In this study, the effects of a single dose of the indirect dopamine agonists amphetamine (AMPH) and methamphetamine (METH) on mRNA expression of c-fos, a member of the leucine zipper family, and zif268 (NGFI-A, egr1 and Krox-24), a member of the zinc finger family, and the opioid peptide, preprodynorphin (PPD), in various regions of rat forebrain were investigated with quantitative *in situ* hybridization histochemistry 1, 2, 3, 6 or 30 h after injection. A different and more intensive behavioral syndrome was induced following METH (15 mg/kg, i.p.) as compared with that observed after AMPH (5 mg/kg, i.p.). METH induced a far greater increase in c-fos and zif268 mRNA in sensorimotor cortex, dorsal striatum (caudoputamen) and ventral striatum (nucleus accumbens) than did AMPH. The increase in c-fos mRNA expression peaked at 1 h and returned to basal levels in all regions by 3 h. In contrast, the increase in zif268 mRNA expression in the cortical regions was equally strong at 1 and 2 h, gradually returning to basal levels by 6 h after either drug. However, in the striatal regions, zif268 mRNA levels peaked at 1 h and declined gradually to basal levels by 6 h. Interestingly, METH caused an actual suppression of zif268 gene expression (>50%) in both caudate and nucleus accumbens at 3 h. PPD mRNA expression was increased in a patchy motif in the caudoputamen and nucleus accumbens beginning 2 h and returning to basal levels by 30 h after injection of either drug. This study, together with our recently published observation that PPD mRNA is induced in the caudate 3, 6 and 18 h after AMPH or METH injection (Smith and McGinty, Mol. Brain Res., 21:359-362, 1994), provides a detailed description of the differential modulation of c-fos, zif268, and PPD mRNA expression in the cerebral cortex and striatum by amphetamines over time (Supported by DA03982).

MDMA-INDUCED NEUROTOXICITY IN RAPHE PRIMARY CULTURE INVOLVES L-ARGININE-NO AND OXIDATIVE PATHWAYS. C. Cerruti*, P. Sheng, B. Ladenheim, and J.L. Cadet. Molecular Neuropsychiatry Section, NIDA/ARC, Box 5180, Baltimore, MD. 21224

Methylenedioxymethamphetamine (MDMA) is a neurotoxic drug of abuse. Its use is also associated with long-term depletion of serotonin that correlates with morphological damage to serotonergic terminals. The mechanisms by which these drugs destroy 5-HT terminals have yet to be elucidated. It has been pointed out that free radical-mediated events may form a final common pathway in neurotoxic processes. In order to test the role of the free radical, nitric oxide (NO), we have used an *in vitro* model of serotonergic cells cultured from raphe nuclei of rat fetuses. In these cells, MDMA causes dose-dependent cytotoxicity. Cell death was attenuated by the NO synthetase inhibitors, nitro-L-arginine and L-nitro-methylarginine. Moreover, the toxic effects of MDMA were attenuated by benzamide, an inhibitor of ADP-ribosylation. Primary cultures of serotonergic cells obtained from SOD-transgenic mice were also protected against MDMA-induced toxicity. These results suggest that MDMA induces neurotoxicity via NO formation and by the production of superoxide radicals.

DIRECT EFFECTS OF METHAMPHETAMINE ON GLUTAMATERGIC NEURONS. S.S. Chirwa* and M. Clayton. Physiology, Meharry Medical College, 1005 D.B. Todd Blvd, Nashville, TN 37208.

Experiments to determine the direct effects of methamphetamine (METH) on glutamatergic neurons were conducted in hippocampal slices (400 μ m thick) obtained from male guinea pigs (100-150 g). Briefly, slices were maintained in a chamber that was superfused with oxygenated and warmed ACSF (30° C). METH (0.1-1.0 μ M) was superfused for 5-10 min, as appropriate. The bioelectrical parameters of CA1b pyramidal cells were determined, and synaptic efficacy was evaluated via the analyses of dendritic EPSPs associated with single and paired-pulses. Briefly, CA1b neurons exposed to METH showed significant dose-dependent decreases in rheobase (50-83% of controls; n=18 cells; p<0.05, ANOVA/Duncans tests in this and subsequent entries) and in afterhyperpolarization (32-97% of control; n=18 cells). Resting membrane potential was unaltered in all cells and, therefore, could not account for the above changes. Similarly, there were insignificant changes to action potential and input resistance. METH caused reversible augmentation of single EPSPs (140-470% of controls; n=6 slices) and attenuation of paired pulse facilitation (65-80% of controls; n=6 slices). A decrease in rheobase could reflect drug-induced changes to specific ionic conductance. An augmented EPSP to single stimuli, taken together with attenuation of paired-pulse facilitation, suggests increases in evoked glutamate release. Supported by NIH grant G12-RR03032.

H.M.'s MRI SCAN SHOWS SPARING OF THE POSTERIOR HALF OF THE HIPPOCAMPUS AND PARAHIPPOCAMPAL GYRUS S. Corkin*, D. G. Amaral, K. A. Johnson, and B. T. Hyman. Dept. of Brain and Cognitive Sciences and the Clinical Research Center, MIT, Cambridge, MA, 02139; Center for Behavioral Neuroscience, SUNY, Stony Brook, NY, 11794; Dept. of Radiology, Brigham and Women's Hospital, Boston, MA, 02115; Dept. of Neurology, Mass. General Hospital, Boston, MA, 02114.

Decades of research with H.M. and other amnesic subjects has established that the hippocampus and surrounding medial temporal-lobe structures are necessary for long-term explicit memory. Yet we continue to explore the importance of particular medial temporal areas for memory function, and examine the correspondence between the critical lesion in human amnesia and in the nonhuman primate model. An important step is to document as precisely as possible the extent of the lesions in human amnesic subjects. We therefore performed high-resolution MRI studies in H.M. (at age 66), using a 1.5 Tesla GE Signa System. Axial and coronal T1-weighted (TR=550 msec; TE=16 msec) and T2-weighted (TR=2500 msec; TE=90 msec) images were acquired with a 5-mm slice thickness and a 1-mm interval between slices (matrix=256 x 192 pixels; NEX=1; FOV=22 cm). The bilateral lesion includes the medial temporal pole, amygdala, and entorhinal cortex. Approximately the anterior 2 cm of the dentate gyrus, hippocampus, and subicular complex are removed, but the posterior 2 to 2.5 cm of these fields are intact but shrunken. The rostral perirhinal cortex is also removed, but because the collateral sulcus and its medial cortex are visible, at least some of the posterior perirhinal and parahippocampal cortex may be intact. Neocortical atrophy is slight and consistent with his age. The cerebellum is noticeably atrophic (likely due to antiepileptic drug therapy). Future imaging studies with MRI and PET, respectively, will provide volume measurements of specific brain areas, and will assess the functional status of the remaining hippocampal tissue.

COGNITIVE PROCESSES UNDERLYING RECOGNITION MEMORY: EVIDENCE FOR A SPECIFIC IMPAIRMENT OF RECOLLECTION IN AMNESIA. A. D. Wagner*, M. Verfaellie, P. Croce, and J. D. E. Gabrieli. Dept. of Psychology, Stanford University, Stanford, CA 94305 and Memory Disorders Research Center, Boston University School of Medicine and DVAMC, Boston, MA 02130.

Studies of recognition performance in normal subjects suggest that two separable processes mediate recognition memory: controlled recollection and automatic fluency. It has been proposed that recognition failure in amnesia (AMN) reflects a disproportionate impairment of recollection and that fluency may be spared. We examined the status of recollection and fluency in AMN by equating the recognition memory performance of 8 AMN patients and 11 control (CON) subjects. CON subjects were presented single study and yes/no recognition test trials for separate lists of high-frequency (HF) (mean of 135/mil) and low-frequency (LF) (mean of 2.5/mil) words. For each list, AMN patients had the same initial study and test trial followed by seven additional study-test sequences with these same words and new distractors in each test. CON subjects had better recognition than AMN patients in the first trial and also showed superior recognition accuracy for LF versus HF words. The additional study-test trials equated AMN patients' recognition accuracy with that of CON subjects for HF words, but failed to equate the same patients' recognition of LF words. A separate study with 96 college students indicated that recollection may play a greater role in recognition of LF than HF words. Taken together, these results suggest that the improved recognition performance exhibited by AMN patients following extra study-test trials reflects fluency processes and not recollection processes. These findings indicate that the processing basis of recognition performance in AMN patients following extra study is not the same as that of CON subjects, even when recognition accuracy is numerically equated, and that recollection, relative to fluency, is disproportionately impaired in AMN. Supported by grants from the NSF and NIH (NINDS 1P50NS26985 and NIA RO1AG11121).

DISSOCIATION BETWEEN FORMS OF ASSOCIATIVE IMPLICIT MEMORY THAT ARE INTACT OR IMPAIRED IN GLOBAL AMNESIA. E. D. Levy*, J. D. E. Gabrieli, S. L. Reminger, and W. S. Francis. Depts. of Psychology, Stanford University, Stanford, CA 94305 and Northwestern University, Evanston, IL 60208.

Patients with amnesia have a deficit in learning new associations between words when memory is measured by explicit tests. Amnesic patients have a more variable pattern of results when learning of such new associations is measured by implicit tests. They are impaired when the implicit test is one of stem completion (SC), but they have shown normal learning when the test is one of reading speed (RS) or perceptual identification (PI). In the present studies, we examined whether normal subjects show a similar dissociation between different measures of implicit memory for new associations. In the first study, subjects either read aloud word pairs or generated sentences. In the test phase, subjects performed either a SC or a PI test with word pairs identical to those studied (same context), recombinations of studied words (different context), and new items (baseline). The measure of associative learning was the difference in priming between same-context and different-context pairs. For SC priming, associative learning occurred only if subjects performed the more elaborative sentence-generation task. In contrast, subjects showed associative PI priming after both reading and sentence-generation study tasks. Additional studies examined associative priming as measured by RS. In one experiment, subjects read aloud word pairs with or without imagery instructions in the study phase. While explicit memory was superior in the imagery condition, associative priming was similar in both conditions. Further experiments indicated that associative priming, as measured by RS, includes both a perceptual component (it was diminished when words were studied auditorially and tested visually) and a productive component (it was eliminated if subjects read the word pairs aloud in reverse order). Results indicate that different implicit tests of the learning of new associations provide measures of dissociable memory mechanisms. The PI and RS tests may reveal perceptual and productive associative mechanisms that do not require study-phase elaboration and that do not depend upon declarative memory processes. SC tests may reveal lexical or semantic associative mechanisms that require elaborative study and that depend upon declarative memory processes. Supported by grants from the NSF and NIH.

H.M. SHOWS IMPAIRED WORD-STEM COMPLETION PRIMING WITH NOVEL WORDS B. R. Postle* and S. Corkin. Dept. of Brain and Cognitive Sciences, and the Clinical Research Center, MIT, Cambridge, MA, 02139.

Evidence of intact perceptual priming with novel stimuli (patterns, pseudowords) in amnesic subjects suggests that they may be able to learn novel information when tested with other repetition priming paradigms. To test this hypothesis, we examined word-stem completion priming with novel words in the amnesic patient H.M. (age = 67 yrs; ed. = 12 yrs), who shows normal word-stem completion priming with familiar words. He underwent bilateral medial temporal resection in 1953 to alleviate intractable epilepsy. His performance was compared to that of 10 age- and education-matched control subjects (NCS). Subjects were tested on word-stem completion priming, cued recall, and a vocabulary test (four-alternative forced-choice). The stimuli were common English words that entered the dictionary after 1965, and thus came into general usage after the onset of H.M.'s amnesia, i.e., words for which he presumably lacked a lexical representation. We computed the mean percentage of word stems completed to studied versus unstudied words. As expected, H.M.'s cued recall score (10.5%) was inferior to the NCS's score (35.3%) ($p < .001$). On priming, H.M.'s score (1.3%) was also inferior to the NCS's score (16.1%) ($p = .0001$). His failure to prime with post-1965 words suggests that word-stem completion priming relies on pre-existing lexical representations of the stimulus material. Further support for this view comes from the finding that NCS showed greater priming with words pronounced correctly at study than with mispronounced words ($p = .0001$). Correct pronunciation may be an index of lexical representation because the NCS had higher vocabulary scores for words pronounced correctly at study (89.3%) than for mispronounced words (73.4%) ($p < .03$). H.M.'s mean vocabulary score (43.9%) was inferior to the NCS's (84.8%) ($p = .0001$). We propose that activation of pre-existing lexical representations at study and test is the mechanism for word-stem completion priming. Word-stem completion priming, unlike perceptually dependent forms of priming with words, requires subjects to engage in lexical retrieval.

THE CORE MEMORY DEFICIT IN AMNESIA IS NEITHER ONE OF CONCEPTUAL PROCESSING NOR ONE OF EXPLICIT RETRIEVAL. C. J. Vaidya, J. B. Domb, M. M. Keane*, L. A. Monti, N. J. Cohen, R. A. Poldrack, and J. D. E. Gabrieli. Dept. of Psychology, Stanford Univ, Stanford, CA 94305; Memory Disorders Research Center, Boston VA, Boston, MA 02130; Dept. of Neurological Sciences, Rush Med Center, Chicago, IL 60612; Beckman Institute, Univ of Illinois, Urbana-Champaign, IL, 61801.

Amnesic patients' memory is often intact on implicit tasks, despite severe deficits on explicit tasks. Because most implicit tasks depend on perceptual processing, and most explicit tasks on conceptual processing, it has been proposed that the core memory deficit in amnesia is one of conceptual processing. By this view, amnesic patients should be impaired on both implicit and explicit tasks that require conceptual processing, and intact on both implicit and explicit tasks that require perceptual processing. To test this view, 23 amnesic and 23 control subjects performed four tasks: implicit-perceptual (word fragment completion), implicit-conceptual (word association), explicit-perceptual (word fragment cued-recall), and explicit-conceptual (word associate cued-recall). A study-phase modality (auditory/visual) manipulation validated the nature of processes (perceptual and conceptual) engaged by each task. Amnesic patients were impaired on both explicit tasks (perceptual and conceptual) and intact on both implicit tasks. Thus, the core memory deficit in amnesia is not one of conceptual processing. Alternatively, amnesia may reflect impaired declarative processes, rather than impaired explicit retrieval per se, because explicit tasks require processing of declarative or relational information. By this view, amnesic patients should be impaired on any task that requires declarative processing, regardless of the retrieval instructions. To test this view, 10 amnesic and 11 control subjects performed the general knowledge task, under implicit and explicit retrieval instructions. Amnesic patients were impaired under both implicit and explicit instructions. Results are consistent with multiple memory systems views positing that amnesia reflects a selective impairment in a limbic-diencephalic memory system that is engaged during declarative processing.

MAPPING IMPLICIT MEMORY WITH ELECTRICAL BRAIN STIMULATION: DISSOCIATIONS BETWEEN AUDITORY AND VISUAL STUDY MODALITIES. T. A. Blaxton*, B. Malow, C. Figliozzi, S. Sato, C. Kuffa, S. Bookheimer, and W. Theodore. Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892.

Functional mapping of implicit memory was examined via electrical stimulation of subdural electrodes implanted in the speech dominant hemispheres of eight temporal lobe epilepsy patients. All patients were undergoing speech mapping prior to temporal lobe resection for treatment of intractable seizures. Memory materials were presented as subjects performed language tasks such as confrontation naming of single pictures and identification of objects from an array of four pictures. Auditory presentation of memory materials occurred as patients performed an auditory responsive naming task (e.g., answering questions such as "Tell me what you carve at Halloween"). These and other tasks were interleaved together and electrical stimulation (2-15mA) was delivered periodically to selected brain sites as patients performed the tasks. Implicit memory was assessed as subjects performed a category member production task without stimulation. In this task patients were asked to name three items from a given category and priming was observed when patients were more likely to provide target items recently presented during the language tasks as category exemplars than nonstudied targets. Priming on category member generation was unaffected by stimulation of parietal cortex, which served as a control region. Priming for both visually and auditorily presented items was disrupted from electrical stimulation of lateral temporal cortex. Priming from visually presented targets was eliminated altogether when brain sites in the inferior and basal temporal cortex were stimulated during study, although stimulation in this region did not impair auditory priming nearly as severely. In contrast, priming from auditorily presented items was disrupted by stimulation of frontal cortex more than priming from visually presented items.

PET ACTIVATION MEASURES REVEAL A DISSOCIATION BETWEEN BRAIN REGIONS UNDERLYING PERCEPTUAL AND CONCEPTUAL PROCESSES IN PICTURE-NAMING PRIMING. S. M. Park*, T. A. Blaxton, J. D. E. Gabrieli, C. M. Figlozzi, and W. H. Theodore. Department of Psychology, Stanford University, Stanford, CA 94305; Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892.

Picture-naming (PN) priming has been shown to be mediated by perceptual and conceptual processes. Priming produced by repeated picture naming (P-P) involves perceptual and conceptual processes; priming produced by prior reading of picture labels (words) (W-P) involves conceptual processes. The neuroanatomical bases for the perceptual and conceptual processes underlying PN priming were examined using positron emission tomography (PET). While performing a PN task, regional cerebral blood flow was measured in 12 normal subjects tested in a Scanditronix II scanner using six injections of ^{15}O . The design employed 3 study-test conditions that were administered twice; scans were taken during each test phase. In the baseline condition, subjects named pictures and then different, nonstudied pictures. In the P-P condition, subjects named pictures and then renamed those same pictures. In the W-P condition, subjects read words and then named pictures corresponding to those word labels. PET images were analyzed using Statistical Parametric Mapping (all tests were set at $p < .01$). Deactivations for P-P priming relative to baseline were found in right lingual gyrus, right inferior occipital gyrus, and bilateral fusiform gyri, and for W-P priming in the left transverse temporal gyrus. A comparison between P-P and W-P naming revealed more activation in right precuneus, right superior temporal gyrus, right middle frontal gyrus, and cingulate for P-P priming, and more activation in left hippocampus, left temporal gyrus, left inferior frontal gyrus, bilateral fusiform, and left inferior occipital gyrus for W-P naming. Across comparisons, perceptual processes tended to involve bilateral posterior regions of the brain, whereas conceptual processes engaged more left temporal and anterior regions. These results suggest that separable neural substrates mediate perceptual and conceptual priming processes.

530.9

HIPPOCAMPAL ACTIVATION IN fMRI EVOKED BY DEMAND FOR DECLARATIVE MEMORY-BASED BINDING OF MULTIPLE STREAMS OF INFORMATION. N. J. Cohen*, C. Ramzy, X. Hu, H. Tomaso, J. Strupp, P. Erhard, P. Anderson, & K. Ugurbil. Beckman Institute & Department of Psychology, University of Illinois, Urbana-Champaign, IL, 61801; Center for Magnetic Resonance Research, University of Minnesota Medical School, Minneapolis, MN, 55455.

Despite abundant evidence linking the hippocampal system to memory, it has been difficult to find reliable hippocampal activation in functional brain imaging studies of memory performance. Here we report robust hippocampal activation in a functional MR imaging (fMRI) study that was based on Cohen and Eichenbaum's (1993) proposal linking hippocampal system function to declarative memory for the relations among perceptually distinct objects. Seven normal volunteers participated in two tasks involving the processing of color images of faces. In different conditions, the faces were presented alone, or with the superimposition of a name, or of a name and an occupation-related icon. In the baseline task, S's made gender decisions about each face, ignoring any names or icons that were presented with them. In the memory task, S's had a series of alternating study and test conditions requiring the binding together of the 3 different streams of information. The declarative-memory dependence of this task was verified in behavioral testing of one well-characterized amnesic patient who performed at chance levels (vs 78% correct for the normal S's). Using a TURBO FLASH gradient-echo pulse sequence, 18 sagittal slices of the brain were collected at the rate of 1 per sec throughout the entire 30-minute (baseline and memory task) session. In each of the 7 S's, activation (increased signal intensity on 99%-confidence T-maps) was observed in left hippocampal and parahippocampal regions in a comparison of baseline task versus memory task. Activation was initiated at the outset of the study phase of the first memory test condition and stayed elevated above baseline levels throughout the 8 memory (study + test) task conditions.

530.11

VERBAL MEMORY IMPAIRMENT AFTER RIGHT TEMPORAL-LOBE EXCISION: THE ROLE OF ABNORMALITY ON THE UNOPERATED SIDE AS REVEALED BY ^1H MRS AND T_2 RELAXOMETRY. A. Incisa della Rocchetta, D.G. Gadian, A. Connelly, C.E. Polke, G.D. Jackson, K. Watkins, C.L. Johnson, M. Mishkin, and F. Vargha-Khadem. SPON: European Brain and Behaviour Society. Neurosciences Unit, Institute of Child Health, University of London, Mecklenburgh Square London WC1N 2AP U.K.

Verbal memory deficits are not usually observed following unilateral right anterior temporal excision for the relief of pharmacologically intractable epilepsy. In individuals in whom this pattern occurs, there could be undetected abnormality in the unoperated left temporal lobe. Performance on verbal memory tests was assessed in relation to both side of temporal lobe surgery and the presence or absence of abnormalities in the contralateral, unoperated, temporal lobe as revealed by MR spectroscopy or T_2 relaxometry. Forty-eight patients who had undergone either en-bloc temporal lobectomy or selective amygdalo-hippocampectomy were tested on Logical Memory and Paired Associate Learning from the Wechsler Memory Scale Form I. ^1H MRS and T_2 Relaxometry were used to detect temporal-lobe abnormalities on the side contralateral to the operated one. Excision in the left temporal lobe impaired immediate and delayed recall of the Logical Memory prose passages as well as performance on the third learning trial and delayed recall of paired associates, irrespective of the presence or absence of contralateral abnormality. Excisions in the right temporal lobe also impaired delayed recall of both the prose passages and paired associates, but only if there was abnormality on the contralateral side. Verbal memory deficits in the right temporal-lobe patients can be attributed to abnormality in the left temporal region, contralateral to the excision; therefore the present results underscore the usefulness of MRI and MRS in uncovering abnormalities in the temporal lobe that can go undetected using other diagnostic procedures.

530.8

A FUNCTIONAL MRI STUDY OF LONG-TERM EXPLICIT MEMORY IN HUMANS. CE Stern*, S. Corkin, AR Guimaraes, R. Sugita, CA Carr, JR Baker, PJ Jennings, RG González, BR Rosen. Harvard Medical School and MGH-NMR Center, Charlestown, MA 02129, Dept. of Brain and Cognitive Sciences and the Clinical Research Center, M.I.T., Cambridge, MA 02139.

It has been postulated that during learning an interaction is established between the medial temporal memory system and distributed storage sites in the neocortex. Using functional MRI (fMRI), we studied young normal subjects while they performed picture encoding ($n = 7$) and picture recognition ($n = 5$) tasks. High speed echo-planar imaging (EPI) techniques were combined with asymmetric spin-echo imaging sequences to simultaneously evaluate fMRI signal changes throughout the whole brain. To assess picture encoding, subjects were asked to look at a consecutive series of complex, colored pictures so that they could recognize them later. As a control condition, subjects were scanned while viewing a single repeating picture. Subtraction images (encoding minus control) showed significant signal intensity increases bilaterally in hippocampal and parahippocampal regions and at the temporal-occipital junction. Recognition memory was assessed by subtracting images obtained during a two-alternative, forced-choice recognition test (identify previously viewed pictures) from images obtained during a two-alternative, forced-choice identification test (identify indoor vs. outdoor pictures). The subtraction images revealed significant fMRI changes bilaterally in prefrontal cortex (areas 46 and 10). This fMRI experiment provides new evidence about the participation of the medial temporal system during information encoding and also about the locus of cortical areas that support picture recognition memory.

530.10

A FUNCTIONAL MRI (fMRI) STUDY OF SEMANTIC ENCODING AND MEMORY IN THE LEFT INFERIOR FRONTAL GYRUS. J.B. Demb*, J.E. Desmond, A.D. Wagner, M. Stone, A.T. Lee, G.H. Glover, and J.D.E. Gabrieli. Depts. of Psychology and Radiology, Stanford University, Stanford, CA 94305.

Brain imaging (PET) and clinical studies have indicated a role for the left inferior frontal gyrus (LIFG) in semantic processing. We investigated this system using fMRI and a levels-of-processing paradigm. A standard 1.5T GE Signa Magnet was used with a T_2^* sensitive gradient echo spiral sequence ($\text{TR}=75$ ms, $\text{TE}=40$ ms, flip angle= 23°). Two 7-mm functional slices were acquired separately in the Talairach & Tournoux (1988) coronal plane ($y = +32, +39$; 1.8mm pixel size). Images were acquired every 1.5 seconds for 5.5 minutes. Subjects viewed words continuously and switched between performing semantic judgements (e.g., respond to abstract but not concrete words) and nonsemantic judgements (e.g., respond to words printed in upper but not lower case) every 20 words for four cycles. Data were analyzed by correlating activation over time to a sinusoidal reference vector. Areas in the LIFG, but not in the analogous region in the right hemisphere, showed activation that correlated significantly with the reference vector ($r=.30$). There was an increase in activation during the semantic task. In a second experiment at the same slices, subjects performed the semantic task on blocks of 20 words shown for a first time (new) and then repeated for a second time (old) in successive blocks. There was less activation in the LIFG for old than for new words. The deactivation may reflect implicit conceptual memory (repetition priming) for old words. Thus, it appears that the same LIFG region that was important for semantic encoding was also the locus for item-specific semantic memory for words. These results indicate that fMRI may be useful in detecting the brain locus of semantic encoding and memory. Supported by grants from the NIH (F32NS09628), the Alzheimer's Association, Stanford Office of Technology and Licensing, and the Lucas Foundation.

530.12

A POSITRON EMISSION TOMOGRAPHY (PET) STUDY OF REGIONAL CEREBRAL BLOOD FLOW (rCBF) DURING LONG- AND SHORT-TERM VERBAL MEMORY. D.S. O'Leary*, N.C. Andreasen, R.R. Hurtig, Mental Health Clinical Research Center, Dept of Psychiatry, Univ of Iowa College of Medicine, Iowa City IA 52244

We assessed rCBF with PET using the bolus ^{15}O -labelled water method in 13 normal adult volunteers performing auditory, verbal memory tasks. One week prior to PET imaging subjects learned a 15 word list and a short verbal passage. Subjects practiced the material to 100% correct recall again one day before imaging. During two conditions of the eight condition PET study, the list and passage were read to the subjects immediately prior to image acquisition. During two other conditions a novel word list and novel passage were read to the subjects. Following reading of the material each subject immediately began recall; this was timed for each condition to occur about 10 s prior to arrival of the bolus of ^{15}O -labelled water in the brain. Other conditions in the study were a resting baseline, recall of a personal episode from the subject's past, a verbal fluency task, and a repeat of the familiar verbal passage to assess replicability of rCBF changes. Compared to resting baseline, there were increases in rCBF in left precentral gyrus in all conditions which were related to the quantity of verbal production during each task. There were also large increases in flow in cerebellum in all conditions which were less directly related to vocal output. Subtraction of the familiar from the novel verbal conditions showed increased flow in the short-term memory conditions in right cerebellum for both the word list and passage, and in the left dorsolateral frontal lobe for the list. Flow in mesial temporal lobe structures did not differ significantly from baseline in any memory task. Interestingly, although all activation conditions required the subject to speak, the left frontal region corresponding to Broca's area showed increased flow over baseline only in the verbal fluency task. The present findings as well as other PET studies from our group and other centers suggest that current conceptions of the localization of memory and other functions based on lesion data will require major revision.

530.13

THE ACQUISITION AND RETENTION OF A MOTOR SKILL: A FUNCTIONAL MRI STUDY OF LONG-TERM MOTOR CORTEX PLASTICITY A. Kami¹*, G. Meyer¹, J. P. Jezzard², M. Adams¹, R. Turner² and L.G. Ungerleider¹, ¹NIMH & ²NHLBI, NIH, Bethesda MD 20892.

The speed at which a short sequence of finger-to-thumb-oppositions is accurately performed more than doubles with practice over a period of several weeks. This learning does not generalize to a matched sequence made of identical component movements, nor to the contralateral hand. These results suggest that a discrete, highly lateralized, motor representation of the learned sequence undergoes experience dependent plasticity. We studied the local blood-oxygenation-level-dependent fMRI signal in primary motor (M1) cortex on consecutive weekly sessions by comparing the activation maps induced by 2 matched sequences (A, B) tapped at a fixed rate of 2 taps/sec. Four contiguous parasagittal slices (centered 30mm from midline; slice thickness 5mm) were acquired at 4T using gradient echo EPI (TR=2000ms; TE=26ms; FOV=16cm; 64x64). A rest-X1-rest-X2-rest design was employed where X1 and X2 were, respectively, sequences AB, BA, BB or AA. Subjects were taught both sequences, and initial performance was measured immediately before the first scanning session. Thereafter, one sequence was selected to be practiced daily for several weeks, while the other was performed only during scanning.

Results (4 Ss): 1) Before training, a comparable area was activated in M1 by both A and B. However, a given sequence consistently gave a smaller area if executed second rather than first ("ordering" effect). 2) By week 4 of training - concurrent with superior performance - the extent of cortex activated by the practiced sequence had increased significantly, overriding the ordering effect. This change persisted for at least several weeks, as did improved performance.

These results suggest 2 independent activity-related changes in M1: A short-term, within-session, habituation-like effect, and a slowly evolving, long-term reorganization which may underlie the acquisition of the motor skill. As the latter is highly specific for sequence, not component movements, we conjecture that practice recruits M1 units into the representation of the learned sequence.

Differences in Processing Spatial Information by Women and Men as Revealed by PET. Lauber, E.*, Jonides, J., Koeppe, R., Awh, E., Schumacher, E., Smith, E., and Minoshima, E.

Re-analysis of work presented previously (Jonides, et al., 1993, *Nature*, 363, 623-625) allowed us to search for sex differences in processing of spatial information. In the original work seven women and eleven men were given a spatial working memory task while PET blood flow measures were taken. Three dots were presented briefly on a CRT, followed by a brief delay, followed by a probe circle to which subjects indicated if it encircled one of the previous dots. No differences in behavioral performance were observed between males and females. However, after subtracting a control condition that was similar in all respects except for the absence of a delay period, PET blood flow data revealed differences in activation patterns for the two groups. Though both groups showed activation in Right Brodmann's Areas 40 and 6, only women showed activation in Left Area 44, 40, and 6. In contrast, areas unique for the men were Right and Left Areas 47 and Medial Area 32. The data are interpreted as supporting differences in processing spatial information by women and men. Women showed a clear left hemisphere dominance for spatial working memory while men revealed more right hemisphere activation. Activation of Broca's area (Left Area 44) suggests that the women may have adopted a verbal encoding strategy resulting in performance similar to men.

PROCESS OUTGROWTH AND ADHESION MOLECULES

DEVELOPMENTAL INCREASE IN POLYSIALIC ACID ON NCAM FACILITATES COLLATERAL BRANCHING OF CORTICOSPINAL AXONS. M.M. Daston¹*, M. Bassemeyer¹, U. Rutishauser² and D.D.M. O'Leary¹, ¹The Salk Institute and ²Case Western Reserve University.

Corticospinal tract (CST) axons innervate their spinal cord targets by extending collateral branches. These branches begin to arise along the axon on P4, days after the primary growth cones have passed their targets. The neural cell adhesion molecule (NCAM) is often modified by the addition of polysialic acid (PSA). PSA has been implicated as a regulator of axon growth and pathfinding because of its ability to alter cell-cell interactions. We have found that the extension of collateral branches from CST axons is influenced by the PSA moiety on NCAM.

To assess the distribution of NCAM-PSA, we immunostained transverse sections of rat spinal cords over the first postnatal week. At all ages, NCAM is broadly distributed in the spinal cord, found in the spinal grey terminal fields and in the CST. However, PSA staining is weak or absent over most of the spinal cord, with the exception of the CST. The PSA staining in the CST is weak at P0 to P2, but becomes intense by P4, the age when collateral branches begin to form.

To examine the role of PSA in the extension of collateral branches, we injected endo N, which cleaves PSA from NCAM, into the fourth ventricle of neonatal rats. Immunostaining revealed that PSA was completely eliminated whereas NCAM appeared normal. CST axons were labeled by Dil injected in motor cortex. In endo N-treated rats examined at P4, 5 or 6, many fewer axon collaterals extended from the CST into the surrounding spinal grey compared to normal rats or rats injected with inactive endo N. These results suggest that the increase in PSA that occurs preferentially in the CST facilitates innervation of the spinal grey. The role of PSA may be to attenuate axon-axon interactions in the CST and thus enhance an axon's ability to respond to targeting cues.

L1 EXPRESSION MARKS TRANSLAMINAR AXON SPROUTING IN RAT DENTATE GYRUS FOLLOWING ENTORRHINAL CORTEX LESION Styren, S.D.* S.T. DeKosky, P. D. Miller, G. C. Styren and C.F. Lagenaur Depts. of Psychiatry, Neurobiology, Neurological Surgery, and Neurology Western Psychiatric Inst. & Clinic and Univ. of Pittsburgh Sch. of Med. Pittsburgh, PA 15123

L1 is a cell adhesion molecule important in axonal growth and fasciculation within the CNS. We examined the role of L1 in reactive synaptogenesis and axonal growth following denervation of the hippocampal dentate gyrus molecular layer (ML) by entorhinal cortex (ERC) lesion. We compared immunohistological and ultrastructural distribution of L1 in the denervated ML and employed image analysis to evaluate lamina-specific changes over time. L1 staining was uniformly distributed over the ML in unlesioned animals. 2 days after ERC lesion there was a paucity of staining in the denervated outer ML, while inner ML staining was unchanged. During the 30 days following lesion, commissural and associational (C/A) afferents from inner ML sprouted pathway into the denervated zone. L1 was expressed on these sprouting afferents and exactly corresponded to fiber outgrowth as assessed by Holmes fiber stain. As the L1-bearing axons of the C/A projection expanded, staining for embryonic N-CAM (re-expressed on the dendrites of the denervated zone) appeared to recede; there was never overlap of L1 and embryonic N-CAM staining. Ultrastructural analysis confirmed localization of L1 staining to axonal profiles. These changes in cell adhesion molecule expression closely paralleled the known sequence of reactive synaptogenesis and axonal sprouting, and demonstrate a link between cell adhesion molecule expression and axonal sprouting and attempts at self-repair by the CNS.

REGIONAL LASER INACTIVATION OF L1 AND NCAM AFFECTS GROWTH CONE MOTILITY IN CHICK DRG NEURONS. K. Takei*, T. Chan and D. G. Jay, Dept. of Cell. and Mol. Biology, Harvard University, Cambridge, MA 02138.

L1 and NCAM are neural cell adhesion molecules that belong to the Ig superfamily and are abundantly expressed in the developing nervous system. We have used regional inactivation of these molecules to investigate the role they play in growth cone motility. Microscale chromophore-assisted laser inactivation (micro-CALI) was performed on chick DRG neurons cultured on laminin and L1 substrates. Using micro-CALI, we are able to produce highly localized damage of target molecules in the growth cone that are bound with malachite green (MG)-labeled antibodies. To inactivate intracellular domains of the molecules, the MG-labeled antibodies were loaded into cells by trituration; a high level of retention of the antibodies was observed up to 8 hr later by immunocytochemistry. Micro-CALI of L1 and NCAM (180kD isoform) in the growth cone of DRG neurons grown on laminin substrate induced filopodial and lamellipodial collapse. When DRG neurons were grown on L1 substrate, micro-CALI of L1 resulted in dramatic retractions of the whole neurite as well as regional retractions of the growth cone. Laser irradiation of neurons loaded with MG-labeled bovine serum albumin, MG-labeled non-specific antibodies or without antibodies did not affect growth cone behavior. These data strongly suggest that L1 and NCAM play a key role in growth cone motility. Our findings may help us to define the physiological role of L1 and NCAM in axonal pathfinding mechanisms.

531.4

REMOVAL OF PSA FROM NCAM ENHANCES NEURITE GROWTH FROM AMACRINE CELLS IN CULTURE. L.J. Kijavini¹*, C. Lagenaur², M.L. Ignatius¹, ¹Dept. MCB, U.C.Berkeley, ²Dept. Neurobiol. U. Pittsburgh.

Amacrine cells are retinal interneurons that project relatively short processes onto neighboring cells exclusively within the inner plexiform layer (IPL). Our studies have focused on defining the factors that regulate amacrine cell neurite growth. Recently, we demonstrated that NCAM functions as a neurite growth-promoting factor for rat amacrine cells in culture. However, NCAM can exist in a number of different forms which can alter its function, one of which involves a decrease in the polysialic (PSA) content as the nervous system matures. We have found similar decreases in PSA levels within the IPL. At postnatal day 3 (P3) in the rat retina the IPL is highly immunoreactive for PSA, whereas at later ages (P25) PSA immunoreactivity is absent. The loss of PSA has been shown to enhance NCAM-NCAM adhesion and inhibit NCAM dependent neurite growth in other cell types. We tested the effectiveness of NCAM to promote neurite growth from amacrine cells in culture after PSA was removed. Amacrine cells derived from P3 rat retina were cultured on affinity purified NCAM rich in PSA. PSA was removed from the culture substrate by using neuraminidase before plating cells or removed from both the culture substrate and amacrine cell surfaces using the enzyme Endo-N. Total neurite lengths for amacrine cells after 24 hours in culture increased by 49% when PSA was removed from the substrate and 78% when PSA was removed from both the substrate and amacrine cell surfaces (Control, 67.4µm±1.9; Neuraminidase, 97.2µm±1.0; Endo-N, 116.7µm±1.6). After 8 hours in culture, 68%±2.1 of the amacrine cells had formed distinct lamellipodia following PSA removal whereas only 8%±4.3 did in control cultures. These results show that removal of PSA causes an increase in the rate of neurite growth from amacrine cells cultured on purified NCAM substrates. FUNCTIONAL ANALYSIS OF CELL ADHESION MOLECULE L1 USING DEFECTIVE HERPES SIMPLEX VIRUS VECTORS.

T. Yazaki*, R. L. Martuza and S. D. Rabkin. Dept. of Neurosurgery, Georgetown University Medical Center, Washington, D. C. 20007.

L1, a member of immunoglobulin superfamily, is a transmembraneous glycoprotein that promotes neurite outgrowth and cell migration. L1 is expressed in neurons and peripheral schwann cells, and potentially involved in neural regeneration through a homophilic adhesion mechanism. Plasmid-based defective herpes simplex virus (HSV) vectors are an efficient means to transfer genes into the central nervous system (CNS). To characterize the functional role of L1, we constructed several defective HSV vectors containing the CMV_{IE} or GFAP promoter upstream of human or rat L1 cDNA.

Primary, cultured rat astrocytes and several cell lines, which do not express L1, were infected with defective HSV vectors containing human or rat L1. At 30 hours after infection, cells were fixed and stained with polyclonal antibody against L1. The CMV promoter efficiently drove L1 expression in both primary astrocytes and cell lines, whereas GFAP promoter drove L1 specifically in primary astrocytes. Primary astrocytes, Vero cells and rabbit skin cells expressing L1, after infection with defective HSV vectors, were morphologically altered. The cells contained long processes with many branches. The morphological change was not observed in cells infected with defective HSV vectors expressing β -galactosidase or alkaline phosphatase.

These defective HSV vectors will be used to study the functional role of L1 in neural regeneration.

531.7

SUBSTRATE-BOUND L1 ACCELERATES AXONAL GROWTH BY CULTURED RAT HIPPOCAMPAL CELLS. T. Esch¹, V. Lemmon², and G. Banker¹. ¹Dept. Neurosci., Univ. of Virginia Sch. of Med., Charlottesville, VA, 22908 and ²Dept. Neurosci., Case Western Reserve Univ., Cleveland, OH, 44106.

We examined the influence of the cell adhesion molecule L1 on the development of polarity by embryonic rat hippocampal neurons in culture. Neurons were cultured on nitrocellulose-treated glass coverslips coated with 8D9, the chick homolog of L1, or on coverslips coated with polylysine (PL). L1 selectively stimulated axonal growth and accelerated the development of morphological polarity. After 8 h. in culture, 37% of cells grown on L1 had formed axons compared with less than 1% of cells grown on PL. By 24 h., 99% of cells on L1 and 71% of cells on PL had formed axons, and the axons of cells grown on L1 were about four times longer than those on PL. In addition, 24% of cells on L1 developed two axons after 24 h. The length of minor processes did not differ on the two substrates. Despite these pronounced changes in cell shape, polarity markers segregated similarly on the two substrates. L1 became restricted to axons while MAP2, transferrin receptor, and LDL-receptor related protein segregated to somata and dendrites on both L1 and PL. By 3 weeks in culture, cells grown on L1 had formed well-differentiated dendrites, as indicated by their morphology after MAP2 staining, and they were contacted by numerous synaptophysin-positive presynaptic terminals. The selective effect of L1 on axonal growth is not surprising, since substrate-bound L1 would be expected to bind homophilically to neuronal L1, which is restricted to the axonal surface. The relatively normal development of dendrites on the L1 substrate may have been mediated by small amounts of L1 on the dendrites. Alternatively, an adhesion molecule that interacts with L1 in a heterophilic manner may be present on dendrites. Finally, other proteins secreted by the cultured cells or present in the medium may bind to the nitrocellulose and permit dendritic growth.

This work was supported by NIH grant NS17112, NEI 05285 (V.L.) and by a graduate research fellowship from the NSF.

POLARITY AND MORPHOLOGY OF RAT HIPPOCAMPAL NEURONS IN CULTURE IS INFLUENCED BY CELL ADHESION AND ECM MOLECULES. J. A. Drazba*, S. Kaech, and V. Lemmon. Lab. of Neurobiology, NINDS, NIH, Bethesda, MD 20892 and Dept. of Neurosciences, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Hippocampal neurons grown on poly-lysine (PL) seem to replicate their *in vivo* program of axonal and dendritic development. To see whether this inherent program can be influenced by cell-surface interactions, we plated the neurons on purified cell adhesion molecules L1 or N-cadherin and on the extracellular matrix (ECM) component laminin. We found that cells on L1 extended multiple, extremely long processes that acquired axonal characteristics (i.e. enrichment in L1 and tau, and the exclusion of MAP-2) by 12 hrs in culture. These axons continued to elongate rapidly, did not fasciculate, and branched in perpendicular patterns. Dendrites were short, extended over underlying axons, and rarely grew on L1 itself. In contrast, neurons in sister cultures on PL had only a few minor processes while some had extended a single axon. The morphology of neurons grown on N-cadherin was very similar to that on PL, but the development of both axon and dendrites was greatly accelerated. By 12 hrs in culture cells already had a single, very long axon and well-developed minor processes expressing high levels of MAP-2. In comparison, neurons on laminin only exhibited a selective increase in axonal outgrowth over that seen on PL. Thus, substrates dramatically influence the growth pattern of hippocampal neurons *in vitro*. We show that the interaction of neurons with molecules they may encounter in their *in vivo* environment may influence the program of axonal and dendritic development and may alter the differential distribution of axonal and dendritic components.

SELECTIVE HIPPOCAMPAL NEURITOGENESIS: AXON GROWTH ON LAMININ OR PLEIOTROPHIN, DENDRITE GROWTH ON POLY-D-LYSINE. B.C. Wheeler¹*, and G.J. Brewer². ¹Neuroscience Program, Univ. Illinois, Urbana, IL 61801 and ²Southern Illinois Univ. Sch. Med., Springfield, IL 62794.

Toward the goal of engineering live neuronal networks, we have begun a search for culture substrates that are selectively adhesive for specific cell types and their neurites, either axons or dendrites. This investigation is possible because of the development of a serum-free medium for growth of isolated neurons without glia (B27/Neurobasal, GIBCO; Brewer et al. (1993), J. Neurosci. Res. 35:567). Glass substrates were coated with either poly-D-lysine (PL), PL followed by laminin, or pleiotrophin. Neurons from embryonic day 18 rat hippocampus were plated at 80 cells/mm². Survival (live/total cells) was equivalent on the three substrates. After 1 day, neuritogenesis was dramatically enhanced on laminin or pleiotrophin, compared to polylysine. After 4 days, the uniform narrow processes on pleiotrophin had continued to grow, while those on laminin largely stopped. In contrast, cells on PL grew shorter tapered processes, characteristic of dendrites. The shorter tapered processes reacted with antibodies against the cytoskeletal dendritic marker MAP2. The long, narrow processes reacted with antibodies recognizing the cytoskeletal axonal marker tau. By selective patterning of substrates, it may be possible to specifically direct axonal and dendritic growth.

Neurofilament subunit composition specifies axonal caliber. Z.-S. Xu¹, J. Marszalek¹, M.K. Lee¹, P.C. Wong¹, T. Crawford²*, S.-T. Hsieh^{2,3}, and D.W. Cleveland^{1,3}. Dept. of ¹Biol. Chem., ²Neurol. and ³Neurosci., The Johns Hopkins Univ. School of Medicine, 725 N. Wolfe St., Baltimore, MD 21205.

Neurofilaments are neuronal intermediate filaments comprised of three polypeptide subunits NF-L, NF-M and NF-H. Increasing evidence has shown that neurofilaments are required for the development of normal axonal caliber, a crucial determinant of axonal conduction velocity. To test the role of each individual subunit, we have over-expressed different subunits in transgenic mice. Surprisingly, a simple increase in number of filaments by a 2-fold increase in NF-L inhibits radial axonal growth, producing *smaller* axons. An increase (by 2 fold) in either NF-H, NF-M or both, (presumably increasing the side arms), inhibits radial axonal growth to an even larger extent. However, combined increase of NF-L with either NF-M or NF-H produces *larger* axons. These data demonstrate that radial axonal growth requires not only an appropriate number of filaments but also filaments comprised of a balanced composition of the different subunits and in particular, a normal ratio between the content of NF-L and either of two large subunits, NF-M and NF-H.

MAP2 EXPRESSION AND NEURITIC BRANCHING ARE REDUCED WHEN SPINAL CORD NEURONS ARE CO-CULTURED WITH WOBBLER MOUSE ASTROCYTES. D. Hantaz-Ambroise^{1,2}, A. Alt-Ikhlef¹, M. Murawsky¹, F. Rieger¹. ¹- INSERM, Unité 153, 17 rue du Fer-à-Moulin, Paris 75005; ²- Université Paris VI, 4 place Jussieu, Paris 75005.

Embryonic normal mouse neurons can be cultured on layers of primary astrocyte culture and are identified by microtubule-associated proteins, MAP2, exhibiting a high degree of neuronal cell-type specificity. With the aid of specific antibodies to MAP2, we studied the neuritic outgrowth and examined the intensity of MAP2 staining which allows a direct visualization of neurite outgrowth. We performed cocultures of embryonic normal neurons with both normal and wobbler astrocytes. These mutant astrocytes are strongly GFAP-reactive and develop, *in vivo* and *in vitro*, morphological modifications in process outgrowth and arrangement (J. Neurocytology, 23, 179-192, 1994). We found that the number of MAP2 negative-neurons coupled to wobbler astrocytes was much higher compared to those coupled to normal astrocytes, pointing towards a defect in neurite outgrowth mediated by wobbler astrocytes. We thus studied the expression and cell distribution of MAP2 proteins in both conditions. Quantitative image analysis showed a reduced number of neurites and neuritic branching points in the wobbler astrocyte-neuron coupled cultures compared to the normal cocultures. These results are in agreement to the recent observation of Weiya and Vacca-Galloway (1991) showing that *in vivo* the extent and branching of neuritic arborization is abnormal in wobbler mice. Similar observations were made when normal neurons and astrocytes were cocultured in the presence of conditioned medium from wobbler astrocyte cultures. Altogether, these data strongly support the hypothesis that neuritic outgrowth is inhibited under the influence of soluble factors secreted by wobbler astrocytes and not normal astrocytes. These observations suggest that wobbler astrocytes possibly produce high amounts of glia-derived growth inhibitors.

532.3

CHARACTERIZATION AND REASSEMBLY OF ALPHA-INTERNEURIN (NF66) ISOFORMS FROM BOVINE SPINAL CORD. M.E. Miller* and B.J. Ballin. Med. Coll. of PA, Dept. of Pathology and Lab Med., 3200 Henry Ave., Phila., PA 19129.

We have demonstrated previously that alpha-interneuron (NF66), a member of the type IV family of intermediate filaments, can be isolated from bovine spinal cord and that purified NF66 is capable of reassembly (as well as coassembly with other type IV intermediate filaments) into ~10nm-diameter filaments (Ballin & Miller (1994) J. Neurosci. Res., in press). During purification, a high molecular weight isoform of NF66 was found to co-elute with the high molecular weight neurofilament subunit (NF-H) following anion exchange chromatography of an enriched cytoskeletal fraction. These two proteins were found to be inseparable by gel filtration and a gel elution strategy (Miller et al. (1994) J. Neurosci. Meth., submitted) was used to purify NF66 to homogeneity for reassembly studies. We now demonstrate the existence of lower molecular weight isoforms (< 66kD) of bovine NF66 that can be isolated by successive cation and anion exchange chromatography. These isoforms of NF66 are also shown to be capable of reassembly into ~10nm-diameter filaments by negative staining and immunoelectron microscopy. Characterization of these NF66 isoforms by 1- and 2-D gel electrophoresis and Western blotting suggests that these polypeptides are NF66 phosphoisoforms. Supported by PHS grant AG10160.

OVER-EXPRESSED DREBRIN FORMED THICK, CURVING BUNDLES OF ACTIN FILAMENTS, FROM WHICH TROPOMYOSIN WAS DISSOCIATED, IN FIBROBLASTS. T. Shirao*, K. Hayashi¹, K. Isa¹ and R. Ishikawa². ¹Dept. of Neurobiol. & Behav. and ²Dept. of Pharmacol., Gunma Univ. Sch. of Med., Maebashi 371, JAPAN

Drebrin is an actin binding protein rich in the neuron. During the development of the brain, it is localized at the submembranous region of migrating neuroblasts and growing axons and dendrites. By transfection of fibroblasts with drebrin cDNA, the outgrowth of highly branched, neurite-like cell processes is induced from the cells that the protein is expressed at high levels. We demonstrate by an immunocytochemical method that the drebrin expressed in transfected cells binds to stress fibers and, as a consequence, thick, curving bundles of actin filaments are formed. Such bundles were observed not only in the highly branched, neurite-like cell processes but also in the cell bodies of transfectants. Tropomyosin was dissociated from actin filaments in these cells. Biochemical analysis also revealed that drebrin strongly inhibited the actin-binding activity of tropomyosin by competitive binding. These data suggest that actin filaments that bind drebrin form a novel class of actin filaments, which may play a role in neuronal morphogenesis.

532.7

LOCALIZED RE-EXPRESSION OF A DEVELOPMENTALLY-REGULATED FORM OF MAP 1B DURING AXONAL REGENERATION IN VITRO. D.A. Tonge, J.P. Golding and P.R. Gordon-Weeks*. Biomedical Sciences Division, King's College, Strand, London WC2R 2LS, U.K.

Microtubule organization in growth cones is known to be essential for neurite extension. Phosphorylation of microtubule-associated proteins (MAPs) modifies their affinities for microtubules and this might affect neurite growth. Monoclonal antibody 150 (mab 150) recognizes a novel phosphorylation epitope on MAP 1B which is transiently expressed during development of the nervous system (Eur. J. Neurosci. 5, 1302-1311). In the present study, expression of this form of MAP 1B was studied during axonal regeneration *in vitro*.

