration, or (2) an inhibitory factor is retrogradely transported from targets via intact axon(s), but does not enter, nor influence regeneration of, proximal axon stumps.

To resolve these two hypotheses, we attempted to completely remove both axons of neuron B4 by crushing *in situ* the buccal commissure and ipsilateral ET. The morphology of the neuron was examined 8-10 days post-lesion by Lucifer Yellow dye-filling. No sprouting should occur if hypothesis #1 was true; alternatively, the cell should regenerate both axons. Neither situation was the case, however. Regeneration was profuse, but confined mostly to the contralateral axon; a result which may be due in part to incomplete removal of the contralateral axon. Much weaker regeneration was observed after close axotomy of the contralateral axon alone. As both axotomy procedures produce contralateral axon stumps of similar length (the ipsilateral axon intact or absent) the main difference between the two is a loss of contact with the target. Our results thus appear to support hypothesis #2, although final resolution will require more precise removal of the contralateral axon.

PROTEIN KINASE C BINDING SITES DURING NEURONAL PLASTICITY FOLLOWING ENTORHINAL CORTEX LESIONING IN RAT. J. Poirier, A.R. Parent, A. Baccichet and R. Quirion. Douglas Hospital Research Centre, Verdun, Quebec, Canada. H4H 1R3.

Entorhinal cortex lesioning (ECL) produces a loss of more than 80% of the synapses in the outer molecular layer of the hippocampus. The loss of synapses, however, is transient. Beginning a few days after denervation, new synapses are formed, virtually replacing the lost inputs within two months. These new synapses originate from the cholinergic septal neurons, glutamatergic commissural-associational pyramidal cells of the CA3/Hilus areas and, to a lesser extent, from neurons of the contralateral entorhinal cortex. We hypothesize that the protein kinase C (PKC) has a role to play in the process of reinnervation that follows deafferentation. PKC is considered to be an important second messenger coupled to different neurotransmitters and it induces cellular proliferation. By autoradiography analysis on ECL rat brain sections labelled with tritiated phorbol 12,13-dibutyrate, we have evaluated the density of PKC binding sites. The PKC site density was significantly increased (> 25%) between 4 and 6 days post-lesion in molecular layer, in granular layer of dentate gyrus and in hilus. Similar increases of the PKC were observed in both the ipsilateral and contralateral side of the lesion. This result is consistent with the known location of the entorhinal cortex projections. Ten days after lesions, the values return to control levels. The profile of PKC binding sites in the hippocampus correlates quite well with the distribution of reactive astrocytes in this animal model. This phenomena could conceivably be involved in the process of terminal sprouting. Supported by Alzheimer Society of Canada and the American Health Assistance Foundation.

CELL-SPECIFIC SURFACE COMPONENT SELECTS THE RESPONSE TO TRANSMITTER DURING SYNAPSE FORMATION BETWEEN IDENTIFIED LEECH NEURONS.

D. Merz, and P. Drapeau. McGill Univ. Dept. Biology and Centre for Research in Neuroscience, Montreal, Quebec, Canada H3G 1A4.

When serotonergic Retzius (R) neurons of the leech contact pressure sensitive (P) neurons in culture, they selectively eliminate the cationic response to 5-HT and reform the Cl-dependent synapse seen *in vivo*. P cells were paired in culture with other identified neurons. Contact with sensory neurons (T,P, or N), non-serotonergic synaptic partners (AE and AP), or with serotonergic non-synaptic neurons (VL and DL) failed to alter the P cell responses to 5-HT. In contrast to standard segmental R cells, R cells from the two sex ganglia were also ineffective in selecting P cell responses to 5-HT. Treatment of standard R cells with trypsin or exposure to wheat germ agglutinin, but not to other lectins, blocked the loss of the cationic response in the P cell. We conclude that the selection of 5-HT responses in the P cell may be mediated by surface glycoproteins specifically expressed on the presynaptic (standard) R neurons. Contact with the presynaptic partner clears the non-synaptic response to transmitter as an early functional event during neuronal recognition.

MUSCARINIC RECEPTOR SUBTYPES AND OTHER CHOLINERGIC MARKERS ARE DIFFERENTLY AFFECTED IN RAT DENTATE GYRUS FOLLOWING ENTORHINAL CORTEX LESIONS. J. Aubert, J. Poirier, A. Baccichet and R. Quirion. Douglas Hospital Research Centre and McGill University, Department of Neurology & Neurosurgery, Montreal, Quebec, Canada H4H 1R3.

It has been shown that lesions of the entorhinal cortex in rat promote the sprouting of cholinergic septal fibers in the dentate gyrus of the hippocampus. In our model, lesions of the entorhinal cortex in adult Fisher-344 rats were performed and the status of various cholinergic markers was assessed using receptor autoradiography, histological and enzymatic techniques in controls and at several times following the lesions (2, 6, 8, 14, 30 and 64 days post-lesion, DPL).

As reported by other groups, acetylcholinesterase (AChE) staining was significantly increased in the ipsilateral dentate gyrus (DG) from 6 to 64 DPL. However, muscarinic-M2 binding sites, labelled with [³H]AF-DX 384, appeared to be increased significantly only at 14 DPL. In contrast, choline acetyltransferase (ChAT) activity and [³H]pirenzepine/muscarinic-M1 receptors remained unchanged throughout the time course.

These findings suggest that AChE staining may not be fully adequate as a marker of cholinergic sprouting in this model. Moreover, the different effects of the lesions on putative pre (M2 and ChAT) and post (M1) synaptic markers reveal the complexity of this sprouting model in regard to the reorganization of the cholinergic synapse. Supported by the Alzheimer Society of Canada, the American Health Assistance Foundation and MRCC.

ALTERED CHOLESTEROL METABOLISM DURING REACTIVE SYNAPTOGENESIS IN THE DEAFFERENTED HIPPOCAMPUS

A. Baccichet, D. Dea and J. Poirier. McGill Centre for Studies in Aging, 1650 Cedar Ave., Montreal, Canada, H3G 1A4 and the Douglas Hospital Research Centre, 6875 LaSalle Blvd., Verdun, Canada, H4H 1R3.

The hippocampus can be induced by deafferentation to selectively reorganize its neuronal inputs. In a widely studied rat model, entorhinal cortex lesioning (ECL) induces sprouting of glutamatergic commissural/associational fibers and cholinergic septal projections in the molecular layer of the dentate gyrus. Recent evidences were given for altered synthesis of the apolipoprotein E (apo E) mRNA in the hippocampus in response to ECL. The increase synthesis was shown to coincide with the acute phase of terminal proliferation, reactive synaptogenesis and protein synthesis. Apo E is a protein that facilitates cholesterol movement both in and out of cells. We have further documented the cascade of events leading to cholesterol up-take by regenerating neurons. Using a fluorescent Dil-LDL binding assay on frozen brain sections, we found that the apo E receptor binding activity (also called LDL receptor) is significantly increased (>2 fold) in the granule cell neurons in response to ECL. In contrast, the activity of the hydroxymethylglutaryl-CoA reductase (a rate limiting enzyme in cholesterol synthesis) was shown to be significantly reduced in the hippocampus during the acute phase of reactive synaptogenesis and apo E synthesis. These results are compatible with a receptor mediated down-regulation of the neuronal cholesterol synthesis in response to acute cholesterol uptake during the synaptogenesis phase. Supported by the American Health Assistance Foundation, a scholarship from the Medical Research Council of Canada and a studentship from the Alzheimer's Society of Montreal.

295.13

GLUCOCORTICOID MODULATION OF APOLIPOPROTEIN E AND LDL RECEPTOR EXPRESSION IN THE HIPPOCAMPUS DURING REACTIVE SYNAPTOGENESIS. D. Dea, A. Baccichet and J. Poirier. McGill Centre for Studies in Aging, 1650 Cedar Ave., Montreal, Canada, H3G 1A4 and the Douglas Hospital Research Centre, 6875 LaSalle Blvd., Verdun, Canada, H4H 1R3.

Partial deafferentation in the hippocampus following entorhinal cortex lesion (ECL) induces a sequence of compensatory events in both the remaining afferent fibres and denervated dendrites, resulting in a reorganization of the circuitry in the denervated area. It is known to trigger complex sprouting responses in the denervated molecular layer of the dentate gyrus from cholinergic as well as glutamatergic surviving afferent systems. It was recently demonstrated that the apolipoprotein E (apo E), a protein that facilitates cholesterol movement both in and out of cells, shows a particularly close temporal relationship with the early phase of the reinnervation process in the hippocampus of rat with ECL. In order to further examine the role played by the cholesterol metabolism during reactive synaptogenesis, corticosterone (10 mg/Kg/days for 6 days) was administered (s.c.) to rats with ECL and the mRNA prevalence for the apo E and its receptor (the LDL receptor) was determined by Northern blot and PCR quantification. Northern blot hybridization of a rat apo E probes on pooled samples showed that glucocorticoid potentiates the apo E mRNA induction caused by the deafferentation process. In contrast, the hippocampal mRNA prevalence of the LDL receptor which is increased by more than 100% at 6 days post-lesion, was significantly reduced (~60%) in the corticosterone-treated animals. These results further confirm the key role played by the apo E-LDL receptor pathway during reactive synaptogenesis and suggest a possible biochemical mechanism by which glucocorticoids can block compensatory sprouting and reactive synaptogenesis in adult rats. 5,7-DIHYDROXYTRYPTAMINE (5,7-dHT) CAUSES SPROUTING IN THE ADULT SNAIL CNS. M.W. Baker and R.P. Croll, Dept. Physiology. & Biophysics. Dalhousie Univ. Halifax, N.S. Canada.

The effects of *in vivo* 5,7-dHT administration on neuronal morphology was investigated in the snail *Achatina fulica* by axonal backfilling of the cerebrobuccal connective with nickel-lysine. Backfilling 21 days following a single injection of 5,7-dHT (equivalent to 300 mg/kg, in 1 cc saline with 0.5 mg L-ascorbic acid as an antioxidant) revealed supernumerary staining of fibers in different pathways and staining of novel cell bodies in the cerebral and buccal ganglia, when compared to untreated animals. Control injections using the carrier solution alone, revealed normal labeling. However, injections of the carrier with a high concentration of L-ascorbic acid (10 mg), yielded supernumerary labeling in some of the same fiber tracts as seen with 5,7-dHT treatment. The 5-HT synthesis blocker, PCPA, was also tested for effects on sprouting. One injection of 0.5 mg of PCPA per day for 3 consecutive days was shown to induce a similar supernumerary labeling of fibers and cell bodies. Evidence suggests that some of the same novel neurons were labeled with PCPA and 5,7-dHT treatments. The extent of depletion of 5-HT and the specificity of the effects are currently being investigated.

SYNAPTIC PLASTICITY IN LAMINA II OF THE DEAFFERENTED SPINAL CORD: QUANTITATIVE EM-IMMUNOCYTOCHEMICAL STUDIES. B. Zhang, M.E. Goldberger, W.P. Battisti and M. Murray, Dept. of Anat. & Neurobiol., Med. Coll. of Penn., Philadelphia, PA 19129.

Light microscopic studies show that projections to the dorsal horn change after complete deafferentation. We used quantitative EM-immunocytochemistry to study the changes in synaptic terminals in lamina II of the L5 dorsal horn resulting from unilateral lumbosacral deafferentation L1-S2 in adult rats. Animals survived 10 days (acute), and 60 days (chronic); the contralateral side served as control. We examined the total synaptic population and those terminals containing SP and 5HT. In controls, SP is found in simple and complex terminals, and 5HT is present in simple terminals. Complex terminals in lamina II were eliminated by deafferentation, but the number of simple terminals was greater than normal in deafferented lamina II in both acute and chronic groups. Post-embedding immunocytochemical labeling indicated that the percentage of simple terminals containing SP decreased by 30% in the acute group but recovered to a normal percentage in the chronic group. These results indicate that terminals lost after rhizotomy are replaced by terminals from intact systems and that intrinsic SP systems contribute to the synaptic replacement.

ULTRASTRUCTURE OF AChE-POSITIVE FIBERS AFTER EXCITOTOXIC DAMAGE IN THE MOUSE HIPPOCAMPUS. RC Green, SM Hirsch, HD Rees, RAE Bakay. Depts. of Neurology and Neurosurgery, Emory University School of Medicine, Atlanta, GA 30322

Hippocampal acetylcholinesterase (AChE) fiber reorganization has been described in human diseases such as temporal lobe epilepsy and Alzheimer's disease. Previous light microscopic studies of AChE histochemistry after intraventricular injections of kainic acid (KA) in mice revealed increased staining over areas of cell loss in the hippocampal stratum oriens and stratum pyramidale, primarily in the CA3 region (Green et al. *Soc Neurosci Abstr* 16:947,1990). Since AChE staining was enhanced in an area where target neurons were lost without obvious deafferentation, we studied the region of increased staining with electron microscopy.

Male C57BL/6J mice, aged 2-3 months, received intracerebroventricular injections of KA (0.3 µg/side) or saline. After two weeks, the mice were perfused and brain sections were stained for AChE using a modified Karnovsky-Roots technique which gives detailed staining of fibers (Mesulam et al., *Ann Neurol* 22:683, 1987), followed by osmium fixation and embedding in Epon. In saline-injected control mice, AChE reaction product was principally extracellular in association with unmyelinated axons and axon terminals, and was intracellular within dendrites. In KA-treated animals, AChE reaction product was similarly distributed and neuronal degeneration with gliosis was observed. There was no association between reaction product and degenerating processes. In some animals with severe neuronal degeneration, there appeared to be an increased amount of AChE reaction product in stratum oriens.

SUPPRESSION OF REACTIVE COMPENSATORY CHANGES IN THE BRAIN BY MORPHINE. A. Gorio, M.L. Malosio*, B. Tenconi*, M.L. Donadoni*, P. Mantegazza* and A.M. Di Giulio. Dept. of Medical Pharmacology, Univ. of Milano, v. Vanvitelli 32, 20129 Milano, Italy.

We are reporting that perinatal exposure to low doses of morphine, supplied in drinking water to pregnant rat and, after weaning, directly to the offspring, can impair compensatory events triggered by a neurochemical lesion. Neonatally administered 6-hydroxydopamine (6-OHDA) causes a permanent depletion of noradrenaline innervation of the cerebral cortex. By means of HPLC and immunocytochemistry we have observed that the denervated cortical territories are occupied by serotonin, dopamine and met-enkefalin neurons. In morphine exposed rats these compensatory events are absent. The inhibitory effect of opiates on CNS plasticity is detectable also in the mesencephalon, where a hyperinnervation by the short noradrenergic collaterals is normally observed following 6-OHDA neonatal injection. We have investigated the possible molecular mechanisms underlying these processes. The transcripts of several proteins thought to be involved in neurogenesis, like GAP-43 and Go, or in receptor signal transduction, like Gi, Gs and Gq, were assayed.

HIGH-RESOLUTION IMAGING OF GROWTH CONE BEHAVIOR *IN VITRO* ON PATTERNED SUBSTRATES

A. Soekamo, B. Lom & P. E. Hockberger. Dept. of Physiology, Northwestern Univ. Medical School, Chicago, IL 60611.

We have studied the behavior of rat neuroblastoma cells (NIE-115) growing on photolithographically patterned substrates (Kleinfeld et al., *J. Neurosci.* 8: 4098, 1988) using high-resolution digital imaging microscopy. The use of a homogeneous population of cells in a controlled and defined environment allows observation of behaviors that are poorly understood, e.g., guidance, turning, sampling, and decision making. Using time-lapse recording we have observed that cells migrating on ethylenediamine (EDA) lines, 10 μ m in width, exhibited ruffling and filopodial extension similar to what is seen on unpatterned substrates. While attachment and extension occurred preferentially on EDA, cells occasionally did the same on the non-preferred (hexadecane) substrate. At junctions between lines, cells sampled their choices and made 'decisions' to either turn, go straight ahead, or retract. One of the most remarkable and consistent events involved nuclear translocation to the junction where it often remained. We also observed violent bouts of cellular blebbing both on and off EDA regions, which was sometimes followed by a return to normal cell activity. When this type of blebbing occurred at the growth cone, it was followed by retraction. Fluorescent images of patterned cells that were double-labelled for actin (rhodamine-phalloidin) and tubulin (FITC-antibody) showed compartmentalization of these cytoskeletal proteins. Actin filaments were restricted to the distal region of the growth cone, often radially arrayed, whereas tubulin was seen along the neurites and proximal growth cone. This arrangement was seen in cells on and off lines, indicating that these substrates do not differentially affect cytoskeletal organization. Actin filaments and tubulin were also concentrated in the hyaline membranes of blebbing cells.

This research was funded in part by a Biomedical Engineering Grant from the Whitaker Foundation.

296.3

RELATIONSHIP OF RETROGRADE MOVEMENTS OF NEURITE SURFACES TO RETROGRADE MOVEMENTS OF CYTOPLASM.

C.L. Smith. Laboratory of Neural Control, NINDS, NIH, Bethesda, MD 20892.

We are using videomicroscopy to study interactions of chick sympathetic ganglion neurons with beads coated with different substrate molecules in order to understand the cellular mechanisms involved in neurite outgrowth. Sympathetic neurons grown on polyornithine-coated glass coverslips form filopodia around their entire circumferences but rarely form neurites. However, their filopodia can be stimulated to transform into neurites by contact with laminin or polyornithine-coated 10 μ m latex beads. A filopodium that contacts a coated bead first straightens and then lifts off the substrate. Then a lamellipodium moves anterogradely toward the tip of the filopodium followed closely by a bolus of cytoplasm containing actin, microtubules and neurofilaments. As the bolus moves, the thickened region of the filopodium sprouts new filopodia, thereby resembling a growth cone. However, when the bolus reaches the bead, it dislodges the bead which then moves retrogradely to the cell body. The bolus accompanies the bead as it moves. The rate at which the bead is transported and the bolus of cytoplasm recedes (7.1 \pm 3.5 μ m/min) is comparable to the rate at which smaller beads are transported retrogradely along the surfaces of filopodia (8.6 \pm 1.7 μ m/min) in separate experiments. This correlation between retrograde bead and cytoplasmic movement suggests that the mechanisms responsible for moving cytoplasm within developing neurites are linked to the mechanisms that move molecules on the cell surface.

296.5

MODULATION OF GROWTH CONE MORPHOLOGY BY SUBSTRATE-BOUND ADHESION MOLECULES.

H.R. Payne, S.M. Burden and V. Lemmon. Department of Neurosciences, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Neuronal growth cones mediate axon growth by providing a motile structure that can interpret and respond to environmental cues. As a result, growth cones can choose among different pathways to grow to their appropriate targets. The molecules that encode the guidance information along alternative pathways are not known, but these cues are thought to be responsible for the position-specific morphological complexity of growth cones. We have investigated substrate-based influences on growth cone morphology *in vitro*. We used scanning electron microscopy to analyze the morphologies of chick retinal ganglion cell growth cones on substrate-bound molecules. L1/8D9, N-cadherin, and laminin each induced distinctive morphological characteristics in growth cones. Growth cones elaborated lamellipodial structures in response to the cell adhesion molecules L1/8D9 and N-cadherin whereas laminin supported filopodial growth cones with small veils. The growth cones on L1/8D9 attained the largest sizes and extended more filopodia. Filopodial associations between adjacent growth cones and neurites were frequent on L1/8D9 but were uncommon on laminin or N-cadherin. These data establish that substrates normally present in the developing optic pathway can influence the details of growth cone morphology *in vitro*. Our observations are consistent with a hypothesis that variations in growth cone morphology *in vivo* are due to alterations in substrate-bound guidance cues along developing axonal pathways.

296.2

PATTERNS OF NEURONAL ADHESION ON SUBSTRATES THAT DO AND DO NOT PROMOTE NEURITE OUTGROWTH.

J. Drazba, M.I. Weiner and C.L. Smith. Laboratory of Neurobiology and Laboratory of Neural Control, NINDS, NIH, Bethesda, MD 20892.

Neuronal process outgrowth *in vitro* is dependent upon the substrate. In order to better understand the cellular mechanisms underlying the observed differences between substrates, we have used reflection (IRM) and differential interference videomicroscopy to study adhesion and neurite outgrowth of chick sympathetic ganglion neurons grown on polyornithine and laminin substrates. Sympathetic neurons grown on polyornithine-coated glass coverslips form a lamellipodium and filopodia around their entire circumferences which adhere closely to the substrate as seen by IRM. The filopodia rarely transform into neurites. However, if a filopodium contacts another cell it lifts off of the substrate, thickens and transforms into a neurite. Filopodia that contact polyornithine coated latex beads also lift off the substrate and transform into neurites as described in another abstract (C. Smith). Neurons grown on a laminin substrate form a lamellipodium and filopodia around their entire circumferences, but they adhere closely to the substrate only in discrete patches. Filopodia typically adhere more closely at their tips than along their shafts. Multiple filopodia around the circumference of individual neurons thicken and transform into neurites, thus making the neurons multipolar. These observations suggest that transformation of a filopodium into a neurite requires that it be tightly adherent at its tip but not tightly adherent along its length. We are in the process of examining other substrates to further characterize the correlation between patterns of adhesion and process outgrowth.

296.4

DIRECTIONAL, MORPHOLOGICAL, AND ELONGATION RATE CHANGES OF GROWTH CONES AS THEY ENCOUNTER LAMININ-FIBRONECTIN BORDERS.

T. M. Gomez and P. C. Letourneau. The University of Minnesota, Minneapolis, Minnesota 55455.

Previous studies have shown that when presented with a parallel array of alternating laminin (LMN) and fibronectin (FN) substrata, neurites elongate preferentially on LMN (Vielmetter et al., *Exp Brain Res* 81:283-287, 1990). Since both FN and LMN support neurite outgrowth of chick sensory neurons *in culture*, we examined closely the detailed behavior of the growth cones (GC) of these neurons as they encountered FN-LMN borders.

Using a silicon matrix consisting of an array of parallel channels, patterns of alternating LMN and FN substrata were bound to a glass coverslip. A small percentage of the total LMN applied to the coverslip was rhodamine conjugated in order to determine its distribution, homogeneity and concentration. FN distribution was localized by immunofluorescent staining. Dissociated dorsal-root ganglia neurons from E10 chicks were plated onto the patterned substrata and were examined using time-lapse video microscopy.

After 24 hours in culture, neurites were largely restricted to the LMN lanes, however outgrowth could be found on FN. We analyzed GC morphology and changes in rate, as well as direction of neurite outgrowth, as GCs contacted the FN-LMN borders. GCs crossing from LMN onto FN often collapsed and/or were deflected back onto the LMN substratum. Conversely, GCs on FN that encountered LMN rarely remained on FN. Further, these GCs were often seen to spread into lamellipodial structures, orient toward LMN and increase their rate of outgrowth. GCs that were migrating parallel to the substrata borders predominately did so in association with LMN.

These data suggest that if present along an axon pathway, LMN and FN could alter the direction and rate of neurite outgrowth. Further, our results imply that selection of one matrix molecule over another may involve alterations in growth associated intracellular mechanisms, leading to changes in membrane and cytoskeletal dynamics.

296.6

A NOVEL SUBMEMBRANOUS MOLECULE ENRICHED IN GROWTH CONE SHAFTS

G. E. Pollerberg, Dept. Biochemistry Max-Planck-Institute for Developmental Biology, W-7400 Tübingen, Germany

A group of three molecules (app. molecular weights of 150, 130 and 120 kD in western blot analysis of chicken neural tissue) was initially defined by two different monoclonal antibodies. One of the antibodies crossreacts with the N-CAM180-specific, cytoskeleton-associated intracellular domain of the Neural Cell Adhesion Molecule. Several cDNA clones (isolated from a chicken retina gt11 expression library employing the two monoclonal antibodies) show no homology to any known sequences. The three molecules (which might represent splice forms of one molecule) are differentially regulated during the development of the chick retinotectal system with a expression maximum in the phase of axonal outgrowth and target finding. The molecules are intracellular and appear to be distributed in a fine filamentous submembranous meshwork, indicating that the molecules might be components of the cortical cytoskeleton or the inner surface of the cell membrane, possibly linkerproteins. In retina single cell culture, antibody staining is most intense in a subpopulation of growth cone shafts, *in vivo* the molecules are predominantly expressed by postmitotic, postmigratory cells, so one might speculate that the molecules play a role in growth cone stabilisation.

296.7

Transfection of "Sense" and "Anti-Sense" Tau cDNA into PC12 Cells: Tau Regulation of Net Microtubule Assembly and Neurite Outgrowth. **B. Esmaceli-Azad*** and **S.C. Feinstein**, Neuroscience Research Institute and Department of Biological Sciences, University of California, Santa Barbara CA 93106.

The tau family of proteins are known to induce tubulin polymerization and suppress microtubule dynamics *in vitro* and to promote microtubule stabilization and bundling *in vivo*. Employing the NGF mediated induction of neurite outgrowth in PC12 cells, we and our colleagues had previously observed that the NGF mediated (i) induction of tau, (ii) accumulation of microtubule mass and (iii) induction of neurite outgrowth all proceeded in concert. These correlative data led to the model that tau is a fundamental and limiting factor promoting *in vivo* microtubule accumulation, which in turn promotes neurite outgrowth.

One experimental paradigm allowing direct examination of this correlative model is to alter the normal pattern of tau expression during neurite outgrowth and then examine the biochemical and morphological consequences. In the present study, we have isolated stable PC12 "sense" and "anti-sense" tau cDNA transfectants, which over-express and under-express tau protein, respectively. NGF induced microtubule accumulation and neurite outgrowth are both dramatically affected by the level of active tau protein. Anti-sense tau cells are deficient in NGF mediated microtubule mass accumulation, and project neurites poorly. Sense-orientation tau cells accumulate microtubule mass and project neurites more rapidly than wild type cells. Interestingly, newly synthesized tau in non-NGF treated, over-expressing cells is non-cytoskeletonally associated. Following NGF administration, this tau becomes associated with the cytoskeleton. The NGF mediated "activation" of tau may represent a post-translational modification event. Alternatively, tau may be in excess over its cognate cytoskeletal structures/substrates required for tau function prior to NGF administration. This work provides direct evidence that tau functions *in vivo* to promote net microtubule assembly and neurite outgrowth.

296.9

AXOTOMY ACCELERATES SCb TRANSPORT IN MOTOR NEURONS WITHIN 3-7 DAYS. **J.M. Jacob** and **I.G. McQuarrie**, Neural Regen. Ctr., Cleveland VA Med. Ctr., Cleve., OH 44106.

In sciatic motor neurons of the rat, increases in the outgrowth rate of newly-formed (daughter) axons reflect an increased rate of SCb transport in both parent and daughter axons (McQuarrie and Jacob, *J. Comp. Neurol.* 305:139, 1991; Jacob and McQuarrie, *J. Neurobiol.*, Sept. 1991). The increased SCb rate, which is produced by the initial or conditioning axotomy, can be assayed indirectly by measuring the outgrowth rate after a subsequent testing axotomy. Using this assay, and a variety of intervals between conditioning and testing axotomies, we have examined the time-course of SCb acceleration. With conditioning intervals of 0 and 3 d, outgrowth rates were the same as in sham-conditioned controls, whereas, with conditioning intervals of 7, 14, and 21 d, outgrowth rates were greater ($p < 0.01$ at each interval). This time-course reflects the cell body reaction to axotomy in motor neurons: a catabolic phase, lasting 3-4 d, followed by an anabolic phase (Grafstein and McQuarrie, in *Neuronal Plasticity* (ed. C.W. Cotman), Raven Press, New York, 1978). We conclude that the SCb rate may be regulated, in part, by the magnitude of synthesis of SCb (cytoskeletal) proteins in the nerve cell body.

Supported by grants to IGM from DVA and NINDS.

296.11

REGULATION OF SPINAL NEURITE GROWTH CONE MORPHOLOGY BY TARGET TISSUE. **I. Somasekhar*** and **E.D. Pollack**, Inst. Study of Developmental Disabilities, Dept. of Biol. Sciences and Committee on Neuroscience, Univ. of Illinois at Chicago, IL 60680.

Since the growth cone plays a critical role in target-directed axon extension during development, we sought to determine if target tissue has an influence on neuronal growth cone morphology *in vitro*. Spinal cord explants from *Xenopus* tadpoles were cultured either alone (control) or in co-culture with mesenchymal limb buds on poly-DL-lysine or collagen coated cover glasses. Growth cones were examined at light, scanning, and transmission electron microscope levels. In contrast to control cultures, the majority of growth cones in target tissue-containing cultures were larger with elaborate morphologies characterized by broad lamellipodia and more filopodia. While filopodial branching was seen in control cultures as well as in cord+target cultures, branching of neurites at the growth cone was more common in the latter. The distribution of filopodia was restricted mostly to the neurite tips in cord+target cultures, whereas in control cultures filopodia tended to be more diffusely distributed over neurite shafts as well. Interestingly, within the cord+target cultures, there were variations in growth cone morphologies depending on their proximity to the target tissue. Growth cones that were closest to, or oriented towards, the target had the elaborate morphological configuration; growth cones that were farther from the target or that extended in the opposite direction of the target had the simpler morphology of the control cords. TEM observations revealed that most of the growth cones of cord+target cultures were rich in filamentous material and membrane bound organelles in contrast to those from control cultures. These results revealed profound target-mediated influences on the morphology of neuronal growth cones and provide additional evidence for a target-originated, graded growth influence on extending neurites.

296.8

TAU-HSV1 RESTORES NORMAL POLARITY TO TAU ANTISENSE TREATED NEURONS **¹G.Lee***, **¹S.Book***, **¹G.Hall** and **²A.Geller**. ¹Brigham & Women's Hosp. and ²Dana Farber Cancer Institute, Boston, MA 02115.

Cerebellar neurons in dissociated culture exhibit polarity as defined by the acquisition of a single neurite whose length exceeds that of other neurites. Antisense experiments (Caceres and Kosik, 1990) have shown that this polarization process requires tau protein, a microtubule associated protein which localizes primarily to the axon *in vivo*. We have used this system to study the structure and function of tau protein in neuronal cells. Antisense treatment is used to block endogenous tau expression and neurite elongation, then herpes simplex virus (HSV1) vectors are used to re-introduce tau protein into neurons. We have made a panel of 6 HSV1 vectors - two encode full length isoforms of tau protein, two encode tau fragments which co-localize with microtubules *in vivo* and two encode tau fragments which do not co-localize with microtubules *in vivo*. Virus and antisense are added to the culture media after plating; cells are fixed 2 days later and lengths of processes measured. We find that cells infected with vectors expressing full length tau protein overcome the effects of tau antisense; these cells regain polarity. By using vectors expressing tau fragments, we will assess whether any specific domains of tau protein are required for this activity. Since the elongation of an axon-like process during the acquisition of polarity is anticipated to require the stabilization of microtubules, tau fragments which lack *in vivo* microtubule binding activity are not expected to work. Our panel of vectors will determine if any domains, in addition to the microtubule binding domain, are required for activity.

INHIBITION OF AXONAL GROWTH BY BREFELDIN A IN CULTURES OF EMBRYONIC RAT HIPPOCAMPAL NEURONS. **M.I. Jareb** and **G.A. Banker**, Department of Neuroscience, University of Virginia School of Medicine, Charlottesville, VA 22908.

In culture, embryonic rat hippocampal neurons initially develop several short, minor processes. After a delay of 12 to 24 hours, one of these begins to elongate rapidly, becoming the cell's axon. We have examined the effects of brefeldin A (BFA), which specifically inhibits the translocation of vesicles through the Golgi complex, on the initiation and elongation of axons. To ascertain the effects of BFA on axonal growth we followed individual cells by video microscopy for up to 12 hours. Within 1 hour after adding BFA (1 μ g/ml), axonal elongation was completely inhibited. After several hours axons began to retract, and in some cases this continued until the axon had shortened to the length of a minor process. When BFA was added earlier in development, when cells had only minor processes, axons failed to develop. Minor processes themselves were unaffected by BFA. It did not inhibit their elongation or cause them to retract. The effects of BFA were completely reversible. Within 1 hour after removing the drug, axonal elongation resumed at a normal rate. The effects of cycloheximide, an inhibitor of protein synthesis, were quite different. In the presence of cycloheximide (10 μ g/ml) axonal elongation did not stop abruptly; instead axons became thinner, but continued to elongate for 4 to 6 hours. These results suggest that continuous vesicle transport from the Golgi complex is essential for the elongation and maintenance of axons. This requirement appears to be specific to axons.

296.12

AXONAL MORPHOLOGY IN THE DEVELOPING CHICK OPTIC NERVE. **S.M. Fraley**, **W.M. Ross** and **S.A. Dunlop**, Department of Psychology, University of Western Australia.

The morphology and trajectories of individual axons in the developing chick optic nerve were examined after anterograde labelling with horseradish peroxidase (HRP) *in vitro*. Small groups of axons were labelled by "stabbing" the retina close to the optic disk with an HRP-coated insect pin. After transport, nerves were sectioned longitudinally on a vibratome, reacted with cobalt-enhanced DAB and viewed using Nomarski optics. We examined tissue at E9-11 and E19-21, that is, at times when axon numbers were at their peak or at mature values respectively (Rager & Rager, 1978, *Exp. Brain Res.* 33, 65-78). At E9-11, axons had a very fine calibre and many had complex axonal spines projecting from the main shaft. Spine length varied from less than 1 μ m to over several microns. Axons tipped by growth cones were a prominent feature. Growth cones varied from round with a diameter of approximately 5 μ m to elongate and up to 30 μ m long; all growth cones were characterised by prominent filopodia which were of a similar calibre compared to the main axon shaft. Whereas most axons were aligned with their axes parallel to the length of the nerve, other axons at all levels had aberrant trajectories with kinks or loops, or took sinuous routes across the nerve. At E19-21, axonal calibre varied considerably; axonal spines were rarely seen and growth cones were absent. Axons with aberrant trajectories were prominent only at three levels. These levels were within the length of the optic disk, the junction between the disk and the optic nerve and as axons entered discrete fascicles within the chiasm. We conclude that developing optic axons in the chick undergo considerable remodelling to reach their mature form.

GROWTH CONES OF DESCENDING SEROTONERGIC AXONS IN *XENOPUS* SPINAL CORD. R.H. Nordlander and S-X. Liu, Depts. Oral Biol., Anat., Ohio State Univ., Columbus OH 43210.

Serotonergic axons are among the earliest descending brainstem axons to enter the developing *Xenopus* spinal cord. They enter the cord after longitudinal pathways have already been initiated by local spinal neurons. In this study we examined growth cones of descending serotonin-immunoreactive (5HT-I) axons in *Xenopus* embryos and larvae (st 25-40). There are no intrinsic 5HT-I spinal neurons at these stages. Our primary focus was the patterns of growth cone shape and distribution for these fibers as viewed in whole mounts and sections of the spinal cord.

Growth cones are generally small (4 x 16 um) and vary from simple fusiform to branched filiform shapes. We observed that growth cones at leading (caudal) positions tend to be more elaborate than those that follow, confirming for an identified neuron class what we had earlier observed as a general phenomenon among descending spinal axons (*J Comp Neurol*, 263:485-496, '87). Growth cones and axons of 5HT-I neurons are distributed in the ventral half of the lateral marginal zone. There is no clear evidence that the early 5HT-I axons serve as guides for those that follow. Immunoreactive growth cones do not consistently contact other 5HT-I axons and the axons themselves are dispersed among their non-reactive fellows. Supported by NS 18773.

DEVELOPMENT OF CALLOSAL AXON ARBORS IN HAMSTERS. C. Hedlin-Pereira, S. Jhaveri, R. Lent, Dept. Brain and Cog. Sci., M.I.T., Cambridge, MA 02139; Inst. Biofisica, UFRJ, 21941 Rio de Janeiro, Brazil.

We have used Dil (for younger animals) and biocytin labeling to visualize individual callosal axon arbors. Crystals of Dil were placed in the parietal or occipital cortex of aldehyde-fixed hamster brains (E15-P6; where E16=P0) and the tissue analyzed 1-3 months later with fluorescence microscopy. Older pups (P4-P30) had biocytin injected in the cortex and were sacrificed 24-48h later. Brain sections were treated with an avidin-biotin-HRP complex and DAB.

Parietal axons, bearing simple growth cones, first cross the midline on E15. Over the next few days, increasing numbers of axons pass under the cortical plate of the homotopic target regions and continue to grow laterally, without branching, in the white matter. Simple collateral sprouts, tipped by a tiny bead, appear on callosal axons around P4. On the following days lateral branches are emitted from the pially directed sprouts but arbors are still primitive. By P6, although the sprouts have reached the upper cortical laminae, signs of a more complex arbor are seen predominantly in the infragranular layers. Subsequently, by P9, elaborate, lamina-specific arborization becomes focussed in both the infra- and supra-granular layers. Occipital callosal axons lag behind parietal fibers by about 2 days.

Thus, in contrast to thalamocortical afferents which enter the cortical plate upon arriving at target regions (Catalano et al., PNAS, 1991), the later-arriving callosal axons show a distinct waiting period. Callosal axon morphogenesis is a relatively slow process, occurring over at least 10 days of postnatal life.

DEVELOPMENT AND DISTRIBUTION OF PERIPHERAL AND CENTRAL NEURONS LABELED BY THE MONOCLONAL ANTIBODY LAN 3-6 IN LEECH. K.K. Briggs, K.M. Johansen and J. Johansen, Department of Zoology and Genetics, Iowa State University, Ames, Iowa 50011.

The lan 3-6 antibody recognizes an epitope which is expressed by central and peripheral neurons in hirudinid leeches. The epitope appears to be a reliable marker for the same group of peripheral neurons in all the leech species examined; however, the distribution by central neurons vary considerably between species. In *Haemopsis* approximately 20 different CNS neurons are labeled by the antibody whereas 6 small unidentified neurons are recognized in *Hirudo* and only the two pairs of pressure neurons are stained in *Macrobdella*. This pattern of expression is consistent and reproducible within each species. The functional reason for this diversity in expression of the epitope between central neurons in different species is unknown. However, in order to explore these questions we are in the process of analyzing the antigen(s) biochemically. Since the epitope loses its immunoreactivity after SDS-treatment and thus cannot be identified on SDS Western blots we have assayed dot blots after non-ionic detergent extraction. Under these conditions the antigen retains its immunoreactivity and it can be shown that the antibody binding is abolished by treatment with protease K suggesting that the antigen is a protein. Immunoprecipitation, native gels and IEF-techniques are being applied to further characterize the molecular nature of the antigen. We are also using the antibody as a marker for analyzing axon fasciculation of the peripheral neurons. Supported by NIH grant NS 28857, an Iowa State Biotechnology grant, and an Iowa State University grant.

THE FIRST AXONS IN THE MOUSE CNS. L. S. Ross and S. S. Easter, Jr., Dept. Zool. Biomed. Sci. Ohio U., Athens, OH 45701; Dept. Biology, U. Michigan, Ann Arbor, MI 48109; and INSERM U. 106, Paris, France.

With an antibody to neuron-specific beta tubulin (provided by Dr. A. Frankfurter) and Dil, we visualized axons in whole mounted fixed neural tubes from E8.5-E12.5 embryos. (Convention: at noon on the day after a night's mating, the age is E0.5). The development of individual littermates varied substantially; this description applies to "average" embryos of a given age.

At E8.5, before neural tube closure, the neural folds contain labeled cells (<10 per side) at the boundary of the presumptive neural tube and skin, at the rostrocaudal level of the junction of the presumptive fore- and midbrain. These are the only labeled cells in the embryo. By E9.0, the neural tube has closed, and the labeled cells are more numerous (>20 per side). They flank the dorsal midline in the presumptive midbrain. Their growth-cone tipped axons course caudally and ventrally in the ipsilateral alar plate, the pioneers of what later stages (examined immunocytochemically and with Dil) show is the descending tract of the mesencephalic nucleus of the trigeminal nerve.

At E9.5, two bilaterally symmetrical ventral longitudinal tracts begin to form. One originates from a cell cluster adjacent to the ventral midline at the transverse cephalic flexure, near the junction of the presumptive fore- and midbrain. Its axons course caudally in the ipsilateral basal plate, close to the midline. By E10.0, the leaders extend past the otic vesicle. This tract is the forerunner of the medial longitudinal fasciculus, and the first cells that produce axons in it probably contribute to the interstitial nucleus of Cajal. The second ventral longitudinal tract originates from a cell cluster at the base of the optic stalk. Its axons course caudally through the ipsilateral presumptive diencephalon, and reach the cephalic flexure by E10.0, but by E12.5, have not advanced more caudally. This is the tract of the postoptic commissure, which is joined later by the retinofugal axons. Unlike the other two tracts, it can not now be identified with an adult structure.

SPECIFICITY AND MODE OF GROWTH OF DEVELOPING CORTICOSPINAL AXONS INTO THEIR SPINAL GRAY TERMINAL FIELDS. L. López-Mascaraque and D.D.M. O'Leary, Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037.

Layer 5 is the source of cortical inputs to the brainstem and spinal cord. Layer 5 neurons contact their brainstem targets by extending collateral branches from primary axons that form the corticospinal projection; the branches form days after the axons grow past their targets (O'Leary & Terashima Neuron 1:901 '88; Soc NS Abs 15:875 '89). Here, we address the mode by which layer 5 axons invade their terminal fields in the spinal gray, and the topographic specificity of this process. Corticospinal axons labeled with Dil injected into the forelimb and hindlimb regions of sensorimotor cortex (SMC) were examined in P1, P4, P6, P8 and P11 rats. In mature rats, forelimb axons terminate at cervical levels, hindlimb axons at lumbar levels. To correlate the somatotopic map in SMC with corticospinal projections, the injected cortex was processed for AChE. Early on P1, labeled axons extending down the dorsal funiculus (DF) reach the cervical enlargement. By P4, they attain lumbar levels. By P6, axons reach mid-levels of the lumbar enlargement, and by P8 extend beyond it. Axons labeled from forelimb and hindlimb regions extend similar distances. The spinal gray is invaded by collaterals that branch at right angles from primary axons that have already grown past, and form in a rostral to caudal progression. Only occasionally do primary axons deviate from the DF and grow into the spinal gray. Branches are first seen on P4; the few labeled are found at cervical levels. By P6, branches increase in number and are found mainly in the cervical enlargement, and some at thoracic levels. Most collaterals are simple; many do not extend out of the DF. At P8, collaterals are more complex and are found throughout cervical to lumbar levels, but their number decreases caudally. The timing and patterning of collateral extension is similar for forelimb and hindlimb axons. By P11, collaterals are preferentially found at the correct spinal level. These findings indicate that (1) corticospinal axons initially overshoot their appropriate spinal level; (2) corticospinal axons innervate the spinal gray as they do the brainstem; by the delayed extension of collaterals from the primary axon; (3) the initial extension of collaterals into the spinal gray is topographically inaccurate. DISTRIBUTION OF LAMININ A, B1 AND B2 CHAINS IN THE DEVELOPING MOUSE HINDBRAIN. S.A. Moody and M. Fisher. Dept. Anatomy & Cell Biology, Univ. Virginia School of Medicine, Charlottesville, VA 22908.

Laminin is a large, extracellular matrix glycoprotein that usually consists of three distinct polypeptide chains, A, B1 and B2. Using antisera that specifically recognize each of these chains, and one that recognizes mature basement membrane laminin (EHS), we studied the immunohistochemical distribution of these polypeptides in the hindbrain of the mouse during periods when the longitudinal fascicles of axons are forming and when the postmitotic trigeminal (V) motoneurons migrate. At E9 and 10 the lateral mesenchyme through which V peripheral nerves grow is more intensely stained with all four antisera than other mesenchymal regions. The chain-specific antisera all stained the medial mesenchyme surrounding the notochord very intensely at E10-12, whereas EHS laminin antisera stained this region beginning at E11. At none of the days studied did we detect mature laminin in the parenchyma of the hindbrain. However, at E9 B2 staining was ubiquitous and B1 staining was in cells scattered throughout the neuroepithelium. At E10 all chains were detected in the marginal zone, which contains numerous growing axons and migrating neurons. Staining with B1 was heaviest; staining with B2 did not include the most medial fascicles, and staining with A was the faintest. At E11 B1 and B2 chains additionally were found in commissural axonal paths and the V motor root, whereas A chain was found in a secondary migratory path in the intermediate zone. By E12 B1 and B2 staining in the marginal zone was virtually gone, but staining in the longitudinal axons of the raphe was intense. These results demonstrate that laminin is present in the along neuronal migratory pathways as well as axonal tracts, and is heterogeneous in its chain composition. Perhaps microheterogeneity in the ECM regulates its widespread roles. Supported by NS23158 (SAM) and NS25350 (MF).