Short lengths of spinal nerves with their attached dorsal root ganglia were removed from adult mice, explanted into Matrigel and maintained in serum-free medium for up to 8 days. Profuse growth of naked axons occurred within one day from the cut ends of both the peripheral nerve and the dorsal root, and continued throughout the observation period. Some axons were entirely smooth whilst others showed prominent varicosities. Immunohistochemical staining using mab 150 was observed along the whole length of the axons growing out of the explants, but not within the nerve itself. The staining extended to the growth cones which had elaborate morphology. Other antibodies (e.g. to GAP-43) labeled axons within the nerve as well as those growing in Matrigel. In preparations where the peripheral nerve had been crushed half way along its length, mab 150 staining was absent from the nerve proximal to the crush site, but present in axons which had regenerated within the nerve distal to the crush. These results indicate that re-expression, during axonal regeneration of the form of MAP 1B recognized by mab 150, is restricted to the newly formed segments of axons. The correlation between its expression and axonal growth during development and regeneration suggests that it may play a role in axonal extension. (Supported by MRC).

532.4

ALTERING THE PROTEIN COMPOSITION OF DEVELOPING AXONS: MICROINJECTION OF A NEUROFILAMENT ANTIBODY TO STUDY NEURITE OUTGROWTH IN XENOPUS CULTURED SPINAL CORD NEURONS. W. Lin* and B.G. Szabo. Biol. Sci., SUNY-Albany, Albany, NY 12222.

The cytoskeletons of newly differentiating *Xenopus laevis* spinal cord axons contain a middle- (NF-M) and a lower molecular weight neurofilament protein (XNIF). Microinjection of antibodies against NF-M into embryonic blastomeres subsequently results in abnormal distributions of XNIF-immunoreactivity within the neurons of intact embryos and inhibits peripheral nerve development (J. Comp. Neurol. 308:576). To better understand these effects, we examined the consequences of anti-neurofilament antibody injection on embryonic spinal cord neurons isolated in culture. Single blastomeres of 2-cell stage embryos were microinjected with an anti-NF-M antibody mixed with FITC-dextran. Injections at the 2-cell stage inoculated only half of the neurons, allowing us to compare the injected neurons, which were identified by FITC-fluorescence, to normal ones within the same culture. After injection, neural tubes were dissociated and cultured at stage 22. Immunocytochemistry with rhodamine-labeled secondary antibodies confirmed that for at least the first 24 hrs in culture, the injected antibody was uniformly distributed throughout somas and within neurites. Furthermore, the neurofilament antibody successfully altered the normal distribution of neurofilaments within neurons. For example, neurites of uninjected neurons are evenly filled with XNIF-immunoreactivity. In contrast, in injected neurons, XNIF accumulated within the soma, leaving neurites devoid of detectable neurofilaments. These results resembled the effects observed in intact embryos. Next, we will measure the rates of neurite outgrowth in the absence of neurofilaments. Supported by NIH R29-NS30682.

532.6

DISTRIBUTION OF CYTOSKELETAL PROTEINS IN GROWTH CONES IS INFLUENCED BY CONTACT WITH SUBSTRATE-BOUND L1, N-CADHERIN AND LAMININ. S.M. Burden* and V. Lemmon. Dept. of Neurosciences, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

We have previously shown that retinal ganglion cell (RGC) growth cones exhibit characteristic morphologies dependent upon the substrate on which they are grown (Payne, et al. (1992) *Cell Motil. Cytoskel.* 21:65-73). Upon contact with a sharp border between two substrates, the growth cones display dynamic changes in morphology (Burden, et al. (1992) *Soc. Neurosci. Abst.* 814.10) that may be due to extensive restructuring of the cytoskeleton. In this study, we have used immunocytochemistry to examine the distribution of three cytoskeletal elements in RGC growth cones growing on L1, N-cadherin or laminin individually, as well as on dishes coated with alternating lanes of these substrates.

We have observed distinct staining patterns for f-actin, microtubules (MTs) and neurofilaments (NFs) in growth cones growing on individual substrates. At border regions between two substrates, growth cones that established lamellipodial contact with the new substrate were observed to have f-actin and MT staining patterns appropriate for the newly encountered substrate. Contact via filopodia alone did not evoke this change. Once the majority of the growth cone had crossed onto the second substrate, redistribution of NFs was also observed. These results suggest that the major cytoskeletal elements of growth cones are rapidly restructured in direct response to substrate contact. Such changes are likely to be crucial for growth cone guidance. Supported by NEI grant 05285.

532.8

REORGANIZATION OF MICROTUBULES IN CORTICAL GROWTH CONES DURING CELL-CELL INTERACTIONS. M. Lu* and K. Kalil. Neuroscience Training Program and Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

Growth cone behaviors such as advance, retraction, fasciculation, turning, and branching are accompanied by reorganization of the cytoskeleton. To understand how microtubules contribute to behaviors of CNS neuronal growth cones, we have studied the disposition of microtubules in growth cones of embryonic cortical neurons as they interacted with other neurons and glia in dissociated cultures. We have used high resolution video enhanced Nomarski optics to visualize morphologies of fixed growth cone captured during various behaviors. Matching fluorescent images of the same growth cones stained immunocytochemically with anti beta tubulin were used to localize the positions of microtubules during these behaviors. We found that microtubules were symmetrically distributed in the proximal region of growth cones advancing in straight trajectories. In contrast, growth cones turning away from straight trajectories had microtubules oriented in the direction of turning. When growth cones fasciculated with other neurites the orientation of their microtubules became aligned with those of the neurite. Microtubules also invaded the branches along neurites as well as growth cone bifurcations. In video microscopy, we have previously observed that when growth cones collapse and withdraw they often leave behind a long filopodial strand upon which the growth cone reextends. Immunocytochemistry revealed that these strands were usually invaded by microtubules. Preliminary results in which microtubules were stained with antibodies to deetyrosinated tubulin suggest that the microtubules observed during dynamic growth cone behaviors are relatively labile. These results suggest that the invasion of labile microtubules may underlie growth cone behaviors that require changes in direction. Supported by NIH Grant NS 14428 (K.K.).

532.9

SUPPRESSION BY ANTISENSE mRNA DEMONSTRATES A REQUIREMENT FOR DREBRIN IN THE FORMATION OF NEURITE PROCESSES. M. Toda^{1,2}, T. Shirao³, H. Asou¹, S. Toya², and K. Uyemura¹. Depts. of ¹Physiol. and ²Neurosurg., Keio Univ. Sch. of Med., Tokyo 160, ³Dept. of Neurobiol. and Behavior, Gunma Univ. Sch. of Med., Maebashi 371, Japan.

Drebrin are developmentally-regulated actin-binding proteins. Although neurite outgrowth is the first step in neuronal network formation, the intracellular mechanism of neurite outgrowth is not yet clear. To determine the role of drebrin in these phenomena, we have studied the rat neuroblastoma cell line, B104, which constitutively expresses drebrin. Deprivation of serum or retinoic acid treatment induces a characteristic change in morphology; cells produce drebrin-positive processes. Then, in an effort to interfere with the expression of drebrin in B104 cells, we transfected them with an antisense construct of human drebrin E cDNA (Biochem. Biophys. Res. Commun. 196: 468-472, 1993), driven by a β -actin promoter. Two stable antisense cell lines from separate transfections were isolated and were shown to be drebrin negative by Western blot analysis and immunofluorescence studies. The antisense cell lines were inhibited in their ability to extend significant neurite processes in response to serum deprivation or retinoic acid treatment. These data support the conclusion that the actin-binding protein, drebrin, is required for the formation of stable neurite processes.

MECHANISMS OF AXON GUIDANCE

533.1

LAZARILLO: A GPI-LINKED GLYCOPROTEIN INVOLVED IN AXON GUIDANCE IN THE GRASSHOPPER EMBRYO IS A MEMBER OF THE LIPOCALIN FAMILY. D. Sánchez, M.D. Ganfornina, and M.J. Bastiani*. Department of Biology, University of Utah, Salt Lake City, Utah 84112, U.S.A.

Our work is focused on the signaling events that ensure neurites find their appropriate pathway to target cells during neurogenesis. We are studying a new cell surface molecule called Lazarillo which is expressed by a subset of neurons and neuronal precursors in the grasshopper nervous system. This molecule is linked to the plasma membrane by a glycosyl-phosphatidyl-inositol (GPI) group and possesses abundant N-linked oligosaccharides (native Mr=45 kD, deglycosylated Mr=28 kD). The monoclonal antibody against Lazarillo (10E6 MAb) is able to perturb the direction of several growth cones in cultured embryos. In particular, a pair of commissural pioneer neurons are disrupted; their growth cones are delayed or abruptly change their direction of growth.

We have identified and characterized a cDNA clone coding for the Lazarillo protein. The predicted protein sequence has the signal peptides necessary to target the protein to the endoplasmic reticulum and anchor it to the membrane by the GPI tail. It possesses seven N-linked glycosylation sites and four cysteine residues. The cDNA has a long (2.3 kb) 3' untranslated region. *In situ* hybridization using the whole cDNA sequence as probe shows that Lazarillo mRNA co-localizes with the 10E6 MAb. Sequence comparisons reveal that Lazarillo belongs to the lipocalins family; extracellular carriers of small hydrophobic ligands in a wide variety of systems. A phylogenetic analysis of the family sets Lazarillo in a cluster containing the mammalian Apolipoprotein D, the insect bilin binding proteins, and all the serum retinol binding proteins from vertebrates. Lazarillo is, to the best of our knowledge, the first lipocalin (1) GPI-anchored to the plasma membrane of cells, (2) restricted to a subset of neurons and neuroblasts in a developing nervous system, and (3) involved in growth cone pathfinding. Supported by NIH (NS 25387), Fulbright (M.D.G.) and Fogarty (D.S.) fellowships. M.D.G. and D.S. contributed equally to this work.

ISOLATION OF PROTEOGLYCANS FROM THE DEVELOPING SUPERIOR COLLICULUS OF THE SYRIAN HAMSTER. Diane Hoffman*, Arthur D. Lander, and Sonal Jhaveri. Dept. of Brain & Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA.

Recent experiments suggest important roles for sulfated proteoglycans (PGs) in influencing axonal growth. In addition, chondroitin sulfate and keratan sulfate PG (CSPG, KSPG) expression patterns correlate at certain times with regions where axons preferentially travel, such as the cortical subplate, and at other times with regions which axons distinctly avoid, such as the midline of the superior colliculus. We have examined the expression of PGs in the superior colliculus of the developing hamster, around the time of retinal axon ingrowth and arborization in this target. PGs were isolated from tectal homogenates by anion exchange chromatography, radiolabeled, and digested with enzymes to remove specific glycosaminoglycan (GAG) chains. Resulting protein cores were separated by electrophoresis. During the first postnatal week, we have identified PGs which, on the basis of molecular weight, solubility properties, and GAG type, bear distinct resemblance to developmentally regulated PGs previously isolated from rat brain. Early postnatal tectum contained at least four distinct HSPGs, with molecular weights corresponding to glypican, cerebroglycan, M7 and M10 (see Herndon and Lander, Neuron 4, 1990). CSPGs of sizes consistent with neurocan, S2 and M8 were also expressed. In addition, two novel bands appeared in response to digestion with keratanase, although the possibility of proteolytic contamination in the keratanase has not yet been ruled out. Experiments are currently under way to isolate PGs at other ages, and to localize their sites of expression within the superior colliculus, with emphasis on gaining potential insights from comparing expression along the midline and in retinorecipient zones of lateral regions. Supported by NIH grants EY05504, NS26862, and EY02621.

MECHANISMS REGULATING THE STABILITY OF CYTOSKELETAL MRNAS IN REGENERATING RAT SENSORY NEURONS. P.E. Moskowitz* and M.M. Oblinger. Dept. Cell Biol. and Anat., Chicago Med. School, North Chicago, IL 60064

In eukaryotes, the steady-state mRNA level for a given gene is dictated by the balance of transcriptional and post-transcriptional controls. For cytoskeletal genes, mRNA stability is believed to play a major role in the specification of steady-state mRNA levels, but little is actually known about this issue in mammalian neurons. The model system we have used to study this is the axotomized, regenerating dorsal root ganglion (DRG) neuron wherein it is well documented that neurofilament (NF) mRNA levels are rapidly depressed while those of certain tubulin isoforms are rapidly increased following axonal injury. We have examined whether these mRNA level changes are controlled at the level of cytoplasmic mRNA degradation/stabilization and have examined the role of protein synthesis in the post-axotomy mRNA changes. Half-lives of NF and tubulin mRNAs were assessed in normal and 7 d post-axotomy DRG using Northern blotting of RNA isolated at various intervals after transcriptional blockade was induced by *in vivo* microinjection of actinomycin D. The half-lives of NF mRNA are normally quite long, but a more rapid decay of NF-L, NF-M and NF-H mRNAs was found in axotomized neurons. Interestingly, β -tubulin mRNA decay was also found to be more rapid in axotomized DRG neurons. Protein synthesis was found to be essential for some, but not all, of the post-axotomy mRNA changes since synthesis blockade induced with cycloheximide 4 h prior to axotomy prevented the NF-M mRNA loss, but not the NF-L or NF-H mRNA downregulation that occurred in DRG neurons by 1 d post-axotomy.

CALCIUM ENTRY AND CALCIUM STORES CONTROL NERVE GROWTH IN AN APPLIED ELECTRIC FIELD. R. Stewart & C.D. McCaig*. Department of Biomedical Sciences, University of Aberdeen, Aberdeen AB9 1AS, Scotland.

Cultured nerves show striking growth responses to a small dc applied electric field of physiological magnitude. Calcium entry has been implicated. Neurites from Stage 20 *Xenopus* neural tubes grown on tissue culture plastic in a dc field of 150mV/mm, 1. grow faster than in the absence of the field; 2. grow faster cathodally than anodally; and 3. turn to grow cathodally. Using a pharmacological approach, we have studied both the role of selective voltage dependent calcium channels (VDCCs) and of calcium release from intracellular stores in the control of these three responses. We report 1. that faster growth in an applied electric field is lost in the presence of the P-type VDCC inhibitor omega-agatoxin IVA and in the presence of thapsigargin, which disrupts calcium release from inositoltriphosphate sensitive intracellular stores; 2. that ryanodine, which disrupts calcium-induced calcium release from intracellular stores, abolishes the growth rate differential between cathode and anode facing neurites and 3. that the P- and N-type VDCC inhibitors omega-agatoxin IVA and omega-conotoxin GVIA respectively, as well as ryanodine and thapsigargin each partially inhibit cathodal orientation. We conclude that calcium entry through specific VDCCs in the growth cone, linked to calcium release from specific intracellular stores controls different aspects of electric field-induced growth and orientation.

TWO CHONDROITIN SULFATE PROTEOGLYCANS EXPRESSED DURING THE SEGMENTATION OF THE PERIPHERAL NERVOUS SYSTEM OF THE CHICK. C. Ring* and W. Halfter. Univ. of Pittsburgh School of Medicine, Dept. of Neurobiology, 15261.

Chondroitin sulfate proteoglycans (CSPGs) purified from cartilage have been shown to be inhibitory to neurite outgrowth *in vitro*. Based on these findings, it has been hypothesized that CSPGs function as barrier molecules to neurite outgrowth *in vivo*. We wanted to examine if CSPGs derived from non-cartilaginous embryonic tissues would have similar effects. We have isolated two monoclonal antibodies (mAbs), 2B9 and 9BA12, which recognize two CSPGs that are developmentally expressed in the trunk region of the chick embryo. The 2B9 mAb has been shown to recognize collagen type IX proteoglycan (CIXPG). It is expressed in the posterior sclerotome of the somites at a time when motor axons project, and neural crest cells migrate through the anterior sclerotome. Dorsal root ganglion (DRG) explants can adhere to, and extend short neurites on, nitrocellulose-bound CIXPG. Neurites from DRG explants grown on a combination of fibronectin/CIXPG appear shorter and more fasciculated than control explants grown on fibronectin alone.

The 9BA12 mAb recognizes an as yet unidentified CSPG in neural tissue. It is expressed throughout the trunk region of the developing chick embryo, in the neural tube, throughout the somite, and is absent only from the dermamyotome. As with the CIXPG, DRG explants can adhere to and extend short neurites on, nitrocellulose-bound 9BA12 antigen. Alternatively, in combination with fibronectin, the explants were able to extend neurites on the 9BA12 antigen that appeared identical to control explants grown on fibronectin alone. Our study demonstrates that CIXPG in the posterior sclerotome may contribute to the avoidance of this tissue by developing neurites and migrating neural crest cells. In addition, we conclude that not all species of proteoglycan may be inhibitory to axon outgrowth, and that careful attention be paid to the source and type of proteoglycan used in neurite outgrowth assays.

LAMININ AND FIBRONECTIN GUIDEPOSTS SIGNAL SUSTAINED BUT OPPOSITE EFFECTS ON PASSING GROWTH CONES. T. B. Kuhn, M. F. Schmidt[§] and S. B. Kater*. Dep. of Anatomy and Neurobiology, Colorado State University, CO 80523; [§] Division of Biology, Caltech, Pasadena, CA 91125.

Guidepost cells affect behavior and navigation of growth cones *in vivo*. Yet, the nature of communication and the type of signals employed between growth cones and guideposts are largely undefined. Here we report that in a *in vitro* assay system both navigation and behavior of advancing DRG growth cones of the chick were significantly altered during transient encounters with monomolecular model-guideposts; 4.5µm polystyrene beads covalently coated with potential guidance molecules. Evoked growth cone behavior, a series of stereotypic responses, depended on the molecular nature of the model guideposts. Growth cones routinely paused and displayed filopodial sampling at guideposts. Laminin-model guideposts caused a sustained, two-fold increase of growth cone advance on a fibronectin substrate ($p < 0.01$; $n = 17$) while fibronectin-model guideposts led to a sustained, two-fold decrease of the rate of advance on a laminin substrate ($p < 0.001$; $n = 13$). Notably, these effects lasted substantially beyond the time of physical contact between growth cone and model guidepost. Arrays of laminin-model guideposts produced a saltatory growth cone advance and provided unambiguous, directional guidance. Interestingly, an increased overall growth rate (above that on the poly-L-lysine substrate) was observed equivalent to a homogeneous laminin substrate, despite periodic pausing occurred at each guidepost. Taken together, these results demonstrate that 1) as little as an individual molecular species is required to designate a point in space as a functional guidepost, 2) transient growth cone-guidepost contacts appear to initiate signalling pathways rather than just influence adhesion, and 3) the enforced pausing and sampling may represent a unique feature of guidepost-mediated pathfinding resulting in a periodic reassessment of the environment by the growth cones.

THE CLONING OF A CHICK BRAIN cDNA ENCODING A PROTEIN SEQUENCE RELATED TO COLLAPLIN. Y. Luo*, M. Renzi and J. A. Raper. Department of Neuroscience, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

Collapsin is a recently identified protein (Luo et al. 1993, Cell 75 217-227) that is likely to serve as a repulsive guidance cue during growth cone navigation since it induces the collapse of specific growth cones *in vitro*, is homologous to the axon guidance molecule fasciclin IV (semaphorin I), and is expressed in discrete regions of the developing brain. Partially purified brain-derived collapsin induces the collapse of both DRG and retinal growth cones, yet recombinant collapsin induces DRG growth cone collapse without affecting retinal growth cones. We therefore hypothesize that there is a family of collapsin-related molecules in brain that exhibit distinct neuronal target specificities. To identify possible collapsin relatives, we screened a λ gt10 chick brain cDNA library with collapsin probe under low stringency conditions. One cDNA clone was identified that hybridizes with the collapsin probe at low stringency (45 °C) but not at high stringency (65 °C). The 1.6 kb cDNA insert of this clone encodes a portion of a novel protein that is homologous to a part of the fasciclin IV-like and the Ig-like domains in collapsin. In the fasciclin IV-like domain over 70% of the predicted amino acid sequence is identical to that of the corresponding domain in collapsin. We are now in the process of obtaining the full coding sequence for this collapsin related protein. We then hope to express this recombinant version and test it for collapsing activity on a variety of growth cones *in vitro*.

533.9

DETERMINANTS OF AXON BRANCHING AND GUIDANCE IN THE ACCESSORY OLFACTORY SYSTEM.

K. Yoshida, G.A. Schwarting*, and J.E. Crandall. The Shriver Ctr., Waltham, MA 02254 & Prog. in Neuroscience, Harvard Med. Sch.

CC1 and CC6 are monoclonal antibodies that recognize subsets of vomeronasal (VNO) neurons. Axons from CC1⁺ neurons terminate in the rostral accessory olfactory bulb (AOB), whereas axons from CC6⁺ neurons terminate predominantly in caudal glomeruli of the AOB. In addition, subsets of CC6⁺ axons branch from the main vomeronasal nerve and grow caudally toward the forebrain. Many LHRH neurons utilize these CC6⁺ axon branches as guides to migrate along the medial surface of the olfactory bulb (OB). Occasionally CC1⁺ axons also grow caudally toward the forebrain, but turn at the OB/forebrain border and grow back into the rostral AOB. These data suggest that molecules associated with the pathway determine the trajectories of chemically distinct VNO axons. Whole mount immunohistochemical studies indicate that both attractive and repulsive activities may operate in the developing AOB. Most CC1⁺ axons appear to stop abruptly at the border of the caudal AOB. However, a small number of CC1⁺ axons enter the caudal AOB but alter their direction by turning sharply and entering the rostral AOB. Tissue culture studies are underway to examine factors that affect axon growth and branching. E18 VNO neurons are grown on coverslips coated with alternating stripes of protein homogenates from neonatal rostral and caudal AOBs. Preliminary results suggest that subsets of VNO axons turn and grow on rostral AOB homogenates but appear to be unaffected by caudal AOB homogenates. Supported by DC00953, NS24386 and HD05515.

A NOVEL Ca⁺⁺-BINDING PROTEIN IS EXPRESSED BY A SUBSET OF PERIPHERAL NEURONS WHICH SELECTIVELY FASCICULATE IN A SINGLE AXON TRACT IN LEECH CNS. K.K. Briggs, K.M. Johansen, & J. Johansen*. Dept. of Zoology & Genetics, Iowa State University, Ames, IA, 50011.

The lan 3-6 antigen is expressed in a subpopulation of peripheral neurons whose afferents segregate into a single axon fascicle in the developing leech CNS. By screening an expression vector library with the antibody we obtained a clone which suggests that the antigen is a novel protein possessing two EF-hand Ca⁺⁺-binding domains. The Ca⁺⁺-binding domains are likely to be functional since fusion protein made from the clone and expressed *in vitro* binds ⁴⁵Ca⁺⁺ after SDS-PAGE and transfer to nitrocellulose paper. That the clone corresponds to the lan 3-6 antigen was verified by *in situ* hybridizations with the clone to embryos, the labeling of which exactly matches the lan 3-6 antibody staining pattern. Northern analysis suggests that translation of the lan 3-6 message would result in a protein with a molecular weight of about 18 kD. Immunoaffinity purification with the lan 3-6 antibody followed by SDS-PAGE and analysis of the gels by silver staining yields a protein band of this predicted size. However, a prominent protein band of approximately 200 kD is being selectively co-purified with the lan 3-6 antigen by this procedure. Broad protein bands of this nature are frequently characteristic of glycoproteins. Thus these results suggest that the lan 3-6 antigen is a small Ca⁺⁺-binding protein which may be associated with and regulating a larger 200 kD glycosylated protein. The very restricted expression of the lan 3-6 antigen to a subset of peripheral neurons which specifically fasciculate together into a single tract during development raises the possibility that this putative protein complex may play a role in this process. Supported by NIH grant NS 28857 and NSF grant DIR 9113595.

533.8

THE PATTERN OF COLLAPLIN mRNA EXPRESSION IN THE DEVELOPING CHICK CNS. S. Chang, Y. Luo, and J. A. Raper*. Department of Neuroscience, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

Collapsin is a recently identified protein that induces the collapse and paralysis of specific growth cones *in vitro* (Luo et al. 1993, Cell 75 217-227). Here we examine the distribution of collapsin mRNA in the developing chick brain.

Wholemount *in situ* hybridizations were performed using a full length digoxigenin derivatized collapsin probe that was later reacted with an alkaline phosphatase conjugated anti-digoxigenin antibody. In the chick brain at E2 (HH stage 11), collapsin message was localized to rhombomeres 3 and 5 of the hindbrain. By E3, the rhombomere expression declines and collapsin message is strongly expressed in specific regions of the diencephalon. It is localized dorsally in an annulus around the developing pineal and ventrally as two stripes along either side of the stalk of the pituitary. On E6, collapsin message is also found in a stripe on the lateral wall of the forebrain in a region that may correspond to the archaestriatum. A pair of rostro-caudally oriented stripes on either side of the midline of the hindbrain also express collapsin message. The expressing cells in these stripes are near the ventricular surface. These two pairs of collapsin expressing stripes extend caudally into the ventral portion of the spinal cord.

This highly specific and localized pattern of expression at developmental times when extensive axon outgrowth is occurring in the developing CNS is consistent with collapsin playing a role in growth cone guidance.

533.10

IDENTIFICATION OF MYELIN-ASSOCIATED GLYCOPROTEIN AS A MAJOR MYELIN-DERIVED INHIBITOR OF NEURITE GROWTH. L. McKerracher, S. David, D.L. Jackson, V. Kottis, R.J. Dunn, P.E. Braun*, Centre for Res. in Neuroscience, McGill Univ. and Montreal General Hosp. Res. Inst., 1650 Cedar Ave., Montreal, P.Q. Can., H3G 1A4.

Potent contact-dependent axon growth inhibitory activity is present in CNS myelin. To identify inhibitory proteins present in myelin we used non-denaturing chromatography and tested the fractions for growth inhibition by bioassay. NG108-15 cells extend neurites in response to cAMP. Purified bovine CNS myelin, used as a tissue culture substrate, permitted cell attachment but inhibited cAMP-induced neurite outgrowth. When myelin was extracted with octylglucoside and the extract chromatographed on a DEAE anion exchange column, several peaks of inhibitory activity were eluted with a salt gradient. Analysis of the fractionated proteins revealed that myelin-associated glycoprotein (MAG) co-chromatographed with bioactivity. To determine if MAG contributes to growth inhibition, MAG was removed from these fractions by immunodepletion. Removal of MAG reduced neurite growth inhibitory activity. Direct evidence for the inhibitory effect of MAG on neurite outgrowth was obtained by testing the extracellular domain of recombinant MAG produced in cultured insect cells. This recombinant MAG was a potent inhibitor of neurite outgrowth. These results, which establish an inhibitory activity for MAG, suggest that the growth inhibitory properties of MAG may be critically important after nerve injury in the CNS where myelin debris is not removed very quickly after injury.

NEURITE GROWTH INHIBITORY ACTIVITY IN THE MAMMALIAN PNS AND CNS AND ITS MODULATION BY LAMININ. S. David*, L. McKerracher, D. Jackson, V. Kottis, and P. Braun. Centre for Research in Neurosciences, Montreal General Hospital Research Institute, and Dept. Biochemistry, McGill University, Montreal, Canada.

In addition to the axon growth inhibitor in CNS myelin identified by Caroni and Schwab (J. Cell Biol. 106:1281), we have identified another inhibitor in myelin (see Abstr. McKerracher et al.). We now provide evidence that peripheral nerve (PN) myelin also possesses neurite growth inhibitory activity. Bovine PN myelin was prepared by homogenization with either a Polytron (PN-p), or frozen in liquid N₂, pulverized and homogenized with a Dounce homogenizer (PN-d). These 2 preparations were then subjected to sucrose density gradient centrifugation to purify myelin. PN myelin was plated on to polylysine-coated 96 well plates (8µg/well), and neurite growth assessed with cAMP treated NG108-15 cells. On PN-p myelin 81% of the cells extended neurites, as compared to 1.5% on PN-d myelin. Western blots of the 2 myelin preparations with anti-laminin antibody indicate substantial amounts of laminin in the myelin preparation that was permissive for neurite growth (PN-p). Preincubation of PN-p myelin with anti-laminin antibody reduced neurite growth. In a similar neurite growth assay, the inhibitory activity in bovine CNS myelin (4%) was overridden (80%) by coating the wells with a mixture of myelin (8µg) and laminin (1.5µg). These results suggest that neurite growth inhibitory activity is present in PN and CNS myelin, and can be modulated by laminin.

533.13

IDENTIFICATION OF AN EXTRACELLULAR MATRIX GUIDANCE CUE FOR THE PROXIMAL GROWTH OF INSECT LEG PIONEER AXONS. J.K. Nyhus*, B.A. Norbeck and J.L. Denburg. Biological Sciences Dept. University of Iowa, Iowa City, Iowa 52242.

Molecular gradients of environmental cues have been proposed to be important directional signals for the proximal growth of pioneer axons in embryonic insect legs. We have produced a monoclonal antibody (mAb) that binds to an extracellular matrix protein that is non-uniformly distributed along the proximal-distal axis of embryonic cockroach leg at the time of pioneer axon growth. This mAb was named PROD-2 because it labels the proximal parts of the leg more intensely than the distal end. The spatial and temporal distributions of the PROD-2 antigen make it a good candidate for an environmental guidance cue for T11 pioneer axon growth. To demonstrate a role for the antigen in axon guidance, PROD-2 mAb is added to the medium in which whole embryos are cultured for 48 hours. Under control conditions, the T11 axons grow and follow their normal path. Treatment with PROD-2 mAb has no effect on the rate of elongation of the T11 axon, but alters the direction in which they grow. The perturbation was found to be dose dependent; with increasing concentration of the mAb there was an increase in the total number of pathfinding mistakes as well as an increase in the severity of the mistakes. These results indicate that the PROD-2 antigen is a guidance cue responsible for the formation of the stereotypical projection of the T11 pioneer axons on their normal substrate.

AXONIN-1 PLAYS A ROLE IN GUIDANCE OF COMMISSURAL NEURONS IN THE CHICK SPINAL CORD. E.T. Stoekli* and L.T. Landmesser. Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106

In chicken embryos the cell adhesion molecule axonin-1 has been shown to exist in both a secreted and a GPI-linked form. Its role in growth cone guidance and pathfinding of commissural neurons, which express it during initial axonogenesis, was tested by in-vivo injections of axonin-1 into the spinal cord central canal in early embryos (Stage 18-24). Dorsally located commissural neurons normally extend axons toward the floor plate in response to a diffusible factor. Upon reaching the floor plate they make a sharp turn to cross the midline, then turn rostrally along the contralateral border of the floor plate. In axonin-1 injected embryos, a substantial proportion of commissural axons did not cross the midline, but turned rostrally on the ipsilateral side; in addition they grew in a more defasciculated manner. Since Ng-CAM has been identified as a receptor for axonin-1 on DRG neurons, we tested whether injection of Fab fragments of anti-NgCAM would result in similar pathfinding errors. Although commissural axons grew in a more defasciculated pattern following anti-NgCAM injection, pathfinding errors did not occur. This suggests the existence of at least one other receptor for axonin-1 within the floor plate; saturation of this "floor plate" receptor by injected axonin-1 could lead to the observed misguidance of commissural neurons. The nature of this receptor is currently being investigated.

533.12

AN INSECT PIONEER NEURON USES MESODERMAL CELLS AS A SUBSTRATE FOR NORMAL PATHFINDING. I. Rajan*, J.L. Denburg. Dept. of Biological Sciences, University of Iowa, Iowa City, Iowa 52242.

Previous studies of axon growth of insect pioneer neurons by Bentley's lab have indicated that mesodermal cells are not required for elongation and pathfinding. We report that the formation of the stereotypical axon projection by the Fe₂ pioneer neurons in the limbs of cockroach embryos requires mesodermal cells. Using immunocytochemical and confocal microscopy techniques we show that Fe₂ neurons use the internal core of mesodermal cells as a substrate for growth. Surgical removal of the leg mesoderm and subsequent culturing of the embryos resulted in axonal growth on the epidermal epithelium but with an altered trajectory. Similar changes in path and substrate choice are observed in axons growing in embryos cultured *in vitro* in the presence of the enzyme phosphatidyl inositol phospholipase-C or certain glycosaminoglycans like heparan sulphate, heparan and dermatan sulphate. These results indicate that *in vivo* the Fe₂ axons prefer to grow on the surface of certain mesodermal cells. However after surgical manipulation or addition of chemical perturbants they will grow on ectodermal epithelial cells but with an altered path. There appears to be a myriad of guidance mechanisms of pioneer axon growth in the legs of insect embryos. Supported by NIH grant NS 14295.

LAMININ OLIGOPEPTIDE DERIVATIZED AGAROSE GELS FACILITATE THREE-DIMENSIONAL NEURITE EXTENSION IN VITRO AND ENHANCE PERIPHERAL NERVE REGENERATION IN VIVO. B. Bellamkonda*, J. Ranieri, M. Borkenhagen and P. Aebischer. Surgical Research Division, CHUV, Lausanne University Medical School, Switzerland.

The phenotypic expression of various cells is influenced by extracellular matrix (ECM) molecules. A three-dimensional (3-D), hydrogel based ECM equivalent tailored to support neurite extension from neural cells and promote nerve regeneration was developed. Oligopeptide domains GRGDSP, CDPGYIGSR, and IKVAV which are partly responsible for the cell attachment and neurite promoting properties of laminin (LN), were covalently immobilized to agarose gels. Embryonic day 9 (E9) chick dorsal root ganglia (DRG) and PC12 cells were suspended in three dimensions in derivatized agarose gels and their neurite extension was evaluated. Agarose gels derivatized with CDPGYIGSR and a cocktail of all three peptides, enhanced neurite extension from E9 DRGs while IKVAV derivatized gels inhibited neurite extension. However, IKVAV derivatized gels enhanced neurite extension from PC12 cells compared to undervatized agarose gels and gels derivatized with other LN oligopeptides. The effect of derivatized agarose gels on the regeneration of transected rat spinal dorsal roots was evaluated by using 6 mm long polymer guidance channels filled with CDPGYIGSR-agarose to bridge a 4 mm gap in a transected dorsal root model. After 4 weeks, significantly greater numbers of myelinated axons were observed in the channels filled with CDPGYIGSR-agarose gels compared to channels filled with undervatized agarose gels. Thus 3-D matrices carrying appropriate neuroactive peptides can be tailored to evoke specific responses from cells and tissues exposed to them. They can be used for 3-D neuronal culture and may serve to enhance regeneration by optimally presenting neurite promoting molecules to the regeneration environment.

SUBSTRATES PATTERNED WITH A DOMAIN OF THE B2 CHAIN OF LAMININ GUIDE AXONS OF EMBRYONIC HIPPOCAMPAL NEURONS IN VITRO. M. Matsuzawa*, R. S. Potember*, F. F. Weight* and P. Liesi*²
1. Applied Physics Lab, The Johns Hopkins University, Laurel, MD 20723.
2. Laboratory of Molecular and Cellular Neurobiology, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Substrates patterned with synthetic peptides derived from the B1 and B2 chains of laminin were used to guide axons of embryonic hippocampal neurons *in vitro*. These substrates were formed by attaching the peptides to chemically patterned surfaces fabricated via deep UV lithographic procedures. Neurons grown on the patterned substrates (parallel lines of 5 µm width) developed a bipolar morphology, whereas neurons on uniform (non-patterned) substrates had randomly growing multiple neurites. Substrates patterned with peptide P20, derived from a neurite outgrowth domain of the B2 chain of laminin (Liesi et al, 1989), promoted directional neurite outgrowth and morphological maturation of neurons. Neurons on patterned P20 substrates expressed the 200 kDa neurofilament protein in the longer "axonal" process within a 24 hour cultivation. Substrates patterned with peptide P31, derived from a cell attachment domain of the B1 chain of laminin (Graf et al, 1987), did not support directional neurite outgrowth or axonal differentiation.

The present study provides direct evidence for a role of a neurite outgrowth domain of the B2 chain of laminin as an axonal guidance and differentiation factor for embryonic hippocampal neurons *in vitro*.

Substance P Modulates Chemotropic Influences of Floor Plate on Developing Neurites in the Central Nervous System. C. De Felipe, R.D. Pinnock* and S. P. Hunt. (*Spon. BRA) MRC Laboratory of Molecular Biology, Division of Neurobiology, Hills Road, Cambridge, CB2 2QH, *Parke-Davis Neuroscience Research Unit, Robinson Way, Cambridge, UK CB2 2QB.

The floor plate, a neuro-epithelial structure found at the ventral midline of the developing central nervous system, has been shown to function in dorso-ventral patterning in the spinal cord and at later embryonic stages, in guidance of commissural axons by release of chemoattractants. We have found that embryonic rat floor plate cells express the neurokinin 1 receptor and that there is a transiently appearing subpopulation of commissural axons containing Substance P, the neuropeptide ligand for this receptor. Receptor coupling to an intracellular effector system in dissociated floor plate cells was established by monitoring the intracellular calcium levels of dissociated floor plate cells using the Ca^{+2} indicator fura-2. Bath application of 10 to 1000nM substance P or the selective NK1 receptor agonist $[\text{Sar}^9, \text{Met}(\text{O}_2)^{11}]$ substance P₁₂ for 120s produced a rapid and reversible increase in internal calcium levels which was concentration dependent. Prolonged application of sub-threshold concentrations (0.1-3nM) of substance P applied for up to 10min produced rhythmic oscillations in internal calcium levels. The NK2 and NK3 receptor agonists $[\beta\text{-Ala}^8]$ neurokinin A-(4-10) and senktide (100nm) were inactive. 50nM concentrations of the rat selective NK1 receptor antagonist RP67580 blocked the response to substance P. Finally, Substance P analogues increased the amount of axon outgrowth from dorsal horn explants when co-cultured with floor plate in collagen gels. These results suggest that SP released from pioneering neuronal pathways can subtly change the extracellular environment and influence the growth and differentiation of developing neuronal systems by regulating the release of chemoattractants from floor plate cells.

533.19

IDENTIFICATION AND CHARACTERIZATION OF A NETRIN SYNERGIZING ACTIVITY (NSA). M. J. Galko*, T. Serafini, and M. Tessier-Lavigne. Dept. of Anatomy, Univ. of California at San Francisco, San Francisco, CA 94143-0452.

Floor plate cells at the ventral midline of the spinal cord secrete a factor(s) that promotes outgrowth of spinal commissural axons and reorients these axons *in vitro*. We recently identified two proteins, netrin-1, (which is highly expressed in floor plate) and netrin-2 (expressed at lower levels in ventral spinal cord) which possess the outgrowth-promoting and reorienting activities of the floor plate. Here we report the characterization of a biochemically distinct activity that potentiates the effects of the netrins. This activity, termed NSA (for netrin synergizing activity), was found in high salt extracts of embryonic brain membranes that had been depleted of netrins by passage over a heparin column in high salt. On young (E11) rat dorsal spinal cord, addition of NSA increased the potency of the netrins in promoting commissural axon outgrowth by one order of magnitude. Surprisingly, commissural axons in older (E13) spinal cord were more sensitive to the netrins, and, concomitantly, NSA had relatively little effect at this age. The reasons for the differences in responsiveness of commissural axons of different ages is not known but could be explained if E13 dorsal spinal cord produces NSA.

To determine whether the potentiation observed with E11 dorsal spinal cord is a true synergy, we identified a concentration of the netrins that, alone, evoked relatively little outgrowth from E11 explants, just as the standard concentration of NSA evoked little or no outgrowth. When E11 explants were cultured with the netrins and NSA at only half these defined concentrations, robust outgrowth was observed which cannot be accounted for by a simple additivity of their effects.

Initial experiments revealed that NSA is protease sensitive and has a molecular weight in excess of 100kD. Purification and identification of NSA will make it possible to determine the mechanism of the synergy and to determine whether NSA modulates netrin function and contributes to commissural axon guidance *in vivo*.

533.18

THE FLOOR PLATE INHIBITS TROCHLEAR MOTOR AXON OUTGROWTH AT A DISTANCE IN VITRO. S.A. Colamarino*, and M. Tessier-Lavigne. Dept. of Anatomy, University of California, San Francisco, CA 94143-0452.

Floor plate cells at the ventral midline of the neural tube secrete a diffusible chemoattractant for some ventrally-directed axons. Netrin-1 and netrin-2, two recently identified vertebrate homologues of *C. elegans* UNC-6, possess this chemotropic activity. UNC-6 is required for accurate circumferential migrations in both the ventral and dorsal directions in the nematode, and may function by attracting axons that migrate ventrally and repelling those that migrate dorsally. This raises the question whether in vertebrates the floor plate (and netrins) repels dorsally migrating axons.

To test this hypothesis we have focused on the formation of the trochlear (IVth) nerve in the region of the junction between the midbrain and hindbrain. The cell bodies of neurons in the trochlear nucleus lie ventrally, but their axons extend circumferentially away from the floor plate to exit the brain dorsally. When explants of the ventral portion of the midbrain/hindbrain junction containing the trochlear nucleus are isolated from E11 rat embryos and cultured in collagen gels, a distinctive bundle of axons exits the dorsal cut-edge of the explants and projects into the collagen. Visualization of the cell bodies and axons with the motoneuron marker F84.1 (Prince et al, 1992) reveals that the axons appear to grow in a narrow corridor within the explant. When a floor plate explant is placed directly opposite the trochlear explant at a distance, the F84.1+ axon bundle grows through the neuroepithelium as usual but now stops when it reaches the cut edge and does not grow into the collagen. This inhibitory effect of the brainstem floor plate is mimicked by spinal cord floor plate. The possible involvement of netrins in mediating this long-range inhibition is under investigation.

EXPRESSION PATTERN OF NETRINS SUGGESTS MULTIPLE ROLES IN AXON GUIDANCE AND CELL MIGRATION. J. R. de la Torre*, T. E. Kennedy, T. Serafini, E. D. Leonardo, and M. Tessier-Lavigne. Dept. of Anatomy, Univ. of California, San Francisco, CA 94143-0452.

During the development of the spinal cord, commissural axons extend ventrally toward the floor plate. Previous studies have identified two related proteins, netrin-1 and netrin-2, homologues of the *C. elegans* protein UNC-6, which are capable of orienting commissural axons and promoting their outgrowth *in vitro*. Here we report the patterns of expression of the netrins genes during development. RNA *in situ* hybridization revealed that both netrin genes are expressed in the developing spinal cord during the period of commissural axon growth. Netrin-1 is expressed in the floor plate from the earliest stages of floor plate development, extending from the caudal diencephalon to the spinal cord. Netrin-2 is expressed at lower levels and more diffusely in the ventral neural tube at similar axial levels. Expression of both genes persists throughout the period of commissural axon growth, and well after commissural axons have reached the floor plate and projected to different axial levels. The netrin genes are also expressed in the developing forebrain. Northern analysis indicated that expression of both genes in the brain and spinal cord persists throughout development and into adulthood. Both are also expressed outside the nervous system. At early stages, netrin-1 is expressed in the notochord as soon as it forms. Netrin-1 and netrin-2 are present in the developing paraxial mesoderm, and are significantly enriched in the developing dermamyotome. In addition, netrin-1 is expressed in heart, and at lower levels in lung. Netrin-2 is also expressed at high levels in the developing gastro-intestinal tract and lung, and at lower levels in heart. These patterns persist into the adult, where netrin-1 expression is also detected in muscle and the ovary, and netrin-2 expression is found in the spleen, ovary and testes. These diverse patterns of expression suggest that the netrins may function as chemotropic factors for multiple neuronal or migratory cell types.

FORMATION AND SPECIFICITY OF SYNAPSES IV

NEUROTROPHINS POTENTIATE NEURONAL EXCITABILITY BY INHIBITING GABAERGIC SYNAPTIC TRANSMISSION IN CORTICAL NEURONS. Han G. Kim*, Ti Wang and Bai Lu. Roche Institute of Molecular Biology, Roche Research Center, Nutley, NJ 07110.

Neurotrophins (including NGF, BDNF, NT-3, NT-4/5) have traditionally been regarded as slowly acting signals essential for neuronal survival and differentiation. A recent study showed that BDNF and NT-3 can rapidly potentiate synaptic activity in developing neuromuscular synapses. However, little is known about the role of neurotrophins on functional synapses in the central nervous system. Here we report that NT-3 and NGF rapidly increased the frequency of spontaneous action potentials, and synchronized synaptic activities in developing cortical neurons. In addition, the inhibitory synaptic transmission mediated by GABA_A receptors was reduced by NT-3. Thus, the excitatory effects of neurotrophins on spontaneous action potentials were attributable to a reduction of GABAergic transmission. Our finding, together with previous report of the rapid regulation of CNS neurotrophin expression by neuronal activity, suggest a new mechanism for modulation of synaptic transmission and activity-dependent synaptic plasticity.

NGP, a Synaptically Released Protein with Homology to Acute Phase Proteins of the Immune System.

A.K. Schlimgen, J.A. Helms, H. Vogel and M.S. Perin*. Division of Neuroscience, Dept. of Otorhinolaryngology, Dept. of Pathology, Baylor College of Medicine; Houston, Texas 77030.

We have identified, by affinity chromatography, a binding protein for the snake venom toxin, Taipoxin. The sequence of this 47 kD protein is unique, is suggestive of a secreted protein and has homology to the acute phase proteins, serum amyloid P protein and C-reactive protein, of the pentraxin family. Northern analysis reveals a brain specific message. *In situ* hybridization shows high NGP message levels in neurons of the cerebellum, CA3 and dentate gyrus of the hippocampus, layer 6 of the cortex with no message in glia. Antibody to this protein stains synapses on cerebellar Purkinje cell somas and glomeruli and a subset of glia. Reflecting this, we have named this protein, Neuronal-Glial Pentraxin or NGP. Because NGP appears to be released synaptically and has homology to immune proteins potentially involved in uptake of lipidic, toxic or other antigenic material, we suggest that NGP may be involved in the uptake of synaptic molecules during synaptic remodeling.

534.3

EFFECT OF UNILATERAL SENSORY DEPRIVATION ON SYNAPTIC VESICLE PROTEIN'S EXPRESSION IN RAT OLFACTORY BULB. B. Tavittan, I. Doignon, Kenneth L. Moya, O. Stettler*, INSERM U334, CEA, SFHJ, Orsay, France.

Little is known about the regulation of expression of the growing number of proteins identified on synaptic vesicles. One possible regulatory factor could be the level of neuronal activity, which in sensory systems is dependant on the level of afferent stimulation. We examined the effects of unilateral suppression of odor-mediated stimulation to the olfactory bulb (OB) on 3 synaptic vesicle proteins (SVPs): synaptophysin, SV2, and rab3a, a small GTP-binding protein of the ras superfamily.

The right nostrils of six newborn rats were cauterized under anaesthesia. The animals were sacrificed 6 weeks later, their brains removed and the left and right OBs immunostained using specific antibodies against the 3 SVPs. Tyrosine hydroxylase (TH) immunohistochemistry served as a control for the efficiency of the sensory deprivation. Sections were digitized and densitometry analysis performed in the glomerular (GLOM), the internal plexiform (PLEX) and the granular (GRAN) layers. The level of staining in the striatum was used as an internal standard to normalize between animals.

TH staining was reduced in the GLOM (-30%, p<.0001) but not in the other layers. Among the SVPs, only rab3a showed a reduction, both in the GLOM (-15%, p<.0001) and in the PLEX (-21%, p<.002). In contrast, staining for synaptophysin and SV2 was similar in all layers in the left and right OBs.

These results demonstrate that the level of expression of rab3a, but not of synaptophysin or SV2, are influenced by the afferent input to the OB. One possible interpretation is that rab3a would act as a regulatory element of SV trafficking, while synaptophysin and SV2 could be regarded more as "constitutive" components.

NEURONAL SURFACE PHOSPHOPROTEINS ASSOCIATED WITH NEURITOGENESIS AND SYNAPTOGENESIS. Z. Pawlowska, W. Chen, M. V. Hogan, H.-A. Yang and Y.H. Ehrlich*. CSI/IBR Ctr. Dev. Neurosci., CUNY at Staten Island, NY 10314

Ecto-protein kinases provide the powerful regulatory machinery of protein phosphorylation to the extracellular environment of the nervous system, where delicate interactions among cells, and between surface proteins and components of the extracellular matrix, play significant roles in neuritogenesis and synaptogenesis. The present study identified proteins whose surface phosphorylation coincides with these developmental events. Cultured, embryonic chick-brain neurons possess proteins of MW 12K and 13K whose surface phosphorylation was maximal during the onset of neuritogenesis. Surface phosphorylation of such a low MW protein duplex was detected early in the development of pyramidal neurons cultured from embryonic mouse hippocampus, and this activity decreased after neuritogenesis was completed. Upon maturation and during synaptogenesis, the phosphorylation of another protein duplex (MW of 48K and 50K) appeared. As anticipated from the results listed above, we found that a hybrid, pyramidal-neurons cell line (HN9) derived from embryonic cells has high phosphorylation of the low MW protein duplex associated with neuritogenesis, and a more mature line (HN33) displayed the high surface phosphorylation of the 48K-50K protein duplex, associated with synaptogenesis. The functions of these surface protein phosphorylation systems can now be studied in homogenous populations of cloned neural cells.

THE NITRIC OXIDE/ CYCLIC GMP SYSTEM IS INVOLVED IN THE MATURATION OF INSECT NEURONS J.W. Truman & E.E. Ball*. Res. Sch. Bio. Sci., Australian Nat. Uni., Canberra, ACT, 2601 Australia

We have used immunocytochemical techniques (De Vente et al., 1987, *Neuroscience* 22:361) to monitor cGMP changes in identified neurons in *Locusta migratoria* in response to agents such as sodium nitroprusside (SNP) that generate nitric oxide (NO). Although relatively few neurons respond to SNP during postembryonic life, most motor, sensory and interneurons show a window of NO sensitivity during embryogenesis. Observations on identified neurons such as RP2, ACC and the H cell show that NO responsiveness begins after the completion of axon navigation, is strong throughout axonal branching, and ends after synaptogenesis is apparently completed. During this embryonic window, the main site of cGMP accumulation is the nucleus, possibly providing a direct link between cell-cell signaling and transcription. Using NADPH-diaphorase staining to detect possible sites of NO synthase, we found diaphorase staining first associated with nerve fibers at 40-45% of development and it increased in intensity in the neuropil through the remainder of development. These observations suggest that the maturational phase of neurons is a period uniquely characterized by the presence of the NO/cGMP signaling system and of nuclear targets for cGMP. NO-synthase inhibitor experiments are being used to define the exact role of this system in neuronal maturation.

LONG TERM MAINTENANCE OF NERVE TERMINAL FUNCTION IN THE ABSENCE OF MUSCLE FIBERS IN THE FROG. A. Dunaevsky and E. A. Connor*. Neuroscience and Behavior Program, Univ. of Massachusetts, Amherst, MA 01003.

Although some of the signals involved in forming and maintaining the synaptic specializations of a target cell are now identified, little is known about the processes that lead to the differentiation and maintenance of the presynaptic nerve terminal. Here the role of the muscle fiber in the maintenance of nerve terminal function has been investigated. We demonstrate that motor nerve terminals permanently deprived of targets maintain the ability to release and recycle synaptic vesicles in response to stimulation. We assayed nerve terminal activity in preparations of innervated muscle basal lamina sheaths using a fluorescent dye FM1-43 that stains nerve terminals in an activity-dependent fashion. Innervated basal lamina sheaths were prepared by excising cutaneous pectoris muscle fibers without damaging nerve terminals. X-irradiation prevented regeneration of the muscle fibers. One to five months after muscle fiber excision, the function of target-deprived nerve terminals was tested by exposure to FM1-43 dye in high K⁺ Ringer's solution. Synaptic sites were identified with rhodamine-labeled peanut agglutinin which stains terminal Schwann cell and synaptic basal laminae. Like intact preparations, nerve terminals deprived of target for 1-5 months incorporated FM1-43 when stimulated. Further, the same terminals were destained by either nerve stimulation or depolarization with high K⁺ Ringer. The ability of these nerve terminals to release and recycle synaptic vesicles indicates that the molecular machinery required for vesicular release is maintained in a functional state for long periods without muscle.