LAMININ/PROTEOGLYCAN IMMUNOREACTIVITY AND DEVELOPMENTAL LOSS OF REGENERATIVE SPECIFICITY.

M.L. Meeker and P.B. Farel. Dept. of Physiol. Univ. N. Carolina Sch. Med., Chapel Hill, NC 27599.

Regenerating lumbar motoneuron axons can specifically reinnervate their hindlimb targets during the first third of larval (tadpole) life in the bullfrog, after which time regenerative specificity is lost. We hypothesize that non-neural structures develop in the hindlimb which prevent regenerating axons from responding to guidance cues. The most likely structure is the Schwann cell basal lamina which surrounds all axons of the peripheral nerve.

Ultrastructural appearance of the basal lamina coincides with the loss of regenerative specificity, consistent with our hypothesis. We have analyzed the immunocytochemical distribution of two major constituents of the basal lamina, laminin and heparan sulfate proteoglycan (HSPG, antibody provided by M.J. Anderson), in relation to neurofilament protein (NF) in tadpole hindlimbs at stages when regenerative specificity is present and after it is lost. Controls for nonspecific staining included omission of the primary antibody and the substitution of a non-immune serum or irrelevant antibody. Even at the earliest stages examined, where no basal lamina is seen ultrastructurally, both laminin and HSPG immunofluorescence are present in regions of NF staining. These observations indicate that the molecular components of the basal lamina are present prior to their organization into a discrete structure. This finding reinforces the need for morphological studies in order to interpret correctly the results of immunocytochemical analyses.

297.5

A GROWTH CONE COLLAPSING ACTIVITY FROM ADRENAL MEMBRANES THAT AFFECTS RETINAL GANGLION GROWTH CONES MORE THAN DORSAL ROOT GANGLION GROWTH CONES. J.L. Baird and J.A. Paper. Dept. of Anatomy, Univ. of Penn. Sch. of Med., Philadelphia PA 19104.

Factors that repulse growth cone advancement may influence pathway choice. When neuronal explants from peripheral and central nervous tissues are cocultured, growth cones will collapse when they encounter neurites of unlike origin. Growth cone collapse can also be induced when plasma membrane extracts are applied to neuronal explants. Membrane extracts of the rat pheochromocytoma cell line PC12 have previously been shown to collapse chick retinal better than DRG growth cones in culture.

We have found that plasma membrane extracts of neonatal bovine adrenals contain a growth cone collapsing activity that, like PC12 extracts, is more active towards retinal as compared to DRG growth cones. This activity is inhibited by low concentrations of several irreversible serine proteinase inhibitors, such as 10 μ M p-nitrophenyl p'-guanidobenzoate, suggesting that it is a serine proteinase. Retinal growth cones respond to the adrenal membrane extract within 15 minutes of application. When the adrenal membrane extract is washed out of the medium, growth cone collapse is rapidly reversed and treated explants return to control values within 1 hour. Thus the growth cone collapsing activity from neonatal bovine adrenal membranes exhibits several features that are consistent with an activity that may play a role in growth cone guidance. These include differential effectiveness, rapid onset, and termination of action.

297.2

AN INTEGRIN LAMININ RECEPTOR INVOLVED IN NEURITE OUTGROWTH. Ivan de Curtis and Louis F. Reichardt, Dept. of Physiology and HHMI, University of California, San Francisco, CA 94143-0724.

Chick embryo neural retinal cells show extensive neurite outgrowth when cultured on laminin. Cell attachment and neurite outgrowth on laminin diminish between embryonic day 6 and 12, when the production of retinal ganglion cells has ceased, and the majority of their axons have entered the target tissue, the tectum. The monoclonal antibody CSAT, against the chick integrin β 1 subunit, completely abolishes neurite outgrowth on laminin, and immunoprecipitation of metabolically labeled retinal neurons from day 6 and day 12 embryos shows different profiles of α integrin subunits coprecipitated with β 1. The integrin α 6 β 1 is a prominent laminin receptor expressed in the retina. We have cloned the chick α 6 subunit and we have studied the expression of this protein in retinal cells. We show that in retinal ganglion cells the loss of the ability to extend neurites on laminin is correlated with a dramatic decrease of both α 6 mRNA and polypeptide, suggesting that changes in gene expression account for the developmental regulation of the interactions of these neurons with laminin. In other retinal neurons the level of α 6 mRNA and polypeptide remain high, while function is lost, suggesting that integrin function is regulated at the posttranslational level in these cells. Recently we have obtained a polyclonal antibody against a fusion protein containing 70 kD of the amino-terminal extracellular portion of the chick α 6 integrin. This antibody reduces dramatically neurite outgrowth by retinal neurons on laminin, providing more direct evidence for the role of this laminin receptor in the retina.

DISTRIBUTION OF TENASCIN ALONG THE DEVELOPING VISUAL PATHWAY IN CHICK AND MOUSE. R.G. Perez, A. Smetanka, W. Halfter and M.H. Hankin. Dept. Neurobiology, Anatomy & Cell Science, Sch. of Medicine, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Tenascin (TN) is an extracellular matrix protein reported to be a non-permissive substrate for cell migration and neurite outgrowth *in vitro*. We have studied the distribution of TN in developing chicks and mice to determine whether its expression is temporally and spatially related to regions of the visual pathway where the outgrowth of retinal axons is confined to stereotyped patterns. Such crucial "decision" areas include the optic disc, the optic chiasm and tract, and the optic tectum (superior colliculus (SC) in mammals) - the principal termination site for optic axons.

In the chick between E4-8, high concentrations of TN were found at the optic disc within the retina, and at the supraoptic commissure. In the optic tectum, TN was expressed prior to neurite ingrowth in a rostral to caudal gradient in the optic fiber layer.

In the SC of the normal mouse, TN was seen at E15 in a narrow band 20-50 μ m below the pia. By E16, the staining intensity increased and extended from the pial margin to a depth of approximately 100 μ m. By E18, TN expression had decreased in the 100 μ m below the pia, but increased in deeper regions of the SC.

These findings show that TN is distributed in regions of the developing visual pathway where optic axons make major decisions regarding directional outgrowth or terminal arborization. The data are consistent with the idea that TN is a non-permissive substrate, and may provide a "stop" signal for retinal axons in the tectum/SC.

Supported by NIH grant NS26777 (MHH), NSF grant BNS-9021474 (WH) and a graduate fellowship NIMH 5T32-MH18882-04 (RGP).

297.6

THE BARRIER FUNCTION OF TECTAL MIDLINE GLIAL CELLS AND ITS ASSOCIATION WITH PROTEOGLYCAN DISTRIBUTION. D.-Y. Wu, J. Silver, G.E. Schneider, and S. Jhaveri. Dept. of Brain & Cogn. Sci., M.I.T., Cambridge, MA 02139 and Dept. of Neuroscience, Case Western Reserve Univ., Cleveland, OH 44106.

A group of radial glia, present along the midline of the superior colliculus (SC), may serve as a barrier in the establishment and maintenance of laterality in the retinectal projection (Wu et al., '90, SN abstr.). Keratan sulfate proteoglycan (KSPG), a molecule which inhibits axon growth, has also been detected in this midline region (Snow et al., Dev. Biol., '90). We have examined the growth of retinal axons which abnormally cross the tectal midline after selectively severing the glial processes. The distribution of KSPG was also studied in the SC during normal development and in the cases with lesions.

KSPG is first detected at the tectal midline on E13 just prior to the entry of retinal axons in the SC. Its expression continues at least into early postnatal life. In animals with the midline glia severed, the apical processes degenerate within 12 h, and by 72 h retinal axons have crossed the midline. The crossing is observed only in regions where the glial processes have degenerated. Correlated with this, KSPG immunostaining also disappears from the same regions, whereas the molecule persists along the basal, non-degenerated regions of the glia.

We conclude that 1) the degeneration of apical processes of radial glia in the superior colliculus precedes abnormal growth of retinofugal axons across the midline; 2) KSPG is co-localized with the tectal midline glial processes and 3) KSPG is a likely contributor to the barrier function of the glial cells at the SC midline.

297.7

A MOVING GRADIENT OF CHONDROITIN SULFATE PROTEOGLYCAN MAY BE A CONTROLLING FACTOR DURING NEURONAL PATTERN FORMATION IN THE DEVELOPING MAMMALIAN RETINA. P. Brittis, D. Canning, and J. Silver, Dept. of Neuroscience, Case Western Reserve Univ., Cleve. OH 44106

We have developed a rat retinal organ culture model to elucidate the roles that different proteoglycans play during neuronal pattern formation. On E12.5, chondroitin sulfate proteoglycan (CSPG) was detected in the marginal zone over the entire vitreal surface of the retina. On E13, the neuroepithelium nearest to the optic fissure loses CSPG. With further development through E16.5, CSPG disappears from the retina in a moving wave that progresses outwardly in all directions. Differentiating ganglion cells and axons, identified with anti-beta tubulin antibodies, are found first in the reduced CSPG region near the fissure. Thereafter, ganglion cells appear sequentially toward the periphery but always in a region of diminished CSPG staining. The moving boundary between high and low CSPG levels is not sharp but, rather, appears as a gradient that dissipates gradually over 75µm. Ganglion cells without axons have been found in the distal regions of the gradient. Axons are initiated from endfeet processes near the mid-point of the gradient. As axons emerge they turn away from the high CSPG zone and grow toward the fissure amid other ECM molecules.

Retinal perturbation using chondroitinase resulted in polarity reversals of the ganglion cell bodies as well as gross axon guidance abnormalities with ectopic axons travelling toward the pupil and/or in the wrong level of the retina. Our data suggest that CSPG, and possibly other sulfated proteoglycans, may play several roles during retinal development. First, CSPG may suppress ganglion cell differentiation and axonogenesis and second, by offering an unfavorable substratum, may guide the growth cone away from sites where it is transiently in abundance.

MOLECULAR GRADIENTS ALONG THE PROXIMAL-DISTAL AXIS OF EMBRYONIC INSECT LEGS: POSSIBLE GUIDANCE CUES OF PIONEER AXON GROWTH. J. L. Denburg, B. A. Norbeck*, and Y. Feng*, Biology Department, University of Iowa, Iowa City, IA 52242.

The existence of gradients of environmental cues has been proposed to explain the proximal growth of pioneer axons in embryonic legs of insects. Hybridoma techniques have been used to produce 3 monoclonal antibodies that bind to components associated with the basal lamina/extracellular matrix that are distributed in a gradient along the proximal-distal axis of cockroach legs at the time of pioneer axon growth. Two of these, PROD-1 and PROD-2, label the proximal parts of the leg more intensely than the distal ones. The other, DIP-1 has the inverse pattern of binding with the distal parts of the leg labeled more intensely. The gradient distribution of these antigens only exists just before and during the period of growth of the pioneer axons. Western blot analysis has identified the PROD-1 antigens as 4 major proteins of 112, 74, 69, 59 kd, and the PROD-2 antigen as a 225 kd protein. The spatial and temporal distribution of these molecules makes them good candidates for environmental guidance cues of pioneer axon growth.

297.11

MOLECULAR CHARACTERIZATION OF EMBRYONIC GLIA AND THEIR ROLE DURING GROWTH CONE GUIDANCE IN DROSOPHILA. V.J. Auld, C. Klämbt*, R. Tsao*, and C.S. Goodman, Howard Hughes Medical Inst. Dept of Molecular and Cell Biology, U. of California, Berkeley, CA 94720

The growth cones that pioneer many of the major CNS axon tracts and nerve roots in the *Drosophila* embryo extend towards and along specifically positioned glial cells. When these glial cells are eliminated selectively by either laser (in grasshopper) or genetic (in *Drosophila*) ablation, specific pathways do not form or form abnormally. In order to obtain new molecular lineage markers that selectively label different subsets of glia, and most important, to identify new genes expressed in these glia that might function in the formation of the early axon pathways, we conducted a large scale enhancer trap screen. Over 11,000 enhancer trap lines were screened (representing over 6,000 different genes or at least 1/5 of the genome), and of these, 54 express β -galactosidase (β -gal) in subsets of glia. These 54 lines represent 46 independent sites of insertion: 22 are expressed in midline glia, 10 in nerve root and peripheral glia, and 14 in longitudinal glia. Of particular interest are the four glial cells positioned just outside the CNS (called "exit" glia) that specifically mark the point at which the intersegmental and segmental nerve roots come together before they split into several peripheral axon pathways. Detailed analysis of exit and peripheral glia lines show that some genes are likely to be expressed in only two or a small group of these cells per segment. Several lines are under further molecular genetic analysis to determine the nature and function of their gene products, and the potential role of these genes in establishing the pattern of early axon pathways.

297.8

A ROLE FOR PROTEOGLYCAN IN THE GUIDANCE OF A SUBSET OF PIONEER AXONS IN CULTURED EMBRYOS OF THE COCKROACH. L.S. Wang and J.L. Denburg, Biology Department, University of Iowa, Iowa City, IA 52242.

Many of the interactions that proteoglycans make with molecules involved in the development of the nervous system are mediated by their glycosaminoglycan (GAG) side chains. The addition of free GAGs should compete for the proteoglycan binding site, inhibit these interactions and perturb development. It is demonstrated that GAGs perturb axon guidance in cockroach embryos cultured *in vitro* during the period of growth of several pioneer axons. The specificity of this phenomenon is evident from the observation that of all the GAGs tested only heparin and heparan sulfate produced perturbation. In addition, of the 6 axon tracts being pioneered during the culture period the GAGs alter only 2 of them, the median fiber tract in the CNS and the T11 axons in the leg. In the perturbed median fiber tract the pioneer axons no longer grow along the midline. The perturbed T11 pioneer axons defasciculate and follow various alternate paths. These results indicate that subsets of neurons may be characterized by their heparan sulfate proteoglycans which in some pioneer axons are involved in selective fasciculation while in others are involved in axon pathfinding.

Supported by NIH grant NS 15350.

CONNECTIN: A SURFACE PROTEIN EXPRESSED ON A SUBSET OF MOTONEURON AXONS AND THE TARGET MUSCLES THEY INNERVATE IN DROSOPHILA. A. Nose* and C.S. Goodman, Howard Hughes Medical Inst, Dept of Molecular and Cell Biology, U. of California, Berkeley, CA 94720

Each hemisegment of the *Drosophila* embryo contains 31 or fewer identifiable muscle fibers, each of which is innervated in a highly stereotypic fashion by a small number of specific motoneurons. We have screened over 11,000 enhancer trap lines and have isolated 6-8 lines which express β -galactosidase in small subsets of muscle fibers prior to and during innervation, and are thus good candidates for target recognition molecules which guide motoneuron growth cones.

One of these lines, F400, expresses β -gal in the nuclei of four lateral and one ventral muscle fiber, and also in a small subset of CNS neurons. We cloned and sequenced the F400 cDNA and found that it contains a signal peptide and eight 24-amino-acid leucine-rich repeats (LRR); many proteins with LRR repeats have been implicated in adhesion and/or recognition. In *Drosophila*, LRR repeats are also found in Toll, chaptin and slit (interestingly, Toll is one of our other lines). We next generated antibodies against the F400 protein. The protein is expressed on the surface of the same muscle fibers that express β -gal, and on the surface of the motoneuron axons and growth cones which innervate these muscles. It is also expressed on several cells (probably glia) along the peripheral pathway of these motoneuron axons.

These results strongly support the notion that F400 plays a role as a recognition molecule in neuro-muscular connectivity and thus we call this molecule connectin. We are currently conducting a genetic analysis of the function of connectin to test this hypothesis.

COMMISSURELESS, A MUTATION IN DROSOPHILA THAT SPECIFICALLY DISRUPTS GROWTH CONE GUIDANCE TOWARDS THE MIDLINE. M.A. Seeger, G. Tear*, D. Ferrer-Marco*, and C.S. Goodman, HHMI, Dept of Molecular and Cell Biology, University of California, Berkeley, CA 94720.

To understand the mechanisms by which commissural and longitudinal axon pathways are established in the *Drosophila* embryonic CNS, we have initiated an F2 genetic screen for mutations that disrupt the formation of these pathways. Our goal is to saturate the *Drosophila* genome (by screening ~20,000 independent lines with roughly 2-3 lethal hits per chromosome) for mutations that produce specific defects in the major CNS pathways. Mutant phenotypes are identified by staining embryos with MAb BP102 which recognizes all CNS axons.

A relatively discrete number of phenotypic classes have emerged from our initial analysis of >5,000 lines, the most dramatic being a CNS lacking all commissural tracts but with normal longitudinal tracts, peripheral nerve roots, muscles, sensory organs, and body organization. We have isolated two independent mutations in a single gene that produce this phenotype, which we name *commissureless*. Neurons, such as RP1, that normally project their axons across the midline fail to do so in *commissureless* mutant embryos; instead they make an ipsilateral projection that is normal in all aspects except for their failure to cross the midline. The projection of commissural axons across the midline is a property common to arthropods and vertebrates. We suspect that the *commissureless* gene product represents either the signal or the receptor for the guidance of growth cones towards the midline. To test this hypothesis, we have begun a molecular analysis of *commissureless*.

297.13

ROLES OF SECOND MESSENGERS IN AXON INITIATION AND GUIDANCE OF T11 PIONEER NEURONS IN THE GRASSHOPPER. K. L. Lankford, Dept. of Molecular & Cell Biology, Univ. California, Berkeley CA 94720.

During normal embryonic development in the grasshopper limb, T11 pioneer axons navigate along a stereotyped route to the CNS that includes an initial proximal directed outgrowth and two sharp turns in the region of the Tr/Cx segment boundary. To assess the possible roles of different second messenger systems in specific steering events during pioneer growth cone navigation, I exposed cultured grasshopper embryos to a variety of second messenger agonists, antagonists, and analogues at different developmental stages and for variable lengths of time and examined the resulting T11 pathways. Although many treatments affected the fasciculation of the T11 axon pairs, axon diameter, or rate of neurite outgrowth, the steering itself was extremely resistant to manipulation. One notable exception was an apparent delay or inhibition of axon initiation caused by very early calcium manipulations, and a misdirection of initial outgrowth in some neurons exposed to transient calcium elevations. A second exception was an increased frequency of anomalous turns and Tr/Cx boundary crossing caused by exposure to cGMP analogues. These effects were very age specific.

297.15

A ROLE OF POLYSIALIC ACID IN SPECIFIC AXONAL GUIDANCE. J. Tang*, L.T. Landmesser and U. Rutishauser. Dept. Physiology & Neurobiology, University of Connecticut, Storrs, CT 06269 and Depts. Genetics & Neuroscience, Case Western Reserve University. School of Medicine, Cleveland, OH 44106.

Axon-axon interactions during early motoneuron axon outgrowth and pathway formation are mediated by a variety of cell adhesion molecules. Polysialic acid (PSA), a post-translational modification of NCAM, can regulate cell-cell interactions mediated not only by NCAM, but by other cell-cell ligands as well. To test whether modulation of PSA levels was involved in motoneuron axonal pathfinding, we determined the temporal and spatial pattern of PSA expression during motoneuron outgrowth using Mab 5A5, which recognizes highly sialylated NCAM. PSA expression was increased on motoneurons only at stage 23 as their growth cones converged at the plexus region (a region where axons segregate into motoneuron pool-specific groups) and was found to differ dramatically between motoneurons projecting to different targets; specifically PSA was higher on motoneurons that project to dorsal thigh, and lower on those that project to ventral thigh and shank. When PSA was removed by injecting a PSA specific endosialidase into the limb bud during different stages of axon outgrowth, retrograde HRP labeling of motoneuron pools indicated that projection errors had occurred on both the antero-posterior and dorsal-ventral axes. These results indicate that PSA may modulate the interactions of these growing motoneuron axons with guidance molecules, and thereby contribute in a permissive and/or instructive manner to axonal pathway selection.

297.17

REGIONAL DISTRIBUTION OF NEURAL CELL ADHESION MOLECULES (NCAMs) IN RODENT HIPPOCAMPUS. P. I. Miller*, W-W. Chung, C.F. Lagenaur, and S.T. DeKosky, Depts. of Neurobiology, Anatomy & Cell Science, Psychiatry, and Neurology, Univ. of Pittsburgh Sch. of Med. and Western Psychiatric Inst. & Clinic, Pittsburgh, PA 15213.

Cell surface adhesion molecules NCAM and L1 are implicated in CNS cell migration and axon outgrowth *in vitro* and *in vivo* developmental studies. The distribution of these two molecules is quite distinct in CNS development, suggesting that NCAMs and L1 subserve different roles in process outgrowth and tissue organization. A variety of NCAM isoforms are known, and individual NCAMs undergo post-translational modification. These changes may mediate development of specific neural cell contacts and circuitry. We evaluated immunohistochemical staining of antibodies to total NCAM, embryonic NCAM, and L1 in rat and mouse hippocampus. Staining patterns in the two species were similar. A distinctive pattern of staining was found, corresponding to the known anatomy of the structure. Total NCAM staining was intense in the hilus and inner molecular layer (ML) of the dentate gyrus with less marked staining in the dentate outer ML. The mossy fiber tract (MFT) was well demarcated. There was abundant staining the stratum radiatum (SR) and stratum oriens (SO) of CA1. Stratum lacunosum-moleculare (L-M) had very little staining. L1 staining was more evenly distributed throughout the hippocampus and dentate, with little hilar staining, no MFT staining, and even staining through the SR, SO, and L-M. Embryonic NCAM had little CA1 staining but strong hilar and MFT staining; thus, this "embryonic" molecule continues to be expressed in limited regions in the adult. These distinctive patterns suggest that the distribution of the NCAM and L1 molecular species have clearcut structural and functional roles in the laminated circuitry of the hippocampus.

RNA SYNTHESIS DEPENDENCE OF GROWTH CONE PATHWAY CHOICE DURING EMBRYONIC DEVELOPMENT. R. von Bernhardi and M. J. Bastiani, Dept. of Biology, University of Utah, Salt Lake City UT 84112.

The role of transcription in the ability of growth cones to make pathway choices has been largely unexplored. Actinomycin-D was used to examine if synthesis of new mRNA was necessary for 1) neurite outgrowth of pioneer neurons, 2) neurite outgrowth along an established axonal pathway, and 3) change in the direction of outgrowth when the neuron reaches a "pathway choice" point. Grasshopper embryos of 32-33% development were cultured for 24 to 48 hrs in media containing 0.01-0.05 µg/ml of Actinomycin-D (control embryos are cultured in absence of transcription blockers). At this stage the aCC, pCC and Q1 neurons have just initiated axonogenesis. After the culture period, the embryos were fixed, the cells were labeled by iontophoresis with 0.5% Di-I in ethanol, and the extension of their axons was evaluated with standard epi-fluorescence or confocal microscopy.

Inhibition of transcription at a stage when the growth cone approaches its choice point specifically blocks its ability to change the direction of extension. Of 64 aCC axons evaluated, 86% were unable to choose their correct pathway. There is no blocking affect upon either neurite outgrowth of pioneer neurons (Q1, n= 34) or axons that grow along a single pathway without changing their direction of extension (pCC, n= 106). Our results suggest that the extending axon is able to grow for a period of time in the absence of transcription. However, neurons require new mRNA in order to change their direction of growth at a pathway choice point.

297.16

POLYSIALIC ACID PROMOTES GROWTH OF AXONS ON NEURONAL MEMBRANES BY MODULATING L1 FUNCTION. H. Zhang*, R.H. Miller, and U. Rutishauser. Dept. of Neuroscience and Genetics, Case Western Reserve Univ., Cleveland, OH 44106

During development, growing axons reach their targets by interacting selectively with both neuronal or non-neuronal surfaces in their environment. A variety of cell adhesion molecules, such as NCAM, N-cadherin, L1 and integrins appear to promote axonal outgrowth, and regulation of the expression of these adhesion molecules may contribute to formation of specific axonal pathways. We have proposed previously that cell-cell interactions can also be regulated by the presence of an unusual cell surface carbohydrate, called polysialic acid (PSA). PSA, which is attached to NCAM, is strongly expressed by growing axons but is largely lost from the surface of mature fibers.

In the present studies, the influence of PSA on axonal outgrowth has been examined *in vitro* using two substrates, a monolayer of cortical astrocytes and a carpet of neuronal membrane vesicles. Effect of PSA on outgrowth of single embryonic retinal axons on these substrates were studied using a PSA-specific endoneuraminidase (endo-N) while the molecular basis of this effect was analysed by antibodies that block the function of adhesion molecules. Enzymatic removal of PSA from retinal axons and tectal membrane substrate was found to decrease embryonic retinal axon elongation. This decrease was reversed by antibody against L1 but not by antibodies against NCAM, N-cadherin, or integrins. In contrast, growth of axons on astrocytes was not affected by endo-N. These results suggest that presence of PSA produces optimal retinal axon outgrowth on the neuronal substrate by attenuation of L1-mediated interactions, and that this mechanism of regulation is related to axon-axon but not axon-glia interaction.

cDNA CLONING OF THE AXON-ASSOCIATED ADHESION MOLECULE AXONIN-1. R.A. Zuelig¹, C. Rader¹, A. Schroeder¹, M. Kalousek¹, F.v. Bohlen¹, A. Fritz², E. Stoeckli³, E. Hafen², H.U. Afollter³, P. Sonderegger³. ¹Biochemisches Institut, ²Zoologisches Institut, and ³Institut für Hirnforschung, Universität Zürich, CH-8057 Zürich, Switzerland.

Axonin-1 is an axon-associated cell adhesion molecule (AxCAM) occurring both as a membrane-bound and secreted form in the chicken embryo. Recent studies have revealed that it is a potent promoter of neurite outgrowth, when presented as a substratum to cultured neurons. Here we report the molecular cloning and nucleotide sequence determination of axonin-1. About 50% of the amino acid sequence of axonin-1 was determined by Edman degradation of randomly selected peptides generated by enzymatic cleavage. The amino acid sequence of most of the peptides showed homology to F11. The axonin-1 peptides were aligned to F11 and primers for PCR were selected. mRNA from retina of 12-day-old chicken embryos was isolated and first strand cDNA was produced. With PCR a fragment of 560 bp was amplified. It was confirmed to represent a segment of axonin-1 by nucleotide sequencing. Screening of an oligo(dT)-primed cDNA library from 14-day-old embryonic chick brain resulted in the isolation of two different clones with a 2.4 kb and a 4.0 kb cDNA insert, respectively. The nucleotide sequence of both clones was determined. The shorter cDNA overlapped entirely with the 3' part of the longer cDNA. The longer cDNA contained an open reading frame of 3108 nucleotides, 132 noncoding nucleotides at the 5' end, and 727 noncoding nucleotides at the 3' end. The open reading frame codes for a polypeptide of 1036 amino acids including a putative hydrophobic N-terminal signal sequence of 23 amino acids and a C-terminal hydrophobic sequence of about 25 amino acids which may be cleaved at the time of connecting the GPI-anchor. As in TAG-1 of the rat and F11 of the chicken, the predicted primary structure comprises six immunoglobulin-like domains, followed by a short collagen-like segment of 8 amino acids, followed by four fibronectin type III repeats. The following overall sequence identity between axonin-1 and other neural CAMs was found: TAG-1 74.5%; F11 52.7%; F3 51.4%; Ng-CAM 29.2%; L1 27.6%; N-CAM 19.6%. Thus, among chicken AxCAMs, the closest relative of axonin-1 is F11. In view of the high degree of sequence similarity to TAG-1 of the rat, it appears likely that axonin-1 and TAG-1 are species homologues.

EXPRESSION OF NEURAL CELL ADHESION MOLECULE AXONIN-1 IN DEVELOPING FIBER TRACTS OF THE MOUSE NERVOUS SYSTEM. D.P.Wolfer, A.Beatty*, P.Sonderegger, E.T.Stoeckli and H.P.Lipp. Institutes of Anatomy and Biochemistry, University of Zürich, Zürich CH-8057, Switzerland.

The neural cell adhesion molecule axonin-1 of the chick occurs in two forms, one axonally secreted, one phosphoinositol-anchored to the axonal membrane. It shares 75% of the amino acid sequence with TAG-1 of the rat. *In vitro* it stimulates axonal growth and affects neurite fasciculation. We have used an antiserum raised against axonin-1 purified from chick embryos to study the expression of axonin-1 in the developing nervous system of the mouse.

Starting at embryonic day 8, we find immunoreactivity mainly localized to developing tracts formed by long axons. Axonin-1 first appears in outgrowing peripheral nerves, in ascending tracts and commissural fibres in the spinal cord. Later it can be seen in corpus callosum and anterior commissure, fimbria and alveus hippocampi, fornix, internal capsule, fasciculus retroflexus, as well as in the olfactory and optic tract. At early stages of axon outgrowth, corresponding neuronal somata may be identified (e.g. in motor neurons or projection neurons of the cortex), often, however, somata are unstained. Staining in terminal zones, as seen in cortex, hippocampus or olfactory nuclei, is usually less intense than in related fiber tracts. In the cerebellum, axonin-1 is found within forming parallel fibres and in neurons descending into the granular cell layer. At 3 weeks of age most of the immunoreactivity has disappeared, except for weak neuropil staining in the hippocampus and olfactory bulb.

The tract-related patterns of axonin-1 expression during development are consistent with a role in axoaxonal interactions in developing fiber tracts, as postulated from experiments in culture. *Supp. by SNF Grant 31-027737.89.*

DIFFUSIBLE FACTORS FROM INNERVATED TARGET REGIONS INFLUENCE OPTIC AXON OUTGROWTH IN VITRO. M.H. Hankin. Dept. Neurobiology, Anatomy & Cell Science, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Studies *in vivo* have demonstrated "homing" of optic axons toward the superior colliculus (SC), and a variety of substances have been shown to have trophic effects on retinal ganglion cells and their neurites in tissue culture. Although these studies suggest that target-derived diffusible factors influence optic axons, previous studies using explants of retina and pre-innervation targets have been inconclusive regarding such trophic (or tropic) influences. Recent studies using retinal transplants, however, raise the possibility that optic axons respond to target-derived factors only after the first optic axons have reached the SC (reviewed in Hankin & Lund (1991) *TINS*).

To address this issue, retinae (E16/17) were co-explanted in hydrated collagen gels with SC (E16/17) - a developmental stage after the initial innervation by retinal axons. Cortical co-explants were used as non-target control tissue. During the first 3 days after explanting, very little outgrowth was seen from retinal explants under any of the conditions. By day 4, however, optic axons in the presence of innervated target and competing non-target regions grew preferentially (although not exclusively) toward targets. Between 4-6 days, individual retinal neurites could be seen to make sharp turns towards innervated targets, but apparently avoided non-target explants.

These data show that target regions can exert trophic effects on optic axons, and they support the hypothesis that the initial optic input to the SC initiates the release of diffusible factors that influence the outgrowth of optic axons.

REGULATION OF NEURONAL DEVELOPMENT BY SURFACE PROTEIN PHOSPHORYLATION. M.V. Hogan*, Z. Pawlowska* and Y.H. Ehrlich. CSI/IBR Center for Developmental Neuroscience, City University of New York, Staten Island, NY 10301

Ecto-protein kinase (ePK) utilizes extracellular ATP to phosphorylate proteins localized at the outer surface of the neuronal plasma membrane. To determine the role of ePK in neuronal development we studied the phosphorylation of surface proteins in CNS neurons cultured from the telencephalon of 7-day chick embryos, and in cloned PC12 cells induced to differentiate with nerve growth factor (NGF). Enzymatic assays were carried out with cells attached to 48-well plates incubated for 10 mins with extracellular [γ - 32 P] ATP (0.1 μ M; 15 μ Ci). Phosphorylated proteins were identified by autoradiography of slab gels. In CNS neurons, two surface phosphoproteins (M.W. of 11.7K and 13K) were found to be exclusive substrates of ePK activity. Their extracellular phosphorylation is developmentally regulated and peaks at the onset of rapid neuriteogenesis. Stimulators of neurite extension (5nM gangliosides) increased this surface phosphorylation whereas preincubation of the cells with neuraminidase (0.1U) inhibited this activity. In PC12 cells, NGF (50ng/ml) stimulated ePK activity whereas a known inhibitor of NGF-stimulated protein kinase, 6-thioguanine (6-TG), inhibited surface protein phosphorylation in PC12 cells. 6-TG also potentially inhibited the phosphorylation of surface proteins by ePK in primary CNS neurons. These results suggest a significant role for ePK in neuronal development. Supported by the AFOSR.

DEVELOPMENT OF NEUROTRANSMITTER SYSTEMS

LABETALOL-INDUCED DIRECT AND LONG-LASTING NEUROCHEMICAL CHANGES AFTER POSTNATAL EXPOSURE IN RATS. E.Erdtsieck-Ernste*, M.Feenstra*, M.Botterblom*, G.Boer* (spon:ENA) Neth. Inst. for Brain Research, Amsterdam, The Netherlands.

Interference with the noradrenergic system during brain development was hypothesized to result in an altered functioning of this system in adulthood. Rat pups were injected from postnatal day (PN) 1-10 with the α - and β -adrenergic antagonist labetalol (2x10 mg/kg SC) or received one injection on PN 10. Labetalol levels and monoamine metabolism were determined with HPLC 90 min after last injection and β -receptors with [125 I]CYP 20 h after the treatment in several brain areas. One injection on PN 10 resulted in brain labetalol levels of 2.1 μ g/g, PN 1-10 treatment in 3.3 μ g/g. Acute as well as chronic labetalol exposure increased NA metabolism (MHPG/NA +20-100%), suggesting that adaptation did not develop. Minor direct effects on 5-HT or DA metabolism were seen. After chronic treatment brain β 1- but not β 2-adrenoceptors, were up-regulated (30%). Lasting effects, which were measured on PN 60, could not be detected for NA and DA metabolism or for β -adrenoceptors. 5-HT metabolism, however, was strongly increased (20-70%) in adulthood. In conclusion, chronic labetalol exposure during rat brain development did not cause long-lasting changes in β -receptor number or NA metabolism, but was critical for the setting of 5-HT metabolism later in life.

SEROTONIN-GATED CONDUCTANCES OF AN IDENTIFIED NEURON FROM THE SNAIL *HELISOMA TRIVOLVIS*. C. J. Price and J. J. Goldberg. Dept. of Zool., U. of Alberta, Edmonton, Alta., Canada T6G 2E9.

Serotonin (5-HT) influences the regeneration and development of identified neuron B19 from the snail *Helisoma trivolvis*. This action of 5-HT involves the influx of calcium through voltage-gated calcium channels. The specific mechanism through which 5-HT exerts its effects on B19 membrane potential, however, is unknown. To examine this, tight-seal whole-cell recordings were performed on B19s isolated in cell culture. Bath application of 25 μ M 5-HT evoked a robust depolarization (5-20 mV) that persisted as long as 5-HT was present. In voltage clamp, 5-HT induced an inward shift in the holding current level that ranged between 30 and 100 pA (Vhold: -70 mV). To understand the ionic conductances associated with this inward current, a ramp depolarization protocol coupled with ion substitution was used. The ramp protocol involved stepping the membrane potential by 2 mV every 2 s, from -110 mV to -50 mV. The net 5-HT - induced current was calculated by subtracting the ramp-generated current before 5-HT addition from that generated in the presence of 5-HT. When extracellular Na^+ was replaced by choline, the 5-HT - induced current was outward at potentials negative to the calculated K^+ equilibrium potential (E_K), and inward at potentials positive to E_K , suggesting that serotonin closes a K^+ conductance that is normally open at rest. When K^+ was substituted by N-methylglucamine in the pipette, and extracellular Na^+ was normal, another 5-HT - induced current was revealed. While this current was inward throughout the voltage ramp, its amplitude decreased at more positive voltages. Extrapolation of this curve indicated a reversal potential quite positive to 0 mV, suggesting Na^+ selectivity. Therefore, the depolarizing effect of 5-HT on neuron B19 involves both the closure of a K^+ conductance and the opening of a Na^+ conductance.

ORGANIZATION OF PROJECTIONS FROM RAPHE NUCLEI TO SENSORY CORTICES IN PERINATAL RATS? M.J. Leslie, N.L. Chiaia and C.A. Bennett-Clarke. Dept. of Anatomy, Medical College of Ohio, Toledo, OH, 43699.

We have shown that the dense and precisely patterned serotonin (5-HT) immunoreactivity (IR) present transiently in the developing somatosensory (S-I) and visual (area 17) cortices arises from nucleus raphe dorsalis (NRD) and perhaps also the median raphe nucleus (MRN). We undertook this experiment to determine whether the patterned 5-HT-IR seen in the sensory cortices of perinatal rats arises from topographically organized projections from NRD and MRN. Neonatal rats (P-5) received injections of rhodamine (RB) and fluorescein (GB) labeled beads into the right parietal cortex, diamidino yellow (DY) into the left parietal cortex, and true blue (TB) into the left occipital cortex. Only cases demonstrating retrogradely filled cells in appropriate portions of the ventrobasal and dorsal lateral geniculate nuclei were analyzed. An average of 90 NRD cells and 42 MRN cells were labelled after parietal cortical injections. The respective values were 92 and 60 after occipital cortical injections. Ten percent of retrogradely filled cells from paired parietal cortical injections contained both GB and RB, with 78% of these located in NRD and 22% in MRN. Six percent of cells retrogradely labelled from paired injections of parietal and occipital cortex contained both DY and TB, 84% of these were located in NRD and 16% were in MRN. Only 2 bilaterally projecting cells were noted. In several cases, brainstem sections were also immunocytochemically stained for 5-HT; 61% of the back-filled cells were immunoreactive. Patterns of retrograde labelling for these neurons did not differ significantly from those reported above. These results indicate that the dense and patterned 5-HT-IR in developing sensory cortices is not the result of topographically organized raphe-cortical projections. DE07734, DE08971

EMBRYONIC GLIAL CELLS EXPRESS 5-HT RECEPTORS AND EXHIBIT REGIONAL DIFFERENCES IN NEURONOTROPHIC ACTIVITY IN RESPONSE TO 5-HT. J. Liu*, J. Raymond*, H. Tamir, D. Millhorn and J.M. Lauder. Univ. N.C. Sch. Med., Chapel Hill, NC 27599-7090

In the embryonic rat brain, 5-HT neurons appear to influence the early differentiation of target cells such as dopamine (DA) neurons of the substantia nigra (SN). Since astrocytes can promote growth of DA neurons in a regionally specific manner, express 5-HT receptors, and neuronal growth factors in response to 5-HT agonists, we have asked whether 5-HT neurons may regulate prenatal neurogenesis by mediating region-specific interactions of neurons with glia. In support of this hypothesis we have found different effects of glia from E14 raphe (RN) and SN on the growth and survival of 5-HT and DA neurons, in response to 5-HT. 5-HT1A and 5-HT1C receptor mRNAs were localized in RN and SN glia using combined *in situ* hybridization (oligonucleotide probes) and GFAP immunocytochemistry. Immunoreactivities for 5-HT1A and 5-HT1C/2 were also found in these cells suggesting that receptors are being synthesized. These results suggest that embryonic glia may produce region-specific neuronotrophic activities following activation of 5-HT receptors.

PRENATAL ADRENERGIC RECEPTOR BINDING SITES IN RAT CEREBRAL CORTEX X.K.Gao, A.J.Friedhoff, J.C.Miller, and K.A.Bonnet, Millhauser Lab, Dept. of Psychiatry, New York Univ. Sch. of Med., New York, NY 10016

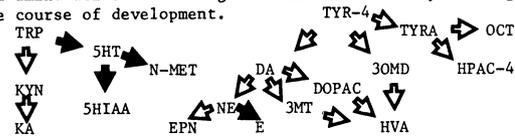

Prenatal adrenergic alpha-1, alpha-2, and beta receptor binding sites in fetal rat cerebral cortex are detected respectively by [3H]-prazosin, [3H]-paralindolol (3H-PAC) and [3H]-dihydroalprenolol (3H-DHA). Some degree of specificity of ligand binding sites can be detected early in gestation. Specificity of [3H]-prazosin binding sites appears on GD15, but does not exhibit good kinetic properties until GD20. Specificity of [3H]-PAC binding sites is seen early in GD13 and exhibits mature kinetic properties by GD14. The density of binding sites increases two-fold by GD20. Specificity of [3H]-DHA binding sites also appears early in GD12-13, and has some degree of kinetic properties by GD15-16 and has relatively mature kinetic properties after GD16. These different receptor subtypes have different maturation courses from the protoreceptor to the mature receptor.

DYNAMICS OF NEUROTRANSMITTER METABOLISM IN THE CENTRAL NERVOUS SYSTEM OF FROGS. NAOKUNI TAKEDA & HIDEO TAKAOKA * Department of Biotechnology, COSMO Research Institute, Satte, Saitama, 340-01, JAPAN.

The dynamics of neurotransmitters including biogenic amines, neuroactive amino acids and acetylcholine were examined with the progress of embryonic development and metamorphosis. These compounds were analysed by three dimension coulometric HPLC system (ESA Inc., USA) and HPLC system with ECD using enzyme column.

The main species were *Rana japonica*, *Bufo bufo japonica* and *Xenopus laevis*. In *Rana*, the main metabolic pathways in monoamines during embryonic development () and metamorphosis () are shown below. With the development of hind limb, E, 5HT, 5HIAA and N-methylserotonin (N-MET) detected. In *Xenopus*, 5HT-MEL pathway was found in larvae. In adults, N-MET, EPN and OCT disappeared. Acetylcholine and amino acids also changed characteristically during the course of development.

These results will be discussed from the view points of ontogeny and phylogeny.

298.6

FIRST DESCRIPTION OF THE CENTRAL CATECHOLAMINE (CA) SYSTEMS IN 6-8 WEEK-OLD HUMAN EMBRYOS. Zečević N., Verney C., Milošević A. and B.Berger*. Inst. for biol.res. Belgrade 11000, Yugoslavia and *INSERM, U106, Paris, France.

Dopamine and noradrenaline systems were identified with antibodies raised against tyrosine-hydroxylase (TH) and dopamine-β-hydroxylase (DBH) in human embryos of 6-8 gestational weeks (g.w.) and 9-11 g.w. fetuses. In 6 week-old embryos, only a few DBH-IR cells and fibers were observed in the myelencephalon and pons, while the diencephalon only contained labeled fibers. In contrast, numerous TH-like reactive (TH-IR) neuronal cell bodies and fibers were seen in the myelencephalon, pons (locus coeruleus), ventral mesencephalon (prospective ventral tegmental area and substantia nigra) and ventral diencephalon (hypothalamus). TH-IR fibers reached the intermediate zone of the latero- and rostroventral telencephalon only from 8 g.w. on, following the gradient of cortical plate development. At 11 g.w., TH positive axons had penetrated the subplate layer of the telencephalon running rostrocaudalwards, but did not reach the most posterior areas. Very few DBH-IR axons were present in the same areas and layers. Presently 6 g.w. is the earliest age of CA systems identification in the human CNS.

COUPLING BETWEEN NEURONES OF THE DEVELOPING RAT LOCUS COERULEUS REVEALED BY INTRACELLULAR INJECTION OF BIOCYTIN. M.J.Christie and H.F. Jelinek*. Department of Pharmacology, The University of Sydney, N.S.W. 2006 AUSTRALIA.

Simultaneous intracellular recordings from pairs of locus coeruleus neurones in neonatal rat brain slices revealed synchronous, rhythmic oscillations of membrane potential (rats less than 27 days old) and electrotonic coupling between 40% of pairs of neurones (rats less than 10 days old; Christie et al., *J.Neurosci.*, 9: 3584, 1989). In the present study, slices from rats 1 to 20 days old were stained with avidin-HRP (Vector Labs.) only if the first neurone impaled was maintained for longer than 10 min with an electrode (30 - 50 Mohm) containing biocytin (2%, Sigma). In slices from rats 1 to 10 days old, multiple stained neurones (3.7 ± 0.6 neurones/slice) were observed in 12 of 17 slices studied. Contacts between stained neurones were observed at varying distances along dendrites. In rats older than 10 days multiple stained neurones were observed in 2 of 14 slices studied (2 neurones/slice). The presence of multiple stained neurones was not correlated with the frequency of rhythmic oscillations, cell input resistance, or the shape of electrotonic potentials. These results suggest that low resistance pathways between locus coeruleus neurones are common in brain slices from rats less than 10 days old, consistent with electrotonic coupling studies. However, this coupling cannot fully explain synchronous rhythmic activity, because the latter persists until at least the 27th postnatal day.

298.9

ONTOGENY OF SENSITIVITY TO NEUROMODULATORS IN RAT NEOCORTICAL NEURONS. Lorenzon, N. M. and Foshring, R. C., Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38103-4901.

We tested the hypothesis that rat neocortical neurons from developing (PND 6-28) and adult rats are differentially affected by noradrenergic (NE) and muscarinic agonists. Intracellular recordings were obtained from an *in vitro* slice preparation.

Action potential width decreased and the rate of action potential repolarization increased over the first 2-4 postnatal weeks. Input resistance also decreased during development. We observed the same AHP components (fast, medium, and slow) in adult and immature neurons. However, in several of the 1-2 week old rats, an extremely long slow AHP (> 4 s) was observed after repetitive firing which was not seen in the adult rats.

In adult neurons, 10-100 μ M NE or muscarinic agonists reversibly reduced the amplitude of the medium and slow AHPs after repetitive firing. This led to an increase in the f-I slope and reduced spike frequency adaptation. Neurons at all ages responded to NE and muscarinic agonists and similar reductions in the medium and slow AHPs were observed at all ages tested (PND 6-28). Both NE and muscarinic agonists eliminated the late slow AHP that was seen in some of the immature neurons resulting in AHPs which resembled those of the adult neurons.

Most neurons tested were regular-spiking pyramidal cells located in layers II-V (confirmed from biocytin filled cells). We also sampled burst-firing and fast-spiking neurons from animals two weeks to adult in age. Supported by NINDS grant #R29NS27180.

DEVELOPMENT OF NEUROPEPTIDE EXPRESSION IN RAT SYMPATHETIC GANGLIA. S. Tyrrell, J. S. DeJonge and S. C. Landis. Department of Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

Many neurons contain one or more neuropeptides which can modulate neuronal transmission. Although neuropeptide distribution and colocalization in the mature autonomic nervous system are well characterized, their patterns of expression and the factors which regulate them in the developing nervous system are incompletely understood. Using immunocytochemistry, we have examined the development of several neuropeptides in two sympathetic ganglia, the stellate and superior cervical ganglia (SCG), which lie in the thoracic and cervical regions respectively and innervate overlapping but distinct target tissues. Neurons in the embryonic stellate ganglia contained immunoreactivity (-IR) for neuropeptide Y (NPY), vasoactive intestinal peptide (VIP) or leucine-enkephalin (L-Enk). In addition, calcitonin gene related peptide (CGRP) was found in a subset of VIP-IR neurons. With the exception of L-Enk, all these peptides were present in neurons of the adult stellate ganglion. In the SCG, NPY, L-Enk and a small number of VIP-IR neurons were present in both developing and adult ganglia. Substance P-IR was not detected in neurons from either ganglion. There were significant alterations in the proportion of neurons possessing immunoreactivity for the different peptides. NPY-IR was first seen on E15 and the percentage of NPY-IR neurons steadily increased until adult levels (approximately 50%) were reached at E19. In contrast, the number of VIP-IR neurons decreased between E14 and E18. Furthermore, while L-Enk-IR neurons were present in both SCG and stellate ganglia early in development, L-Enk-IR neurons are found in adult SCG but not adult stellate neurons. These data indicate that there are changes in neuropeptide expression in sympathetic neurons during the period when they become post-mitotic, become innervated and begin to contact their targets.

DIFFERENTIATION OF PROLACTIN AND GROWTH HORMONE SECRETING CELLS IN THE RAT ANTERIOR PITUITARY. S.-W. Kim, A.E. Morris*, L.A. Chasin*, & S.A. DeRiemer. Dept. of Biological Sciences, Columbia Univ., NY NY 10027.

The growth hormone secreting somatotrophs (ST) and prolactin secreting mammatrophs (MT) differentiate from a common precursor cell. There exists a third cell type in the pituitary which secretes both prolactin and growth hormone called a somatomammatroph (SMT). It has been proposed that these cells are intermediate in the development of some, if not most, STs and MTs. We are addressing this question by characterizing the functional properties of these three cell types and their developmental regulation. We have developed a procedure for producing enriched fractions of each type of cell using discontinuous and continuous Percoll gradient separation. Cells were identified by immunofluorescence using antibodies to prolactin (PRL) and growth hormone (GH) or with a sequential reverse hemolytic plaque assay. At day P5, 46%±16 of the total cells in the pituitary are recovered in the ST-SMT-MT fraction. A similar percentage is found in the adult (45±16). The ratio of SM:SMT:MT cells, however, changes from 5:84:12 at day P5 to 60:1:39 in the adult. When the GH positive cells are further separated they distribute into three density classes (1.062, 1.069 and 1.075). Binding of the G-protein (G) activator cholera toxin has been used to distinguish ST and MT cells. We have compared GH secretion by the two denser classes in the presence and absence of the other G-protein regulating toxin, Pertussis Toxin (PTX). The mean and the distribution of basal plaque sizes were the same in both cell types. Pertussis toxin had both inhibitory and stimulatory effects on both cell classes, but the relative magnitudes differed. In the 1.075 cells the predominant effect was inhibition while secretion was enhanced in the lighter fraction. We are continuing to characterize the properties of SM, SMT and MT cells. In addition, we are correlating the changes in the differentiation state of these cell populations with the expression of transcription factors known to regulate the GH and PRL genes. POSTNATAL DEVELOPMENT OF THE PROENKEPHALIN SYSTEM IN THE RAT HIPPOCAMPUS: DETECTION BY IN SITU HYBRIDIZATION AND IMMUNOCYTOCHEMISTRY. D. D. Song and R. E. Harlan. Dept. Anatomy, Tulane University School of Medicine, New Orleans, LA, 70112.

Immunocytochemistry (ICC) and in situ hybridization (ISH) was performed on sections through the hippocampus on embryonic day 14 (E14), E16, E18, E20, postnatal day 0 (P0), P5, P10 and P15. Antisera to synenkephalin (syn-enk) and to methionine enkephalin (met-enk) and a PPE cDNA were used. PPE mRNA, syn-enk and met-enk first became detectable by P5 in the hippocampus. Cell bodies expressing PPE were located predominantly in the molecular layer (ML) of hippocampal fields CA1 and CA3 and in the hilar margin of the granular layer (GL) of the dentate gyrus (DG). A few labeled cell bodies were also detected in the oriens (OL) and pyramidal cell (PCL) layers of the hippocampus and the polymorph layer (PL) of the DG. Scattered immunoreactive fibers were detected in the medial margin of the fimbria, the ML of the DG, and the ML and OL of fields CA1 and CA3. By P10 there was a general increase in the numbers of PPE labeled cell bodies and immunoreactive fibers in the above regions. Additionally, cells expressing PPE were found in the PCL and OL of fields CA3 and CA1 and the ML of the DG. A few scattered immunoreactive fibers in the PCL of CA1 and CA3 and in the PL of the DG also became detectable at this age. However, there was a sharp decline in the number of PPE expressing cells in the GL of the DG. At P15 no remarkable changes from P10 were detected. No significant differences were found in the results obtained by the syn-enk antiserum over that of the met-enk antiserum. No cells were detected by ICC with either antisera, despite heavy labeling of cell bodies for PPE by ISH. These results indicate expression of the enkephalinergic system is postnatal in the rat hippocampus. Supported by NS 24148.

Characterization of neurons differentiating in cultures of mammalian neural crest cells. Matsumoto, S.G* and J.F. Brons Dept. Anat. SD OHSU Portland, OR 97201

Collectively the cells of the neural crest give rise to all of the neurons of the sympathetic, parasympathetic and enteric systems and the sensory neurons of the dorsal root ganglia as well as many of the cranial sensory neurons. These neurons possess different classes of voltage-sensitive and ligand-gated channels, neuro-transmitters and have specific growth factor requirements. Neurons differentiating in cultures of neural crest cells are heterogeneous in their morphology, transmitter expression and growth factor (eg. NGF, CNTF) dependence. There is evidence for NGF/CNTF-dependant and -independant neurons. The neurons display little variation in their physiological traits. For example, when crest cells are grown alone the neurons that differentiate are devoid of neurotransmitter receptors commonly found on crest-derived neurons *in vivo*. Thus there is no evidence for receptors for ACh, 5-HT, NE, DA, ATP or glutamate. Both nicotinic and muscarinic-mediated ACh responses are detected however, when the crest cells are co-cultured with ganglionic non-neuronal cells dissociated from adult sympathetic ganglia. Experiments are in progress to further investigate the possible role of target cells and ganglionic non-neuronal cells in inducing neurotransmitter receptors.

Neonatal exposure to GABA-transaminase inhibitor: Effects on behavior and neurochemistry in rat. T. Taira, E.R. Korpi & T. Porkka-Heiskanen. Univ. of Helsinki, Dept. Physiology and Research Laboratories, Alko Ltd, 00170 Helsinki, Finland.

Effects of GABA-transaminase inhibitor ethanalamine O-sulphate (EOS) (200mg/kg/d IP during postnatal days 3-21) were studied in rats. EOS increased the amount of REM-sleep (152% of control, p<0.01) on postnatal day 7. At the age of 1-4 months the EOS rats showed reduced activity in the open-field test (60% of control p<0.01) and increased voluntary alcohol intake (161% of control, p<0.05). Maximal GABA-stimulated [³H] flunitrazepam binding was decreased (72% of control, p<0.05) in cerebral cortex and EC₅₀ value for stimulation increased (203% of control, p<0.05) in hippocampus of the EOS rats. No changes were seen in the hypothalamic monoamine concentrations.

The results suggests that during the EOS treatment the central GABAergic mechanisms may be permanently desensitized by elevated GABA concentrations. On the other hand, after the EOS treatment there may prevail enhanced GABAergic tone, which could explain the down-regulation of the coupling between the GABA and benzodiazepine binding sites.

THE EFFECTS OF Ca^{2+} ON HISTAMINE RELEASE IN THE CEREBRAL CORTEX OF SPRAGUE DAWLEY RATS.

B. Washington, K.Y. Nguyen, S. Williams-Scott, M.O. Smith, T.J. Robinson and R.F. Ochillo. Labs. of Pharmacology and Toxicology, Biomedical Research Center, Xavier University of Louisiana, New Orleans, LA 70125.

There is growing evidence that calcium ions (Ca^{2+}) are involved in the release of histamine in the brain. Also, histamine has been postulated to be a neurotransmitter in the central nervous system (CNS). The purpose of this investigation was to use a technique, combining microdialysis and high performance liquid chromatography (HPLC), to investigate the effects of Ca^{2+} on the release of histamine in the cerebral cortex of conscious freely-moving Sprague Dawley rats using diltiazem, a specific Ca^{2+} channel blocker, as a tool. This method involves implanting a dialysis probe stereotaxically into the cerebral cortex. Three to 5 days following surgery, the cerebral cortex was perfused with an isotonic artificial cerebrospinal fluid (ACSF) or ACSF containing diltiazem (0.5 μ g/ μ l) at a flow rate of 1.2 μ l/min for 120 minutes. The analysis of the perfusate for histamine was done using a modified HPLC procedure published previously (Washington et al., 1991). The results showed that diltiazem reduced control levels of histamine from 92 ± 7.39 pmols/ μ l to 50 ± 4.1 pmols/ μ l in perfusate within 75 minutes. This study adds additional evidence that the release of histamine in the cerebral cortex is calcium dependent. (Supported by RCMI grants #SRCR, 1 G12 RR050750 & #RR08008 from NIH).

CHANGES IN THE ELECTRICAL PROPERTIES OF CHICK CILIARY GANGLION NEURONS DURING DEVELOPMENT

M.M. Dourado and S.E. Dryer, Department of Biological Science Florida State University, Tallahassee, FL 32306.

Electrically mature neurons of the chick ciliary ganglion (stages 40-44) are known to express TTX-sensitive sodium currents (I_{Na}), high threshold (L-type) calcium currents (I_{Ca}), several calcium dependent potassium currents [$I_{K(Ca)}$] and a group of voltage dependent potassium currents (I_A , I_{DR}). In order to study the development of the electrical properties of these neurons, whole cell recordings were made at embryonic stages 26, 30, 35 and 40 from acutely dissociated cells. This ensured that the developmental changes observed occurred *in ovo*. Stage 26 is a time at which the cells have just undergone terminal mitosis. By stage 40 the cells have formed synapses with their target tissue and naturally occurring cell death is nearly complete. Densities of various ionic currents were determined from the ratio of peak current to the cell surface area. Neurons at stage 26 were found to express I_{Na} , I_{Ca} and I_{DR} . The potassium currents I_A and $I_{K(Ca)}$ when present, were barely detectable. Nevertheless these cells could be made to fire regenerative spikes under current clamp conditions. Most of the currents were found to increase in density between stages 26 and 40. However the increase in $I_{K(Ca)}$ and I_A was especially dramatic between stages 30 and 35. This coincides with the time when these neurons form synapses with their target tissues. In contrast, no significant change was observed in I_{DR} density during embryonic development.

DEVELOPMENT: VOLTAGE-GATED CHANNELS

299.1

SLOW POSTSYNAPTIC K^+ CURRENT OF *APLYSIA* LUQ NEURONS IN CULTURE. M. Nakashima, M. Yanaura, S. Yamada and S. Shiono. Central Research Laboratory, Mitsubishi Electric Corp., Amagasaki, Hyogo 661, Japan.

We have studied synaptic mechanism of co-cultured neurons dissociated from the abdominal ganglion of *Aplysia californica*. Puffing acetylcholine (ACh) or FMRFamide on left upper quadrant (LUQ) cells *in vivo* was found to elicit slow IPSP response, possibly involving 'S' like K^+ current mediated by a G protein (Brenzina, J. Physiol., 407, 1988). We found neuron L10, L12 or L13 made specific synapses onto an LUQ cell in culture, exhibiting similar slow IPSP of the postsynaptic LUQ cell by repetitive firing of the presynaptic neuron.

Tissue culture procedures were used as described by Schacher et al. (J. Neurosci., 3, 1983), and standard two-electrode voltage-clamp techniques were used.

The reversal potential of the slow postsynaptic current shifted with altered extracellular K^+ concentration. The K^+ current was partially blocked by extracellular application of 4-aminopyridine, but not blocked by tetraethylammonium and apamin. Since bath application of ACh or FMRFamide partially desensitized the K^+ current, a presynaptic cell is thought to release both ACh and FMRFamide simultaneously. Pressure injection of GTP- γ -S into the postsynaptic cell occluded the K^+ current, eliciting outward current. These results suggested that the K^+ current had similar characteristics to that found *in vivo*.

WHOLE CELL RECORDING OF VOLTAGE ACTIVATED CURRENTS IN EMBRYONIC *XENOPUS* SPINAL NEURONS DURING DEVELOPMENT *IN VIVO*. M.G. Desarmenian and N.C. Spitzer. Department of Biology and Center for Molecular Genetics. UCSD, La Jolla CA 92093.

Analysis of the differentiation of excitability has been facilitated by studies of *Xenopus* spinal neurons developing *in vitro*. Although action potentials are similar to those recorded *in vivo*, currents and perturbation experiments in culture have not been compared with recordings *in situ*. We have applied the whole cell patch-clamp technique in a freshly isolated spinal cord preparation to study the mechanisms of development of voltage-activated currents in neurons in their natural environment. Interneurons in the dorsal anterior cord were recorded under direct visual control. Sodium current served both as a neuronal marker and to demonstrate adequate control of membrane potential.

As predicted by previous studies performed on primary cultures, inward calcium and sodium currents predominate in young cells. The density of outward potassium currents increases during the first embryonic day, and they eventually largely overcome calcium currents. These findings are in agreement with the observation that action potentials are long lasting and Ca/Na -dependent in young *Xenopus* spinal neurons whilst they are short and predominantly Na -dependent in mature cells. The development of the delayed rectifier potassium current (I_{Kv}) is completed during the first day; the current density increases more than 3 fold and the rate of activation is accelerated by more than 2 fold.

In culture, the acceleration of the rate of rise of I_{Kv} is dependent on calcium influx triggered by action potentials during a critical period and on the activation of the calcium- and phospholipid-dependent protein kinase (PKC). Intracellular application of protein kinases and phosphatases during recording from young and mature neurons can now be used to study the metabolic pathways controlling the development of voltage-dependent currents *in vivo*.

VOLTAGE SENSITIVE CALCIUM CHANNELS DEMONSTRATE A PRECISE NEURODEVELOPMENT PATTERN IN MOUSE CORTEX. C.L. Mouritsen, B.B. Grover, M.L. Smart, M.J. Litzinger. Depts. of Pediatrics, Physiology, and Biology, Univ. of Utah, SLC, UT.

The development of voltage sensitive calcium channel (VSCC) types shows a critical period in Swiss Webster mouse neurodevelopment (Grover et al., 1990, Litzinger et al., 1990). In mouse whole brain omega conotoxin (ω -CgTx), believed to mark the presynaptic N type VSCC, and PN-200, a 1,4-dihydropyridine which marks L type VSCC's, have shown a rapid period of increase of 40 - 50% in postnatal days 10 - 15. This critical period parallels that observed by Himwich in 1962, and corresponds to dendritic sprouting, increase in cortical width and weight and maturation of EEG potentials.

Previous experiments in our lab have shown that regional binding differences between days 11 - 14 are due predominately to cortex binding site increase. The purpose of this study was to further define the specific days of developmental increase of ω -CgTx binding. Our most recent data shows 40% increase during a precise 48 hour period - postnatal days 11 and 12. This narrowed cortical period suggests a developmental time frame to begin to look for potential maturational factors for central nervous system VSCC development. This work was sponsored by NICHD K08 00886-02.

299.4

EXCITATORY AMINO ACID DISTRIBUTION DURING DEVELOPMENT OF ELECTRORECEPTORS IN *EIGENMANNIA* (GYMNOTIFORMES). H.A. Vischer and E. Trenkner. SIO, Neurobiology Unit, UCSD, La Jolla CA 92093 and Institute for Basic Research, Staten Island, NY 10314.

Weakly electric, South American glassknife fish of the genus *Eigenmannia* were bred under laboratory conditions. To study the uptake of excitatory amino acids, 1-3 μ l solutions of tritiated Glutamate, Taurine, GABA, Aspartate, Glycine and β -Alanine (activities: 1μ Ci/ μ l) were injected subcutaneously into animals of various ages. After survival times of 1-9 hours, fish were processed for autoradiography. Glutamate, Taurine and Aspartate were strongly concentrated in the supporting cell layer of tuberosus electroreceptor organs (TO), whereas no uptake was observed for GABA, Glycine and β -Alanine. Aspartate was taken up by ampullary organs (AO) even after shorter survival times, whereas Glutamate and Taurine-uptake was only observed after longer survival times (>4hrs), suggesting a slower uptake mechanism in AO. Pre-injection of the Glutamate-uptake blockers Ibotene, AP-4, AP-5, CNQX and MK 801 [10^{-4} M] inhibited Glutamate-uptake, indicating the existence of NMDA and quisqualate controlled receptors. In contrast to β -Alanine, GES [10^{-2} mg/ml] blocked Taurine-uptake. Since AP-4, AP-5, Ibotene and GES did not block the uptake of Glutamate and Taurine in primordial electroreceptors, it is suggested that the uptake mechanism is not yet specific at this early stage.

299.5

MECHANISM OF NA CHANNEL INDUCTION BY NGF AND FGF IN PC12 CELLS. G. D'Arcangelo, D. Shepherd*, P. Brehm, S. Halegoua* and G. Mandel*. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

Nerve growth factor (NGF) and basic fibroblast growth factor (bFGF) elaborate a sympathetic neuron-like phenotype in PC12 cells, which includes neurite outgrowth and the establishment of a Na⁺-based action potential. NGF-treatment results in an increase in the density of functional Na channels which correlates with the induction of Na channel type II-specific mRNA. We show here that the addition of NGF and bFGF to PC12 cells leads to the induction of at least three Na channel mRNAs of different sizes. Two of the three transcripts encode the previously identified rat brain type II Na channel: levels of these mRNAs increase three to five fold within 24 hrs and remain at this level over the next several days. The third and largest transcript, to be further characterized, is regulated with a distinct time course: this mRNA is rapidly induced five to seven fold within 5 hrs of NGF treatment and declines to two to three fold over the next several days. We have been investigating whether induction of Na channel mRNA is regulated by signal transduction pathways mediating other aspects of NGF and bFGF action. We have found that the non-receptor tyrosine kinase pp60^{c-src} as well as the GTP binding protein p21^{c-ras} mediate NGF- and bFGF-induced neurite outgrowth in PC12 cells. Both A-kinase and C-kinase mediate at least some NGF actions. The A-kinase, but not p21^{c-ras} has been suggested to mediate the NGF induction of Na channels measured electrophysiologically (Kalman *et al.*, 1990, *Neuron* 2, 355). However, a role for cAMP in this NGF response has been refuted (Pollock *et al.*, 1990, *J. Neurosci.* 10, 2626). To resolve the mechanism of Na channel induction by neuronal growth factors at the molecular level, we have created unique, permanent PC12 sublines expressing inducible oncogenic forms of either Src or Ras proteins, an inducible dominant inhibitory form of Ras, or expressing high, blocking levels of the A-kinase inhibitor protein. The kinetics of induction of Na channel mRNA and Na channel activity by growth factors, oncogenes or by cAMP elevation in these cell lines will be presented. This work was supported by NIH grants to G.M. and S.H.

EXPRESSION OF M-RNA FOR A NONALPHA NICOTINIC ACETYLCHOLINE RECEPTOR SUBUNIT IN THE DEVELOPING MOUSE BRAIN. T.R. Podleski and A. Woo*. Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

We are studying the regulation of the synthesis of the receptor subunits for the nicotinic acetylcholine receptor in the developing mouse brain. We have cloned the nonalpha2 subunit from a c-DNA library of a 20 day old mouse brain. We have isolated, and sequenced the mouse c-DNA. This c-DNA is about 2kb in length, it is missing portion of the 5' end, and it is approximately 500bp longer on the 3' end compared to the rat. It is 96% identical to the rat at the amino acid level. We have labelled this c-DNA with ³²S d-CTP, and have used it for *in situ* hybridization studies on mouse brains, beginning on prenatal day 13, and extending through to the adult. In the youngest brains studied, prenatal day 13, positive hybridization was obtained throughout the intermediate zone (IZ) with no binding above background in the ventricular zone. All cells in the IZ appeared to be labelled to approximately the same extent. At prenatal day 15 to 19, labelling to the IZ persisted, and positive hybridization was observed in virtually all cells in the cortical plate (CP) and in the regions between the IZ and CP. Therefore, a gene for this receptor subunit is expressed very early in development, probably soon after the cells undergo their last mitotic cycle. Acetylcholine has been suggested to play a general morphogenic role in the development of the nervous system (Kostovic and Rakic, *J. Neurosci.* 4:25 [1984]), but similar results to those we have described have been obtained with somatostatin receptors (Gonzalez *et al.*, *J. Comp. Neurol.* 305:177 [1991]). This work was supported by a grant from the Cornell Biotechnology Program which is sponsored by the New York State Science and Technology Foundation, a consortium of industries, the U.S. Army Research Office and the National Science Foundation.

CO-CULTURE WITH STRIATED MUSCLE CONFERS DIHYDROPYRIDINE SENSITIVITY TO EVOKED RELEASE OF ³H-ACh FROM EMBRYONIC CILIARY GANGLION NEURONS. D.B. Gray, C. Rossi*, J. L. Bruses*, and G. Pilar. Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06269.

The intact neuromuscular junctions between chick ciliary ganglion neurons and their peripheral muscle targets have been used to analyze the pharmacology of the Ca²⁺ dependency of evoked ³H-ACh release (Gray *et al.*, *J. Neurosci.*, 10:2687,1990). In the following experiments this analysis has been extended to tissue culture where manipulation of neuron-target relationships is much more convenient.

In dissociated cell culture for 24 hours, st. 40 CG neurons and their processes display K⁺ evoked ³H-ACh release which is not sensitive to DHPs. In control samples, incubation in 55 mM K⁺ Tyrodes resulted in 102% increase in ³H-ACh over baseline. With addition of 10 uM nifedipine, 55 mM K⁺ caused a 108% increase in label over baseline. However, if st. 40 choroid neurons are co-cultured with embryonic myotubes for the same 24 hr period, DHP antagonists can abolish evoked release from these cultures. In the presence of 10 uM nifedipine, ³H-ACh release evoked by 55 mM K⁺ is actually 10% less than baseline release. This is similar to Ca²⁺ dependent ACh release at the intact st. 40 ganglionic terminals which are also in contact with their muscle targets *in vivo*.

Although it is clear that transmitter release is coupled to different Ca²⁺ channels in each culture condition, it is not yet clear whether the presence of muscle induces expression of new (L type?) Ca²⁺ channels in neurons or whether formation of more extensive neuronal processes and synaptic endings in co-cultures result in clustering or selective segregation of channels already present in cells. Supported by NIH grant # 5R01 NS 10338.

299.6

cAMP-DEPENDENT PROTEIN KINASE IS REQUIRED FOR INDUCTION OF FUNCTIONAL SODIUM CHANNELS BY NGF David D. Ginty¹, John A. Wagner¹, and Robert A. Mauz². ¹Dept of Biological Chemistry and Molecular Pharmacology, Harvard Medical School and Dana Farber Cancer Institute, Boston, MA 02115; ²Dept of Physiology, Dartmouth Medical School, Hanover, NH 03756.

The molecular mechanisms underlying the biological effects of nerve growth factor (NGF) on the electrical membrane properties of neuronal cells are not well understood. To determine whether cAMP-dependent protein kinase (A kinase) activity is necessary for the NGF-mediated induction of voltage-dependent sodium (Na) channels in rat pheochromocytoma (PC12) cells, whole-cell patch clamp recordings and Northern Blot hybridization studies were used to analyze Na channel expression in a variety of A kinase-deficient PC12 subclones we have created. AB-11 and 123.7 cells (Ginty *et al.*, *JBC* in press), stably transfected with genes encoding inactive mutant forms of the type I regulatory subunit of A kinase (courtesy of S. McKnight, Univ. of Wash.; *JBC* (1987) 262:13111), as well as A126-1B2 cells, a chemically mutagenized subclone (*Mol. Cell. Biol.* 5(1985):1984), all responded to NGF treatment, as evidenced by increased neurite outgrowth, cell size, changes in gene expression (EGR-1, fos, GAP-43, ODC), and protein phosphorylation. In normal PC12 cells, the percentage of cells exhibiting large Na currents, the magnitude of the Na currents, and the Na current density all increased ~ 5-fold in response to NGF. In contrast, there were no increases in the expression of functional Na channels in the AB-11 and 123.7 cells treated with NGF, and only small increases in the NGF-treated A126-1B2 cells. Northern Blot analysis of mRNA from control and NGF-treated cells revealed 3- to 5-fold increases in the steady state levels of Na channel mRNA in both A kinase-deficient cells (AB-11 and 123.7) and in normal PC12 cells. The results indicate that A kinase activity is necessary for the NGF-mediated induction of Na channel expression at a posttranscriptional level. In addition, when coupled with the biochemical differences between the A126-1B2 cells and the AB-11 and 123.7 cells, the results may also suggest differential roles for the two isozymes of A kinase in mediating Na channel expression and the biological actions of NGF during neuronal differentiation.

DEVELOPMENT AND AGING OF SODIUM-DEPENDENT EXCITATORY AMINO ACID TRANSPORT BINDING SITES. L.J. Mitchell, L. Skipper*, M. Sapper* and K. J. Anderson. Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

High affinity transport of excitatory amino acids such as L-glutamate is necessary for the termination of its excitatory signal and the prevention of excitotoxicity. The removal of glutamate from the synaptic cleft is carried out by primarily by a sodium-dependent system that can be assessed by D-[³H]aspartate autoradiography. Furthermore, there appears to be at least two distinct D-[³H]aspartate recognition sites designated Type I (primarily forebrain) and Type II (primarily cerebellar). In this study we have examined the development and aging of these binding sites in rat brain. Briefly, assays were conducted using 6µm-thick, horizontal sections of rat brain. D-[³H]Aspartate binding (100 nM in 50 mM Tris-acetate with 300 mM NaCl, pH 7.4) was carried out in delipidated sections at 0-2°C. Following rinsing in ice-cold buffer, sections were air dried and exposed to [³H]-sensitive film for 3-4 weeks. Sodium-dependent D-[³H]aspartate binding sites were first observed in the neonate at approximately postnatal day 8 and the density of these sites reached peak values and equivalence with adults at postnatal day 21. No differences were observed between the development of type I (primarily forebrain) and type II (primarily cerebellar) sites. Once transporter levels reached adult levels, they appeared to remain stable even in aged (24-26 month-old) rats. The ontogeny of transporter sites contrasts with EAA receptors which can be detected at postnatal day 1 and show a developmental "overshoot" with respect to adult levels (Insel *et al.*, *Neurosci.* 35:31-51). This suggests that the developmental differences between receptors and transporters may play a role in neonatal sensitivity to excitotoxicity. Supported by AG-08843 (KJA).

CONSEQUENCES OF CEREBELLAR SYNAPTIC CIRCUITRY CHANGES ON GABA_A/BZ RECEPTOR α₁ SUBUNIT GENE EXPRESSION IN PURKINJE CELLS. D. Zdilár, A. Rotter and A. Frøstholm, Dept. of Pharmacology, Ohio State University, Columbus, OH 43210.

Expression of GABA_A/benzodiazepine receptor α₁ subunit mRNA in Purkinje cells of developing normal and adult weaver (*wv/wv*), staggerer (*sg/sg*) and reeler (*rl/rl*) mutant mice were studied by *in situ* hybridization with a riboprobe, transcribed from a cDNA clone provided by Dr. A.J. Tobin (*Neuron*, 3:745-753, 1989). In the normal developing mouse cerebellum, diffuse labeling was present in the Purkinje cell layer from birth. Purkinje cells acquired their characteristic punctate appearance only later, between P5 and 7. In the 60 day old *wv/wv* cerebellum, in which most granule cells are lost by approximately day 30, the clusters of high grain density characteristic of Purkinje cells were still present. In the *sg/sg* mutant cerebellum, a defect in Purkinje cells results in the failure of synapse formation with granule cells. Although Purkinje cells were fewer in number and were scattered throughout the cerebellar cortex, they remained densely labeled. In the *rl/rl* mutant, Purkinje cells fail to migrate to their final destination remaining in cellular masses beneath the cerebellar cortex. The heterotopic Purkinje cells also contained high levels of α₁ subunit mRNA from birth, despite their lack of excitatory and inhibitory afferent input. These studies suggest that α₁ subunit gene expression in Purkinje cells precedes synapse formation and remains stable despite the loss of both afferent inhibitory (basket and stellate cells) and excitatory (parallel fiber) input.

ONTOGENY OF GABA_A/BZ RECEPTOR β_2 AND β_3 SUBUNIT GENE EXPRESSION IN MOUSE CEREBELLUM. V. Luntz-Leybman, D. Zdilic, A. Frostholm and A. Rotter. Department of Pharmacology, The Ohio State University, Columbus, OH 43210.

[³⁵S]-oligo and cRNA probes were used to study the developmental expression of β_2 and β_3 subunit mRNAs in the mouse cerebellum by *in situ* hybridization. The signal for β_2 subunit mRNA hybridization was detectable at birth and was most concentrated in the molecular/Purkinje cell layer. The deep cerebellar nuclei were also labeled, but less intensely. This pattern persisted up to postnatal day (P) 9 when additional labeling became visible in the granule cell layer. By P11, the granule cell layer was densely labeled, the intensity approaching that of the adult. At P20, the highest labeling was present in the granule and Purkinje cell layers; the molecular layer and white matter were unlabeled. Hybridization signal was absent from the external germinal layer (egl) throughout its existence.

Whereas the β_2 hybridization signal was completely absent in the egl, the β_3 signal was observed over the premigratory cells of the external germinal layer and in the internal granular layer at birth. The deep cerebellar nuclei were also densely labeled. Low grain density was present in the molecular layer. By P7-9, the external germinal and internal granule cell layers were labeled at equal density. Between P11 and P13, the hybridization signal over the external germinal layer became gradually reduced as granule cells completed their migration into the granule cell layer. The adult distribution was reached by approximately P15: the highest grain density was present over the granule and Purkinje cell layers, and lower signal in the molecular layer was associated with basket and stellate cells.

These studies suggest that the expression of β_2 and β_3 subunit genes occurs during, or prior to, cell migration, and before granule cells form afferent and efferent synaptic connections.

GABA_A RECEPTOR ACTIVATION CAUSES ELEVATION OF INTRACELLULAR CALCIUM IN EMBRYONIC RAT SPINAL CORD CELLS. M.K. Walton, A.E. Schaffner, and J.L. Barker. Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

GABA_A receptor activation has previously been shown to produce depolarization in neurons dissociated from rat spinal cord embryos. The intracellular calcium level response to externally applied muscimol was examined in dissociated embryonic rat spinal cord cells using computerized digital imaging microscopy and the calcium sensitive fluorescent dye fura-2. Cervical regions of spinal cords were removed from rat embryos and divided into dorsal and ventral portions. The tissue was enzymatically dissociated into single cell suspensions, placed onto culture dishes and allowed to adhere. Recordings were made both within hours of dissociation and after 1 day in culture. The intracellular calcium response due to activation of functional GABA_A receptors was probed for by adding muscimol (2.5 μ M) to the dish perfusate.

Muscimol raised intracellular calcium levels by a factor of 2-3 in cells showing a response. Calcium elevations occurred in a larger fraction of cells from ventral portions of the spinal cord than from the dorsal region. Dishes that had been in culture for 24 hours showed a greater fraction of cells producing calcium rises than cells recorded within hours of dissociation, and this was true for both dorsal and ventral cells. The response was effectively blocked by bicuculline as well as by addition of cobalt or cadmium to the perfusate, indicating that calcium entry may be through voltage sensitive calcium channels. These results indicate that GABA_A receptor activation can lead to calcium elevation in embryonic neurons, and this may have a role in spinal cord development.

300.3

DEPOLARIZING RESPONSES TO 3 α OH-REDUCED PREGNANE STEROID METABOLITES AND GABA OCCUR IN THE MAJORITY OF EMBRYONIC RAT CORTICAL CELLS. S.V. Smith* and J.L. Barker. Lab. of Neurophysiology, NINDS, Bethesda, MD 20892.

Rat cortical cells from embryonic (E) day 15 to postnatal day 2 were enzymatically dissociated with papain and run through a FACStar Plus flow cytometer. The effects of steroids and the GABA_A receptor ligands, GABA and muscimol, were studied using oxonol, a fluorescent, voltage-sensitive dye. The majority of the cortical cells recorded during this period were polarized according to a K⁺ ion gradient. By E15 3 α OH-reduced steroid metabolites and GABA ligands consistently depolarized cells with progressively more cells responding at later developmental ages. Curiously, 3 β OH-reduced steroids hyperpolarized cells and antagonized 3 α OH-reduced agonist responses. The depolarizing responses to steroids and GABA_A agonists were blocked by bicuculline and picrotoxin, both of which often hyperpolarized cells, and not affected by Na⁺-free conditions. EC₅₀ values for the depolarizing responses were ~0.2 μ M (steroids), ~0.4 μ M (muscimol), and 1 μ M (GABA). The widespread cellular distribution of depolarizing GABA_A receptors (75-80% of all cells) sensitive to submicromolar steroids and GABA suggests important roles for GABA and steroid metabolites during embryogenesis of the rat cortex.

300.2

PARALLEL EXPRESSION OF GABA_A RECEPTOR AND GABA IN EMBRYONIC RAT SUBCORTICAL BRAIN. W. Ma, T. Behar, A. Schaffner, S. Smith and J. Barker. Lab of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

The temporal relationship between the expression of GABA_A receptor and transmitter GABA was investigated in the diencephalon, mesencephalon and rhombencephalon of E11-E21 rat embryos. The functional appearance of GABA_A receptors was recorded in acutely dissociated cell suspensions by flow cytometric analysis of membrane potential responses to GABA and muscimol using the voltage-sensitive fluorescent dye oxonol. GABA was demonstrated immunocytochemically in 10 μ m-thick sections through the subcortical regions. At each age, embryos used for GABA_A receptor examination and GABA immunostaining were taken from the same mother. At E12 functional Na⁺ channels appeared in a minority of subcortical neurons that did not respond to GABA or muscimol, whereas a few GABA-immunoreactive (IR) fibers were seen coursing through these regions. By E13 membrane potential responses to supramicromolar GABA and muscimol became detectable in a minority of cells, while some GABA-IR cell bodies were visible in the pontine flexure region, developing substantia nigra, zona incerta and hypothalamus. Well developed GABA-IR fiber bundles passed through the marginal zone from the myelencephalon to the diencephalon. GABA and muscimol consistently depolarized progressively more subcortical cells over E14-21. The responses were blocked by bicuculline or picrotoxin. During this period GABA immunoreactivity increased dramatically in cells and axons throughout subcortical brain regions. Our results show that in subcortical regions functional GABA_A receptors and GABA develop in parallel, suggesting that GABA might mediate important signals during the development.

300.4

ELECTRICAL AND CHEMICAL EXCITABILITY DEVELOP ALONG ANATOMICAL GRADIENTS IN THE EMBRYONIC RAT SPINAL CORD. A.E. Schaffner, S.V. Smith* and J.L. Barker. Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

Spinal cords from embryonic (E) and early postnatal (PN) rat pups were divided into 6 regions- cervical dorsal (CD), and ventral (CV), thoracic dorsal (TD) and ventral (TV) and lumbosacral dorsal (LSD) and ventral (LSV), dissociated in papain and incubated with a fluorescent, voltage-sensitive oxonol dye. Changes in fluorescence (FL) intensity were monitored in a FACStar Plus flow cytometer. At E13 consistent, TTX-sensitive, depolarizing responses to veratridine were recorded in C>T>L>S cells. Responses to muscimol, kainate and the progesterone metabolites 5 α -pregnan-3 α -ol-20-one and 5 β -pregnan-3 α -ol-20-one were negligible. Over E14-E16 depolarizing responses to veratridine, muscimol, kainate and the steroid metabolites were recorded in progressively more V than D and C>T>L>S cells. Interestingly, these gradients in excitability parallel the gradient of terminal cell division in the cord, the first neurons to withdraw from the mitotic cycle being motoneurons in the ventral horn of C regions. Dose-response curves to muscimol in CV and LSV at E15 had similar slopes with an EC₅₀ of ~200 nM. Since more cells respond in CV, this suggests that differences are due to numbers of responding cells and not efficacy of the ligand. At E19 the gradients had reversed such that D>V but there was no longer a clear C to LS gradient. By PN3, D>V and LS>C and T. A low forward angle light scatter, high FL (progenitor?) population appeared at E19 and did not express these forms of excitability.

NOISE ANALYSIS OF CULTURED EMBRYONIC RAT HIPPOCAMPAL NEURONS REVEALS SPONTANEOUS Cl^- ION CHANNEL ACTIVITY. A.Y. Valev¹, R.A. Cruciani¹, G.D. Lange², V. Smallwood¹ and J.L. Barker¹. ¹Lab. of Neurophysiology, ²Instrumentation and Computer Section, NINDS, NIH, Bethesda, MD, 20892, U.S.A.

Whole-cell voltage clamp recordings with CsCl-filled pipettes were performed on E17-21 hippocampal neurons cultured for 1-15 days. In many of these cells the baseline current noise was voltage-sensitive, becoming minimal at 0 mV, which corresponds to the reversal potential of Cl^- according to the Nernst equation. Spectral analysis of the baseline noise revealed that a multi-component Lorentzian equation fit better than the expected $1/f$ for a random process. The application of antagonists at $GABA_A$ receptors (bicuculline, picrotoxin) decreased the spontaneous noise and evoked detectable changes in membrane current, which became null at 0 mV. The resulting spectra approximated a $1/f$ function. Surprisingly, similar results were obtained with the $GABA_B$ agonist (-)baclofen and the steroid 5 β -Pregnane-3 β -OL-20-ONE. Under these conditions current changes were also elicited that reversed polarity at 0 mV. The results suggest that under these recording conditions many embryonic hippocampal neurons exhibit spontaneously active Cl^- channels that may be differentiating $GABA_A$ receptors.

300.7

POSTNATAL DEVELOPEMENT OF GABA-B RECEPTORS IN RAT HIPPOCAMPUS

J.L. Gaïarsa*, R. Rovira* and Y. Ben-Ari. INSERM U29, 123 Bd de Port-Royal, 75014 Paris (France).

An earlier study from this laboratory has shown that γ -aminobutyric acid (GABA) acting on $GABA_A$ receptors has a depolarizing effect until postnatal day 5, and a mixed hyperpolarizing-depolarizing action, as in adult, afterwards (Ben-Ari & al, J. Physiol. 416, 303-325, 1989). We have now examined the development of $GABA_B$ mediated synaptic events and evoked currents.

Intracellular recordings were made from immature CA3 rat hippocampal neurons (P6-P10) in the *in vitro* slice preparation. Functional postsynaptic $GABA_B$ receptors are present in P6 neurons and afterwards since *i*-stimulation of the hilar region evoked, at resting potential (-57 \pm 7 mV), a fast and slow ipsp. The slow ipsp reversed polarity at -90 \pm 4 mV, and was blocked by phaclofen (1mM); *ii* bath application of phaclofen increased the frequency of spontaneous large hyperpolarizing potentials from 0.05 \pm 0.01 to 0.2 \pm 0.08 Hz; *iii* bath application of baclofen (10 μ M) induced an outward current which reversed polarity near -100 mV.

We conclude that functional postsynaptic $GABA_B$ receptors are present in immature hippocampal neurons starting from P6. Experiments are currently performed to determine whether $GABA_B$ mediated events are present at a earlier stage of development.

300.9

GLUTAMATERGIC PROPERTIES OF DEVELOPING NEURONS IN RABBIT RETINA.

M.F. Haberecht, C.K. Mitchell, S. Agarwal and D.A. Redburn. Dept. of Neurobiology and Anatomy, U.Tex. Med. Sch., Houston, TX.

Glutamate functions as an important neurotransmitter in the adult retina; in addition, it may also influence neuronal development and synaptogenesis. Glutamate immunoreactivity is expressed at birth by neurons which are immature and have few if any synapses. Furthermore glutamate uptake sites are not preferentially localized on cells which are immunoreactive to glutamate. Metabolism of ³H-glutamate through its conversion to ³H-glutamine and the first expression of avid uptake by glial cells do not occur to any significant extent until day 9 thus potentiating a mechanism for maintaining a high extracellular concentration of glutamate. The concentration of endogenous glutamate present in effluents released from neonatal retinas (35 μ M) is significantly higher than that collected from adult retinas (15 μ M). The concentration is doubled after exposure to potassium depolarization in neonates but not adults. These results suggest that, in the neonate, glutamate is not restricted to synaptic compartments although it is highly localized in maturing glutamatergic neurons. Secondly, in the absence of the rapid buffering capacity of glial cells, extracellular concentrations of glutamate in the neonate are relatively high and they may increase more dramatically during periods of stimulation. Supported by EYO-1655-15.