PHOSPHORYLATION OF EXTRACELLULAR DOMAINS OF MICROTUBULE-ASSOCIATED PROTEIN (MAP) 1B MAY BE INVOLVED IN SYNAPSE FORMATION BETWEEN CORTICAL NEURONS. K. Muramoto*, M. Kawahara, K. Kobayashi, H. Taniguchi* & Y. Kuroda. Department of Molecular & Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, Fuchu-shi, Tokyo 183, Japan, and *Division of Biomedical Polymer Science, Institute for Comprehensive Medical Science, Fujita Health University, Toyoake-shi, Aichi 470-11, Japan.

Synapse formation between cultured rat cortical neurons is inhibited by the continuous application of K-252b, an ecto-protein kinase inhibitor, which can not permeate the cell membrane (Muramoto, et al., Proc. Jpn. Acad., 64, 319, 1988; Kuroda, et al., Neurosci. Lett., 135, 255, 1992). In order to identify membrane proteins which may be involved in synapse formation, [γ -³²P]ATP was applied to the cultured cells for brief periods to phosphorylate their extracellular domains. The phosphorylated proteins were separated by SDS polyacrylamide gel electrophoresis and detected by autoradiography. Some of these bands were immediately phosphorylated and this phosphorylation was suppressed by the addition of K-252b to the medium. We examined the partial amino acid sequence of these substrates. Phosphorylated bands were cut from the gel and digested with lysyl endopeptidase. Peptide fragments were separated by capillary HPLC and analyzed by mass spectrometry. The band with the highest molecular weight, whose phosphorylation was strongly inhibited by K-252b, was identified as microtubule-associated protein (MAP) 1b. These results suggest the possibility that the phosphorylation of extracellular domains of MAP1b is involved in synapse formation between cortical neurons.

BLOCKADE OF SPONTANEOUS NEURAL ACTIVITY IMPAIRS THE DEVELOPMENT OF THE DENDRITIC SPINES IN CULTURE. Teng Wu*, Mark J. Maguire, Ford F. Ebner. Institute for Developmental Neuroscience, John F. Kennedy Center, Vanderbilt University, Nashville, TN 37203

Blocking patterned neural activity has been shown to prevent the normal development of dendritic spines *in vivo*. We have investigated whether spontaneous neural activity is necessary for induction of spine formation *in vitro*. Neurons from rat somatic sensory cortex were enzymatically dissociated on postnatal day 1 and plated on a glial monolayer. Pyramidal neurons were injected with Lucifer yellow at the end of 2, 3 or 4 weeks in culture to label dendritic spines. Injected neurons were fixed with 4% paraformaldehyde, dehydrated and mounted in krystaton before imaging them with a Leica confocal microscope. Confocal images of control cultures showed only a few dendritic spines after two weeks in culture, whereas pyramidal neurons were densely covered with spines by the end of weeks 3 and 4. Mushroom, stubby, long-thin and branched dendritic spines were clearly discernible in the confocal images. Tetrodotoxin (1 μ M, TTX) added to the culture medium interfered with the development of dendritic spines depending on the onset and duration of exposure. The presence of TTX throughout weeks 1, 2, 3 or only weeks 2, 3 dramatically decreased the number of spines when examined at the end of week 3. TTX exposure only during week 2 blocked the development of dendritic spines at the end of week 3; however, high densities of dendritic spines did develop by the end of week 4. This delay in spine initiation suggests that induction of dendritic spine formation is critically dependent upon spontaneous neural activity. (Supported by NS-13031)

DEVELOPMENTAL ELECTRICAL ACTIVITY CHANGES IN CULTURED CORTICAL NEURAL NETWORKS P.J. Charley, Y. Jimbo, E. Maeda, H. Kamioka, and A. Kawana* NTT Basic Res. Labs., Atsugi, Kanagawa, 243-01 Japan

Long term multi-site monitoring of electrical activity in neural networks should yield insight into the mechanisms of network development. Here we describe the long term profile of electrical activity in both dissociated and organotypically cultured cortical neural networks of rat, recorded using planar electrode arrays (PEA).

The methods for fabricating the PEA and culturing the dissociated cortical neurons were described before (Y. Jimbo et al, IEEE Trans BME). In the case of organotypic cultures, P0 cortical slices were fixed on the PEA using coagulated chicken plasma and cultured in the same way as dissociated cultures. The electrical activities were measured under culture conditions. At 4 or 5 days *in vitro* (DIV), periodic bursting appeared in the dissociated culture, with a period of more than 20 sec and large delays between burst initiation between the electrodes. The period and the delay became shorter and shorter with further days of culture. As these burstings were reversibly inhibited by TTX and APV, they are accompanied by transient Ca^{2+} increases as described before (Robinson et al, J. Neurophys.). After 21 DIV, the electrical activity changed into a more complex profile consisting of burstings and spiking which appeared to be inherent or stable activity profile of the networks. In the case of organotypic culture, no signals was observed through electrodes until 7 DIV. Periodic bursting appeared from 8 DIV and changed into a more complex profile from 11 DIV. Taking into the consideration the data on the development of NMDA receptors and inhibitory synapses in the cortex, these results suggest that the periodic bursting effects a change in the networks from a developmental stage to the inherent one.

Embryonic Epinephrine Synthesis: Association with Cardiogenesis S.N. Ebert*, M. Fujinaga, J.M. Baden, B. Siddall and D.L. Wong, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305

Phenylethanolamine N-methyltransferase (PNMT) is the final enzyme in the pathway for epinephrine synthesis; hence, PNMT serves as a marker for the cells which produce this neurohormone/neurotransmitter. While much is known about the developmental expression of PNMT in the adrenal gland and the brain, very little is known about its developmental expression elsewhere. We demonstrate that PNMT mRNA can be detected in rat embryos as early as gestational day 9.5. By gestational day 11, PNMT mRNA and active enzyme can be specifically localized to the heart. Immunocytochemical analysis further reveals that PNMT protein is predominantly contained within the embryonic cardiac cells. Our results therefore suggest that the embryonic heart is the primary site of PNMT expression early in development. The presence of PNMT mRNA, enzyme activity and protein well before the appearance of nerve cells around the heart suggests that the embryonic heart may be capable of synthesizing epinephrine during early cardiogenesis. Since cardiac cells are already beating and can respond to epinephrine at this stage of development, our findings indicate a potential role for epinephrine in early cardiac function.

NEONATAL 6-OHDA LESIONS ALTER THE DEVELOPMENTAL EXPRESSION OF STRIATAL DA D1 RECEPTORS AND D1 mRNA. P.A. Frohna*, B.S. Neal-Beliveau, and J.N. Joyce, Depts. Psychiatry and Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA, 19104.

The postnatal developmental profile of striatal dopamine innervation and dopamine receptor expression suggest that the two may be related. Our previous studies have shown that adult rats that received postnatal day 1 (P1) 6-OHDA lesions have a significant loss of D1 receptors and a significant increase in D1 mRNA in the dorsolateral (DL), dorsomedial (DM) and ventromedial (VM) caudate (CPu), regions with the greatest loss of TH-positive fibers. Thus, normal DA innervation during postnatal development may be important for the appropriate control of DA D1 mRNA and receptor expression. To determine the temporal relationship between the loss of DA innervation and the changes in DA receptors/mRNAs we have examined the developmental profile of D1 receptors and D1 and D2 mRNA in rats with P1 6-OHDA lesions.

Lesion-induced changes in D1 receptor binding were found within a week of the lesion (P7) with significant ($p < .05$) losses in the DM (-11%) and VM (-15%) CPu that coincided with a significant loss of D1 mRNA (-10% & -18% respectively). D1 receptors remained significantly decreased in the DL (-9-16%), DM (-10-16%), and VM (-9-15%) CPu at P14, P35, and P90. However, in the medial CPu there was a rebound by P14 when lesioned animals showed a significant increase (+20-29%; $p < .05$) in D1 mRNA. This increase in D1 mRNA was also seen at P35 in the DL (+15%), DM (+19%), and VM (+20%) CPu. This suggests that the earliest postnatal DA innervation may be necessary for the initial expression of D1 receptors and the appropriate coupling between D1 mRNA and D1 receptor expression. 6-OHDA lesions initially decreased D2 mRNA (-10%; $p < .05$) in the DL CPu of the P7 group, but was significantly increased by P14 in the DL (+10%) and DM (+8%) CPu. D2 mRNA levels returned to control levels by P35, similar to P90. Therefore, P1 6-OHDA lesions cause only a transient upregulation of D2 receptor mRNA. These results further suggest that the developmental expression of striatal D1 and D2 receptors/mRNAs are differentially regulated, and that D1 receptors require normal DA innervation for proper expression. This work supported by MH 48813.

LAMININ AND NEUROPEPTIDE Y ARE INCREASED BY SYNAPSIN TRANSFECTION IN CULTURED NG108 NEUROBLASTOMA/GLIOMA HYBRID CELLS. G. Fried*, H-Q. Han, B. Meister, T. Hökfelt and P. Greengard, Dept. of Molecular and Cellular Neuroscience Rockefeller University, New York, Dept. of Physiology, Pharmacology and Neuroscience, Karolinska Institute, Stockholm, Sweden

We have investigated the presence and expression of some neuronal markers in several NG108 cell lines transfected with synapsin Ib, Iia or Iib and differentiated with prostaglandin E1 plus IBMX. Laminin, a basal membrane glycoprotein that promotes adhesion and induces neurite outgrowth and neuronal differentiation, was increased in all transfected cell lines examined. Neuropeptide Y (NPY) was also increased in all transfected cell lines examined. Immunohistochemical analysis combined with confocal laser microscopy showed that NPY staining was granular and very often enriched in neuritic varicosities. The distribution and the staining pattern of NPY was consistent with storage of NPY in large dense cored vesicles. The catecholamine-synthesizing enzymes tyrosine hydroxylase (TH) and dopamine- β -hydroxylase (DBH) were more frequently expressed in transfected cell lines, although both were also present in mock-transfected cell lines. The results indicate that, in differentiated neurons, the synapsins increase the levels of a biochemical marker for large dense cored vesicles and of an extracellular matrix protein associated with neuronal maturation.

535.2

EVIDENCE FOR DOPAMINE RECEPTOR PRUNING IN CORPUS STRIATUM BUT NOT IN NUCLEUS ACCUMBENS M.H. Teicher*, J.C. Hostetter, & S.L. Andersen, Mailman Research Center, McLean Hospital, Harvard Med. Sch., Belmont, MA 02178.

The most important developmental change to take place in the brain immediately before adulthood, is the pruning of overproduced synapses or receptors. Previously, we demonstrated that dopamine (DA) D₁ and D₂ receptors density in rat striatum peaked at approximately 40 days of age (onset of puberty), and declined by 58-75% by adulthood (120 days). In this experiment, we sought to more specifically establish the time course of synaptic elimination in the striatum and to compare the time course in the striatum with the nucleus accumbens.

D₁ and D₂ receptor density were determined in 9 male rats at 40, 60, 80, 100, and 120 days of age (n=45) with quantitative autoradiography. D₁ receptors were assessed using [³H]-SCH-23390, while D₂ receptors were quantified using [³H]-YM-09151-2. Binding data were corrected for protein content. We found that pruning occurred predominately between 40 and 60 days of age. For the D₁ receptor system, 91% of DA receptors lost between 40 and 120 days, were lost by day 60. Bmax decreased from 1583 ± 53 at day 40 to 790 ± 22 by day 120. In the D₂ system, the decline in receptor number appeared to take place more gradually (Bmax at day 40 was 941 ± 39, declined to 672 ± 23 by day 60, and 535 ± 21 by day 120). In contrast, we found no evidence for either D₁ or D₂ receptor elimination in the nucleus accumbens (Bmax increased from 890 - 962 for D₁, and 380 - 445 for D₂ between 40 and 120 days).

This finding suggests that synaptic elimination may not be a universal phenomenon. An alternative possibility is that elimination occurs at an earlier age. We are in the process of investigating this possibility.

PERINATAL INSULTS TO DEVELOPING DOPAMINE SYSTEMS IN RAT. K.C. Langley* and C.C. Ouimet, Program in Neuroscience, Florida State University, Tallahassee, FL 32306.

Perturbation of developing dopamine systems in neonatal rat brain may lead to cytoarchitectural restructuring that persists into adulthood. Such disarrangements allow a functional compensation for the animal and yet provide an excellent opportunity for investigation of pathology proposed for neurological disease states. In these studies day-old Sprague-Dawley rat pups received injections of the neurotoxin 6-hydroxydopamine (6-OHDA) into striatum or prefrontal cortex (PFC). These brain regions reflect differentially organized dopamine systems: the striatum is a dopaminergic target of the substantia nigra (SN) while prefrontal cortical regions receive dopamine from the ventral tegmental area. Immunohistochemistry for tyrosine hydroxylase was employed to assess effects of experimental manipulations. As expected, cell body staining in the SN was absent from those rats who had received 6-OHDA injections in striatum. Apparent axonal sprouting was observed in prefrontal cortical areas of rats who had been subjected to 6-OHDA in PFC. Such sprouting was not seen in control animals nor in rats who had received striatal 6-OHDA lesions. These results suggest that an early insult to developing dopamine systems can lead to viable aberrant neuronal circuitry in PFC. D₁ DOPAMINERGIC AGONISTS INCREASE THE EXPRESSION OF DYNORPHIN AND C-FOS IN PRIMARY STRIATAL CULTURE OF RAT. G. Bing*, G. Wu, H. Kim, M. McMillian, Q. Qi, X. He and J. S. Hong. LMIN, NIEHS/NIH, Research Triangle Park, NC 27709

The effects of dopamine receptor agonists on the expression of dynorphin (DYN) and Fos or Fos related antigens (FRA) were studied in primary striatal cultures from 7-day old rat pups. Levels of DYN, c-Fos or FRA immunoreactivity and their mRNAs were investigated by using immunocytochemistry, *in situ* hybridization and radioimmunoassay techniques. Activation of DA receptors by (\pm)-chloro-APB hydrobromide (APB), a specific D₁ dopamine receptor agonist, at 10 μ M (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal culture and increased DYN level in the media 3 to 4 fold compared to control or quinpirole, a specific D₂ agonist. Apomorphine, a mixed D₁ and D₂ agonist, also increase the level of DYN in the media to 2 fold. *In situ* hybridization experiments showed that both DYN and c-fos mRNA were increased by APB treatment but not by quinpirole. In order to further understand the cellular mechanisms underlying the regulation of DYN expression by the dopamine system, the effects of forskolin, an adenylate cyclase activator, were studied. Forskolin caused an increase in the number of both DYN and c-Fos positive cells indicating that cAMP may be involved in the regulation of DYN expression.

CENTRAL ADMINISTRATION OF rhGDNF CAUSES AUGMENTATION OF DOPAMINERGIC ACTIVITY IN VIVO. G. Miller*, P. Martin and T. Cullen. Dept. Pharmacology, Synergen Inc., 1883, 33rd St., Boulder, CO 80301.

Glial-derived neurotrophic factor (GDNF) a member of the TGF- β superfamily was recently cloned, expressed, and shown to manifest potent trophic activity for embryonic midbrain ventral mesencephalic dopaminergic neurons *in vitro* (Lin et al., 1993).

The present studies were designed to investigate the behavioral and neurochemical effects of rhGDNF (0.1-100 μ g/ μ l) or vehicle (2 μ l) after administration into either the striatum, substantia nigra or intraventricular (icv) in F344 male rats. The injection of rhGDNF into either of the three sites produced dose-dependent increases in motor activity when compared to vehicle controls. Motor activity returned to baseline within 7-10 days for striatal or icv administered rhGDNF. This effect was extended (14-21 days) when rhGDNF was administered into the substantia nigra.

Neurochemical analysis was performed on the substantia nigra at the two week time point, dopamine levels were elevated in the substantia nigra compared to the contralateral non injected side. The increase in dopamine levels by rhGDNF was dose-dependent and was not dependent upon whether rhGDNF was given into the striatum or substantia nigra. Eight weeks post rhGDNF administration into the substantia nigra, dopamine levels were back to control levels.

Taken together, these results suggest that rhGDNF elicits an augmentation of the substantia nigra dopaminergic system *in vivo*. Therefore, rhGDNF may be worth investigating in restoring the compromised dopaminergic system in Parkinson's disease a neurodegenerative disorder.

535.9

EXPRESSION OF SOLUBLE AND MEMBRANE CHOLINE ACETYLTRANSFERASE DURING DEVELOPMENT. J.H.F. Peng*, P.G. Rhodes and Z. Cai. Dept. of Pediatrics/Newborn Medicine, Univ. of Miss. Med. Ctr., Jackson, MS 39216.

Choline acetyltransferase (ChAT) exists as soluble and membrane forms. However, the developmental changes of these isoforms during fetal and postnatal life are currently unknown. In this study, the brains of rat pups at various ages were obtained to assess the developmental changes of ChAT activities in these brains. Rats were sacrificed by decapitation at 7, 20, and 30 days after birth and their brains were removed. Brains were homogenized in a glass-TEFLON motor driven homogenizer, and soluble and membrane ChAT fractions were prepared by differential centrifugation. ChAT activity was assayed radiochemically. At 7 days of age, each brain contained soluble ChAT of 2.7 units (U: nmol ACh formed/min) and membrane of 1.1 U with specific activity (s.a.: U per mg protein) of 0.22 and 0.15, respectively. ChAT activity was drastically increased with increasing age. At 20 and 30 days of age, soluble ChAT increased 12-fold to 33 UGW (units/gram wet weight) and 16-fold to 43 UGW with s.a. of 1.1 and 1.3, respectively, while membrane ChAT increased 12-fold to 13 UGW and 14-fold to 15 UGW with s.a. of 0.51 and 0.62, respectively. Furthermore, there was a higher percentage of membrane ChAT at a younger age (7 days) as compared to soluble ChAT at an older age (20 and 30 days).

535.6

DEVELOPMENT OF SEROTONIN UPTAKE SITES IN BRAIN REGIONS OF THE OFFSPRING OF CONTROL AND ETHANOL-FED RATS. J.-A. Kim* and M.J. Druse-Manteuffel. Neuroscience Program and Molec. & Cell. Biochem. Loyola U. Med. School, Maywood, IL 60153.

This laboratory previously demonstrated that *in utero* ethanol exposure markedly impairs the development of the serotonergic system. As an extension of these studies we examined the effects of *in utero* ethanol exposure on the development of serotonin (5-HT) uptake sites in multiple brain areas. [³H]-Citalopram was used to radiolabel 5-HT uptake sites on twenty micron brain sections. Brains were obtained from 19- and 35-day-old offspring of pair-fed control, pair-fed ethanol or ad libitum control dams that consumed a liquid diet on a chronic basis prior to parturition. The relative density of [³H]-citalopram binding in each brain area was determined using the NIH Image program.

In all brain areas examined [³H]-citalopram binding was comparable in the age-matched offspring of pair-fed and ad libitum control rats. In addition, the offspring of ethanol-fed dams demonstrated a normal concentration of 5-HT uptake sites in the dorsal and median raphe at 19 and 35 days of age. However, [³H]-citalopram binding appears to be decreased in the hippocampal CA3 region and in the substantia nigra of the ethanol-exposed offspring.

DEVELOPMENTAL PROFILE OF VARIOUS CHOLINERGIC MARKERS IN THE RAT MAIN OLFACTORY BULB USING QUANTITATIVE AUTORADIOGRAPHY. H. Le Jeune¹*, J. Aubert¹, F. Jourdan¹ and R. Quirion². ¹Douglas Hospital Res. Ctr., Dept. Psychiat. McGill Univ, 6875 Boul. Lasalle, Verdun, Canada H8P 2H8 and ²Laboratoire de Physiologie neurosensorielle, CNRS UA180, UCB Lyon I, 69622 Villeurbanne cedex, France.

The main olfactory bulb (OB) is considered to be a good model of centrifugal cholinergic innervation in a cortical region. Accordingly, we investigated the development of various cholinergic markers in the OB of Wistar rats at post-natal days 2, 9, 14, 20, 30, and in 3 month-old adults. Using *in vitro* receptor autoradiography, the comparative profiles of the high affinity choline uptake ([³H]hemicholinium-3, HC-3), acetylcholine vesicular transporter ([³H]vesamicol, Ves), muscarinic M1 and M2 ([³H]pirenzepine and [³H]AF-DX 384, respectively) and nicotinic ([³H]cytisine) receptors were determined. Well established pre-synaptic cholinergic markers ([³H]Ves and [³H]HC-3) were not necessarily in close register with either muscarinic M1 and M2, and nicotinic receptors in both immature and adult OB. For example, a subset of atypical olfactory glomeruli known to receive strong and precocious cholinergic centrifugal inputs was most enriched with HC-3 and Ves labelling but only contained low amounts of M1 and M2 sites. Developmentally, most markers exhibited their lowest levels of expression at birth increasing gradually during the first 4-5 post-natal weeks to reach their adult level. Interestingly, both [³H]Ves and [³H]HC-3 bindings were relatively abundant early after the birth (day 2) preceding the clear appearance of acetylcholinesterase (AChE) staining in the atypical glomeruli (Le Jeune and Jourdan, 1991, J. Comp. Neurol. 314). A transient over-expression of [³H]Ves sites was noted around day 20th, corresponding to the increase in AChE staining in intrinsic neurons. The ontogenetic profiles of M1 and M2 receptors were rather similar in all laminae of the OB, except for a somewhat earlier appearance of the M1 sub-type. Thus, presynaptic cholinergic markers appear to develop earlier than muscarinic M1 and M2 receptors during the post-natal ontogeny of the OB.

DEVELOPMENT OF BUTYRYLCHOLINESTERASE-POSITIVE CELL POPULATIONS IN THE MESENCEPHALON OF THE RAT. S.J. Rauth*, S. Darvesh and D.A. Hopkins. Dept. of Anatomy and Neurobiology, Dalhousie University, Halifax, N.S., Canada, B3H 4H7.

The enzyme butyrylcholinesterase (BuChE, E.C. 3.1.1.8) is found in a distinct population of midline mesencephalic neurons which project to the spinal cord. BuChE has been implicated in neuronal development and neurotransmission, and may function in development prior to the appearance of acetylcholinesterase. Therefore, we have investigated changes in the spatiotemporal distribution of this enzyme during late prenatal and early postnatal development in the midline mesencephalic area which includes the region containing ciliary preganglionic neurons. Brain sections from rats at ages E14, E16, E19, P0, P7 and P14 were stained for BuChE using a modification of the histochemical method of Karnovsky and Roots, 1964. Adjacent sections were stained with AChE, ChAT and NADPH-d histochemistry, and their distributions were compared to that of BuChE. The intensity of BuChE staining within neurons located in the region of the mesencephalon increased with age. At days E14 and E16 somata within the region of the medial tegmental neuroepithelium, ventrolateral to the cerebral aqueduct, exhibited a light BuChE stain. At P0 the corresponding mesencephalic region showed a much more intense BuChE stain than seen in the embryo but the distinct pattern of distribution seen in the adult had not yet emerged. By P7 the staining pattern of these neurons approximated the adult BuChE distribution. P14 showed the same spatial distribution of BuChE that is seen in the adult, with comparable BuChE cell populations in the midline mesencephalon, anterior median nucleus, nucleus Darkschewitsch and the nucleus raphe dorsalis. The results show that BuChE can be used as a developmental marker for populations of neurons in the mesencephalon, and changes in the distribution of BuChE may reflect the maturation of neural structures within this region. BRAIN AND ENDOTHELIAL NITRIC OXIDE SYNTHASE EXPRESSION IS REGIONALLY AND TEMPORALLY REGULATED IN FETAL SHEEP BRAIN. F.J. Northington, R.C. Koehler, R.J. Traystman*, and L.J. Martin. Dept. of Pediatrics, Anesthesiology/Critical Care Medicine, Pathology, and Neuroscience. The Johns Hopkins Medical Institutions, Baltimore, MD 21287.

Using immunohistochemistry, we tested the hypothesis that brain NOS (bNOS) and endothelial NOS (eNOS) expression is regulated developmentally in fetal sheep brain at 60, 71, 93, 110 and 136 days (d) of gestation (term=145d). No nonspecific immunoreactivity (IR) was found if the 1° antibody was omitted; no cross reaction between bNOS and eNOS was seen at any gestational age; and neither isoform was localized to glial cells. At 60d, bNOS has a laminar localization in neuropil of the lower cortical plate of the telencephalic vesicle which becomes less distinct as the cortical plate matures, dissipating by 136d. A subset of nonpyramidal cortical neurons first shows discrete bNOS IR at 71d. By 136d, two subsets of interneurons with somatodendritic IR for bNOS are dispersed throughout cerebral cortex. Regional differences in bNOS IR within cortex occur at 71 and 93d but not at 110 and 136d. IR for bNOS in striatum increases from first appearance at 71d to peak density of bNOS-positive medium sized aspiny neurons at 110d. Labeling of cerebellar basket cells peaks at 136 days. The vascular bed expresses eNOS throughout gestation. The radial vascular architecture evolves into a complex branching pattern between 60 and 110d. A dense capillary bed with eNOS IR is found within white matter in contrast to the relative absence of bNOS IR in this area. By 136d, eNOS in vascular beds of brainstem, diencephalon, basal ganglia, and cortex is homogeneously distributed, in contrast to the absence of eNOS IR in the ventricular zone. We conclude that bNOS and eNOS are present prior to midgestation in the fetal sheep, and the developmental regulation of NOS expression, particularly bNOS, parallels regional brain maturation.

REGULATION OF EXPRESSION OF NADPH-DIAPHORASE ACTIVITY (NADPH-DA) AND NEURONAL NITRIC OXIDE SYNTHASE (NOS) IN PRINCIPAL NEURONS OF RAT AND MOUSE SUPERIOR CERVICAL GANGLIA. MD Johnson*, JA Garcia, PB Senatus, DG Green, and DD Potter. Department of Neurobiology, Harvard Medical School, Boston, MA 02115

Preganglionic sympathetic axons of adult rats and mice express NADPH-DA and NOS immunoreactivity *in vivo*; however, principal neurons of the superior cervical ganglion (SCG) express these markers for NOS lightly or not at all (e.g. Grozdanovich et al, 1992, Neuroscience 48:225; Dun et al 1993, Neurosci. Lett. 158:51; Johnson et al, unpublished). When postnatal rat and mouse SCG neurons (and some adult SCG neurons) were cultured for 1 week in medium containing 5% rat serum, however, NADPH-DA was visibly induced in about 80% of such cells; the staining varied from barely detectable to intense (Senatus et al, 1992, Abstracts 18:772). In many neurons, NADPH-DA was co-localized with immunoreactivity for the neuronal isoform of NOS (antibody provided by Dr. Bernd Mayer). In mice homozygous for deletion of the neuronal NOS gene (provided by Dr. Paul Huang; cf Huang et al, 1993, Cell 75:1273), and in which there was no NADPH-DA in the preganglionic sympathetic fibers *in vivo*, clear light NADPH-DA was present in principal neurons in adult ganglia, and in cultured postnatal neurons; the staining of the cultured neurons was significantly lower than in neurons from wild-type mice. The presence of numerous ganglionic non-neuronal cells in the cultures reduced the proportion of NADPH-DA stained cells. Supported by NS02253 and the Freudenberger Fund. We thank Kara Dunn for technical assistance.

BRAIN DEVELOPMENT DURING SMOLT TRANSFORMATION IN SALMON MAY BE AFFECTED BY ENVIRONMENTAL CONDITIONS. L.O.E. Ebbesson, K. Drew and S.O.E. Ebbesson*. Institute of Marine Science and Institute of Arctic Biology, Univ. of Alaska, Fairbanks, AK 99775.

Smolt transformation (ST), which occurs midlife, is associated with olfactory imprinting and dramatic physiological adaptations. Our studies have also revealed that it is a critical period of neural development characterized by new neural connections, sequential surges of neurotransmitters, and receptors of various types. These events probably reflect orderly changes in the brain necessary for subsequent survival and return to the natal stream.

It is well known that ST is affected by environmental factors such as light and water temperature. Significantly different return rates have been observed for chinook salmon reared under normal conditions as compared to those whose growth and maturation has been accelerated by rearing in warm water. We have begun studies to determine if brain development necessary for olfactory imprinting and survival is the same in different rearing conditions. We report here that during ST, there are significant differences in the surges of select brain monoamine and amino acid neurotransmitters under the two rearing strategies. The plasma thyroxine levels are also different. The significance of these findings in relation to normal versus inadequate brain development are, however, not known and require further investigations. Supported by the Alaska Sea Grant Program and the NIH.

EFFECTS OF SERA ON INDUCTION OF NADPH DIAPHORASE ACTIVITY (NADPH-DA) IN CULTURED PRINCIPAL NEURONS OF THE SUPERIOR CERVICAL GANGLION (SCG) OF THE POSTNATAL RAT. J.A. Garcia, M.D. Johnson and D.D. Potter*. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Induction of NADPH-DA was reported in dissociated and cultured SCG neurons of the postnatal Long Evans rat by Senatus et al., 1992. Characterization of the time course and level of induced NADPH-DA in cultured SCG using growth medium with 5% normal rat serum (NRS; Sigma) demonstrated NADPH-DA in less than 1% of SCG neurons at time of plating and in about 80% of neurons after 1 week in culture. The inductive effects of 5% NRS have now been compared to growth medium supplemented with 5% dialyzed fetal calf serum (dFCS; 10,000 MW cut-off; Sigma). SCG neurons cultured in 5% dFCS also displayed a positive inductive effect on NADPH-DA, but the percentage of neurons expressing NADPH-DA was significantly lower (<1% at time of plating and about 30-40% after 1 week in culture). Culture in a serum-free medium resulted in 15-20% of neurons expressing NADPH-DA after 1 week, and culture in growth medium supplemented with 5% heat inactivated serum resulted in 20-25% of neurons expressing NADPH-DA after 1 week.

To characterize further the time course and nature of these positive inductive effects, a serum reversal experiment was performed. Neurons cultured in 5% NRS were switched to 5% dFCS and *vice versa*. Serum reversal on culture Day 19 had no subsequent effect on the percentage of NADPH-DA positive neurons. Serum reversal on culture Day 6-7 had the following effects: neurons cultured first in 5% NRS and later switched to 5% dFCS maintained an 80% level of NADPH-DA (no change); however, neurons cultured first in 5% dFCS and later switched to 5% NRS went from a 30-40% NADPH-DA level to an 80-85% level of NADPH-DA. These data suggest that the factor(s) in serum that promotes induction of NADPH-DA is heat labile and is effective under these conditions in only a limited period in culture. Supported by PO1 NS 02253 and the Freudenberger Fund.

MEASUREMENT OF NEUROTENSIN (NT), NT1-11 AND NT1-8 IN THE DEVELOPING RAT BRAIN. S.H. Moss, G.W. Bennett and C.A. Marsden (SPON: Brain Research Association) Dept. Physiology and Pharmacology, Medical School, Queens Medical Centre, Nottingham, NG7 2UH, UK.

Neurotensin (NT) appears to function as a neurotransmitter or neuromodulator in the adult rat brain, whilst in the developing rat brain, an early transient appearance of NT precursor mRNA in some brain regions (Sato et al. (1990) Dev. Brain Res. 54:249-255), suggests a developmental role for NT, perhaps in the establishment of neuronal organisation.

In the present study NT-LI has been quantified in the diencephalon, telencephalon and ventral mesencephalon of Wistar rat brains aged from embryonic day 15 (E15), through birth (22nd day of gestation), to postnatal day 2 (P2), using a sensitive radioimmunoassay technique (0.9 fmole/tube).

NT-like immunoreactivity (NT-LI) appeared during the prenatal period in all three regions studied and exhibited two general ontogenic patterns. In the diencephalon and telencephalon NT-LI levels peaked at birth and E20, respectively, then declined, whilst, in the ventral mesencephalon, where levels were approximately 25% of those in the diencephalon and telencephalon, NT-LI after an initial increase reached a plateau around E18, which was maintained through to P2.

The polyclonal NT antibody used was N-terminally directed and thus recognised and measured the NT metabolites, NT1-8 and NT1-11, in addition to NT itself. Therefore, a High Pressure Liquid Chromatography (HPLC) method, utilising a methanol gradient from 30% to 60% over 30 minutes, was developed to separate these three peptides prior to measurement by a RIA of increased sensitivity (0.3 fmole/tube). The latter two techniques are thus presently being used to quantify the proportions of NT, NT1-11 and NT1-8 in foetal rat brain regions.

COORDINATED REGULATION OF *TRKA* AND *CHAT* EXPRESSION IN DEVELOPING RAT BASAL FOREBRAIN: EVIDENCE THAT ENDOGENOUS NGF REGULATES CHOLINERGIC DIFFERENTIATION THROUGH *TRKA*. Y. Li, D.M. Holtzman, L.F. Kromer, D.R. Kaplan, J. Chua-Couzens, D.O. Clary, B. Knusel, W.C. Mobley*. Dept. of Neurology & Howard Hughes Medical Institute, UCSF, San Francisco, CA 94143; Dept. of Cell Biology, Georgetown Univ. Med. Ctr. Washington, DC 20007; Eukaryotic Signal Transduction Group, ABL-Basic Research Program, NCI-Frederick Cancer Research & Dev. Ctr., Frederick, MD 21702; & Div. of Neurogerontology, Andrus Gerontology Ctr. & Dept. of Biological Sciences, USC, Los Angeles, CA 90089.

To understand the role of NGF in the differentiation and maturation of basal forebrain cholinergic neurons (BFCNs), we examined the expression of *trkA* in rat BFCNs during postnatal development. Using *in situ* hybridization, we have previously shown that *trkA* and *ChAT* are colocalized to the same group of cells throughout development. In the present work, we further characterized the regulation of *trkA* expression in BFCNs during development. Northern analysis showed that expression of *trkA* was highly regulated and the temporal pattern was very similar to that for *ChAT*, suggesting that expression of both genes was coordinately regulated. Immunocytochemical and Western analysis confirmed that *trkA* protein was present in the basal forebrain during the postnatal period. Intraventricular (ICV) injection of NGF induced tyrosine phosphorylation of *trkA* protein by postnatal day 7. Furthermore, *in vivo* infusion of NGF resulted in increases of both *trkA* and *ChAT* mRNA in BFCNs, while ICV injection of an anti-NGF antibody inhibited expression of *trkA* and *ChAT* as well as suppressed the normal developmental increase in BFCN cell size. Our findings indicate that NGF is a neurotrophic factor for developing BFCNs and regulates *trkA* and *ChAT* expression in BFCNs during development.

NERVE GROWTH FACTOR ADMINISTRATION ALTERS THE EXPRESSION OF OTHER NEUROTROPHINS IN ADULT SENSORY GANGLIA. S. C. Apfel*, C. Dormia, M. E. Newell and J. A. Kessler. Depts. of Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461

During neural development, specific neuronal subpopulations in the dorsal root ganglion are dependent upon different members of the neurotrophin family, including nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), and neurotrophin 3 (NT3). However, regulatory mechanisms in adult sensory ganglia may differ because of paracrine/autocrine interactions. To address this issue, the effects of exogenously administered recombinant NGF on expression of BDNF mRNA, in the dorsal root ganglia of adult (150-200 gm) female rats, was examined. Each animal was injected subcutaneously with 1 mg/kg NGF and the cervical dorsal root ganglia were removed 24 hours later for measurement of BDNF mRNA, using a solution hybridization/nuclease protection assay. Administration of NGF significantly elevated levels of BDNF mRNA within 24 hours. We are currently investigating this type of regulation with other neurotrophins, and in other peripheral nervous system tissues. The ability of one neurotrophin to regulate the expression of another may have important implications for choosing neurotrophins for clinical use.

INDUCTION OF NGF AND bFGF mRNA BY GLUCOCORTICOID IN RAT BRAIN. A. Colangelo¹, I. Moccetti¹, V. Y. Hayes and P. J. Isackson*. ¹Dept. of Cell Biology, Georgetown Univ. Sch. of Med., Washington DC 20007, and Mayo Clin. Jacksonville, FL 32224.

Nerve growth factor (NGF) and basic fibroblast growth factor (bFGF) exert trophic activity in selective neuronal populations. Glucocorticoid hormones have been shown to possess neurotrophic activity in the adult brain. In view of the massive release of adrenal steroids during stress and their potential role in neuronal survival and function, we deemed it important to verify whether glucocorticoids modify the expression of NGF and bFGF mRNAs. Dexamethasone (DEX), administered to rats at a concentration (0.5 mg/kg, s.c.) that mimics the blood-borne steroid levels following stress, elicited, within 3 hr, a three-fold increase in the content of NGF mRNA in the cerebral cortex only. By 6 hr the content of NGF mRNA declined to the control levels. In contrast, DEX elicited a two-three fold increase in bFGF mRNA in the hippocampus, hypothalamus and cerebral cortex. In all of these areas the DEX-induced bFGF mRNA was rapid (within 3 hr) and lasted up to 24 hr. Aldosterone failed to change either NGF or bFGF mRNA at any time points. Accumulation of bFGF mRNA following DEX occurred also in the hippocampus and cerebral cortex of 8 day old and 2 year old Fisher 244 rats, suggesting that glucocorticoids regulate trophic factor expression throughout life. *In situ* hybridization studies were attempted to characterize the anatomical specificity and cell types wherein DEX increases bFGF and NGF mRNAs. The increase in NGF mRNA was localized in the superficial layers of the neo- and entorhinal cortex and to a less extent to the rostral portion of the hippocampus dentate granule cell layer, suggesting that NGF expression is induced in selected neuronal populations. bFGF mRNA follows a different pattern of expression. Indeed, DEX increased bFGF mRNA throughout the brain, suggesting that DEX increases bFGF mRNA in glial cells. Our data suggest that glucocorticoids by inducing NGF and bFGF mRNA expression in the brain could potentially possess a neurotrophic activity.

536.2

MULTIPLE LEVELS REGULATION OF *TRKA* IN PC12 CELLS BY NGF. J. Zhou, J.S. Valletta, M.L. Grimes*, W.C. Mobley. Dept. of Neurology and the Neuroscience Program, UCSF, San Francisco, CA 94143.

Induction of *TrkA* gene expression is a feature of NGF responses in both PNS and CNS neurons. To discover the significance, we asked whether increased *TrkA* gene expression resulted in an increase in NGF receptors and NGF signaling. *TrkA* mRNA was first increased 48 h after NGF exposure, and by 7 days it was induced 5.3-fold. Using Western blot analysis, we found that gp140^{trk} was down-regulated within the first 24 hours of NGF treatment. Thereafter, protein synthesis increased in parallel with the increase in *TrkA* mRNA. ¹²⁵I-NGF binding and chemical cross-linking analysis showed that there was an increase in gp140^{trk} at the surface of cells treated with NGF for 7 days. NGF primed cells bound and internalized more NGF than unprimed cells. Significantly, in response to NGF the level of tyrosine phosphorylation of gp140^{trk} and PLC-γ1 was increased in primed cells. Our results suggest that after an initial down-regulation of gp140^{trk} in response to NGF, induction of gene expression eventually leads to an enhanced ability for PC12 cells to respond to NGF.

536.4

STERIOD REGULATION OF NEUROTROPHIC FACTORS IN THE RAT HIPPOCAMPUS. H.M. Chao*, R.L. Spencer, M. Frankfurt and B.S. McEwen. Lab. of Neuroendocrinology, The Rockefeller University, New York, NY 10021

In the rat hippocampus, glucocorticoids modulate neuronal morphology and plasticity, and may play a role in the neuronal loss associated with aging. Neurotrophic factors, such as brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT3) and basic fibroblast growth factor (bFGF), can affect the plasticity, integrity and function of hippocampal neurons, both *in vitro* and *in vivo*. In the hippocampus, the colocalization of these neurotrophins with their receptors, suggests that the factors may act locally through autocrine mechanisms to protect against damage and promote neuronal survival. We have examined the adrenal steroid regulation of the genes encoding these neurotrophins, their receptors and the neuronal growth-associated protein GAP-43. Adrenalectomy resulted in an increase in GAP-43 mRNA expression in CA1 and CA3 and a decrease in bFGF mRNA levels in the CA2 subfield; these effects were reversed by corticosterone replacement. In CA3 and the dentate gyrus, there was evidence for glucocorticoid modulation of the BDNF and NT3 mRNAs, but not of the bFGF mRNA or of the mRNAs encoding the receptors for these neurotrophic factors.

β-amyloid peptides, which accumulate in neuritic plaques and are derived from the amyloid precursor protein (APP), can be either trophic or toxic to hippocampal neurons. We have examined the steroid regulation of the most abundant APP mRNA isoform in rat brain, APP695. In aged female rats we observed a decrease in the level of APP695 mRNA relative to young female rats, while no such age difference was evident in male rats. Physiological, surgical and pharmacological manipulation of glucocorticoids appeared to have no effect on APP695 levels in the hippocampus. Ovariectomized rats treated with estrogen and progesterone exhibited higher levels of APP695 mRNA than ovariectomized controls.

536.6

GLUCOCORTICOID REGULATION OF BASIC FIBROBLAST GROWTH FACTOR GENE EXPRESSION IN THE RAT BRAIN. M.A. Riva^{1,2}, J.M.C. Blom², F. Fumagalli², E. Donati², E. Lovati² and G. Racagni², ¹DIBIT, San Raffaele Hospital, and ²Center for Neuropharmacology, Institute of Pharmacological Sciences, University of Milan, Italy.

Several trophic factors have been identified which are important for CNS neurons not only during development but also in the repair and maintenance of neuronal integrity after injury. Basic fibroblast growth factor (bFGF), one of such factors, is expressed in astrocytes and in specific neuronal populations. We have previously demonstrated that bFGF gene expression can be modulated with a specific spatio-temporal pattern by limbic seizures produced by focal application of bicuculline or systemic injection of kainate. We investigated the mechanisms regulating bFGF gene expression during limbic motor seizure examining the role of glucocorticoid hormones in kainate-induced bFGF induction. Bilateral adrenalectomy produced a significant reduction of bFGF mRNA levels in hippocampus and striatum at 3 and 7 days following surgery; no effect was observed in hypothalamus. *In situ* hybridization showed a general decrease of bFGF expression with a marked reduction of labelling in CA2 pyramidal layer of hippocampus. The regulatory influence of glucocorticoid hormones was confirmed by *in vitro* experiments showing a robust induction of bFGF gene expression in rat cortical astrocytes following dexamethasone exposure. Despite adrenalectomy, kainate was still able to produce a significant elevation of bFGF mRNA levels in striatum and hippocampus when measured 6 hr following convulsant injection. In conclusion, although bFGF gene expression in the rat brain appears to be under the control of glucocorticoid hormones, removal of this 'tonic' influence does not influence acute modulation of bFGF gene expression by neuronal activity. As bFGF and other neurotrophic factors exert trophic actions on different neuronal populations, these mechanisms can be important for the regulation of neuronal plasticity in physiological as well as pathological situations.

536.7

CATECHOLAMINERGIC MEDIATION OF COCAINE-INDUCED INCREASE IN REGIONAL LEVELS OF bFGF mRNA. D. Masco*, I. Mocchetti¹ and K. Gale. Departments of Pharmacology and ²Cell Biology, Georgetown Univ. Medical Center, Wash., DC., 20007.

The behavioral stimulant response produced by cocaine is known to show a long-lasting increase with repeated administrations. Such long term plastic changes are likely to involve trophic factors. We have previously shown that the mRNA encoding basic FGF (bFGF) is increased in selected brain areas after a single, prolonged cocaine exposure. In this study, we examined the neurotransmitter receptors that mediate this effect. Rats (450g) received 40 mg of cocaine over 8 hr, after which they were sacrificed and bFGF mRNA was measured. Cocaine induced a significant increase (2-3 fold) in bFGF mRNA in striatum, substantia nigra and frontal cortex. Pretreatment with haloperidol (3.5mg/kg) or chlorpromazine (20mg/kg) prevented the cocaine-induced increases in bFGF mRNA. However, pretreatment with either pimozide (2mg/kg), prazosin (1mg/kg), or a low dose of chlorpromazine (2mg/kg) did not attenuate the cocaine-induced effect on bFGF; pretreatment with propranolol (20mg/kg) was likewise ineffective. It therefore appears that concurrent blockade of dopamine receptors and noradrenergic alpha receptors is necessary for preventing the induction of bFGF mRNA expression in response to cocaine. This suggests that cocaine may influence neurotrophic factor expression via either dopaminergic or alpha adrenergic mediated processes. Studies in progress with selective alpha antagonists \pm selective dopaminergic receptor antagonists will more precisely identify the relative contribution of these receptors to the changes in bFGF mRNA levels that follow cocaine exposure.

INDUCTION OF NGF AND BDNF BY THYROID HORMONE IN ADULT RAT BRAIN. S. Carswell*, E.R. Brown, E. Robbins, K.C. Hartpence, and M.S. Saporito. Cephalon, Inc., 145 Brandywine Parkway, West Chester, PA 19380.

There is evidence that thyroid hormone (TH) is required for the differentiation and maintenance of septal cholinergic neurons. It is also well-documented that NGF prevents the degeneration of basal forebrain cholinergic neurons. In previous studies, chronic treatment with TH (0.5 mg/kg) induced NGF in the hippocampus, but not the cortex, of aged rats (Giordano et al., 1992). Our interest was to determine whether the effects of TH on cholinergic cells are mediated through induced NGF. RNase protection analyses of NGF mRNA after acute systemic administration of various doses of either T₃ or T₄ revealed induction of NGF in the hippocampus and cortex, but not in the septal region of adult Sprague Dawley rats. Peak increases (approximately 1.5-fold) occurred at 0.5 and 5mg/kg with T₃ and T₄, respectively. The effect of each hormone on NGF synthesis was shown to be stereospecific. TH induced BDNF as well as NGF in the cortex, and the induction of both neurotrophins was sustained for at least 20 h. Evaluation of TH in the fimbria fornix lesion model of basal forebrain cholinergic neuronal degeneration will also be discussed.

536.11

REGULATION AND POLARITY OF NEUROTROPHIN SECRETION. Laurie J. Goodman and Franz Hefti*. Department of Neuroscience, Genentech Inc. South San Francisco, CA 94080.

The neurotrophins, BDNF and NT4/5 are factors that regulate the growth and survival of selected populations of peripheral and central nervous system neurons. In this study the regulation and polarity of neurotrophic factor secretion was investigated. Analysis of expression of either BDNF or NT4/5 following expression in the pheochromocytoma-derived cell line, PC12, resulted in the constitutive secretion of immunoreactive proteins migrating at a molecular weight identical to mature BDNF or NT4/5. In the presence of KCl (50mM), secretion of NT4/5 from PC12-transfected cells increased 10-fold as determined by radiolabeling/immunoprecipitation and western blot analysis. This indicates that the protein is primarily released by a regulated pathway of secretion. As an initial approach to understanding the polarity of neurotrophin secretion, the release of BDNF and NT4/5 was investigated in the polarized epithelial cell line, MDCK. Previously studies have determined that many of the same protein sorting mechanisms exist in MDCK cells as do in polarized hippocampal neurons *in vitro*. Cells expressing BDNF or NT4/5 were grown on transwell filters so as to establish a tight monolayer displaying high electrical resistance. Under these conditions, 80-90% of the BDNF secreted from transfected MDCK cells was released from the apical domain, whereas NT4/5 was secreted equally from both the apical and basolateral domains. This suggests that BDNF may be released primarily from the axonal domain in polarized hippocampal neurons. We are currently testing our hypothesis in transfected hippocampal neurons grown *in vitro*.

536.8

ALTERED STRIATAL NEUROTROPHIC mRNA LEVELS IN HYPOTHYROID WEAVER MUTANT MICE Mariann Blum*, Emilee Carrasco, Nancy Goodman and Cynthia Shannon Weickert. Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029

The degeneration of nigrostriatal dopamine neurons that occurs in the *weaver* mutant mouse can be viewed as failed postnatal development. For example, nigrostriatal neurons do not make the normal transition from a primarily patchy innervation to a more diffuse innervation of the striatum during the first weeks of postnatal life. It is possible that insufficient levels of target-derived neurotrophic support is responsible for the abnormal dopaminergic neuronal development and subsequent degeneration. Therefore, we measured the levels of the mRNAs encoding two putative dopaminergic trophic factors using a quantitative nuclease protection assay. Unexpectedly, we observed that at P22 the levels of BDNF and GDNF mRNA levels are elevated in the *weaver* mutant striatum relative to controls ($p < .05$ and $p < .01$, respectively).

Not only does the *weaver* brain appear to develop abnormally, but also their body growth is stunted and their eyelid opening is delayed. Since body growth rate and timing of eyelid opening are regulated by thyroid hormone, we hypothesize that *weaver* mice are hypothyroid. Using radioimmunoassay, we determined that the mutant mice have significantly lower thyroid hormone (T₄) levels during the third postnatal week of life ($p < .001$). This corresponds to the time when the development of mutant dopaminergic neurons is arrested. We speculate that the reduction in thyroid hormone, which is a potent regulator of brain development, could account for altered trophic factor mRNA levels and/or altered dopaminergic neuronal development.

536.10

NGF RECEPTOR low affinity IMMUNOSTAINING IN CHOLINERGIC NEURONS DURING ADULT HYPOTHYROIDISM. L. Calzà*, SL. Aloe, L. Giardino, M. Zanni, SR. Levi Montalcini*. Inst. Of Human Physiology, University of Cagliari; ¹Inst. of Neurobiology, CNR, Rome, Italy; ²Inst. Otolaryngol., University of ³Milano and ⁴Modena, Italy.

Adult hypothyroidism is characterized by neurochemical abnormalities involving neurotransmitters, neuropeptides, neuronal proteins and also trophic factors. Several clinical and experimental data suggest that the cholinergic system of the basal forebrain is sensitive to the peripheral levels of thyroid hormones. In this paper we investigated the NGF receptor low affinity (LNGFR)-like immunostaining in the horizontal nucleus of the diagonal band of adult hypo- and hyperthyroid male rats, in basal conditions and after intracerebral injection of colchicine (75µg/µl/animal, survival time 24 hours). Hypothyroidism was induced by thyroidectomy after 60 days from birth, hyperthyroidism by treatment with T₄ (.18mg day, added to the food pellets). The LNGFR was detected by means of indirect immunofluorescence using monoclonal antibody (clone IgG192, generously supplied by E.M. Johnson). The staining intensity was measured by means of computerized microdensitometry. In colchicine untreated rats, we found a significant increase of LNGFR-like immunostaining in the basal forebrain neurons of hypothyroid rats. The colchicine treatment induces an increase of LNGFR expression in these brain area which is not different in hypo-, eu- and hyperthyroid rats. These data confirm an effect of thyroid hormone on neurons during adulthood also in extrahypothalamic areas and they support a possible role of thyroid hormone in aging brain quality and cognitive performance.

Identification of a potential estrogen response element in the gene coding for brain derived neurotrophic factor (BDNF). F. Sohrabji*, R. C. Miranda and C. D. Toran-Allerand. Dept. Anatomy and Cell Biology, Columbia University CPS, New York, N.Y. 10032.