CHARACTERIZATION AND DEVELOPMENTAL FUNCTION OF DEPOLARIZING RESPONSES TO GABA IN ROHON-BEARD CELLS. B. Clendening and N.C. Spitzer. Department of Biology and Center for Molecular Genetics, UCSD, La Jolla, CA 92093.

GABA, which typically acts as an inhibitory neurotransmitter, causes depolarization when applied to Rohon-Beard (RB) cells in the embryonic *Xenopus* spinal cord. We are using whole cell voltage clamp techniques to study the currents underlying this unusual response to GABA in RB cells. Reversal potentials for Na^+ , K^+ and Cl^- , calculated on the basis of internal and external recording solutions, are +65 mV, -90 mV and -61 mV, respectively.

Most RB cells respond to 250 ms puffer applications of 100 μ M GABA with an inward current when held at -80 mV. 40% of all RB cells have GABA currents which reverse at -38 \pm 4 mV. This reversal potential is indicative of a current carried by more than one type of ion. Another 20% of the RB cells have responses to puffer applications of GABA that reverse at -63 \pm 5 mV, close to the calculated equilibrium potential for Cl^- . The final 40% of RB cells respond to the application of GABA with either a small inward current or a small outward current when held at -80 mV. These currents reverse at -80 \pm 5 mV and have current-voltage relationships with negative slopes. This is consistent with the involvement of a K^+ current that is blocked by GABA. Ion substitution experiments show that K^+ is involved in two of these response types; the one that reverses at -38 mV and the one that reverses at -80 mV and that Na^+ is involved only in the GABA response that reverses at -38 mV.

Neurotransmitter-induced depolarization inhibits neurite outgrowth in several systems. GABA has a depolarizing effect in RB cells and might be expected to inhibit neurite outgrowth. In preliminary studies we find no difference in the lengths of neurites in spinal cord cells from early neural plate stage embryos grown in culture in either the presence or absence of 100 μ M GABA for varying lengths of time.

NMDA REGULATES THE EXPRESSION OF THE ENKEPHALIN PHENOTYPE IN DEVELOPING SPINAL CORD CULTURES.

R.W. Summers*¹, D.E. Brenneman², S.E. Fitzgerald*² and D.V. Agoston². Dept. Int. Med., Univ. of Iowa College of Medicine, Iowa City, Iowa 52242¹ and Lab of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892².

In developing embryonic spinal cord dorsal root ganglia (SC-DRG) cultures, spontaneous electrical activity regulates the establishment of the enkephalin phenotype during neurodifferentiation in a calcium-dependent manner (J. Neurosci. Res. 28:140, 1991). Since a large proportion of the ongoing synaptic activity is mediated by excitatory amino acids in the central nervous system, we have tested different agonists of the glutamate receptor for their effects on enkephalin biosynthesis in differentiating mouse SC-DRG cultures. Cells were treated on day 10 postplating with N-methyl-D-aspartate (NMDA), quisqualate, kainic acid or 2-amino-5-phosphonopentanoic acid (AP5) (10⁻⁶ to 10⁻⁴ M) either with or without blocking the spontaneous electrical activity with 1 μ M tetrodotoxin (TTX). Enkephalin transcripts were analyzed by Northern blot hybridization using a complementary DNA probe. In electrically active cultures, NMDA treatment increased the expression of mRNA *enkephalin* in a concentration-dependent manner, showing maximum effect at 1 μ M. Treatment with 1 μ M NMDA doubled mRNA transcripts after 12 hrs and reached the maximum effect after 48 hrs of treatment however showing little increase between 24 and 48 hr of treatment. Co-treatment of electrically active cultures with NMDA (1 μ M) and the competitive antagonist of the NMDA receptor, AP5 (10 μ M) caused no increase in enkephalin transcripts. None of the concentrations of NMDA tested showed any effect on enkephalin expression when electrical activity was blocked by TTX. Furthermore, pretreatment of the cells with 1 μ M NMDA did not prevent TTX-induced down-regulation of the enkephalin transcripts. Application of 1 μ M quisqualate or kainic acid, agonists of the glutamate receptor of the non-NMDA subtype, failed to increase enkephalin transcripts. Our results indicate that the selective stimulation of NMDA glutamate receptor positively influences the establishment of the enkephalin phenotype probably through intracellular calcium as second messenger.

INFLUENCE OF RETINOIC ACID-INDUCED DIFFERENTIATION ON NMDA RECEPTORS IN CULTURED NEURO-2A CELLS. M.K.

Baumgartner, D.C. Martin, R.L. Dennison and R. S. Aronstam. Departments of Pharmacology & Toxicology and Anesthesiology, Medical College of Georgia, Augusta, GA 30912.

Retinoids have a variety of potent effects on cell growth and differentiation. Neuroblastoma cell cultures can be induced to differentiate (i.e., to sprout neurites) by retinoic acid. In the present study, the influence of retinoic acid on the expression of NMDA receptors by Neuro-2A mouse neuroblastoma cells was investigated. Neuro-2A cells were exposed to retinoic acid (1 μ M) for 7 days. NMDA receptors were characterized using [³H]MK-801 as a probe. [³H]MK-801 binding was measured in the presence of 100 μ M glutamate and 100 μ M glycine. The number of NMDA receptors decreased by approximately 50% after treatment with retinoic acid (B_{max}, control = 765 \pm 93 fmol/mg protein; B_{max}, retinoic acid-treated = 375 \pm 51 fmol/mg protein; p < 0.01). NMDA stimulated ⁴⁵Ca uptake into Neuro-2A cells by about 50%. This stimulated uptake was blocked by MK-801 (IC₅₀ = 3 μ M) as well as a number of other NMDA receptor antagonists and ion channel blockers. The magnitude of the NMDA-stimulated ⁴⁵Ca uptake was depressed = 50% following treatment with retinoic acid, closely paralleling the decrease in receptor number. Exposure of Neuro-2A cells to NMDA (10 μ M) resulted in a rapid (t_{1/2} = 10 sec) desensitization of NMDA-stimulated ⁴⁵Ca uptake. This rate of desensitization was markedly slowed following treatment with retinoic acid. The decrease in NMDA receptors following treatment with retinoic acid is consistent with results with muscarinic receptors in neuroblastoma cells (Baumgartner and Aronstam, *FASEB J.* 5:A856, 1991), and suggests that a decrease in the expression of neurotransmitter receptors is a common feature of neuronal differentiation. (Supported by USPHS grant AA-07698).

300.11

POSTNATAL DEVELOPMENT OF SYNAPTIC EXCITATION AND INHIBITION IN RAT NEOCORTEX. E.C. Burgard and J.J. Hablitz. Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, AL. 35294.

Whole cell patch clamp recordings were obtained from neocortical brain slices prepared from rat pups 3-12 days of age. Synaptic potentials were evoked in layer II-III pyramidal cells by stimulation in layer IV-V. At a membrane potential of -60 mV, excitatory postsynaptic potentials (EPSPs) could be evoked at all ages. In 3-7 day old rats, EPSPs were typically 10-20 mV in amplitude and 300-450 msec in duration. EPSPs generally had a latency-to-peak of 50-90 msec; some neurons exhibited multiple-component EPSPs consisting of an early (8-10 msec) and late response. Late EPSPs increased in amplitude with depolarization and decreased when stimulation frequency was changed from 0.03-1 Hz. In addition, the NMDA receptor antagonists AP5 and AP7 (10 μ M) reversibly depressed the amplitude of the late component by approximately 40-60% in this age group. No evidence of chloride-dependent inhibitory postsynaptic potentials (IPSPs) was observed until day 7. Late potassium-dependent IPSPs were routinely observed by day 11-12.

These results demonstrate that an NMDA receptor-mediated component of the EPSP is present early in postnatal development, and that development of synaptic excitation precedes that of inhibition in the neocortex (NS22373).

DENERVATION *IN VITRO*: COMPARATIVE STUDIES OF THE MULTIPLE CONDUCTANCE CLASSES OF NICOTINIC RECEPTORS IN *RANA PIPPIENS* AND *LEPTODACTYLUS OCELLATUS*. R. Rozental and M.M. Fróes-Ferrão. Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, RJ 21941, Brazil & Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Our previous work showed the appearance of altered conductance states of junctional nicotinic receptors (AChR) of the frog *Rana pipiens* after muscle denervation *in vitro* and suggested that this phenomenon could be due to post-translational modifications (*Soc. Neurosci. Abs.* 15:298, 1989). To test whether the AChR subconductance classes also appeared in another species, the patch-clamp technique (cell-attached configuration, 10°C) was applied to single muscle fibers of the frogs *Rana pipiens* (*Rp*) and *Leptodactylus ocellatus* (*Lo*). Single fibers from interosseal muscles of *Rp* and *Lo* were kept at 4°C for a period of up to 14 days and treated with 10 μ g/ml cycloheximide (a protein synthesis inhibitor) and 0.1 mM phenylmethylsulfonylfluoride (a protease inhibitor). After acute dissociation of *Rp* fibers, ACh (0.4 μ M) induced single channel openings with 40 pS conductance and voltage-dependent lifetimes. On the 2nd-3rd day after dissociation in *Rp*, we observed a second conductance state (30, 18 or <18 pS) and by the 7th day several conductance classes were expressed (40, 30, 18 and <18 pS). In contrast, immediately after acute dissociation of fibers from *Lo*, all above conductance classes were induced by ACh. The channel lifetimes of the lower conductance states were shorter than the 40-pS population for both *Rp* and *Lo* and all currents were blocked by α -bungarotoxin (5 μ g/ml). Chronic treatment of the fibers with cycloheximide did not prevent the appearance of the multiple conductance classes in *Rp*. Our data show a different time course for the conductance changes in AChR in *Lo* compared to *Rp* frogs. Support: U.S. Army Med. Res. & Devel. Comm. Contr. DAMD-17-88-C-8119, USPHS NS25296, FINEP/UMAB Mol. Pharmacol. Training Program and CNPq.

SINGLE CHANNEL CURRENTS ACTIVATED BY PHYSOSTIGMINE AT JUNCTIONAL NICOTINIC ACETYLCHOLINE RECEPTOR (AChR) OF MAMMALIAN AND AMPHIBIAN. M.M. Fróes-Ferrão, R. Rozental and E.X. Albuquerque. Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, RJ 21941, Brazil and Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. of Medicine, Baltimore, MD 21201, USA.

Shaw *et al.* (*Mol. Pharmacol.* 28:527, 1985) showed that physostigmine (Phy), a reversible cholinesterase inhibitor, has agonistic effects on the AChR in the frog *Rana pipiens*. Recently, Okonjo *et al.* (*Neuron*, in press) suggested that Phy induced cation flux into AChR-rich *Torpedo* membrane vesicles, even in the presence of α -bungarotoxin, a competitive antagonist of AChR. In light of these findings we decided to evaluate the agonist property of Phy on peripheral AChR present in different animal species. Single fibers were dissociated from interosseal muscle of the frog *Leptodactylus ocellatus* and flexor digitorum brevis muscle of adult Wistar rat. Cell-attached patch-clamp technique was used to record single channel currents generated by the activation of AChR. All records were obtained at 10°C in frog and 27°C in rat. ACh (0.1 - 0.4 μ M) induced single channel openings with several conductance classes (45/40, 30, 18 and < 18 pS) in the frog and only one conductance class of 55 pS in the rat. Lifetimes were voltage dependent and increased with hyperpolarization. Phy did not induce single channel currents (10 μ M-100 μ M) in isolated muscles of adult rat. However, in the frog, Phy (10 μ M) activated channel openings with at least three conductance classes. Our data suggest an important molecular difference between the AChRs located at the end-plate regions of adult rats and frogs. Support: DAMD-17-88-C-8119, FINEP, UFRJ/UMAB Mol. Pharmacol. Training Program and CNPq.

A POSSIBLE INTERACTION BETWEEN THE ACCUMULATION AND EXPRESSION OF ACETYLCHOLINE RECEPTORS IN CULTURED MAMMALIAN MYOTUBES. C.G. Carlson and Y. Feng. Dept. Physiology, Univ. N. Dakota, School of Medicine, Grand Forks, ND 58202.

We have examined the expression of embryonic low conductance-long burst duration acetylcholine receptors (LL-AChRs) and high conductance-short burst duration acetylcholine receptors (HS-AChRs) in myotube cultures derived from embryonic mouse muscle (Day 16-19 embryos, C57Bl6J or C57Bl10/SnJ, DMEM-HAMS F12, 10% Fetal Bovine Serum, penicillin-streptomycin, laminin substrate). Cell-attached patch clamp recordings (5x10⁷ M AChCl in 0 Mg²⁺ Ringer solution) obtained prior to day 15 in culture exhibited only LL-AChRs. Between days 15 and 29, approximately 80 to 90% of recordings exhibited both receptor classes with an average percent HS-AChRs of 12.8%. LL-AChR accumulation preceded and slightly overlapped the period of HS-AChR expression. Individual culture runs that had higher LL-AChR densities (minimum channels per patch) prior to day 15 also had greater percent HS-AChR values after day 15. In two experiments, surface AChRs were blocked by alpha bungarotoxin (5 μ g/ml, 2 hrs) on day 15. In one case, receptor density was rather low and only LL-AChRs were observed following receptor blockade (days 18-27). In a second case, receptor density was higher and both classes were observed following receptor blockade (days 18 to 29). These results are consistent with the hypothesis that factors associated with the expression and accumulation of LL-AChRs are responsible for activating the expression of HS-AChRs (UND-Epsc90, NDBHE-NSF).

GROWTH FACTORS AND TROPHIC AGENTS III

301.1

GABAergic NEURONS OF THE BASAL FOREBRAIN MAGNOCELLULAR COMPLEX (BFMC): EFFECTS OF NEUROTROPHIC FACTORS AND PATHOLOGY IN ALZHEIMER'S DISEASE (AD). G.K. Gouras, V.E. Koliatsos and D.L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Balto., MD 21205.

Previously, we have described that GABAergic neurons of the BFMC labeled by glutamic acid decarboxylase (GAD) *in situ* hybridization degenerate after fimbria-fornix transection. These GABAergic neurons do not express the nerve growth factor (NGF) receptor nor do they respond to NGF in control animals or following axotomy. Employing *in situ* hybridization with digoxigenin-labeled riboprobes antisense to rat GAD, we report that degenerating GABAergic neurons are also refractory to NT-3, ciliary neurotrophic factor, and the pluripotent basic fibroblast growth factor. Effects of brain-derived neurotrophic factor on these neurons will be discussed. Digoxigenin-labeled human GAD antisense riboprobes have allowed us to visualize GABAergic neurons of the BFMC in human tissue. Preliminary findings suggest that there is a loss of these GAD-hybridizing neurons in AD. Further research is necessary for the identification of factors that might influence this very important transmitter-specific subpopulation of the BFMC.

301.2

HIGHLY SELECTIVE EFFECTS OF NERVE GROWTH FACTOR (NGF), BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF), AND NEUROTROPHIN-3 (NT-3) ON NEURONS OF THE BASAL NUCLEUS COMPLEX (BNC). D.L. Price, V.E. Koliatsos, G.K. Gouras, L.E. Burton, J.W. Winslow and K. Nikolic. Neuropathol. Lab., The Johns Hopkins Univ. Sch. of Med., Balto., MD 21205; Genentech, Inc., S. San Francisco, CA 94080.

Cholinergic neurons of the BNC respond to NGF. Recently, molecular genetics have revealed that NGF belongs to a polypeptide gene family (neurotrophins), the other identified members of which include BDNF and NT-3. Because all three neurotrophins are enriched in hippocampus, we sought to examine the specificity and selectivity of the effects of these peptides on injured cholinergic and GABAergic BNC neurons that project through the fornix in the rat. Following a complete transection of the fimbria-fornix, recombinant human (rh) NGF as well as rhBDNF prevented the shrinkage and loss of phenotype of cholinergic neurons in the medial septal nucleus (MSN). rhNGF had no effects on GABAergic neurons. The influences of BDNF on GABAergic neurons and of rhNT-3 on cholinergic and GABAergic neurons of the MSN will be presented. Our data indicate that some neurotrophins act upon MSN neurons and that specific neurotrophins influence certain neurons of the MSN but do not have effects on other neurons. Thus, neurotrophins exert highly selective trophic effects on the septohippocampal circuit.

301.3

SEXUALLY DIMORPHIC VS. NONDIMORPHIC SPINAL MOTOR NEURONS: TWO PERIPHERAL SYSTEMS WITH DISTINCT TROPHIC PROFILES THAT MAY RESPOND TO DIFFERENT TROPHIC FACTORS.

V.E. Koliatsos, R.E. Clatterbuck, N.Y. Ip, G.D. Yancopoulos and D.L. Price. Neuropathol. Lab., The Johns Hopkins Univ. Sch. of Med., Balto., MD 21205; Regeneron Pharmaceuticals, Tarrytown, N.Y. 10591.

Although most motor neurons express the nerve growth factor receptor (NGF-R) following axonal injury, some lumbar motor neurons in the male express NGF-R under normal conditions. These cells comprise the equivalent of Onuf's nucleus, as shown by the colocalization, in their perikarya, of HRP-WGA or Fluoro-Gold transported from perineal muscles and immunoreactivity for NGF-R (192-IgG). To examine potential factors active on conventional motor neurons and neurons of Onuf's nucleus, we performed Northern blotting for neurotrophin and ciliary neurotrophic factor (CNTF) mRNA on the muscles gastrocnemius and bulbospongiosus of two-week male rats. Although CNTF was very abundant in the gastrocnemius, CNTF mRNA was not detected in the bulbospongiosus. NGF and BDNF were very low in both muscles, whereas NT-3 was highly expressed, especially in the bulbospongiosus. The above results suggest that the presence of the low-affinity NGF-R in Onuf's nucleus is associated with a possible role of neurotrophins on the differentiation and, possibly, survival of these sexually dimorphic neurons.

COMPARISON OF THE TRANSFORMING GROWTH FACTOR- β 1 (TGF β 1) mRNA RESPONSE IN THE HIPPOCAMPUS AFTER PERFORANT PATH TRANSECTION AND KAINIC ACID INDUCED LIMBIC SEIZURES. T.E. Morgan*, N.R. Nichols, N.J. Laping, C. Peterson, and C.E. Finch. Andrus Gerontology Center, Department of Neurogerontology, University of Southern California, Los Angeles, CA 90089-0191.

Three TGF β genes have been cloned and sequenced from numerous mammalian sources. These genes belong to a multigene family and share extensive homology with each other but appear to be regulated differentially. Using a cRNA probe directed against the coding region of TGF β 1, we showed that a 2.5kb mRNA increased in the ipsilateral hippocampus after partial deafferentation by an electrolytic entorhinal cortex lesion (ECL) (Nichols et al., 1991 J. Neurosci. Res. 28:134-139). A DNA oligomeric probe that is specific for TGF β 1 was synthesized and used to confirm that this mRNA species was: (1) TGF β 1 and (2) not an alternately spliced TGF β 1 mRNA of same size (as found in porcine tissues). TGF β 1 mRNA was also examined in other rat brain lesion models involving neurodegeneration/regeneration. TGF β 1 mRNA levels increased in the ipsilateral hippocampus and entorhinal cortex after perforant path transection in a time course similar to the electrolytic ECL response. TGF β 1 mRNA levels increased rapidly in the hippocampus after the onset of limbic seizures induced by systemic kainic acid injection. It has been shown that TGF β 1 modulates the production of extracellular matrix molecules and receptors, proteases and protease inhibitors, cellular migration and growth factor activities in the periphery. Therefore, TGF β 1 may influence similar mechanisms during reactive synaptogenesis in the hippocampus. (Supported by AG07909 to CEF)

EFFECTS OF TGF- α AND TGF- β ON VENTRAL MESENCEPHALIC DOPAMINERGIC CULTURES. T. Alexi, T.L. Denton, and F. Hefti. Andrus Gerontology Center, U.S.C., Los Angeles, CA 90089.

Transforming growth factor- α (TGF- α) is a known mitogen for several cell types, it is expressed in the brain (including the striatum, Wilcox and Derynck, J. Neurosci. 8:1901,1988) and has been proposed as a trophic agent for dopaminergic cells. We therefore characterized trophic actions of TGF- α on rat fetal dopaminergic neurons in culture. E15 ventral mesencephalic dissociated neurons were grown in the presence of TGF- α for 5-8 days. TGF- α elevated dopamine uptake in a variable manner by 25-50%. There was a parallel increase in the total number of cells and protein content, reflecting a general growth promoting action of TGF- α and suggesting that the effect on dopaminergic neurons is mediated by non-dopaminergic cells. Preliminary evidence shows that the TGF- α induced elevation in dopamine uptake is blocked by neutralizing antisera to TGF- β , a mitogen structurally unrelated to TGF- α and thought to participate in the regulation of neurotrophic factor expression. The trophic actions of TGF- α on dopaminergic neurons will be further characterized by testing whether it affects their survival, neurite extension, and expression of tyrosine hydroxylase. In order to characterize the specificity of TGF- α , its actions will be compared with those of EGF, its structural and functional analog. Furthermore, we will explore the possibility that TGF- α 's actions are mediated by non-dopaminergic cells and TGF- β .

EFFECTS OF TROPHIC FACTORS ON ANTERIOR THALAMIC NEURONS. R.E. Clatterbuck, V.E. Koliatsos and D.L. Price.

Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Anterior thalamic nuclei show abnormalities in several neurological disorders, including Alzheimer's disease. Previously, we reported that peripheral nerve grafts exert both trophic and tropic effects on axotomized anterior thalamic neurons. The present investigation was designed to test the hypothesis that previously identified neurotrophic factors, known to be abundant in these grafts, might be responsible for the observed effects. Such factors include nerve growth factor (NGF), ciliary neurotrophic factor (CNTF), and basic fibroblast growth factor. After making unilateral aspiration cingulectomies in adult male Sprague-Dawley rats, we placed cannulas attached to mini osmotic pumps into the ventricle for the delivery of trophic factors or vehicle. Following two weeks of treatment, animals were sacrificed, and tissues were processed for morphometric analysis. Although NGF did not prevent retrograde degeneration of anterior thalamic neurons, CNTF appeared to have some protective effect on these thalamic neurons. Currently, we are examining this possible trophic interaction further as well as testing other trophic factors in this model.

BIOLOGICAL ACTIVITY OF THE SECRETED FORM OF AMYLOID β A4 PROTEIN PRECURSORS: III THE GROWTH REGULATORY EFFECT ON NEUROBLASTOMA CELLS.

L.-W. Jin^a, M. Sundsmo^a, B. Bhasin^b, D. Goldhaber^b, and T. Saitoh^a. ^aDept. of Neurosciences, Univ. of California, San Diego, La Jolla, CA 92093, & ^bDept. of Psych. & Behavioral Science, SUNY, Stony Brook, NY 11794.

We previously demonstrated that secreted forms of amyloid β A4 protein precursor (APP) have growth regulatory activity on fibroblasts (Cell 58:615-622, 1989) and modulate adhesion of neuron-like cultured cells to substrata (Neuron 3:689-694, 1989). In the current study, we further analyzed the biological functions of two secreted APP isoforms, one without the protease inhibitor domain (APP-695) and the other with protease inhibitor domain (APP-751). Conditioned media from cell clones overproducing APP-695 (Amy5), APP-751 (Amy6) and control-transfectant (293) were applied to cultured neuroblastoma Lan-5 cells. Amy6 at 20% reduced Lan-5 growth by 30%, although 293 and Amy5 had no effect. At the same concentration, both Amy5 and Amy6, but not 293, restored the growth of A-1 fibroblast, the cell line that secretes very low amount of APP and depends on exogenous APP in the medium for normal growth. Essentially the same results were obtained with secreted APP-695 and APP-751 produced by recombinant baculovirus expression system. The difference between APP-695 and APP-751 was also seen in the signal transduction systems affected by these proteins. By immunoblotting technique, only APP-695 was shown to reduce PKC(α) level in prolonged cultures of Lan-5 or fibroblast. Since the ratio of APP-751/APP-695 is reported to be changed in AD brains (Science 248:854-857, 1990), the differential effects of two forms of secreted APP may be involved in the neuronal degeneration in AD.

Localization of Transforming Growth Factor alpha Precursor and Epidermal Growth Factor in Forebrain Regions of the Vervet Monkey (*Cercopithecus Aethiops*). J. Callaway, R. Kinyamo*, J. Opolo*, J. Kimani*, S.E. Loughlin and J.H. Fallon. Department of Anatomy and Neurobiology, Univ. of California Irvine, Irvine, Calif. 92717 and Department of Human Anatomy, Univ. of Nairobi, Kenya.

Transforming growth factor alpha (TGF α) and the structurally related epidermal growth factor (EGF) have been immunocytochemically localized in the rodent brain, (Fallon et al. '84, '87, '90; Loughlin et al. '89). In the present study, TGF α precursor and EGF-like immunoreactivity were localized in the primate brain. Adult Vervet monkey brains (Univ. of Nairobi, Kenya) were processed for immunoperoxidase and immunofluorescence (double labeling). As in the rat brain, TGF α -LI was localized in a subpopulation of glial fibrillary acidic protein immunoreactive astrocytes. In the forebrain, TGF α -LI was observed in astrocytes of the corpus callosum, external capsule, anterior commissure, dorsal striatum and globus pallidus. In addition, EGF-LI was localized in axonal-like processes in the globus pallidus. These data support previous findings in the rat suggesting that TGF α and EGF are potential candidates for neurotrophic function in these regions of the mammalian brain. Supported by the National Parkinson Foundation, NS 15321, NS 26761 and a Bud Corbin Neuroscience Award.

PLATELET-DERIVED GROWTH FACTOR RECEPTOR EXPRESSION IN RAT NEURONAL AND ASTROGLIAL CULTURES. J.B. Hutchins and M.D. Ard, Dept. of Anatomy, Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

Platelet-derived growth factor (PDGF) is known to play a role in the differentiation of glial cell precursors into oligodendrocytes or type-2 astrocytes. It is not yet clear which cell types in the developing brain synthesize and release PDGF, or which cells respond to the presence of this growth factor via surface receptors. Three isoforms of PDGF exist (AA, AB or BB dimeric forms) and there are thought to be at least three receptor types ($\alpha\alpha$, $\alpha\beta$, and $\beta\beta$, with various binding specificities). We have used an antibody to the β subunit of the PDGF receptor (anti-PDGF-R β) to study the cell types which express this protein *in vitro*.

Neurons were cultured from 15-day embryonic rat cerebral cortex, either as explants or as dissociated cells. Astrocytes were prepared from newborn rats by standard methods. Following maintenance of cells or explants *in vitro* for two to four days, the tissue was fixed and processed for PDGF-R β -like immunofluorescence. Some tissue was double-labeled with antibodies to either glial fibrillary acidic protein or phosphorylated neurofilaments. This combination of labels allowed us to identify PDGF-R β cells as either astrocytes or neurons.

Neurites express both PDGF-R β and phosphorylated neurofilament in isolated culture, in a co-culture with astrocytes, or in cortical explants. PDGF-R β processes extend for relatively long distances in these cultures. As expected, astrocytes have moderate but detectable levels of PDGF-R β in culture. The levels of PDGF-R β are much higher on embryonic astrocytes than on those cultured from newborn rats, consistent with the findings of others that the response of these cells to PDGF declines with maturity.

PDGF may influence the differentiation and development of neurons as well as glial cell precursors. These observations, combined with earlier studies demonstrating the possible release of PDGF by neurons, further support a fundamental role for PDGF in neuronal as well as glial development. REGULATION OF TRANSFORMING GROWTH FACTOR- β 1 mRNA IN BRAIN: IMPLICATIONS FOR TISSUE REPAIR AND PLASTICITY. N.R. Nichols, M. Lampert-Etchells*, N.J. Laping, T.E. Morgan*, G.M. Pasinetti, J.D. Rittenberg* and C.E. Finch, Andrus Gerontology Center and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles CA 90089-0191.

Transforming growth factor- β 1 (TGF- β 1) is a growth regulatory peptide with well-known roles in differentiation and wound repair in peripheral tissues. Recently, we cloned TGF- β 1 from hippocampus of 3 mo old rats as a mRNA that was decreased in response to glucocorticoid treatment. We also showed by RNA blot hybridization that TGF- β 1 mRNA increased 5-fold in the deafferented hippocampus and striatum after entorhinal cortex lesion and decortication, respectively. *In situ* hybridization studies show that sites of increased TGF- β 1 mRNA in response to both lesions include the edge of the wound cavity as well as the deafferented area. In addition, hippocampal TGF- β 1 mRNA is elevated in 15 and 24 mo rats compared with 6 mo control male Fisher 344 rats. These data indicate that TGF- β 1 might be involved in neural plasticity. If these changes in mRNA levels result in changes in active peptide, then TGF- β 1 could play an important role in brain injury, aging and neuroendocrine adaptation, particularly in view of the similarities between tissue repair and disease processes regulated by TGF- β peptides in peripheral tissues. (Supported by PHS #AG-07909 and The Brookdale Foundation)

TRANSFORMING GROWTH FACTOR β MODULATES NGF EFFECTS ON CULTURED SENSORY NEURONS. A. Chalazonitis(1), J. Kalberg(1), *D.R. Twardzik(4), *R.S. Morrison(3) and J.A. Kessler(1,2), Depts of Neurosci.(1) and Neurol.(2) Albert Einstein Coll. Med., New York, NY 10461; (3) Portland, OR 97209 and Bristol Myers Squibb Pharm. Res.Inst.(4) Seattle, WA 98121.

TGF β exerts potent growth stimulatory and differentiating effects on a wide variety of non-neuronal cells during embryogenesis and in wound healing. Two dimeric forms of TGF β (β 1 and β 2) were tested for their neurotrophic actions on rat neonatal dorsal root ganglion (DRG) neurons in dissociated culture. TGF β 1 and β 2 (10 ng/ml) significantly increased neuronal survival (2 fold) and the level of the neurotrophic substance P (SP) (3 fold) per culture. Maximal effects occurred at 1 ng/ml for TGF β 1 and 10 ng/ml for β 2. Treatment with both factors was not additive. Co-treatment of DRG cultures with a 2.5S NGF antibody prevented the neurotrophic effects of TGF β , implicating a role for NGF. TGF β did not significantly alter endogenous expression of NGFmRNA in DRG cultures nor content of NGF in the conditioned medium. However, TGF β 1 (5ng/ml) potentiated neuronal survival induced by exogenous (1-100 ng/ml) NGF. These data suggest a modulatory role for TGF β in the actions of NGF on sensory neurons. Supported by NIH grants NS 26766 (AC) and NS 20013 and NS 20778 (JAK).

COORDINATE EXPRESSION OF STRIATAL TGF β -1 AND FIBRONECTIN mRNA FOLLOWING CORTICAL DEAFFERENTATION. G.M. Pasinetti, N.R. Nichols, M. Gordon, D.G. Morgan and C.E. Finch, Andrus Gerontology Center and Dept. of Biological Sciences, University Southern California, Los Angeles, CA 90089-0191

Striatal deafferentation by frontal cortex ablation in adult rat induced fibronectin mRNA 3 days postlesioning, while TGF β -1 mRNA increased 10 days postlesioning as assessed by northern blot hybridization. By *in situ* hybridization, the apparent elevation of fibronectin mRNA signal at 3 days postlesioning was localized to cells lying on the border of the wound cavity rostral to the deafferented striatum. TGF β -1 mRNA signal on the wound cavity surface was also elevated 3 days postlesioning. In striatum, the *in situ* hybridization assay of fibronectin mRNA and TGF β -1 mRNA showed an identical schedule of change with an overlapping peak of elevation 10 days postlesioning. The elevation of striatal fibronectin and TGF β -1 mRNA recovered toward control levels by 27 days postlesioning, as assessed by northern blot and *in situ* hybridization assay. By *in situ* hybridization combined to immunocytochemistry on the same tissue section, fibronectin mRNA was localized to glial fibrillary acidic protein (GFAP) immunostained astrocytes; TGF β -1 mRNA appears to be colocalized with microglia immunostained by OX-42 antiserum which specifically recognize the microglia CR3 complement receptor. This study indicates the *in vivo* coordinated expression and differential cellular localization of fibronectin and TGF β -1 mRNA following brain injury. Supported by National Parkinson Foundation to GMP and NIH grant AG-7909 to CEF.

301.12

TGF- β AS A POTENTIAL REGULATOR OF SCHWANN CELL PROLIFERATION. J.B. Davis*, A.J. Shores*†, A.G. Watts, P. Stroobant*†, The Salk Institute for Biological Studies, San Diego, CA 92186; †Ludwig Institute for Cancer Research, London W1P 8BT, UK.

In order to respond to PDGFs or FGFs rat Schwann cells require cooperation from other factors which are able to induce expression of the requisite polypeptide growth factor receptor. Using DNA synthesis studies, normal Schwann cells and a Schwann cell line, the cooperative effects of TGF- β have been studied and a role for TGF- β in an autocrine loop demonstrated.

TGF- β supports a Schwann cell response to PDGF-AB, PDGF-BB, acidic-FGF or basic-FGF, factors otherwise inactive, and to serum platelet-derived factors. The requirement for TGF- β is saturable and the effect dose dependent. These effects are similar to the reported cooperation between polypeptide growth factors and forskolin, suggesting a similar mechanism involving receptor regulation.

A rat Schwann cell line, made during these studies, is able to proliferate in response to platelet-derived factors alone and secretes a soluble factor that is mitogenic for normal Schwann cells. The mitogenic effect is blocked by an anti-TGF- β antibody, suggesting that paracrine or autocrine secretion of TGF- β may enable Schwann cells to respond to other growth factors during development or tumorigenesis.

The development of sympathetic innervation in footpads of Tabby mutant mice. M. Rao and S.C. Landis, Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH. 44106

Tabby is an X-linked mutation in mice that causes a number of abnormalities in the development of epidermal derivatives (Falconer, 1952), including the absence of sweat glands (Sofaer, '69; Blecher et al., '90). Despite the lack of sweat gland ducts and secretory tubules in adult male hemizygous Tabby mice, the epidermis and underlying connective tissue which contains blood vessels and nerve fibers appears normal. We have examined the sensory and sympathetic innervation of footpads in Tabby and control mice using catecholamine histofluorescence and immunocytochemistry. The distribution and number of Substance P and CGRP-labelled sensory fibers in Tabby appeared similar to those of control mice. In addition, arteries and arterioles were innervated by noradrenergic sympathetic fibers in both control and Tabby mice. In contrast to control mice, however, no VIP and choline esterase positive fibers were evident in Tabby footpads. This observation suggests that the absence of sweat glands is accompanied by a corresponding lack of sweat gland innervation. The absence of gland innervation in adult Tabby mice could be due either to a failure of sympathetic axon growth to the footpads or the subsequent failure of the glandless pads to support an initially normal innervation. To distinguish between these possibilities, we examined the sympathetic innervation of footpads in young Tabby mice. At 10 days, in both Tabby and control mice, catecholaminergic fibers were present. In footpads of normal mice, the fibers are associated with developing sweat glands and blood vessels. In footpads of Tabby mice, some fibers are associated with blood vessels while others ramify in the connective tissue and beneath the epidermis. These observations suggest that despite the absence of their normal target, sympathetic fibers initially project appropriately to the footpads but are subsequently lost. Supported by NS23678 and the AHA.

ACETYLCHOLINE PROMOTES THE DEVELOPMENT AND MAINTENANCE OF SECRETORY FUNCTION IN RAT SWEAT GLANDS. M. P. Grant and S. C. Landis. Depts. of Pharmacology and Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

Previous studies have suggested that the sympathetic cholinergic innervation of rat sweat glands plays a critical role in regulating the development and maintenance of secretory gland function. To learn more about the nature of the molecular signal(s) responsible, we disrupted muscarinic cholinergic transmission in developing postnatal rat pups and adult rats by administering atropine, and replaced muscarinic transmission in acutely denervated sweat glands by administering pilocarpine.

Treatment of neonatal rat pups for 7 days (P11-P18) with 1-atropine (20 mg/kg/day) using Alzet minipumps resulted in the failed development of sweat gland secretory function. Secretory function was absent for 4 days following the withdrawal of atropine and then developed over the next 5 days, reaching control levels on P27. Atropine treatment did not impair development of appropriate gland morphology. In adult animals, a similar treatment protocol produced a loss of secretory function for 3 days; function recovered to control levels by day 7. This was not due to the presence of residual atropine since both the pupillary light response, and acetylcholine-mediated decrease in blood pressure recovered within 24 hrs; further, direct testing of the serum for atropine indicated residual atropine was not present 1 day following the treatment protocol. In addition, we treated adult rats whose sweat glands were denervated by sciatic nerve section with pilocarpine, a muscarinic agonist. A seven day treatment of pilocarpine begun immediately after denervation resulted in a 60% preservation of gland function; untreated animals lost all function within 3-5 days. These results suggest that acetylcholine itself released from sympathetic nerve terminals is required for the normal development and maintenance of secretory function in sweat glands. Supported by NINDS 23678.

PROTEASE NEXIN I (PNI) INCREASES THE SURVIVAL OF SPINAL CORD NEURONS. B.W. Festoff and D.E. Brenneman, Neurobiology Res. Lab., KC VA and Univ. Kansas Med. Centers, Kansas City, MO 64128 and KS 66103; Lab. of Dev. Neurobiol., NICHD, NIH, Bethesda, Maryland 20892

Neuron-glia interactions have important roles in regulating the development of the nervous system. Neuropeptides released from neurons can stimulate receptors on glia that result in the release of substances that, in turn, affect neuronal maturation and survival. Our goal is to identify these neurally evoked, glia-derived proteins. Previous studies have indicated that low concentrations of vasoactive intestinal peptide (VIP) increase the survival of neurons grown in dissociated spinal cord cultures (PNAS 83: 1159, 1986) and that this action is mediated through a nonneuronal cell type (J. Cell Biol. 104: 1603, 1987). VIP has been shown to increase the release of protease nexin I (PNI) from rat cortical astrocyte cultures (Neurosci. Abs. 16:909, 1990). We studied whether PNI, a 43-47 kD serine protease inhibitor (Serpin) that stimulates neurite outgrowth, has an additional effect on neuronal survival. Purified PNI was added to dissociated spinal cord cultures that were co-treated with tetrodotoxin (TTX), to prevent the release of endogenous VIP. After a five day test period, a 70-75% increase in neuronal survival was observed in cultures treated with 1 nM PNI as compared to those treated with TTX alone. Concentrations of PNI \geq 100 nM were not effective. Similarly, spinal cord cultures treated with leupeptin, a tripeptide protease inhibitor, also increased neuronal survival within a narrow range of concentrations (10 nM); whereas, ammonium chloride, a lysosomal protease inhibitor, did not increase neuronal survival. Thus, PNI may participate in VIP-mediated regulation of neuronal maturation and survival possibly by preventing the degradation of extracellular growth-promoting substances which determine the structure of the developing nervous system. Supported by DVA and American Health Assistance Foundation.

INTERLEUKIN-1 β PROMOTES LONG-TERM SURVIVAL OF CULTURED RAT HIPPOCAMPAL NEURONS. J.W. Francis, T.H. Oh and G.J. Markelonis. Dept. Anatomy, Univ Maryland Sch Med., Baltimore, MD 21201.

Interleukin-1 (IL-1) is known to have potent effects on various CNS cells *in vivo* and *in vitro*. Since several studies have shown the presence of IL-1 β and its mRNA in rat hippocampus, we examined the effects of IL-1 β on dissociated rat hippocampal neurons. Cultures enriched in neurons were prepared from E18 rat hippocampus by treating the cultures with an antimetabolic. Control cultures survived for one to two weeks and then gradually degenerated. These cultures were comprised of 90-95% neurons as determined by neurofilament immunopositivity. However, addition of IL-1 β increased neuronal survival two-fold over control cultures. While basic fibroblast growth factor also increased long-term survival, IL-2 and epidermal growth factor showed no effect. The survival promoting effect of IL-1 β was dose-dependent. Although IL-1 β treatment also increased the number of astrocytes, the proportion of astrocytes in these cultures was actually slightly decreased relative to controls. Furthermore, when the antimetabolic was added to cultures at the time of initial plating, the survival-promoting effect of IL-1 β was observed in the absence of increased [3 H]-thymidine incorporation. Based upon these initial results, it appears that the survival enhancing effect of IL-1 β upon neurons may be independent of its effect on astrocytes. (Supported by NIH grant NS 15013).

TRANSFORMING GROWTH FACTOR- β 1 INCREASES GLIAL FIBRILLARY ACIDIC PROTEIN mRNA IN THE HIPPOCAMPUS OF YOUNG ADULT MALE RATS 24 HOURS AFTER AN INTRA-VENTRICULAR INFUSION. N. J. Laping, T. E. Morgan, N. R. Nichols, and C. E. Finch. Andrus Gerontology Center, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

Transforming growth factor- β 1 (TGF- β 1) is a cytokine implicated in many cellular responses involving both differentiation and responses to lesion. Functions of this factor in peripheral tissues include chemotaxis of fibroblasts and macrophages, as well as the regulation of proteases and modification of extracellular matrix proteins. Recently, our laboratory showed that TGF- β 1 mRNA is increased in the hippocampus after an entorhinal cortex lesion (ECL) which deafferents the hippocampus without causing cell death in the hippocampus (Nichols et al., J. Nsc. Res. 28:134-139, 1991). To examine the potential role of TGF- β 1 in regulating or mediating the astrocyte responses to ECL, TGF- β 1 was infused into the lateral ventricle in young adult male Fisher 344 rats. The rats were infused with 2 μ l vehicle or vehicle containing either 15 ng or 100 ng TGF- β 1. Astrocyte mRNA levels of glial fibrillary acidic protein (GFAP) and sulfated glycoprotein-2 (SGP-2) were determined in the hippocampus and entorhinal cortex 24 hours after the infusion by RNA blot hybridization analysis. Hippocampal GFAP mRNA levels increased 40% in rats infused with 100 ng of TGF- β 1 vs. vehicle, with indications of dose response. The entorhinal cortex showed similar trends. In contrast, another astrocyte marker, SGP-2 mRNA was not affected by TGF- β 1 24 hours after the infusion in either tissue examined. These results implicate TGF- β 1 as an intermediate signal that activates certain astrocyte functions in response to deafferentation. Activation of other cell-cell interactions which might involve SGP-2 might be delayed or require longer exposure to TGF- β 1. (Supported by AG-07909 to CEF and AG-05528 NRSA fellowship to NJL).

PURIFICATION OF ACTIVITY DEPENDENT NEUROTROPHIC FACTOR (ADNF) D.E. Brenneman, R. Barth*, D. Warren*, A. Davidson and I. Gozes. Lab. of Developmental Neurobiol., NICHD, Bethesda, MD 20892, Dept. of Pathol. Chem., Tel Aviv Univ., Tel Aviv, Israel.

The survival of developing spinal cord neurons has been shown (PNAS 83: 1159, 1986) to be dependent on glial-derived substance(s) that can be released by vasoactive intestinal peptide (VIP). The survival-promoting activity present in the conditioned medium of VIP-stimulated astroglia cultures (J. Cell Biol. 104:1603, 1987) can be detected in test cultures made from dissociated spinal cord which have been electrically blocked with tetrodotoxin, a condition which decreases the release of the endogenous secretagogue, VIP. An activity-dependent neurotrophic factor (ADNF) has been purified from conditioned medium of rat cortical astrocytes stimulated for three hours with 0.1 nM VIP. Sequential chromatographic separations by anion exchange, molecular sieving and reverse phase were utilized to obtain an electrophoretically (SDS-PAGE and IEF) pure peptide that increased the survival of spinal cord neurons effectively at concentrations of 10^{-14} M during a five day test period. The isolated neurotrophic substance has an apparent molecular weight of 7300 Daltons and a basic pI. A 3000-fold increase in specific activity was achieved from the isolation procedures. On the basis of total amino acid composition and other physical characteristics, ADNF does not appear to be any of the already identified neurotrophic growth factors. ADNF was heat- and trypsin-sensitive and did not bind to heparin or Con A affinity columns. The glia-derived ADNF may play a significant role in the mechanism of neurotrophism elicited by VIP in CNS cultures.

301.20

EXPRESSION OF MURINE INTERFERON- α / β IN THE CENTRAL NERVOUS SYSTEM. B. Tedeschi, F.J. Liuzzi and C.W. Morgan. Dept. of Anatomy & Neurobiology, East. Va. Med. Sch., Norfolk, VA 23501.

Previous studies have shown that cultured astrocytes (but not neurons), isolated from neonate mouse cerebral cortex, can be induced to produce interferon- α / β (muIFN- α / β) when exposed to a polyribonucleotide stimulus (Tedeschi et al., J. Cell Biol. 102:2244, 1986). In the present study, we examined (1) the *in vivo* expression of muIFN- α / β in the CNS and (2) the *in vitro* induction of IFN- α / β from a neural cell line by growth factors.

1-day and adult mouse brain/optic nerves were either frozen or paraffin-embedded and immunohistochemically examined for the presence of IFN- α / β . Results showed that neural cells in both neonate and adult optic nerve expressed IFN- α / β . The cell type(s) expressing IFN- α / β in optic nerve has not yet been identified while the expression of IFN- α / β by other brain regions will be described.

Since these data showed that IFN- α / β is expressed in normal CNS, we investigated whether growth factors might be an inducing stimulus for IFN- α / β . Growth-arrested C6 glioma cells were grown in the presence of EGF (a growth factor for C6 glioma), polyribonucleotides, or serum-free media. Results showed that both EGF and polyribonucleotides induced the expression of immunoreactive IFN- α / β , while cells grown in serum-free media did not express detectable immunoreactive IFN- α / β . These results suggest that growth factors can serve as an inducing stimulus for the expression of neural IFN- α / β .

EFFECTS OF PLATELET DERIVED GROWTH FACTOR ON THE DEVELOPING RAT CENTRAL NERVOUS SYSTEM. **MB Giacobini¹, A Smits², K Funa², B Westermark³, L Olson¹.** ¹Dept of Histology & Neurobiology, Karolinska Institutet, Stockholm, Sweden, ²Ludwig Institute for Cancer Research, Biomedical Center, Uppsala, Sweden and ³Dept of Pathology, University Hospital, Uppsala Sweden

The two forms of platelet derived growth factor, PDGF AA and PDGF BB, and one of their receptors have recently been found to be expressed in the central nervous system (CNS). These discoveries have prompted us to investigate a possible functional role of PDGF in the developing CNS. Growth and survival of grafts from different regions of the developing rat CNS were followed by using the *in vivo* method of intraocular transplantation. Grafts were incubated in either PDGF AA (100ng/ml), PDGF BB (100 ng/ml) or vehicle solution alone (0.5 mg/ml HSA) at the time of transplantation and 5 µl injections of the same solution was administered to the anterior chamber of the eye on day 5, 10 and 15 postgrafting. Both PDGF AA and PDGF BB significantly increased the volume of transplanted E16 parietal cortex grafts when compared to grafts treated with vehicle alone. PDGF BB also seemed to sustain growth of transplanted E18 hippocampal tissue whereas PDGF AA showed a volume decrease when compared to PDGF BB and vehicle alone treated grafts. Histochemical and immunohistochemical studies were carried out on cryostat sectioned grafts to look at effects on glial and neuronal populations and vascularization, among others. An increased gliosis was seen in both PDGF AA and PDGF BB treated cortical grafts whereas all the hippocampal grafts, regardless of treatment, maintained a normal cytoarchitecture. These studies suggest that administration of exogenous PDGF can enhance survival and/or stimulate proliferation of cells in fetal brain tissue grafts, and that the effects of the different PDGF family members are region-specific. Furthermore, the two PDGF family members, AA and BB, are probably acting on different cell populations in the developing rat central nervous system.

CHARACTERIZATION OF A FACTOR WITH NEUROTROPHIC PROPERTIES ON TYROSINE HYDROXYLASE-POSITIVE VENTRAL MESENCEPHALIC NEURONS. **B.A. Maguire, T.J. Collier, and J.E. Springer,** Dept. of Neurology, Hahnemann University, Philadelphia, PA, 19102 and Dept. of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

We have previously shown that conditioned medium (CM) from peripheral nerve or a Schwann cell line contain a protein(s), designated as dopaminergic neurotrophic factor (DNTF), that exhibits neurotrophic effects on ventral mesencephalic neurons immunoreactive for tyrosine hydroxylase (TH). Recent studies have indicated that one of these molecules may be related to brain-derived neurotrophic factor or BDNF. We used protein purification strategies to isolate and characterize fractions from Schwann cell CM that exhibit neurotrophic properties on TH positive ventral mesencephalic neurons. In addition, we tested various fractions of Schwann cell CM in explant cultures of chick retinal ganglion cells, which are thought to be responsive to BDNF. A Schwann cell line was grown in a stirring culture flask containing OPTIMEM plus 1% fetal bovine serum. Schwann cell CM was precipitated in 70% ammonium sulfate, dialyzed against 0.1M phosphate buffer, and eluted from carboxy-methyl cellulose with sodium chloride (NaCl). Protein peaks were collected, dialyzed, and tested using measures of cell number and neurite outgrowth in embryonic day 15 (E15) rat ventral mesencephalic neurons. In addition, embryonic day 6 (E6) chick retinal ganglion cells were cultured to test for the presence of BDNF-like activity in different eluted fractions of Schwann cell CM. An increase in the number of TH-positive ventral mesencephalic neurons was observed following treatment with Schwann cell CM fractions eluted with 0.5M NaCl. A similar procedure is used to isolate BDNF, although we have subsequently determined that the molecular weight of DNTF is different from BDNF. Chick retinal ganglion cells did not respond to any concentrations of fractions previously shown to exhibit DNTF-like bioactivity. Although DNTF can be isolated using techniques similar for BDNF, we have shown that the molecular weight and biological activity of DNTF is not similar to BDNF. GM1 GANGLIOSIDE CORRECTS THE LOSS OF DA UPTAKE ACTIVITY IN EMBRYONIC MESENCEPHALIC CULTURES TREATED WITH MPP⁺. **A. Dalia¹, N.H. Neff^{1,3} and M. Hadjiconstantinou^{1,2,3}.** Depts. of Pharmacology¹ and Psychiatry² and the Neuroscience Program³. The Ohio State Univ. Col. of Med., Columbus, OH 43210.

We have reported that treatment with GM1 partially restores the biochemistry, pharmacology, morphology and behavior of MPTP-treated mice. The mechanism(s) for this activity of the compound is unknown. It has been reported that MPP⁺, the neurotoxic metabolite of MPTP, decreases dopamine (DA) uptake activity in embryonic mesencephalic cultures. We have used embryonic mesencephalic cultures to investigate the action of GM1. Cultures were treated with MPP⁺, 3 µM, for 24 hr, then GM1 was added to the medium and DA uptake assayed 12 days later. GM1 restored DA uptake activity in a dose-dependent manner, with about 500 nM GM1 returning transport activity to control values. Pretreatment or cotreatment with GM1 did not prevent the MPP⁺-induced neurotoxicity. As has been reported, GM1 increased the DA uptake activity in control untreated cultures in a dose-dependent manner as well. For both MPTP-treated and untreated cultures the EC₅₀ for GM1 was about 200 nM.

301.22

TYPE I ASTROCYTES MEDIATE THE REGION SPECIFIC SUPPORT CELL INCREASE IN SUBSTANTIA NIGRA DOPAMINERGIC NEURON SURVIVAL. **E.K. O'Malley, B.-A. Sieber, L. E. Black, and C.F. Dreyfus,** Dept. Neuroscience & Cell Biology, R.W.J. Med. Sch, UMDNJ, Piscataway, NJ 08854.

Previous work in our laboratory has demonstrated that substantia nigra (SN) support cells selectively increase SN dopamine (DA) neuron survival in primary cell culture. Moreover, increased DA cell survival was elicited specifically by nigral support cells; glia from other brain regions exerted lesser effects. We now present evidence that Type I astrocytes, the principal components of SN support cell monolayers, mediate the enhanced DA survival.

Initially, we established the identity of the predominant glial subtypes present in SN support cell cultures. Pooled tissue from postnatal day 1 rat SN was dissociated and cells were grown to confluence (7-9 days *in vitro* (DIV)). Fixed monolayers were immunostained with antibodies against GFAP (an astrocyte specific marker), MBP (an oligodendrocyte cell marker), or A2B5 (identifying O-2A progenitors and Type II astrocytes). GFAP+ cells constituted more than 82% of monolayers, suggesting that astrocytes were the predominant subgroup comprising support cell monolayers. Further, direct comparison of GFAP+ (Type I & Type II astrocytes) and A2B5+ (Type II astrocytes) cell number indicated that the population consisted primarily of Type I astrocytes. Greater than 98% of cells were stained with these antibodies.

To definitively characterize the glial subtype that augments survival, individual cultures of each glial subpopulation were established (McCarthy and DeVellis, 1980). At 2 DIV, enriched populations of Type I or Type II astrocytes, or oligodendrocytes, were tested for ability to elicit DA neuron survival. Embryonic day 16 rat SN dissociates were added and DA cell number was assessed with antibody against tyrosine hydroxylase (TH), the DA biosynthetic enzyme. After 2 days in coculture, the Type I astrocyte group exhibited greater than a 2-fold increase in TH cell number, while oligodendrocyte and Type II astrocyte cocultures did not differ from control. Our observations suggest that the Type I astrocyte subtype specifically elicits enhanced DA neuron survival in the SN. (Support: NINDS, NICHD, March of Dimes, JDF, McKnight)

301.24

MODULATION OF IMMEDIATE-EARLY GENE EXPRESSION BY GM1 GANGLIOSIDE. **D. Krajnc¹, A.M. Duchemin¹, N.H. Neff^{2,3} and M. Hadjiconstantinou^{1,2,3}.** Depts. of Pharmacology¹ and of Psychiatry² and The Neuroscience Program³. The Ohio State Univ. Col. of Med., Columbus, OH 43210 USA

We have previously shown that brief hypoxia in neonatal rats induces transient neurochemical changes and permanent neurochemical pathology. Moreover, we showed that treatment with GM1 ganglioside corrects both the long- and short-term hypoxia-induced deficits.

Immediate-early genes, that act as transcriptional modulators, are induced following acute insults to the brain, such as injury, ischemia and seizures. We now report that transient hypoxia, O₂ 8% balance N₂ for 3 hr, induces the expression of *c-fos* and *NG2F-A* mRNA in the hippocampus and frontal cortex of 7 day old rats. The time-course for the hypoxia-induced expression of the mRNAs for these genes is similar, with a maximal increase of about 8-10-fold over control values, occurring within 1-2 hr after exposure and return to normal within about 3 hr. Treatment with GM1, 50 mg/kg i.p. daily, starting on day 5 and one dose immediately after the insult, appears to enhance expression as well as induce earlier expression of the genes.

301.26

PLATELET-DERIVED GROWTH FACTOR INCREASES INTRACELLULAR CALCIUM LEVELS IN CULTURED NODOSE SENSORY NEURONS. **G. Hajduczuk, R.V. Sharma*, R.C. Bhalla*, and F.M. Abboud*.** Depts. of Internal Medicine, Anatomy, and Cardiovascular Ctr., Univ. of Iowa Coll. of Med., Iowa City, IA 52242.

Accumulating evidence indicates that neurons are dependent on specific trophic factors for their growth and maintenance. Platelet-derived growth factor (PDGF) is a crucial factor for oligodendrocyte differentiation. We tested the hypothesis that PDGF has neurotrophic actions on visceral sensory neurons *in vitro*. Cytosolic free Ca⁺⁺ concentration ([Ca⁺⁺]_i) was measured in cultured adult rat nodose ganglion neurons using fura-2 as the fluorescent Ca⁺⁺ indicator and a microscopic digital image analysis system. In 13 of 21 neurons (62%), addition of PDGF (BB-homodimer; 10ng/ml) on average resulted in a 6-fold rise in [Ca⁺⁺]_i above basal levels. The results are shown below (*; significantly different from Control; p<0.05).

[Ca ⁺⁺] _i (nM)	PDGF	
	Control	Peak Response
	70 ± 6	472 ± 100*
		Absolute Change
		357 ± 103*

PDGF mobilized [Ca⁺⁺]_i promptly within 10-20 sec and reached maximum levels within 2 min. These results suggest that in addition to its known mitogenic effects on nonneuronal cells, PDGF may have important neurotrophic activity in nodose sensory neurons mediated via Ca⁺⁺ transduction pathways.

SUPEROXIDE DISMUTASE AND GLUTATHIONE PEROXIDASE EXPRESSION IN THE HUMAN MESENCEPHALON: IMPLICATION FOR PARKINSON'S DISEASE. P. Damier*, P. Zhang*, E. Hirsch, J. Ceballos⁽¹⁾, P.M. Sine⁽¹⁾, Y. Agid, F. Javoy-Agid, INSERM U 289, Hôp. Salpêtrière, 75013 PARIS, ⁽¹⁾URA CNRS 1335, Lab. de Biochimie Génétique, Hôp. Necker 75015 PARIS

Parkinson's disease (PD) is characterized by a massive loss in dopaminergic neurons in the midbrain, primarily the melanized neurons of the substantia nigra pars compacta. Although the cause of neuronal death remains unknown, oxygen free radicals have been implicated as a potential cytotoxic mechanism.

Examination of toxic species defence system in human midbrain post mortem showed: 1) the levels of expression of the gene of CuZn superoxide dismutase (SOD) (the enzyme catalysing conversion of superoxide radicals to hydrogen peroxide) were high in the neuromelanin-containing neurons, as revealed by *in situ* hybridization analysis at cellular levels. This indicates a neuronal localization of SOD mRNA. The high levels of transcripts in these neurons suggest biochemical pathways leading to oxygen species formation are particularly active. 2) Glutathione peroxidase (GPx), the enzyme scavenging hydroxyl radicals was exclusively detected in glial cells by immunocytochemistry. The density of GPx positive cells was high in dopaminergic cell regions preserved in PD (central grey substance), low in the substantia nigra pars compacta dramatically affected. The density of GPx positive cells in dopaminergic cell subgroups in controls, was negatively correlated to estimated neuronal loss in PD. Dopamine neurons surrounded by GPx positive glial cells may be better protected against oxidative stress. Melanized dopaminergic neurons represent a subset of dopaminergic cells with respect to their oxygen defence system. A critical role of glial cells in neuronal protection against free radicals is suggested.

ISCHEMIA SENSITIVE AND ISCHEMIA RESISTANT PRIMARY CULTURES OF CEREBELLAR GRANULE CELLS. W. Code, L. Peng*, L. Heriz*, A. Shuaib and B.H.J. Juurlink. Depts. Anesthesiology, Pharmacology, Medicine and Anatomy, University of Saskatchewan, Saskatoon, SK, Canada S7N 0W0.

Brain hypoxia and ischemia cause neuronal damage via a number of mechanisms, including, ATP depletion, free radical formation and excitotoxicity leading to receptor activated accumulation of calcium. It is difficult to sort out the contributions to neuronal damage of each of these. We describe here culture preparations that should facilitate a more ready dissection of these mechanisms. Cerebellar neurons were prepared from 7-day-old mouse pups and cultured in the presence of serum at either a normal (NK: 5.4 mM) or elevated (HK: 25.4 mM) potassium concentration. Both culture types are viable for a period of three weeks. Cultures grown in the presence of HK developed a calcium-dependent glutamate release during superfusion with 50 mM potassium of ≈ 10 nmol/min/mg protein which is much larger than that seen in corresponding cultures grown in chemically defined medium. This response was absent in cultures grown in the NK medium although the voltage dependent uptake of calcium was not diminished. The ultrastructure of the cell bodies and the neuropil of cells grown in HK closely resembled those of cerebellar granule cells *in vivo*. Although cell bodies and axonal profiles including synaptic vesicles looked normal, dendritic development was poor with NK. Thirty min of hypoxia or ischemia caused death of neurons grown with HK; this death was prevented by the NMDA receptor blocker MK801. In contrast, approximately 6 hr of ischemia and more than 6 hr of hypoxia were required to cause death of the neurons grown with NK. Several factors might account for these differences in resistance to ischemia-hypoxia: 1) the release of glutamate under ischemia-hypoxia conditions may be less in NK cultures, or 2) glutamate release to the medium may be more toxic to HK cultures that are known to express NMDA receptors, than to NK cultures expressing quisqualate receptors (Cox et al., 1990, Neuron, 4: 941). The two conditions described for culturing granule cell neurons should enable us to dissect the contributions of excitotoxicity to neuronal death from that of free radical formation and ATP depletion.

INCREASE IN PROTEIN SYNTHESIS FOLLOWING TRANSIENT "ISCHEMIA" IN CA1 OF RAT HIPPOCAMPUS.

C. Charriaud-Marlangue*, M. Khrestchatsky and Y. Ben-Ari. INSERM U29, 123 bld de Port-Royal, 75014 Paris, France.

CA1 pyramidal cells of the hippocampus are particularly vulnerable to brief episodes of ischemia *in vivo*, exhibiting a prolonged inhibition of protein synthesis and a delayed morphological deterioration. In the present study, CA1 slices were maintained *in vitro* in a Krebs-bicarbonate solution at 32°C and gassed with 95% O₂/5% CO₂. After 2 hours equilibration, slices were then submitted to 3 to 10 min ischemia in glucose-free Krebs gassed with 95% N₂/5% CO₂, then transferred to normal Krebs for 30 min recovery in presence of ³⁵S-Met (10 μ Ci/ml media). We have compared the effects of 3-4 min to 5-10 min anoxia since the former but not the latter produced a reversible block of synaptic transmission (Hasboun D., Papas S., Crepel V. and Ben-Ari Y., unpublished results). A brief anoxia (<4') increased significantly (to 30% of control levels, Student's *t*-test *p*<0.005) ³⁵S-Met incorporation into proteins. By two-dimensional gel analysis, the increase in protein synthesis concerned particularly a few proteins namely 20 kDa (pHi = 4.6); 30 kDa (pHi = 5); 38 kDa (pHi = 5.5) 68 kDa (pHi = 5.2) and 70 kDa (pHi = 5.9). In contrast a longer anoxia (>4') decreased ³⁵S-Met incorporation (to 20-25% of control levels).

When slices were incubated with MK-801, a non-competitive antagonist of NMDA receptor-channel complex, 15 min prior and during a 5 min ischemia episode, protein synthesis rates were essentially identical to control rates. Although the functional consequences of increased expression of some proteins remain unknown, these results reflect the importance of protein synthesis on the anoxia cell damage.

SEVERAL MECHANISMS CAUSE NEURONAL LOSS IN THE SUBICULUM IN ALZHEIMER DISEASE AND AGING. P. Cras*, M. Kawai*, M. Stanik*, P. L. Richey*, S. G. Younkin, G. Perry, Div. of Neuropathology, Inst. of Pathology, Case Western Reserve Univ., Cleveland, OH 44106.

Development of neurofibrillary tangles (NFT) and neuronal loss are important pathologic events in Alzheimer disease. An unresolved question, however, is how many neurons die after developing NFT and what happens to the extracellular NFT (E-NFT) that remain. Alz-50, a monoclonal antibody to a modified form of τ exclusively stains intracellular NFT (I-NFT), while basic fibroblast growth factor (bFGF) binding is a sensitive assay for E-NFT. If all the neurons would follow the same path, develop I-NFT and all the E-NFT would remain indefinitely after the perikaryon disappears, the sum of I-NFT, E-NFT and the number of normal neurons would have to add up to a constant number. We determined the densities of SMI-32 (a marker of neuronal cytoplasm)-positive, Alz-50-negative pyramidal neurons (normal neurons), Alz-50-positive neurons (I-NFT) and of bFGF-positive E-NFT in the subiculum of 16 Alzheimer disease and 5 aged non-demented patients. Densities were calculated using the Abercrombie formula, but cerebral atrophy was not corrected for. We could divide our patients into 4 groups: group I consisted of 3 non-demented aged patients with normal subicular pyramidal neurons with a density ≈ 250 /mm²; group II consisted of 4 patients (2 of whom were not demented) with significant neuronal loss, but only a few Alz-50 positive I-NFT and no E-NFT; group III consisted of 11 Alzheimer patients with varying numbers of I-NFT, E-NFT and normal pyramidal neurons; group IV consisted of 3 Alzheimer patients with a very high number of E-NFT and only a few I-NFT and pyramidal neurons left. In groups II and III, the sum of I-, E-NFT and normal neurons was well below the normal number of pyramidal neurons. In group IV, the sum of densities was ≈ 250 mm² and therefore approached the number of normal pyramidal neurons found in the non-demented patients. These findings suggest: 1. In Alzheimer disease and aged patients not all neurons die by developing NFT. 2. A small group of Alzheimer patients has a high propensity to develop subicular NFT and all of these probably remain indefinitely as E-NFT after neuronal loss. This study was supported by a Fogarty International Fellowship to Drs. Cras and Kawai and by NIH grants K04-AG00415, AG-007552, AG09287.

POST-ISCHEMIC SURGE IN CORTICOSTEROIDS AGGRAVATES ISCHEMIC DAMAGE TO GERBIL CA₁ PYRAMIDAL CELLS. G.D. Miller* and J.N. Davis, VA Neurology Laboratory and Duke University, Durham, NC

Glucocorticoids regulate CA₁ pyramidal cell damage after transient forebrain ischemia. To determine if normal glucocorticoid secretion contributes to damage after 5 minutes of carotid artery occlusion, we studied 4 groups of gerbils: 1) adrenalectomized 4 days before ischemia and then steroid replaced (10 mg cortisol / 3 mg corticosterone or 2 mg cortisol daily, n=9), 2) sham adrenalectomized (n=9), 3) no adrenal surgery, sham carotid occlusion (n=4), or 4) no adrenal surgery and carotid occlusion. The groups without adrenal surgery both showed an increase in plasma glucocorticoids at the time of anesthesia with halothane and continued to show elevated levels plasma levels for at least two hours after reperfusion. There was no statistically significant difference in body temperatures during or after ischemia between the adrenalectomized animals treated with glucocorticoids and the other groups. The animals were sacrificed 72 hours after reperfusion and CA₁ pyramidal cells were counted. Neurons were lost to the same extent in sham adrenalectomized animals (0.64 \pm 0.10 neurons / 10 μ CA₁ length) and non-adrenalectomized animals subjected to ischemia (0.67 \pm 0.10). Adrenalectomized animals with steroid replacement had significantly more CA₁ neurons than the non-adrenalectomized, ischemic animals (1.27 \pm 0.20, *p*<0.01) but not as many as animals subjected to sham carotid occlusion (2.63 \pm 0.19). Previous experiments have shown that steroid administration after ischemia worsens hippocampal damage. These data show that even the approximate doubling of plasma glucocorticoid levels during and after carotid occlusion significantly worsens hippocampal damage. (Supported by NS 06233)

THE (1S,3S)-ISOMER OF 1-METHYL-1,2,3,4-Tetrahydro- β -CARBOLINE-3-CARBOXYLIC ACID, A BREAKDOWN PRODUCT OF PEAK 97 IMPLICATED IN THE L-TRYPTOPHAN EOSINOPHILIA MYALGIA SYNDROME (L-TRP-EMS), STEREOSPECIFICALLY PREVENTS NEURONAL DEATH IN SPINAL CORD CULTURES. E.M. Sternberg, S.W. Page*, Mark Smith and D.E. Brenneman. Clinical Neuroendocrinology Branch, NIMH; Center for Food Safety and Applied Nutrition, FDA and Lab. of Dev. Neurobio., NICHD, Bethesda MD 20892 and Washington D.C. 20204.

L-TRP-EMS, an inflammatory syndrome characterized by eosinophilia, perimyositis, fasciitis, neuropathies including Guillain-Barre syndrome, occurred in epidemic proportions in the United States in 1989, and was related to ingestion of contaminated batches of L-tryptophan (L-TRP). One high performance liquid chromatography peak (Peak 97), which is most highly statistically associated with human L-TRP-EMS, has been identified as 1,1'-ethylidenebis(L-tryptophan) (EBT). At pH 2, or conditions present in gastric secretions, EBT decomposes to a diastereoisomeric mixture of (-)-(1S,3S)- and (-)-(1R,3S)-1-methyl-1,2,3,4-tetrahydro- β -carboline-3-carboxylic acid (1S- and 1R- β -C). We evaluated the effects of synthetic EBT, the diastereoisomeric mixture, and pure 1R- β -C and 1S- β -C isomers (1 to 300 μ M) on neuronal cell survival in dissociated spinal cord cultures derived from fetal mice. After a 5 day test period, 100 μ M of the 1S- β -C, but not 1R- β -C or EBT, prevented the 30% cell death which normally occurs in these cultures. The dose response characteristics of this effect falls within the dose effect range for amino acids in this assay system. The stereospecificity suggests these effects may be receptor mediated.

302.7

Deprenyl Rescues MPTP-Exposed Nigrostriatal Neurons Independently of Blocking the Conversion of MPTP to MPP+. W.G. Tatton, C.E. Greenwood and P.T. Salo. Center for Research in Neurodegenerative Diseases and the Depts. Physiol. and Nutr.Sci., University of Toronto, Toronto, Canada M5S 1A8

Deprenyl has been hypothesized to slow the death of dopaminergic nigrostriatal neurons (DNSNs) based on its slowing of the progression of Parkinsons Disease (PD). Previous workers co-administered MPTP and deprenyl to show that deprenyl blocks the astroglial conversion of MPTP to the active radical, MPP+, thereby protecting the DNSNs from the toxin. To determine whether deprenyl protects DNSNs independently of the above mechanism, 8 week old C57BL mice were treated with 30 mg/kg MPTP daily for 5 days. 72 hours after the last MPTP dose (day 8), the mice received L-deprenyl, either 0.25 or 10 mg/kg, or saline, i.p.3 times per week until day 25. Serial sections through the entire substantia nigra compacta (SNc) were alternately Nissl stained or immunoreacted for tyrosine hydroxylase (TH). Counts relative to the cross sectional areas of the Nissl and TH+ SNc somata were made for each entire nucleus. A proportion of the mice had Fluoro-Gold (FG; 8 nl) injected into one striatum 1 week before the MPTP treatment to unambiguously identify nigrostriatal somata. Collectively the immunocytochemistry, Nissl staining and FG identification showed that MPTP-exposed DNSNs died gradually until day 25 with average losses of 18, 26, 35, 38, 39 and 37% at days 5, 10, 15, 25, 40 and 65 respectively. Whole nuclear counts at day 25 for animals only treated with saline were 3014 +/- 304 (mean +/- SEM) and were 1872 +/- 187 (38% loss) for MPTP followed by saline. Counts at day 25 for animals treated with MPTP followed by deprenyl were 2536 +/- 161 (14% loss) and 2535 +/- 169 (16% loss) for the 10 mg/kg and 0.25 mg/kg doses respectively. Since MPTP and MPP+ are completely cleared from the murine brain by 48 hours after an injection (Lau et al., Life Sciences 43, 1459-1464, 1988), these results show rescue of dying DNSNs by deprenyl that is independent of the blockage of the conversion of MPTP to MPP+ and is similar to the rescue that can be effected by treatment with growth factors or gangliosides. (MRC & Parkinson Found. of Canada.)

ABSENCE OF C-FOS INDUCTION IN NEONATAL RAT BRAIN FOLLOWING SEIZURE. S.S.Schreiber, G.Tocco, I.Naim, and M.Baudry. Dept. of Neurology and Neurosciences Program, Univ. of Southern Calif., Los Angeles, CA 90033.

Activation of the proto-oncogene, c-fos, by a variety of extracellular stimuli has been implicated in the regulation of long-term adaptive changes within the mammalian central nervous system (CNS). We have been studying the pattern and time course of expression of c-fos following systemic administration of the excitatory neurotoxin, kainic acid (KA). In adult rats, KA induces a well-characterized seizure syndrome that results in irreversible morphologic changes and neuronal death in selectively vulnerable cell populations. In contrast, a behaviorally distinct seizure pattern occurs in neonatal rats characterized by prolonged seizure activity without subsequent neuronal death. We used *in situ* hybridization to localize and quantify c-fos messenger RNA (mRNA) in brain sections following KA treatment. There was no evidence of c-fos induction in hippocampus or other cortical structures 1 hour following seizure onset in rat pups less than 13 days old. In contrast, after postnatal day 13 elevated levels of c-fos mRNA were observed in the hippocampus and piriform cortex. Following seizure activity the level of c-fos mRNA gradually increased to reach adult values by 25 days of age. The increase in cortical structures was delayed by 5-6 days as compared to that seen in hippocampal structures. These results suggest that stimulus transcription coupling during early postnatal life may be different than in the adult. More importantly, the results suggest that the expression of c-fos may be an important determinant of neuronal survival. Finally, c-fos induction cannot be considered a reliable index of neuronal activation.

RESPONSE OF MDCK AND "IMMORTALIZED" SEPTAL CELLS TO IONOMYCIN-INDUCED RISES IN INTRACELLULAR CALCIUM.

A.M. Danks, R. VanBuskirk*, R.L. Isaacson, Dept. of Psychology & Biology, SUNY-Binghamton, Binghamton, NY, 13902-6000.

Increases in intracellular calcium were induced in SN56 B5 G4 (septal x neuroblastoma, derived from 21-day old mice) and MDCK (canine kidney) cells by incubation with 0.01 to 100 uM concentrations of the calcium ionophore ionomycin. The cells' response was monitored *in situ* using fluorescent probes in a multiple-endpoint assay system with the Cytofluor 2300 fluorescent plate reader (Millipore). Lysosomal integrity (neutral red), mitochondrial activity (rhodamine 123), intracellular Ca²⁺ (Fluo3-AM), intracellular pH (cfda-AM), and plasma membrane integrity (calcein-AM) were examined after 15 min incubation with the ionophore.

Fluo 3 indicated that [Ca²⁺]_i increased in response to increasing concentrations of ionomycin. In MDCK cells, intracellular pH and mitochondrial activity decreased in response to low concentrations of ionomycin, but increased in response to higher concentrations. Largest effects were seen on lysosomal integrity, where there was greater than 50% dissipation of neutral red. Plasma membrane was not compromised at any of these concentrations of the ionophore. Septal cells showed greater buffering capacity of ionomycin-induced rises in intracellular Ca²⁺, as these indicators remained unchanged after 15 min incubation with the ionophore. Time-course studies are currently underway to examine when changes occur in these cells.

EFFECTS OF LONG-TERM ALCOHOL CONSUMPTION IN THE HYPOTHALAMUS OF THE RAT. M.M. Paula-Barbosa, N. Sousa*, A. Mendes*, A. Cadete-Leite* and M.D. Madeira*. Dept. of Anatomy, Porto Medical School, Porto 4200, Portugal.

Chronic alcohol consumption (CAC) induces marked changes in blood hormonal levels. Notwithstanding, studies of the effects of CAC upon the structure of the hypothalamus are non-existent. To address this issue we analysed the following 6 groups of 6 male and 6 female rats: 1) alcohol-treated (A) with a 20% ethanol solution for 18 months, 2) respective pair-fed controls (C) and 3) withdrawn (W) animals following 12 months of CAC. The volume of the supra-chiasmatic (SCN), supraoptic (SON), and paraventricular (PVN) nuclei was determined in celloidin sections and corrected for the shrinkage. The cross-sectional area of the neurons was calculated in semithin sections. The volume of the SON and of the magnocellular division of PVN was 30% larger in (A) than in (C). The nuclear volumes of (W) did not differ from those of (C). We found that in (A) the increase in size of magnocellular neurons reached 40%. The volumes of SCN and of the parvocellular division of PVN were reduced in (A) and (W). The sexual differences observed between controls remained among the experimental groups. We suggest that the widely known alcohol induced degenerative changes do not reflect on the volume of the magnocellular nuclei. This might be due to changes of hydric metabolism, which is altered after CAC leading to a continuous stimulation of the surviving cells. (Project PMCT/C/SAU/33/90 - JNICT).

MDMA, A SUGGESTED 5-HT NEUROTOXIN, INCREASES CALCIUM INFLUX IN RAT BRAIN SYNAPTOSOMES. W.K. Park and E.C. Azmitia. Dept. of Biology, New York University, Washington Square East, NYC, NY 10003.

Excessive Ca²⁺ entry into neurons is one of the initial steps in cell death. 3,4-methylenedioxymethamphetamine (MDMA), a drug of abuse, produces neuronal degeneration by a mechanism involving 5-hydroxytryptamine (5-HT) release. The effect of MDMA is blocked by the calcium channel blocker nimodipine (Azmitia et al. Brain Res. 510:97,1990), suggesting that MDMA-induced degeneration may be linked to excessive calcium influx, probably through an interaction with 5-HT receptors. In the present study, we test if MDMA or 5-HT can stimulate calcium uptake using CNS synaptosomes. A micro-assay uptake system was modified to study the basal and stimulated (68.5 mM K⁺) uptake of ⁴⁵Ca (Triggle, D.J. Trends Pharmac. Sci.5:4, 1984). Rat brain P₂ fractions are prepared for ⁴⁵Ca uptake by CNS synaptosomes using 96 well plates. Total uptake volume is 150 ul: 10 ul of ⁴⁵Ca (NEN, S.A. 16mCi/mg), 20 ul of tissue suspension, 10 ul of drug and 120 ul of buffers. The uptake is quenched by buffer containing 12 mM EGTA after 1s. K⁺-stimulated ⁴⁵Ca-uptake is approximately 100% higher than that of basal conditions (4.5mM K⁺). MDMA and 5-HT produced significant stimulation (40% of controls) in ⁴⁵Ca uptake in both conditions. Interestingly, MDMA-induced calcium uptake is blocked when synaptosomes are pretreated with the 5-HT uptake blocker fluoxetine. Current studies are aimed at understanding the possible involvement of the serotonergic system in the regulation of CNS calcium channels (NIDA contract. 271-87-8144).

NEURONAL PLASTICITY AFTER SELECTIVE HIPPOCAMPAL DAMAGE; DETECTION BY CALCINEURIN IMMUNOHISTOCHEMISTRY. Y.Yamasaki*, H.Onodera*, K.Adachi*#, H.Sho-zuhara*, Y.Matsuo* and K.Kogure, Dept. of Neurology, Tohoku Univ. Sch. of Med., Sendai, 980, Japan #; Sec. of Biology, Synphar Lab. Inc., Edmonton, Canada

We observed regional alteration of immunoreactivity for calcineurin subunits (A and B) after selective hippocampal damage (CAL:transient ischemia, CA3:kainic acid injection) in rats. In control rats, the dentritic field of the CA1, CA3 and dentate gyrus exhibited high immunoreactivity (C-IR) of both subunits. After selective pyramidal cells damage in the CA1 and CA3 subfields, C-IR in the dentritic fields of the CA1 and CA3 was reduced, respectively. Interestingly, both CA1 and CA3 damages induced marked enhancement of C-IR (A and B subunits) in the CA3 stratum lucidum, where mossy fiber terminates, 4 to 100 days after lesioning. These increasing patterns for A and B subunits were different particularly after CA3 damage.

These results suggest that both calcineurin subunits are located predominantly on the CA1 and CA3 pyramidal cells and that enhanced C-IR of mossy fibers reflect plastic responses of dentate granule cells after hippocampal pyramidal cell depletion.

KAINIC ACID INDUCES PRODUCTION OF AMYLOID PRECURSOR PROTEIN IN RAT NEURONS. K. Shigematsu, T. Ishii and P.L. McGeer. Kinsmen Lab. for Neurol. Res., University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3.

Wistar rats received unilateral intrastriatal injections of either 1 µg of kainate or saline and were sacrificed 1 day to 3 months thereafter. Brains were stained immunohistochemically with antibodies to various segments of amyloid precursor protein (APP) (R17:597-620, R36:528-540, R37:681-695, Ishii et al, Neuropathol App Neurobiol 15:135-147). Immunoreactivity of APP (R36 and R37) was observed in neurites and neurons 1 day after the kainate injections. The neurites were often thick and distorted with swollen varicosities. After 4 days immunoreactivity began to appear in macrophage/microglial cells and in the neuropil. This immunoreactivity increased for a further 1-2 weeks and then began to decline but was still present after 2-3 months. By double immunostaining it was demonstrated that the phagocytic cells loaded with APP immunoreactivity were Ia, LCA (OX1), c3bi receptor (OX42), and ED1 (macrophage) positive, but GFAP negative. No amyloid fibrils were detectable, and immunostaining for beta-amyloid protein (R17, 597-620) was consistently negative. These results suggest that APP production is upregulated in damaged neurons and accumulates in degenerating axons. In the rat, phagocytosis of APP by reactive microglia/macrophages does not result in amyloid production under the experimental conditions employed.

The Rate of Cell Growth Determines Susceptibility to the Mitochondrial Toxin MPP⁺. A. Roghani, Y.-J. Liu*, R.H. Edwards. Department of Neurology, UCLA School of Medicine, LA, CA 90024.

Cells vary markedly in their vulnerability to the neurotoxin MPP⁺. In PC12 cells, uptake of the drug through the plasma membrane catecholamine transporter appears required for toxicity. However, we find that CHO fibroblasts, without such transport activity, show even greater sensitivity to the toxin. Further, contact-inhibited confluent cultures show much greater vulnerability than rapidly growing subconfluent cultures. The effects seen under both conditions of growth occur with a similar half-maximal dose, suggesting that the differences in toxicity do not derive from differences in drug handling. These results suggest that the rate of cell growth constitutes a major determinant of susceptibility to a mitochondrial toxin.

In light of the modulation of toxicity by changes in growth rate, we have treated the NGF-responsive PC12 cell line with the toxin in the presence and absence of NGF. In these cells, NGF induces terminal neuronal differentiation to a postmitotic state. In accordance with the finding in CHO cells, NGF also markedly potentiates the toxicity of MPP⁺ in PC12 cells.

"Striatal D₁ and D₂ Receptor-containing Neurons in Culture: Susceptibility to Kainic Acid: E.R. Mesco, J.A. Joseph, G.S. Roth* Gerontology Research Center, NIA/NIH Baltimore, MD. 21224 USA

Previous work in this laboratory showed a selective sensitivity of striatal D₂ receptor neurons to kainic acid (KA) in mature (6 mo.) Wistar rats. The receptor binding (B_{max}) for the D₂ receptor in the KA-treated rats resembled the binding seen in old (24 mo.) rats. In order to see if this phenomenon exists in cultured cells, which could provide a very accessible model for subsequent mechanistic studies, we examined striatal cultures grown for up to 30 days and labeled with either [³H]-spiperone, for D₂ receptors, or with [³H]-SCH23390, for D₁ receptors. Analysis of the cells was done using a digital imaging system (RAS). The cultured cells were examined for receptor binding, for cell size, and for susceptibility to KA. The D₂ cells showed an increased mortality over D₁ cells in the presence of KA [receptor x KA, F(1,172)= 14.5, p <.002], similar to *in vivo*, with larger D₂ cells showing the highest loss [mean cell area: -KA = 169.6 ± 5.0 µm²; +KA = 155.5 ± 2.7 µm²; F (1,358) = 5.1, p <.03].

302.16

APOPTOSIS IN A MOTOR NEURON-LIKE CELL LINE INDUCED BY SERUM DEPRIVATION OR 5-AZACYTIDINE.

N.R. Cashman, A. Abdollah*, J.T. Shaw*, J. Nalbantoglu*, A. Beaudet. Montréal Neurological Institute, Montréal, Québec, CANADA, H3A 2B4.

Selected neuronal growth factors may serve to suppress an apoptotic "cell death program" important in developmental matching of neuron number to target field. We have developed a model of apoptosis induced by growth factor deprivation in the motor neuron-like hybrid cell line NSC34 (Cashman *et al*, Soc Neurosci Abs 1987). NSC34 apoptosis, induced by replacement of 10% fetal calf serum (FCS) with 1% bovine serum albumin (BSA) in base DMEM, is accompanied by generation of "nucleosome ladders" on ethidium bromide-stained DNA gels, possibly due to activation of endogenous nucleases. Nucleosome ladders were also induced in DMEM 10% FCS with 3 µM 5-azacytidine, an inhibitor of maintenance methylase which reduces CpG methylation of proliferating cells and allows expression of previously quiescent genes. Ultrastructural features of BSA-induced NSC34 apoptosis include heterochromatinization, prominent nuclear indentation, and free membrane-bound nuclear fragments. Cell death, quantitated by propidium iodide exclusion on cytofluorometry, was inhibited to 50% at 3 days by 0.5 µM cycloheximide, an inhibitor of protein translation. We conclude that NSC34 cells, on serum deprivation or CpG demethylation, undergo cell death which exhibits molecular and morphologic features of apoptosis, and which requires expression of a cycloheximide-sensitive cell death gene cascade. The data are consistent with our hypothesis that developmentally silenced cell death genes, ectopically expressed in aging, could be responsible for selected neurodegenerative syndromes (Schwob *et al*, Ann Neurol 1990). NSC34 cells provide a convenient model to study the cell and molecular biology of apoptosis.

PATTERN FORMATION, COMPARTMENTS AND BOUNDARIES II

303.1

METALLOPROTEINASE IMMUNOREACTIVITY IN RAT BRAIN. G.Nilaver, J.P.Alexander*, E.M.Shannon* and T.S.Acott*. Depts. of Neurology, Ophthalmology and Biochemistry, Oregon Health Sciences University, Portland, OR 97201.

Metalloproteinase (MP) activity has been implicated in remodelling of the extracellular matrix and in certain disease states (rheumatoid arthritis & tumor metastases). In the CNS, MPs are associated with neurite outgrowth. Growth cone extension is also blocked by inhibiting MP activity. We examined the distribution of transin [stromelysin (STR)] immunoreactivity in neonatal rats, adult rats, and rats bearing brain grafts. STR specific antibodies were used in immunohistochemical and Western (WoB) analyses. Staining in adult brain was confined to astrocytes and axon terminal profiles outlining neuronal somata. While astrocytic staining was present in most brain regions, axosomatic profiles were most intense in hypothalamus (preoptic, supraoptic, peri & paraventricular areas), amygdala, habenula and thalamus (periventricular & centromedian nuclei). Staining in neonate brain was diffuse and host brain around implant showed intense reactivity. A 30 and 138 kDa band were detected in neonatal and adult brain by WoB (in addition to the 57 & 45 kDa bands). The 30 kDa band was dominant in neonate with the 138 kDa band predominating in adult. Transin and type IV collagenase activities were detected in conditioned media from cultured mouse astrocytes, implying production in glial cells. The significance of the axosomatic staining is unknown. The expression of transin in brain has implications for CNS development and neurodegenerative diseases.

TOOTH PULP (TP) DEAFFERENTATION: CHANGES IN FUNCTIONAL PROPERTIES OF TRIGEMINAL (V) BRAINSTEM NEURONES IN RATS. J.W. Hu, C. Kwan* and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

This study was undertaken to determine if TP deafferentation can lead to functional changes in neurones in the V spinal tract nucleus of rats. Single neurone activity was recorded in V subnucleus oralis of adult anaesthetized rats 7-15 days after removal of the coronal TP of the mandibular molars. Compared with control animals, animals deafferented for 7-15 days showed no significant difference (Fisher's test; p>0.05) in incidences of low threshold (LTM) neurones (92% in deafferented rats Vs 97% in controls), LTM neurones with rapidly adapting (81% Vs 87%) Vs slowly adapting (19% Vs 13%) properties, and neurones showing habituating tap sensitivity (1% Vs 1%); mean latencies to electrical stimulation of the mechanoreceptive field (RF) were also not significantly different. Deafferented animals did however show significantly increased incidences of LTM neurones with a RF involving 2 or 3 V divisions (28% Vs 9%), maxillary and mandibular divisions (17% Vs 3%) and periodontal input from both divisions (8% Vs 2%), and with spontaneous activity (16% Vs 8%). These findings show many similarities with TP deafferentation effects on oralis neurones in the cat and indicate that the rat can be used as a model for TP-induced V brainstem neuroplasticity. Supported by NIH grant DE04786.