We are studying the role of estrogen in the survival and differentiation of neurons in the basal forebrain, and its targets in the cerebral cortex, hippocampus and olfactory bulb. We have shown previously that estrogen-target neurons in these regions widely co-express the mRNAs for the neurotrophin peptide growth factors, NGF, BDNF, and NT-3, suggesting a potential substrate for estrogen-neurotrophin interactions. Recent evidence suggests that estrogen may regulate BDNF mRNA in regions of the cortex and hippocampus (M. Singh, personal communication). Since the estrogen receptor is a ligand-activated transcription factor, we have begun to address whether estrogen can regulate gene transcription of members of the neurotrophin family. We have identified a sequence in the gene coding for BDNF that appears to bind the estrogen receptor. Using a band shift assay, we found that nuclear protein extract, harvested from diethylstilbestrol (DES, a synthetic estrogen)-treated MCF-7 mammary tumor cells, resulted in a shift in the migration of a 47 bp DNA fragment from the BDNF gene. Competition studies and receptor antibody recognition assays indicate that the shift results from the binding of the estrogen receptor-ligand complex to this DNA fragment, suggesting that estrogen may potentially regulate transcription of the BDNF gene. We are currently examining the regulation of this gene by estrogen in *in vitro* models. Supported by grants from NIH, NIMH, NSF, AHAF and an ADAMHA-RSA to C.D.T.-A.)

BDNFmRNA LEVELS IN THE CHICK OPTIC TECTUM ARE REGULATED BY NEUROTRANSMITTERS DURING SYNAPTOGENESIS. **K.-H. HERZOG*** AND **Y.-A. BARDE**. Dept. of Neurochemistry, Max Planck Inst. for Psychiatry, Am Klopferspitz 18a, 82152 Martinsried, Germany.

We previously reported that BDNFmRNA is expressed in the visual system of the chick embryo. During the earliest time of target encounter, BDNFmRNA levels are regulated in the tectum by electrical activity of the innervating retinal ganglion cells (RGC). When applied onto the chorioallantoic membrane, nicotinic acetylcholine receptor antagonists do not cause a reduction in BDNFmRNA expression in the optic tectum at E7.5, whereas muscarinic blockers (atropine or pirenzepine) do. Similar results were obtained following optic stalk transection, intraocular TTX application, and of the GABA_A-receptor agonist muscimol. Whether the cholinergic contribution in the regulation of the BDNF gene is due to RGC or derives from the tectum is currently under investigation.

BDNFmRNA is not only detected in the tectum, but also in the retina, and at E11, comparable levels are observed. Using BDNF-peptide antibodies, we observed a BDNF-like immunoreactivity in the retina, but not in the tectum. The most prominent expression was in the ganglion cell layer, but not all ganglion cells were labelled. Surprisingly, following optic stalk transection, the levels of this BDNF-like immunoreactivity did not seem to be dramatically reduced when compared to the control retina. We are currently investigating whether BDNF is actually synthesized in RGC or taken up from their surrounding cells in the retina.

SIGNALS THAT INDUCE EXPRESSION OF LEUKEMIA INHIBITORY FACTOR (LIF) IN RAT SUPERIOR CERVICAL GANGLIA (SCG) AND THEIR NERVES AFTER AXONAL TRANSECTION. **Y. Sun***, **S. C. Landis** and **R. E. Zigmond**. Department of Neurosciences, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

We previously have shown that LIF contributes to the axotomy induced neuropeptide expression in rat and mouse superior cervical ganglia (SCG). The expression of LIF itself is also induced in SCG within 2h after axotomy or explantation. The initial time course of LIF mRNA induction (from 30min to 6h after nerve transection) are similar *in vivo* and *in vitro*, suggesting that the two systems possess common early LIF-inducing signals after axonal transection. However, there is a difference in the duration of the increase in LIF mRNA levels between the two systems. LIF mRNA levels start to decline 12h after axotomy *in vivo*, while they remain elevated until 48h in culture. To examine the early signals responsible for the rapid induction of LIF mRNA after axon transection, we used short term explant cultures. Defined medium conditioned for 30min by freshly dissected adult rat SCG (SCM) contained LIF mRNA inducing activity when tested in dissociated neonatal SCG cultures with non-neuronal cells. Like SCM, defined medium conditioned by portions of the three major nerve trunks of the SCG for 3h (NCM) also increased LIF mRNA levels in dissociated SCG cultures. Further, LIF mRNA induction was observed in those nerve pieces themselves, suggesting that Schwann cells along the axons are one of the sources of LIF production after nerve lesion. The LIF-inducing activity of both SCM and NCM was present in a >10kd fraction and its appearance did not require new protein synthesis. SCM and NCM induced peptide expression in SCG of normal, but not LIF-deficient, mice, suggesting that the effect of SCM and NCM on peptide expression is mediated by LIF. Based on these observations, we hypothesize that when SCG are axotomized, an existing molecule is activated and/or released by transected axons and possibly by axotomized neuronal cell bodies as well. This molecule in turn causes local Schwann/satellite cells to produce LIF which participates in regulating neuropeptide expression in SCG neurons.

CHANGES IN GPA LEVELS IN CILIARY GANGLION TARGETS DURING AND AFTER THE CELL DEATH PHASE. **T.P. Finn** and **R. Nishi***. Dept. of Cell Biology and Anatomy, Oregon Health Sciences University, Portland, OR 97201

During normal development of the avian ciliary ganglion, the neurons become dependent upon their targets in the eye for survival. The process begins about E8 and continues until about E14, by which time half of the original neurons present have died off. Production by the targets of specific neurotrophic factors may mediate the level of neurons which ultimately survive. Growth promoting activity (GPA), a 21.5 Kd protein originally purified from adult chicken sciatic nerves and E15 chick eyes, is one such candidate trophic factor. To help determine what role GPA plays in ciliary ganglion survival, the cellular location and timing of GPA expression in ciliary targets was investigated by immunocytochemical, bioassay, and western blot analysis. Antibodies prepared to a purified and highly active form of recombinant GPA detected a 21.6 Kd protein in choroid-iris extract on western blots. The intensity of the band increased with embryonic age. Immunocytochemical staining of isolated choroid layers revealed that GPA immunoreactivity was localized to smooth muscle cells, and in the anterior portion of the eye, GPA-like immunoreactivity was localized to muscle fibers of the ciliary body. Both of these cell populations are normal targets of CG neurons. GPA expression was first detectable at E10, and increased through the end of the cell death phase at E14. GPA expression continued to intensify after the cell death phase, possibly indicating a continued dependence of the neurons for GPA. To test this possibility we are performing neuronal survival assays on various age ganglia to determine the age at which CG are no longer dependent upon GPA. We are also comparing GPA-like biological activity before, during, and after the cell death-phase in an effort to correlate GPA levels with neurotrophic activity in target extracts. CO-LOCALIZATION OF BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) AND PARVALBUMIN IN THE RAT CEREBRAL CORTEX **M.P. Berzaghi¹**, **T. Freund²**, **E. Papp²**, **E. Castren¹**, **U. Zirngiebel¹**, **H. Thoenen¹** and **D. Lindholm^{1*}**. ¹Department of Neurochemistry, Max-Planck-Institute for Psychiatry, Martinsried, Germany & ²Department of Functional Neuroanatomy, Institute of Experimental Medicine, Hungarian Academy of Science, Budapest, Hungary

The expression of BDNF mRNA (brain-derived neurotrophic factor) in neurons has been shown to be regulated by neuronal activity. The cholinergic system is essentially involved in the regulation of BDNF mRNAs in the developing brain. The aim of the present study was to analyse to which extent the cholinergic system is also involved in the regulation of BDNF protein in the cortex. We have used a polyclonal rabbit antiserum directed against specific peptide from the N-terminus of mouse BDNF to study the distribution of BDNF protein in the rat cerebral cortex. BDNF was localized to a subset of neurons in different cortical layers. Administration of pilocarpine, a muscarinic agonist, up-regulates the BDNF-positive cells in cortex of adult rats. The BDNF immunoreactive cells are also positive for the calcium binding protein parvalbumin, as demonstrated with the mirror technique analysis. The possibility of crossreactivity of the BDNF antiserum with parvalbumin was excluded by means of Western blotting analysis. The results suggest that BDNF protein is upregulated in an activity-dependent manner and accumulated in parvalbumin containing neurons in the rat cerebral cortex.

INCREASES IN VASOACTIVE INTESTINAL PEPTIDE (VIP) LEVELS IN CULTURED RAT SUPERIOR CERVICAL GANGLION (SCG) CAN BE REDUCED BY AN ADENYLATE CYCLASE INHIBITOR. **R. P. Mohney*** and **R. E. Zigmond**. Department of Neurosciences, Case Western Reserve University, School of Medicine, Cleveland, OH 44106.

The expression of a number of neurotransmitters changes after axonal injury, possibly reflecting a shift in the priorities of these neurons from synaptic transmission to maintenance and regeneration. For example, VIP is normally present in extremely low quantities in sympathetic neurons of the adult rat SCG, but levels of this peptide increase dramatically after SCG are placed into explant culture. The gene that encodes for VIP contains a cAMP-response element that is required for cAMP-regulated transcription. Ganglionic cAMP levels are relatively low under normal conditions and do not significantly increase in short-term cultures. Previously, we have shown that agents which elevate intracellular cAMP levels (forskolin and secretin) are also capable of increasing VIP-like immunoreactivity. We now demonstrate that the increases in VIP levels produced by the addition of cAMP-elevating agents to cultured SCG can be prevented by the addition of an adenylate cyclase inhibitor, 2',5'-dideoxyadenosine (DDA). DDA (1 mM) reduced elevations in both cAMP and VIP levels by greater than 60% in SCG cultured in medium containing cAMP-elevating agents or in control medium alone. Histological examination was performed to determine if DDA adversely affected the health of the neurons. No apparent differences in neuronal morphology were found between SCG cultured in control medium or in medium containing DDA for 48 h. An increase in the concentration of DDA to 2 or 6 mM was effective in reducing VIP levels measured in the presence of cAMP-elevating agents by 85% or 95%, respectively. These data support the observations that VIP levels in sympathetic neurons can be regulated by alterations in cAMP levels. Furthermore, they suggest that the increase in VIP that occurs by placement of the SCG into culture with control medium is dependent on the maintenance of basal cAMP levels.

OKADEIC ACID POTENTIATES AND GENISTEIN INHIBITS THE PLATELET-ACTIVATING FACTOR (PAF) ENHANCEMENT OF INDUCIBLE PROSTAGLANDIN SYNTHASE **P.K. Mukherjee, D.L. Smith** and **N.G. Bazan***. LSU Neuroscience Center, LSU Medical Center, New Orleans, LA 70112

PAF accumulates in brain during ischemia or convulsions. TIS10/PGS-2 is a primary response gene encoding the inducible form of prostaglandin synthase. In the presence of retinoic acid, a PAF-dependent (1-50 nM) activation of luciferase reporter constructs driven by regulatory regions of the TIS10/PGS-2 gene transfected in the neuroblastoma cell, NG 108-15 was observed (N. Bazan et al., Proc. Natl. Acad. Sci., in press). Here we report that when DOTAP is used for transfection of TIS10/PGS-2 promoter luciferase constructs, PAF elicits a 5- to 10-fold activation in neuroblastoma cells and CV-1 cells. Deletion studies restrict the major PAF cis-acting response element of the TIS10/PGS-2 gene to a 70-nucleotide sequence as an intracellular inducer of TIS10/PGS-2 expression. Okadaic acid (10 ng/ml) elicits a 3-fold potentiation of the PAF inductive effect. Genistein (100 µg/ml), on the other hand, inhibits the PAF-induced effect. These results strongly suggest that, in the intracellular pathway of signal transduction between the membrane-derived lipid mediator PAF and the modulation of gene expression of TIS10/PGS-2, there is a necessary step that comprises protein tyrosine kinase-protein tyrosine phosphatase. These regulatory events may play a role in neural plasticity responses such as long-term potentiation and epileptogenesis (NINDS NS23002).

OPTIC NERVE GLIA EXPRESS NEUROTROPHINS AND FULL-LENGTH TRK RECEPTORS: AN IMMUNOCYTOCHEMICAL STUDY DURING DEVELOPMENT. S. Elkabes*, W. J. Friedman and I. B. Black. Neurosci. & Cell Biol., Robert W. Johnson Med. Sch., UMDNJ, Piscataway, NJ, 08854.

We have previously reported that neurotrophin (NGF, BDNF, NT-3 and NT-4/5) mRNAs are expressed in the developing and adult optic nerve. Developmental decreases in trk B and especially in trk C expression were also shown by reverse transcriptase-polymerase chain reaction (RT-PCR) using primers that selectively amplified the extracellular domains (Elkabes et al. 1993, Abstr. Soc. Neurosci., 19, 251). To investigate whether mRNA levels detected by RT-PCR are sufficient for the synthesis of neurotrophin and trk proteins, and to determine whether glia express full-length trk receptors, we have performed immunocytochemical studies utilizing antibodies specific for neurotrophins and for the extracellular or intracellular domains of trk A, B and C (kindly provided by Dr. D. R. Kaplan, NCI, Frederick, MD).

BDNF, NT-3 and NT-4/5-like immunoreactivities were detected in glia of developing and adult optic nerve. Antibodies to the extracellular and intracellular domains of the trks also labeled cells in the optic nerve, suggesting that glia express full-length forms of the receptors. These findings were confirmed by RT-PCR, using primers that amplified the intracellular domains. The number of cells expressing trk B and trk C in the postnatal day 10 optic nerve appeared to be higher than in the adult, supporting our previous findings. Our studies suggest that neurotrophins are elaborated by optic nerve glia and that responsiveness in glial cells may be mediated through the full-length receptor. Further studies are in progress to determine which glial subtypes express neurotrophins and trks (This work was supported by NIH grant PO1 HD 23315-06A1).

NERVE GROWTH FACTOR RECEPTOR GENE EXPRESSION IN HUMAN AGING. S.D. Kittur*, L. Song, H. Endo, W.H. Adler. National Institute of Aging, 4940 Eastern Avenue, Baltimore, MD 21224 (*current address, Perry Point VA Medical Center, Perry Point, MD 21902).

Nerve growth factor modulates the immune function as a consequence of binding to the nerve growth receptor (NGF-R). Therefore we hypothesized that NGF-R will be made by the immune system in the peripheral blood lymphocytes. Northern Blot analysis of mRNA from human peripheral blood lymphocytes was performed using cDNA probe for low affinity - NGF-R (p75 NGF-R). We show that p75 NGF-R mRNA is present in human peripheral lymphocytes and expressed maximal levels at 14 hours after stimulation with phytohemagglutinin. Also, we shows that p75 NGF-R did not change with the aging process in peripheral blood lymphocytes in human volunteers.

HIGH MOLECULAR WEIGHT NGF-LIKE ACTIVITY IN THE RAT PITUITARY. S. Soinila* and J. Lakshmanan. Dept. Anatomy, PO Box 9, 00014 University of Helsinki, Finland.

We previously reported evidence for NGF immunoreactivity and biological activity in the rat pituitary gland (PG). Since the biological properties of the PG NGF differed from those reported for the rat iris muscle, we examined the molecular properties of the rat PG NGF-like material and compared it with those found in the mouse submaxillary gland (SMG). Homogenized PG tissue was subjected to immunoblotting using antiserum against mouse β -NGF. For bioassay studies, PG homogenate supernatants were subjected to ultrafiltration and fractions with $M_r > 30$ kD were tested for neurite outgrowth response from newborn superior cervical ganglion explants. Mouse β -NGF antiserum identified two proteins with M_r 53 kD and 73 kD. The 13 kD band was absent in the PG. PG ultrafiltrates containing proteins of $M_r > 30$ kD produced neurite outgrowth from newborn ganglia. Based on our data, we suggest that rat PG expresses 53 kD and 73 kD NGF prohormones and that they represent the post-translationally modified products of the short and long NGF prohormone transcripts, respectively.

DIFFERENTIAL GENE EXPRESSION OF TROPHIC FACTORS BETWEEN EMBRYO AND EXTRAEMBRYONIC MEMBRANES IN CULTURED E9 MICE. G. W. Glazner*, D. E. Brenneman, N. Jain, and J. M. Hill. Lab. of Dev. Neurobiol., NICHD, NIH, Bethesda, MD, 20892

Whole mouse embryo cultures have been used to examine the effects of trophic factors on embryonic growth and development in the absence of maternal influences. Exogenous application of vasoactive intestinal peptide has been shown to increase relative size, protein and DNA content, and anatomical stage of development (Gressens et al., *Nature*, 1993, 362:155-158). In an effort to characterize the underlying trophic milieu in which these embryos grow, RT-PCR techniques were used to determine the presence and relative amounts of mRNA for known neurotrophic and mitogenic factors. Mouse embryos (20-24 somites), with intact extraembryonic membranes, were cultured in 75% human serum and 25% rat serum for 6 hours. At the end of this time, embryos were detached from the membranes, and total RNA was purified from each embryo and corresponding membranes separately. Equal amounts of RNA were reverse transcribed, and these DNA products used as templates in PCR reactions. Specific PCR primers were designed to detect the following mouse mRNAs: β -actin, brain-derived growth factor (BDNF), leukemia inhibitory factor (LIF), transforming growth factor β (TGF β), basic fibroblast growth factor (bFGF) and insulin-like growth factor 2 (IGF-2). Each primer pair gave a single band of the expected size. There was no difference in actin relative to total RNA between embryos and membranes. Although present in both, there was no significant difference in IGF-2 gene expression relative to actin or total RNA between embryos and membranes. TGF β was also present in both, and tended to be more abundant in membranes, but the difference was not significant. bFGF and BDNF were both significantly higher (> 50 fold) in embryos than in membranes relative to actin and total RNA. LIF was significantly higher (> 20 fold) in membranes than in embryos relative to actin and total RNA. These data show that not only are these messages present in cultured mouse embryos, but also there is a differential level of expression between embryo and extraembryonic membranes.

537.4

SUBCELLULAR LOCALIZATION OF NGF IMMUNOREACTIVITY IN BASAL FOREBRAIN CHOLINERGIC NEURONS. AN ULTRASTRUCTURAL DOUBLE-LABELLING STUDY IN THE RAT. Linsen Hu, A. Ribeiro-da-Silva, L. Garofalo* and A.C. Cuellar. Dept. Pharmacology & Therapeutics, McGill University, Montréal, Québec, Canada H3G 1Y6

Nerve growth factor (NGF) is produced in target areas (e.g., cerebral cortex) and retrogradely transported to basal forebrain neurons where it exerts biological effects. However, it is not clear yet whether basal forebrain neurons themselves have the capacity to produce NGF. To address the above issue, we developed an improved protocol allowing the ultrastructural demonstration of NGF immunoreactivity with good preservation of the ultrastructure. NGF-immunoreactive (IR) sites were demonstrated by means of the ABC method, using a polyclonal anti-NGF antibody (Conner et al., *J. Comp. Neurol.* 319:454-462, 1992), and choline acetyltransferase (ChAT)-IR sites by means of a monoclonal antibody (Boehringer Mannheim) revealed by a pre-embedding immunogold protocol. In nucleus basalis magnocellularis (NBM) ChAT-IR neurons, NGF immunoreactivity occurred predominantly in multivesicular bodies, which were shown in a previous study to be immunoreactive for the low affinity NGF receptor (Pioro et al., *Brain Res.* 527: 109-115, 1990) and probably represent the final form of the internalized ligand-receptor complex, within secondary lysosomes. Some NGF immunoreactivity was also detected in association with ribosomes and in the Golgi apparatus. These results would indicate that most of the NGF in NBM cholinergic neurons originates from the accumulation of retrogradely transported neurotrophin. However, ultrastructural evidence for limited NGF synthesis by the cholinergic neurons themselves was found. These observations may suggest that the NGF acting on the cholinergic NBM neurons is not entirely target-derived. Some of it may originate from the cholinergic cells and act autotrophically.

BDNF mRNA in the human locus ceruleus. S. Borson*, M. Miller, J. Leverenz, A. Unis, M. Bothwell. Depts of Psychiatry, Neurology, and Physiology & Biophysics, Univ Washington Sch Med, Seattle, WA 98195. The brainstem locus ceruleus (LoC) participates in learning, memory, and other behavioral functions through its regulatory effects on input responsiveness of its targets, gating of stimuli for further processing, and interactions with other neurotransmitter systems including the septohippocampal cholinergic system. In the rat, some LoC neurons express BDNF mRNA, but its function in this site is not known; embryonic cell cultures of rat LoC respond to BDNF with increased numbers of TH+ neurons. In humans, loss of LoC neurons occurs during aging and is exaggerated in Alzheimer's disease (AD). We examined BDNF mRNA expression in noradrenergic neurons of the human LoC using *in situ* hybridization with an S^{35} -labeled riboprobe synthesized from a 477 bp EcoRI/PstI fragment subcloned from a human BDNF cDNA (gift of K. Jones and L. Reichardt). Fresh frozen brainstems were obtained at autopsy from 3 adult human brains (1 AD, 1 dementia with gliosis, 1 control) and from a 20-week fetal human specimen following elective abortion. *In situ* hybridization was performed on 20 μ m cryosections using 2 pmol/ml of labeled antisense or sense riboprobe and tissues examined by film and emulsion autoradiography. Expression of BDNF mRNA was found in noradrenergic neurons of all 3 adult nuclei, and in cells lining the 4th ventricle and in the region of the developing LoC in the fetus. These results suggest that BDNF in the human LoC may have a functional autocrine or anterograde role during development and into late adult life. Supported by grants from the Alzheimer's Association [S Borson PI] and NIA (UW ADRC [G Martin PI]), and by the UW Fetal Tissue Program [A Fantel PI].

TRANSIENT EXPRESSION OF BDNF mRNA IN RAT LOCUS COERULEUS FOLLOWING ACUTE RESERPINE ADMINISTRATION. K.B. Serogy*. Department of Anatomy & Neurobiology, University of Kentucky, Lexington, KY 40536.

In vitro studies indicate that certain members of the neurotrophin family of trophic factors can support the survival of, and are neuroprotective for, populations of catecholaminergic neurons. In the present study, the expression of brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) mRNAs in neurons of the locus coeruleus was examined *in vivo* following acute reserpine administration. Adult rats received a single injection of reserpine (10 mg/kg; i.p.) or vehicle followed by survival times of 4hr, 8hr, 16hr, 24hr, 3 days, 4 days and 8 days. Cryostat-prepared tissue sections through the locus coeruleus were subsequently processed for the *in situ* hybridization localization of BDNF, NT-3 and TH mRNAs using ³⁵S-labeled cRNA probes. BDNF mRNA was barely detectable in locus coeruleus in normal, untreated rats and in vehicle-injected rats. After reserpine treatment, a substantial increase in hybridization density for BDNF mRNA was observed in locus coeruleus which peaked at 24 hrs and gradually returned to control levels by 8 days post-injection. Expression of TH mRNA in the nucleus exhibited a similar transient elevation, in agreement with previous studies. In contrast, no change in expression of NT-3 mRNA was detected. Administration of the tricyclic antidepressant desipramine (25 mg/kg; i.p.), 30 min prior to reserpine treatment, partially attenuated the elevation in BDNF mRNA. These data indicate that depletion of catecholamines induces a transient increase in BDNF mRNA expression in locus coeruleus neurons and raises the possibility of BDNF involvement in neurological disorders associated with the locus coeruleus, such as depression. Supported by the National Parkinson Foundation and the Scottish Rite Schizophrenia Research Program.

537.9

IMMUNOHISTOCHEMICAL STUDY OF THE EXPRESSION OF BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) IN ADULT RAT BRAIN. Q. Yan*, C.R. Matheson, O.T. Lopez, N. Hawkins, R.D. Rosenfeld, and L. Bennett. Amgen, Inc., Amgen center, Thousand Oaks, CA 91320

We examined the expression of endogenous BDNF in adult rat brains using a BDNF specific antibody by immunohistochemistry. We found distinct BDNF immunoreactivity (IR) in many structures which are known to be BDNF mRNA positive from previous studies. These structures included neocortex, piriform cortex, amygdaloid complex, hippocampal formation, claustrum, supramammillary region and other thalamic nuclei, some hypothalamic nuclei, substantia nigra, and neurons in many brain stem structures. In the hippocampal formation, very heavy BDNF IR was found in the granular layer of dentate gyrus and pyramidal and radiatum layers of CA3 and CA4, but not in CA1 and CA2 regions of hippocampus. However, with kainic acid treatment (i.p.), which is known to upregulate BDNF mRNA, BDNF IR was readily detected in CA1 and CA2 regions. Staining was also seen in areas not previously reported as BDNF mRNA positive. These included the bed nucleus of stria terminalis, dorsal endopiriform nucleus, lateral septum, medial preoptic nucleus, olivary pretectal nucleus, lateral paraventricular nucleus, and nucleus ambiguus. The results of this study suggest BDNF may play a broad role in the adult central nervous system.

537.11

STRUCTURE, EXPRESSION AND FUNCTION OF RAT GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF). M. Trupp¹, M. Rydén¹, E. Arenas¹, T. Timmusk¹, N. Lindefors^{2*} and C.E. Ibáñez¹. ¹Laboratory of Molecular Neurobiology, MBB and ²Department of Clinical Neurobiology, Karolinska Institute, S-17177 Stockholm, Sweden.

A cDNA encoding rat GDNF was cloned by RT-PCR from P1 rat brain RNA. An alternatively spliced variant (termed GDNFβ), similar to that described by Schaar et al. (1993), with a 78 bp deletion in the prepro region was also cloned. Both mRNAs were expressed in developing striatum, cerebellum and some peripheral organs as assessed by RNase protection analysis. GDNF mRNA expression was developmentally regulated and appeared to be altered by neuronal lesions. The cellular localization of GDNF mRNA expression during rat development is being studied by *in situ* hybridization.

Western blotting and immunoprecipitation analysis with anti GDNF antibodies generated against predicted loop regions of the molecule showed that the deletion decreased the level of GDNF protein produced by transiently transfected COS cells. Recombinant GDNF produced in baculovirus-infected insect cells was correctly processed and glycosylated. GDNF protein purified to homogeneity promoted survival and neurite outgrowth from embryonic sympathetic ganglia with a time-course and morphology clearly different from nerve growth factor, suggesting activation of distinct signalling pathways. Genetically engineered fibroblast cell lines producing both GDNF mRNA forms were generated and are currently being used to investigate the function of GDNF *in vivo*.

537.8

INCREASED EXPRESSION OF BDNF mRNA IN ADULT VENTRAL MIDBRAIN FOLLOWING ACUTE 6-OHDA LESIONS OF THE NIGROSTRIATAL PATHWAY. S. Numan* and K.B. Serogy. Department of Anatomy & Neurobiology, University of Kentucky, Lexington, KY 40536.

In vitro studies have demonstrated that BDNF and NT-3 support the survival of fetal rat mesencephalic dopamine neurons. Furthermore, several studies have provided evidence that BDNF may be neuroprotective for cultured dopaminergic neurons undergoing various toxic insults. *In vivo*, adult dopaminergic neurons, which express BDNF and NT-3 mRNAs, may initially respond to various toxic insults by altering the expression of neurotrophin mRNAs. To examine this possibility, adult rats received a unilateral injection of 6-OHDA or vehicle into the ascending medial forebrain bundle. Following various survival periods (8, 16, 48, and 120 hrs), *in situ* hybridization of ³⁵S-labeled cRNA probes for BDNF, NT-3, and TH mRNAs was performed in midbrain sections. After 8, 16 and 48 hours, an increase in the hybridization density for BDNF mRNA was observed in the substantia nigra and ventral tegmental area ipsilateral to the 6-OHDA injection, as compared to the uninjected control side. In contrast, no alterations in the hybridization density for NT-3 or TH mRNAs were observed at these time points. After a 120 hour survival period, there was a decreased hybridization density for TH, BDNF, and NT-3 mRNAs in the ventral midbrain ipsilateral to the 6-OHDA injection, as compared to the control side. No alterations in the hybridization density for BDNF, NT-3, or TH mRNAs were observed in the ventral midbrain of rats that had received unilateral injections of vehicle. These data indicate that there is an early transient response by BDNF mRNA in the ventral midbrain to the neurotoxin 6-OHDA, which may suggest a role *in vivo* for this neurotrophin in neuronal protection. Supported by the National Parkinson Foundation and the Scottish Rite Schizophrenia Research Program.

537.10

BRAIN-DERIVED NEUROTROPHIC FACTOR mRNA IS EXPRESSED IN THE DEVELOPING TASTE BUD-BEARING TONGUE PAPILLAE OF RAT. C. A. Nosrat, S. H. Sun*¹, L. Olson. Dept of Neuroscience, Karolinska Institute, S-171 77, Stockholm, Sweden; ¹Institute of Neuroscience, National Yang-Ming Medical College, Taipei, Taiwan.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, is expressed in many areas of the central nervous system. Its possible roles in the peripheral nervous system have been less studied. Using *in situ* hybridization we now have investigated the possible presence of BDNF mRNA in the developing fungiform and circumvallate papillae of the rat tongue. BDNF mRNA is present in the epithelium of the developing fungiform papillae in E15, E16 and E17 rat embryos. BDNF mRNA was also located in the epithelium of the developing circumvallate papillae on the dorsum of the tongue in E16 and E17 rat embryos. The expression of BDNF mRNA in areas where taste buds are to be formed suggests that BDNF may be one crucial factor in the formation of the papillary and/or taste bud innervation apparatus. Further studies are needed to clarify which nerve fiber types within the two main sources of innervation of the taste bud-bearing papillae, the chorda tympani (n. VII) and the lingual branch of the mandibular nerve (n. V), that may respond to BDNF.

DEVELOPMENTAL EXPRESSION OF GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) mRNA IN RAT CNS AND PERIPHERY. D. Choi-Lundberg and M. C. Bohn*. Dept. of Neurobio. & Anat., Univ. of Rochester Med. Ctr., Roch., NY 14642.

GDNF is a newly described member of the TGF-β family isolated from the rat glial tumor cell line, B49. GDNF promotes survival, dopamine uptake, and neurite extension of embryonic dopaminergic (DA) neurons *in vitro*.¹ We have used a semi-quantitative RT-PCR with primers specific to GDNF to study the development of GDNF expression in CNS and peripheral tissues of embryonic rat on gestational days E13.5 and E18, neonatal rat on postnatal days P0 and P10 and adult rat. GDNF mRNA is expressed in all major regions of the CNS; however, the level of expression is both region and age dependent. The highest levels of GDNF mRNA are expressed in P0 spinal cord and in P0 and P10 striatum. Lower levels are expressed in brainstem (including ventral mesencephalon, which contains the substantia nigra), cerebellum, diencephalon and telencephalon. GDNF mRNA is also expressed in many peripheral tissues. In some tissues, GDNF expression is higher than in brain, particularly in embryonic limb bud, kidney and gut; neonatal kidney, gut, lung and testis; and adult lung, liver and ovary. Interestingly, GDNF mRNA is also present in the head, torso and chorion/amnion of the E11.5 embryo.

These observations suggest that GDNF may be a target derived and/or locally acting neurotrophic factor for DA neurons of the substantia nigra, as well as for other classes of CNS neurons. Moreover, GDNF may play an early role as a neurotrophic factor in the PNS or serve as a growth factor for non-neuronal cells. (Supported by the Markey Charitable Trust & NIH grant ES01247). ¹ L.-F. H. Lin et al., *Science* 260, 1130-2 (1993).

ISOLATION OF MULTIPLE GDNF TRANSCRIPTS FROM THE C₆ GLIOMA CELL LINE. M. D. Swope*, A. Y. Deutch, and E. Lolis. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Glial cell line-derived neurotrophic factor (GDNF) is a newly discovered member of the transforming growth factor β superfamily which exhibits neurotrophic effects on midbrain dopamine neurons both *in vitro* and *in vivo*. GDNF was originally isolated from the B49 glial cell line. We have analyzed two other glial cell lines, the rat C₆ glioma and the human Hs683 glioma, for expression of GDNF. Polyadenylated mRNA was isolated from these cell lines and subjected to RT-PCR for first strand cDNA synthesis. Polymerase chain reaction was used with primers against regions near the initiating methionine and terminal stop codon to amplify the sequence. Two bands were seen from C₆ cells when the PCR reaction products were analyzed by agarose gel electrophoresis and visualized with ethidium bromide. In contrast, no bands were present in the Hs683 PCR reaction.

These results indicate that expression of GDNF is not limited to B49 cells but also occurs in C₆ cells. In addition, the C₆ cells express two GDNF transcripts, which has not been previously reported. Further characterization of these transcripts is in progress.

EXPRESSION OF STEM CELL FACTOR AND ITS RECEPTOR, c-kit PRODUCT, IN NEURAL CELLS. Su-Chun Zhang* and Sergey Fedoroff, Dept. of Anatomy, Univ. of Saskatchewan, Saskatoon, SK, S7N 0W0, Canada.

The protooncogene, c-kit, encodes the tyrosine kinase receptor (c-kitR) for stem cell factor (SCF). This receptor/ligand plays a central role in hematopoiesis, gametogenesis and melanogenesis. It is found in other tissues including brain, yet its function in the nervous system is unknown. By immunostaining the isolated mouse cortical neurons (E15), astroglia and microglia (newborn) in culture with the monoclonal antibodies against c-kitR and stem cell factor (generously provided by Immunex Corp.), we analysed the cellular localization of the ligand and receptor. In 2-3 day-old cultures, only some of the neurons expressed c-kitR and SCF. Subsequently, most neurons became strongly positive for SCF and few expressed c-kitR. In contrast, their expression in astroglia appeared mainly in the first 5-7 days in culture and became weak thereafter. Microglia strongly expressed c-kitR and SCF throughout the culturing period. These observations indicate that the expression of c-kitR and SCF is developmentally regulated and that both paracrine and autocrine signalling may be involved in neuron-glial and glia-glial interactions. Recombinant SCF (Immunex Corp.) by itself had no observable effects on neural cells. However, SCF, in combination with other cytokines such as CSF-1, IL-1 β , TNF α , affect cytokine production by glial cells. Apparently, the function of c-kitR/SCF is to modulate the production of trophic factors (cytokines) by glia.

IMMUNOLOGICAL LOCALIZATION OF A POSSIBLE NEUROTROPHIC FACTOR, ACTIVIN A, IN RAT BRAIN RELATING TO PROTEIN MALNUTRITION. H. Fujimura¹, T. Murata¹, M. Funaba¹, A. Nijima² and K. Torii^{1,3}. ¹ERATO, R&D Corp. of Japan, Yokohama, 221 Japan.; ²Dept. Physiol., Sch. of Med., Niigata Univ., Niigata, 951 Japan.; ³Ajinomoto Co., Inc., Central Research Lab., Yokohama, 244 Japan.

In serum of rats fed a diet with or without proper protein, an increase of inhibin, a heterodimer of α - β subunits, or activin A, a homodimer of β subunits was detected respectively by an ultra-sensitive bioassay of *Hyrda Japonica* for peptide hormones and growth factors (Torii et al. 1993).

Activin A has been known to be implicated in several brain functions. We recently demonstrated the presence of immunoreactive activin β A subunit in some regions of the brain relating to control of food intake and homeostasis of nutrients, such as the arcuate N. (ARN), supraoptic N. (SON) and PVN. In this study, the localization of β A subunit was precisely examined with a laser scanning confocal microscope by indirect immunofluorescence assay using affinity-purified antisera against synthetic β A(1-11). The immunoreactivity was localized in the neuronal cell bodies of the NTS, ARN, SON and PVN. Fluorescence was detected in the perinuclear cytoplasm as scattered granular spots. These results suggest that activin may modulate the functions of neurosecretory cells in PVN, SON or ARN in an autocrine or paracrine manner in recognition and adaptation to protein malnutrition.

Developmental Expression in the CNS of LERK-2, a Ligand for the Receptor-Tyrosine Kinase ELK M.K. Carpenter*, H. Shilling, T. Van den Bos, M.P. Beckmann, B. L. Davison, J.N. Kott†, L.E. Westrum†, F.A. Fletcher. Dept. of Molecular Immunology, Immunex Corporation, 51 University St., Seattle, WA 98101, † Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

Elk is a member of the *eph* family of receptor-like tyrosine kinases and is expressed only in brain and testes in adult animals. The function of this receptor is unknown although it has been postulated to play a role in the development of the nervous system. Using Northern analysis, we have found that RNA coding for elk is expressed at high levels in many areas in the embryonic and postnatal rat brain. Expression decreases with age in some areas, but shows moderate expression in the adult diencephalon, brain stem and cerebellum. LERK-2 (elk ligand) RNA is expressed at high levels in all areas of the developing rat brain we examined. Expression decreases dramatically with age in all but one of these areas. In the adult rat brain, the olfactory bulb has a moderate level of LERK-2 expression. A unique feature of the adult olfactory bulb is that it is continuously innervated by the olfactory epithelium. These data are consistent with the idea that elk and LERK-2 play a role in development of the nervous system.

BONE MORPHOMETRIC PROTEINS ARE EXPRESSED IN DEVELOPING MOUSE BRAIN AND ARE NEUROTROPHIC IN VITRO. Z. Zang*, M. F. Mehler, R. Marmur, J. M. Wozney¹ and J. A. Kessler, Departments of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, New York, 10461 and ¹Genetics Institute, Cambridge, MA, 02140

The bone morphometric proteins (BMPs) are a group of proteins within the TGF β superfamily. To investigate the potential role of these trophic factors in CNS development, the expression of BMP mRNAs in the developing mouse brain (striatum, hippocampus, cerebral cortex, cerebellum and brain stem) was examined and effects of BMPs on cultured embryonic neurons were defined. Nuclease protection assays for BMP-2, 3, 4, 5, 6, 7 and 8 demonstrated distinct regional and temporal patterns of expression for each mRNA in the developing mouse brain. BMP-2, 6 and 7 mRNAs were expressed as early as E12. By contrast, BMP-3, 4 and 5 mRNAs were present in higher levels in later developmental stages and remained high in adult brain. Regional studies indicated that BMP-2 and 4 had similar patterns of expression, whereas BMP-6 and 7 were expressed in other areas in a parallel fashion. Treatment of dissociated cultures of embryonic brain demonstrated enhanced neuronal survival and process outgrowth in response to the BMPs (0.1-10 ng/ml). There was region-specific neurite outgrowth effects of BMP-2 on cerebral cortex, BMP-5 and 6 on cerebellum, and BMP-4 on the other brain regions. These findings suggest that the BMPs may play significant roles in regulating brain development.

537.18

PREPROINSULIN I AND II mRNA ARE PRESENT IN FETAL RAT CENTRAL AND PERIPHERAL NERVOUS SYSTEM. R. Schechter*, T. Gaffney and J. Whitmire. William K. Warren Med. Res. Inst., Univ. of Okla. Health Sci. Ctr., and Dept. of Neonatology, Saint Francis Hosp., Tulsa, OK 74136.

We demonstrated the presence of insulin-like substance (ILS) within the central nervous system (Brain Res 582:27-37, 1992). The present study was undertaken to demonstrate the presence of insulin mRNA within the nervous system. Total RNA purified from 19 day gestation fetal rat brain, spinal cord and dorsal root ganglia (DRG) was subjected to reverse transcription (RT) and polymerase chain reaction (PCR) or reverse transcriptase template specific PCR (RS-PCR) to minimize nonspecific hybridization during PCR. All samples were digested with DNase before the RT or RS-PCR reaction. Pancreatic RNA served as positive control. Negative controls were performed without the presence of pancreatic or brain RNA. PCR was performed using a primer corresponding to the prepro-region and a primer corresponding to the A chain. The PCR products of 330 bases from the fetal brain were further identified by restriction enzyme digestion (RE) to demonstrate their identities as preproinsulin (PP) I and II. RsaI cleaved PP I into two fragments 118 and 212, but did not cut PP II. HinfI cleaved PP II into two fragments 140 and 190, but did not cut PP I. The predicted fragments were obtained by RE in the brain, spinal cord, DRG and pancreatic RNA products. In solution hybridization using a 32 P rat PP I and II cRNA probe demonstrated the presence of PP I and II mRNA within the nervous system. The sequence of the PCR products showed a 100% homology with rat pancreatic PP I and II. Radioimmunoassay showed an ILS within the brain. Thus, 1) preproinsulin I and II mRNA are present within the rat fetal central and peripheral nervous system, 2) these data are highly suggestive of the local synthesis of insulin within the the nervous system.

THE NERVOUS SYSTEM OF BASIC FGF OVER-EXpressING TRANSGENIC MICE. F. Eckenstein*, C. Hicks
Dept. of Cell Biology and Anatomy
Oregon Health Sciences University, Portland, OR 97201

Fibroblast growth factors (FGFs) *in vitro* exhibit a wide variety of neurotrophic and mitogenic effects. Nine members of the FGF multigene family are currently known. The adult central nervous system contains very high levels of acidic and basic FGF (aFGF and bFGF), molecules that lack hydrophobic signal peptide sequences and are not efficiently released from normal healthy cells. Consistent with these observations is our hypothesis that aFGF and bFGF function as initiators of injury responses in CNS.

In order to test this hypothesis we have obtained (a generous gift from Drs. D. Coffin and R. Florkiewicz) transgenic mice that overexpress human bFGF. Initial characterization of these animals showed a highly significant increase in bFGF levels in the CNS of transgenic animals. No gross morphological abnormalities were detected in the brains of these animals, and highly preliminary experiments did not show marked changes in the immuno-histochemical distribution of neuropeptides and neurotransmitter synthesizing enzymes.

A CALCIUM RESPONSIVE PROMOTER IN THE RAT BDNF GENE. J. F. Bishop*, G. P. Mueller and M. M. Mouradian. Genetic Pharmacology Unit, Experimental Therapeutics Branch, NINDS, and Department of Physiology, USUHS, Bethesda, MD 20892.

Transcription of the rat brain-derived neurotrophic factor (BDNF) gene results in multiple transcripts containing at least five alternate first exons that are separately spliced to a common protein coding exon. Since Ca^{2+} is a prominent second messenger involved in the regulation of BDNF expression, rat C6 glioma cells, known to express BDNF, were exposed to the Ca^{2+} ionophore A23187 and BDNF mRNA levels were measured by reverse transcription (RT) followed by quantitative PCR (QPCR). The cells were incubated with A23187 (5×10^{-6} M) or vehicle for 1 hour, rinsed, incubated another 3 hours in culture medium and total RNA was extracted. QPCR results indicated that BDNF coding exon containing transcripts were elevated approximately 9-fold compared with vehicle treated controls. Inclusion of the RNA polymerase inhibitor actinomycin D ($10 \mu\text{g/ml}$) in culture medium led to significant decreases in both basal and A23187-stimulated BDNF mRNA concentrations indicating that, in C6 cells, BDNF expression is regulated primarily at the level of transcription. To identify which of the multiple promoters in the BDNF gene is transactivated by increased calcium, the effects of A23187 on the expression of each of the alternate 5' exons were investigated. Of the three alternate 5' exons expressed in C6 cells, only one (exon 1e) increased significantly (approximately 4-fold) which is less than the response of the common coding exon measured in the same samples. Additional calcium-responsive promoters directing the expression of the BDNF gene not detected in the present investigation may account for this observation.

Identification of an Inducible Promoter in the Nerve Growth Factor Gene that Initiates Transcription at Exon 3.

MM Racke, PJ Mason, MP Johnson, BW Siegel*, MD Linnik, Marion Merrell Dow Research Institute, Cincinnati, OH 45215.

NGF has been demonstrated to facilitate neurite outgrowth, rescue neurons from injury, and prevent programmed cell death. However, the therapeutic potential of NGF is limited by pharmaceutical difficulties common to many multisubunit proteins. These limitations might be circumvented by identifying compounds which facilitate endogenous transcription of NGF in the brain. Thus, we sought to determine the site of all pharmacologically inducible promoters in the NGF gene using a differential analysis based on semi-quantitative reverse transcription PCR. L929 cells were serum deprived and NGF was induced by treatment with PMA and calcitriol (1,25-dihydroxy-vitamin D₃). Of the 4 major transcripts previously identified in mouse (Mol Cell Biol, 7:3057,87), a 2.5 - 4 fold increase in transcripts initiated at exon 1 was noted in cDNA from cells induced with PMA and calcitriol, confirming the previous demonstration of a promoter region near exon 1 (Mol Brain Res, 15: 67,92). In addition, we also noted a 3 - fold increase in cDNA transcripts initiated at exon 3, suggesting a second, previously unidentified inducible promoter in this region. Sequence analysis revealed a consensus HRE in the 3' region of exon 3 which might be responsible for this increased expression. In conclusion, these studies demonstrate a second inducible promoter in the NGF gene near exon 3 that could be targeted for therapeutic intervention.

538.2

REGULATION OF RAT BDNF GENE PROMOTERS IN TRANSGENIC MICE. T. Timmusk, U. Lendahl*, H. Funakoshi, E. Arenas and M. Metsis*. Lab. of Molecular Neurobiology and *Dept. of Developmental Biology, Karolinska Institute, 17177 Stockholm, Sweden.

The rat brain-derived neurotrophic factor (BDNF) gene consists of four 5' exons linked to separate promoters and one 3' exon encoding the prepro-BDNF protein. Transgenic mice have been generated, that express bacterial chloramphenicol-acetyl transferase (CAT) under the control of six different promoter constructs of the BDNF gene. When fused separately to bacterial CAT gene the upstream regions of the 5' exons of rat BDNF gene were able to direct the transgene expression in tissues that partially overlapped with the endogenous sites of particular BDNF promoter activities. High-level expression of reporter gene in correct neuronal populations of mouse brain was achieved by using the combinations of longer promoter regions that lie close to each other in the genome (promoters I+II and promoters III+IV respectively) and by including sequences of BDNF intron/exon splice junctions and 3' UTR in the constructs. The genomic regions responsible for the *in vivo* upregulation of BDNF expression after kainic acid-induced seizures and KCl-induced spreading depression were mapped. We also report that 5.5 kb of BDNF promoter IV sequence directs axotomy-induced expression of reporter gene in the sciatic nerve of transgenic mice in a manner similar to the regulation of endogenous BDNF mRNA in the same paradigm. These BDNF promoter constructs provide useful tools for targeted expression of neurotrophic factors to study their function and regulation in central and peripheral nervous system.

Exon III of the rat BDNF gene can be induced in the presence of protein synthesis inhibitors: evidence for an immediate-early gene.

J. C. Lauterborn*, C. T. Stinis, V. Y. Hayes, P. J. Jackson, and C. M. Gall.

¹Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717 &

²Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Jacksonville, FL 32224.

The rat brain-derived neurotrophic factor (BDNF) gene has been shown to contain four short 5' exons (Exons I-IV), associated with distinct promoters, and one 3' exon (Exon V) that encodes the mature BDNF protein. BDNF mRNA transcripts containing the different 5' exons can be differentially induced in brain following seizure although the mechanisms by which this occurs have yet to be elucidated. In the present study, the effect of anisomycin, a protein synthesis inhibitor, on the expression of Exon I and III mRNAs following a stimulated epileptiform afterdischarge of hippocampal neurons was analyzed in adult rat brain. Treatment groups were: 1) single hippocampal afterdischarge (AD) via perforant path stimulation (10 Hz, 4-6 sec) and sacrifice 1.5 hrs post-AD; 2) anisomycin (25mg/kg, s.c.), injected 30 min prior to and 30 min following AD, and sacrifice 1.5 hrs post-AD; 3) 2 injections of anisomycin 1 hr apart and sacrifice 1 hr after last injection; 4) naive controls. Changes in BDNF exon mRNA content in the granule cells were assessed by *in situ* hybridization using ³⁵S-labeled cRNAs. Following AD, Exon I mRNA was increased 10 to 30-fold above control levels in the granule cells. This effect was reduced by 82% with anisomycin. Like Exon I, Exon III mRNA was markedly increased following AD to approximately 7-fold above control levels. However, the effect of AD on Exon III expression was not reduced by anisomycin. Anisomycin alone had no effect on either Exon I or III. The present results show that Exon III expression can be increased in the presence of protein synthesis inhibitors suggesting that this exon, as opposed to Exon I, is directly induced by physiological activity without intervening protein synthesis (i.e., as an immediate-early gene). The presence of distinct mechanisms regulating the transcription of the 5' exons within one cell type suggests each may be induced under different circumstances. Supported by NS26748 to C. G., EFA & Abbott Labs award to J. L., and Mayo Foundation funds to P. I.

PRODUCTION AND PROCESSING OF THE NGF FAMILY OF NEUROTROPHIC FACTORS. D.P. Lamb, W. Zhu, Q. Lu, J. Stanis and M. Fehnestock. Department of Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

The neurotrophic factors NGF, BDNF and NT-3 are translated as pre-pro peptides which require proteolytic processing at dibasic amino acid residues to attain their mature, biologically active forms. Little is known about the processing of the pre-pro forms of the neurotrophins. The ability of furin to process NGF, and the presence of related enzymes in human brain, suggest these serine proteases may play a role in neurotrophic factor processing. The study of neurotrophic factor processing has been hindered by the lack of sufficient substrate for analysis. We report here the production of quantities of pre-pro and mature neurotrophic factors sufficient for processing studies.

Baculoviruses were constructed expressing cDNAs for NGF and NT-3 as well as PC2, a member of the prohormone convertase family of proteases related to furin. The resultant recombinant viruses were used to infect Sf9 insect cells, and both mature and pre-pro trophic factors were identified on SDS-PAGE gels and analyzed by Western Blotting. The biological activities of the neurotrophins were confirmed in neurite outgrowth assays using neonatal mouse SCG and DRG neuronal cultures. Expression of PC2 was confirmed by Western blotting and protease assays using synthetic substrates.

Coinfections were carried out using NGF and NT-3 recombinant virus along with PC2 recombinant virus to determine if PC2 could enhance neurotrophic factor processing in insect cells. The extent to which PC2 could enhance processing was determined by photoimage analysis of the bands from the Western Blots. The NGF+PC2 coinfectant supernatants showed approximately seven fold more mature trophic factor than the control infection, whereas NT-3+PC2 coinfectant supernatants showed about a three fold increase in mature NT-3. (Supported by NIH and MRC

Beta- Nerve Growth Factor (NGF) is an artifact. J. Lakshmanan¹*, S. Soinila², K. Pesonen², T. Lahtinen², A. Baker¹, J. Perheentupa² and D. A. Fisher¹. Harbor UCLA Medical Center, CA, USA¹ and University of Helsinki, Helsinki, Finland².

We previously reported the presence of beta NGF in normal adult mouse sera of both sexes (1-2 ng/ml) and in sera of adult male aggressive mice (115-490 ng/ml) [Am. J. Physiol. 250: E386-E392 1986]. We now have examined the molecular species of serum NGF both by immunoblotting and column chromatographic analysis. Aliquots (250 µl) of mouse sera were immunoprecipitated with beta-NGF antiserum and the precipitates analyzed by immunoblotting. Similar volumes of sera were subjected to Sephadex G-100 chromatography; column fractions were analyzed by beta-NGF RIA. Immunoblotting analysis revealed the presence of a 53 kDa NGF protein but no 13 kDa NGF immunoreactive protein in sera of either normal or aggressive male mice. The radioactive intensity of 53 kDa NGF protein was several fold greater in aggressive mouse sera compared to normal mouse sera. By chromatographic analysis, the NGF-immunoreactivity of normal male mouse sera eluted as a single peak that appeared in the void volume while that of aggressive mice eluted in two distinctive peaks. The first appeared in the void volume (as in normal mice sera) and the second corresponded to the elution profile of 13 kDa NGF. The latter peak accounted for more than 92% of total immunoreactivity. Both aggressive mouse serum and SMG-53 kDa NGF stimulated neurite outgrowth from chick embryo dorsal root ganglion explants. The absence of 13 kDa NGF in neat mouse sera immunoprecipitates and its presence in aggressive serum samples subjected to Sephadex-chromatography suggest that the 13 kDa NGF is an artifactual proteolytic fragment of 53 kDa NGF generated *in vitro* during chromatography.