303.3

REGIONAL DIFFERENCES IN CELL PROLIFERATION AND NEURITE GROWTH IN THE MAMMALIAN TELEENCEPHALIC VESICLE. I.F. Coburn and A.S. LaMania. Dept. of Neurobiology, Duke University Medical Center, Durham, NC 27710.

We have sought evidence of cellular differentiation in the mammalian telencephalic vesicle prior to its division into the rudiments of the olfactory bulb, hippocampus, basal ganglia, basal forebrain and neocortex. At this stage (mid-gestation in mice or birth in the Brazilian opossum) most cells in the vesicular epithelium are still actively dividing; few are post-mitotic. We analyzed the distribution of cells in S-phase of the cell cycle labelled after a brief pulse of bromo-deoxyuridine (BrdU) in mice and opossums at these ages. There was a high density of labelled cells at the dorsal anterior pole of the vesicle and at several foci along the lateral surface. A low density of labelled cells was seen at the mid-ventral region of the medial wall and the posterior pole. Further characterization of the epithelium showed that immunoreactivity for GAP-43, MAP-2, a synaptic vesicle antigen SVP-48, and a novel antigen found in growing neurites, EA1B1, was limited to regions with higher densities of BrdU-labelled cells. For each marker, immunoreactivity was observed around cells at the vesicular surface, suggesting the early appearance of a marginal zone in regions with high rates of cell proliferation. Anti-GAP-43 showed the sharpest boundaries between regions with high and low rates of cell proliferation; cells in both the marginal area and the underlying columnar epithelium were immunoreactive. Electron microscopic examination of the marginal regions revealed immature neurites and vesicle-filled profiles among otherwise undifferentiated neuroblasts; however, no neuritic processes were seen in the underlying columnar epithelium. These results indicate appreciable cellular and molecular differentiation in the telencephalic vesicle that may prefigure its division into the major regions of the forebrain.

303.5

ANALYSIS OF CEREBELLAR CIRCUITS IN ENGRAILED-2 DEFICIENT TRANSGENIC MICE. K. Herrup, H. Zanjani, K. Millin*, J. Rossant* & A.L. Joyner*. E.K. Shriver Center, Waltham, MA, and Univ. of Toronto, Toronto, ONT

One of the mouse homologs of the *Drosophila engrailed* gene (*En-2*) has been mutated by homologous recombination in ES cells and introduced into the germ line through ES cell chimeras. Homozygous mutants survive but have unusual cerebellar foliation. Quantitative analysis of several different cell types reveals a reduction in Purkinje cell number of almost 40% in the mutant. This deficit, however, is not uniform. The Crus I folium of the hemisphere is missing, and the size of the paraflocculus is reduced. In the vermis, all folia are present, but certain folia (e.g. declive and uvula) show reductions in Purkinje cell number while others (e.g. culmen and tuber vermis) show little or no change. The number of granule cells is also reduced, by around 40%, but the density of granule cells is unchanged. In no region examined does the thickness of the granule cell layer differ from normal values, nor does the density of cells in the Purkinje cell layer change. This latter observation is in contrast to known neurological mutants where a late postnatal loss of Purkinje cells occurs. This suggests that the cell number deficits exist from early stages of postnatal cerebellar development. Preliminary cell counts of the neurons of the inferior olive also reveal a decrease in cell number. Breeding experiments with *reeler* and *weaver* mutants in progress as is a developmental profile of both the morphological abnormalities and the pattern of *En-2* expression.

THE DEVELOPMENT OF CRUDE AND REFINED MAPS IN THE RAT SI CORTEX. L. Zhang and N.G.F. Cooper. Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38163

Patterns of thalamocortical projections from the ventrobasal complex of the thalamus to SI cortex were examined with the carbocyanine dye, Dil, in aldehyde-fixed neonatal rats. Patterns of neurons in layer IV of SI cortex were also examined in cresyl violet stained sections. Patterns of molecular expression evident as "boundaries" within layer IV of SI cortex were observed in sections labeled with the monoclonal antibody to the HNK-1 epitope. Thalamocortical axon projections are organized into several patches in the cerebral cortex by late P1 (day of birth). These patches, together, represent the complete body surface in the cortex. Five rows of distinctive axonal arbors, representing individual mystacial vibrissae of the contralateral face, are clearly present in the face subfield by late P2. However, distinctive axonal arbors within lower lip, forelimb and hindlimb subfields become evident, sequentially, between P3 and P5. Layer IV neurons are similarly aggregated into several dense cellular patches by P3. These patches indicate the presence of subfields which become more distinct by P4. Barrels are first detected in the snout and posterior medial barrel subfield on P4. Barrels in other subfields become clear, sequentially, between P5 and P7. Subfields, labeled with anti-HNK-1 antibodies were evident prior to the appearance of barrel boundaries. These data indicate that the development of cortical representation of the body surface proceeds from the development of a crude anatomical map to one that is shaped and refined further with increasing postnatal age. supported by NIH:NEI EY02708.

303.4

GRAFTING ANALYSIS OF THE MATERNAL EFFECT MUTANT JERKY OF XENOPUS LAEVIS. R. Tompkins, Q. Le*, D. Reinschmidt*. Cell and Molecular Biology Dept., Tulane Univ., New Orleans, LA 70118

A mutant allele, *jerky*, which causes a lethal maternal effect targeting anterior neural development is described in *X. laevis*. All offspring of homozygous females exhibit abnormal swimming behavior and die during late embryonic stages. Chimeras consisting of a normal anterior half, including the brain and anterior spinal cord, and a maternally affected posterior half, developed normally whereas the reciprocal chimeras died of the maternal effect. Grafts of normal heads including the brain to posterior maternally affected bodies incorporating the anterior spinal cord resulted in normal anterior neural development but mutant swimming behavior and death. Orthotopic grafts of eyes from maternally affected embryos to normal hosts developed normally. The unusual localized lethal maternal effect on anterior neural development is exceedingly fine grained. The chimeras revealed autonomous expression of behavioral effects and lethality in the anterior spinal cord, autonomous retarded development and lethality in head transplants, yet only secondary or dependent effects on eye development.

303.6

A NOVEL ROLE FOR SYNAPTIC COMPETITION IN THE DEVELOPMENT OF CORTICAL LAMINATION. Z.F. Mainen*, B.J. Claiborne*, and T.H. Brown. Dept. of Psychology, Yale University, New Haven, CT 06520 and ¹Division of Life Sciences, Univ. of Texas, San Antonio, NW Loop 1604, 78285.

Numerous studies have supported the hypothesis that activity-dependent synaptic competition partly mediates the formation of neuronal connection patterns in the visual cortex (reviewed in C. Shatz, 1990, *Neuron*, 5, 745-756). Using computer simulations, we have investigated the possibility that similar competitive mechanisms may act within single neurons to sharpen the spatial lamination of different sets of afferent fibers.

Standard compartmental techniques were used to model the electrotonic structure of hippocampal CA1 pyramidal neurons based on data from anatomical reconstructions and physiological recordings (see Brown, T.H., Zador, A.M., Mainen, Z.F., and Claiborne, B.J., 1991, in M. Baudry & J. Davis, eds., *LTP: A Debate of Current Issues*, MIT Press). Individual lamina with different distributions of afferents were chosen and stimulated such that synaptic activity within a lamina was more strongly correlated than that between laminae. The initial distributions of afferents were subject to modification based on a Hebbian rule with potentiation and depression terms linked to subsynaptic voltages.

Our results suggest that synaptic competition may act to eliminate afferents with less "favorable" locations—those located among afferents with whose activity they are not correlated or those located in regions that have less dense synaptic contacts. Thus, activity-dependent processes may help to fine tune a less precise distribution of afferents specified by other processes earlier in development. These processes could be important to the development and maintenance of lamination in the hippocampus as well as other laminated structures such as neocortex. (Supported by ONR and DARPA grants to T.H.B. and NSF to B.J.C.)

303.8

QUANTITATIVE ANALYSIS OF SPARED INFRAORBITAL (IO) PRIMARY AFFERENTS IN PARTIALLY DENERVATED SUBNUCLEUS INTERPOLARIS (SpVi). S.S. Stansel, M.F. Jacquin and W.E. Renehan. Dept. of Anatomical Sciences and Neurobiology, University of Louisville; Dept. of Anatomy and Neurobiology, St. Louis Univ. School of Medicine and Div. of Gastroenterology, Henry Ford Hospital, Detroit, MI.

We have previously shown that complete transection of the IO nerve at birth results in expansion of the central terminal arbors of vibrissa-sensitive primary afferents reinnervating the periphery (Renehan et al., JCN 289:493-508, 1989). In the present study we have partially denervated the trigeminal brainstem nuclear complex by cauterizing the mystacial vibrissae of rows A, C and E. This paradigm permits a more effective evaluation of the role of competition in arbor development. Thirty physiologically characterized afferents supplying the spared B and D row vibrissae were labeled by intraaxonal injection of HRP. Central terminal arbors in SpVi were compared with previously obtained normative data (Jacquin et al., JCN 267:107-130, 1988), revealing: 1) a significant (two-tailed, independent t-test, $p < 0.001$) increase in the area (13512 ± 7052 vs. $6130 \pm 2060 \text{ um}^2$) perimeter (657 ± 292 vs. $379 \pm 87 \text{ um}$) and circularity (form factor: 0.74 ± 0.14 vs. 0.55 ± 0.11) of the central terminal arbors as well as a marginally significant ($p < 0.05$) decrease in the number of boutons per collateral (83 ± 13 vs. 124 ± 28). The results of this investigation suggest that 1) spared IO primary afferents undergo arbor expansion but not sprouting following partial denervation of the trigeminal brainstem nuclear complex at birth, and 2) arbor dimensions are constrained by terminals of adjacent vibrissae. Supported by DE07734 and DE07662.

SEX-DEPENDENT ASYMMETRY IN BARREL CORTEX ORGANIZATION DURING POSTNATAL DEVELOPMENT. A.L. Roca, J.E. Crandall, D. Butler*, R.C. Whorf, & S.A. Tobet, Depts. of Biochem. & Develop. Neurobiol., EK Shriver Ctr., Waltham MA 02254 & Prog. Neurosci., Harvard Med. Sch., Boston, MA 02115.

Layer IV of rodent somatosensory cortex contains discretely patterned morphological units characterized as barrels which correspond to physiologically functional units. In rats, Nissl-stained barrels become increasingly difficult to distinguish after postnatal day 20 (P20; Rice, 1985). We investigated sex-dependent barrel patterns in rat cortex in 3 independent experiments. Barrel field areas were estimated from 2-D composites of flattened tangential Nissl-stained sections. An asymmetry index (AI) was calculated: $(R-L)/(0.5(R+L))$, with R the right side area and L the left side area. In P20 Long-Evans rats, the barrel field in females was significantly larger on the right (AI = $+0.31 \pm 0.08$); in males, on the left (AI = -0.33 ± 0.15). In P20 Sprague-Dawley rats, females tended toward lateral asymmetry (AI = $+0.32 \pm 0.23$) whereas males did not (AI = $+0.06 \pm 0.06$). Another experiment using Long-Evans rats confirmed that the barrel field in females (AI = 0.45 ± 0.14) was significantly different from males (AI = -0.20 ± 0.11) in the direction and magnitude of asymmetry. No significant sex differences in symmetry were found at P10 or P30, although the absolute degree of asymmetry increased between P20 and P30. We hypothesize that sex-dependent asymmetries result from lateralized, developmental differences in cellular reorganization. Ongoing experiments test this using cytochrome oxidase histochemistry to demarcate barrel boundaries in the same sections that Nissl stains determine cellular patterns.

303.11

THE EXPRESSION OF 3-FUCOSYL-N-ACETYL-LACTOSAMINE (FAL) ON GLIA IN RELATIONSHIP TO NEURONAL LAYER DEVELOPMENT.

J. Mavity-Hudson, J. Witt* and V.A. Casagrande^{1,2}, Depts. of Cell Biology¹ and Psychology², Vanderbilt University, Nashville, TN 37215-2175. Recent studies from our laboratory have suggested that glial cells may play an active role in the Lateral Geniculate Nucleus (LGN) cell layer development (Hutchins and Casagrande, PNAS, 1988 and JCN, 1990). In this study we examined the possibility that specific glial associated cell adhesion molecules (CAMs) may be involved in this process. Evidence suggests that FAL is a carbohydrate epitope on a glial CAM (Niedieck and Loehler, Acta Neuro-Path., 1987) that may be developmentally regulated in the LGN (Mai and Schoenlau, Soc for Neurosci. Abst., 1990; Mavity-Hudson et al. Invest. Ophthalmol. Vis. Sci. Suppl., 1991). We examined the expression of an antibody to FAL (Leu-M1) and to Glial Fibrillary Acid Protein (GFAP) in developing ferret LGN from birth (P0) to adult. At P0 no cell layers are present and GFAP and FAL appear mainly in radial glia. As Interlaminar Zones (ILZs) first appear (P7-P14) both antibodies show darkest staining in these zones. Staining is also somewhat heavier in the A layers than in the C layers. At P21 ILZ staining with FAL is still distinct; GFAP staining of astrocytes is uniform from this stage on. In adults FAL shows a mirror image pattern to that exhibited in development, with light staining confined to the layers and absent from the ILZs. Taken together with previous results showing that FAL is developmentally regulated in the visual system, these results suggest that LGN layer formation may involve the differential expression of CAMs on subsets of astrocytes. Supported by EYO5038 and core grants EYO8126 and HD15052.

GLYCOCONJUGATES IN A DEVELOPING OLFACTORY SYSTEM. C.E. Krull, D.B. Morton, and L.P. Tolbert, ARL Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

During the development of the olfactory (antennal) system of the moth *Manduca sexta*, glial cells may play an intermediary role in the influence of olfactory axons on their target neurons in the antennal lobe (Tolbert & Oland, 1989). Glia envelop developing olfactory glomeruli and appear to be necessary for induction of glomeruli by the olfactory axons. To begin to explore the molecular basis for these intercellular interactions, we have examined the distribution of glycosylated molecules, implicated in many cell-cell associations (Lander, 1989). We have examined the patterns of binding of an antibody to the J1/tenascin molecule (gift of Dr. M. Schachner) and of a panel of lectins in antennal lobes at various stages of normal development and in antennal lobes deprived of olfactory axons throughout development. We find J1/tenascin immunoreactivity associated with glial cells, just as it is associated with the glial boundaries between barrels in the developing mouse somatosensory cortex (Steindler et al., 1989). While other lectins show no specific staining patterns, the lectin peanut agglutinin (PNA) binds to the target neurons of the antennal lobe. PNA specifically labels the fine terminal branches of the neurons as they grow and form synapses. Both PNA and anti-J1/tenascin binding appear even before afferent axons from the antenna arrive in the lobe, and also are present in unafferented antennal lobes. Western-blot analysis of the PNA binding in normal antennal lobes has revealed multiple protein bands underlying the histological staining pattern; two bands appear during development at potentially interesting stages. Experiments are under way to explore whether the molecules we are labeling play important roles in the development of glomeruli. (Supported by NS20040 to LPT.)

303.10

EXPRESSION OF MOLECULES WITH THE HNK-1 EPITOPE IN BARRELFIELD AND NON-BARRELFIELD CEREBRAL CORTEX OF POSTNATAL RATS. N. G. F. Cooper, and L. Zhang, Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38163

We have used the monoclonal antibody to the HNK-1 epitope to determine how many molecules bearing this epitope are present in the rat cerebrum and also to determine if there is any variability in the expression of such molecules with respect to space and time. Postnatal day 7 and 26 rat pups (3 experimental groups from different litters) were anesthetized with Ketaset. Cerebral cortex was removed and 100 micron tangential vibratome sections of the fresh tissue were examined under a dissecting microscope for the presence of barrels. Barreld field cortex (BFLD) and more posteriorly located areas in non-barreld field cortex (N-BFLD) were dissected out and homogenized separately in tris-buffered saline. The tissue extract was solubilized and separated by PAGE. Western blots were incubated with anti-HNK-1 antibody, followed by secondary antibody coupled to peroxidase. Molecules bearing the HNK epitope were visualized following peroxidase chemistry. Anti-HNK-1 antibody was omitted from incubations of control blots which were otherwise similarly treated. Four novel pieces of information can be discerned from these blots: (1) approximately 10 molecules are labeled by the antibody, with major glycoproteins having relative molecular weights of 240K, 200K, 175K, 150K and 145K; (2) there is not a reduction in the number of molecules between P7 and P26. This is not consistent with the loss of boundaries observed with tissue immunocytochemistry between these ages; (3) the presence of an additional glycoprotein 175K in the P26 animals is seen in both BFLD and N-BFLD; (4) reduction in the amount of a glycoprotein 145K in BFLD relative to N-BFLD is seen at both P7 and P26. These data lead us to suggest that several cell adhesion molecules bearing the HNK epitope could be involved in barrel formation. Glycoprotein 145K maybe down regulated in barrel hollows during barrel formation. This could be due to the invasion of thalamocortical afferents which may inhibit glia from producing cell adhesion molecules. Supported by NIH:NEI EY02708.

303.12

CC1 GLYCOCONJUGATES DEFINE A DEVELOPMENTALLY REGULATED ROSTROCAUDAL GRADIENT IN THE ACCESSORY OLFACTORY SYSTEM AND IN SYMPATHETIC GANGLIA IN RATS. G. Deutsch*, D. Gaitsev*, C.M. Story*, J.E. Crandall and G.A. Schwarting, Developmental Neurobiology Dept., EK Shriver Ctr, Waltham, MA 02254; and Program in Neuroscience, Harvard Medical School, Boston, MA

The CC1 monoclonal antibody reacts with beta-N-acetylgalactosamine terminal glycolipids which are expressed selectively on cells of sympathoadrenal lineage and on sensory neurons in the vomeronasal organ (VNO). In the accessory olfactory system, CC1-immunoreactivity (CC1ir) was demonstrated throughout the VNO and vomeronasal nerves from E15 to P0. Postnatally CC1ir was spatially restricted in the VNO to centrally located cell bodies. In the accessory olfactory bulb, where vomeronasal axons terminate, CC1ir became restricted postnatally to the rostral half of the nerve and glomerular layers in the target area.

In cells of the developing sympathoadrenal lineage, CC1ir was detected in the superior cervical ganglion (SCG) and stellate ganglion perinatally. At E15-17, most cells in the SCG were CC1ir. Between E18 and P3, CC1ir became restricted to groups of cell bodies predominantly in the rostral half of the SCG. CC1ir was no longer detectable in the SCG after P5. In the stellate ganglion at E15-18, CC1ir was concentrated in cells located in the rostral half and along the perimeter. These studies raise the possibility that CC1ir glycoconjugates participate in a specific chemical guidance system for subsets of peripheral axons. Alternatively, CC1ir glycoconjugates may play a role in establishing selective target regions for innervation by CNS neurons.

303.14

DEVELOPMENTAL EXPRESSION OF MEMBERS OF THE ANNEXIN FAMILY OF PROTEINS IN THE DEVELOPING CNS OF THE MOUSE. D. Goldowitz, K. Hamre, H. Horn*, N. Ahn* and K.P. Chepenik* University of Tennessee College of Medicine, Memphis, Howard Hughes Medical Institute, Seattle, and Jefferson Medical College, Philadelphia.

This study was carried out to examine the role that the annexins, a family of proteins that have calcium/phospholipid binding activity, play in the development of the murine CNS. Antibodies specific for 5 members of this family (lipocortinI, lipocortinII, endonexin, endonexinII, and 67K calelectrin) were used for immunocytochemical localization.

Of the 5 annexins studied, lipocortinI & II and endonexin had the most interesting temporal and spatial patterns of expression. Lipocortin immunoreactivity was first noted on embryonic day 11 (E11) in the floorplate of rostral spinal cord. The staining extended anteriorly through the brainstem as a densely immunopositive midbrain raphe. LipocortinII immunoreactivity was noted at E10; staining was present throughout the floor plate of the spinal cord and was co-extensive with lipocortinI staining along the midbrain raphe. Endonexin-positive staining was present at E9 in the floor plate of the spinal cord. Staining was also evident in the roof plate at E10, in regions of postmitotic cells, and in the developing CNS vasculature. Not only was endonexin immunoreactivity expressed earliest, but was the most extensive along the rostral-to-caudal axis. Furthermore, dense endonexin immunopositivity in the adjacent notochord preceded staining in the floor plate by 24 hours.

These findings indicate that members of the annexin family have specific roles in the early development of the mammalian CNS.

SPECIFIC AXONAL PATHWAYS EXPRESS A DEVELOPMENTALLY REGULATED ANTIGEN RECOGNIZED BY A MONOCLONAL ANTIBODY. J.D. Peduzzi, A.M. Stewart and E.E. Geisert, Jr. Department of Physiological Optics, School of Optometry (J.D.P.) and Department of Cell Biology, Neurobiology Research Center (A.M.S. & E.E.G.), University of Alabama at Birmingham, Birmingham, AL 35294.

Within the developing CNS, putative axonal pathways can express a variety of proteins that appear to be involved in the guidance of growing axons. We have identified a mAb designated 11-59 that labels the plasma membranes of a subpopulation of cultured living astrocytes and appears to interfere with neuron-astrocyte interactions in culture. This antibody also labels discrete regions of the developing and mature rat brain. At E17, 11-59 binds to fibers in specific pathways of the brain including the internal capsule and fasciculus retroflexus. Heavy labeling is also observed in the median raphe glial structure. Labeling in the neocortex is present deep to the cortical plate. In the adult, there appears to be a generalized increase in the expression of the 11-59 antigen. However, localized concentrations are observed in the supragranular layers of neocortex, CA1, substantia nigra, basal ganglia and granular cell layer of cerebellum. The pattern of 11-59 labeling in the developing and adult brain appears to differ from other known developmental markers such as NCAM, TAG-1 and S-100. Taken together, these data suggest that the 11-59 antigen may play an important role in the development of specific pathways within the CNS. Supported by The Whitehall Foundation, Inc.

NON-SEGMENTAL PATTERN FORMATION IN THE VERTEBRATE SPINAL CORD. A. Chen and R.D. Heathcote. Department of Biological Sciences, University of Wisconsin, Box 413, Milwaukee, WI, 53201.

Early in development, a population of interneurons differentiated in a distinct pattern within the central nervous system. These neurons extended from the base of the brain to the tip of the tail in larvae of the frog *Xenopus laevis*. Throughout this domain, the number and spacing of cells was similar. The iterative spatial pattern differed from that known for other central neurons and appeared to be generated independently from the segmental somites.

The population of neurons was identified by the presence of catecholamines within their cell bodies. Shortly after hatching (2.3 days or stage 39), catecholamine-containing cells were visible following treatment with glyoxylic acid. Cells containing immunoreactivity to tyrosine hydroxylase, the enzyme needed to synthesize catecholamines, were present in the same location and pattern within the spinal cord. The neurons bordered the central canal and their location was limited to 2 columns centered around the midline within the narrow sheet of floor plate cells. At 1 week of development, the spacing between catecholamine-containing neurons was variable, with cells apparently located at random points along the spinal cord. However, the cells maintained a mean distance of approximately 21 μ m. The average distance maintained between cells within a single column was roughly twice this value. This pattern is what would be expected of cells that differentiated in a density-dependent manner. In this situation, the field over which the differentiation occurred was restricted to the essentially 1 dimensional array of floor plate cells. Perhaps this simple pattern is unusual because it consists of interneurons. Motor and sensory neurons project to the periphery and are patterned by the mesodermally-derived segments, but the catecholamine-containing interneurons appear to be patterned by a mechanism operating entirely within the central nervous system.

A ROLE FOR ENGRAILED GENES IN ZEBRAFISH MUSCLE PATTERNING. M. Westerfield, J. Wegner, M. Akimenko, M. Ekker, J. Eisen, M. Halpern. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Homeoproteins, like *engrailed* (*eng*), are DNA-binding proteins which regulate cell fate and pattern formation in *Drosophila*. To better understand their functions during vertebrate development, we have examined the expression of *eng*-like genes in zebrafish embryos.

In zebrafish, *eng* proteins are expressed by a variety of cells including a small subset of axial muscle cells, called muscle pioneers (MPs). MPs express *eng* before differentiation of the muscle, and patterning depends upon these cells; ablation of the MPs disrupts subsequent organization of the muscle. DNA, RNA and protein analyses and the sequences of cloned cDNAs demonstrate that zebrafish have at least two *eng* genes that share common features with mouse and *Drosophila* homologues. We have studied ectopic expression of one of these genes, *eng-2*, in transgenic embryos and find that its expression in non-pioneer muscle cells is insufficient to change them into MPs.

The MPs and *eng* expression in the muscle are both absent in *ntl-1* mutants, which lack notochords, and after notochord ablation in wild-type embryos. This suggests that the notochord and the MPs are developmentally related. One possibility is that the notochord induces *eng* expression in precursors of the MPs which, in turn, pattern the axial muscles. Supported by NIH HD22486 and NS21132.

EXPERIMENTAL EVIDENCE THAT AN INHIBITORY BOUNDARY DELAYS NEURAL CREST MIGRATION.

C. Lasky, R.A. Oakley, D. Dehnbostel and K.W. Tosney. Biology Dept. and Neuroscience Prog., Univ. of Michigan, Ann Arbor, 48109.

Last year we reported that neural crest cells delay their migration into the dorsolateral path between the ectoderm and the dermamyotome: they enter 24 hours after the first neural crest cells have invaded the anterior sclerotome, during the period when the dorsolateral path is losing peanut agglutinin (PNA)-binding sites (Schroeter et al., 1990, Neurosci. Abs. 16: 313). This year we report experimental evidence that the early dorsolateral path does inhibit neural crest migration.

We deleted the dermamyotome before neural crest cells left the neural tube and later identified neural crest cells with HNK1 (kind gift of Carol Erickson) or dil-label in serial frozen sections. We found that when the dermamyotome is absent, PNA-binding activity is greatly diminished in the dorsolateral path and neural crest cells enter this path precociously. We conclude that the early dorsolateral path normally inhibits neural crest migration. In addition, since neural crest cells enter the path without delay when PNA-binding activity is prematurely diminished by surgery, we conclude that inhibitory activity and PNA-binding sites are expressed coordinately. Since PNA-binding sites are also expressed in the inhibitory posterior sclerotome before neural crest cells encounter it, and since PNA-binding sites typify all tissues shown to inhibit the outgrowth of motor and sensory axons, we suggest that molecules that bind PNA or co-regulated molecules are likely to restrict the advance of both neural crest cells and axons.

RETINOIC ACID REGULATES EXPRESSION OF HOX 1.6 PROMOTER-LAC Z TRANSGENE IN DEVELOPING MOUSE HINDBRAIN. M. Zhang, M.T. Gendron-Maguire^{*1}, D.A. Lucas^{*}, A. Baron^{*2}, T. Gridley^{*1} and J.E. Grippo^{*}. Dept. Toxicology and Pathology, Hoffmann-La Roche, Nutley, NJ 07110, ¹Dept. Cell and Developmental Biology, Roche Institute of Molecular Biology, Nutley, NJ 07110, ²Institute for Immunology, Hoffmann-La Roche, Basel, Switzerland.

A fragment of mouse homeobox gene Hox 1.6 is fused with a reporter gene lac Z and used to generate transgenic mice via pronuclear injection. This construct contains 6.3 kb of Hox 1.6 genomic sequence upstream of the transcription initiation site, 0.7 kb of the first exon fused in-frame with lac Z and a SV40 polyadenylation signal. The transgene is prominently expressed in a restricted region of the developing mouse hindbrain at days 7.5 - 10.5 pc, exhibiting a more anterior boundary of expression than endogenous Hox 1.6. During this time a lower level of expression is seen in the somites. When the embryos are exposed to retinoic acid at 7.5 pc, expression of the transgene in the hindbrain is repressed, while that in somites is not affected.

303.20

MORPHOLOGICAL EVIDENCE OF SEGMENTATION IN THE DEVELOPING VERTEBRATE RETINA. D. Nordquist and S.C. McLoon. Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455.

It is now well established that the development of the anterior-posterior axis of the vertebrate CNS involves a genetic and morphological segmentation of the neural tube. However, little attention has been given to whether similar mechanisms of segmentation may play a role in the development of the retina, a derivative of neural tube. We have found morphological evidence in embryos of chicken and a teleost fish, *Esox lucius*, that is suggestive of retinal segmentation. Shortly after the infolding of the optic vesicle to form an optic cup, a dorsal "fissure" was observed in the gross morphology and in histological sections of both species. This structure was most striking in the teleost fish, where it appeared to demarcate nasal and temporal compartments in the retina. In addition to the dorsal structure, two indentations were also noted in the nasal and temporal sides of the retina, indicating a possible division between dorsal and ventral retina. The stage of development at which this morphology first appeared is curiously similar to that at which nasal-temporal and dorsal-ventral retinal polarity is specified. It is possible that the morphological pattern observed in the early retina may reflect underlying patterns of genetic determination.

DISTANCES BETWEEN "REELER" AND NEARBY LOCI ON MOUSE CHROMOSOME 5. A.M. Goffinet. Dept. Physiology, FNNDP Sch. Med., B-5000 Namur, Belgium.

Reeler (rl) is a recessive mutation of the mouse leading to widespread anomalies of the central nervous system. The reeler locus is in the paracentromeric region of chromosome 5, in the vicinity of the P-glycoprotein locus (Pgy-1) and the engrailed-2 gene (En-2), and proximal to the T31H translocation breakpoint (Goffinet and Dernoncourt, Mammalian Genome, 1991).

In this study, genetic distances were estimated between reeler, Pgy-1, the sorcin locus (Sor) and En-2, as well as between reeler and T31H. Recombination frequencies between reeler, Pgy-1, Sor and En-2 were measured using a N2 backcross panel (127 mice) between rl/rl-BALB/c and C57 mice. The distance estimates are: 7.9 ± 2.4 cM between En-2 and reeler (10 recombinants); 7.1 ± 2.3 cM between Pgy-1/Sor and reeler (9 recombinants); and 15.0 ± 3.2 cM between Pgy-1/Sor and En-2 (19 recombinants). No recombination was found between Pgy-1 and Sor. Analysis of 32 N2 backcrosses between rl/rl-BALB/c and mice with the T31H translocation showed no recombination, so that T31H is located less than 3 cM from reeler.

These observations suggest the following gene order: Cen - Sor/Pgy-1 - rl - T31H - En-2 - other loci.

An Extended Family of Protein-Tyrosine Kinase Genes Differentially Expressed in the Vertebrate Nervous System. C. Lai* and G. Lemke. Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037.

We have used PCR to identify 13 novel protein-tyrosine kinase genes (tyro-1 to -13), six of which (tyro-1 to -6) are preferentially expressed in the developing vertebrate nervous system. The tyro-2 and tyro-9 genes encode kinase domains that exhibit strong amino acid sequence similarity to the equivalent regions of the receptors for EGF and FGF, respectively, and may encode novel receptors for these or related polypeptide ligands. The tyro-1 to -6 genes are all expressed during central nervous system neurogenesis and exhibit distinct and highly regionalized patterns of expression in the adult brain. Together with recent studies from other laboratories, which demonstrate that the transmembrane protein-tyrosine kinase, *trk*, is required for the high-affinity recognition of nerve growth factor, these data are consistent with the hypothesis that protein-tyrosine kinases play a central role in neural development. (Supported by grants from the N.I.H. and the National Multiple Sclerosis Society)

LAR GENE: A TYROSINE PHOSPHATASE MEMBER OF THE N-CAM FAMILY IS EXPRESSED IN THE NERVOUS SYSTEM. F.M. Longo¹, J.P. Barnes¹ and J.A. Martignetti². Dept of Neurology¹, UCSF Sch. of Med., San Francisco, CA 94143 and Fishberg Center for Neurobiology², Mt. Sinai Med. Ctr., NY, NY 10029.

The Leukocyte common Antigen-Related (LAR) gene is a member of a novel class of cell growth-regulating receptors known as the tyrosine phosphatases (Science 251:744, 1991). Human LAR is expressed as 8 kb or shorter transcripts *in vitro* in non-neural cell lines (Streuli M. et al, J Exp Med 168:1523, 1988). Extracellular domains of LAR have 16-33% sequence similarity to N-CAM, a molecule which promotes neurite outgrowth. While screening a Sprague-Dawley rat cDNA brain library for NGF receptor-like genes, we found a 1.8 kb insert with approximately 90% sequence similarity to human LAR and which corresponds to the 3' end of the full-length human transcript. Poly (A) RNA was isolated from rat cortex, cerebellum, brainstem, heart, liver, cultured neurons, astrocytes and PC12 cells. Northern blots probed with a riboprobe derived from our 1.8 kb insert and washed under high stringency demonstrate predominant 8 kb and 5 kb transcripts in neural-derived tissue and 5 kb transcripts in heart and liver. The relative abundance of different-sized transcripts expressed in specific brain regions varies during development. These studies suggest that LAR is expressed *in vitro* and *in vivo* in neuronal and non-neuronal cells and that its expression is developmentally regulated. These observations along with LAR's extracellular sequence similarity to N-CAM and its association with tyrosine phosphatase activity lead to the hypothesis that the LAR molecule may constitute a novel mechanism regulating neural development. (Supported by United Cerebral Palsy and a travel award from the American Paralysis Association)

304.2

EXPRESSION AND CHARACTERIZATION OF STY, A MEMBER OF THE MULTIFUNCTIONAL PROTEIN KINASE FAMILY. M.P. MYERS*, G.M. DOBREA, M.B. MURPHY* AND G.E. LANDRETH. Alzheimer Research Laboratory, Departments of Neurology and Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

A novel class of protein kinases has recently been identified which phosphorylate proteins on serine, threonine, and tyrosine residues. One member of this class, termed STY (or CLK) is closely related to the *cdc2/cdc28* family of kinases (Howell et al. *MCB* 11, 568-572 (1991)). STY kinase was expressed as a trpE fusion protein and was shown to undergo autophosphorylation on serine and tyrosine residues. STY phosphorylated myelin basic protein exclusively on serine residues, whereas MAP2 and enolase were phosphorylated on both serine and tyrosine residues. STY is expressed at high levels in the rat brain. *In situ* hybridization studies using a 600nt cRNA probe revealed that STY was expressed throughout the adult rat brain. STY mRNA levels were greatest in association with fiber tracts including the corpus callosum, anterior commissure and cerebellar white tracts, suggesting expression of this gene within oligodendroglia.

ND-1: A HELIX-LOOP-HELIX PROTEIN PROMINENTLY EXPRESSED IN BRAIN ¹M. Armanini, ²Y. Li*, ¹G. R. Laramée*, ²E. Peralta*, ¹J. W. Winslow, and ¹H. S. Phillips. ¹Dept. Dev. Biol., Genentech, S.S.F., CA 94080 and ²Dept. Biochem. & Molec. Biol., Harvard U, Cambridge, MA 02138

Certain aspects of differentiation are controlled by a class of transcriptional regulation factors which share a structural motif known as the helix-loop-helix (HLH) domain. We report here the distribution of a recently cloned HLH protein, ND-1, in the developing and differentiated mammalian CNS (Winslow *et al*, in prep.). Northern blot analyses revealed that among cell lines of neuronal and glial lineage, ND-1 expression was limited to lines of neuronal character. *In situ* hybridization revealed that ND-1 is prominently expressed in telencephalon and cerebellar cortex of postnatal rat brain. Comparisons with the distribution of MASH and Id, potential dimerization partners of ND-1, revealed that MASH is expressed in many of the same regions shown to express ND-1, albeit at apparently much lower abundance, while n-Id is largely excluded from regions of ND-1 expression. Although the general pattern of ND-1 and MASH expression were similar, some areas were seen to hybridize almost exclusively for ND-1 (amygdala, layers 4-6 of neocortex), while other regions (layer 2 of entorhinal and piriform cortex) displayed significant hybridization signals for MASH as well as ND-1. Comparisons of ND-1 and MASH expression in developing postnatal brain revealed that hybridization for ND-1 declines from P1 to P60, while hybridization for MASH in most sites maintains a low, but constant, level. These results suggest that ND-1 may play a role in neuronal differentiation and/or maintenance of neuronal plasticity in the adult brain.

304.5

DEVELOPMENTAL REGULATION OF IMMEDIATE EARLY GENES IN RAT BRAIN. R.V. Bhat, B.A. Christy*, Y. Nakabeppu*, A.J. Gole, J.M. Baraban and P.F. Worley. Depts of Neuroscience, Neurology, and Howard Hughes Med. Inst., Johns Hopkins University School of Medicine, Baltimore, MD 21205-2185.

We have examined the regulation of several immediate early genes (IEGs) during postnatal development in rat brain. Northern analysis of unstimulated forebrain RNA indicates that mRNA levels of *c-fos*, *fos-B*, *zif268*, *Krox20* and *nur77* are low between postnatal days 1 and 10 but increase markedly between days 12 and 21 and thereafter variably decline in adult brain. Gel shift assays indicate a robust age dependent increase in AP-1 and *zif268* binding activities that parallels mRNA levels. Peak developmental IEG expression occurs during a period of exuberant excitatory synapse formation and may be regulated by natural synaptic activity. Manipulations that reduce excitatory synaptic activity result in rapid reductions of IEG expression supporting this concept. Restriction analysis of the *zif268* promoter region (2.5 Kb 5' to message) fails to detect changes in methylation during postnatal development suggesting that developmental changes in expression are not due to altered DNA methylation. Moreover, certain stimuli that induce IEG responses in adult brain can induce their expression in brain as early as postnatal day 1. These data suggest that IEGs are "available" for activation prior to normal developmental increases and are poised to respond to appropriate stimuli.

304.7

DEVELOPMENTAL REGULATION OF RAB3A IN THE RAT BRAIN. B. Taviian, K.L. Moya, A. Zahraoui*, O. Stettler* and A. Tavitian*. INSERM U334, C.E.A., S.F.H.J., Orsay and INSERM U248, Paris, France.

RAB3A is a small G protein member of the *ras* superfamily that is expressed preferentially in the brain and implicated in exocytosis. Immunoblot analysis of total brain homogenates using a monospecific antiserum showed that relative levels of RAB3A increase markedly during brain development. The lowest levels were observed in the late embryonic brain and remained low on the day of birth (P0) and postnatal day 4 (P4). At P7 relative levels began to increase and by P14, RAB3A had attained the high levels seen in adult brain.

Localization of RAB3A by immunohistochemistry revealed striking changes in its anatomical distribution. In general, the early stages of development were marked by dense staining of neurons with abbreviated processes. An intermediate pattern in which both cell bodies with more elaborate neurites and a diffuse neuropil staining followed. By the end of the first month, an adult-like distribution of RAB3A was seen with dense staining in the neuropil and virtually none in cell bodies.

For example, in the neonatal cortex we found numerous RAB3A-positive cells against a background that was virtually devoid of staining. These cells had an elongated morphology, were radially oriented and formed a band in the presumptive layer IV. By P14 the cortical neuropil was moderately stained and few immunoreactive cells could be observed.

Whereas in the adult hippocampus, the pyramidal cell layer was not stained for RAB3A, this layer showed considerable immunoreactivity from embryonic day 18 (E18) through P14. While at earlier ages the terminal zones of the hippocampus were not marked by the antibody, starting at P14, the strata oriens and radiatum assumed a marked labeling that by P21 was indistinguishable from the adult pattern.

These results show that RAB3A undergoes a striking shift in its cellular localization during brain maturation. The protein is present within cell bodies at early stages of development, and then shifts to the neuropil coincident with the elaboration of terminals and formation of synaptic contacts. Furthermore, this shift coincides with the marked increase of RAB3A in the brain.

304.9

DIFFERENTIAL EXPRESSION OF PLASMA MEMBRANE Ca^{2+} -ATPASE MRNAS IN DEVELOPING RAT BRAIN AND IN RAT BRAIN SUBREGIONS. P. Brandt and R.L. Neve. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

In rat brain at least seven mRNAs encode the plasma membrane Ca^{2+} -ATPases. Because Ca^{2+} regulation is crucial to cell function, especially in excitable cells, any alteration in Ca^{2+} -ATPase regulation may be important. We have used PCR amplification of reverse transcribed mRNA to examine the patterns of mRNA expression for the Ca^{2+} -ATPases (termed PMCA mRNAs) in developing rat brain and in rat brain subregions. Of the PMCA1 mRNAs, PMCA1b was initially expressed at embryonic day (E) 10, whereas PMCA1a and c appeared at E14. There was a slight increase in PMCA1a between postnatal (P) 2 and P18, while PMCA1b expression steadily declined and PMCA1c remained fairly constant. There was little expression of any PMCA2 mRNA until E18, at which point PMCA2a and two PMCA2-related transcripts appeared. The levels of these PMCA2 mRNAs were relatively invariant from P2 to P8. PMCA3b mRNA was expressed from E10 to P28, increasingly steadily from E10 to P2, and then remaining constant through P28. The PMCA3a transcript appeared at E14 at low levels and steadily increased in abundance until P3, then remained constant through P28. Examination of the developmental expression of PMCA mRNAs in specific brain subregions revealed some isoform variability from region to region. *In situ* RNA hybridization with isoform-specific probes is presently under way.

304.6

LOCALIZATION OF GAP JUNCTION MRNAS DURING DEVELOPMENT OF THE RODENT CNS. D.J. Belliveau and C.C.G. Naus. Dept. of Anatomy, University of Western Ontario, London, Ontario, Canada, N6A 5C1

We have previously described the developmental expression of gap junction mRNA and protein utilizing Northern and Western analysis. We extended this study to examine the cellular localization of connexin32 (cx32) and connexin43 (cx43) mRNA by using *in situ* hybridization to follow the pattern of expression during development of the rodent CNS. The brains of three Sprague Dawley rats were used at each postnatal time point studied and *in situ* hybridization was performed on cryosections using an ^{35}S labelled riboprobe. The first time point examined, postnatal day 3 (P3) showed very little hybridization with cx32, that which occurred was found in fibre tract areas of the brain stem. At P10 the signal increased significantly with hybridization to cells of various fibre tracts of the brainstem. The forebrain regions showed signal only in the corpus callosum and hippocampal regions. Hybridization signal was seen in the white matter of the cerebellum by P15. The forebrain showed signal in the corpus callosum, cortical layers, hippocampus and dentate gyrus. The signal in fore- and hindbrain regions increases through P20 and began to decline by P32. The signal distribution for cx43 differed from cx32, being more dispersed throughout regions of the fore- and hindbrain. Cx43 positive cells were present at P3, the number increasing through to P32. The strongest signal was found in the leptomeninges. The differential expression of cx32 mRNA during development suggests a cell specificity, probably being localized to oligodendrocytes and neurons as evidenced by fibre tract and discrete neuronal nuclei labelling. The hybridization pattern of cx43 is consistent previously reported astrocytic localization due to the more general distribution of signal. Supported by the Medical Research Council of Canada.

MOLECULAR CLONING AND EXPRESSION OF SC1, A NOVEL ADHESION MOLECULE EXPRESSED ON EARLY MOTONEURONS. H. Tanaka, T. Matsui*, A. Agata*, M. Tomura*, A. Lee*, H. S. Phillips, and D. L. Shelton. Gunma U. Sch. Med., Maebashi 371, Japan. and Genentech, Inc., South San Francisco, CA. 94080.

SC1 is an integral membrane protein, first identified by generation of a monoclonal antibody using chick spinal cord membranes as immunogen. Among the neurons of early spinal cord, SC1 is unique to motoneurons, although SC1 is expressed in other tissues and neurons of the peripheral and central nervous systems at other developmental stages. SC1 was purified by affinity chromatography, and N-terminal sequence and polyclonal sera were obtained. cDNA clones were isolated by screening an E4 chick embryo cDNA library, positive clones being verified by sequence analysis. The predicted amino acid sequence of SC1 consists of a signal sequence, five immunoglobulin-like repeats, a single transmembrane domain, and a short cytoplasmic tail. Its sequence is most similar to MUC18, a marker of melanoma progression. Northern analysis demonstrates two transcripts, of 4.5 and 3.9 kb. *In situ* hybridization shows a pattern similar to that obtained using immunocytochemistry with either the mono- or polyclonal antibodies. Transfection of SC1 into mammalian cells leads to expression of immunoreactive protein at the cell surface and an increase in adhesion to other cells expressing SC1. SC1 expression *in vivo* may play a role in lateral motor column formation or axon growth or fasciculation.

304.10

EMBRYONIC GAD STOP CODON MESSAGE DISAPPEARS COINCIDENT WITH THE EMERGENCE OF GABA IMMUNOREACTIVITY IN DEVELOPING RAT CNS.

T. Behar¹, L. Hudson², S. Komoly³, W. Ma¹ and J.L. Barker¹. LNP¹, LVMP², and LENP³, NINDS, NIH Bethesda, Md. 20892

During embryogenesis, the gene encoding the enzyme glutamic acid decarboxylase (GAD) is spliced to include an exon containing a premature stop codon (ES), which lies upstream of the sequence encoding the enzyme's co-factor binding domain. While a translated product of the embryonic transcript is predicted to be enzymatically inactive, it has not yet been reported. In these studies, we used the GAD product, GABA, as an index of functional enzyme activity. Sections of embryonic rat brain and spinal cord were probed for GAD messages using *in situ* hybridization and ^{35}S -labeled synthetic oligonucleotides that correspond to either the exon containing the ES codon or to the functional, full-length enzyme. GAD protein and GABA expression were analyzed in adjacent tissue sections by immunocytochemistry. GAD⁺ cells were present in regions that expressed messages for the ES codon and/or full length enzyme. GABA⁺ cells were not detected in regions of the CNS that expressed the ES message. Disappearance of the stop codon coincided with the emergence of full length message and GABA⁺ cells. Full length GAD message and GABA⁺ cells first appeared in the brainstem. In the spinal cord, message for full length GAD appeared along a rostral-to-caudal and ventral-to-dorsal gradient during development, preceding the appearance of GABA. Coincident emergence of full length GAD message and GABA immunoreactivity suggests that the translated product of the ES transcript is enzymatically inactive.

305.1

ANALYSIS OF GENE EXPRESSION IN THE RAT SOMATOSENSORY CORTEX DURING DEVELOPMENT. M. Hennegriff, M. M. Heeb*, R. Neve and H. Killackey. Department of Psychobiology, University of California, Irvine, CA 92717.

It has recently been suggested that the ingrowth of thalamocortical afferents into rat neocortex correlates temporally with differentiation of each cortical layer from the cortical plate (Catalano, Robertson and Killackey, 1991). The present study is an initial attempt to determine whether changes in gene expression are also correlated with these events. We are using RNA blot analysis coupled with *in situ* hybridization to examine the temporal and spatial expression of the mRNAs encoding synapsin Ia and Ib in rat brain from embryonic day E16 to adulthood. Previous Northern blot analysis revealed that synapsin I is encoded by two mRNAs (Haas and DeGennaro, 1988). We currently show that the 3.4 kb mRNA appears in rat brain as early as E16 and displays sharp increases on P2, P8 and P21, after which the level of the mRNA drops to adult levels. The 4.5 kb mRNA shows a more restricted pattern of temporal expression. It is present at P2, with increased levels at P8, after which it falls to adult levels by P15. It is not present at E16. *In situ* hybridization studies, utilizing an mRNA probe that detects both synapsin I mRNAs, indicates that synapsin I expression is highly localized during the development of the embryonic and postnatal rat brain.

305.3

DEVELOPMENT OF RAT THALAMUS AND CEREBRAL CORTEX AFTER EMBRYONIC INTERRUPTION OF THEIR CONNECTIONS Zoltán Molnár¹, Kathleen Yee², Raymond Lund² and Colin Blakemore¹
1:University Laboratory of Physiology, Parks Road, Oxford OX1 3PT U.K.
2:University of Pittsburgh, School of Medicine Department of Neurobiology Anatomy and Cell Science, Pittsburgh, PA 15261, U.S.A.

We are interested in the various interactions between thalamus and cerebral cortex during the establishment of their specific interconnections. Without removing any part of the cortex or thalamus the developing connections between them were mechanically disrupted with a cut in one hemisphere near the internal capsule, made during intrauterine surgery at various stages (embryonic day 16, 18 or 20).

Thalamocortical projections were examined by application of carbocyanine dyes (DiI, DiA, DiAsp) to various thalamic nuclei on each side in paraformaldehyde-fixed brains. In newborn and postnatal (P) two-day-old rats, there was a drastic reduction in thalamic innervation of the cortex on the lesioned side posterior to the cut. Despite the isolation of a large region of cortex from thalamic input, its basic laminar organization was intact, with cell densities similar to those on the non-lesioned side and in normal controls of the same age. The thalamus was not obviously smaller on the lesioned side. Dyes were applied to the cortex at symmetrical points in the lesioned and normal hemispheres at P0 and P2. Anterior to the cut, corresponding groups of cells were back-labelled in the thalamus, symmetrically positioned and very similar in appearance on the two sides. But for cortical sites posterior to the cut, very few thalamic cells were labelled on the lesioned side. In addition, descending corticofugal axons often ended in neuromas near the cut. Application of dye to isolated regions of the cortex also back-labelled large numbers of neurons in the subplate with substantial local projections in the white matter. Labelled subplate cells were not seen on the non-lesioned side or in matched control animals.

The innervation of cortex by thalamic axons may, then, influence the distribution of the axons of subplate cells within the cortical plate. It is not needed for the emergence of the fundamental six-layered structure of the cortex, though it may play a role in determining regional cytoarchitectural differentiation.

THALAMOCORTICAL AXONS PREFERENTIALLY EXTEND ALONG A CHONDROITIN SULFATE PROTEOGLYCAN ENRICHED PATHWAY COINCIDENT WITH THE NEOCORTICAL SUBPLATE AND DISTINCT FROM THE EFFERENT PATH A.R. Bicknese, A.M. Sheppard, D.D.M. O'Leary¹ and A.L. Pearlman Depts. of Cell Biology, Neurology and Pediatrics, Washington Univ. Sch. of Med., St. Louis, MO 63110, and ¹Molecular Neurobiology Lab, Salk Inst., La Jolla, CA 92037

The first postmigratory cells in the neocortex form the preplate zone [PPZ], which is split by arriving cortical plate neurons into the marginal zone [MZ] and subplate [SP]. Previously, we have shown that immunolabeling of both fibronectin and the glycosaminoglycan chains of chondroitin sulfate proteoglycans (CSPG) is associated with cells of the PPZ, MZ and SP, but is sparse in the cortical plate (Sheppard et al., Soc. Neurosci. Abstr. 16:315). Here we examine the prospect that specific ECM components may delineate the pathways taken by the growth cones of cortical efferent or afferent axons. We used the fluorescent tracer DiI to define the trajectory of early axons in the neocortex of embryonic mice and compared it to the distribution of CSPG defined by immunolabeling. As early as embryonic day (E) 12, prior to cortical plate formation, efferent axons of preplate neurons leave the CSPG-rich PPZ and extend tangentially through the upper intermediate zone (IZ) which contains much less CSPG immunolabeling. Neurons of the early (E13-15) cortical plate extend axons that cross the CSPG-rich subplate, then turn abruptly to run in the upper IZ. In contrast, thalamocortical axons, which arrive on E14-15, travel long distances within the CSPG-rich subplate, above the path taken by the efferent axons from preplate/subplate and cortical plate neurons. Our findings demonstrate a molecular distinction between afferent and efferent pathways in the developing neocortex; early afferents preferentially travel in the CSPG-rich subplate, while efferents cross it to follow a pathway that contains much less. In neither case does the CSPG labeled by the antibody we used form a barrier to axonal extension.

EARLY CORTICAL REGIONALIZATION DETECTED BY AN AREA-SPECIFIC MONOCLONAL ANTIBODY.

Y. Arimatsu, M. Miyamoto* I. Nihonmatsu*, and K. Hirata*. Lab. of Neuromorphology, Mitsubishi Kasei Inst. of Life Sci., Machida-shi, Tokyo 194, Japan.

The timing and mechanism of the areal specification in the cerebral cortex remain to be mostly unknown. We have begun to examine this process using a monoclonal antibody, designated PC3.1, that binds selectively to a neuronal subpopulation located in lateral but not dorsomedial cortical areas in the adult rat. Here we address when instructions for PC3.1 expression are given in the limited cortical region. When cultured *in vitro*, significant percentages of neurons derived from lateral portion of the cortical primordium at E14, E15, E16 and P4 expressed PC3.1-immunoreactivity, while virtually none (E16, P4) or very small numbers (E14, E15) of PC3.1-positive neurons were found in the culture of dorsal cortical cells. Double labeling experiments combining PC3.1-immunohistochemistry and [³H]thymidine-autoradiography showed that presumptive PC3.1-immunopositive neurons undergo their final mitosis around E15. These results support the assumption that the capacity to produce PC3.1-immunopositive neurons is restricted to some extent within the lateral cortical primordium before the final mitosis of presumptive PC3.1 neurons and that the dorsolateral cortical regionalization is established by the end of neurogenesis.

DEVELOPMENT OF ACETYLCHOLINESTERASE-POSITIVE THALAMOCORTICAL AFFERENTS TO EMBRYONIC RAT NEOCORTEX. J.A. De Carlos, B.L. Schiagar, and D.D.M. O'Leary Molecular Neurobiology Laboratory, The Salk Institute, La Jolla CA 92037.

We examined the growth of ventrobasal thalamocortical (VB) afferents to presumptive somatosensory cortex (SI) using AChE histochemistry, a transient marker of VB neurons and their axons (Kristt JCN '79; Neurosci '89), and DiI in fixed tissue. At E15 (E0 is day of insemination) AChE labels, but is not restricted to, VB and VB afferents in the internal capsule. At E16, AChE reaction product in VB is more intense than at E15, but AChE-positive afferents have yet to emerge from the internal capsule into the cortical mantle. However, DiI labeling shows that thalamic afferents already reach the cortex on E16. Thus, early expression of AChE by developing VB afferents is limited to more proximal portions of the axons. By E17, though, entire axons, including growth cones, contain AChE. AChE-positive growth cones, with morphologies ranging from simple to complex, travel tangentially in the subplate (layer 6b) and upper intermediate zone. The presence of AChE in growth cones is, to our knowledge, a novel finding. AChE histochemistry and DiI, placed in VB, appear to label the same population of thalamocortical axons. Axons labeled by these methods have common dispositions, branching behavior, and timecourse of growth into the cortical plate (CP). On E18, VB afferents begin to invade the CP by sending, in a directed manner, radially oriented collaterals into its deepest part. Ingrowing VB afferents branch profusely beneath, but rarely enter the dense undifferentiated CP. These fibers preferentially invade a distinct region of the developing CP, clearly delineating presumptive SI by E21, in the absence of any indication of cytoarchitectonic borders that demarcate this area. This regionally specific ingrowth of VB afferents is the first overt indication of a parcellation of the undifferentiated cortex into areas. The finding that the growth cones of VB axons contain AChE as they invade the developing CP is consistent with a significant function for AChE in the subsequent differentiation of primary sensory areas of cortex. THE EARLY DEVELOPMENT OF VISUAL CORTICOTHALAMIC AND THALAMOCORTICAL PROJECTIONS IN THE GOLDEN HAMSTER. B. Miller, L. Chou* and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, New York, 14853.

We examined the development of corticothalamic and thalamocortical projections with particular attention to the possible roles of these systems in axonal pathfinding and cortical area specification. DiI or DiA was placed in the presumptive visual cortex or dorsal thalamus of fixed brains of E12 to P5 hamster pups. After two months the brains were sectioned with a vibratome at 75-150µm and examined with fluorescent microscopy.

In the hamster, visual cortex is produced between E10 and P1 (birth is E16), and the lateral geniculate between E9.5 and E12.5. At E14 cortical fibers are partly through the internal capsule, but have not yet reached the thalamus. In contrast, thalamic fibers have grown to visual cortex by this age. The first visual cortical axons reach posterior thalamus at one day after birth and are in very small numbers. These first axons come from subplate (SP) and layer 6 cells. By P3 axons of layer 5 cells reach the posterior thalamus, and they greatly outnumber the layer 6 and SP cells. The number of layer 6 and SP cells projecting to the thalamus does not increase at P5, while layer 5 projections do increase in number. Double injections of DiI and DiA show that the corticofugal and thalamocortical pathways are physically separate during their development. The corticofugal axons travel deep in the intermediate zone to the thalamic axons.

Thus, cortical fibers do not reach the thalamus until 3 days after thalamic fibers reach visual cortex. Also, these pathways are physically separated during development and have no opportunity to interact except at their respective targets. Supported by NIH R01 NS19245 and NIMH 5 T32 GM07469.

TEMPORAL & SPATIAL RELATION BETWEEN CORTICAL NEURON MORPHOGENESIS, GENICULOCORTICAL AXON INGROWTH AND SYNAPTOGENESIS IN RAT VISUAL CORTEX: A WGA-HRP, DiI - E.M. STUDY. G.H. Kageyama, M.A. Bielestein*, R. Khoo*, J. Yu & R.T. Robertson. Dept. Anat. & Neurobiol., Univ. of Calif., Irvine, CA 92717.

In order to study the temporal relation between the morphogenesis of cortical neurons and the ingrowth geniculocortical (GC) axons, several related studies were undertaken in pre-fixed (4% paraformaldehyde) neonatal rat brains: (1) DiI, placed in the LGN or optic radiation for 1-2 weeks at 37°C was used as an anterograde GC axon tracer, and compared with previous results using transneuronal WGA-HRP (Kageyama and Robertson, '90), (2) DiI, placed in the cortical layers or subcortical white matter in or adjacent to visual cortex was used as a selective Golgi-like stain to examine the dendritic maturation of superficial and deep cortical neurons, respectively, and (3) DiI fluorescence labeled GC axons were then photo-oxidized with DAB in order to study the developing laminar pattern of GC axon morphogenesis at the light microscope level and GC synaptogenesis at the E.M. level. At all ages studied, the DiI labeled geniculocortical axon arborizations matched closely the temporal and spatial pattern of geniculocortical projection as shown previously using transneuronal WGA-HRP. DiI-labeled GC axons formed axodendritic and axosomatic synapses throughout the developing terminal field. An outward (deep to superficial) wave of basal dendrogenesis also accompanied the sequential pattern of GC axon ingrowth and synaptogenesis. The results demonstrate that developing GC terminals form synapses earlier and more extensively than previously thought, at a time and place where they may influence the elaboration of dendrites (especially in layer IV) as each laminar cohort of cortical neurons begins to differentiate at the base of the cell dense CP. It is possible that GC axons may play an important role in cortical histogenesis. Supported by NSF 87-08515 and NIH NS 25674.

CROSSED CORTICORUBRAL AXONS IN NEWMORN KITTENS AND HEMISPHERECTOMIZED KITTENS ARE COLLATERALS OF UNCROSSED AXONS. F. Murakami, Y. Kobayashi*, T. Uratani* and A. Tamada*. Dept. of Biophysical Engineering, Fac. of Engineering Science, Osaka University, Toyonaka, Osaka 560, Japan.

Crossed corticorubral projections occur in early postnatal development and after early hemispherectomy in kittens, although they are virtually absent in adults. The present study was performed to determine whether crossed corticorubral axons are collaterals of uncrossed ones. Fluorescence labeled latex microspheres were injected bilaterally into the red nucleus (RN) of normal (3 weeks postnatal) and hemispherectomized (lesioned at 3 weeks postnatal and were allowed to survive for 3 - 7 weeks) kittens, red ones on one side and green ones on the other, through a glass micropipette. The RN was activated orthodromically from the interpositus nucleus and field potentials were recorded by the micropipette to locate its tip. Survival ranged from 4 - 7 days, and after removal the RN and the cerebral cortices were sectioned at 50 µm and observed with a fluorescence microscope.

Both in normal and lesioned kittens the tracers were well restricted to the RN in most of the animals and many corticorubral cells were labeled in layer V of the sensorimotor cortex, mainly in area 4, ipsilateral to the injection site. Labeling also occurred on the contralateral side, though the number of labeled cells were fewer. A major part of the contralaterally labeled cells were also labeled ipsilaterally in normal kittens, suggesting that a single cortical cell innervate the RN bilaterally. Bilateral cells were also found in lesioned kittens. Bilaterally or contralaterally projecting cells were intermixed among ipsilaterally projecting cells. These results are consistent with the view that bilateral cells which existed at the time of lesion participate in the establishment of lesion-induced bilateral innervation.

INDUCTION OF CEREBROCORTICAL HETEROTOPIAS BY PUNCTURE WOUNDS TO THE NEONATAL RODENT NEOCORTEX. G.D. Rosen, L.V. Stone*, J.M. Richman*, G.F. Sherman, and A.M. Galaburda. Beth Israel Hospital and Harvard Med. School, Boston, MA 02215.

Cerebrocortical heterotopias have been seen in the molecular layer of dyslexic humans (Galaburda et al., *Ann Neurol.* 18:222-33, 1985) and in immune-disordered mice (Sherman et al., *Acta Neuropath.* 74:239-42, 1987). These ectopias can be seen as early as E14 in the NZB mouse and are associated with breaks in the external glial limiting membrane and with disturbances in the radial glial fibers beneath the ectopias (Sherman et al., *Soc. Neurosci. Abs.*, 16: 1152, 1990). The present study attempted to induce cerebrocortical molecular layer ectopias by mechanically damaging the external glial limiting membrane by puncture wound.

Rat and mice pups were anesthetized by hypothermia at P0 and a puncture wound induced by manual placement of a 25 gauge needle through the skull and into the underlying developing cortical plate. Animals were sacrificed from 2 hours to 30 days later by transcardial perfusion with saline followed by 4% paraformaldehyde. Sections were Thionin-stained for Nissl substance and adjacent series immunohistochemically stained for radial glial fibers with Rat-401 (obtained from S. Hockfield) or vimentin.

Puncture wounds resulted in the formation of molecular layer ectopias in both rats and mice. These ectopias ranged in size from small (<10 cells) to large (>50 cells). Here too, immunohistochemical staining revealed disturbance of the external glial limiting membrane as well as changes in the disposition of underlying radial glial fibers. These results support the hypothesis that a disturbance of the external glial limiting membrane is the primary factor in the formation of molecular layer ectopias.

DEVELOPMENT OF GENICULOCORTICAL PROJECTIONS: DiI AND ACHE STUDIES IN RATS. K.A. Gallardo*, G.H. Kageyama, M.A. Bielestein*, J. Yu and R.T. Robertson. Depts. of Anatomy and Neurobiology & Physical Medicine and Rehabilitation, Univ. California, Irvine, CA 92717.

We have been studying the development of geniculocortical axonal projections to primary visual cortex in the rat, with particular attention paid to the time of ingrowth of geniculocortical axons in relationship to the differentiation of cortical neurons (Kageyama and Robertson, 1990). In the present studies, we investigated development of individual and populations of fibers in visual cortex using DiI fluorescent microscopy and acetylcholinesterase (AChE) histochemistry. Experiments used Sprague-Dawley rats from late fetal stages through postnatal age P-10. Aldehyde fixed brains received placements of DiI into the lateral geniculate body and were then stored at 37°C for 1-2 weeks. Other brains were prepared for AChE histochemistry using the Tago et al. (1986) technique.

AChE and DiI techniques both resulted in patterns of distinctly labeled axons in visual cortex. In pups younger than P-1, most DiI labeled geniculocortical axons were found oriented tangentially in the cortical subplate zone. Fewer labeled axons could be seen leaving the subplate zone to course radially or obliquely through the deeper cortical layers. At P-2, when layer IV can first be identified, some DiI labeled axons have reached layer IV, and the projection to layer IV is robust by P-4. Some labeled axons course through layer IV to reach the pial surface. AChE stained axons show areal and laminar patterns similar to the DiI labeling, with a dense plexus in visual cortex in layer IV with some axons reaching layer I. However, fewer fibers appear stained with AChE than with DiI. Neonatal enucleation results in reduced numbers of AChE labeled axons in layer IV of visual cortex. These data demonstrate an early ingrowth of geniculocortical axons into visual cortex and these techniques allow morphological characterization of individual axons.

AXONAL BRANCHING IN THE DEVELOPING HAMSTER CORPUS CALLOSUM. H.I. Kadhim*, P. G. Bhide, W.C. West*, D.O. Frost. Dept. of Neurology, Massachusetts General Hospital, Charlestown, MA 02129

Single axons of the developing corpus callosum (CC) were labeled in hamster pups by placing crystals of the fluorescent tracer DiI unilaterally at multiple cortical sites in paraformaldehyde fixed brains. After 3-6 months, the brains were cut horizontally and the DiI was photoconverted to a DAB reaction product. Labeled axons were then studied using a light microscope linked to a computer or a drawing tube and, in some cases, subsequently examined by electron microscopy.

Many immature callosal axons branch transiently within the corpus callosum. Branching is prominent between the day of birth (P0) and postnatal day 3 (P3). Branching is reduced by P6-P8 and is completely absent by P11. Callosal axons branch both before and after crossing the midline. Axonal branching occurs across the full extent of the CC. On P0-P3, collaterals contained within single 100 µm thick sections are 5-90 µm long, (n=390; mean=15.1 µm; SD=12.7 µm), but other collaterals extended up to 136 µm before being cut at the surface of a section, and thus, were even longer. Occasionally, axons in the CC had multiple first order branches or higher order branches.

In cats and monkeys, the developing CC transiently contains more axons than the mature CC. It has been reported that in cats but not monkeys, the developmental overproduction of callosal axons occurs, at least in part by a transient excess of cortical neurons that send an axon through the CC. Our results show that transient branching of callosal axons can also contribute to their apparent overproduction. We are now examining cats and monkeys to see if transient branching contributes to the apparent overproduction of callosal axons in those species.

THE DEVELOPMENT OF NEURONAL ECTOPIAS IN FETAL NEW ZEALAND BLACK MICE. G.E. Sherman, L.V. Stone*, G.D. Rosen, and A.M. Galaburda. Department of Neurology, Harvard Medical School, and Beth Israel Hospital, Boston, MA 02215.

Previous studies have shown that the New Zealand Black mouse strain (NZB), which spontaneously develops severe autoimmune disease, has ectopic collections of neurons in layer I of the cortex with underlying distortion of the cortical layers (Sherman et al., *Acta Neuropathol.* 74:239-242, 1985). These ectopias have been seen on the day of birth, and it is expected that they originate during the prenatal period after the beginning of neuronal migration to the cortex on day (E)13. Therefore in the present study we examined the fetal NZB brain from E14 to E19 with a Nissl cell stain for evidence of ectopias and with a radial glial antibody for evidence of a disturbance of the glial fiber patterns.

NZB mice were time-mated (E1 was the day a vaginal plug was found). The pregnant females were anesthetized on E14-E19, the fetuses removed and the heads immersion fixed in 4% paraformaldehyde for 4 hours. The specimens were placed into 10% buffered sucrose overnight, followed by 30% buffered sucrose for 24 hours, after which they were frozen using dry ice and cut coronally at 30 µm on a sliding microtome. Every fifth section was stained with thionin, and some adjacent series were stained for radial glial fibers using Rat-401 antibody (provided by S. Hockfield).

Nine of the 34 brains examined thus far had large ectopias that were similar in appearance to those seen in adulthood. Fully formed ectopias were detected as early as E14. The ectopias consisted of extrusions of cells from the underlying cortical plate into layer I and the overlying meninges. Under most of the ectopias there was a narrow channel perpendicular to the pial surface involving the entire width of the cortical plate. This channel had a decreased cell density, contained some distorted cells, and often a blood vessel was seen lying within this area.

As in previous work in the newborn NZB, there was aberrant organization of radial glial fibers focally in the area of the ectopias. The most striking aspect was the increased density of the fibers under the ectopias. In addition, the external limiting membrane was interrupted in the area of the ectopia and it appeared that neurons had migrated into the space created by the interruption. (Supported in part by NIH grant HD 20806.)

305.13

DEVELOPMENTAL SCULPTING OF THE TANGENTIAL DISTRIBUTIONS OF CORTICAL PROJECTION NEURONS OCCURS EVEN IN THE ABSENCE OF CNS MYELIN: OBSERVATIONS IN *JIMPY* MUTANT MICE. B. Stanfield. Lab. of Neurophysiology, NIMH, NIH Animal Center, Poolesville, MD 20837.

The developmental restriction of the tangential distributions of cortical projection neurons through collateral elimination occurs fairly late in cortical development and, in at least some systems, at around the same time as the relevant axons become myelinated. Observations from several studies suggest that neuronal activity may be involved in the determination of which collaterals are eliminated and which are maintained. Since myelination clearly contributes to the functional maturation of developing axonal systems, the possibility that myelination may be causally related to collateral elimination would seem to merit serious consideration. I have therefore examined the distributions of neocortical commissural and corticospinal neurons in dysmyelinated *jimpy* mice, and in unaffected littermate controls, during the first and third postnatal weeks. *Jimpy* is an X-linked, juvenile-lethal mutation in which the lack of oligodendrocyte differentiation, together with frank oligodendrocyte loss, results in the virtual absence of myelin from the developing and mature CNS.

First, it was confirmed that the relevant projection neurons are widely distributed in early postnatal mice. For this I injected 2% fast blue into either the cerebral cortex on one side, or into the pyramidal tract at its decussation, on postnatal day 2 or 3. The mice were killed 1 or 2 days later. In these early postnatal mice both callosally projecting and corticospinal neurons are distributed essentially throughout the tangential extent of the neocortex. Next, I made similar injections, only in 16 to 19 day old *jimpy* mice and littermate controls. These mice were killed after 1 to 2 days. By this age, both callosally projecting and corticospinal neurons are spread discontinuously through the *jimpy* neocortex, and the distributions of these cortical projection neurons in *jimpy* are indistinguishable from those seen in the cortex of the control mice. Thus the congenital absence of CNS myelin in *jimpy* does not affect the normal developmental sculpting through collateral elimination of the distributions of these cortical projection neurons.

MAP2-IMMUNOREACTIVE NEURITES OF PREPLATE NEURONS IN REELER MUTANT EMBRYONIC CORTEX. J.E. Crandall and V.S. Caviness, Jr. Develop.

Neurobiol., E.K. Shriver Ctr, Waltham, Dept. Neurol., Mass. Gen. Hosp. and Neuroscience Program, Harvard Med. Sch., Boston, MA.

We have used antisera to MAP2 to study neuritic development of preplate neurons in normal and reeler cortex. At this developmental age, the cortical plate is just beginning to form in the mid-lateral region of the cerebral wall, whereas dorsal and medial cortical regions are still in a relatively undifferentiated stage consisting of only a primordial plexiform zone (PPZ). Total neuritic length of PPZ neurons is similar in the two genotypes on embryonic day 13. However, there are major differences in the organization of the neurites. In the normal PPZ, MAP2-positive neurites are distributed predominantly parallel to the pial surface. In the reeler PPZ, many neurites extend radially from cell somata toward the ventricular zone. Polar plots of neurite distribution were generated to quantify neurite orientation using the Eutectics Neuron Trace program. The difference in orientation of the neuritic trees between normal and reeler preplate neurons was reflected in a statistically significant genotype by angle sector interaction. The mean number of neurite branches per branch order was significantly greater for reeler neurons only for higher order branches. The organizational anomaly of neurites from reeler preplate neurons occurs despite apparent positional similarity to normal developing cortical neurons and is prior to the major epoch of neuronal migration. We hypothesize that this network of neurites in the mutant PPZ forms a disoriented mesh beyond which successive cohorts of migrating neurons may be incapable of navigating.

DEVELOPMENT OF OVER REPRESENTED AREAS IN SOMATIC MAPS. D. R. Riddle, A.-S. Lamantia, A. Richards* and D. Purves. Department of Neurobiology, Duke University Medical Center, Durham, NC 27710.

Since the discovery of cortical maps it has been recognized that central representations are not proportional to the dimensions of the body; body parts involved in fine discrimination or movements are over represented relative to other structures. This observation raises the question of whether early somatic maps are configured as in the adult, or whether over representation arises by disproportionate growth of the appropriate cortical regions. To address this issue, we have asked whether the sensory representation of the rodent face (an over represented feature) grows to the same extent as the cortex as a whole. Neonatal (4-5 days old) and adult (10-12 weeks old) mice were perfused with fixative and the brains removed. The cerebral cortices were flattened, cut tangentially, and stained for cytochrome oxidase. The cortical barrels representing the anterior face (excluding the lower jaw region, which is poorly defined in mice) were counted, and the area of the facial barrel field was compared to that of the flattened cortex as a whole. In neonatal animals the average area of the hemispheric cortex was $43.0 \pm 1.3 \text{ mm}^2$ (mean \pm SEM, N = 17 cortices from 12 animals); the facial representation (about 80 barrels) measured $2.0 \pm 0.1 \text{ mm}^2$. In adult animals the mean cortical area was $76.4 \pm 2.8 \text{ mm}^2$ (N = 12 cortices from 9 animals), and the facial representation was $6.0 \pm 0.2 \text{ mm}^2$. Thus, the map of the face increased from 4.7% of the total cortical area in the neonate to 7.9% at adulthood. These findings are consistent with previous measurements of the subset of barrels that represent the mystacial vibrissae (Rice and Van der Loos, 1977), and suggest that over represented areas in cortical maps grow relatively more postnatally than other cortical regions.

305.14

MYELINATION OF THE CEREBRAL COMMISSURES OF THE HAMSTER, AS REVEALED BY THE RIP MONOCLONAL ANTIBODY. R. Lent, S. Jhaveri & B. Friedman. Instituto de Biofísica, UFRJ, Brazil; M.I.T. Cambridge, Ma. 02139; Regeneration, Tarrytown, NY.

Myelination of the cerebral commissures of the hamster was studied by immunostaining with a monoclonal antibody specific for myelin and oligodendrocytes (Rip). Cells expressing the Rip antigen were first observed in the anterior commissure (AC) on P8 (day of birth = P1), and in the corpus callosum (CC) and the hippocampal commissure (HC) on P8. By P8, myelinated fibers appeared around immunopositive oligodendrocytes within the posterior limb of the AC, and also ventrally at the rostral half of the CC. On P12, all the commissures had myelinated fibers throughout their extent, but in the CC and in the HC, a gradient had formed with a higher density of myelinated fibers rostrally. On P15 and P22, the pattern of myelination approached that of the adult. In the context of other developmental events, myelination of the CC and of the AC is a late event, occurring predominantly after stabilization of the axon number, either at the end of the progressive accretion of axons, as in the AC, or after the selective elimination of callosal projections.

DEPLETION OF LAYER IV HAS NO EFFECT ON SURVIVAL OF SUBPLATE NEURONS. T.U. Woo and B.L. Finlay. Department of Psychology, Cornell University, Ithaca, New York 14853.

In the cat, thalamocortical axons make temporary functional synaptic contacts with subplate neurons during development before establishing permanent connections with layer IV neurons. After thalamic invasion of the cortex, most of the subplate neurons die. In the golden hamster, normally 50 to 80% of subplate neurons die by adulthood. Perhaps the excessive loss of subplate cells results from loss of their thalamic afferents to layer IV. We thus tested if depletion of layer IV might rescue part of the subplate neurons by maintaining some of the temporary thalamocortical connections with the subplate, depleting the number of neurons in layer IV by injecting methylazoxymethanol (MAM), a mitotic inhibitor, during the time of their generation.

MAM (20mg/Kg) was injected into pregnant hamsters on embryonic day 14 (E14) when the major population of layer IV neurons are being generated. Animals were examined prior to and after the cell death period. Layer IV was reduced in thickness compared to control although it was not completely deleted. Reduction in thickness and cell density of layer II and III was also observed. The absolute number of cells in the subplate was not changed significantly by the manipulation (normal adult = $207,000 \pm 31,600$; experimental = $181,000 \pm 7,000$).

Our results suggest that loss of competition of subplate neurons for thalamic afferents is not a cause of cell death. Supported by NIH Grant R01 NS19245.

DEVELOPMENTAL REGULATION OF BRAIN DERIVED NEUROTROPHIC FACTOR mRNA IN NEURONS OF FETAL AND ADULT MONKEY PREFRONTAL CORTEX. G.W. Huntley, D.L. Benson, P.J. Isackson and E.G. Jones. Depts. of Anatomy and Neurobiology and Biological Chemistry, University of California, Irvine, CA 92717.

Brain Derived Neurotrophic Factor (BDNF) is thought to be a target-produced, CNS-derived neurotrophic factor with homologies to nerve growth factor that is thought to be produced by target cells of responsive neurons. In situ hybridization with cRNA probes was used to examine the expression and distribution of BDNF mRNA in a series of prefrontal cortices taken from six fetal (E110-E155) and two adult rhesus monkeys (*Macaca mulatta*). In adult prefrontal cortex, cells labeled by hybridization of the probe were located throughout all areas of the prefrontal cortex with their greatest density in the deeper half of layer III and layer VI. In the developmental series, no specific labeling was present at the youngest age examined (E110), and few, sparsely hybridized cells were present by E121. By E130 and thereafter, intensely hybridized cells were present and the areal and laminar distribution was similar to that seen in the adult. These data demonstrate that developing and adult neocortical cells express BDNF and suggest that expression of this neurotrophic factor may be important in the establishment or maintenance of functional interactions between prefrontal cortical cells and the widely distributed sets of cells projecting to them. 306.1

IN VIVO AND IN VITRO STUDIES OF THE DEVELOPMENT OF CORTICAL CONNECTIONS. D.Carić*, S.Rennie* and D.J.Price. Dept. of Physiology, Univ. Med. Sch., Teviot Place, Edinburgh EH8 9AG, U.K.

Geniculocortical fibres start to grow towards the cortical plate during the final third of gestation, as their cortical target cells are being born. Corticocortical development occurs later, largely postnatally.

Embryonic explants of murine lateral geniculate nucleus (LGN) were cultured alone or with slices of occipital cortex. Outgrowth from the LGN was seen only if cortex was present, and was more prolific the closer the explants. Cortex may secrete a neurotrophic substance stimulating outgrowth from the LGN.

We have tested the possibility that the presence of the geniculocortical pathway at birth is required to guide the development of corticocortical connections by lesioning the LGN in neonatal kittens. The results suggest that the loss of geniculocortical inputs prevents the normal maturation of corticocortical pathways.

These findings suggest that geniculocortical projections are stimulated to grow by the neurotrophic influence of their targets, and corticocortical pathways develop within the framework of the geniculocortical pathway.

A THERMODYNAMIC MODEL FOR SELF-ORGANIZATION PREDICTS PATTERNS OF SYNAPTIC CONNECTIONS FROM THE LGN TO THE VISUAL CORTEX FOR MONKEYS AND CATS. S. Tanaka. Fundamental Research Laboratories, NEC Corporation, Tsukuba, Ibaraki 305, Japan.

A thermodynamic formulation previously proposed on the basis of a local Hebbian learning mechanism and synaptic competition for the limited amount of available postsynaptic trophic factors is applied to the development of the afferent projection from the LGN to the visual cortex. For model (A) in which ocularity, retinotopy and either on-center or off-center pathway are considered, computer simulations give rise to striped ocular dominance patterns and isotropic receptive fields without orientation selectivity. For model (B) in which both on-center and off-center pathways are considered in addition to ocularity and retinotopy, simulations yield irregular beaded ocular dominance patterns and simple-cell-like receptive fields. The on-center and off-center terminals also segregate superposing the ocular dominance patterns. Furthermore, for model (B), iso-orientation domains can be reproduced according to the orientation of individual receptive fields. Comparing simulated and experimental results, it is found that the ocular dominance patterns and receptive fields for models (A) and (B) are consistent with those observed in monkeys and cats.

SHORT-TERM SYNAPTIC PLASTICITY IN THE DEVELOPING RAT VISUAL CORTEX. A. Ramoa and M. Sur. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139, and Biophysical Institute, Federal University of Rio de Janeiro, 21941, Brazil.

Short-term, stimulus-dependent changes in synaptic efficacy may contribute to information processing and to the formation or rearrangement of connections in the visual cortex during development. Therefore, we have examined the physiological properties of short-term synaptic plasticity in the developing visual cortex.

Intracellular recordings were made in slices of visual cortex using potassium acetate microelectrodes. Bipolar electrodes were used to deliver pairs of electrical stimuli (0.05 msec duration, 0.1 mA, 0.25-0.5 Hz) to the underlying white matter. At postnatal day (P) 20-22, paired stimulation at short interstimulus intervals (<200 msec) caused the second synaptic response to be depressed (8 of 12 cells) or facilitated (2 cells) relative to the first response, even though the first response had decayed to baseline before the second stimulus. Depression was reduced by phaclofen but not by bicuculline, suggesting the involvement of GABA-b receptors. Depression was not observed with electrodes containing cesium acetate, consistent with a role for postsynaptic potassium-dependent mechanisms. At earlier ages (P13-16), the second response was either only potentiated when elicited within 100 msec of the first epsp (3 of 8 cells), or else was independent of the first response (5 cells), consistent with less intracortical inhibition at early ages. Potentiation may require NMDA receptor activation, since it was reduced by APV.

These results indicate that temporal interactions between inputs can lead to short-term changes in synaptic transmission in the developing visual cortex; such physiological modifications may be a crucial substrate for function as well as normal development and plasticity in the cortex.

LAMINAR SPECIFICITY OF EXTRINSIC VISUAL CORTICAL CONNECTIVITY STUDIED IN COCULTURE PREPARATIONS. N. Yamamoto, K. Yamada*, T. Kurotani* and K. Toyama.

Department of Physiology, Kyoto Prefectural University of Medicine, Kamigyo-ku, Kyoto 602, Japan.

The previous study demonstrated that laminar specific neural connections were established between cocultured lateral geniculate nucleus (LGN) and visual cortex (VC) (Yamamoto et al., *Science* 245:192, 1989). We further studied the mechanisms responsible for the formation of extrinsic cortical connectivity by using VC-VC, VC-superior colliculus (SC) and somatosensory cortex (SMC)-LGN cocultures in addition to the VC-LGN coculture. The subcortical blocks and cortical slices were dissected from fetal (ED15-17) and neonatal (PD1-2) rats respectively and cultured on the collagen-coated membrane for 2-3 weeks. Retrograde labeling with a fluorescent dye (Dil) showed that most of the cortical efferent cells were located in layers 2/3 in VC-VC, in layer 5 in VC-SC and in layer 6 in VC-LGN as well as in SMC-LGN cocultures. Anterograde labeling with Dil and current source density analysis indicated that in SMC-LGN or VC-LGN cocultures the thalamic fibers established synaptic connections in and around layer 4 of the cortices while in VC-VC cocultures the cortical fibers formed synaptic connections in layers 2/3 and 5. These results suggest that interactions between the neuron and its target are sufficient to produce the laminar specific neural connectivity, although other factors may be required for the formation of the modality specificity.

GENICULO-CORTICAL REROUTING FOLLOWING NEONATAL MONOCULAR ENUCLEATION IN THE GOLDEN HAMSTER. A.J.Trevelyan* and I.D.Thompson*.

(SPON: Brain Research Association). University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K.

The effect of early eye removal on the development of the geniculo-cortical pathway was studied in golden hamsters. Small, discrete injections (150nl) of rhodamine- and green-latex microspheres (Katz and Larovici, 1990, *Neurosci.*, 34:511-520) were made in visual cortex of adult hamsters, and the resultant backlabelling of the dorsal lateral geniculate nucleus (dLGN) examined. In normal adults, the projection has a precise topographic order. This is also true of the projection contralateral to the remaining eye in animals monocularly enucleated at birth. However, on the side ipsilateral to the remaining eye, visual cortex appears to receive two convergent projections from the deafferented dLGN, one mirroring the other. A very lateral cortical injection labels cells in two discrete regions of the dLGN. As the injections are made progressively more medially, the two foci of labelled cells converge until eventually just one patch of labelling is seen. The borders of area 17 and the dLGN were confirmed histologically. Despite this dual geniculate input to lateral area 17, electrophysiological recording has shown that cells here each have a single receptive field originating from the temporal retina of the remaining eye.

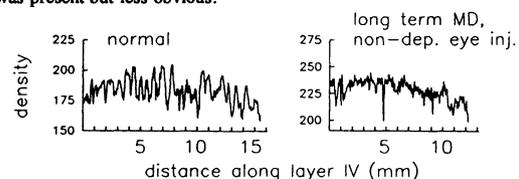

By postnatal day 12 the geniculo-cortical pathway can not be altered in this way. In animals enucleated at this stage, the projections on both sides appear normal.

OCULAR DOMINANCE PATCHES: DEVELOPMENT AND DEPRIVATION EFFECTS VIEWED WITH TRANSDURONAL WGA-HRP. Ying Tseng, Dane Copeland*, Kenneth Tovar*, and Barbara Gordon. Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

We have used WGA-HRP, rather than [³H]proline, as a transneuronal marker to study the development of ocular dominance (OD) patches and the effects of monocular deprivation (MD) on these patches. Staining in layer IV of the cat visual cortex was first seen in animals injected at 29 days of age, but at this age staining was weak and uniform. OD patches first appeared in animals injected at 5 weeks of age, but at this age large regions were still unsegregated. OD patches appeared adult-like by about 9 weeks. Both short term MD (14 days beginning at 35 days of age) and long term MD (3 mos beginning at eye opening) produced expansion of the patches served by the nondeprived eye. In fact, after long term deprivation, injection of the nondeprived eye produced almost continuous label (see figure). Contraction of the patches served by the deprived eye was present but less obvious.

Sample density tracings through layer IV ipsilateral to injected eye.

ALTERED VISUAL TOPOGRAPHY IN AREA 17 OF THE PIGMENTED RABBIT FOLLOWING NEONATAL MONOCULAR ENUCLEATION. R.J. Clarke,¹ B.W. Datskovsky,¹ A.M. Grigoris,² and E.H. Murphy.¹ ¹Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129, and ²Department of Anatomy, Hahnemann University, Philadelphia, PA 19102-1192.

In the rabbit 90% of retinal fibers decussate at the chiasm. The ipsilateral retinogeniculo-striate pathway, representing 15-20% of the ipsilateral visual field, terminates in a region 2 mm wide at the area 17/18 border. This region is binocular and also contains the cells and terminals of the visual callosal projection. In rabbits monocularly enucleated at birth (ME), the callosal zone ipsilateral to the intact eye extends as much as 4 mm medial to the 17/18 border, but the callosal zone contralateral to the intact eye is limited to the normal 2 mm. Unless cortical visual topography is modified, these callosal projections must link cortical areas with disparate visual fields. In order to determine whether the topography of the ipsilateral visual projection is modified in the cortex of ME rabbits, we mapped multiunit cortical receptive fields. In ME rabbits (n=7), the ipsilateral visual field representation extended 3.5 mm medially from the 17/18 border, compared with 2 mm in normal rabbits (n=13). Visual topography was normal in the lateral 2 mm, but in the anomalous medial region, receptive fields were highly clustered in the extreme nasal visual field. In one ME rabbit, in which the cortex contralateral to the intact eye was ablated 3 hr prior to recording, the ipsilateral visual field representation also extended 3.5 mm medially from the 17/18 border. This indicates that the expansion of the area in cortex representing the ipsilateral visual field in ME rabbits is not dependent on callosal input and must result from modification of the retino-geniculo-cortical projection. The results suggest that altered visual topography in ME rabbit cortex may influence the abnormal development of callosal projections. Supported by NINDS grant NS26989.

ACTIVITY-DEPENDENT DEVELOPMENT OF ORIENTATION SPECIFICITY IN FERRET PRIMARY VISUAL CORTEX. B. Chapman and M.P. Stryker. Dept. of Physiology, UCSF, San Francisco, CA 94143-0444.

We have studied the orientation selectivity of neurons in primary visual cortex in normal ferrets of different ages and in ferrets deprived of vision or of visual cortical activity during development. In normal animals, when the earliest visual cortical responses could be recorded at postnatal day 23, only a very few cells showed any orientation bias. By week 7 cortical responses had matured to an adult-like state, with approximately 50% of cells showing clear orientation preference.