PROCESSING OF NGF, BDNF, AND NT-3 PRECURSORS BY PROHORMONE CONVERTASES. N. G. Seidah^{*}, S. Pareek^{*}, S. Benjannet^{*}, J. Laliberté^{*}, M. Chrétien^{*}, and R. A. Murphy^{*}. Montreal Neurological Institute, McGill University and the *Clinical Research Institute of Montreal, Montreal, Quebec, CANADA

Conversion of prohormones and precursor proteins into biologically active molecules involves the concerted action of a number of convertases. Furin can process the precursor of mouse β -NGF (Bresnahan *et al.*, *J. Cell Biol.*, 111, 2851-2859, 1990) but no information is yet available to explain how other members of the neurotrophin family are generated. In this study, we have compared the processing of NGF, BDNF and NT-3 by prohormone convertases. Recombinant vaccinia virus vectors were used to co-express the convertases PC1, PC2, and furin together with NGF, BDNF or NT-3 in human colon carcinoma LoVo cells, lacking endogenous furin. Virally infected cells were metabolically labeled with ³⁵S-methionine and conditioned medium was treated with antibodies to NGF which immunoprecipitate NGF and NT-3. BDNF was identified on Western blots using a BDNF-specific peptide polyclonal antibody. Results show that NGF is synthesized in LoVo cells as a 48 kDa precursor (probably glycosylated) and processed into 14.5 (probably glycosylated) and 13.2 kDa products. NGF processing was effectively carried out by furin and no other convertase. NT-3 was processed efficiently by furin with a small amount of processing carried out by PC1 and PC2 as well. BDNF was effectively processed by furin, with some processing by PC1. These studies suggest that the neurotrophins are most effectively processed by furin, and that other convertases have limited activity as well.

538.11

RETROGRADE TRANSPORT AND SIGNALING MECHANISMS BY NERVE GROWTH FACTOR AND LEUKEMIA INHIBITORY FACTOR IN SYMPATHETIC NEURONS. D. R. Ure^{*} and R. B. Campenot. Department of Anatomy and Cell Biology, University of Alberta, Edmonton, AB T6G 2H7.

Nerve growth factor (NGF) and leukemia inhibitory factor (LIF) are both retrogradely transported by rat sympathetic neurons in a compartmented culture system. We have further characterized the retrograde transport of ¹²⁵I-NGF and ¹²⁵I-LIF. The level of NGF transport appears to be unaffected by the acute presence of LIF. Reciprocally, LIF transport is equivalent whether neurons are supplied with 10 or 200 ng/ml NGF. In contrast, pretreating neurons for 6 days with LIF leads to the reduction of both NGF and LIF transport by at least 50%, suggesting that LIF-differentiated neurons may display attenuated NGF-dependent responses. NGF transport levels are not affected by brain derived neurotrophic factor or neurotrophin-3 applied concurrently and at concentrations in 100-fold excess of ¹²⁵I-NGF. Kinetic analysis of NGF transport/processing revealed that following a 5-hr pulse of ¹²⁵I-NGF to peripheral neurites, most of the radiolabel is transported and released within the first 24 hr. However, cell-associated radiolabel is still present several days following the pulse. Experiments are now being performed to address whether the retrograde transport of NGF or LIF is necessary for transcriptional changes induced by these signaling ligands.

IDENTIFICATION OF RNA BINDING PROTEINS WHICH MAY CONTROL NERVE GROWTH FACTOR mRNA STABILITY. B. Tang^{*}, S.P. Pshenichkin, and B.C. Wise. Fidia-Georgetown Institute for the Neurosciences and Department of Pharmacology, Georgetown University, Washington, D.C. 20007

Our previous studies have shown that interleukin-1 and okadaic acid, a phosphoprotein phosphatase inhibitor, increase the half-life (*t*_{1/2}) of the nerve growth factor (mRNA) in primary cultures of cortical astrocytes. The 3'-untranslated region (UTR) of the NGF mRNA contains an AU nucleotide rich region which, similar to other short-lived mRNAs, might modulate its rate of degradation. Using Northwestern blotting analysis, we have now identified a protein with a MW of about 140 kDa which binds to a radiolabeled RNA probe containing the AU-rich domain in the 3'UTR of the rat NGF mRNA. RNA binding activity was observed using a full-length NGF RNA probe, but was not seen using a probe lacking the 3'-UTR or using a β -actin RNA probe. The binding activity or amount of this protein was increased in astrocytes treated with okadaic acid (5-20 nM). Maximal induction of binding activity was seen following 9 h of treatment at the maximal okadaic acid concentration tested. Under these conditions NGF mRNA content was also elevated by about 15-fold compared to untreated astrocytes. The RNA binding activity was abolished by treating astroglial cell extracts with trypsin, and the induction of the RNA binding protein by okadaic acid was prevented by cotreatment with cycloheximide (10 µg/ml) indicating that okadaic acid stimulates the synthesis of this putative modulator of NGF mRNA degradation. Finally, the induction of this binding activity by okadaic acid is associated with an increase (4-fold) in the *t*_{1/2} of the NGF mRNA. Transfection of cell lines with expression vectors containing the full-length NGF cDNA or NGF cDNA lacking the 3'UTR are underway to study the role of the 3'-UTR and the putative modulator in the control of NGF mRNA degradation.

538.10

DETECTION OF PROHORMONE CONVERTASES IN DEVELOPING AND ADULT MOUSE SUBMANDIBULAR GLANDS. H. Farhadi^{*}, S. Pareek^{*}, M. Marcinkiewicz^{*}, N. G. Seidah^{*}, M. Chrétien^{*}, and R. A. Murphy. Montreal Neurological Institute, McGill University and the *Clinical Research Institute of Montreal, Montreal, Quebec, CANADA

The processing enzyme(s) responsible for generating mature β -NGF from its precursor at the amino terminal end have not been identified. Prohormone processing enzymes, called convertases, have been implicated in the processing of precursor proteins at pairs of basic amino acids and a companion study from our laboratories presented at this meeting (Seidah *et al.*, 1994) have shown that at least one member of this family can cleave NGF, BDNF, and NT-3. The aim of this study was to investigate the relationship of NGF and convertases in the mouse submandibular gland. Northern blot analysis and *in situ* hybridization revealed high levels of mRNA coding for PC1, PC2, PC5 and furin in the salivary glands of neonatal and pubescent male mice; levels in NGF-containing granular tubule cells of adults are significant but lower than during pubescence. These results were confirmed by immunocytochemistry. Levels of PC1 mRNA and protein were significantly lower than those of the other processing enzymes. Adult female salivary glands expressed only low levels of NGF and processing enzymes. Our results suggest that one or more prohormone convertases may be involved in processing the precursor of NGF in mouse submandibular glands.

538.12

ASSAY-DEPENDENT VARIABILITY IN THE CROSS-REACTIVITY OF β -NGF ANTIBODIES WITH RELATED NEUROTROPHINS S. Varon^{*} and J.M. Conner. UCSD, Department of Biology, La Jolla, CA 92093

Previous studies have indicated that antibodies raised against purified β -NGF may cross-react with other neurotrophin family members sharing similar sequence homology, such as BDNF, NT-3 and NT-4/5. New antibodies generated against any one neurotrophin must, therefore, be examined for potential cross-reactivity with the others. The assay system used to evaluate cross-reactivity is frequently chosen for its convenience. While characterizing our β -NGF antibodies, we have found that the choice of the assay system markedly affects cross-reactivity results. In an **immunoblot assay** (following SDS-PAGE), mouse and human NGF were robustly detected by the antibodies while NT-3 and BDNF were virtually undetectable. In a **slot-blot assay**, the antibodies recognized NGF and NT-3 but BDNF and NT-4/5 were only detected after fixative treatment of the blot. In a **one-site ELISA** (antigen coupled to the solid phase) the antibodies recognized both BDNF and NT-3, but more weakly than β -NGF. Using a **two-site ELISA** (with the same antibody for capture and detection), no cross-reactivity with BDNF, NT-3 or NT-4/5 occurred. When **injected into normal rats** (intrastriatal injection; 600ng each), all four neurotrophins were immunohistochemically detected to about the same extent. **In vitro assays** with dissociated E8 chick sensory neurons showed that BDNF, NGF, and NT-3 all supported cell survival (to varying degrees), but the antibodies could only block the biological activity of NGF. These findings clearly demonstrate that cross-reactivity between NGF antibodies and related molecules is a function of the assay used for the evaluation and caution against transferring antibody specificity data across assay systems. Supported by NINCDS NS-16349.

A RAPID ASSAY FOR NGF-ACTIVITY IN NEURONS BASED ON INDUCTION OF LUCIFERASE UNDER CONTROL OF THE NGFI-A PROMOTER. S.M. Elsas, F.F. Eide* and W.C. Mobley. Dept. of Neurology, Univ. of California, San Francisco, CA 94143.

Detailed characterization of neurotrophin structural features important for activation of receptors of the *trk* gene family would benefit by the availability of a rapid and versatile screening assay in neurons. We designed an assay for NGF activity based on rapid induction of the NGFI-A gene by NGF.

PC12 cells were transiently transfected with a plasmid containing the luciferase gene under control of the NGFI-A promoter. Two days after transfection the cells were exposed to NGF or other compounds and were then lysed. After addition of luciferin substrate, light output was measured.

NGF induced a specific, dose-dependent increase in luciferase activity. The dose-dependency ($EC_{50} = 2.7$ ng/ml) correlated well with that for neurite outgrowth and for autophosphorylation of the *trk* receptor. At 50 ng/ml the signal to noise ratio was about 1:100. An exposure of 30 min. was sufficient to induce a maximum activation after a delay of 4 hrs. Ligand specificity was evaluated by comparing the NGF response to that for bFGF and EGF. While all elicited a response, only that for NGF was inhibited by K252b. In that this assay can be carried out in 96-well plates, it represents a useful new tool for defining NGF - NGF receptor recognition determinants.

The authors thank J. Milbrandt for the NGFI-A/luc construct.

NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION IV

539.1

INCREASED INSULIN-LIKE GROWTH FACTOR II GENE EXPRESSION IN DIABETIC RAT LUMBAR DORSAL ROOT GANGLIA AND MOTONEURONS. F.J. Liuzzi*, A.S. Depto and A.I. Vinik. The Diabetes Institutes, Eastern Virginia Medical School, Norfolk, VA 23501.

Neuropathy is a major complication of diabetes mellitus and can involve sensory as well as motoneurons. While no single cause of diabetic neuropathy has been identified, the contributions of a number of pathogenic mechanisms have been extensively studied. The insulin-like growth factors (IGFs) promote neurite outgrowth *in vitro* and axonal regeneration *in vivo*. These data coupled with reports of reduced IGF serum levels suggest the possibility that a decline in IGFs available to neurons contributes to the pathogenesis of diabetic neuropathy. To address this possibility, we examined IGF-II gene expression in lumbar dorsal root ganglia (DRGs) and spinal cords of rats made diabetic by a single dose (55mg/kg, i.p.) of streptozotocin. Age-matched, sham-injected rats served as controls.

After nine weeks of diabetes (blood glucose levels maintained between 200-400mg/dl) the diabetic rats and the age-matched controls were sacrificed and tissues harvested for *in situ* hybridization with a cRNA probe to IGF-II. Contrary to our expectations, preliminary quantification revealed a three to four-fold increase in IGF-II mRNA levels in lumbar DRGs of diabetic rats as compared to those of normal, non-diabetic rats. Similar changes were observed in lumbar spinal motoneurons.

These observations seem enigmatic in light of the diminished regenerative capacity of sensory and motoneuron axons in diabetic rats. It is possible, however, that a compensatory up-regulation of local IGF-II synthesis by neurons, in response to low serum levels or reduced uptake in diabetes, inhibits axonal regeneration by switching-off the regenerative program normally exhibited by axotomized sensory and motoneurons.

539.3

SELECTIVE EXPRESSION OF NEUROTROPHIN-3 mRNA IN MUSCLE SPINDLES OF THE RAT. J.C.V.M. Copray* and N. Brouwer. Department of Medical Physiology, University of Groningen, 9712 KZ Groningen, The Netherlands.

To evaluate the possible involvement of NT-3 in the formation and maintenance of muscle spindles, an *in situ* hybridization study was set up to analyze the expression of neurotrophin-3 (NT-3) mRNA in rat muscle spindles from the first embryonic stages of their formation unto their mature appearance in adult animals. Serial, sagittal cryosections of 25 μ m were made of 4% paraformaldehyde-fixed intact hindlimbs or dissected hindlimb muscles derived from embryonic (E15-E21), neonatal (P1, P6, P17 and P30) and adult Wistar rats. *In situ* hybridization for NT-3 mRNA was done in combination with the immunohistochemical detection of desmin, calretinin and slow tonic MHC. Starting from the appearance of the firstly formed intrafusal fiber, i.e. the nuclear bag2 fiber, at E19, the intramuscular expression of NT-3 mRNA was confined to the intrafusal fibers of the muscle spindles. High levels of NT-3 mRNA were found in the equatorial region of the nuclear bag type intrafusal fibers and remained present in these intrafusal fibers throughout life. During the entire period of muscle formation, examined from E15 on, as well as in mature muscles, no NT-3 mRNA could be detected in extrafusal fibers. The exclusive intramuscular expression of NT-3 mRNA within intrafusal fibers substantiates the involvement of NT-3 in the formation as well as the maintenance of muscle spindles.

539.2

DEVELOPMENTAL EXPRESSION OF NEUROTROPHINS IN THE SPINAL CORD AND LIMB BUDS OF THE RAT EMBRYO. L.A. Scarisbrick*¹, P.J. Isackson*² and E.G. Jones¹. Dept. of Anatomy and Neurobiology, University of California, Irvine, CA, 92717¹ and Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Jacksonville FL, 32224².

The expression patterns of nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3), and neurotrophin 5 (NT-5) were examined within the spinal cord and limb bud from E13 to E19, a period corresponding to the main period of naturally occurring spinal motoneuron degeneration in the rat. The domains of gene expression were compared with the appearance of NCAM and HNK-1 immunoreactive cells and nerve fibers in parallel sections. From the onset of expression of multiple neurotrophins on E14, a partially overlapping pattern of expression of each was observed in the ventral horn of the spinal cord and in the mesenchymal and epithelial components of the limb bud. The peak expression of each neurotrophin, at each site, occurred from E14 to E16. Over this period, NT-3 transcripts are the most abundant in the spinal cord and developing limb bud muscle masses. Significantly lower levels of each neurotrophin are detected at each site by E19. Only NT-5 transcripts are detected at significant levels in the limb bud on E13, when NCAM immunostained myoblast condensations, in some cases already associated with NCAM immunostained nerve fibers, are observed. The transient, dense expression of multiple members of the neurotrophin gene family in select regions of the limb bud and spinal cord implicates the neurotrophins in early critical events at several levels of the developing spinal motoneuron-muscle cell axis. Peak levels of expression coincide with the early phases of naturally occurring spinal motoneuron cell death in the spinal cord and with the early stages of arrival of NCAM immunostained nerve fibers and the differentiation of myoblasts in the limb bud. The development of the spinal cord and limb bud are therefore linked by the co-ordinate expression of members of the neurotrophin gene family. Supported by NIH grant NS 30109-02.

REGULATION OF BDNF, NT-3 AND NT-4 mRNA EXPRESSION IN RAT MUSCLE DURING DEVELOPMENT AND AFTER SCIATIC NERVE LESION. A.Sh.Parsadanian, O.Griesbeck, P.Carroll, R.A.Hughes, M.Sendtner, H.Thoenen*. Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, 82152 Martinsried, Germany.

Expression of BDNF, NT-3 and NT-4, was examined in rat skeletal muscle during development (E15-adult) and in adult rat gastrocnemius muscle at different times after transection of the sciatic nerve using quantitative Northern blot analysis of poly A⁺ RNA and *in situ* hybridization. At E15, the highest level of expression was found for NT-3 (63pg/ μ g poly A⁺ RNA), approximately 20 times greater than that of either BDNF or NT-4. During later development, the levels of all neurotrophin mRNAs fell. BDNF and NT-3 mRNA remained low in adulthood, whereas NT-4 mRNA levels increased postnatally, such that adult muscle contained similar quantities of NT-3 and NT-4 mRNA, but very little BDNF message. *In situ* hybridization of E15 limb bud showed a clear signal for NT-4 only in epidermis, for BDNF mostly in mesenchyme and in some muscle cells, while NT-3 was abundantly expressed in muscle. 24 hours after sciatic nerve lesion, the levels of BDNF and NT-4 mRNA in muscle were reduced considerably. While the amount of NT-4 mRNA remained low, BDNF mRNA levels increased with time after lesion, reaching a level 2.6-fold greater than control 14 days after lesion. In contrast, NT-3 mRNA was not affected after nerve injury. Hybridization of transverse sections of denervated muscle with a BDNF riboprobe gave a signal over peripheral nerve. No significant labeling was found in the surrounding muscle tissue. The same riboprobe also labels cells in a distal segment of the sciatic nerve 4 weeks after lesion, suggesting that the source of increased BDNF mRNA production in denervated muscle is Schwann cells in peripheral nerves leading through the muscle.

539.5

DISTINCT REGULATION OF NT-4 mRNA IN THE SKELETAL MUSCLE SUGGESTS A ROLE FOR NT-4 IN THE MAINTENANCE OF THE NEUROMUSCULAR JUNCTION.

H. Funakoshi¹, N. Belluardo^{1,3}, E. Arenas¹, Y. Yamamoto², H. Otsuka², H. Persson¹ and C. F. Ibáñez¹. ¹Laboratory of Molecular Neurobiology, MBB and ²Department of Nobel Neurophysiology, Karolinska Institute, S-17177 Stockholm, Sweden and ³Institute of Human Physiology, University of Catania, Catania, Italy.

We have previously shown that the levels of NT-4 mRNA in skeletal muscle, in contrast to those of the other neurotrophins, decreased 1 day after sciatic nerve transection (Funakoshi et al., J. Cell Biol. 123:455, 1993). We now show that, as opposed to the other neurotrophins, NT-4 mRNA levels in muscle increase during postnatal development. The differential regulation of NT-4 mRNA expression suggested that its level may be regulated by motoneuron activity. In agreement of this, electrical stimulation of the sciatic nerve increased NT-4 mRNA levels in gastrocnemius and soleus muscles in a dose-dependent manner. NT-4 mRNA levels peaked 12 hrs after stimulation and decreased thereafter, reaching basal levels 24 hrs after stimulation. Elevated NT-4 mRNA levels could be sustained after repeated stimulations. A similar effect could be obtained after direct stimulation of the muscle. In contrast, the mRNA levels of the other neurotrophins are not affected by electrical stimulation. These observations suggest NT-4 may play a local role in the maintenance of the neuromuscular junction in an activity-dependent manner. This possibility is currently being explored using purified recombinant NT-4 protein and grafts of genetically engineered fibroblasts producing NT-4.

AN RNA SPLICING MUTATION THAT DISRUPTS THE HUMAN CILIARY NEUROTROPHIC FACTOR (CNTF) GENE. R. Takahashi¹, H. Misawa¹, H. Yokoi², M. Hayashi², T. Komori², A. Inaba², T. Ohtake², J. Jiang³ and T. Deguchi^{1,3}. Department of Neurology (1), Tokyo Metropolitan Institute for Neuroscience, 2-6 Musashidai, Fuchu City, Tokyo, Department of Neurology (2), Tokyo Metropolitan Neurological Hospital, Tokyo, and Research and Development Center (3), BML, Inc., Saitama, Japan

Ciliary neurotrophic factor (CNTF) promotes the survival of a variety of neurons. A recent report showed that disruption of the CNTF gene in mice caused motor neuron degeneration, suggesting an essential role of CNTF in the survival of motor neurons (Masu et al, 1993). We report a null mutation in the human CNTF gene. The mutated allele shows a G to A transition producing a new splice acceptor site and the resulting mRNA species codes for an aberrant protein. Analysis of tissue samples from various genotype subjects and transfection of CNTF minigenes into cultured cells demonstrates that the mutated allele expresses only the mutated mRNA species. Mutated CNTF protein is not detected either by immunoblot or immunohistochemical analyses of human tissue samples. In 391 Japanese people tested, 242 (61.9%) were normal homozygotes, 140 (35.8%) heterozygotes, and 9 (2.3%) mutant homozygotes; the mutated allele frequency was 20%. The distribution of the three genotypes is similar in healthy and neurological disease subjects. Detailed electrophysiological tests on 30- and 64-year-old mutant homozygotes reveals no apparent abnormalities. In contrast to the report on mice, our findings indicate that human CNTF deficiency does not induce obvious neurologic dysfunction.

NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION V

540.1

GLIAL-DERIVED NEUROTROPHIC FACTOR cDNA SEQUENCE AND mRNA LOCALIZATION AND REGULATION. J.E. Springer¹, J.L. Seeburger, L.W. Bergman, and J.O. Trojanowski. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA 19102, and Dept. of Neuropathology, University Pennsylvania, Philadelphia, PA. 19104.

The use of GDNF and other neurotrophic factors as potential therapeutic agents in the treatment of Parkinson's disease has been proposed. However, recent studies provide evidence that the distribution, and thus the actions of GDNF may be more widespread than previously suggested. In the present study, we report that GDNF mRNA is expressed in a Schwann cell line previously shown to exhibit GDNF-like activity, in adult rat skeletal muscle, a tissue known to contain several neurotrophic factors, and in a number of rat and human CNS structures. Two GDNF transcripts were amplified by RT-PCR from Schwann cell total RNA. The predicted (GDNF₆₃₃) and a smaller (GDNF₅₅₅) product were found in these samples, with GDNF₅₅₅ being consistently more abundant than GDNF₆₃₃. The sequence of GDNF₅₅₅ was identical to GDNF₆₃₃ with the exception of a missing 78 base pair segment containing a cryptic splice site. It is likely, given our Southern blot data, that GDNF mRNA is transcribed from a single gene, and GDNF₅₅₅ mRNA is a splice variant of GDNF₆₃₃. The expression of some neurotrophic factors in skeletal muscle is modified following peripheral nerve damage, possibly as a compensatory response to denervation. In our experiments, the medial gastrocnemius muscle was denervated, and the treated animals allowed to survive for 1, 7, 14, or 42 days. The expression of GDNF₆₃₃ in denervated muscle was found to be elevated at 7 to 14 days compared to controls. In conclusion, while GDNF has been reported to be a selective neurotrophic factor for embryonic mesencephalic dopamine neurons, the results of this and other studies provide evidence that GDNF mRNA is expressed and regulated in different tissues. It is possible that this neurotrophic factor may be of biological significance for other neuronal populations, including those ensheathed by Schwann cells and innervating skeletal muscle.

SEIZURES CAUSE ELEVATIONS OF BRAIN DERIVED NEUROTROPHIC FACTOR mRNA IN WIDESPREAD AREAS OF DEVELOPING RAT BRAIN.

H. I. Kornblum^{1,2}, R. Sankar^{2,3}, D. Shin³, C. G. Wasterlain³, K. Tatsukawa^{1,2} and C. M. Gall⁴. Departments of Pharmacology¹, Pediatrics², and Neurology³, UCLA School of Medicine, Los Angeles, CA 90024, and Department of Anatomy and Neurobiology⁴, UC Irvine, School of Medicine, Irvine, CA, 92717.

Prior studies have demonstrated that seizures induce an elevation in messenger RNAs for nerve growth factor (NGF) and brain derived neurotrophic factor (BDNF) within adult rat brain, but that seizures prior to 2 weeks of life do not produce similar changes. In the present study, we demonstrate that limbic seizures, using two different experimental models, dramatically enhance hybridization densities for BDNF mRNA in developing rat brain. Rats from 7 to 60 days of age were pretreated with lithium chloride followed 16 hr later by 100 mg/kg pilocarpine. Some animals were treated with kainic acid (3 mg/kg). Controls were treated with vehicle. Additional animals were pretreated with diazepam to prevent seizures. Animals were killed 1, 2, 4, or 8 hrs post injection. Brains were then processed for *in situ* hybridization using ³⁵S-labeled cRNA probes. Both treatments induced electrophoretic and clinical seizures at all ages studied. At P12 and older, pilocarpine-induced seizures resulted in dramatic elevations of hybridization densities in multiple brain areas including neocortex; hippocampus; piriform, cingulate and entorhinal cortices; and amygdala. Maximal effects were observed between 2 and 4 hrs post injection. Elevations in hybridization were prevented by pretreatment with diazepam. On P7 there were significantly elevated hybridization densities within cingulate, piriform and entorhinal cortex. Kainate-induced seizures led to markedly enhanced hybridization only within the CA3 subfield of the hippocampus of 9 day old rats. The present study demonstrates that neurotrophin expression can be dramatically altered by seizures within the developing brain, at ages when significant maturational events are taking place. Furthermore, different models of limbic seizures produce different effects on neurotrophin expression.

540.2

SEIZURES INCREASE GDNF mRNA IN RAT HIPPOCAMPUS. C. M. Gall¹ and J.E. Springer².

¹Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717 and ²Dept. of Neurology, Hahnemann Univ. School of Med., Philadelphia, PA. 19102

Glial-derived neurotrophic factor (GDNF) is a recently described neurotrophic factor with trophic activity for mesencephalic dopamine neurons. In rat brain GDNF mRNA expression decreases during postnatal development to very low levels in the adult. In the present study, the influence of lesion- and kainic acid-induced seizures on GDNF mRNA content in adult rat brain was examined. In untreated rats, *in situ* hybridization to GDNF mRNA labeled cells in the olfactory tubercle and anterior thalamus but was not detected in hippocampus. In association with hilus lesion-induced limbic seizures (which recur from 2 to 10 hrs after surgery), hybridization was markedly increased in the dentate gyrus granule cells. GDNF mRNA reached half-maximal levels by 4 hrs and maximal levels by 10 hrs after seizure onset and then declined to near control levels by 24 hrs. In these rats hybridization was not increased in other brain areas. RT-PCR analysis of total mRNA isolated from the dentate gyrus/CA1 of hilus lesion rats demonstrated a preferential increase in GDNF₆₃₃ compared to GDNF₅₅₅. Intraventricular injection of 0.5 µg kainic acid stimulated a similar bilateral increase in GDNF mRNA in the granule cells. However, at 10 hrs post-injection, hybridization to GDNF mRNA was also elevated in fields of neuronal damage in the ipsilateral hemisphere including stratum pyramidale of hippocampal region CA3, medial thalamus, and perirhinal cortex. These results indicate that the intense physiological activity of seizure is sufficient to induce GDNF mRNA expression in hippocampal granule cells but not in other populations of neurons engaged in the seizure episode (i.e., cortical pyramidal cells). The additional fields of hybridization in kainic acid-treated rats indicate that GDNF expression is also increased in some populations of neurons following neurotoxic insult. Supported by NS26748.

REGULATION OF BDNF PROTEIN AND NEUROPEPTIDES AFTER LIMBIC SEIZURES.

H. Nawa¹, J. Carnahan², and C. M. Gall³. ¹Beckman Neuroscience Ctr, Cold Spring Harbor Lab. Cold Spring Harbor, NY 11724, ²Amgen Ctr, Thousand Oaks, CA 91320, and ³Dept. of Anatomy & Neurobiology, Univ. of Calif., Irvine, CA 92717.

Messenger RNA for brain-derived neurotrophic factor (BDNF) is distributed in many brain regions and regulated by excitatory neuronal activity. Despite numerous studies of BDNF mRNA, the production of BDNF protein is poorly understood because of a lack of its quantitative measurement. Recently, we have established a two-site enzyme immunoassay (ELISA) for BDNF protein. The combination of high-affinity antibodies and fluorometric detection has increased sensitivity to 1 pg/well, which enables us to measure trace amounts of BDNF protein in tissues. In normal rat brain, BDNF content was highest in hippocampus, followed by hypothalamus, neocortex, thalamus, cerebellum and striatum. This resembles the distribution of BDNF mRNA, suggesting accuracy of the ELISA. To test the hypothesis that seizure-induced BDNF mediates later changes in neuropeptide expression, we evaluated the temporal and spatial correlation between changes in BDNF protein and neuropeptide levels after limbic seizures. In hippocampus BDNF was rapidly increased about 2-fold by 4 hr, reached maximal levels at 16 hr, and remained elevated through 96 hr after seizure onset. In contrast, the BDNF increase was delayed in cortex and returned to the basal level by 24 hr. After an initial decline, neuropeptide Y content increased to control levels by 16 hr and to well above control levels at 24-96 hr in all regions examined. Enkephalin content was also clearly increased by 16 hr after seizure onset in all areas. In contrast, hippocampal dynorphin levels were markedly below control values from 2 through 96 hr after seizure onset. These data demonstrate increases in BDNF protein precede the major change in enkephalin and neuropeptide Y content and are thus consistent with the hypothesis that BDNF may play an important role in neuropeptide regulation after limbic seizures.

540.5

INDUCTION OF BDNF AND trkB BY ELECTROCONVULSIVE SEIZURE (ECS): REGIONAL REGULATION AND ROLE OF CREB. M. Nibuya*, L. Rydelek-Fitzgerald, S. Morinobu, D.S. Russell, E.J. Nestler, and R.S. Duman. Lab. of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. Med., New Haven, CT

Recent studies from our laboratory demonstrate that acute ECS increases the expression of BDNF (brain derived neurotrophic factor), and that chronic ECS enhances the induction of BDNF in rat frontal cortex. This work has been extended to studies of the regional regulation of BDNF and trkB, the protein tyrosine kinase receptor for BDNF, and to studies of CREB (cAMP response element binding protein) in mediating the induction of BDNF by ECS treatment. In situ hybridization demonstrates that acute ECS (2 h) increases the expression of BDNF mRNA in several regions of hippocampus (dentate gyrus, CA1, and CA3) and cerebral cortex (piriform, occipital, and frontal cortex). Acute ECS (2 h) also increases levels of trkB mRNA and immunoreactivity, determined by northern and western blot, respectively, whereas chronic ECS down-regulates trkB immunoreactivity in frontal cortex. Unilateral, local infusion of CREB antisense oligonucleotide, which we have shown to decrease levels of CREB immunoreactivity, into the hippocampus blocks the induction of BDNF mRNA in the area surrounding the infusion site. In contrast, local infusion of CREB sense strand oligonucleotide, which does not alter levels of CREB, into the contralateral hippocampus does not influence the induction of BDNF by ECS. These studies provide a preliminary characterization of the regional regulation of BDNF and trkB expression by ECS, and demonstrate that CREB may be necessary for the induction of BDNF mRNA.

540.7

UNILATERAL NEONATAL BUT NOT ADULT HIPPOCAMPAL LESIONS DECREASE BDNF mRNA IN THE CONTRALATERAL HIPPOCAMPUS. H. van Praag*, R.C. Elliott, P. Qu, C.F. Dreyfus and I.B. Black, Dept. Neuroscience & Cell Biology, UMDNJ/Robert Wood Johnson Med School, Piscataway, NJ 08854.

Unilateral neonatal hippocampal lesions cause a longlasting impairment in spatial memory, whereas unilateral lesions made in the adult rat do not. The discrepancy between the adult and the neonatal lesions may be due to a deficit in the remaining hippocampus. We hypothesized that hippocampal trophic factors may play a role since we found previously that the projecting septum and locus coeruleus are dysfunctional after the neonatal hippocampal lesion. Moreover, previous work had suggested that trophic molecules are involved in learning and memory.

Unilateral electrolytic hippocampal lesions were made on postnatal day 1 or in 3 month old adult rats. Using a solution hybridization assay we measured NGF and BDNF mRNA in the remaining hippocampus and adjacent cortex at 4 weeks after the lesion. BDNF but not NGF mRNA was significantly decreased by 30% in the remaining hippocampus 4 weeks after a neonatal but not an adult unilateral lesion. Neither BDNF nor NGF mRNA was changed in the overlying cortex. These findings raise the possibility that a decrease in the level of BDNF mRNA in the remaining hippocampus may contribute to the spatial memory deficit observed after a unilateral neonatal hippocampal lesion. Supp. NIH HD23315.

540.9

CHANGES IN NGF AND BDNF mRNA EXPRESSION INDUCED BY ENTORHINAL CORTEX LESIONS. M.J. SHIFMAN* and D.G. STEIN, Brain Research Laboratory, I.A.B., Rutgers University, Newark, NJ, 07102.

Injury to the mammalian brain induces plasticity processes (e.g. axonal sprouting) that may contribute to behavioral recovery of function after injury. Unilateral ablation of the entorhinal cortex (EC) in adult rats leads to robust sprouting responses by remaining intact afferents in the hippocampus (HC). Axons from the contralateral EC and C/A hippocampal projections sprout collateral terminals that reinnervate the dentate granule neurons. Axons from the septal nucleus also reinnervate portions of hippocampus. We were interested in examining expression of injury-induced neurotrophic factors and induction of axonal sprouting in the hippocampus caused by unilateral damage to the rat's EC.

The effects of unilateral, electrolytic EC lesions on NGF and BDNF mRNAs expression were determined by non-radioactive Northern blot analyses. Seven days after lesion, the expression of NGF mRNA in the hippocampus ipsilateral to the injury, was increased by 20%, but did not change on the contralateral side compared to intact animals. An 40% increase of NGF mRNA was also detected in the ipsilateral and contralateral HC at 14 d after lesion. The expression of BDNF mRNA in the hippocampus ipsilateral to the injury was elevated by 40% one week after EC lesion, but returned to control level by 14 days. The expression of BDNF mRNA on the contralateral side did not change at any of the time points in comparison to intact animals.

These results suggest that the evaluated expression of NGF and BDNF may contribute to the induction or maintenance of sprouting in the hippocampus after EC lesions.

Regional Increase in Brain-Derived Neurotrophic Factor and Nerve Growth Factor mRNA, but not in Acidic and Basic Fibroblast Growth Factor mRNA in Kindling. K. Sato^{1,2}, K. Kashihara³, K. Morimoto⁴, K. Otsuki¹, Y. Fujiwara¹, K. Akiyama¹, T. Hayabara² and S. Kuroda¹.

¹Department of Neuropsychiatry and ²Department of Neurology, Okayama University Medical School, Okayama 700, Japan. ³Clinical Research Institute, National Sanatorium Minamiokayama Hospital, Okayama 701-03, Japan.

⁴Department of Neuropsychiatry, Kagawa Medical School, Kagawa 761-07, Japan.

The levels of mRNA for nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), acidic and basic fibroblast growth factor (FGF) have been studied in the kindling model of epilepsy. Using in situ hybridization and ³²S-labeled oligonucleotide probes, the induction of mRNAs was evaluated in the rat brain 1h after generalized seizures induced by daily electrical stimulations from the amygdala. BDNF mRNA levels were markedly elevated bilaterally in the granule cell layer of the dentate gyrus and the pyramidal cell layer of CA1, CA2, CA3 and CA4. The magnitude of increase in the dentate gyrus was 4- to 5-fold of that of the sham-operated controls, whereas moderate increase was observed in other regions. The significant increases in NGF mRNA were observed in the granule cell layer of dentate gyrus, CA1, CA2, CA3, CA4 and amygdala. Acidic FGF mRNA slightly increased in the granule cell layer of the dentate gyrus.

No detectable changes, however, were observed in basic FGF mRNA in response to kindled seizures in the regions examined.

These results indicate that the mRNA inductions of neurotrophic factors, especially BDNF mRNA expression in the dentate gyrus, corresponded to increases in metabolic and electrical activity associated with seizures or neuronal vulnerability coincident with the kindling-induced seizures. The observed differences in the spatial pattern of the neurotrophic factor mRNAs suggest that the mechanisms underlying expression of individual neurotrophic factors in kindling are heterogeneous.

540.8

CONSTITUTIVE EXPRESSION OF BDNF AND TRKB mRNAs IN RAT BRAIN WITH AGE AND LEARNING IMPAIRMENT S.D. Croll*, N.Y. Ip, R.M. Lindsay, & S.J. Wiegand, Regeneron Pharmaceuticals, Tarrytown, NY 10591.

mRNAs for the neurotrophin BDNF and its receptor, TrkB, have been localized in most regions of the adult rat brain. These messages reach peak expression late in development, and remain at high levels into adulthood. We examined the constitutive expression of mRNA for BDNF and TrkB in rat brain from young adulthood into old age. The levels of many neuroactive chemicals in old age have been found to depend on the functional state of the animal. To determine if the constitutive expression of BDNF and TrkB mRNAs depend on the cognitive status of aged rats, animals were pre-screened on the Morris water maze task, and were subsequently divided into aged learning-impaired and aged learning-unimpaired groups. Northern blot analyses were completed for olfactory bulb, neocortex, hippocampus, diencephalon, striatum, midbrain, hindbrain, and cerebellum of 4 mos, 13 mos, 24-26 mos (aged) learning-unimpaired, and aged learning-impaired rats. Results demonstrate that BDNF and TrkB mRNA levels do change with age in some, but not all, brain regions studied. Both BDNF and TrkB mRNAs were decreased with normal aging in olfactory bulb, cortex, and hippocampus, but were increased with age in the diencephalon. mRNA levels for both BDNF and TrkB in olfactory bulb and cortex, and for TrkB in striatum, were higher in aged learning-impaired animals compared to aged learning-unimpaired animals. Northern analysis was performed for CNTF to test the specificity of these impairment-related mRNA differences. CNTF mRNA did not show the same impairment-related changes as BDNF mRNA. An *in situ* hybridization study of BDNF and TrkB mRNA expression with age and learning impairment is currently being conducted.

540.10

REGULATION OF FGF-2 AND RECEPTOR IN BRAIN INJURY. F. Gómez-Pinilla*, L. Vu and C. Cotman. Dept. Neurology and IRU Brain Aging, Univ. of California, Irvine, CA 92717.

We focused our studies in an action of FGF-2 on astrocytosis, and its possible modulation by FGF receptors and extracellular matrix components. A bilateral lesion in the motor-sensory cortex was performed, and either FGF-2 alone, FGF-2 plus heparan sulfate proteoglycan (HSPG), or saline contained in a piece of gelfoam was applied unilaterally within the wound cavity. Rats that received treatment with recombinant FGF-2 showed an induction of: astrocytes, FGF-2 cells, and FGF receptor-1 (FGFR-1) cells by the area surrounding the lesion. The group of rats that received FGF-2 combined with HSPG showed a larger increase than FGF-2 on the same cellular parameters. Application of HSPG without FGF-2 also triggered an induction of FGFR-1 cells, although, to a much lesser extent compared to FGF-2 alone. Our results indicate that the FGF-2/FGFR system is involved in the regulation of astrocyte proliferation *in vivo*, and its action is potentiated by HSPG. The co-induction of FGF-2 and receptor suggests that FGFR-1 plays a critical role in astrocytosis.

540.11

DIFFERENTIAL EFFECTS OF THE ABSENCE OF RETINAL CONNECTIONS ON BDNF GENE EXPRESSION IN THE MOUSE VISUAL SYSTEM. M.H. Hankin* and J.S. Reese. Department of Anatomy, Medical College of Ohio, Toledo, OH 43614.

In the present study we examine how BDNF mRNA levels in visual target regions (superior colliculus, SC; visual cortex, vCtx) is affected by the absence of retinal connections. To determine the effect of eye removal before innervation of the primary visual nuclei, we have taken advantage of congenitally blind *ocular retardation (orJ)* mice in which the optic nerve fails to form. We have also studied normal mice with bilateral eye removal either at birth (5d after initial retinocollicular contact) or from adults. Preliminary data from RNase protection assays indicate that BDNF RNA levels in the vCtx are normally about 30% greater than in the SC. While BDNF message levels in the *orJ* SC were comparable to normal, levels in *orJ* vCtx were approximately 3 times greater than in normal vCtx. Eye removal at birth had differential effects in the SC and vCtx (examined up to 5m): while BDNF RNA in the SC was reduced to approx. 30% of normal, it appeared to be increased to nearly 3 times normal in vCtx (similar to the *orJ* vCtx). Eye removal from adult mice resulted in downregulation of BDNF RNA in both SC and vCtx by 7d - an observation consistent with work showing a similar effect of dark-rearing and TTX on BDNF gene expression in vCtx of postnatal and adult rats (Castrén et al. *PNAS* 89:9444). Our observations suggest that different brain regions involved with visual input (1° & 2°) respond differently to eye removal during the perinatal period: BDNF gene expression was downregulated in the SC, while the vCtx showed upregulation. Continuing work will determine (1) how the normal postnatal increase in BDNF RNA in the vCtx (which is attenuated by blocking light input to the brain) compares in the complete absence of retinal connections, and (2) whether BDNF is expressed in retinorecipient layers of the SC. Supported by NIH Grant NS26777.

INDUCTION OF GLIA-DERIVED GROWTH FACTOR (S100 β) IN RATS FOLLOWING CARDIAC ARREST. S.P. Jaw*, R.R. Matsumoto and D.D. Truong. Dept. of Neurology, Univ. of California Irvine, Irvine, CA 92717.

S100 β , a small, dimeric, acidic calcium-binding protein, is known to stimulate neurite outgrowth and promote survival of serotonergic neurons. After resuscitation from 8 min of cardiac arrest (CA), Sprague-Dawley rats developed motor impairments, e.g. post-hypoxic myoclonus. Biosynthesis and metabolism of 5-HT were also altered in post-CA rats; cortical 5-HT_{2A} receptors were reduced; and treatment with the 5-HT_{2A} agonist, (+)-1-2,5-dimethoxy-4-iodophenyl-2-aminopropane (DOI), significantly attenuated myoclonus. These results indicate alteration of functions of serotonergic neurons may occur in post-hypoxic rats. In contrast, by 45 days following CA, motor functions of rats recovered and cortical 5-HT_{2A} receptors of these animals were increased from low levels at early timepoints. In the present study, we, therefore, investigated involvement of S100 β in the recovery process. Brain levels of S100 β were examined with quantitative immunoblot analysis. Significantly increased levels of S100 β were found in rats 14 days and >45 days post-CA ($P < 0.05$). The results indicate that reactive astrogliosis and elevated levels of S100 β may participate in the recovery processes following hypoxic-ischemic insults to the brain.

THE EFFECT OF OVARECTOMY AND ESTRADIOL-REPLACEMENT ON BRAIN-DERIVED NEUROTROPHIC FACTOR mRNA EXPRESSION IN BRAIN REGIONS OF FEMALE SPRAGUE-DAWLEY RATS. M. Singh*, E.M. Meyer and J.W. Simpkins. Center for the Neurobiol. of Aging, Univ. of Fla., Gainesville, FL 32610.

In Alzheimer's disease (AD), the most consistent and widespread deficit seen is that of the basal forebrain cholinergic system. We have previously demonstrated that estradiol (E2) modulates the function of these neurons and maintains them by preventing the ovariectomy (OVX)-induced decrease in ChAT activity. As such, we hypothesized that E2 affects cholinergic function by modulating the levels of certain neurotrophic factors. We previously showed that 3 month OVX leads to a significant reduction in cerebral cortical NGF mRNA levels. In the present study, we extended our original hypothesis to include the effects of OVX and E2-replacement on BDNF mRNA levels using *in situ* hybridization. BDNF mRNA levels were evaluated in 3 groups of animals: ovary-intact, OVX (9 weeks and 28 weeks), and E2-replaced animals. After 9 weeks of OVX, significant decreases in BDNF mRNA in the frontal (28%) and temporal cortex (38%) were observed. E2 replacement to OVX animals normalized BDNF mRNA levels in both these regions. 28 week OVX led to significant reductions in the frontal (34%), parietal (29%) and temporal (34%) cortices although E2 replacement at this longer time point was without effect. In the hippocampus, 9 weeks of OVX resulted in significant reductions in the pyramidal cell layer of CA 1 (23%) and the granule cell layer of the dentate gyrus (DG; 12%) while E2 replacement normalized BDNF signal only in CA 1. 28 week OVX resulted in significant reductions in the CA1 by 20%, CA 2 by 31%, CA 3 by 39%, CA 4 by 36% and DG by 31% while E2 replacement increased BDNF mRNA levels in all subregions except the CA 1 region. Collectively, the data demonstrate that E2 deprivation leads to a reduction in BDNF mRNA which becomes more widespread as the length of OVX is increased. Our data support the potential importance and therapeutic merit for E2 replacement in such disorders like AD. Supported by Grants AG 10485 and IT32AG00196.

NERVE GROWTH FACTOR (NGF) IS LOWER IN SEMEN FROM SPINAL CORD INJURED (SCI) MEN COMPARED TO NORMAL MEN. O.F. Padron, N.L. Brackett, C.M. Lynne*, J.A. Weingartner and K.A. Crutcher. The Miami Project to Cure Paralysis and the Dept. of Urology, Univ. of Miami Sch Med, Miami, FL 33136; Dept. of Neurosurgery, Univ. of Cincinnati Med Ctr, Cincinnati, OH 45267.

In many cell types, NGF is required for normal cellular function in man. Sperm cells from SCI men are lower in motility and viability than sperm cells from normal men. The present study tested the hypothesis that levels of NGF in the semen of SCI men are lower than in the semen of normal men.

SCI men were subjects in The Male Fertility Research Program of The Miami Project to Cure Paralysis. We analyzed the antegrade semen of 8 SCI men (mean age 29.3 \pm 2.4 SEM, mean duration of injury 8.4 \pm 2.5 years) and 9 healthy controls (mean age 31.2 \pm 1.3 years). Complete semen analysis was performed on each sample. Semen was obtained in SCI men via electroejaculation (n=3), vibratory stimulation (n=4) or masturbation (n=1). Controls produced samples via masturbation. Whole semen samples were analyzed via a 2-site enzyme-linked immunosorbent assay (ELISA) for NGF.

There was a ten-fold decrease in NGF levels in the semen of SCI men (0.03 \pm 0.02 ng/ml) compared to controls (0.29 \pm 0.07 ng/ml). This difference was statistically significant ($p < 0.01$, ANOVA).

Our data indicate that the semen of SCI men has significantly lower levels of NGF than the semen of normal men. This condition may contribute to the asthenospermia and necrospermia seen in SCI men.

Supported by The Miami Project to Cure Paralysis and by NIH grant NS31410.

NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION VI

541.1

Expression of estrogen and androgen receptor mRNAs in immortalized oligodendrocyte cell lines. R. Stoika, L. Foster, A. Campagnoni, and P. E. Micevych*. Mental Retardation Research Center and the Laboratory of Neuroendocrinology, UCLA School of Medicine, Los Angeles CA 90024-1763

Oligodendrocytes may mediate developmental effects of sex steroids on the CNS including the production of neurotrophins. The effect of the sex steroids, estrogen and androgen, in the development and regulation of oligodendrocytes has not been studied. To begin addressing the questions of the effect of sex steroids on oligodendrocyte growth, proliferation and the expression of neurotrophins during development, we used a series of cell lines immortalized at specific stages in the oligodendrocyte lineage (Foster et al., *Dev Neurosci* 1993 15:100-109). All of the cell lines stained positively for markers of the oligodendrocyte lineage, A β , and 2'3'-cyclic nucleotide 3'-phosphodiesterase (CNP); none of the cell lines, however, expressed myelin basic protein which suggests that these were immature oligodendrocytes. Poly A⁺ RNA was isolated from 10 oligodendrocyte cell lines. Northern blot analysis indicated that several of these lines expressed mRNA coding for the estrogen receptor (N7, N9, N11, N19) while mRNA for the androgen receptor was expressed in the N2, and the N19 cells. All the cell lines expressed mRNAs coding for both brain derived neurotrophic factor and nerve growth factor. Cell lines identified to have specific steroid receptors as well as the N16 line, which does not express either estrogen or androgen receptor mRNA, were grown at the permissive temperature (34°) in a defined (serum and phenol red free) medium with and without sex steroids. These results suggest that sex steroids support the proliferation and growth of these cell lines and may also regulate the expression of neurotrophins that influence the development and survival of other cells in the nervous system. Supported by NS21220 and HD04612.

β -INTERFERON INCREASES ASTROCYTE PRODUCTION OF NEUROTROPHIC FACTORS. T. Boutros and V. W. Yong*. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4.

Recent clinical evidence has suggested that β -interferon is efficacious in the treatment of multiple sclerosis although the mechanism of action remains unclear. Given that astrocytes can provide trophic support to neurons, and since ciliary neurotrophic factor (CNTF) has been reported to protect oligodendrocytes against apoptotic-damage, we examined whether β -interferon could increase the production of specific neurotrophic factors by astrocytes. Mouse β -interferon (1 to 1000 U/ml) was added to confluent or non-confluent neonatal mouse astrocyte cultures for varying periods of time. Total RNA was extracted and subjected to Northern blot analyses for levels of mRNA for CNTF, nerve growth factor (NGF) and the astrocyte filament protein, glial fibrillary acidic protein (GFAP). Doses of β -interferon from 100 U/ml significantly increased the mRNA for CNTF and NGF, but not for GFAP. Increase in mRNA for both CNTF and NGF (2-fold) was evident by 24 hours following β -interferon treatment. The β -interferon-enhanced trophic factor production was not reproduced by interleukin (IL)-2, IL-6 or γ -interferon. Western blot analysis is currently in progress to evaluate the corresponding protein levels. We conclude that the astrocyte production of neurotrophic factors by β -interferon may be relevant to its clinical efficacy.

541.3

SYNERGISM OF PHORBOL ESTERS WITH IL-1 β ON IL-6 RELEASE AND GENE EXPRESSION IN ASTROCYTES.