To determine whether the development of orientation-selective responses occurs through an activity-dependent mechanism, we silenced cortical neuronal activity during the time that orientation selectivity normally matures by infusing tetrodotoxin (TTX) into area 17 from postnatal week 4 through week 7. Four days after the infusion ended, neurons within the TTX-treated area were found to respond vigorously to visual stimulation, but lacked orientation selectivity. Neurons in the opposite (untreated) cortex and neurons in NaCl-treated control cortex showed a normal, adult-like distribution of orientation selectivity.

To test whether the development of orientation selectivity depends on visually driven activity, or whether spontaneous neural activity is sufficient, ferrets were visually deprived by binocular lid suture beginning before the time of natural eye-opening. In these animals, unlike in TTX-treated animals, some cells showed clear orientation specificity, but a larger fraction of cells lacked specificity than in control animals. Thus the development of any orientation specificity in ferret visual cortex appears to require neuronal activity, and normal development requires visually driven activity.

306.11

SHORT-TERM CONTOUR DEPRIVATION RESULTS IN INCREASES IN VISUAL CORTEX METABOLIC ACTIVITY IN RESPONSE TO FLASHING DIFFUSE LIGHT IN RATS. A.C. Gafka and R.M. Cooper. Behavioral Neuroscience Research Group, Department of Psychology, University of Calgary, Calgary, Alberta, Canada. T2N 1N4.

Previous 2-deoxyglucose (2-DG) work has demonstrated that, contrary to the null response in adult animals, visual cortex metabolic activity is increased by flashing diffuse light in neonatal rats (eye-opening at postnatal day [PND] 14 to PND 28). By PND 35, visual cortex shows little or no response to flashing diffuse light, indicating that adult status of visual cortical neurons is reached by this time. To test whether changes that occurred with development were the result of maturational processes or were experience-dependent, rats were either monocularly or binocularly lid-sutured prior to eye-opening to prevent contour experience. At PND 35 (following 21 days of contour deprivation) rats were injected with 2-DG, and monocularly exposed to 4 Hz flashing diffuse light (contour-deprived eye covered with a translucent mask, the other eye by an opaque occluder). Comparison of the two cortical hemispheres (stimulated vs occluded) indicated that regardless of whether the animal had received monocular or binocular lid-suture, the stimulated hemisphere demonstrated greater 2-DG uptake than the nonstimulated hemisphere. Combined with previous findings that contour deprived rats respond cortically to steady diffuse light (normally reared rats, at any age, do not), the present results argue that the increase in cortical metabolic activity by the deprived hemisphere is the result of the type of visual experience received during development. Thus, it appears that limiting visual experience to diffuse light may act to modify cortical neuronal response properties to match the type of visual experience.

EXUBERANT CALLOSAL CELL DISTRIBUTION IN THE STRIATE CORTEX OF THE RABBIT FOLLOWING CORTICAL EPILEPTIC ACTIVITY DURING DEVELOPMENT. A.M. Grigoris,¹ B. Ju,² and E.H. Murphy.² ¹Department of Anatomy, Hahnemann University, Philadelphia, PA 19102-1192, and ²Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Cells which connect the two visual cortices via the corpus callosum are distributed throughout most of area 17 in the neonatal rabbit but are restricted, in the adult, to the area 17/18 border. Modification or elimination of activity in the retino-geniculo-cortical pathway during development through monocular enucleation, dark rearing, and intraocular injection of TTX, results in the maintenance of an immature, exuberant callosal cell distribution, whereas synchronous activity produced by strobe rearing results in a callosal cell zone which is more restricted than normal. In the present study we examined the effects of synchronous cortical activity on the development of visual callosal projections. Beads (Innovative Research of America), 1.5 mm diameter, which release an epileptogenic agent continuously for 3 weeks (1.5 mg penicillin), were placed on the surface of the posterior neocortex of 5 newborn rabbits (aged 2-5 days postnatal). In 2 control animals, beads containing only matrix were used. Rabbits were raised until adult, at which time multiple injections of HRP (Boehringer, 20% in H₂O) were made throughout one visual cortex. Animals were perfused 24 hours later and the brains were cut and reacted with TMB. The callosal cell distribution was normal in control animals. However, in the cortex which had penicillin released during development, the tangential extent of the callosal cell zone was twice as large as the normal distribution. The callosal cell zone was equally expanded in the cortex contralateral to the bead implant, indicating spread of epileptic activity to the opposite hemisphere. The results indicate that synchronous epileptic cortical activity, which is not correlated with visual input, prevents the normal process of retraction of early exuberant callosal projections. Supported by NINDS-NS26989.

SPATIAL FREQUENCY TUNING OF CELLS IN AREA 17 OF ARTIFICIALLY INDUCED BILATERAL ESOTROPIA IN CATS.

S. Quessy,^{*} L. Richer,^{*} M. Pluto, F. Lepore, J.-P. Guillemot. Dept. of Psychology and Kinesiology, Univ. of Montréal and Univ. of Québec, Montréal H3C 3P8, Québec.

Unilateral esotropia induced early in life results in amblyopia of the deviated eye and changes in the spatial frequency tuning of cells driven through this eye in visual cortex of cats. These functional changes are attributed to competitive interactions between the good and esotropic eye, the former generally gaining some functional and structural advantages over the latter. In order to modify the nature of this interaction, cats were made strabismic in both eyes and the spatial frequency characteristics of cells in area 17 were assessed. Strabismus was induced by cutting the lateral rectus muscle in each eye at about 21 days of age. Recording in visual cortex was carried out when the animals were at least 12 months of age. Micropipettes recorded extra-cellular activity, which was displayed and analyzed in conventional manner. Preparatory surgery to recording was carried out using Halothane-N₂O anesthesia and single cell activity was measured under paralysis, local anesthesia and N₂O. Stimulation consisted of sinusoidal gratings, swept at optimal orientation, direction and contrast, and whose spatial frequency could be varied in discrete steps. Results indicated that cells in the visual cortex responded well to the gratings. When compared to normal cats, however, a number of differences were observed: substantially more cells were monocularly driven; the spatial frequency ranges of both narrow-band and low-band pass cells were higher in the normal animals; the half-widths of the narrow-band pass cells were larger in the latter. These results are confronted to behavioral acuity measures and discussed in terms of the relative deleterious effects of unilateral vs bilateral deviation of the eyes.

306.12

CALLOSAL TRANSFER OF THE INTEROCULAR COMPETITION DURING DEVELOPMENT IN VISUAL CORTEX CELLS OF CATS. U. Yinon and A. Milgram. Physiol. Lab., Goldschleger Eye Res. Inst., Tel-Aviv Univ. Fac. Med., Sheba Med. CTR, Tel-Hashomer, 52621, Israel.

Sagittal transection of the direct contralateral pathways at the optic chiasm and monocular deprivation (OCMD) were carried out in 9 kittens (age:6 weeks). In 3 of them reversal of the eye closure (OCMDREV) was carried out (age:10 weeks). Other 6 kittens served as chiasm transected (OC) controls. Unit recording was carried out in visual cortex areas 17,18 boundary. While in the OC cats equal proportions of cells reacted via the corpus callosum (indirectly contralaterally driven) to stimulation of each eye, in the OCMD cats the distribution was asymmetric; 12% of the cells had reacted contralaterally to the open eye and only 1.2% contralaterally to the deprived eye. In the OCMDREV cats 3.4% and 3.2% of the cells reacted contralaterally to the previously open and closed eye, respectively. Thus, the invasion of indirect contralateral input from the open eye via the callosum to the "weak" hemisphere (ipsilaterally to the deprived eye) is obstructed by the reversal of the deprivation effect. This indicates that an interocular competition takes place interhemispherically and it is bidirectionally mediated by the corpus callosum.

CORTICAL RESPONSIVENESS IN SPLIT-CHIASM STRABISMIC CATS M. Di Stefano¹, G. Tassinari². (Spon.: European Brain and Behaviour Society) ¹Dept. of Physiol. and Biochem., Univ. of Pisa ²Inst. of Physiology, Univ. of Verona, Italy.

Behavioural studies of the visual fields in cats raised with unilateral convergent strabismus provide controversial results. Kalil (1977) and Ikeda and Jacobson (1977) reported that in esotropic cats there is an almost complete suppression of the nasal field of the deviated eye, whereas Berman and Murphy (1981) found that the esotropic eye retains a normal visual field. In partial agreement with the former finding, electrophysiological data revealed a response deficit through the esotropic eye in the ipsilateral area 17 (Kalil et al., 1984). Since visual information from the nasal field of each eye is conveyed to the ipsilateral cortex by the temporal hemiretina, behavioural and electrophysiological deficits might be accounted for by a failure of the temporal pathway from the deviated eye to drive cortical cells. To study this retinocortical pathway in isolation, we examined the cortical responsiveness of adult esotropic cats in which the optic chiasm had been sectioned by a trans-buccal approach. Recordings from single units were performed in areas 17 and PMLS of the two sides, which were fed by the normal or the deviated eye through their temporal projections only. Preliminary results indicate that in both 17 and PMLS the temporal projections from the deviated eye were as effective as the projections from the normal eye in driving cells on the respective side. Response properties and RF sizes of 17 and PMLS neurons did not differ in the two hemispheres. At variance with otherwise intact esotropic cats (Kalil et al., 1984), in both striate and extrastriate cortices ipsilateral to the deviated eye a large sample of binocular cells could be recorded. Due to the chiasmatic section, binocular cells in these areas must be driven by the contralateral eye through a commissural pathway. Some correspondence appeared to be preserved in their monocular RFs. It seems that chiasmatic section removes some influence exerted by the crossed projections from the normal eye on the direct projections from the deviated eye.

TRANSPLANTATION: ANIMAL MODELS OF PARKINSON'S DISEASE II

307.1

HUMAN FETAL TRANSPLANTS FOR PARKINSON'S DISEASE. C.R. Freed, R.E. Breeze, S.A. Schneck, C. Kruse, and N.L. Rosenberg, Depts. of Med., Surg., and Neurol., Univ. Colo. Med. Ctr., and Colo. Neurol. Institute, Denver, CO 80262.

We have previously reported successful transplantation of human fetal tissue in a patient with Parkinson's disease (Arch. Neurology 47: 505, 1990). We have now extended these experiments to three patients. Candidate patients have had Parkinson's disease for 10 to 20 years. Two of the three patients showed severe "on-off" phenomena while a third had a flat response to L-dopa. All patients had computers and video cameras in their homes for four months to one year prior to surgery for frequent measurements of motor performance. Single embryos of 7 or 8 weeks gestation were used for each patient. Two patients received implants of fetal tissue via 10 or 12 needle passes into caudate and putamen on one side of brain. The third patient was implanted bilaterally in putamen using 7 needle passes on each side of brain. One of the patients was immunosuppressed with cyclosporine and prednisone for one year. The two patients with the "on-off" phenomenon showed improvement beginning one to two months after surgery despite the fact that neither was immunosuppressed. The patient with less response to L-dopa had no response to transplant. These results suggest that patients with severe Parkinson's disease and the "on-off" phenomenon may be the best candidates for transplant with human fetal mesencephalic dopamine cells.

307.3

EFFECT OF HUMAN FETAL VENTRAL MESENCEPHALIC XENOGRAFTS ON D₁ AND D₂ DOPAMINE RECEPTOR BINDING IN THE UNILATERALLY 6-HYDROXYDOPAMINE (6-OHDA)-LESIONED RAT NEOSTRIATUM. C.E. Adams, I. Stromberg, C. Van Horne, B.J. Hoffer and S.J. Boyson. Depts. of Neurology and Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262

Neostriatal D₁ and D₂ dopamine receptor binding was examined in two groups of rats using quantitative autoradiography. Animals received either a unilateral 6-OHDA lesion of the medial forebrain bundle alone (6-OHDA control group) or a unilateral 6-OHDA lesion followed by an intraventricular transplant of human fetal ventral mesencephalic tissue (transplant group). D₁ receptors were labeled with ³H-SCH-23390 (1.2 nM) while D₂ receptors were labeled with ³H-spiperone (1.4 nM). In the 6-OHDA control group, D₂ receptor density was increased (5%) while D₁ receptor density was decreased (11%) within the lesioned as compared to the intact neostriatum. D₂ receptor density within the lesioned striatum was normalized when the transplant was present for 8 but not for 4 months. However, none of the transplants normalized the decrease in D₁ receptor density observed after unilateral 6-OHDA lesions. This study indicates that fetal cell transplants may only partially correct neostriatal dopamine receptor deficits associated with Parkinson's disease.

306.14

DEATH OF NEURONS IN AREA PMLS FOLLOWING ABLATION OF AREAS 17 AND 18 IN THE NEWBORN CAT. B.R. Payne, C. Conners and P. Cornwell. Dept. of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA 02118.

The long term morphological consequences of removal of areas 17 & 18 from neonatal cats was assessed in cortical area PMLS. Measurements of laminar thickness revealed a significant thinning of layers III, V & VI and a significant loss of neurons in layers III & VI. The loss was greater in layer III than in layer VI. Following excision of the same areas in adult cats, there was no detectable thinning of any layer except layer V. No neurons were lost from any layer. Pathway tracing studies in adult cats show that the projections from areas 17 & 18 terminate most heavily in layers I, III & V in area PMLS, and that layers III & VI contain the largest number of neurons which project back to these same areas. In kittens, the laminar distribution of cells in area PMLS that project to areas 17 & 18 is similar to that in the adult, but the laminar terminations of the reciprocal projections from these same areas to area PMLS is relatively poorly differentiated. Thus, in the lesion part of the study, layer III of area PMLS contained neurons that were deprived of their target cells and/or deafferented by removal of areas 17 & 18, whereas neurons in layer VI were only target deprived, and neurons in layer V were partially deafferented. We conclude that following the lesion in the neonate, deafferentation in addition to target deprivation resulted in greater loss of neurons than target deprivation alone, and deafferentation alone resulted in no significant cell loss in layer V. There was no significant loss of neurons in layers II & IV; and neither of these layers forms a major connection with the ablated region. (Supported by MH44647.)

307.2

FIRST WEEKS OF DEVELOPMENT OF CENTRAL CATECHOLAMINERGIC (CA) NEURONS IN THE HUMAN EMBRYO. J. Cadusseau, R. Jény, M. Hammami and M. Peschanski, Groupe Recherche Scie Méd. Nuc., CHU H. Mondor 94010 Créteil, Hl Esquirol, 94410 St Maurice, France. Intraatrial transplantation of CA neurons dissected from human embryos is presently being carried out in several countries in the search for a therapy for parkinsonism. Brundin et al. (Exp. Br. Res. '88) have defined the general framework of this dissection by studying human-to-rat xenografts. In this study, we further define this protocol by analyzing the development of central CA neurons in human embryos ranging in age from 5 to 10 weeks of gestation. Embryos were obtained from regular aspiration abortions under ultrasound guidance, according to a protocol accepted by the National Ethical Committee (12/3/90). They were immediately fixed with aldehydes then cut on a cryostat. Sections were immunostained with antibodies raised against either tyrosine hydroxylase or dopamine. CA neurons appear at the mesencephalic flexure in 5 wk+5 d (14 mm) embryos. CA fibers are already present during the 6th week in large areas of the CNS, including the spinal cord and the rostralmost portions of the diencephalon. After 7 weeks of age, CA neurons are widespread in most of the tegmental primordium at the level of the mesencephalic flexure. They also extend in a more caudal area. Most mesencephalic CA neurons start differentiation and axogenesis well before the end of the 6-8 week period that was presumed to be optimal for transplantation. 5+ to 7 wk-old embryos may therefore be preferable. The distribution of CA neurons in the tegmental primordium suggests that dissection should include more than the ventral half and should extend caudally. (supp by Réseau INSERM).

TARGET SPECIFIC AND LONG-DISTANCE OUTGROWTH FROM HUMAN FETAL MESENCEPHALIC GRAFTS. Ingrid Strömberg¹, Marc Bygdeman², Erik Sundström³ and Per Almqvist³. Depts. of ¹Histol. & Neurobiol., ²Obstetrics & Gynecol. and ³Geriatics, Karolinska Institute, 104 01 Stockholm, Sweden.

Human fetal ventral mesencephalic tissue was grafted to unilaterally dopamine-depleted, immunosuppressed rats. Tissue was grafted as solid pieces and placed either in the lateral ventricle or in the cingulate cortex. The grafts and newly formed nerve fibers were visualized by immunohistochemistry using antibodies against TH, human specific Thy-1 and neurofilament (hNF). All rats showed reduced numbers apomorphine-induced rotations, beginning two months postgrafting. TH-positive nerve fibers reinnervated the entire striatum both when the graft was placed in the ventricle and in cortex. When the graft was placed in the cingulate cortex, fiber bundles penetrated corpus callosum to reach striatum. Thy-1-positivity was found only in the lesioned striatum, indicating that the graft reinnervated only the lesioned side. Nerve fibers from the graft placed in cortex, formed a bundle that followed the medial side of the ventricle and reinnervated the ventral limbic areas, where TH-positivity was overlapping with hNF- and Thy-1-immunoreactivity. The intact side of the ventral limbic areas were totally Thy-1-negative. When the graft was placed in the ventricle, cell migration had occurred from the graft into host striatum. No cell migration was seen into other areas. Septum was sparsely reinnervated while globus pallidus was totally devoid of TH-positive nerve fibers. In conclusion, fetal human mesencephalic grafts innervate only areas that are normally target for dopaminergic neurons if they previously are dopamine denervated. Ongoing studies with injections of MPTP to rats with intraventricular human grafts are performed.

307.5

FUNCTIONAL COMPARISON OF FRESH VERSUS CULTURED HUMAN DOPAMINE (DA) NEURONS FOLLOWING TRANSPLANTATION. B.D. Boss, Michael Lee*, M.E.C. Hancock*, and D.H. Spector*. Somatix Therapy Corp., Alameda, CA 94501.USA.

In an effort to test the relative effectiveness of our cultured embryonic human DA neurons, we compared the functional effects of transplanted fresh, uncultured human DA neurons to cultured human DA neurons. Donor tissue was obtained from the ventral mesencephalon of stage 15-16 embryos, mechanically dissociated, and transplanted (45,000 cells/rat) or cultured for 15 days prior to transplant (1,2, or 3 wells/rat). For culture, cells were seeded at 15,000 cells/well and grown as aggregates in serum-supplemented media for 5 days, then switched to a serum-free formulation (N2) for the remaining 10 days. Transplants were made into the DA-denervated striata of host rats, and functional recovery was tested by amphetamine-induced rotations scheduled at 4-wk. intervals for 24 weeks post-grafting. Preliminary results indicate cultured tissue is at least as effective as fresh tissue grafts and may be more viable. Immunohistochemical analysis of the transplanted cells corroborates the observed behavioral results.

307.7

FETAL DOPAMINE CELL IMPLANTS IN MONKEYS WITH UNILATERAL MPTP LESIONS. C.J. Hutt*, E.H. Kriek, M.L. Reite, M. Yamamoto*, Y. Kuroyanagi*, L.N. Heddeleston*, G. Davila*, and C.R. Freed, Depts. of Med., Pharm., Surgery, Ob/Gyn, and Psych., Univ. Colo. Sch. of Med., Denver, CO 80262.

To test the value of fetal dopamine cell grafts in the treatment of Parkinson's disease, Bonnet monkeys were made Parkinsonian with a unilateral carotid infusion of MPTP.HCl (0.8 mg/kg). Monkeys were trained to reach for a food reward in a computer timed test and were tested for circling with apomorphine (APO) 0.15 mg/kg. Lesioning reduced the ability to reach for a food reward in the arm contralateral to the lesion. Lesioned animals showed spontaneous circling ipsilateral to the side of the lesion while APO led to circling contralateral to the lesion. Mesencephalic tissue from 18-45 mm crown rump length fetus was transplanted into the caudate and putamen on the lesioned side of brain via 5 needle injections. Half of the animals were immunosuppressed with cyclosporine 15 mg/kg/day p.o. Within 12 weeks after transplant, animals recovered the ability to spontaneously circle contralateral to the side of lesion while contralateral circling induced by APO slowed. At sacrifice, fetal dopamine cells were identified by tyrosine hydroxylase immunocytochemical staining. Graft growth was best in animals receiving tissue from 18-20 mm crown-rump-length fetuses. Preliminary evidence indicates that animals immunosuppressed with cyclosporine A had graft results similar to animals not receiving immunosuppressive treatment.

307.9

β APP AND GAP-43 GENE EXPRESSION IN NORMAL AND WEAVER MICE AND IN INTRASTRIATAL DOPAMINE NEURON GRAFTS. C. Sola*, G. Mengod, W.C. Low, B. Ghetti, J.M. Palacios & L.C. Triarhou. Preclin. Res., Sandoz Pharma AG, 4002 Basel, Switzerland, Dept. Neurosurg., Univ. Minnesota, Minneapolis, MN 55455, and Dept. Pathol. (Neuropathol.) & Med. Neurobiol. Pgm, Indiana Univ., Indianapolis, IN 46202.

The cellular localization of β -amyloid protein precursor (β APP) and growth-associated phosphoprotein GAP-43 RNA transcripts was studied by *in situ* hybridization in normal and weaver (*wv*) mice, which lose midbrain dopamine (DA) neurons, and in ventral mesencephalic grafts placed into the *wv* striatum. Both β APP and GAP-43 genes are localized on chromosome Mmu 16, on which the *wv* locus has been assigned as well. Transcripts encoding GAP-43 and isoforms β APP₆₉₅, β APP₇₁₄ and β APP₇₅₁ were present in normal SN and progressively reduced in *wv* SN, being correlated with DA neuron loss. Non-affected *wv* brain areas did not show changes. Graft survival was documented by rotation tests and TyrOHase immunocytochemistry. GAP-43, β APP₆₉₅, β APP₇₁₄ and β APP₇₅₁ transcripts were present in the grafts; the β APP₇₇₀ species—normally seen in striatum and not SN—was not expressed in the grafts but was present in the host striatum. These findings (i) provide evidence for β APP and GAP-43 gene expression by SN DA cells, (ii) indicate that the *wv* gene defect on Mmu 16 does not influence the expression of the closely linked β APP gene, (iii) offer a correlate of structural protein gene transcription by grafted mesencephalic DA cells. (Supported in part by USPHS R29-NS29283 and RO1-NS14426).

EMBRYONIC MESENCEPHALIC AND STRIATAL CO-GRAFTS IN MPTP-TREATED MONKEYS. J.R. Sladek Jr., T.J. Collier, J.D. Elsworth*, J.R. Taylor*, R.H. Roth* and D.E. Redmond Jr.* Dept. Neurobiology and Anatomy, Univ. Rochester School of Medicine, Rochester, NY 14642 and *Depts. Psychiatry and Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06510.

Studies in rodents indicate that intrastriatal co-grafts of dopamine (DA) neurons of the embryonic ventral mesencephalon and their embryonic target tissue, the striatum, enhances the development of the grafted DA neurons and their innervation of the surrounding host striatum (Brundin et al., Devel. Brain Res. 24:77, 1986; Yurek et al., Exper. Neurol. 109:191, 1990). As part of our continuing program studying the efficacy of DA grafts in MPTP-treated monkeys, we have performed DA neuron-striatal co-grafts to determine whether this co-grafting procedure can augment graft survival and integration with the host brain. Two MPTP-treated African Green monkeys exhibiting mild parkinsonian symptoms served as subjects for co-grafting. Each monkey received block implants of embryonic ventral mesencephalon at each of three rostral-caudal sites in the caudate nucleus of one hemisphere, and mixed grafts of ventral mesencephalon and striatum from the same embryonic donor at three sites in the caudate nucleus of the other hemisphere. Monkeys survived for 8 months following grafting, and then were prepared for combined regional "punch" biochemistry and tyrosine-hydroxylase immunocytochemistry to assess the biochemical and morphological status of the grafts and the surrounding host striatum. Comparisons of measures derived from DA grafts alone and DA-striatal co-grafts will be presented. Supported by NS24032.

GRAFTING SURGERY PROTECTS AGAINST 6-HYDROXYDOPAMINE-INDUCED DOPAMINERGIC TOXICITY IN RATS: BEHAVIORAL AND MORPHOLOGICAL EVIDENCE. M. LEVIEUR, S. PRZEDBORSKI*, V. KOSTIC*, V. JACKSON-LEWIS*, D.M. GASH*, S. FAHN*, J.L. CADET*. Dpts. of Neurosurgery and *Neurology, Univ. Libre de Bruxelles, B-1070 Brussels, Belgium; Dpt of Neurology, Columbia Univ., New York, NY 10032.;Dpt of Neurobiology and Anatomy, Univ. of Rochester, Rochester, NY 14642.

Administration of the neurotoxin 6-hydroxydopamine (6-OHDA) to rat brain causes biochemical and neuroanatomical changes to the nigrostriatal dopaminergic pathway similar to those observed in Parkinson's disease (PD). Although the cause of PD remains unknown, it has been hypothesized that the neurodegenerative changes seen in PD might result from exposure to a neurotoxin. Therefore, strategies for limiting neurotoxin-induced dopaminergic damages, like those caused by 6-OHDA, may be of both clinical and basic interest. Accordingly, we tested the ability of both fetal neural (striatum) and fetal non-neural (liver) tissue implants to protect the rat striatum against the toxic effects of a subsequent intrastriatal injection of 6-OHDA. Non-grafted rats (lesion only) showed amphetamine-induced rotational behavior and a decrease in striatal [³H]mazindol-labeled dopamine uptake sites after 6-OHDA injection. In contrast, the animals grafted with striatum or liver showed no behavioral or biochemical changes. Interestingly, sham-transplanted animals were also protected against the 6-OHDA-induced toxicity. These results suggest that the resistance of the dopaminergic system against 6-OHDA neurotoxicity observed in grafted and sham-transplanted animals is likely to be related to the surgical procedure itself. This observation points to the possible role for surgery-related events in the clinical improvements described in PD patients who underwent intracerebral transplantation.

IMPLANTED SYNTHETIC DOPAMINE (DA)-CONTAINING MICROSPHERES STIMULATE GROWTH OF DA FIBERS IN RATS WITH EXPERIMENTAL HEMI-PARKINSONISM. A. McRae, S. Hjorth, A. Dahlström, L. Dillon*, D. Mason* and T. Tice*, Depts. of Histology and Pharmacology, Univ. of Göteborg, Box 33031, S-400 33 Göteborg, SWEDEN, and Southern Research Institute, Birmingham, AL 35205, USA.

Biocompatible poly (DL-lactide co-glycolide) injectable microspheres represents a novel means for controlled-release delivery of DA to target brain regions to substitute for subnormal levels of the endogenous transmitter. Male Sprague-Dawley rats were unilaterally lesioned in the MFB using 6-OH-DA (8 μ g/4 μ l; pentobarbital anesthesia). The rats were tested on a weekly basis until a stable contralateral rotational response was established to 0.1 mg/kg SC of the DA agonist apomorphine (APO). They were then stereotaxically implanted under ether anesthesia with 3 μ l of a DA microsphere suspension, or a suspension of empty microspheres, in 2 sites in the denervated striatum. DA-microsphere implanted rats (n=13) and empty microsphere implanted rats (n=4) were subsequently challenged weekly for 8 weeks with APO and their contralateral rotatory behavior was recorded. Another group of DA microsphere-implanted rats (n=5) received no APO challenge during the 8-week period. Upon conclusion of the studies, immunocytochemical examination unexpectedly revealed growth of DA immunoreactive fibers in the striatum of DA microsphere implanted rats whether challenged or not with APO. No growth was noted in empty microsphere-implanted rats. Furthermore, functional recovery appeared related to the degree of DA fibers in the denervated striatum. These results suggest that implantation of DA microspheres may promote fiber growth and extended recovery of surviving dopaminergic neurons and therefore could be of therapeutic usefulness in Parkinson's disease.

AGING IMPAIRS ESTROGENIC SUPPRESSION OF HYPOTHALAMIC PROOPOMELANOCORTIN (POMC) mRNA IN THE MOUSE. K. Karelus* and J.F. Nelson. Dept. of Physiology, University of Texas Health Science Center, San Antonio, TX 78284.

The objective of this study was to determine whether altered responsiveness of hypothalamic POMC mRNA to estradiol (E2) is part of the age-related loss of neuroendocrine sensitivity to estrogen in the mouse. Young (4 mo), middle-aged (13 mo), and old (25 mo) C57BL/6J mice were ovariectomized, implanted 2 weeks later with Silastic capsules containing E2 or cholesterol (CHOL), and sacrificed 3 days later. POMC mRNA was measured by solution hybridization/RNase protection, using a cRNA probe complementary to a transcribed portion of the mouse POMC gene. POMC mRNA in middle-aged and old CHOL-treated mice was 36% lower than in young animals. E2 treatment reduced POMC mRNA levels by 44% in young mice, but failed to suppress POMC mRNA in middle-aged and old animals. Polyadenylated RNA content was unaffected by either age or E2, indicating that the changes in POMC mRNA were not attributable to an overall change in hypothalamic messenger RNA content. These results confirm earlier evidence that levels of POMC mRNA are reduced in hypothalami of aging rodents, and indicate that the ability of E2 to suppress hypothalamic POMC mRNA is lost by middle-age in mice. In view of evidence that estrogenic suppression of hypothalamic POMC mRNA and beta-endorphin facilitates the preovulatory luteinizing hormone surge, the loss of estrogenic suppression of POMC mRNA may contribute to the reduction in the E2-dependent luteinizing hormone surge of middle-aged mice.

TYPE II GLUCOCORTICOID INCREASES CALCIUM CURRENTS IN HIPPOCAMPUS BY A CYCLOHEXIMIDE-SENSITIVE MECHANISM. D.S. Kerr, L.W. Campbell, O. Thibault and P.W. Landfield. Dept. Pharmacol., Univ. Kentucky Col. of Med., Lexington, KY, 40536-0084.

Previous studies have shown that adrenalectomy (ADX) decreases the calcium(Ca)-dependent, K-mediated afterhyperpolarization (AHP) in hippocampal slice neurons, whereas Type II glucocorticoid (GC) activation can restore or increase the AHP (Jöel and de Kloet, 1989; Kerr et al, 1989, *Science*, Vol. 245). The GC-dependent component of the AHP is greater with aging, and ADX also can reduce Ca spikes (Kerr et al, 1989), which are larger with aging (Pitler and Landfield, 1990, *Brain Res.*)

However, it is uncertain whether GCs can influence Ca spikes or currents directly (as opposed to effects on K) or if the effect is mediated by protein synthesis. The present studies investigated these questions using current clamp and single electrode voltage clamp (SEVC) analyses of Ca currents in hippocampal slices from animals that had been surgically or pharmacologically (with metyrapone) adrenalectomized. Approximately half of the ADX slices were exposed to RU 28362 (Roussel-UCLAF), a potent Type II GC receptor agonist, for 1-2 hr. In some experiments, slices were co-incubated with cycloheximide (CXM), to inhibit protein synthesis.

RU 28362 (RU) dramatically increased Ca spike width. In SEVC, TTX, TEA and Cs-treated CA1 pyramidal neurons, exposed to RU exhibited larger voltage-activated Ca currents. CXM blocked the actions of RU. Thus, the activation of Type II GC receptors increases inward Ca current through protein synthetic mechanisms. This effect may provide a link between the glucocorticoid and Ca hypotheses of brain aging. (e.g., Kerr et al, 1989).

AGE DEPENDENT INCREASE OF POSTERIOR PITUITARY VASOPRESSIN IN RATS. Alan G. Robinson, Mark D. Fitzsimmons, and Michelle M. Roberts. Department of Medicine, University of Pittsburgh, Pittsburgh, PA 15261.

The amount of vasopressin stored in the posterior pituitary is often used as an index of chronic hormone secretion. With hypernatremia, pituitary vasopressin decreases and with recovery it increases. During recovery from prolonged hypernatremia, we found that pituitary vasopressin content increased above starting baseline. We therefore studied pituitary vasopressin content over time. In Sprague-Dawley Rats (SDR), studied over 3 weeks, posterior pituitary vasopressin increased parallel with weight: weight, 301 ± 7 g to 487 ± 5 g; pituitary AVP, 1,139 ± 55 ng to 2,650 ± 206 ng. Fischer Rats (FR) showed less weight gain but similar changes in pituitary content: weight, 206 ± 3 g to 297 ± 5 g; pituitary vasopressin, 1,202 ± 96 ng to 2,429 ± 351 ng. Because we thought the vasopressin increase was due to the increasing size of the animals, weight was maintained constant for both SDR and FR by restricting feeding, 304 ± 7 g to 303 ± 7 g and 236 ± 3 g to 245 ± 5 g, respectively. Pituitary content still increased: 1,139 ± 55 to 2,406 ± 135 ng; and, 1,202 ± 96 to 1,959 ± 168 ng, respectively. Vasopressin mRNA in the supraoptic nuclei did not increase over the same 3 weeks: 8.1 ± 1.8 to 8.5 ± 1.1, arbitrary units. Studies at 6 and 9 months have demonstrated continued increase in pituitary vasopressin but again, no increase in vasopressin mRNA. When secretion of vasopressin was inhibited by chronic hyponatremia in Sprague-Dawley Rats (sodium less than 110 mEq/L) the vasopressin increase over 3 weeks was completely inhibited: 1,254 ± 122 ng to 1,022 ± 140 ng. Thus, while synthesis can be turned off by chronic severe hyponatremia, we conclude that on-going synthesis in excess of release in basal conditions is responsible for the formation and continued accumulation of vasopressin in the posterior pituitary with aging.

REGIONAL CHANGES IN GLIAL FIBRILLARY ACIDIC PROTEIN mRNA ACROSS THE ESTROUS CYCLE AND AGE. S.G. Kohama, C.E. Finch and T.H. McNeill. Andrus Gerontology Center and the Department of Biological Sciences. University of Southern California, Los Angeles, CA 90089-0191.

Anatomical studies have shown increased glial activity with age in the female rodent hypothalamus as a consequence of exposure to estradiol (E2). However, previous studies in our laboratory have shown that E2 treatment for 12 weeks failed to increase arcuate nucleus glial fibrillary acidic protein (GFAP) levels, measured by *in situ* hybridization (ISH) or immunohistochemistry (IHC), when compared to intact or ovariectomized controls. Similarly, aging alone did not increase arcuate nucleus levels of GFAP, although generalized increases were observed in both the gray and white matter. Therefore, we examined astrocyte responsiveness in the hypothalamus of young mice as a function of normal physiological stimulation, the estrous cycle. Young C57BL/6J mice exhibiting 4-day cycles were anesthetized and perfused in the late morning to generate a pool of brains representative of each cycle day. An additional group was collected on proestrous night. GFAP ISH revealed fluctuations of mRNA in the arcuate nucleus of the hypothalamus with the area of hybridization increasing on the day of proestrous, peaking proestrous night and decreasing thereafter. In summary, because ARC GFAP mRNA fluctuates during the estrous cycle this suggests a role for astrocytes in regional plasticity that may occur around proestrous.

Support for this study was from Grant AG-7909 and AG00300.

CHRONIC EXPOSURE TO ELEVATED CORTICOSTERONE ALTERS SPATIAL MEMORY IN MID-AGE, BUT NOT YOUNG RATS. S.R. Bodnoff, S. Sharma & M.J. Meaney. Douglas Hospital Research Center, Montreal, Canada, H4H 1R3.

Chronic exposure to elevated, stress-like levels of corticosterone (CORT) results in the loss of neurons in the hippocampus (Sapolsky et al., *J. Neurosci*, 1985), a brain region of considerable importance for learning and memory. In previous experiments from this lab, young (3-4 months) rats were treated for 3 months with CORT and spatial memory was assessed in the Morris water maze, a task sensitive to hippocampal damage. We observed rather unimpressive impairments in the CORT-treated rats. Here, we attempted to re-examine the effects of CORT by treating mid-aged rats. We implanted young and mid-aged (11-12 months) Long-Evans rats with fused pellets of CORT that produce plasma CORT levels of 20-25 ug/dl. Spatial memory was assessed using the maze procedure described by Dekker et al. (*Neurosci Abst*, 1990, p. 479). After 3 months of treatment, the mid-aged CORT-treated rats showed significant spatial memory impairments compared with age-matched cholesterol-treated rats and young rats of both treatment conditions. While the groups did not differ during the first 4 days, impairments became obvious during Days 5-7, and by Day 8, all groups attained the same level of performance. These data will be discussed in the context of hippocampal and cortical neuron loss and their relevance for the study of aging.

VASOPRESSIN AND OXYTOCIN CELL NUMBERS IN THE HUMAN HYPOTHALAMUS DURING AGING AND IN ALZHEIMER'S DISEASE. E. Goudsmit and D.F. Swaab*. Netherlands Inst. for Brain Res., Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands.

In order to clarify age-related changes in the human hypothalamo-neurohypophyseal system, total cell numbers and numbers of immunocytochemically identified vasopressin (VP) and oxytocin (OT) cells were determined in the supra-optic (SON) and paraventricular nucleus (PVN) in a series of human hypothalami ranging in age from 10 to 97 years including 10 Alzheimer's disease (AD) cases.

No changes in total cell numbers were observed in the human SON and PVN during the life-span or in AD. The number of OT cells in the PVN also remained unaltered during aging and in AD. In contrast, the number of VP-expressing cells in the PVN showed a gradual increase during aging, suggesting an increase in the rate of synthesis of this peptide. This increase was absent in AD patients. Animal studies suggested that an increase in VP synthesis in senescence might be caused by osmotic stimulation due to a decrease in renal sensitivity to VP.

In contrast to the SON and PVN, the suprachiasmatic nucleus (SCN) shows a marked cell loss in human senescence and even more so in AD, which might be related to a reduced input via the optic nerve. Therefore, differences in age-related cell loss between these hypothalamic nuclei might be related to differences in stimulatory input.

Human brain material was obtained from the Netherlands Brainbank in Amsterdam.

REPRODUCTIVE HISTORY AFFECTS AGING OF GnRH SYSTEM IN THE MALE RAT.
J.W. Wilkin. Dept. Anat. & Cell Biol., Columbia Univ. New York, NY 10032

Gonadotropin releasing hormone (GnRH) neurons receive an increased synaptic input with age beginning as early as 10 months in the virgin male rat. By 20 months, there is a tenfold increase in the density of synapses onto these neurons. (Wilkin, Neurosci. 232:1003, '87). The present study is an examination of this parameter in reproductively active aged male rats. GnRH neurons from three month old rats (N=6) were compared to those from 20 month old rats (N=6) that had been retired from breeding for 3-5 months. Tissue from the preoptic area was prepared for electron microscopic examination using a double label immunocytochemical protocol (Chen et al., J.Comp.Neurol. 232:534, '89) so that we could identify the input by the inhibitory transmitter, gamma amino butyric acid (GABA) to GnRH neurons. Sites of GABA immunoreactivity were visualized after incubation in GAD 6 (a mouse monoclonal antibody to glutamic acid decarboxylase, a gift of Gottlieb, Chang and Gottlieb, J.Neurosci.8:2123, '88) using DAB; sites of GnRH, after incubation in LR1 (a rabbit polyclonal, Benoit) using TMB stabilized with DAB. Photographic montages of GnRH neurons (recognized by the presence of TMB crystals) printed at a final magnification of 25,000X (a minimum of 5 neurons per animal) were measured using a morphometric program (R&M Biometrics). The percent of perikaryal membrane with postsynaptic modification was calculated for each neuron. Similar measurements and calculations were made on random unidentified neurons (one from each section in which a GnRH neuron had been photographed). The density of total synaptic input to GnRH neurons from young and aged animals was not found to be different, using a nonparametric test (Mann-Whitney U, $p < 0.05$). There was also no difference in the density of input to unidentified neurons. However, a larger percentage of the synapses were GABAergic in both the general neuronal population and in GnRH neurons in the older animals, perhaps indicating a general aging phenomenon. The increase in synaptic input to GnRH neurons which was so striking in aging virgin male rats was not observed in the retired breeders. GnRH neurons in aged male rats that have been reproductively active are innervated to the same degree as those in young adult animals. These results suggest that the reproductive history of the animal affects the anatomical milieu of the preoptic area in the male rat and in particular, that of the GnRH neuron. NIH AG05366

Neuronal L-type calcium channels: molecular cloning of an α_1 subunit cDNA and localization in rat brain.

Hyung-Lae Kim*^{||}, Mark A. Smith#, Hyun Kim^{||}, and Hemin Chin^{||}
^{||} Laboratory of Molecular Biology, NINDS, #Clinical Neuroendocrinology Branch, NIMH, NIH, Bethesda, MD, 20892.

We have cloned and sequenced a cDNA (prBCCA1) encoding an α_1 subunit of voltage-sensitive L-type calcium channels (dihydropyridine receptor) of rat brain. The cDNA (8,608 bp) encodes a protein of 2,108 amino acids with a Mr of 236,919. Northern blot analysis revealed that prBCCA1 was transcribed from a ~12 kb mRNA species present in rat brain. The neuroanatomic distribution of prBCCA1 mRNA in rat brain was examined by *in situ* hybridization histochemistry. The highest concentrations of the calcium channel α_1 subunit were found in the olfactory bulb, granular layer of the dentate gyrus, suprachiasmatic nucleus of the hypothalamus, and pituitary and pineal glands. The distribution of the α_1 subunit protein was mapped immunohistochemically with rabbit polyclonal antibodies raised against synthetic peptides containing amino acid sequences specific for the calcium channel α_1 subunit. Brain areas showing strong hybridization signals with the α_1 subunit antisense RNA probes also had high immunoreactivity levels. Thus, regional distribution of the α_1 subunit of L-type calcium channels in rat brain suggest that this type of calcium channel plays an important role in excitation-secretion coupling functions.

309.3

CLONING AND EXPRESSION OF A NOVEL HUMAN NEURONAL CALCIUM CHANNEL. D.H. Feldman, M.E. Williams*, A.F. McCue*, R. Brenner*, G. Velicelib, S.B. Ellis*, M.M. Harpold*, SIBIA Inc., P.O. Box 85200, San Diego, CA 92186.

We have cloned genes encoding subunits of voltage-dependent calcium channels (VDCCs) expressed in human brain and IMR-32 human neuroblastoma cDNA libraries. We report here the cloning and expression of a novel human α_1 subunit gene that encodes a 2161 amino acid protein, with 77.3% similarity to the α_1 subunit of rabbit skeletal muscle [Tanabe *et al* Nature 328:313 (1987), Ellis *et al* Science 241:1661 (1988)] and 80.7% similarity to the rabbit cardiac α_1 subunit [Mikami *et al* Nature 340:230 (1989)]. The predicted a.a. sequence suggests an overall topography shared with other VDCC α_1 genes. We also report α_2 and β subunit genes expressed in human brain that encode proteins of 1091 and 478 amino acids respectively, with 97.2% and 98.3% similarity to the homologous rabbit skeletal muscle genes [Ellis *et al* 88; Ruth *et al* Science 245:1115].

The mRNAs transcribed *in vitro* from the α_1 , α_2 , and β genes were injected in various combinations into *Xenopus* oocytes which were then studied under voltage clamp to detect barium currents. Co-injection of α_1 , α_2 , and β transcripts elicited currents that first activated near -30 mV, reached a peak near 0 mV, inactivated slowly, and were weakly sensitive to holding potential. Bay K 8644 (1 μ M) augmented the currents and dramatically prolonged the tail currents. Nifedipine (5 μ M) blocked the current in a holding potential dependent manner. The currents were reversibly blocked by 50 μ M Cd²⁺ and by 15 μ M ω -conotoxin. Whereas neither α_1 transcripts alone nor α_1 and α_2 together elicited currents, α_1 and β transcripts together elicited DHP-sensitive currents similar to, albeit smaller than, those elicited by α_1 , α_2 , and β in combination.

Thus, we have identified a neuronal L-type VDCC α_1 gene that diverges significantly from previously cloned muscle L-type VDCC α_1 genes. The β subunit appears to serve an obligatory function, whereas the α_2 subunit appears to serve an accessory role that enhances expression of the channel.