M. Grimaldi, R. Arcone, A. Marino, G. Ciliberto and G. Schettini*
Dip. Neuroscienze, Sec. Pharmacology, *CEINGE, Univ. of Napoli, Via S. Pansini 5, I-80131; #IRBM, Via Pontina Km 30,400, Pomezia Roma

Cultured Astrocytes produce and release interleukin 6 (IL-6) in basal and following stimulation with various agents. We have already demonstrated that Phorbol esters (PMA) can increase the release of IL-6. Moreover, it has been reported that interleukin 1 β (IL-1) released IL-6 by astrocytes. PMA concentration-dependently stimulated IL-6 release with an EC₅₀ of about 50 nM. The effect of PMA linearly increased from a minimal stimulation of secretion after 3 h. of exposure to a maximal stimulation at 24 h. At 24 h the concentration-related curve showed saturation at 300 nM of PMA, indicating that PMA actions required at least 24 h to be fully exerted. PMA effect upon IL-6 release by cortical astrocytes was inhibited by the treatment with PKC blockers. Similarly, PKC-desensitization, by means of PMA pretreatment, caused a complete block of IL-6 release stimulated by PMA. The basal release of IL-6 resulted set at a higher level following PKC desensitization. IL-1 stimulated IL-6 release concentration-dependently and its effect was potentiated by the blockade or by the desensitization of PKC. Conversely, calphostin C, over 24 h lasting incubation, did not affect IL-1 stimulation. Both IL-1 and PMA increased IL-6 mRNA expression, but, IL-1 stimulated more consistently IL-6 mRNA expression than PMA. Finally, the costimulation of astrocytes with either IL-1 and PMA resulted in a synergistic stimulation of IL-6 release that was not affected by blocking PKC. This synergism, was also found at level of mRNA expression. (Supported by MPI 40%, CNR 9100612 and TP on Aging, AIRC 92-93)

541.5

BASIC FIBROBLAST GROWTH FACTOR (bFGF) EXPRESSION IN ASTROCYTES AND GLIOMA CELLS. M.K. Stachowiak, J. Moffett, K. Neary, J.R. Shapiro, W. Shapiro*, E.K. Stachowiak, Barrow Neurological Institute, Phoenix, AZ 85013

Expression of bFGF is transiently induced during a reversible transition of quiescent to proliferating reactive astrocytes. In constantly proliferating glioma tumors expression of bFGF is constitutively elevated. To model the molecular mechanisms underlying induction of bFGF we developed cultures of human astrocytes and glioma cells. Confluent cultures of astrocytes were quiescent and did not express bFGF. By reducing cell density, events occurring *in vivo* in reactive astrocytes were mimicked: induction of bFGF proteins, their accumulation in the nuclei, cell hypertrophy and proliferation that lasted until a new confluent state was reached. Changes in bFGF protein content reflected changes in the levels of bFGF mRNA. We used bFGF-luciferase reporter plasmids to show that the depletion of bFGF mRNA in confluent astrocytes results from repressed transcription and is mediated by sequences upstream from the transcription start site of the bFGF gene. In U251 and SF767 glioma cells bFGF proteins, mRNA, and bFGF-luciferase constructs were expressed at constitutively high levels and were not susceptible to the inhibition at confluence. The growth of the SF767 glioma cells was stimulated by either the 18kd or the 22, 23, and 24 kd isoforms of bFGF expressed intracellularly from the CMV promoter, but not by exogenously added bFGF. This suggests an intracrine mechanism of action. The growth of astrocytes was stimulated by exogenous bFGF. Our results suggest that: (1) bFGF participates in the regulation of the cell cycle in human astrocytes, and (2) deregulated expression of bFGF gene may underlie abnormal growth of glioma cells, and (3) deregulation of bFGF reflects altered trans-regulation of the bFGF gene promoter. EXTRACELLULAR GUANOSINE AND GTP STIMULATE NGF AND FGF-2 SYNTHESIS BY ASTROCYTES. J.W. Gysbers*, P.J. Middlemiss, S. Hindley and M.P. Rathbone, Dept. of Biomed. Sci. McMaster Univ. Hamilton, ON, Canada, L8N-3Z5.

Extracellular guanosine (Guo) and GTP affect both nerve cells (Gysbers and Rathbone (1992) *NeuroReport* 3:997-1000, 1992) and astrocytes (Kim et al. (1991) *J. Neurosci. Res.* 28:442). Guo or GTP also stimulate neurite outgrowth and branching from mouse hippocampal neurons co-cultured with astrocytes (*Soc. Neurosci. Abs.* (1993), 19:24.7). Astrocytes in culture synthesize and secrete a number of neurotrophins, e.g. NGF, BDNF, FGF-2 and NT-3. We determined whether the neurotrophic effects of Guo and GTP might be due to stimulation of trophic factor production by the astrocytes. Guo or GTP (10 μ M) was added to cultures of proliferating mouse astrocytes. After 24 hours total mRNA was extracted and analyzed by Northern blotting. Cultures treated with Guo or GTP increased both FGF-2 and NGF mRNA over that in untreated cultures. The release of NGF into the astrocyte culture medium, as determined by ELISA, was also increased under these conditions. Since Guo and GTP stimulate neurite outgrowth from PC12 cells in the absence of astrocytes we questioned whether Guo and GTP stimulated the production of neurotrophins in PC12 cells. Both Guo and GTP induced c-fos as determined by Northern and Western blotting. This may lead to activation of other genes involved in neurogenesis. Moreover FGF-2 neutralizing antibody added to culture medium inhibited the enhancement of NGF-induced neurogenesis by Guo. This raises the possibility that Guo induces FGF-2 synthesis in PC12 cells that contributes to their ability to enhance neurite outgrowth. INCREASED ¹²⁵I-IGF-2 BINDING IN THE COLCHICINE LESIONED HIPPOCAMPUS: FUNCTIONAL mRNA EXPRESSION FOLLOWING NEURONAL CELL DEATH AND GLOSSIS. C.R. Breese, R.M. Booze, A. D'Costa, W.E. Sonntag, and S.S. Leonard, Department of Pharmacology Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262

Insulin-like growth factors (IGFs) are a family of small molecular weight peptide hormones which may act as neurotrophic factors in the central nervous system. We have previously examined ¹²⁵I-IGF-1 and ¹²⁵I-IGF-2 binding in the rat brain following cytotoxic colchicine lesions to the dentate gyrus of the hippocampus at time points up to 10 days post-lesion. These results demonstrated a time dependent increase in ¹²⁵I-IGF-2 binding in the lesioned region and overlying cortex (*Neuroscience Abstracts* 26.9, 1991). Nissl stained sections showed an ablation of the granular cell layer of the dentate gyrus, and extensive glial ingrowth into the lesioned and damaged areas. *In situ* hybridization revealed no observable mRNA for type-2 receptors in the lesioned area, while demonstrating normal expression to the ipsilateral CA1/CA3 and the contralateral hippocampus. Western ligand blotting for IGF-binding proteins (IGF-BP) has suggested that the increase in ¹²⁵I-IGF-2 binding may be due to expression of IGF-binding proteins. Our laboratory is currently examining colchicine lesioned animals for IGF-BP mRNA expression, as well as the expression of IGF-1, IGF-2, and other neurotrophic factors. Such expression would suggest that astrocytes produce IGF-BPs in response to neuronal injury, possibly to attract or maintain levels of the IGF peptides, which may in turn influence astrocytic proliferation and protein expression following neuronal cell death.

REACTIVE ASTROCYTES IN THE IMMUNOLESIONED BASAL FOREBRN PRODUCE NERVE GROWTH FACTOR-LIKE MOLECULES. J. Yu*, R. Wiley, and R. Perez-polo, Dept. of Human Biological Chemistry and Genetics, U. of Texas Medical Branch, Galveston, Texas 77555-0652.

It is currently believed that under normal conditions hippocampal neurons synthesize nerve growth factor (NGF) which provides trophic support to cholinergic neurons projecting from the basal forebrain. The hypothesis that reactive glial cells may produce NGF under lesioned conditions was examined in this study. The immunotoxin 192-saporin is a covalently linked complex made up of the monoclonal antibody to the low affinity NGF receptor and the ribosome inactivating protein saporin. We injected 192-saporin into the left lateral ventricle of rats. The cellular location of NGF-like immunoreactivity (NGF-LIR) was studied in the septum and hippocampus at 5, 11, and 29 days after treatment. A double immunostaining technique, which allowed a simultaneous localization of NGF-LIR and of the astroglial marker glial fibrillary acidic protein, was used. Our data showed that cholinergic neurons of the basal forebrain were lost as early as 5 days but more completely by 11 days after lesion. The NGF-LIR content of the cholinergic neurons was also reduced while many reactive glial cells in the basal forebrain became NGF-like immunoreactive. Also, NGF-LIR levels were increased in hippocampus. These results support the hypothesis that a characteristic response of central cholinergic neurons to injury might be to provide signals that stimulate the production of endogenous trophic agents, such as NGF in neurons and reactive glial cells. Our findings may be of importance in considerations concerning trophic support to the cholinergic neurons of the basal forebrain whose impaired function is a component of cognitive deficits in neurodegenerative disease such as Alzheimer's dementia. This is publication 21A from USPHS grant P01 AG10514 awarded by NIA. Also supported by NINDS NS 18708.

THE REGULATION OF ASTROCYTE FUNCTION BY DEPOLARIZING SIGNALS. H. Wu*, P. Qu, J. B. Black, C. F. Dreyfus, Dept. Neurosci. & Cell Biol., UMDNJ/Robert Wood Johnson Med. Sch., Piscataway, NJ 08854.

Previous studies from our laboratory and others have indicated that astrocytes produce neurotrophins. To understand regulatory mechanisms and the potential interaction of neuronal signals, we have evaluated effects of depolarizing signals on astrocyte NGF and BDNF mRNAs.

Purified astrocyte cultures were established from P1 rat basal forebrain using published techniques (McCarthy and DeVellis; O'Malley et al). The cultures contained > 95% astrocytes, revealed by GFAP immunocytochemistry. Solution hybridization was used to define levels of neurotrophin mRNA in the cultures. NGF mRNA was expressed at a higher level (0.48pg/ug of total RNA) than BDNF mRNA (0.32pg/ug of total RNA). To determine whether depolarizing signals influence neurotrophin expression, cultures were exposed continuously to KCl (25 mM) for 4 hours or 48 hours. Both 4 and 48 hours of exposure resulted in a significant increase in BDNF mRNA. Effects were greatest at 4 hours (3-fold increase) and decreased at 48 hours (50% increase). This increase in BDNF mRNA was relatively specific, since NGF mRNA was not similarly affected. Increases in neurotrophin expression at 48 hours were accompanied by significant decreases in GFAP expression and the alteration of astrocyte morphology from mature process-bearing cells to more immature flat cells.

Our data suggest that depolarizing signals influence astrocyte function by modulating neurotrophin expression and astrocyte morphology. We are presently exploring the roles of neurotransmitters and mechanisms underlying these events. (Supp: NICHHD:HD23315 and the UMDNJ Foundation)

5-HT SELECTIVELY PROMOTES THE SURVIVAL OF O-2A PROGENITOR CELLS PREPARED FROM THE STRIATUM OF THE E16 RAT: INTERACTION WITH bFGF. J.W. Commissiong,* T. Takeshima,¹ Jane M. Johnston and K. Shimoda,² NTU-LMCN-NINDS-NIH, Bldg. 10/5N214, Bethesda, MD 20892. ¹Div. Neurol., Tottori Univ. Sch. Med., 86 Nishimachi, Yonago 683, Japan. ²Div. Neurol., Natl. NishiTottori Hosp., 876 Mitsu, Tottori 689-02, Japan

We showed recently that oligodendrocyte-type-2 astrocyte (O-2A) progenitor cells prepared from the striatum of the E16 rat, produce a potent neurotrophic factor that is secreted, and causes a marked increased survival of dopaminergic neurons in culture (Takeshima et al., Neurosci. Letts. 166: 178-182, 1994). A similar, target-derived factor that is transported retrogradely to the dopaminergic neurons in the substantia nigra, might be produced in the striatum, in the adult, by an O-2A-like cell, in response to neuroeffectors released in the striatum. Since dense serotonergic and dopaminergic innervations are present in the striatum, we tested the effect of dopamine (DA), and 5-hydroxytryptamine (5-HT), (and norepinephrine as a control) at 1.0×10^{-6} M, for their ability to promote the survival of O-2A progenitors in culture, after plating at $5.0 \times 10^4/\text{cm}^2$. The cells were primed with serum (5.0%) for the first 24 hr, and then grown in a serum-free medium. DA was severely toxic. Only the small number of type-1 astrocytes in the DA-treated cultures survived beyond the second day in culture (DIV2). NE had no significant effect. 5-HT caused a significant protection ($P < 0.05$). bFGF (10 ng/ml) caused a significant ($P < 0.05$) inhibition of the toxic effect of DA. 5-HT + bFGF caused a robust effect that was significantly greater ($P < 0.01$) than that produced by bFGF alone at DIV5. Experiments to: 1) determine if 5-HT is mitotic; 2) purify the putative dopaminergic neurotrophic factor (DNTEF) produced by primary O-2A progenitor cells; 3) screen the striatum for A2B5-positive cells during critical stages of development; 4) determine the dose-response effects of 5-HT and the 5-HT receptor(s) involved are in progress. One function of the serotonergic innervation of the striatum might be to provide neurotrophic support of an A2B5-like cell.

MOLECULAR AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT

542.1

MODULATION OF GAP-43 mRNA EXPRESSION IN CULTURES OF RAT CEREBELLAR GRANULE CELLS.

L. Console-Bram,¹ D. Baird,² S.G. Fitzpatrick-McElligott,³ and J.G. McElligott,¹ ¹Dept. of Pharm., Temple Univ. School of Med., Phila., PA 19140, ²Dept. of Anatomy and Neurobiology, Med. Coll. of Penn. and Hahnemann Univ., Phila., PA 19129 and ³Medical Products Division, DuPont Co., Wilmington DE 19898.

In situ hybridization studies from our lab have localized GAP-43 mRNA in granule cells of the developing and adult rat cerebellum (Soc. Neurosci. Abstr. 16:813, 1990). The level of GAP-43 mRNA expression was found to be developmentally regulated since higher levels of GAP-43 mRNA were present in the neonatal cerebellum as compared to adult cerebellum. The objective of this present study was to determine if putative cerebellar neurotransmitters (e.g. GABA and excitatory amino acids), acting at granule cell synapses, are involved in the modulation of GAP-43 mRNA expression. Both GABA and glutamate have been implicated in granule cell trophic activity and their relative levels appear critical for granule cell maturation. The model system chosen for our study was dissociated cerebellar cultures enriched for granule neurons. Cells were exposed to agonists and antagonists of GABA and EAAs in serum-free media for 7 days in tissue culture chamber slides. Cultures were hybridized with a ³³P-labeled oligonucleotide to GAP-43 mRNA and the amount of hybridization within process-bearing cells was quantitated via an image analysis system. Results from these studies indicates that addition of the inhibitory amino acid GABA, (25 and 50uM), the GABA_B agonist, baclofen (25 and 50uM), as well as the glutamate receptor antagonists, MK-801 (25 and 50uM) and CNQX (25uM), decrease GAP-43 mRNA expression. This study shows that GAP-43 mRNA expression in granule cell bodies could be modulated by synaptic input from both excitatory glutamatergic mossy fibers and inhibitory GABAergic Golgi interneurons. Thus, GAP-43 modulation by these neurotransmitters may contribute to the growth of parallel fibers and neuroplasticity at the parallel-Purkinje cell synapse.

STRAIN AND AGE-DEPENDENT ATYPICAL CREATINE KINASE ISOENZYME TRANSITIONS AND SPECIFIC ACTIVITY OF CHICK NEUROMUSCULAR TISSUES. O.C. Ramirez* and E. Jiménez. Departamento de Bioquímica, Centro de Investigación y de Estudios Avanzados del I.P.N., México, D.F. 07000.

It is currently believed that only isoenzyme BB of creatine kinase (BB-CK) initiates in all vertebrate neuromuscular organs during ontogeny. In White Leghorn chick and rat skeletal muscle, BB-CK is replaced by MB and finally by MM-CK. It is thought that BB-CK remains the sole type in brain. Here, we found that Rhode Island chick brain and heart cytosolic(c)CK specific activities showed the lowest and relatively constant values from stage 30 up to month 8, when an abrupt increase occurred. cCK values from breast and thigh muscles increased 223% and 421%, at hatching. At month 8, they returned to basal levels. On the contrary, cCK breast and thigh values increased 2100% and 1260% at year 1.5. Brain isoforms followed a transition pattern opposite to the accepted one. With creatine in heart, typical and atypical MB isoforms were present from stage 30 until hatching, and varieties of MM and MB-CK were found in thigh and breast muscles. BB-CK and varieties of MM and MB-CK were found from hatching up to month 8 in heart, thigh and breast muscles. In senile animals varieties of BB, MB and MM-CK isoenzymes were present in heart and thigh muscles, whereas no MB varieties were found in brain and breast muscle, coinciding with the most anaerobic period of ATP synthesis, when transphosphorylation is indispensable.

Tα1 PROMOTER:NLACZ CONSTRUCT IS INDUCED DURING BOTH REGENERATION AND SPROUTING OF MATURE NEURONS IN TRANSGENIC MICE. W. Wu*, A. Gloster and F. D. Miller. Center for Neuronal Survival, Montreal Neurological Institute, Montreal, PQ H3A 2B4

We have previously demonstrated that one member of the α-tubulin multigene family, termed Tα1 in rats, is regulated as a function of growth in both developing and mature neurons. Furthermore, we have demonstrated that 1.1 kb of the 5' flanking sequence of this gene confers a similar pattern of expression in transgenic mice, and more specifically, i) specifies gene expression as a function of neurogenesis, and ii) regulates levels of gene expression as a function of neuronal growth. Expression of Tα1 mRNA is upregulated during the regenerative growth of axotomized motor and sympathetic neurons. We report here that the expression of Tα1:nlacZ transgene is induced during the regeneration of facial motoneurons (by X-gal staining) and sympathetic neurons of the superior cervical ganglia (by Western blot). The induction is seen at 5 days following injury, when the endogenous Tα1 mRNA is increased to maximal level, and remains at increased levels for up to 49 days if regeneration is prevented. These observations enable us to define the axotomy-induced upregulation of Tα1 gene expression as transcriptional, thereby providing the basis for attempting to define the sequence elements in this promoter that are responsible for modulating Tα1 α-tubulin gene expression as a function of axonal injury. We have also previously demonstrated that Tα1 α-tubulin mRNA levels are increased during collateral sprouting of mature sympathetic neurons and by systemic or locally applied NGF in sympathetic neurons *in vivo* and *in culture*. We report here that the Tα1 promoter fragment also confers NGF-inducibility in sympathetic neurons of transgenic mice *in vivo*, as detected by Western blot analysis. This upregulation occurs both during collateral sprouting and following systemic administration of NGF to newborn litters. Thus, the Tα1 promoter also contains the sequences necessary to mediate NGF-responsiveness in both developing and mature neurons.

542.4

DIFFERENTIAL EXPRESSION OF GLYCINE RECEPTOR ISOFORMS BY EMBRYONIC RAT SPINAL CORD NEURONS DURING DEVELOPMENT *IN VITRO*. M. D. Withers* and P. A. St. John. Program in Neuroscience, Dept. of Anatomy, University of Arizona, Tucson, AZ 85724.

It is well established that acetylcholine receptors undergo a change in subunit composition during development at the neuromuscular junction. By comparison, relatively little is known about developmental changes in neurotransmitter receptors in the central nervous system. We are studying the developmental regulation of glycine receptors expressed by rat spinal cord neurons. Previous results show that embryonic rat spinal cord neurons undergo a change in strychnine-sensitivity of responses to glycine during the first week in culture. To rule out the possibility that strychnine-insensitive responses to glycine are a product of cross-activation of GABA receptors, we have used a monoclonal antibody, mAb 4a, raised against the alpha subunit of glycine receptor to provide independent evidence for the expression of glycine receptors by these neurons. This antibody recognizes an epitope common to all glycine receptor alpha subunits cloned to date, but is not found in any GABA receptors cloned thus far. Initial results demonstrate that embryonic rat spinal cord neurons express glycine receptor alpha subunit immunoreactive material by the first day in culture. This is at a time when these neurons exhibit strychnine-insensitive responses to glycine but before they bind strychnine in radio-ligand binding assays. This suggests that these neurons are expressing different isoforms of the glycine receptor at different times during development *in vitro*. (Supported by NIH and The Robert S. Flinn Foundation).

POSTNATAL DEVELOPMENT OF SERINE/THREONINE PROTEIN PHOSPHATASES IN THE RAT BRAIN: RELATIONSHIP WITH MICROTUBULES. G.V.W. Johnson and S.M. Dudek*. Dept. of Psychiatry and Behavioral Neurobiology, University of Alabama at Birmingham, Birmingham, AL 35294-0017.

Serine/threonine protein phosphatases regulate a wide variety of processes within neurons, and apparently play crucial roles in mediating appropriate structural and functional changes during development. Since alterations in the phosphorylation of specific structural proteins apparently modulates their function and can result in a rearrangement of the cytoskeleton, the levels and activities of specific phosphatases and their association with microtubules during postnatal development were measured. Although expression and activity were low, calcineurin (phosphatase 2B) was detected as early as postnatal day 1 (P1) in both the microtubule preparation and whole homogenate. It appears that calcineurin levels increase with age until P20, after which there is no further increase. These results differ from previous studies which showed no detectable calcineurin before postnatal day 4 (Polli et al., 1991). Interestingly, calcineurin has been shown to exist in growth cones, and apparently depends on an intact cytoskeleton for this localization (Ferreira et al. 1993).

In contrast to calcineurin, activity of phosphatase 2A is highest during the first postnatal week and declines thereafter. It is unknown at this time whether this increased activity early in postnatal life is due to increased levels of an isoform of the phosphatase 2A catalytic subunit, or from lower levels of the 2A regulatory subunits. Phosphatase 1 levels do not appear to change during this time. Studies are underway to determine the relationship between these changes in phosphatases which occur during postnatal development, and the age-related alterations in the phosphorylation state of specific microtubule-associated proteins. Supported by NIH grants EY06509, NS27538, and AG06569.

CHARACTERIZATION OF A CONSERVED LEARNING-ASSOCIATED PROTEIN IN SEA URCHIN OOCYTE: BIOCHEMICAL LOCALIZATION AND PHYSIOLOGICAL EFFECTS. T.J. Nelson*, J.L. Olds, A. Hutter, L. Cameron and D.L. Alkon. Laboratory of Adaptive Systems, NINDS, National Institutes of Health, Bethesda, MD 20892, USA.

It has been shown that protein kinase C (PKC) is translocated from cytosol to membrane fractions following memory formation in several species. Cp20 is an ARF-related GTP-binding protein associated with memory, and is a high-affinity PKC substrate that undergoes changes of phosphorylation during associative learning (Nelson et al. Science 1990). Both cp20 and PKC were identified in *S. purpuratus* oocytes by immuno-staining and fluorescent BODIPY-phorbol acetate binding, respectively. The identity of cp20 was confirmed by dot blot analysis of HPLC.

Treatment of oocytes with Brefeldin A, a fungal metabolite known to interfere with ARF-related proteins, resulted in a transient increase in free-intracellular Ca^{++} as assessed by Fura-2/AM imaging. Subcellular fractionation indicated that cp20 was primarily associated with free ribosomes and rough ER, while only small amounts were found in smooth ER, Golgi, or cytosol. Additionally, approximately 20% of the cp20 was also found in the nucleus. In smooth ER, approx. 50% of the cp20 was in the phosphorylated state, while in rough ER, >90% of the cp20 was found to be phosphorylated. Treatment of oocytes with BFA (200 nM) caused a marked reduction in cp20 recovered from ER, and resulted in a small increase in amount recovered from the nucleus. Previous results (Nelson et al., 1992) indicated that purified cp20 can markedly enhance the incorporation of P-32 uridine into mRNA. Thus, cp20 may play a role in conjunction with PKC in inducing the increases in mRNA and protein previously demonstrated with associative learning.

ONTOGENY OF [3 H]MK-801 BINDING TO THE NMDA-GATED ION CHANNEL. C-S. Li, J. He, J. Haracz*, R. Sircar. Laboratory for Developmental Neuroscience, Departments of Psychiatry and Neurology, Albert Einstein College of Medicine, Bronx, New York.

The NMDA receptor plays an important role in developmental plasticity. Phencyclidine (PCP) and PCP-like drugs (MK-801, ketamine) act as non-competitive antagonists at the *N*-methyl-D-aspartate (NMDA) receptor. We have earlier shown that postnatal PCP treatment in rats produced long-term changes in seizure susceptibility. Here we report the developmental profile of interactions of L-glutamate, glycine and spermidine with [3 H]MK-801 binding in the immature rat brain. Rat pups were sacrificed on specific days after birth. Forebrain crude synaptosomal membranes (CSMs) were prepared. Aliquots of CSM were incubated with [3 H]MK-801 in the absence or presence of L-glutamate, glycine and spermidine. Non-specific binding was determined in the presence of excess unlabelled MK-801. For autoradiographic determinations, fresh frozen brain sections from postnatal days 1, 5, 7, 10, 14, 18 and 21 were incubated with 10 nM [3 H]MK-801 in the absence and presence of excess nonradiolabeled MK-801, washed, dried and juxtaposed against tritium-sensitive film. [3 H]MK-801 binding in postnatal rat brain increased with age. Modulations of [3 H]MK-801 binding by L-glutamate, glycine and spermidine were age-specific. These results may clarify the long-term neurobehavioral effects of postnatal exposure to noncompetitive antagonists.

Oligodeoxynucleotides Antisense to Calmodulin mRNAs Inhibit Proliferation and NGF-Induced Differentiation of PC12 Cells. S.-P. Zhang*, R.A. Nichols, and B. Weiss. Dept. of Pharmacol., Medical College of PA, Phila., PA 19129.

Calmodulin (CaM) is involved in numerous biological processes, including regulation of the cell cycle and cell differentiation. Using the PC12 pheochromocytoma cell line as a model for studying neuronal growth and differentiation, we have previously shown that nerve growth factor (NGF)-induced neurite outgrowth from PC12 cells was associated with increased levels of CaM and CaM mRNA. Our recent immunocytochemical and *in situ* hybridization analyses have demonstrated that CaM and the CaM mRNAs are present not only in cell bodies but also in neurites of PC12 cells differentiated with NGF. In order to address the role of CaM in PC12 cells differentiation, we investigated the effects of antisense phosphorothioate oligodeoxynucleotides (ODNs) targeted to the initiation sites of the CaM mRNAs transcribed from the three CaM genes in PC12 cells. We first assessed the uptake of the ODNs into PC12 cells by incubating a FITC-labeled oligodeoxynucleotide antisense to the mRNAs from CaM gene 1 which was then incubated with the cells. Confocal microscopy revealed that the FITC-labeled ODN was taken up into the cytoplasm and nuclei. The addition of all three ODNs antisense to the mRNAs encoded by the three CaM genes produced a dose-dependent inhibition of the proliferation of the PC12 cells. The three CaM antisense ODNs also inhibited NGF-induced neurite outgrowth when present at concentrations of 16 μ M each. Similar concentrations of an ODN having a randomized sequence did not significantly inhibit neurite outgrowth. Immunocytochemical analyses showed that the CaM antisense ODNs also reduced the levels of CaM in PC12 cells treated with NGF, supporting the view that the inhibitory effect of the CaM antisense ODNs on cell differentiation was due to their ability to block the expression of the CaM genes. Our results suggest that CaM is involved in the proliferation of PC12 cells as well as in their differentiation cells induced by NGF. (Supported by NS30724).

MODULATION OF TAU PHOSPHORYLATION IN DEVELOPING RAT FOREBRAIN. Michelle A. Freeman* and Shelley Halpain. Department of Neuroscience, University of Virginia, Charlottesville, VA 22908

The microtubule associated protein tau promotes microtubule bundling and polymerization and is regulated by phosphorylation. Modulating tau's phosphorylation state may be a means by which neurons regulate the cytoskeleton during neurite outgrowth. We have examined tau phosphorylation in developing rat brain using quantitative immunoblot analysis with the monoclonal antibody AT8, which selectively binds tau when serine 193 is phosphorylated. AT8 immunoreactivity changed dramatically during development: it was undetectable at embryonic day 18, was present at birth and during the first postnatal week, then declined to undetectable levels by the end of the second postnatal week. In homogenates from an *in vitro* slice preparation, we observed that immunoreactivity is reduced to approximately 5% of initial levels after incubation for 30 minutes in ACSF, suggesting that tau is highly vulnerable to endogenous protein phosphatase activity. This loss of immunoreactivity was prevented by the addition to the incubation buffer of inhibitors of protein phosphatases 1 and 2A, okadaic acid or calyculin A (1 μ M), but not the selective PP2B inhibitors FK506 (1 μ M), FK520 (20 μ M) or deltamethrin (50 μ M). These data suggest that PP1 and/or 2A regulate phosphorylation at ser-193 but that PP2B plays little or no role during this period. Neither phorbol esters nor forskolin induced an increase in phosphorylation at this site; however, incubation for 30 minutes with basic fibroblast growth factor increased tau phosphorylation in a dose dependent manner. This is consistent with a role for proline-directed kinases such as MAP kinase in the regulation of this site.

EXPRESSION OF INTERMEDIATE FILAMENTS IN ZEBRAFISH. A. Canger, M. Passini, M. Hagel, E.M. Levine, C. Fuchs, R. Druger, A. Francis, and Nisson Schechter. Dept. of Biochemistry and Cell Biology, Dept. of Psychiatry and Behavioral Sciences. SUNY at Stony Brook, NY 11794.

The visual pathway of fish is an important model system to study molecular events that regulate and support optic nerve growth and regeneration. In addition, zebrafish embryos are amenable to direct observation and manipulation and are thus an excellent model to study molecular events that occur during embryogenesis. Our interest is in the role of intermediate filaments (IFs) in these processes. Although a precise physiologic function for IFs has not been determined, their distinctive cellular distribution and molecular diversity suggest that, in addition to a structural role, they may function to support cell differentiation and growth during embryogenesis. We have previously isolated and characterized several intermediate filaments from the goldfish visual pathway. Goldfish retinal ganglion cells express two novel neurofilament proteins designated plastin and gefitin. In addition, goldfish optic nerve glial cells express keratins as their predominant intermediate filament protein. Currently we are characterizing the expression of these intermediate filament proteins in the zebrafish. (NIH EY05212 to N.S.)

DISTRIBUTION OF CAM KINASE II AND α -INTERNEURIN IN THE RAT DRG AND DORSAL HORN: COMPARISON WITH PERIPHERIN. D.C. Molliver* and W.D. Snider. Dept. of Neurology, CSNSI, Washington University, St. Louis, MO 63110.

Calcium-calmodulin dependent protein kinase (CaMK) plays an important role in the Ca^{++} second messenger cascade and is capable of phosphorylating neurofilaments. We have used immunocytochemistry to examine the distribution of CaMK- α and the type IV intermediate filament protein (IFP) α -internexin in the rat dorsal root ganglion (DRG) and spinal cord. Labelling for the type III IFP peripherin was used as a comparison, because it has been shown to preferentially label small dark DRG neurons. CaMK-like immunoreactivity (CaMK-LI) in the DRG was restricted to a subset of small-diameter neurons. Virtually all cells positive for CaMK also showed heavy labelling for α -internexin, while the remaining neurons contained faint α -internexin-LI. However, a few small, brightly α -internexin-positive cells were not stained for CaMK. Both CaMK and α -internexin antisera labelled a subset of peripherin-positive neurons. In the spinal cord, robust CaMK-LI was seen in the dorsal horn, corticospinal tract and tract of Lissauer but not in the dorsal columns, with the strongest staining in lamina II, somewhat less in I and faint labelling of III-IV. α -internexin labelled processes throughout the cord, but clearly showed afferents from the dorsal root entering both the dorsal columns and lamina I. Little staining was evident in lamina II. Strikingly, peripherin labelling of the dorsal horn was very similar to α -internexin, with extensive labelling of the dorsal columns, lamina I and III-IV, but little staining in lamina II. Despite the fact that both IFP antibodies labelled large cell bodies only faintly, both stained myelinated fiber bundles entering the dorsal horn medially and turning into lamina III, characteristic of A β low-threshold mechanoreceptors. Thus, it appears that the extent of DRG soma IFP-LI is not a good indicator of axonal IFP content.

POSTNATAL HANDLING ALTERS AP-2, NGFI-A, NGFI-B mRNA EXPRESSION IN RAT HIPPOCAMPUS. J. Diorio, L. Donaldson, J. Yau, S. Shama, J.R. Seckl, & M.J. Meaney*. Douglas Hosp Res Ctr, McGill Univ., Montreal H4H 1R3 Canada & Dept. Medicine, Univ. Edinburgh, Western Gen Hosp, Edinburgh, Scotland EH4 2XU, UK

Postnatal handling alters glucocorticoid receptor (GR) gene expression and HPA function in the rat. The effect on GR expression appears to involve activation of intracellular cAMP levels. cAMP is known to increase the expression of a number of transcription factors, including activator protein-2 (AP-2) as well as NGFI-A and NGFI-B. In these studies we examined the acute effects of handling on the expression of mRNA levels for these factors in Day 7 pups that were handled and sacrificed 0, 30, 60, 90 or 120 minutes following handling. Levels of mRNA expression were determined using *in situ* hybridization on brain sections containing dorsal hippocampus.

Constitutive expression for all three transcripts was generally low, but detectable on Day 7 of life. Handling resulted in a modest, but reliable increase in AP-2 mRNA levels throughout the hippocampus. NGFI-A mRNA levels were increased dramatically throughout the hippocampus. In both instances, the increase was observed for at least 120 min following handling. In contrast, handling reduced NGFI-B mRNA levels to below detectable limits, and again the effect persisted for at least 120 min following handling.

The promoter region for the rat GR gene (Jacobson & Yamamoto, unpublished) contains putative binding regions for both AP-2 and NGFI-A. Thus, handling could alter GR expression by increasing cAMP formation and increasing AP-2 and/or NGFI-A expression. Interestingly, environmental enrichment, which results in increased GR expression in peripubertal rats, also increases NGFI-A and decreases NGFI-B expression in rat hippocampus.

POU-DOMAIN GENES AND FEMALE PUBERTY: OCT-2 GENE EXPRESSION AFTER HYPOTHALAMIC LESIONS THAT INDUCE SEXUAL PRECOCITY. J.K. Hill, S.R. Nagalla, R.P. Searles* and S.R. Ojeda. Div. Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Homeobox genes are transcriptional regulators considered to be upstream components of the regulatory hierarchy of genes controlling development. Among these, the POU-domain gene family is expressed in the forebrain during embryonic development. Since brain injury recapitulates early developmental events, we employed hypothalamic lesions that induce precocious puberty to begin examining the hypothesis that POU-domain genes may be involved in the early events that lead to the initiation of puberty. Using deoxyoligonucleotides complementary to the amino and carboxy terminal of the POU domain, we isolated by RT-PCR POU-domain sequences from the anterior hypothalamus of immature rats subjected to puberty-inducing electrolytic lesions. Half of the almost 100 clones analyzed corresponded to Oct-2, a family II POU-domain gene originally discovered in B lymphocytes but now known to be also expressed in brain. A predominance of Oct-2 sequences was evident as early as 24h after the lesion. Hybridization histochemistry revealed an increased prevalence of Oct-2 transcripts in reactive astrocytes surrounding the lesion site. Electrophoresis mobility shift assays employing the DNA octamer motif to which POU proteins bind to initiate their actions demonstrated that hypothalamic nuclear extracts contain proteins with mobilities corresponding to at least two of the known Oct-2 protein variants. One of these proteins also formed a prominent protein-DNA complex with a portion of the 5' flanking region of the transforming growth factor alpha (TGf α) gene harboring a presumptive POU binding site. Since TGf α has been implicated in the initiation of puberty and is also expressed in reactive astrocytes, the results suggest that the Oct-2 gene may participate in controlling the onset of puberty via transregulation of TGf α gene expression. 542.12

EXPRESSION OF AN *engrailed*-LIKE PROTEIN IN *APLYSIA*. R. Marois*, P. Holstadter, D. Zaas & T.J. Carew. Interdepart. Neurosci. Progr., Depts. of Biol. and Psychol., Yale Univ., New Haven, CT 06520-8205.

The homeobox gene *engrailed* is found in invertebrates and vertebrates, where it is thought to play a role in segmentation and neurogenesis. The function or even the presence of homeobox genes in gastropod nervous systems is as yet unknown. We have used the Mab 4D9 (gift of Nipam Patel) to examine the expression of *engrailed*-like gene products in whole animals and in the CNS of developing and adult *Aplysia*.

engrailed-like immunoreactivity (ELI) was found in the nucleus of a specific subset of cells in the CNS of both larval, juvenile and adult *Aplysia*. In juveniles, there is only one ELI cell in the left cerebral ganglion (none on the right), a bilaterally symmetrical cell in the buccal ganglia, and a few scattered cells in the pedal ganglia. By contrast, the abdominal and especially the pleural ganglia contain several ELI cells. In the pleural ganglia, the left pleural giant (LP1) cell is immunopositive, and so are cells of the anterior, medial, and posterior clusters. In the abdominal ganglia, in addition to a few unidentified clusters of cells, the giant cell R2 is immunopositive, as well as cells that we have tentatively identified as R10-R12 and L13. That both R2 and LP1 are immunopositive is consistent with the idea that these cells are bilateral homologues arising from the same developmental program but merging with different ganglia (Hughes & Tauc, 1963).

A cell count performed in the pleural ganglia indicates that there is a significant increase in immunopositive cells during juvenile development ($p < 0.01$). Cells may be fated to express the *engrailed*-like protein before they migrate into the CNS, since preliminary evidence suggests that ELI cells are found in the body wall, a site of neurogenesis in *Aplysia*.

Our results suggest that an *engrailed*-like protein is expressed in the nucleus of a specific subset of neurons in the CNS of *Aplysia*, where its expression pattern is consistent with it having a role in determination of cell fate.

542.14

EFFECTS OF CONGENITAL HYDROCEPHALUS ON HEAT SHOCK PROTEIN, IMMEDIATE EARLY GENES, AND NEUROTRANSMITTERS. J.P. McAllister II*, R.W. Connelly, N.G. Harris and H.C. Jones. Dept. of Neurosurgery, Cleveland Clinic, Cleveland, OH 44195 and Dept. of Pharm. and Therap., Univ. of Florida, Gainesville, FL 32610.

In an attempt to determine the onset of the first neuronal response, and possibly of irreversible neuronal pathology, during infantile hydrocephalus, the present study has examined the expression of heat shock protein (hsp70), immediate early cell genes (v-fos, jun-B), glutamic acid decarboxylase (GAD) and neuron specific enolase (NSE) in the H-Tx rat model of aqueductal stenosis. Affected H-Tx rats develop ventriculomegaly prenatally which progresses rapidly during the first postnatal month. In this study, fresh frozen tissue from rostral neocortex, caudal neocortex, and combined neostriatum and basal forebrain was obtained from 5 hydrocephalic and 5 normal animals at 6, 12 and 21 days of age, corresponding to mild, moderate and severe stages of ventriculomegaly. Northern blot analyses indicate that v-fos, hsp70 and jun-B expression is unchanged at all time points. These findings do not rule out the possibility that changes in hsp70 and IEGs require more severe ventriculomegaly or have occurred transiently at other time points. Ongoing analysis of GAD expression suggests that reductions occur in the hydrocephalic brain at 21 days. These changes are consistent with decreases in neurotransmitters reported in other models, and which appear to be irreversible. Further results for NSE and other time points will be presented and discussed.

542.16

ONTOGENY OF THE MOUSE SEROTONIN TRANSPORTER. S. Schroeter*, J.M. Lauder* and R.D. Blakely*. Dept of Anatomy and Cell Biology, Emory Univ., Atlanta, GA 30322* and Dept of Cell Biology and Anatomy, Univ. of N. Carolina, Chapel Hill, NC 27599*.

Serotonin (5-HT) is specifically accumulated by embryonic tissues in a manner analogous to the molecule's sequestration by the 5-HT transporter (SERT) at adult synapses. Notably, 5-HT transport antagonists block embryonic 5-HT accumulation and lead to craniofacial and heart abnormalities. These results suggest that transport per se may regulate a morphogenetic action of 5-HT in the embryo. A basic prerequisite to understanding the mechanism of this action is to describe the appearance and sequence of features that lead to morphogenetic changes. We have used immunohistochemistry in concert with *in situ* hybridization to document both SERT protein and gene expression in early mouse development. A fusion-protein antibody (CT-2) directed against the carboxy-terminus of SERT and ^{32}P -labeled synthetic RNA probes were used to correlate the location of SERT gene and protein expression with fluoxetine- and sertraline-sensitive [3H]5-HT uptake in whole embryo culture. Our results reveal a precocious and heterogeneous distribution of SERT protein and mRNA at several sites throughout the embryo including craniofacial epithelia and mesenchyme, midbrain, lung, and heart. Correlation of morphogenetic events with the spatial and temporal patterns of SERT expression will more clearly delineate the embryonic involvement of 5-HT in development and provide basic information necessary for interpretation of pharmacological and genetic disruptions of the transporter.

542.17

REGULATION OF THE PKC SUBSTRATE MARCKS IN RETROVIRUS TRANSFECTED HIPPOCAMPAL CELLS: EFFECT OF LITHIUM AND TEMPERATURE INDUCED DIFFERENTIATION. D.G. Watson^{1,3}, J.K. Malhotra¹, E.M. Eves², and R.H. Lenox^{3*}. Dept Psychiatry, University of Vermont¹, Burlington, VT; Ben May Inst., University of Chicago², Chicago, IL; and Dept Psychiatry, University of Florida³, Gainesville, FL.

Previous studies in our laboratory and others have provided evidence for a role of PKC in mediating the effects of chronic lithium in the brain (see review, Manji and Lenox, 1994). Our data have demonstrated that lithium alters the long-term regulation of a major PKC substrate, MARCKS, in both rat hippocampus (Lenox *et al.*, 1992), and in immortalized hippocampal cells in culture (Lenox *et al.*, 1993). In these current studies we have examined the effects of morphological differentiation and lithium exposure on the regulation of MARCKS in the hippocampal cell line H19-7, which was immortalized using retroviral transduction of a temperature-sensitive SV40 T antigen (Eves *et al.*, 1992). Morphological differentiation at the non-permissive temperature (39°C) in the presence of 1% FBS resulted in a significant increase in MARCKS expression as determined by Western blot analysis. However, in the presence of either the phorbol ester TPA (1µM), or lithium ion (10mM) there was a significant reduction in MARCKS expression following the shift to 39°C. Regulation of MARCKS expression in neuronal cells may be a shared molecular target in the action of lithium and the process of differentiation in the brain. (Supported by NIMH grant MH50105).

542.19

TRANSIENT EXPRESSION OF NITRIC OXIDE SYNTHASE IN DEVELOPING RAT CEREBELLUM. J. Leo¹, J.R. West², N.J. Pantazis^{1*}, 1. Anatomy, Univ. of Iowa, Iowa City, IA 52242; 2. Human Anatomy & Medical Neurobiology, Texas A&M, College Station, TX 77843

Nitric oxide (NO) may play a key role in neuronal development. Although nitric oxide synthase (NOS), the enzyme which produces NO, is present in granule cell and basket cell neurons in mature, adult rat cerebellum, the localization of NOS in developing cerebellum is less precisely known. The goal of this study was to examine NOS expression over time in developing rat cerebellum and compare to mature cerebellum.

Sprague-Dawley rats were sacrificed at various ages between PD1 and PD18, a time during which cerebellar development is occurring in the rat. NOS was detected by two methods in cerebellar sections (40 µm) taken from the vermis: 1) NADPH-diaphorase histochemical staining; 2) Immunohistochemical staining. On PD1, Purkinje cell neurons in the anterior lobe of the cerebellum contain NOS. Purkinje cells in the posterior lobe did not express NOS until PD5. Peak staining intensity for NOS occurred on PD10-11 with dense labeling of Purkinje cell soma and apical dendrites. Subsequently, NOS staining in Purkinje cells declined and was no longer detected in these cells at PD16. At the earliest time period studied, PD1, granule cells were NOS positive and retained NOS labeling into adulthood.

In conclusion, developing cerebellum has a different pattern of NOS expression compared to mature cerebellum. Purkinje cells transiently express NOS during development, but not in adulthood. There is a dichotomy of NOS expression in the developing cerebellar vermis, with the anterior lobe preceding the posterior lobe. The functional role of NO in developing cerebellum is unknown, but the possibility that this molecule may help shape cerebellar cytoarchitecture is intriguing. (Support: NIAAA Grant AA05523)

542.21

DISCRETE EXPRESSION OF THE RXRY GENE IN THE CHICKEN HINDBRAIN AND RETINA. F. HOQVER*, A. KIELLAND, and J.C. GLOVER. Institute of Physiology, University of Oslo, 0317 Blindern, Oslo, Norway.

We are interested in identifying regulatory mechanisms underlying regional patterns of neuronal differentiation in the hindbrain of the chicken embryo. The vitamin A derivative, retinoic acid (RA) has been implicated as a signaling molecule involved in patterning this region of the CNS. Retinoic acid exerts its effect by binding to a family of nuclear receptors which upon activation elicit diverse transcriptional cascades. To date six members of the RA-receptor family have been identified, RAR (α, β, γ) and RXR (α, β, γ), but their expression patterns remain poorly characterized in the CNS of the chicken embryo.

We have used non-radioactive *in situ* hybridization to localize chicken RXRY receptor transcripts in embryos. Previous studies have demonstrated RXRY transcripts in neural crest derivatives in the periphery (Rowe *et al.*, Development 111: 771). Here we report on their presence in two regions of the CNS: the hindbrain and the retina. At the earliest time point thus far examined (stage 19) we find RXRY expression along the midline of the optic tectum, in an intermittent ventrolateral cell column in the hindbrain, and in scattered cells in the central region of the retina. By stage 25, when many neuron populations have differentiated in the hindbrain, we find expression in a ventrolateral swath of cells extending from about the level of the trigeminal nerve to the isthmus region. The location of the RXRY-positive cells suggests that they are postmitotic, and that they may include but are not restricted to some of the central components of the trigeminal system. The expression pattern in the retina is similar to that observed earlier, but the RXRY-positive cells in the central retina are more numerous. Since the retina develops in a central to peripheral gradient, this suggests that RXRY expression is highest in developmentally more advanced retinal cells.

542.18

EFFECT OF NITRIC OXIDE SYNTHASE GENE KNOCKOUT OR BLOCKADE ON THE DEVELOPMENT OF RETINAL PROJECTIONS. D.O. Frost^{1*}, X.-F. Zhang¹, P.L. Huang² and M.C. Fishman². ¹Pharm. & Exp. Ther., U. of MD School of Med., Baltimore, MD 21201 and ²Cardiovascular Res. Center, Mass. General Hospital, Charlestown, MA 02129.

Nitric oxide (NO) may be part of the mechanism that determines whether immature neural connections are stabilized or eliminated during development. In developing rodents, retinofugal axons from the two eyes initially overlap in some visual nuclei, then segregate; the axons also project transiently to non-visual targets. Here we examine if elimination of nitric oxide synthase (NOS) activity during the time when transient retinal connections are normally eliminated, affects the final pattern of connections.

Using anterograde transport of HRP, we traced the retinal projections of adult C57Bl6/129 mice in which the gene for the neuronal form of NOS, the synthesizing enzyme for NO, is knocked out. We also traced retinal projections in 14-day-old hamsters that were given daily IP injections of N(ω)-nitro-L-arginine (NA; 5, 25, 50 or 100 mg/kg) from postnatal day 0 or 1 to postnatal day 14 (saline-injected hamsters were controls). NA blocks NO formation by competing with arginine for both the neuronal and endothelial forms of NOS. In adult knockout mice and 14-day-old NA-treated hamsters, retinal projections are normal with respect to their nuclei of termination. In visual centers, the segregation of projections from the two eyes also appears normal as judged by the tangential spread of the projections from each eye, their laminar distribution and the formation of discrete clusters by some crossed and uncrossed projections. We have not excluded small quantitative anomalies in the retinal projections. Thus, lack of neuronal NOS activity may not affect the partial elimination of immature retinal projections. TEMPORAL REGULATION OF CELL ADHESION MOLECULES (CAMs) DURING MYOGENESIS OF CULTURED SECONDARY MYOTUBES. V.F. Rafuse* and L.T. Landmesser. Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106

At the onset of spontaneous contractile activity *in-vivo*, secondary myoblasts align along the surfaces of primary myotubes, later fusing to form independently contracting myofibers. During this process N-cadherin and the structural forms of NCAM are temporally and spatially regulated. To determine whether similar expression patterns occurred in culture, myoblasts were harvested from St 37-38 chick pectoral muscles, plated on collagen coated coverslips, and incubated in F-10 medium. Myoblasts began to fuse by 48 hrs, formed multinucleated myotubes by 72 hrs, and began to spontaneously contract by 4-6 days. CAMs were temporally expressed on these cultured myotubes in a pattern similar to that observed *in-vivo*. Biochemical analysis showed that the 145 kD isoform of NCAM was down regulated with time while the 130 kD GPI-linked form was up-regulated, as occurs *in-vivo*. Immunohistochemistry showed that, as *in-vivo*, N-cadherin was high on myoblasts and newly formed myotubes and was then down regulated, and that overall NCAM remained high throughout myogenesis. In contrast, polysialylated NCAM was not expressed until 6-8 days when myotubes began to contract. Blockade of these contractions by high K⁺ or culturing the myotubes in low Ca⁺⁺ prevented the expression of polysialylated NCAM. The mechanisms regulating such CAM expression, including the role of electrical activity, are presently being examined.

CLONING GENES INVOLVED IN INDUCTION OF CENTRAL NEURONS BY PERIPHERAL TISSUE. T.R. Gershon* & E.R. Macagno. Dept of Biological Sciences, Columbia University, New York, NY 10027

The two midbody ganglia of the leech ventral nerve cord that normally innervate the male organs (MO), the sex ganglia, have many obvious specializations that differentiate them from other midbody ganglia. One such specialization, a unique population of several hundred small neurons, the Peripherally Induced Central (PIC) neurons, is produced by a transient increase in mitogenesis in the sex ganglia late in development. This late round of cell division occurs only after efferents from the sex ganglia contact the MO, and can be prevented from occurring in an individual sex ganglion by disrupting its neural connections with the MO. We have previously determined that an inductive signal travels independently to each of the sex ganglia from the MO in retrograde fashion via efferent fibers. In an effort to understand the molecular mechanisms by which this signalling occurs, we are screening for genes expressed differentially in the sex ganglia as opposed to other midbody ganglia, as well as genes that are expressed in the sex ganglia only if the MO is innervated.

To identify differentially expressed genes, we have developed a PCR technique for amplifying cDNA from pools of a few ganglia that incorporates innovations from Belyavsky *et al.* and Korneev *et al.* that maximize amplification while minimizing artifactual noise. From the amplified cDNA, we have constructed tissue- and state-specific libraries that we are screening for differentially-represented clones. Identified clones will then be selected for further study by *in situ* hybridization on embryonic wholemounts. The resulting expression patterns, considered in light of our observations on the cellular processes of induction, will provide information critical to a molecular analysis of the mechanisms by which the MO induces the specialization of the sex ganglia.

REGULATION OF NEURONAL GENE EXPRESSION BY TARGET INTERACTIONS IN VIVO. L.R. Wolszon* and E.R. Macagno, Dept. of Biological Sciences, Columbia University, New York, NY 10027.

Developing neurons and their synaptic partners exchange information that can affect their subsequent expression of particular genes. For neurons that can innervate either of two very different targets, their resultant patterns of gene expression may be significantly different from each other. We are studying this interactive process in the Retzius (Rz) cell, an identified neuron that is found as a pair in each segmental ganglion of the leech nerve cord and innervates one of two targets, either body wall or the sex organs. The Rz neurons that innervate the sex organs in body segments 5 and 6 have different morphology, physiology and function than their homologues in other body segments, but will attain the same characteristics if the sex organs are ablated early in embryogenesis. Comparing the patterns of gene expression between Rz neurons with different targets should allow us to find the genes that account for the two Rz neuronal phenotypes. To this end, we have amplified mRNA from individual adult Rz neurons in sex and non-sex segments, made cDNA from these mRNAs, and then used a differential display technique to compare expression profiles. We have thus far identified in these profiles a population of genes that are expressed exclusively in either sex- or non-sex Rz cells, and are in the process of obtaining information about their sequences and developmental patterns of expression in the nervous system. This information will help us to understand how neuronal fate is determined by early interactions with potential synaptic partners.

Nova-2: A New Neuron-Specific RNA-Binding Protein Associated With Paraneoplastic Opsoclonus-Myoclonus-Ataxia. Yolanda YL Yang, Ronald J Buckanovich, Robert B Darnell*, Laboratory of Molecular Neuro-Oncology, Rockefeller University, New York, NY 10021 USA.

The Nova proteins were originally identified as target antigens in the neurodegenerative disorder paraneoplastic opsoclonus-myoclonus-ataxia (POMA). Analysis of the first cloned family member, Nova-1, revealed that it was a neuron-specific RNA-binding protein with developmentally regulated expression. Using antiserum from a patient with POMA, we have now cloned a second Nova family member, Nova-2.

Nova-2 shares extensive amino acid sequence homology with Nova-1. Both have homology with the KH RNA-binding domains (RBD's) found in FMR-1 (the familial mental retardation gene), hnRNP-K, and the yeast splicing factor MER-1. Comparison of Nova-2 to Nova-1 reveals 100% amino acid identity in the three RBD's, indicating a possible shared RNA target. Between RBD2 and RBD3, Nova-2 contains a unique domain with several stretches of alanines and glycines and one purine-rich region, suggesting that functional differences between Nova family members may map to this region.

In situ hybridization (ISH) and mRNA analysis indicate that Nova-2 expression is limited to neurons in discrete regions of the developing and adult mouse nervous system, but with a different pattern of expression than Nova-1. We are further defining the expression of Nova-2 by Northern, RT-PCR, and ISH to distinguish between the Nova family members. In summary, we expect that the Nova family of RNA-binding proteins regulates neuronal development and function through their action on RNA metabolism, by such means as alternative splicing, stability, or translational regulation.

ROLE OF AP-1 PROTEINS IN TRANSCRIPTIONAL CROSS-TALK AT SOMATOSTATIN CYCLIC AMP RESPONSE ELEMENT (CRE). C.L. Szymczek-Seay* and D.E. Millhorn. The University of North Carolina at Chapel Hill, Chapel Hill, NC 27599 and The University of Cincinnati, Cincinnati, OH 45267.

The mechanism by which specific gene regulation, such as developmental and tissue-specific regulation, occurs is largely unknown. Given the ubiquitous nature of transcription factors and the large number of genes containing regulatory DNA binding consensus elements, how subsets of genes are transcribed in particular cells at certain stages of development remains an open question. The finding that cross-talk occurs among the bZIP protein families, the Fos/Jun family and the CREB family, at the TRE (12-O-tetradecanoylphorbol-13-acetate response element) and CRE provides a possible mechanism for the specificity of developmental- and tissue-specific gene regulatory events. Our finding that Jun is involved in complexes of cerebellar and diencephalic nuclear protein extracts which bind to the CRE led us to speculate that Jun levels and/or transcriptional activity could mediate CRE-driven transcriptional responses, especially CRE responses which are temporospatially regulated. We tested this hypothesis by phorbol-12-myristate-13-acetate (PMA) and/or forskolin treatment of pheochromocytoma (PC12) cells transfected with the CRE-driven promoter of the somatostatin gene, which is known to be developmentally and tissue-specifically regulated. PMA (50 nM) increased transcription of the somatostatin promoter, presumably through the CRE, as did 25 μ M forskolin. Treatment with both agents resulted in synergistic stimulation of transcription. In addition, gel shift studies showed that treatment of PC12 cells with PMA and forskolin increased binding of nuclear proteins from these cells to the CRE. These data suggest that the ratio of transcription elements, such as Fos/Jun and CREB, which are capable of interaction at each other's cognate DNA sequence, is crucial to determining the specificity of transcriptional events.

CEREBRAL CORTEX AND LIMBIC SYSTEM II

543.1

CONNECTIVITY OF FETAL LIMBIC CORTEX TRANSPLANTED INTO NON-LIMBIC CORTEX AFTER LONG TERM SURVIVAL OF HOSTS. M.F. Barbe*, Physical Therapy Dept, Temple Univ, Philadelphia, PA, 19140.

Previous studies using a molecular marker of limbic phenotype as well as Dil tracing techniques, in combination with brain tissue transplantation, have examined the developmental specification of regional cortical differentiation. The present study was undertaken to determine if connection phenotypes observed in earlier short term survival studies were maintained after long term survival of hosts receiving grafts. Limbic perirhinal (prh) or sensorimotor (Sm) fetal tissue from rats aged embryonic (E) 12-14 was transplanted into neonatal rat Sm cortex. Animals were sacrificed 65 days later and Dil crystals were inserted into the graft. After a 12-14 week incubation period, the location of Dil-labeled neurons and axons were mapped in cortex and thalamus. Homotopic Sm transplants had no limbic thalamic or contralateral cortical connections, and only 1 of 7 had a connection with limbic ipsilateral anterior cingulate cortex (ACg). Most E14 prh grafts in host Sm region had hybrid connections: out of 12 total animals analyzed in this group, 11 had both limbic and sensorimotor connections when one considers contralateral and ipsilateral cortices as well as the thalamus, 9 had hybrid ipsilateral cortical connections, while 7 had hybrid thalamic connections (ventral posterior and lateral dorsal nuclei), the remaining having either just limbic or sensorimotor connections only. None of the E13 or E12 prh into Sm cortex grafts had any connections with limbic thalamic nuclei or limbic contralateral cortices, 2 were connected to ipsilateral ACg. The data suggest that projection pattern phenotypes are subject to complex environmental influences. Supported by NSF grant 9209459.

543.2

REGION SPECIFIC CHANGES IN PARVALBUMIN EXPRESSION IN RABBIT NEOCORTEX FOLLOWING PRENATAL COCAINE EXPOSURE. X.H. WANG*, A. FINLEY and E.H. MURPHY, Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

We previously reported that the number of GABA-immunoreactive (ir) neurons was increased in the anterior cingulate cortex (ACC), but not in the primary visual cortex (VC), in the rabbits prenatally exposed to cocaine (Wang and Murphy, Soc. Neurosci. Abst. 1993, 19:50). In the present study, we investigated the development of the subgroup of GABAergic neurons which are immunoreactive for the calcium binding protein parvalbumin. Since the major effect of cocaine is believed to be on the uptake of dopamine, we compared an area of cortex rich in dopaminergic input (ACC) with an area lacking dopaminergic input (VC) following prenatal cocaine exposure. Pregnant rabbits received intravenous injections of cocaine (4mg/kg, twice daily) from day 8 to day 29 of gestation. The same volume of saline was injected in control animals. The brains of rabbit pups were examined at P10, P20 and P60. Immunocytochemical methods were used to visualize parvalbumin-expressing neurons. Quantitative analysis revealed a significant increase in the number of secondary and tertiary dendrites per neuron which were parvalbumin-ir in ACC in cocaine exposed brains in all age groups examined compared to controls. In VC, however, there is no difference between cocaine and saline animals in the number of secondary and tertiary dendrites per neuron which were parvalbumin-ir. In both ACC and VC, there were no significant difference between cocaine and saline in the number of primary dendrites per neuron which were parvalbumin-ir nor in the number of parvalbumin-ir neurons. Expression of parvalbumin in dendrites is characteristic of immature neurons, and has been associated with kindling and epileptic activity. Our data suggest that the increased distribution of parvalbumin in ACC in cocaine-exposed animals may reflect a disturbance in the normal balance of excitation and inhibition in this dopamine rich neocortical area. Supported by NIDA-DA06871.

543.3

NEONATAL TREATMENT WITH 192 IgG-SAPORIN PRODUCES DEFICITS IN FOREBRAIN CHOLINERGIC SYSTEMS. R.T. Robertson*, B.P. Yu, G.H. Kageyama, K.I. Claytor, J.C. Lauterborn, C.M. Gall and R.G. Wiley, Department of Anatomy and Neurobiology, Univ. California, Irvine, CA 92717, and Laboratory of Experimental Neurology, DVAMC, Nashville, TN 37212.

Previous work demonstrated that an immunotoxin, consisting of the 192 IgG antibody to the low affinity NGF receptor coupled to the ribosome inactivating protein saporin, destroys basal forebrain cholinergic neurons in adults (Wiley et al., *Brain Res.*, 562, 1991). The present studies examined the specificity of this toxin when administered to neonatal animals. Injections of 100-200 ng of 192 IgG-saporin were made intraventricularly in postnatal day 0 (P0) to P2 Sprague-Dawley rat pups. Following survival periods of 3 days to 6 months, animals were sacrificed and forebrains processed for histochemistry, immunocytochemistry, and *in situ* hybridization. AChE histochemical and ChAT immunocytochemical studies indicate that early treatment with 192 IgG-saporin results in long term reduction in number of basal forebrain cholinergic neurons and marked reductions in their axonal projections to cerebral cortex. Cholinergic neurons of the striatum also show a decrease in numbers. *In situ* hybridization studies reveal a decrease in ChAT mRNA positive neurons in basal forebrain and striatum, but no apparent decrease in GAD mRNA positive neurons in basal forebrain. Cortical lamination, subplate neurons, and AChE-positive, but non-cholinergic, neurons of dorsal thalamus, appear not to be affected by the toxin. These data indicate that 192 IgG-saporin has a selective effect on forebrain cholinergic neurons and results in a marked cholinergic deafferentation of developing cerebral cortex. Supported by NIH grant NS 30109 and the Department of Veterans Affairs.

543.5

EARLY PRESENCE OF GAD-CONTAINING INTERNEURONS IN THE DEVELOPING GRANULE CELL LAYER OF THE RAT DENTATE GYRUS. S.T. Dupuy*, B.A. Havens and C.R. Houser, Dept. of Anatomy and Cell Biology, UCLA, Los Angeles, CA 90024.

Postnatal (PN) development studies of GAD67 mRNA-containing neurons within the rat hippocampal formation using non-radioactive *in situ* hybridization methods have revealed a prominent population of GAD67 mRNA-labeled neurons in the dentate gyrus at early ages (PND-PN5). These neurons were highly concentrated both within and slightly above the outer border of the developing granule cell layer, creating a labeling pattern different from that of the adult. In order to determine whether the GAD67 mRNA-labeled neurons were GAD-containing interneurons or granule cells transiently expressing GAD67 mRNA, immunohistochemistry for GAD67 and birthdating studies were performed. At these early PN ages, GAD67 protein was evident in neurons occupying similar positions to the GAD67 mRNA-labeled cells, and the morphology of these neurons suggested that they were not granule cells. Birthdating studies of neurons labeled with bromodeoxyuridine at E14, the birthdate of many GABA neurons in the dentate gyrus, revealed labeled neurons in positions corresponding closely to those of the GAD67 mRNA and protein-containing neurons at the early PN ages. This suggests that the neurons with early birthdates arrive in the granule cell layer at early ages and are GAD67-containing interneurons. Double labeling studies are being conducted to confirm this. These GAD-containing interneurons, due to their position and early appearance, could play a key role in the cytoarchitectural development of the dentate gyrus.

SURVIVAL AND TRANSMITTER SYNTHESIS IN RAT SEPTAL NEURONS FOLLOWING EXCITOTOXIC HIPPOCAMPAL LESION IN EARLY POSTNATAL DEVELOPMENT

M. Plaschke, E.M. Kasper*, T. Naumann and M. Frotscher

Institute of Anatomy, University of Freiburg, P. O. Box 111, 79001 Freiburg, Germany

Target cells are thought to regulate the survival and transmitter expression of basal forebrain cholinergic neurons by supplying neurotrophic factors (Thoenen and Barde, 1980, *Physiol. Rev.* 60: 1284-1335).

It has been shown in adult rats that septohippocampal cholinergic neurons survived after excitotoxic ablation of their target region and retained their immunoreactivity for the transmitter-synthesizing enzyme choline acetyltransferase (ChAT; see Sofroniew et al., 1990, *Science* 247: 338-342).

To investigate whether the hippocampus is essential for survival and transmitter expression of developing septohippocampal neurons we have destroyed the hippocampus by unilateral injections of the excitotoxic amino acid NMDA in 5 and 10 day old rats. Three or ten weeks postoperatively, serial sections of the septal region were immunostained using antibodies against ChAT or the calcium-binding protein parvalbumin (PARV). The latter antibody was used to stain GABAergic neurons (Freund, 1989, *Brain Res.* 478: 375-381).

We have found that a large number of septal neurons retained their immunoreactivity for ChAT and PARV, respectively, at both survival times despite the early loss of their target region.

We conclude from our experiments that the target region has only a limited influence on survival and transmitter expression of developing septohippocampal neurons.

ENTORHINAL-HIPPOCAMPAL CONNECTIONS ESTABLISHED EARLY IN HUMAN FETAL DEVELOPMENT. R. F. Hevner* and H. C. Kinney, Dept. of Pathol., Harvard Med. Sch., Brigham & Women's Hosp., Boston, MA 02115.

Previous studies have shown that the entorhinal cortex (EC), a transitional area of "periallocortex," matures histologically and neurochemically earlier than neocortical areas. To determine if connections between the EC and hippocampus (HC) also develop early (by mid-gestation), we injected the lipophilic tracer diI into the EC and HC of paraformaldehyde-fixed human fetal brains at 17-20 weeks post-conceptional age (CA) ($n = 9$). After 8-40 weeks diffusion, sections were cut on the freezing sliding microtome, counterstained with DAPI, and examined by fluorescence microscopy. Injections into the EC labeled the following: (1) radial glial fibers extending to the temporal horn of the lateral ventricle; (2) heavy anterograde projections to the HC, mainly to stratum radiatum of CA1, but also to dentate gyrus, CA3, subiculum, and presubiculum; (3) retrograde projections to pyramidal neurons in CA1 and subiculum; and (4) retrograde projections to a few neurons in temporal neocortex. Injections into CA1-CA3 labeled neurons in EC layers 2-3 retrogradely, and projections to superficial and deep EC layers anterogradely. Injections into superficial parietal and occipital neocortex labeled radial glial fibers and Cajal-Retzius cells only. Injections of the optic nerve and tract labeled the lateral geniculate nucleus (LGN) specifically; evidence of eye-specific laminar segregation of projections to the LGN was seen with the optic nerve injections. The above findings demonstrate that cortico-cortical connections between EC and HC develop in the first half of human gestation, well before those in other areas, e.g. visual cortex.

To illustrate the potential of this method for studying HC/EC malformations, we injected diI into the medial temporal cortex (presumptive EC) of a 16 wks CA thanatophoric dwarf (in which HC and EC develop abnormally). Labeling of radial glial fibers and a few Cajal-Retzius cells, appropriate for neocortex at that CA, was observed; EC-appropriate connections were absent.

543.6

B-HYDROXYBUTYRATE FUELS SYNAPTIC FUNCTION DURING DEVELOPMENT: HISTOLOGICAL AND PHYSIOLOGICAL EVIDENCE IN RAT HIPPOCAMPAL SLICES Y. Izumi*, AM Benz, CF Zorumski & JW Olney, Dept of Psychiatry, Washington Univ. Medical Sch., St. Louis MO 63110.

In non-precocial species, including rats and humans, β -hydroxybutyrate (β HB), a ketone body, is thought to be able to substitute for glucose as an energy substrate during the suckling period. Although the relatively excellent prognosis of primary ketotic hypoglycemia suggests that ketone bodies may be able to support vital brain functions, there is no direct experimental evidence at a cellular level establishing that ketone bodies can substitute for glucose to maintain bioelectric functions of the neuron or protect the neuron against degeneration under hypoglycemic conditions. To explore this issue, we have directly applied β HB to glucose-deprived hippocampal slices from rats at various ages (PND15, 30, 120) and determined its ability to preserve synaptic function and morphological integrity in the absence of glucose.

Glucose deprivation lasting 1 hour abolished excitatory postsynaptic potentials (EPSPs) in the CA1 dendritic region. Subsequent perfusion of the slice with 10 mM β HB for 30 min restored EPSPs at PND 15 but not at PND 30 or 120. Glucose deprivation for 3 hours induced distinctive pathomorphological changes which were prevented at PND 15 and 30 and partially at PND 120 by administration of 10 mM D- β HB throughout the period of glucose deprivation. L- β HB was ineffective at all ages in preserving morphological integrity. These observations suggest that D- β HB may act at the cellular level in the mammalian CNS during hypoglycemia to maintain brain function, including bioelectric activity, and to preserve morphological integrity. These neuroprotective actions of β HB may be more effective in the immature than mature CNS. Supported by the Diabetes Research and Training Center (YT), MH 45493 (CFZ) and RSA MH 38894 (JWO).

ANALYSIS OF THE DISTRIBUTIONS OF DMAPS 45 AND 55 DURING NEURONAL DIFFERENTIATION. S.L. Rogers¹, S. Srinivasan³, J.A. Kleim², C.Q. Doe^{1*}, W.T. Greenough^{1,2} and T.L. Karr^{1,3}. Depts. of Cell & Struct. Biol¹, Psych², Biochem³, and Beckman Inst. Univ. of Illinois, Urbana, IL 61801.

DMAPs 45 and 55 were originally identified as 45 and 55 kD proteins that co-sedimented with microtubules purified from *Drosophila* embryos (Srinivasan et al, SN Abstr., 1993). DMAP45 is present in the cortical cytoplasm of all cell-types throughout early embryonic development and also accumulates in the developing nervous system to levels above those seen for surrounding tissues. DMAP55 has a cytoplasmic distribution similar to tubulin and is associated with mitotic spindles.

These proteins have also been examined in several neoplastic cell lines. In undifferentiated N1E-115 neuroblastoma cells, DMAP45 is present in an actin-rich girdle of lamellipodia and microspikes protruding from the cell membrane, but is absent from the cytoplasm. Upon differentiation with DMSO, the protein is enriched in the distal tips of advancing growth cones and in microspikes protruding from the neurite shaft. In the fibroblastic NIH-3T3 cells line, DMAP-45 stains the endoplasmic reticulum.

DMAP55 is present along the lengths of the N1E neurite shafts in differentiated cells, and co-localizes with cytoplasmic microtubules in both undifferentiated N1Es and 3T3 cells.

POSTNATAL DEVELOPMENTAL EXPRESSION OF A NOVEL MICROTUBULE-ASSOCIATED PROTEIN IN THE RAT HIPPOCAMPUS. M.K. Johnson, T.A. Comery, A.K. Johnson*, T.L. Karr and W.T. Greenough.

Depts. of Psych., Biochem., Cell and Struct. Bio., Neurosc. Prog., and Beckman Inst., Univ. Illinois, Urbana, IL 61801 and Depts. of Psych. and Pharmacol., Univ. Iowa, Iowa City, IA 52242.

A set of novel microtubule-associated proteins (termed DMAPs [previously termed FLAT-MAPs]) have been identified in *Drosophila* and are present in the purified microtubule protein fraction of the rat brain. Developmental regulation of DMAPs has been observed in the rat cerebral cortex and cerebellum (Comery et al., *Soc. Neur. Abst.*, 1993). The late developing nature of the dentate gyrus and the stereotyped pattern of connectivity within the hippocampal formation provide an ideal system to investigate the potential involvement of these proteins in process extension, differentiation and synapse formation. Expression of DMAP45R in somata and dendrites of the pyramidal cells of the CA regions and the granule cells of the dentate gyrus correlates with process extension and cell differentiation. Expression of DMAP45R in the CA3 pyramidal cells correlates with the innervation of these cells by mossy fibers from the dentate gyrus. DMAP45R is also expressed in the inhibitory interneurons of the hilus and CA3 region with peak expression occurring at P59. DMAP55 immunoreactivity in axons correlates with the development of the mossy fiber projection from the granule cells of the dentate gyrus to CA3. The level of expression of DMAP55R increases during the growth of the mossy fiber system, reaching a peak level at P20, following which the level of expression gradually declines. Similar patterns of immunoreactivity during the development of other fiber systems suggests a possible role for DMAP55R in axonal extension. Supported by NIMH 35321 and R01 GM47962-01.

543.11

EXPRESSION OF A NOVEL MICROTUBULE PROTEIN IN RAT VISUAL CORTEX IS MODULATED BY VISUAL EXPERIENCE. D. Werner, N. Hawrylak, T.A. Comery, T.L. Karr*, W.T. Greenough Depts of Biol., Psych. and Biochem., Neuro. Prog., Beckman Inst., U. of Illinois, Urbana IL 61801

The possible role of cytoskeletal elements in experience-dependent plasticity was investigated. The antibody DMAP-45 raised against a novel microtubule-associated protein isolated from *Drosophila* cross reacts with a developmentally regulated antigen (DMAP45R) in rat brain (Comery et al. *Soc. Neuro. Abst.*, 1993). We examined the immunoreactivity of DMAP45R in layer 5 in the visual cortex of monocularly deprived rats.

One eye of rat pups was sutured closed at P12. A nonsutured control group was used for comparisons. Coronal sections of the visual cortex were stained with DMAP-45. Pyramidal cells were classified on the basis of immunoprecipitate in the soma and associated dendrites (soma/dendrite-positive cell) or in the soma only (soma-positive cell). The number of these two types of cells per unit area (NA) was determined in the visual cortical regions Oc1M (monocular) and Oc1B (binocular) contralateral to the deprived eye.

Deprivation until day 80 resulted in a reduction of DMAP-45 soma/dendrite-positive cells in Oc1M. Removing the sutures at day 75, and allowing 5 days of exposure to light, restored the staining to control levels in the soma/dendrite-positive cells in Oc1M. The density of soma-positive cells was not changed in Oc1M in either condition. No differences were observed in the densities of either soma/dendrite-positive or soma-positive cells in the binocular region. The modulation of DMAP45R by visual experience suggests that MAPs may play a role in experience-dependent structural plasticity. Supported by NIMH 40631, NSF BNS88 21219, GM47962-01.

BRAIN MICRO-EEG FREQUENCY OSCILLATIONS. C.C. Turbes* Creighton University School of Medicine, Division of Anatomy, Omaha, NE 68178

In these studies recordings macro and micro electrode recordings from the cat brain, micro-EEG, are considered. Combinations of ion currents give rise to complex patterns of neuronal electrical activity in the brain cell microenvironment, the extracellular space. The flow of ions through populations of ion channels in the neuronal plasma membrane and give rise to transmembrane ion currents. It is the sum of various currents flowing at any point in time that determines the neurons membrane potential. The multiple ion channels with their diverse and interacting regulatory mechanisms allow the neuron to modulate its electrical properties in complex ways of high frequency oscillations and electrical fields.

Some of the cortical and hippocampal neurons have ionic conductances organized to endow them with auto rhythmicity. In many neurons the kinetics of these ionic voltage dependent conductances are such that the cells may respond preferentially to inputs at a certain frequency or frequencies acting as a resonators.

There are interactive processes between the components of the dorsal hippocampus micro-EEG and the evoked potentials off the cortical-EEG and the micro-EEG.

These findings reflect the interaction between the dorsal hippocampus and cerebral cortical regions in the processes of ordering, sequencing the succession patterned sensory information as it relates to memory and conscious states.

543.10

ENHANCED EXPRESSION OF A NOVEL MICROTUBULE-ASSOCIATED PROTEIN IN THE DENERVATED DENTATE GYRUS FOLLOWING ENTORHINAL CORTEX LESIONS. K.E. Armstrong*, T.A. Comery, T.A. Jones, K.E. Bates, T.L. Karr and W.T. Greenough. Depts. of Psych., Biochem., Cell and Struct. Bio., Neurosc. Prog., and Beckman Inst., Univ. Illinois, Urbana, IL 61801.

Current work suggests that the DMAP proteins may play a role in process outgrowth and cell differentiation during development and in experience dependent structural plasticity in the visual cortex (Johnson et al., and Werner et al., *Soc. Neur. Abst.*, 1994). In the present studies, the expression of a novel microtubule-associated proteins (DMAP45R) was investigated using a well characterized model of post-lesion reorganization in the hippocampus (Steward, Cotman & Lynch, 1974). Unilateral lesions of the entorhinal cortex result in denervation of the ipsilateral dentate gyrus, granule cell dendritic reorganization and perforant path afferent reorganization. Following denervation, DMAP45R expression in the granule cell somata and dendrites increases both in the level of expression as well as the apparent number of cells and processes being labelled. Changes in DMAP45R expression appear greatest in the outer two-thirds of the molecular layer of the ipsilateral dentate gyrus, which is consistent with documented patterns of axon loss, dendritic reorganization and reactive synaptogenesis.

543.12

3D ANALYSIS OF THE ORGANIZATION OF NEURONS AND DENDRITIC BUNDLES IN CEREBRAL CORTEX OF THE RAT T.Skoglund*, R.Pascher, C.H.Berthold, T.Jansson, C.Malmeström Department of Anatomy and Cell Biology and MEDNET laboratory, University of Göteborg, Medicinaregatan 3, S-413 90 Göteborg, SWEDEN.

Light microscopical images of consecutive semithin (0.7 µm) serial sections of rat cerebral cortex (par 1,2) were digitized into an image analysis system (Teragon) via a CCD-camera attached to a microscope. The CCD-camera was connected to a video-mixer which made it possible to prealign the image to the previous one.

Sequences comprising hundreds of images were then automatically realigned by AUTOCENT, a program we have developed, that is based on a succession of pair-wise image thresholding and binary comparison.

A data base was then built up manually in the image-system using the center coordinates of neurons. The apical dendrites located in dendritic bundles were followed to their soma and also followed towards layer I. The data was transferred to a 3-D work-station (MEGATEK) which generated a transformable representation on scale of the defined space and its objects. A stereotyped shape and a color was given to objects of the same class. The dendrites were visualized as wires and were shown together with the neurons in the cortical prism. Our interconnection of the two systems allowed bidirectional on-line transfer of data. In this way, objects in the reconstruction could be identified in the image-handler and vice versa, rearranged, renamed, reshaped, deleted and new ones added. Parameters as cell density and lamellar organization were computed.

This work is supported by Medical Faculty in Göteborg, by the Swedish MRC proj. no. 3157, by Lundbergs Foundation and Anna Ahrenbergs Foundation.

POSTNATAL NEUROGENESIS IN THE DEVELOPING RETINA OF THE BRAZILIAN OPOSSUM. E. Stone^{1,2}, C. Jensen¹, L. Iqbal³, L. Elmquist⁴, C.D. Jacobson^{2,3} and D.S. Sakaguchi^{1,2}. ¹Dept. of Zool. and Genetics, Signal Transduction Training Group, ²Neuroscience Program and ³Dept. of Veterinary Anatomy, Iowa State Univ. Ames, IA 50011, ⁴Dept. of Neurology, Harvard Medical School, Boston, MA 02115.

We are investigating cellular genesis in the retina of the Brazilian opossum, *Monodelphis domestica*, using bromodeoxyuridine (BrdU) labeling of newly generated cells. Typical of marsupials, morphogenesis and neurogenesis in the opossum extends well into the postnatal period. Cell genesis in the retina begins centrally and proceeds towards the periphery. Despite extensive overlap in the time of postnatal neurogenesis, ganglion cells are produced slightly earlier than other retinal cells. To correlate neurogenesis with cellular differentiation, we have used immunohistochemical procedures to characterize the developmental patterns of neurofilament protein (NF), vimentin (VIM), and glial fibrillary acidic protein (GFAP) in the retina. NF-like immunoreactivity (IR), associated with the axons of the retinal ganglion cells, was especially prominent in the central retina in the developing optic fiber layer (OFL) and optic nerve (ON). VIM-IR was present throughout the early postnatal period (postnatal (PN) 1-25). VIM-IR was observed in two distinct structures, in radially oriented processes extending through the entire width of the inner retina and cellular processes situated in the OFL and ON. It is likely that the majority of the radially oriented structures represent Muller cells, however, in the developing retina it is difficult to distinguish Muller cells from the radially oriented neuroepithelial cells. In contrast, GFAP-IR increased with age and was not observed until PN11 along the inner retina and in the ON. Taken together, these results reveal that a great deal of neurogenesis and differentiation occurs postnatally during the development of the visual system in *Monodelphis*.

DETERMINANTS OF RETINAL SPECIALIZATIONS: A NEW APPROACH USING FINITE ELEMENT ANALYSIS. Alan D. Springer* and Haagen Diener. Department of Cell Biology and Anatomy, New York Medical College, Valhalla, New York 10595.

Neither differential cell death nor differential retinal ganglion cell histogenesis adequately account for the progressive increase in the central/peripheral (C/P) retinal ganglion cell (RGC) density ratio during the course of ocular development in the cat. Differential retinal stretch remains the only mechanism that could account for the final RGC topography. However, this hypothesis cannot be tested directly. This model assumes that the central retina stretches less than does the peripheral retina. Differential stretch of the RGC layer could occur if central retina were thicker than peripheral retina. Measurements made in E35 cat retina indicate that the RGC layer of central retina is 2.5 times thicker than that of peripheral retina. The thick spot is located about 0.8mm from the optic disc. This thickness difference is unrelated to differences in the size or density of RGCs in central vs. peripheral retina. By E62 the C/P ratio becomes 18.3:1 and the distance between the optic disc and the area centralis is about 2.5mm (Lia et. al., '87).

The shape of the E35 cat RGC layer, from the optic disc to the retinal margin, was digitized. The RGC layer was modeled as having uniform material properties. A finite element analysis model was used to stretch the E35 RGC layer from 2 to 10mm in length. The model allowed making measurements of RGC density, as well as distance of the area centralis from the optic disc, over the entire duration of the stretching process. In a retina stretched from 2 mm to 8 mm in length, the obtained C/P ratio was 19.3 and the optic disc to area centralis distance was 2.5 mm. These values are very similar to the *in vivo* results reported by Lia et. al. ('87). Therefore, the adult RGC layer topography can be predicted accurately by the non-uniform geometry of the RGC layer and by retinal stretch.

INSULIN-LIKE GROWTH FACTOR-I (IGF-I) STIMULATES PROLIFERATION OF NEURONAL PROGENITORS IN THE ADULT GOLDFISH RETINA *IN VITRO*. S.E.M. Boucher* and P.F. Hitchcock. The University of Michigan, Dept. of Ophthalmology, Anatomy and Cell Biology, and Neuroscience Program, Ann Arbor, MI.

The retina of the goldfish grows throughout the life of the animal and regenerates when injured. We developed an organ culture system to test peptide growth factors for their ability to modulate the proliferation of neuronal progenitors in both normal and injured/regenerating retinas. Normal eyes were enucleated and the anterior structures removed. Eyecups were incubated for three days in Media 199, with or without a peptide growth factor. Cultures were pulsed overnight with bromodeoxyuridine (BUDr) before incubation was halted. Eyecups were fixed, frozen, sectioned and processed for BUDr immunocytochemistry. The number of BUDr-labeled pluripotent neuronal progenitors (in the circumferential marginal zone) and rod precursors (in the outer nuclear layer) were counted and averaged. For retinas incubated in media alone, the average number of BUDr-labeled neuronal progenitors ranged from 5 to 15, and BUDr-labeled rod precursors ranged from 1 to 8. For retinas incubated in IGF-I at concentrations of 20, 100, and 200 ng/ml, the average number of BUDr-labeled neuronal progenitors were 56, 113, and 154, respectively. In contrast, there was no significant increase in the number of BUDr-labeled rod precursors. Insulin gave a qualitatively similar result, but only at higher concentrations. Neither fibroblast growth factor nor epidermal growth factor stimulated proliferation of neuronal progenitors or rod precursors. These data suggest that: 1) IGF-I receptors are expressed by pluripotent neuronal progenitors, but not rod precursors, 2) IGF-I is likely to be synthesized in the retina, and 3) IGF-I may play a role in regulating cell proliferation in both the developing and regenerating retina. Supported by NIH (NEI) grants EY07060 and EY07003 (CORE).

544.2

SPATIAL AND TEMPORAL DISTRIBUTION OF SYNAPSE ASSOCIATED PROTEINS IN THE DEVELOPING RETINA OF *MONODELPHIS DOMESTICA*. D.S. Sakaguchi^{1,2}, J.J. Swanson^{2,3}, and C.D. Jacobson^{2,3}. ¹Dept. of Zool. and Genetics, Signal Transd. Training Group, ²Neurosci. Prog. and ³Dept. of Vet. Anatomy, Iowa State Univ., Ames, IA 50011.

In the present study, we have examined the early postnatal development of the retina in the Brazilian opossum, *Monodelphis domestica*. *Monodelphis* is a small, pouchless marsupial whose young have a protracted period of postnatal neurogenesis and differentiation. Antibodies directed against the synaptic terminal related proteins synaptotagmin (p65), Rab 3a, synaptosomal-associated protein 25 (SNAP-25) and synaptophysin (p38) were used to characterize the distribution of these proteins during the early postnatal period. At birth, postnatal day (PN) 1, the retina is relatively undifferentiated morphologically. Staining for p65 and Rab 3a was observed at PN1 primarily in the axons of retinal ganglion cells (RGCs) in the optic nerve and optic fiber layer (OFL) of the central retina. In addition, occasional presumptive RGC somata were also labeled with the Rab 3a antibody. At PN5/6 the retina is organized into two cellular layers: an inner region of postmitotic cells and an outer region of neuroepithelial, as well as, postmitotic cells. Staining for SNAP-25 and synaptophysin was first detected around PN5/6. SNAP-25 labeling was restricted primarily to the OFL in the central retina, while p38 labeling was observed in the inner portion of the retina. By PN25 the retina is well differentiated, exhibiting p65, Rab 3a, SNAP-25 and p38 reactivities localized in processes of the inner plexiform and outer plexiform layers but showing distinct patterns of distribution. While p65, Rab 3a and SNAP-25 were abundantly expressed in the RGC axons, p38 was not. From these results it is clear that these proteins exhibit developmentally regulated changes in their cellular localization. Since a great deal of the development of the retina occurs postnatally in *Monodelphis*, this species is likely to provide an excellent system for *in vivo* experimental manipulations and analysis.

OPSN GENE EXPRESSION IN ZEBRAFISH (*BRACHYDANIO RERIO*) EMBRYOS. J. Robinson, G.B. Grant* and J.E. Dowling. Cellular and Molecular Biology, Harvard University, Cambridge, MA 02138.

Adult zebrafish (*Brachydanio rerio*) retinas contain 4 types of photoreceptors: rods and three classes of cone (2 single and 1 double cone). Using light microscopy, the first class of photoreceptor to become morphologically distinct (~4 days) and mature (~7 days) is the UV-sensitive short single cone. However, some photoreceptors become post-mitotic as early as 48 hours post-fertilisation (pf). We have used whole mount *in situ* hybridisation to determine the developmental patterns of opsin gene expression in the retina of zebrafish. Zebrafish opsin cDNAs were linearised and used as templates for the production of digoxigenin (DIG)-labelled riboprobes. Whole mount *in situ* hybridisation's were performed at intervals between 18 and 96 hours post-fertilisation. Embryos were hybridised at 65°C overnight with probes generated antisense to each of the cloned zebrafish visual pigment genes (ultraviolet, blue, red and rhodopsin). Using this technique we have determined that the ultraviolet, blue and rhodopsin genes are expressed in a small ventral patch as early as 48 hours post-fertilisation, but the red pigment is only expressed in the pineal region of the brain at this age. These data are in general agreement both with an earlier morphological study (Kjavin, J Comp. Neurol. 260: 461, 1987) and with Raymond and Barthelemy (Invest Ophthalmol Vis Sci 35, 1727, 1994) who studied rhodopsin expression. Interestingly, preliminary data suggest that the UV-sensitive opsin is the first cone opsin to be expressed in the retina. We postulate that this means that the short-single cone may be the lead cone in the development of the zebrafish retina. Supported by NIH grant EY 00811 and by the Wellcome Trust

Pax 6 GENE EXPRESSION IN NORMAL AND REGENERATING RETINA OF THE GOLDFISH. P. Hitchcock*, E. R. E. Macdonald*, S. W. Wilson*, J. T. VanDeRyt*, Ophthalmology and Anatomy and Cell Biology, University of Michigan; *Dev. Biol. Res. Cntr., Kings College London.

The retina of the goldfish grows throughout the animal's life and will regenerate when injured. We investigated the expression of the transcription factor encoding gene *pax6* in normal and regenerating retina. Regeneration was induced by surgically excising a small patch of retina, which is replaced by neuronal regeneration. Rod precursors, which normally make rod photoreceptors only, are the presumptive source of the regenerated neurons. Retinas were exposed to bromodeoxyuridine (BUDr) to label dividing cells at various post-lesion time points. Sections were double-immunostained with antibodies against BUDr and the zebrafish *pax6* fusion protein (I. Mikola, unpublished). In normal retina the *pax6* antibodies stain: 1) nuclei of mature amacrine and some ganglion cells and 2) neuronal progenitors in the circumferential germinal zone. Rod precursors are not stained. This staining pattern is qualitatively identical to that seen in the developing zebrafish retina (Macdonald et al. 1994, Invest. Ophthalmol. Vis. Sci., 35:1404). In the injured retinas, progenitors of regenerated neurons are also stained by the *pax6* antibodies. We make the following conclusions: 1) the *pax6* antibodies recognize the same protein in both zebrafish and goldfish retinas; 2) in both normal and regenerating retina, *pax6* is expressed in pluripotent neuronal progenitors; and 3) rod precursors are normally committed to a rod cell fate and nearby injury causes them to become pluripotent. Supported by grants EY07060, EY07003 and a NSF training grant (PH) and a SERC grant (SWW).

A START AT MAPPING GENES THAT CONTROL RETINAL GANGLION CELL NUMBER: ANALYSIS OF INBRED, F1 HYBRID, AND RECOMBINANT INBRED STRAINS OF MICE. R. W. Williams*, D. S. Rice, and D. Goldowitz. Department of Anatomy and Neurobiology, University of Tennessee, Memphis, TN 38163

Genes that control neuron number play a critical role in the function and evolution of the vertebrate CNS. We have identified one, or possibly two gene loci that are responsible for normal strain variation in the number of ganglion cells in the mouse retina.

Ganglion cell axons were counted on electron micrographs of optic nerves taken from more than 140 animals belonging to 33 different inbred strains of mice, including strains 129, A, AKR, BALB/c, C3H/He, C57BL/6, C57BL/Ks, CAST/Ei, CBA, CD-1, CE, DBA/2, LP, NZB, NZW, PL, SJL, and SPRET/Ei. Cell number varies substantially among strains, from a low of 49,000 in CAST/Ei to a high of 67,000 in NZW. Errors of the mean are typically $\pm 3,400$. Strain averages are distributed bimodally, and most strains have populations that cluster close to 52,000 or 64,000. There is no correlation between cell number and body size, brain weight, or retinal area. Phenotypes of F1 offspring from crosses between high and low strains (BALB/c by C57BL/6, BALB/c by A, and PL by SJL) are consistent with a model involving two gene loci. However, we cannot yet formally rule out a model involving a single locus with three or more alleles. Ongoing analysis of recombinant inbred BXD lines of mice suggests that one of these loci controlling neuron number in the mouse retina maps to chromosome 1, 2, or 6.

ASYMMETRIC RETINAL GROWTH IN ADULT GREEN SUNFISH D.A. Cameron* and S.S. Easter. Dept. Biology, University of Michigan, Ann Arbor, MI 48109-1048.

Teleost fish retinas grow throughout life by a balloon-like expansion and by the appositional addition of neurons and glia at the retinal margin. An earlier report (Cameron & Easter, *Vis. Neurosci.* 10:375, 1993) presented the hypothesis that fish retinas with a curved, non-fused embryonic fissure grow asymmetrically along the retinal margin. We have tested this hypothesis in adult green sunfish (*Lepomis cyanellus*), which have a curved, non-fused embryonic fissure, concave towards temporal retina. The thymidine analogue BrdU was intraocularly injected into adult fish ($n = 6$) and retinal whole-mounts processed for fluorescence anti-BrdU immunohistochemistry 20-377 days later. In each retina an annulus of BrdU-positive nuclei was observed central to the retinal margin (but not along the embryonic fissure). The absolute rates of retinal growth were roughly exponential functions of fish size—small retinas tended to grow faster than large retinas. However, growth asymmetries were present: the normalized distances of the BrdU annuli to the nearest retinal margin were $1.00, 1.03 \pm 0.03, 1.27 \pm 0.03$, and 1.44 ± 0.09 , in temporal, dorsal, nasal, and ventral retina, respectively (means \pm SEM). Thus temporal and dorsal quadrants enlarged less than ventral and nasal quadrants. The normalized densities of cone photoreceptors in the same quadrants roughly matched the normalized growth distances ($1.00, 1.03 \pm 0.09, 1.19 \pm 0.05, 1.55 \pm 0.14$). Growth asymmetry was thus attributable to differential cellular addition rather than differential passive expansion.

EXPRESSION OF C-FOS AND C-JUN IN THE RETINA OF RATS FOLLOWING PROTRACTED ILLUMINATION. J. Pecci Saavedra*, G. Mallo, J. Goldstein, J.J. López Costa. Inst. of Cell Biology, Sch. of Med., U of Buenos Aires, Argentina.

Neuronal expression of the early oncogenes *c-fos* and *c-jun* has been reported following stimulation of different regions. 30/35-day-old Wistar rats were continuously illuminated with 12000 lux during 8 days, followed by different darkness periods. Illumination produces degeneration of photoreceptor outer segments. It is known that this phenomenon is reversible after an adequate period of darkness. Retinas were fixed by perfusion with a 4 % paraformaldehyde solution, in phosphate buffer, after a period of illumination followed by 1, 3, 6, 10 and 18 days of total darkness. Cryostat sections were immunocytochemically stained with antibodies to *c-fos* (Affiniti Res. Prod.) (dil. 1:1000) and *c-jun* (CRB) (dil. 1:1000), biotinylated donkey anti-sheep IgG (Sigma) and the extravidin-peroxidase complex (Sigma). *C-fos* and *c-jun* immunoreactivity was detected in the somata of photoreceptors in all retinas thus observed. It was maximum in the photoreceptor nuclei of rats kept in total darkness for 3 days, and decreased thereafter. Staining stabilization was reached at about 10-18 days. We conclude that the described increases in *c-fos* and *c-jun* products play a role in triggering the molecular events that participate in photoreceptor regeneration.

THE MARKED NASAL-TEMPORAL ASYMMETRY IN GANGLION CELL SIZE IS AN INTRINSIC PROPERTY OF CANINE RETINAS. Dale Hogan* and Robert W. Williams. Dept. Anatomy & Neurobiology, Univ. of Tennessee, 855 Monroe Ave., Memphis TN 38163

The peripheral temporal retina of adult dogs is devoid of alpha ganglion cells (Peichl, '92; Hogan and Williams '94). We are interested in determining how this unusual distribution develops. We measured the sizes of ganglion cells in whole-mounted retinas of neonatal dogs prior to eye-opening.

Like other well-studied carnivores, i.e., cats and ferrets, ganglion cells are much smaller in the neonate than in the adult. The average area of over 2,000 ganglion cells measured is $110.5 \pm 1.2 \mu\text{m}^2$ compared to $490 \mu\text{m}^2$ in adults ($n > 3,000$). The largest ganglion cells in temporal retina are $300 \mu\text{m}^2$ whereas the largest ganglion cells in nasal retina are $400 \mu\text{m}^2$. Although the very large alpha cells are found only in nasal retina, average cell size in temporal retina is substantially larger: $124.0 \pm 2.6 \mu\text{m}^2$ in temporal retina vs. $106.2 \pm 1.3 \mu\text{m}^2$ in nasal retina. Temporal retina contains a much higher percentage of cells with areas between 175 and $225 \mu\text{m}^2$: 21.0% compared to merely 6.9% in nasal retina. There are also twice as many cells with areas between 225 and $275 \mu\text{m}^2$ in temporal retina: 4.1% vs. 1.9%. Nasal cells are more common in the range from 75 to $125 \mu\text{m}^2$; 27.8% in nasal vs. 17.8% in temporal.

This substantial nasal/temporal asymmetry in the size of ganglion cells in the neonatal dog retina is unlike that of other carnivores. It is especially intriguing given the absence of alpha ganglion cells in the temporal retina of adult dogs. This raises the possibility of a unique class of large beta-like cells which may subserve some functions of the missing alpha cells.

NEUROPEPTIDE RETILINE AS A PROTECTOR OF RETINAL DYSTROPHY IN CAMPBELL RATS. M. Rasumovskij*, N. Balashov, A.R. Grigorian, A. Rasumovskaja. Institute of Occupational Guidance, Lab. of Vision Physiology, 195067, St. Petersburg, Bestugevskaya, 50, Russia.

Twenty-eight newborn male rats were injected for 40 days (daily dose 1 mg/kg b.w.) with the physiologically active substance neuropeptide-retiline isolated from bovine retina. The action of retiline was estimated by the amplitude electroretinogram (ERG) and reproduction of frequency of rhythmical flashes. The flash parameters were the following: frequency 1-34 Hz, brightness 5-10 nt. Using electroencephalography, ERGs were recorded in control and experimental animals on the 30th, 47th, and 60th days of postnatal life. Electrophysiologically it was shown that control as well as retiline-injected rats began to lose sight from the 15th day of postnatal life and by the 30th day were blind. Unlike the control animals, retiline-injected rats lost sight only on the 30th day of postnatal life. This was accompanied by a gradual reduction of ERG amplitude due to "a" wave and a decrease of reproduction frequency of rhythmical flashes. Thus, the neuropeptide retiline, chronically injected in Campbell rats at a dose of 1 mg/kg b.w., has a protective action against the development of retinal degeneration.

544.12

EXPRESSION OF D1 AND D2 DOPAMINE RECEPTORS AND DOPAMINE TRANSPORTER mRNA IN THE ADULT AND FETAL MONKEY RETINA. Q.K. Ronnekleiv*, L. Chai and W.S. Choi. Oregon Regional Primate Research Center, Beaverton, OR 97006 and Dept. of Physiology, OHSU, Portland, OR 97201-3098

Expression of D1 and D2 dopamine receptors and dopamine transporter (DAT) mRNAs were studied in the adult and fetal monkey retina by Ribonuclease Protection Assay (RPA). Eyes were dissected from adult and a 70 day old monkey fetus. Monkey specific cDNA clones corresponding to the carboxy terminus of the rhesus monkey D1 and D2 receptors and to the IX-XII transmembrane domains of monkey DAT were cloned and used to generate the cRNA probes. The standard curves were constructed using known amounts of synthesized sense RNA. In the adult monkey retina, dopamine D1 and D2 receptor mRNAs were expressed in equal quantities and at relative high levels. DAT mRNA was also expressed in the retina, but at a more moderate level. In the day 70 fetal eye, D1 and D2 receptor mRNAs and DAT mRNA were all present. The level of D1 receptor mRNA was higher than D2 receptor mRNA and D2 receptor mRNA higher than DAT receptor mRNA. Thus, several of the genes of dopaminergic neurotransmission are expressed early in the developing fetal eye of rhesus monkey. (Supported by DA07165)

IMMATURE NEURONS IN THE RABBIT RETINA ARE PROTECTED AGAINST NITRIC OXIDE MEDIATED GLUTAMATE TOXICITY. M.F. Haberecht, C.K. Mitchell and D.A. Redburn*. Dept. Neurobiology and Anatomy, Univ. Texas Med Sch., Houston, TX, 77030.

We have previously demonstrated that extracellular levels of endogenous glutamate are high in the developing rabbit retina. This amount of glutamate would be toxic in the adult retina; however, immature neurons survive and maintain normal developmental processes. We wished to determine whether NO which has been postulated to mediate glutamate toxicity in the adult CNS is present and functional in the developing and adult retina. First we used immunocytochemistry and histochemistry to localize nitrergic neurons in the adult retina and subsequently determined developmental profiles. Secondly using retinal explants we have analyzed viability of immature and adult neurons in response to NMDA and NOS agonist and antagonists. Results show that prototypic nitrergic neurons are mature early but do not express detectable levels of NOS until day 10. Furthermore immature neurons at day 1 are insensitive to glutamate toxicity, while in the adult retina dose-sensitive toxicity is induced by NMDA and inhibited more than twofold by methyl arginine. We conclude 1) glutamate toxicity in adult retina may be regulated by NO and 2) the resistance of immature neurons to glutamate toxicity may result from a delay in the maturation of the NO system. LONG-TERM EFFECTS ON RETINA OF RHESUS MONKEYS FED TAURINE-FREE HUMAN INFANT FORMULA. H. Imaki*, M.D. Neuringer and J.A. Sturman. NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; Oregon Regional Primate Research Center, Beaverton, OR.

We have been studying the effects of postnatal deprivation of taurine by feeding rhesus monkeys a commercially available human infant formula alone or supplemented with taurine from birth. Previous reports have documented reduced tissue taurine concentration and smaller proportions of bile acids conjugated with taurine in taurine-deprived monkeys at 3 months and 6 months, although at 12 months these parameters were no longer different, suggesting the biochemical dependence on dietary taurine persists for at least the first 6 months, but has regressed by 12 months. At the early ages, the taurine-deprived monkeys have deficits in visual acuity and morphological changes in the retina and visual cortex compared with monkeys fed the same diet supplemented with taurine. The retinal changes persisted at 6 and 12 months. The present study addresses the question of whether or not the retinal changes persist for a substantial period beyond the time at which there are no longer reduced tissue taurine concentrations. Rhesus monkeys raised for 4 years were examined, and although there were no differences in tissue taurine concentrations between taurine-deprived and taurine-supplemented monkeys, as might be expected from our previous results, all taurine-deprived monkeys showed retinal changes, indicating that the retinopathy of taurine deficiency persists long after the differences in taurine concentrations have disappeared.

INFLUENCES ON AXONAL REGENERATION

545.1

ELECTRIC FIELD EFFECTS ON AXONAL TRANSPORT IN THE CORTICOSPINAL TRACT FOLLOWING SPINAL CORD INJURY. J.A. McLane*, T. Cobb and T. Khan, Rehabilitation Research & Development Center, Edward Hines Jr. VA Hospital, Hines, IL 60141.

Unlike axons of peripheral nerves, injured axons of the adult spinal cord seldom undergo a functional regeneration. Recent studies have shown that a direct current field at the injury site enhances neurite outgrowth, and stimulates directed neurite growth. Spinal cord injury in adult rats temporarily increased the level of slow axonal transport to the higher level normally seen in young rats. The present study was designed to test the hypothesis that electrical stimulation increases neurite regrowth by enhancing this period of increased axonal transport following spinal cord injury.

Adult rats received a dorsal spinal cord hemisection at the T8 level. Miniature stimulators were implanted at the time of surgery with platinum disk electrodes placed extradurally proximal (anode) and distal (cathode) to the injury. The stimulators provided a constant 15 uA of DC current. Axonal transport in the corticospinal tract was labeled with ³⁵S-methionine one week, five weeks, or fourteen weeks later by injecting 200 uCi of radioisotope unilaterally into the sensorimotor cortex. One week (fast transport) or three weeks (slow transport) after the isotope injection the animals were perfused with formalin, the entire spinal cord dissected, and the radioactivity in 5 mm segments of the spinal cord determined by scintillation counting.

We found that the amount of radiolabel delivered by slow axonal transport was consistently (but not statistically) higher in the spinal cords of animals treated with electric fields. The spinal cord segment containing the injury site in the electric field treated animals did contain statistically more (154%) label relative to sham animals (no field) one week after injury. This increased label at the injury site disappeared after five or fourteen weeks. Fast transport was not altered at any time point, and therefore likely did not contribute to the increase. These data suggest that electric fields increase the slow transport of materials within the corticospinal tract, and temporarily prevent axonal die back and/or stimulate neuronal sprouting near the injury site.

EFFECTS OF ELECTRIC FIELD APPLICATION IN A MODEL OF TRANSECTED MAMMALIAN MYELINATED NERVE. K. Mosallaei, N. Vasey, and J.D. Sweeney*. Bioengineering Program, Arizona State University, Tempe, AZ 85287-6006.

In vitro and in vivo studies have shown that a steady cathode-distal low-intensity electric field (LIEF) can potentially be used to induce, accelerate and/or guide nerve regeneration. Some possible proposed mechanisms are suppression of axonal injury currents and/or facilitation of organelle movement via electrophoretic action. Our objectives have been (i) to develop a mathematical model describing a transected myelinated nerve, (ii) to simulate the effects of applied steady LIEFs at regenerating nerve tips, and (iii) to predict optimal electrode configurations and stimulus current magnitudes for applied LIEFs. The nerve model is a non-homogeneous compartmental implementation based on iterative solution of a set of coupled finite-difference equations describing intracellular electroneutrality and ionic current conservation (for Na⁺, K⁺, Ca²⁺, Cl⁻ and large anions). The applied LIEF solutions on the nerve trunk consider tissue inhomogeneity and spatial geometry as well as position of the distal and proximal nerve stumps with respect to nerve guide tube electrodes as used in actual experiments. Modeling predicts that, at the transected nerve tip, intracellular sodium and calcium concentrations are increased and the membrane is depolarized. Application of cathode-distal LIEFs tends to further depolarize the tip membrane and shift ionic concentrations along the nerve depending upon electrode positioning. Modeling also predicts that application of LIEFs has only a small effect on injury current suppression. LIEFs may enhance early regeneration by creating an intracellular potential gradient that (i) facilitates organelle electrophoresis and (ii) decreases intracellular free calcium concentrations - thus reducing the degree of axonal dieback.

NEUROMUSCULAR ACTIVITY AND SPROUTING IN RAT HINDLIMB MUSCLES. B. Jassar and T. Gordon*. Dept. Pharmacol., Div. Neurosci., U. Alberta, Edmonton, CANADA T6G 2S2.

Although it has been shown that electrical stimulation can accelerate sprouting, it is not clear whether increased neuromuscular activity during sprouting has any effect on the size of motor units (MUs) once connections are made. To address this question, we subjected rats to high levels of activity during sprouting and determined the size of enlarged MUs in partially denervated muscles (PD) once connections were well established. Rats were divided into 2 groups, exercised (E) and sedentary (S) in which rats were housed in large cages with running wheels (E) or in small cages with limited movement (S). After acclimatization and training, right hindlimb muscles were partially denervated by cutting either L5 or L4. Four weeks later, soleus, plantaris (PL), medial gastrocnemius (MG) and tibialis anterior (TA) muscles were prepared for muscle and MU recording in PD and contralateral control (CC) legs for measurement of MU number and size. In all 4 muscles, the size of the enlarged MUs in PD muscles was significantly larger than in CC but not different in the 2 groups, E and S. For an average of 50% PD in soleus muscles mean (\pm S.E.) MU twitch force (mN) was 16.9 ± 0.91 (E) vs 15.6 ± 0.82 (S) as compared to 10.71 ± 0.9 in CC muscles. For 80% PD in TA muscles, MU forces of 89 ± 11 (E) vs 80 ± 9.6 (S) compare with 21.5 ± 1.55 (CC). Since there was little hypertrophy of the active muscles, the MU force was a reasonable reflection of the number of muscle fibers per motoneuron and therefore of sprouting. These results show that high levels of neuromuscular activity do not influence the capacity of remaining motoneurons to form enlarged MUs. Supported by MDAC.

DETERIORATION OF DISTAL NERVE SHEATHS IS A MAJOR CONTRIBUTOR TO POOR MOTOR RECOVERY AFTER DELAYED NERVE REPAIR. S. Fu*, T. Gordon. Div. of Neuroscience & Dept. of Pharmacology, U. of Alberta, Edmonton, CANADA T6G 2S2.

Contribution of long-term muscle denervation to poor functional recovery after delayed nerve repair was studied using a nerve cross-suture paradigm in which duration of muscle denervation varied independently of motoneuron axotomy. Tibialis anterior (TA) muscle was denervated by cutting the common peroneal (CP) nerve. Its regeneration was prevented for 0-12 months before a freshly cut tibial (TIB) nerve was sutured either to the old CP distal stump or onto denervated TA muscle surface. Six months later the success of regeneration and reinnervation was quantified. After immediate nerve suture, muscle and motor unit (MU) recordings showed that 137 ± 21 TIB motor nerves reinnervated the TA muscle. Compared to the control, reinnervated muscles and MUs developed similar forces and muscle fibers were of similar size ($2702 \pm 47 \mu m^2$) indicating that they completely recovered from denervation atrophy. When nerve suture was delayed after prolonged denervation (> 6 months) a drastic reduction was found in the number of MUs (to 15 ± 4) and muscle fiber size (to $1171 \pm 84 \mu m^2$). When the TIB nerve was sutured directly to freshly denervated TA muscle, number of reinnervated MUs reduced to 52 ± 11 (37% of the control) suggesting that the surface of denervated muscle is a poor substrate for nerve growth. This number further reduced to only 18 ± 9 (13% of the control) in prolonged denervation (> 1 month). Thus a condition in which regenerating nerves grow outside the intramuscular nerve sheath simulates the effects of long-term denervated sheath and muscle in terms of reduced support for regenerating nerves. These findings provide strong evidence for a concept that long-term denervated sheath fails to guide regenerating nerve to denervated muscle. It is also supported by histological findings that regenerating nerve escapes from the sheath and grows on denervated muscle surface in delayed nerve repair (Gutmann & Young 1944 J Anat 78:15-44). [Funded by Canadian MRC and MDAC].

545.5

AXONAL REGENERATION IN THE SPINAL CORD FOLLOWING TREATMENT WITH DC ELECTRICAL FIELDS. M.F. Zanakos*, R. Cebelenski, C. Cook, S. Gelman and B.H. Hallas. Depts. of Neuroscience and Biomechanics, NY Coll. of Osteopathic Med., Old Westbury, NY 11568.

Several previous studies have shown that when the rodent spinal cord is damaged, DC electrical field treatment (DCEFT) can result in partial recovery of function. The objectives of this study were to investigate the conditions which determine whether such recovery involves regeneration or sparing of axons. The methods incorporated a spinal hemisection in rats followed by DCEFT (Traxon®) for 6 weeks, and then sacrifice. Control animals received no DCEFT. Prior to sacrifice, animals were injected with WGA-HRP ipsilateral and caudal to the lesion. After histological processing, WGA-HRP transport to the red nucleus was determined by automated grain counting. The results showed that all DCEFT animals exhibited greater WGA-HRP transport to the contralateral brainstem when compared to the ipsilateral side or to control animals. While previous experiments have shown that sparing and regeneration both occur with DCEFT after contusion injury, these experiments show that DCEFT is at least likely to promote axonal regeneration after axotomy in the spinal cord.

CHARACTERIZATION OF TWO ENDOGENOUS TROPHIC FACTORS INVOLVED IN REGENERATION OF THE GOLDFISH OPTIC NERVE. J.M. Schwalb, N.M. Boulis, M.-F. Gu, N. Irwin, and L.I. Benowitz* Dept. Neurosurgery, Children's Hosp., Harvard Med. Sch., Boston, MA 02115

Unlike mammals, lower vertebrates are able to regenerate injured pathways of the CNS throughout life. In the optic nerve of goldfish, a great deal of research has been directed towards the changes in neuronal gene expression that accompany regeneration. However, the trophic factors responsible for initiating this process are unknown. We have shown that molecules secreted by the glial sheath cells and collected into culture medium (regenerative conditioned medium, RCM) induce neurite outgrowth in both embryonic mammalian cortical neurons (Caday et al., Molec Brain Res 5:45-50) and dissociated goldfish retinal cells (Boulis et al., these Abstracts, 1993). Conditioned media derived from other organs of the goldfish showed no similar activity.

Using the retrograde dye 4-di-10-ASP, we have shown that RCM acts specifically on its natural target cells, the retinal ganglion cells, by promoting neurite outgrowth but not by influencing survival. RCM contains two trophic factors that differ in physical properties and patterns of expression. The smaller of the two, which accounts for most of the biological activity, is <1 kD in size, heat-stable, pronase and trypsin-insensitive, and has a hydrophobic domain. It is actively secreted and is expressed even in the intact optic nerve. The larger is a heat-labile, trypsin-sensitive, basic protein, M_r 70-100 kD, and is upregulated after axotomy.

Since these molecules are secreted from the optic nerve and target the retinal ganglion cells, they are likely to be important in inducing optic nerve regeneration *in vivo*. We are currently working to isolate the two factors and to evaluate the involvement of defined trophic factors in this system. Support: NIH EY 05690, HHMI, Boston Neurosurgical Foundation.

CHANGES OBSERVED FOLLOWING TREATMENT OF CHRONIC INJURIES OF THE BRAIN AND SPINAL CORD WITH AMP1 AND MATRIX. J.D. Peduzzi*, F.R. Fischer¹, and E.E. Geisert, Jr.² ¹Department of Physiological Optics, University of Alabama at Birmingham, Birmingham, AL 35294; ²Department of Anatomy and Neurobiology, University of Tennessee, Memphis, Memphis, TN 38163.

Regeneration is generally not observed after adult mammalian CNS injuries. Our efforts have been directed at manipulating the injury site by disrupting the scar and providing an environment favorable to axonal growth.

Adult Sprague-Dawley rats received a brain lesion with a scalpel blade or contusive spinal cord injury (10 g wt. dropped 5 cm) at the T9 vertebral level. After at least 2 months, animals received an injection at the injury site with one of the following: buffer, AMP1 antibody with EDTA, or AMP1 with EDTA and matrix. AMP1 antigen is a 110 kDa molecule that is upregulated at the scar. In the brain injured animals, AMP1 with EDTA appeared to disrupt the scar and growth cone-like structures were seen extending into the matrix. In spinal cord injured animals that received the AMP1 with EDTA and matrix, a slight but significant improvement was found in the combined behavioral score which is based on motor and sensory tests (modified from Gale, Kerasidis & Wrathall, 1985, Exp. Neur. 88:123). Supported by the Spinal Cord Society.

REPEATED INDUCTION OF ELECTROCONVULSIVE SEIZURES BLOCKS CHOLINERGIC SPROUTING, AN EFFECT THAT MAY BE A RESULT OF A SUPERINDUCTION OF A REACTIVE STATE IN ASTROCYTES. Q. Steward* Departments of Neuroscience and Neurosurgery, Univ. of Virginia, Charlottesville, VA 22908.

Previous studies have demonstrated that molecular and morphological changes that are characteristic of reactive astrocytes, specifically the up-regulation of glial fibrillary acidic protein (GFAP) synthesis and hypertrophy, can be induced by seizures. The present study evaluates whether super-induction of a reactive state in astrocytes alters one form of postlesion synaptic reorganization (the sprouting of cholinergic projections in the dentate gyrus after destruction of the entorhinal cortex).

Unilateral entorhinal cortex lesions were produced in mice and electroconvulsive seizures (ECS) were then induced on a daily basis from the day of surgery until 12 days postlesion. Control animals received EC lesions but did not experience ECS. At 2,4,6,8,10,12, and 30 days postlesion, animals were prepared for acetylcholinesterase (AChE) histochemistry in order to reveal the extent of cholinergic sprouting. The extent of the super-induction of GFAP expression was evaluated by measuring GFAP mRNA levels using *in situ* hybridization techniques.

The *in situ* hybridization analyses revealed that repeated electroconvulsive seizures had the anticipated effect on GFAP expression, dramatically increasing GFAP mRNA levels in comparison to animals with lesions alone. Quantitative evaluation of AChE staining revealed that the cholinergic sprouting response was substantially reduced in the animals that experienced daily ECS. These results indicate that the induction of seizures during the postinjury period disrupts at least one form of postlesion synaptic reorganization that would otherwise occur. This disruption of synaptic reorganization may be a consequence of the superinduction of reactive changes in astrocytes. Supported by NIH grant NS29875.

APOLIPOPROTEIN E AFFECTS ON THE HEALING PROCESS IN THE INJURED RAT OPTIC NERVE. J. Kaster, E. El Gazayerli, B. Patel, R. Anderson and G. Handelsmann* Pharmacology and Toxicology, Univ. of Utah, Salt Lake City, UT 84112.

Apolipoprotein E (apo-E) is a lipid transport protein present in glial cells, whose concentration is greatly increased following injury to most parts of the nervous system. The increase is due to synthesis by glial cells and to secretion by invading macrophages. An exception to this is in the optic nerve, where there is no increase in apo-E synthesis by glial cells following injury and there is a retarded rate of macrophage invasion. In addition, very little recovery or repair of the injured optic nerve occurs spontaneously. This study investigated the possibility that apo-E, administered exogenously, might facilitate the repair or healing of the rat optic nerve following injury.

Crush injuries of the right optic nerve were made in anesthetized adult male rats. Apo-E purified from rat blood was injected into the nerve sheaths at the site of injury at varying doses (0, 1, 10, and 25 µg). A retrograde tracing dye (biotinylated dextran conjugated to lysine) was injected into the vitreous humor at 2, 6, or 13 days after injury. At 3, 7, or 14 days after injury, the nerves were harvested and prepared for immunohistochemistry to visualize: a. dye transport, b. macrophages, c. myelin.

Apo-E administration affected several events associated with healing in a dose-related fashion. First, the transport of the dye was enhanced, both in distance past the injury and in the number of axons containing the dye. Second, the recruitment of macrophages to the crush site was significantly increased. Finally, the rate of myelin degeneration appeared to be increased. These data suggest that the presence of apo-E promotes several events known to be beneficial to nerve repair, and may provide an environment conducive to nerve repair or regeneration.

THE KS/CS-PG, ABAKAN; ITS ISOLATION, CHARACTERIZATION, AND DISTRIBUTION IN THE ADULT RAT OPTIC NERVE. D.J. Bidanset¹, J.R. Baker², M. Höök³, E.E. Geisert, Jr.⁴, R.J. Podhalsky¹, A.R. Blight¹, and B. Caterson¹ ¹Dept. of Surgery, UNC-Chapel Hill, Chapel Hill, NC 27599-7055, ²Dept. of Biochem., UAB-Birmingham, Birmingham, AL 36294, ³Div. of Matrix Biol., IBT, Houston, TX 77030, ⁴Dept. of Anat. and Neurobiol., UT-Memphis, Memphis, TN 38163.

During the development of the central nervous system (CNS), the formation of axonal pathways and appropriate neuronal connections occurs by both adhesive and inhibitory interactions between cells and the extracellular environment. Proteoglycans are one of the many members of the extracellular matrix found to function in both the developing and mature CNS. One such proteoglycan, ABAKAN, was found in previous studies in functional boundaries of the developing rat CNS. In addition, ABAKAN was shown to inhibit both neuronal cell attachment and neurite outgrowth on substrates composed of laminin. In the present study, ABAKAN was isolated to purity from adult rat brain and preliminary biochemical analysis was performed to help determine the structure and possible function of the proteoglycan in the normal CNS. The proteoglycan was found to have an M_r of approximately 410 kDa and to be composed of a 170 kDa core protein to which both chondroitin and keratan sulfate chains are attached. A third carbohydrate moiety which was found to have HNK-1 antigenicity was also found attached to ABAKAN. To ascertain its function after injury in the CNS, the distribution of ABAKAN relative to specific cell markers and other proteoglycans was determined both in normal and crushed optic nerve. ABAKAN, along with other proteoglycans, was found to be significantly upregulated after crush injury suggesting that ABAKAN plays a role in the inhibition of nerve regeneration. Supported by the Whitehall Foundation (EEG), NIH Grant # AR32666 (BC), the Canadian Spinal Research Organization (AB), and the NIH/NRSA Trauma Research Fellowship (DB).

EFFECTS OF *IN SITU* MICROINJECTION OF ANTI-NEUROFILAMENT MABS INTO REGENERATING GIANT CENTRAL NEURONS IN THE LAMPREY. G.F. Hall, D.S. Pijak, E. Lamperti*, and M.E. Selzer Dept. of Neurology, Children's Hospital, Boston MA 02115 and Dept. of Neurology, Univ. of Penn., Philadelphia PA 19104.

Identified giant neurons (anterior bulbar cells or ABCs) in the hindbrain of the larval sea lamprey *Petromyzon marinus* have been shown to be an advantageous preparation for studying the effects of axotomy *in situ* using microinjection techniques. Here we examined the effects of microinjecting monoclonal antibodies (mAbs LCM3 and LCM40) raised against the lamprey neurofilament protein (NF180) into regenerating ABCs. ABCs were injected with either of these mAbs at 4 mg/ml between 7 and 12 days following axotomy at the level of the 5th gill and were reaxotomized in the hindbrain at this time. Lucifer Yellow-dextran (LY-D, 10 mg/ml) was also injected to reveal the injected cells in wholemount. Control injections consisted of rabbit IgG (5 mg/ml) and LY-D. We found that anti NF180 mAbs induced a pronounced axon stump narrowing in treated neurons by 12 days post injection when compared to controls ($p < 0.005$, chi square test). There was otherwise little difference between anti NF180 mAb injected cells and controls in the shape of the cell body and dendrites. In light of the role played by mammalian neurofilaments in maintaining axonal caliber, we propose that microinjection of anti NF180 mAbs blocks the transport of NF180 into regenerating axons. Supported by NIH grant NS29281 to G.F.H.

OLIGODENDROCYTE INHIBITORY PROTEINS RETARD REGROWTH OF RETINAL AXONS BUT DO NOT CHANGE THE BASIC MODE OF GROWTH. D.F. Chen*, M. Schwab & G.E. Schneider. Dept. Brain & Cognitive Sci., M.I.T., Cambridge, MA 02139; Institut für Hirnforschung der Universität Zürich, August Forel-Strasse 1, CH-8029 Zürich, Switzerland.

Oligodendrocyte inhibitory proteins retard axonal growth in mature mammalian CNS. We have found that axons from E14 to P0 retina of hamster can show vigorous growth in the mature tectal environment, despite the presence in this target of differentiated oligodendrocytes. To test whether retinal neurons at these ages have a receptor for the oligodendrocyte proteins, supernatant (30%) from hybridoma cells producing the neutralizing antibody IN-1, or from control cells that produce an antibody against HRP, was added to co-cultures of retina (from animals aged E14 to P0) and adult tectum. Cultures were maintained at 37°C for 5 days, fixed, and crystals of Dil were placed in retinal explants to label the regenerating axons. In the presence of control antibody, the retinal axons were able to grow vigorously into tectum of all ages. In the presence of IN-1 antibody, axonal outgrowth was significantly increased. Thus, E14 - P0 retinal neurons clearly have a receptor for the protein, and their growth can be inhibited by it. In addition, we examined the effects of IN-1 antibody in isochronic co-cultures prepared from animals aged P4 or older, when most retinal axons have lost the ability for axon elongation into the central target. We found that some retinal axons grew into tectal slices in an arborization mode at a rate of up to about 100µm per day. Addition of IN-1 antibody increased the average number of axons innervating tectal slices, but it did not change the basic mode of growth. The results suggest that factors intrinsic to the retina are involved in determining the growth ability of retinal axons, while myelin-associated inhibitory protein can limit the growth of retinal axons once they reach the CNS environment. ALTERATIONS IN GLIAL MORPHOLOGIES AND ANTIGENIC PHENOTYPES FOLLOWING IRRADIATION. T.J. Sims*, D.L. Davies and S.A. Gilmore. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Early postnatal exposure of the lumbosacral spinal cord to X-rays results in dramatic *in vivo* alterations in developing glial populations and in subsequent conversion to a CNS glial environment that is permissive for the regeneration of axons (Sims and Gilmore, Brain Res., 1994). To understand mechanisms involved in this conversion to a permissive environment, the status of the glial populations persisting after x-irradiation (40 Gy) of the 3-day-old spinal cord was further assessed by *in vitro* techniques. Control cultures prepared from non-irradiated spinal cord and experimental cultures established from the cords of irradiated littermates were compared by immunocytochemical and histochemical staining after 8 days in culture. The most conspicuous difference was the profound reduction in numbers of both astrocytes and oligodendrocytes in experimental cultures. In addition to differences in macroglia, the microglial population was severely depleted in experimental cultures (see Gilmore *et al.*, this meeting). Five morphologically distinct astrocyte types were observed in both control and experimental cultures. The latter, however, contained a greater proportion of astrocytes with flat morphologies. Addition of dibutyl cyclic AMP (1 mM for 30 hrs) to control cultures altered the cellular composition to include greater proportions of process-bearing cell types, but failed to elicit a similar change when added to experimental cultures. Unexpected changes in phenotype were observed, however, such as astrocytes with cytoplasmic staining for galactocerebroside, a marker normally associated with oligodendrocytes. This cell culture study strongly suggests that x-irradiation of the spinal cord not only reduces the glial populations, but also dramatically alters its cell composition and generates cells of novel antigenic phenotypes. MAG CAN EITHER PROMOTE OR INHIBIT NEURITE OUTGROWTH. M.T. Filbin*, Y. Shen, P. Doherty, F.S. Walsh, and G. Mukhopadhyay Hunter College, New York, NY 10021 and Guy's Hospital, London, U.K.

Myelin associated glycoprotein (MAG), a member of the immunoglobulin (Ig) superfamily, has been shown to promote neurite outgrowth from rat 1 day old dorsal root ganglion (DRG) neurons. The effect of MAG on neurite outgrowth of neurons from different regions of the nervous system and at different times during development was examined by seeding isolated neurons onto either MAG-expressing transfected Chinese hamster ovary (CHO) cells or control CHO cells. The neurons were cultured for 16-24 h and the neurites were visualized by immunostaining for GAP-43, a protein expressed in abundance in neurites but not in CHO cells. The length of the longest neurite extended from each neuron was measured for at least 200 cells for each experiment. On the control CHO cells, 1 day old rat DRG neurons extended long neurites which, when grown on MAG-expressing cells, almost doubled. In contrast, adult DRG neurons, while still extending long neurites on the control cells, did not do so on MAG-expressing cells; the mean neurite length was decreased by 40% compared to neurons on control cells. Cerebellar neurons, like the DRG neurons, produced extensive neurites on the control cells but for all the ages examined (1.4 and 7 days) neurite extension was decreased by about 70% on MAG cells compared to controls. The specificity of this inhibition was demonstrated by the ability of MAG antibodies to reverse the inhibition by 50%. These results suggest that at different times in development and in different brain regions MAG can have very different effects on the ability of neurons to extend neurites. These results may be important to both axonal guidance during development and to nerve regeneration after injury.

CORTICAL OLIGODENDROCYTES INHIBIT OUTGROWTH IN A MODEL SYSTEM OF REGENERATING PERIPHERAL NERVE IN RAT. B.E. Pulford* and L.R. Whalen, Dept. of Anatomy & Neurobiology, Program in Neuronal Growth and Development, Colorado State University, Fort Collins, CO 80523

Lack of regeneration in the injured mammalian spinal cord appears to be due, at least in part, to the presence of inhibitory proteins on the cell surface of oligodendrocytes. A peripheral nerve model of CNS regeneration provides the opportunity to investigate oligodendrocyte-associated inhibition under conditions which are intermediate in complexity between the spinal cord and *in vitro* environments. The model consists of an axon-free "gap," 5-6mm in length, produced in the sciatic nerve of mature rats into which cultured oligodendrocytes are injected. The gap is produced by severing the nerve 6mm distal to a point marked by sutures in the epineurium, retracting the epineurium of the proximal nerve segment, severing and removing the exposed nerve fascicles, and reattaching the proximal epineurial sheath to the epineurium of the distal nerve stump using 9-0 suture. Cultured rat oligodendrocytes (3×10^7 cells/ml) suspended in a 70:30 (v/v) solution of serum free medium (N1):Matrigel (MG) were injected into the epineurial-enclosed gap using a syringe fitted with a 30ga needle. Control gaps were filled with either a 70:30 solution of N1:MG or rat fibroblasts suspended in a 70:30 solution of N1:MG. Nerves from all 3 groups of rats were removed two weeks after surgery and examined using histochemical, immunocytochemical and ultrastructural techniques. Preliminary results indicate that implanted oligodendrocytes survive within the gap for 2 weeks and that maximal axonal outgrowth and number of myelinated and nonmyelinated fibers are decreased in nerves in which oligodendrocytes are present within the gap compared to controls.

PDGF-BB AND IGF-I IN COMBINATION ENHANCE AXONAL REGENERATION IN A GAP MODEL OF PERIPHERAL NERVE INJURY. M.R. Wells*, D.K. Batter, H.N. Antoniadou, D.G. Blunt, J. Weremowicz, S.E. Lynch, and H.-A. Hansson. Institute of Molecular Biology, Inc., Worcester, MA 01605, and *University of Göteborg, Göteborg, Sweden.

Peripheral nervous system injuries often result in significant functional loss, including painful sequelae, that are often refractory to conventional surgical repair. The objective of the present study was to determine if a single application of the platelet-derived growth factor-BB (PDGF-BB)/insulin-like growth factor-I (IGF-I) combination could enhance the repair of injured peripheral nerve.

Forty-two rats were subjected to unilateral gap (8 mm) injuries of the sciatic nerve, and repaired with silicone tubes containing the growth factors in a 2% methyl cellulose vehicle. Concentrations tested ranged from 15-700 µg/ml PDGF-BB and 30-160 µg/ml IGF-I, with molar ratios from 5:1 to 1:50 of PDGF:IGF (N=6/group). After 4 weeks, animals were evaluated by a "pinch" test to demonstrate the extent of axonal growth, sacrificed, and biopsies were examined for the number of myelinated axons in the center of the tube and distal to the repair site. By these criteria, the PDGF-BB/IGF-I combination produced significantly greater nerve regeneration than treatment with vehicle alone over a broad range of ratios and concentrations. At the optimum molar ratio (1:4, PDGF:IGF), growth factor-treated animals exhibited 6595 ± 1476 myelinated axons (mean \pm SE) compared to 1096 ± 415 myelinated axons in animals which received vehicle alone. These data suggest that the combination of PDGF-BB/IGF-I might prove efficacious in the treatment of peripheral nerve injuries.

EFFECTS OF PRIOR NERVE INJURY ON MORPHOLOGICAL DIFFERENTIATION OF ADULT RAT DRG NEURONS IN CULTURE
Karen L. Lankford*, Jeffery D. Kocsis, Department of Neurology Yale Univ. Med. School New Haven Ct 06510, & Neuroscience Research Center VA Med Center West Haven CT 06516.

Numerous studies have shown that conditioning lesions can enhance the rate of regeneration of subsequently injured peripheral neurons, but it is not clear whether this enhanced rate of nerve regrowth reflects an increased growth capacity of the neurons or changes in the growth environment. To assess whether conditioning lesions alter the properties of the affected neurons, we dissociated neurons from L4 and L5 DRG of adult female Wistar rats subjected to sciatic nerve crush 4-5 days before sacrifice or sciatic nerve ligation 3 weeks before sacrifice. Neurons were then cultured for 1-3 days, fixed, and stained with neurofilament antibodies to visualize neurites. Rates of neurite initiation, neurite outgrowth, and branching frequency in previously ligated or crushed neurons were compared to neurons from control animals or the unoperated side of the same animal. Neurons extended processes at rates of several millimeters per day with interbranch distance being highly correlated with total outgrowth. Neurons which had previously received a crush showed roughly twice as many neurons with processes after 1 day in culture, greater average total neurite length per neurite bearing neuron, and increased interbranch distance compared with control neurons. Ligated neurons also initiated more neurites after 1 day than controls. These results demonstrate that enhanced regeneration of sensory neurons following a conditioning lesion is maintained in isolated cell bodies in culture.

CONTROL OF GAP-43 EXPRESSION CAN BE ACCESSED THROUGH A G-PROTEIN AND ADENYLATE CYCLASE
David J. Schreyer* Department of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6

Dorsal root ganglion (DRG) neurons display increased expression of GAP-43 following peripheral (but not central) axotomy *in vivo*. To study the signaling mechanism which links peripheral axotomy to changes in GAP-43 expression, we established a cell-ELISA technique to measure the GAP-43 content of microcultures of adult rat DRG neurons. As they do following peripheral axotomy *in vivo*, DRG cells which have been excised, dissociated, and maintained *in vitro* for one week display increased GAP-43 expression. This GAP-43 increase is partially suppressed by continuous exposure to cholera toxin, an activator of the stimulatory G-protein G_s . The GAP-43 increase is also suppressed by the cyclic AMP analogs dibutyryl-cAMP and 8-bromo-cAMP, the adenylate cyclase activator forskolin, and the phosphodiesterase inhibitor Ro 20 1724. We propose that GAP-43 expression is normally suppressed by an extracellular agent acting through G_s and adenylate cyclase, and that removal of this repressive agent leads to the elevation of expression of GAP-43 which follows peripheral axotomy.

545.18

ORG 2766 ENHANCES AXONAL REGROWTH ACROSS TRANSECTED RAT SCIATIC NERVE M. Dauzvardis*, S. Sayers, T. Khan, L. Liu, and C. Trausch, Rehabilitation R&D Center, Hines VA Hospital, Hines, IL 60141.

Melanocortins have been found to exert a trophic influence on both the central and peripheral nervous systems. The purpose of this study was to determine whether Org 2766 (a tri-substituted ACTH 4-9 analog) would enhance recovery after complete transection of the rat sciatic nerve as determined by neuronal tracing techniques and twitch tension measurements.

Rats were anesthetized, the left sciatic nerve was cut in the mid-thigh, and the proximal and distal ends were inserted into a silicone tube and held in place with cyanoacrylate adhesive. The right sciatic nerve was left intact. For animals receiving Org 2766 (N.V. Organon, The Netherlands) a 10 µg subcutaneous injection was given after surgery and 1 µg subcutaneous injections at 48 h intervals for a two-week period. After the eight-week survival period, twitch tension measurements were performed, followed by WGA-HRP injection into each nerve distal to the cut. After 48 h, the animals were perfused and the spinal cords were sectioned. The total number of labeled cells were counted from segments L2-S5 on both sides of the spinal cord and results were expressed as a ratio of labeled cells on the experimental side divided by the control side.

The average of the ratios of labeled cells on the experimental (transected) side divided by the control (unoperated) side was 19.2% for the six animals which received injections of Org 2766; three out of the five animals also showed the presence of twitch tension peaks recorded from the experimental side. The average of the ratios of labeled cells was 1.9% for the seven animals which did not receive any injections of Org 2766; only one out of the six animals showed the presence of a twitch tension peak recorded from the experimental side.

This preliminary study demonstrated that Org 2766 did enhance recovery after complete transection of the sciatic nerve as evaluated by neuronal tracing techniques and also by twitch tension measurements.

This research was supported by funds from the VA Rehabilitation R&D Center.

A MONOCLONAL ANTINEURONAL ANTIBODY PROMOTES PRIMARY NEURON OUTGROWTH and NON-NEURONAL CELL SPREADING ON CNS MYELIN. AM LOZANO*, C.L.I. MLABES and A ROACH, Samuel Lunenfeld Research Institute, University of Toronto, Toronto, M5G 1X5

A component of adult mammalian central nervous system (CNS) myelin inhibits axonal growth, a property that may be responsible in part for the lack of regrowth of axons interrupted in the CNS. The mechanism through which the inhibitory activity acts on the neuron to block growth is not known. To identify the neuronal molecules involved, we have generated and selected antineuronal antibodies based on their ability to promote neurite outgrowth on a CNS myelin substrate. We identified one such antibody, 10D, by its ability to promote the outgrowth of neurites from neural cell lines plated on CNS myelin. To test the effect of 10D on primary neurons and non-neuronal cells, we have grown newborn rat superior cervical sympathetic ganglion neurons (SCG) and 3T3 fibroblasts on CNS myelin. SCG neurons did not extend neurites and 3T3 fibroblasts did not spread on 10 µg/cm² of CNS myelin. In contrast, on CNS myelin in the presence of 10D, there was a vigorous outgrowth of neurites from SCG neurons and extensive spreading of fibroblast cell processes. These effects were not seen with control antibodies. The results indicate that 10D influences the process through which myelin substrates exert their inhibitory effects on neuronal and non-neuronal cells.

DYNAMIC REGULATION OF STRIATAL DOPAMINERGIC GRAFTS DURING LOCOMOTOR ACTIVITY. S. Hattori^{1,2}, H. M. Geller³, A. Tessier^{4*} and H. Nishino². Dept. of ¹Orthopedic Surgery and ²Physiology, Nagoya City University Med. School, Nagoya 467, Japan, ³Dept. of Pharmacology, UMDNJ Robert Wood Johnson Med. School, Piscataway NJ 08854-5635 and ⁴Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

After fetal dopaminergic cell grafts into hemiparkinsonian model rats, extracellular levels of DA increased nearly to normal and methamphetamine-induced rotations were reduced completely. However, more complex motor behaviors such as treadmill running at high speeds recovered to a lesser extent. Thus, besides recovery in tonic release of DA, additional mechanisms such as higher levels of DAergic reinnervation under dynamic regulation in the host brain might be necessary for better motor control. The present experiment was designed to estimate the neurochemical activity of DAergic grafts during locomotion and to examine the functional importance of dynamic regulation of the grafted neurons in the host brain. Grafted rats were trained to run on a straight treadmill at various speeds (300, 660, 1200, 1800 cm/min), and extracellular DA and its metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), were measured by *in vivo* microdialysis during and after running. Grafted rats were divided into two groups depending on the running ability (treadmill running test) and data were compared with those of normal and lesioned controls. Although tonic levels of extracellular DA in grafted rats recovered to 70-80 % of control, those of DOPAC and HVA remained 15-20% of controls. Small numbers of grafted rats showed full recovery on treadmill running tasks and percentage increases of DOPAC and HVA showed similar time courses and magnitudes as those of normal rats. The majority of grafted rats showed partial recovery of locomotor ability and percentage increases in DOPAC and HVA remained at lower levels than in normal rats. However, there were no differences in tonic levels of DA, DOPAC and HVA between the two grafted groups. Data suggest that grafted DAergic cells were dynamically regulated by the host brain and that the integrated release of DA might be involved in recovery of complex motor behaviors.

TWO NEURONAL CELL LINES WITH DOPAMINERGIC PROPERTIES AS CANDIDATES FOR NEUROTRANSPLANTATION

K.N. Prasad¹, F.S. Adams^{2*}, E.H. Kriek^{2*}, S. Kentrott^{3*}, A. Vernadakis^{4*}, E. Carvalho¹, C.R. Freed^{2*} and J. Edwards-Prasad¹. Depts. of Radiology¹, Medicine², Pharmacology³ and Psychiatry⁴ Univ. Colorado Sch. of Medicine, Denver, CO 80262

We investigated the dopaminergic characteristics of two established cell lines. The first, 2N₂₇, was derived from ED12 rat mesencephalic cells that were immortalized by transfection with a plasmid vector, pSV_{neo}. The second cell line, NBP₂, was murine neuroblastoma. *In vitro*, both lines expressed tyrosine hydroxylase (TH) and dopamine transporter (DAT) immunoreactivity. Terminal differentiation of NBP₂ cells with 200 µg/ml RO20-1724, a phosphodiesterase inhibitor, and 20 µg/ml β-carotene caused neurite formation and increased TH density. DAT expression appeared unaffected. Compared to the neuroblastoma cells, 2N₂₇ had faint TH and DAT labelling. Treatment with RO20-1724 and dibutyryl-cAMP (1 mM) led to subtle changes in morphology without noticeably affecting TH or DAT. Cells prelabelled with the fluorescent dye, DiI, were transplanted into rat brain and were found to survive one month after transplantation without tumor formation.

546.3

THE EFFECT OF FETAL TISSUE GRAFT PLACEMENT ON BEHAVIORAL RECOVERY IN A RAT MODEL OF PARKINSON'S DISEASE.

R.E. Johnston* and J.B. Becker. Dept. of Psychology, Neuroscience Program and Reproductive Sciences Program, University of Michigan, Ann Arbor, MI 48104.

Rats with unilateral striatal dopamine depletion are often used as an animal model of Parkinson's Disease. Fetal ventral mesencephalon grafts into the striatum of these lesioned rats have been used successfully to reduce asymmetries in both drug-induced and spontaneous behavior. We have found previously that grafts into the substantia nigra can also reduce the amphetamine-induced rotational bias. Thus, in the present experiment, adult lesioned rats received fetal tissue grafts into either the striatum, substantia nigra, or into both. They were tested postsurgery for a reduction in bias of both amphetamine-induced rotation, apomorphine-induced rotation, and spontaneous homecage behavior. Fetal tissue was labeled with bromodeoxyuridine (BrdU). At the conclusion of the experiment, biocytin was infused into the substantia nigra to trace the growth of the grafts. Coronal brain sections were stained for tyrosine hydroxylase, BrdU and biocytin immunoreactivity. Trends in the data indicate that grafts into the striatum are the most effective in reducing drug-induced rotational behavior, followed by grafts into both sites simultaneously, and then grafts into the substantia nigra. Full data will be presented at the meeting. [Supported by NS22157]

THE STUDY OF APOMORPHINE-INDUCED ROTATIONAL BEHAVIOR IN PARTIAL LESIONED RAT PARKINSONIAN MODELS WITH 6-HYDROXYDOPAMINE Jin Woo Chang, Sang Sup Chung, Yong Gou Park, Kwang Se Paik* Dept. of Neurosurgery, Dept. of physiology, Yonsei University College of Medicine, Seoul 120-752, KOREA

An apomorphine-induced rotational test has been used in the evaluation of rat parkinsonian model lesioned with 6-hydroxydopamine. We evaluated 50 partial lesioned rat parkinsonian models using the cylindrical rotometer devices with flat bottom (diameter, 30.5cm). Depending on the pattern of the rotation induced by apomorphine (0.5mg/kg i.p.), the rats were grouped into 4 groups (Group 1: contraversive pivotal rotation, 16 cases; Group 2: contraversive wide rotation, 20 cases; Group 3: ipsiversive rotation including pivotal rotation, 3 cases; Group 4: non-preferred or no rotation, 11 cases). Twelve of 16 rats in group 1 and 14 of 20 rats in group 2 met our criteria of rat parkinsonian model (at least 90 turns/30 min, 10 min after apomorphine injection). Although another 4 rats in group 1 didn't meet our criteria, all of them showed severe losses (more than 95%) of the TH-immunoreactive neurons (SNpc) in the lesioned side. Another interesting finding was that rats in group 2 and 3 showed moderate losses (50-80%) of TH-immunoreactive neurons (SNpc) in the lesioned side even though their rotational responses were different. These results suggest that pattern of rotation (pivotal rotation) is a more reliable index of neuronal losses of SNpc than the total numbers of the rotational response to apomorphine. The exact cause of the abnormal ipsiversive rotation noted in group 3 is unclear. Further research should be pursued to explain this finding.

DOPAMINE IS PRODUCED BY EARLY STAGE FETAL VENTRAL MESENCEPHALON BUT NOT CEREBELLAR TRANSPLANTS IN MPTP MONKEYS J.D. Elsworth*, M.S. Al-Tikriti, D.E. Redmond Jr., J.R. Sladek Jr., J.R. Taylor, T.J. Collier, P. Hoffer, R.B. Innis and R.H. Roth. Depts. Pharmacol. & Psychiatry, Yale Univ. School of Medicine, New Haven, CT 06510, West Haven VA Medical Center, CT 06516; Dept. Neurosci., The Chicago Medical School, North Chicago, IL 60064; Rush Medical School, Chicago, IL 60612.

Occasional studies in parkinsonian animals have suggested that the mechanism of neural transplant-induced beneficial effects may not rely on dopamine (DA) generated from the neural graft. These studies address this issue in MPTP-treated monkeys.

Grafts of fetal ventral mesencephalon (VM) or cerebellum were placed stereotactically in the striatum of MPTP-treated parkinsonian monkeys. Behavior of each animal was rated twice daily. At sacrifice, tissue micropunches were removed from brain slices for biochemical analyses. The remainder of the slice was processed for autoradiography or tyrosine hydroxylase (TH) immunohistochemistry.

Striking elevations (500%) in caudate DA concentration within 2 mm of the graft and improved behavior were associated with transplanted 2.5 - 4 cm crown-rump length (CRL) fetal VM (n = 19). Fetal VM (8 - 11 cm CRL) produced small increases in DA. DA concentration was not increased by grafted fetal cerebellum (n = 12), or 15 - 18 cm CRL fetal VM (n = 11), or after sham implantation (n = 5).

Radiolabeled cocaine derivatives ([¹²⁵I]β-CIT, [¹²⁵I]β-isopropyl-CIT) with extremely high affinity for the DA transporter were used to measure by autoradiography the growth of transplanted 2.5 cm CRL fetal VM cells. High density of binding was seen at the site of the grafts. Graft presence was confirmed by TH immunohistochemistry. At some coronal levels a majority of the caudate was occupied with an increased density of binding to DA uptake sites. Correlative *in vivo* brain imaging by SPECT has been performed in some grafted MPTP-treated monkeys using [¹²³I]β-CIT. Supported by NS 24032, the Axion Research Foundation, RSA MH 00643 to DER.

GRAFTS OF EMBRYONIC MESENCEPHALON IN AN ANIMAL MODEL OF PARKINSON'S DISEASE: BEHAVIORAL EFFECT OF VARYING THE AMOUNT OF GRAFTED TISSUE. F.S. Adams*, E.H. Kriek, C.J. Hunt & C.R. Freed U. Colo. Sch. of Med., Denver, CO 80262.

Grafts of embryonic dopaminergic tissue have shown promise as a therapy for Parkinson's disease in humans. One basic parameter under debate is the amount of tissue necessary to achieve optimal behavioral recovery. To address this, the present experiment contrasted the behavioral effects of grafting ED15 ventral mesencephalic tissue (MESEN) from one (4μl) or four (16μl total) donors into the striatum of adult male Sprague-Dawley rats with unilateral destruction of the mesostriatal dopamine system by 6-hydroxydopamine. Controls received equal volumes of ED15 spinal cord. Before grafting, the tissue was extruded into 200 μm strands. Injections of either 1μl or 4μl each were made at four sites into the striatum of each recipient. Circling after methamphetamine (METH; 5.0 mg/kg) was measured prior to grafting as well as one, two and three months afterwards to assess transplant efficacy. Following the third test, the rats were water deprived and trained to run on a circular treadmill for water reward, ipsi- and contralateral to the side of grafting. Only the animals receiving 16μl of MESEN showed a reduction in contraversive METH-induced turning, whereas those with 4μl MESEN or 4 or 16μl spinal cord did not show a reduction. A deficit in contraversive learned-turning was seen; however, none of the four treatments was effective in alleviating this deficit. Paradoxically, rats receiving 16μl of MESEN showed the worst performance. Tyrosine-hydroxylase (TH) immunohistochemistry revealed TH positive cells in the groups that had received MESEN. We conclude that grafting with MESEN from four embryos produces a better behavioral outcome than from a single embryo.

OPTIMAL SURVIVAL OF GRAFTED MESENCEPHALIC DOPAMINE (DA) NEURONS IS ATTAINED FROM TISSUE TAKEN DURING NEUROGENESIS OF THE SUBSTANTIA NIGRA IN NON-HUMAN PRIMATE J.R. Sladek, Jr.¹, B.C. Blanchard¹, T.J. Collier², J.D. Elsworth³, J.R. Taylor³, R.H. Roth³, and D.E. Redmond, Jr.³

¹Dept. of Neuroscience, Chicago Medical School, N. Chicago, IL 60064, ²Dept. of Neurological Sci, Rush Medical School, Chicago, IL 60612 and ³Depts. of Psychiatry & Pharm., Yale Univ. School of Medicine, New Haven, CT 06510

We examined a model of Parkinson's disease to test the effect of embryonic grafts of ventral mesencephalon on motor disability induced by MPTP. DA increases on average 500% near grafts (see Elsworth abst). Although staining revealed 20,000+ DA neurons in grafts derived from a single embryo, we have seen variability in the percentage of DA neuroblasts that survive grafting. This may be related to the age of the donor tissue; neurons that have extended axons would be subject to degeneration while cells taken from ages prior to neurogenesis might lack appropriate developmental cues. Grafts were selected from pregnant monkeys by ultrasonography; 14 donors were chosen from embryonic days 30-47. Solid tissue grafts were placed into the caudate nucleus. Brains were collected at 3-6 months after surgery and were stained for tyrosine hydroxylase (TH). DA neurons ranged from 1,300 to 28,000 per host; 9 of 14 animals contained between 8,200 and 28,400 TH neurons. The numbers of TH neurons in grafts seen at each age examined were: E30 (3,500), E38(13,780), E39(9,288), E41(21,296), E42 (n=4; 1,300, 18,000, 11,700, 12,136), E44(n=4; 3104, 4,100, 15,064, 28,400), E47(n=2; 8,200, 13,344). The average of donors (n=11) taken during putative neurogenesis (E36-E43 ± 24hrs.) of the substantia nigra was 12,560±2456. The adult African green monkey has about 80,000 DA neurons in both substantia nigrae. Thus, an average survival of 12,560 neurons is about 16% of the adult population; the best survival obtained (i.e. 28,400) is about 36% which is substantially better than results obtained from studies using xenografted human cells. Supported by NIH grants NS 24032 and RSA MH 00643(DER).

HOST STRIATUM PROJECTS FIBERS INTO TRANSPLANTED FETAL MESENCEPHALON IN A PARKINSONIAN PRIMATE MODEL. R.T. Wechsler*¹, B.C. Blanchard¹, T.J. Collier², J.D. Elsworth³, J.R. Taylor³, R.H. Roth³, D.E. Redmond, Jr.³, and John R. Sladek, Jr.¹. ¹Dept. of Neurosci., Chicago Med. Sch., N. Chicago, IL 60064; ²Dept. of Neurol. Sci., Rush Med. Sch., Chicago, IL 60612; ³Depts. of Psychiat. & Pharm., Yale Univ. Sch. of Med., New Haven, CT 06510

Fetal mesencephalic grafts into the striata of partially dopamine (DA)-depleted African green monkeys become well developed and show numerous TH-positive neurons when examined with immunohistochemical (IHC) staining. These neurons project fibers into the adjacent host striatum. Since control of DA synthesis/release may be influenced by the host brain, the establishment of reciprocal connections is of importance. A double label IHC staining technique was used for simultaneous evaluation of both graft and host fiber projections. TH-containing neurons were stained as before. Endogenous host striatal projecting neurons, which normally communicate with the intact substantia nigra using the neurotransmitters GABA and substance-P, were stained using antibodies against glutamic acid decarboxylase (GAD), a GABA synthetic enzyme, and substance-P. Different chromogens were used to label the different cell types. This staining protocol was performed on 8 grafted animals. Numerous GAD-positive and substance P-positive fibers were identified within the TH-positive grafted fetal mesencephalic tissue. Many of these fibers were found in proximity to TH-positive graft cells. Some of the fibers adjacent to TH-positive cells exhibited enlargements suggestive of potential contact points. These preliminary results provide a morphologic basis for the presence of reciprocal connectivity between the host striatum and the transplanted fetal mesencephalon. Electrophysiological and electron microscopic studies of an analogous experimental paradigm will be needed to verify this suspected connectivity. FUNCTIONAL RECOVERY IN HEMIPARKINSONIAN MONKEYS FOLLOWING GRAFTS OF ENCAPSULATED PC-12 CELLS Y.-T. Liu¹, S.R. Winn², F.T. Gentile², P. McDermott^{3*}, D.F. Emerich², and J.H. Kordower¹ Dept. Neurological Sciences, Rush Presbyterian Med.Ctr., Chicago, IL 60612; ²CytoTherapeutics Inc. Providence R.I., 02906; ³Dept. Neurosci. Chicago Med. School, North Chicago, Ill. 60064.

Following training for 2- months on a hand reaching task, Rhesus monkeys were rendered hemiparkinsonian via an intracarotid injection of n-methyl-4 phenyl 1,2,3,6 tetrahydropyridine (MPTP). Following the unilateral lesion, these animals were greatly impaired or would not perform with their affected limb while function was not affected on the intact side. Three months following the lesion, monkeys received 2 grafts into the caudate nucleus and three grafts into the putamen of polymer capsules containing PC-12 cells (n=3) or empty capsules (n=1). Over the next 6 months, two of the three monkeys receiving the PC-12 cell grafts recovered their use of the affected limb and performed at near-baseline levels. The third PC-12 grafted monkey and the one control monkey remained impaired. The capsules were then removed. The capsules from monkeys which behaviorally recovered contained numerous PC-12 cells which expressed high levels of basal and potassium evoked release of dopamine. The capsules from the PC-12 grafted monkey which did not recover contained very few viable cells and both basal and potassium evoked release of dopamine was undetectable. Following the removal of the capsules, the functional recovery in the two PC-12 grafted monkeys was sustained for up to 2 months. These data suggest that grafts of PC-12 cells can induce functional recovery in nonhuman primates although the mechanism of action remains unclear.

546.11

THE AGED MONKEY BASAL FOREBRAIN: RESCUE AND SPROUTING OF DEGENERATING CHOLINERGIC NEURONS FOLLOWING GRAFTS OF POLYMER-ENCAPSULATED NGF-SECRETING CELLS. J.H. Kordower¹, S.R. Winn², W.C. Benzing¹, E.J. Mufson¹, Y.-T. Liu¹, J.R. Sladek Jr.³, E. Doherty², J.P. Hammang², E.E. Baetge² and D.F. Emerich² ¹Dept. Neurological Sciences, Rush Presbyterian Med.Ctr., Chicago, IL 60612; ²CytoTherapeutics Inc. Providence R.I., 02906; ³Dept. Neurosci. Chicago Med. School, North Chicago, Ill. 60064

Six aged Rhesus monkeys (24-29 years old) received unilateral transections of the fornix. Three monkeys then received intraventricular transplants of polymer-encapsulated baby hamster kidney (BHK) fibroblasts which had been genetically modified to secrete human nerve growth factor (hNGF). The remaining three monkeys received identical grafts except the cells were not modified to secrete hNGF. Monkeys receiving control grafts displayed extensive reductions in the number of ChAT (57-75%) and p75 NGFr-immunoreactive (ir) (53%) medial septal neurons ipsilateral to the lesion/graft. In contrast, monkeys receiving grafts of encapsulated hNGF-secreting cells display only a modest loss of ChAT-(0-36%) and p75 NGFr-(7-22.4%)-ir septal neurons. Additionally, all monkeys receiving the hNGF-secreting implants, but none receiving control implants, displayed robust sprouting of cholinergic fibers within the septum ipsilateral to the transplant. Just prior to sacrifice, the capsules were retrieved and determined to contain viable BHK cells releasing biologically relevant levels of hNGF. These data demonstrate that hNGF can provide trophic and tropic influences to degenerating cholinergic basal forebrain neurons in aged nonhuman primates supporting the contention that hNGF may prevent degeneration of basal forebrain neurons in Alzheimer's disease.

546.13

HYPERTROPHY OF CHOLINERGIC AND NPY CONTAINING STRIATAL NEURONS FOLLOWING IMPLANTS OF POLYMER ENCAPSULATED CELLS GENETICALLY MODIFIED TO SECRETE HUMAN NGF. E.-Y. Chen¹, D.F. Emerich², S.R. Winn², B.R. Frydel², J.P. Hammang^{2*}, E.E. Baetge², and J.H. Kordower¹ ¹Dept. of Neurological Sciences, Rush Presbyterian Medical Center, Chicago, IL 60612 and ²CytoTherapeutics Inc., Providence, RI 02906

The present study examined the effects of polymer encapsulated grafts containing baby hamster kidney fibroblasts (BHK) genetically modified to secrete human NGF (hNGF) upon the size of cholinergic and noncholinergic striatal neurons following implantation into the intact rodent striatum. Three groups received BHK-hNGF grafts into the right striatum and were sacrificed 1, 2, or 4 weeks post-implantation. The remaining three control groups were treated identically except that BHK cells were not modified to secrete hNGF. In control BHK grafted rats, the size of ChAT-ir striatal neurons was unchanged (<2%) at all time points. In the BHK-hNGF grafts, there was a hypertrophy of ChAT-ir striatal neurons 1 (29.4%), 2 (34%) and 4 weeks (32%) following grafting relative to the intact striatum. Optical density measurement within ChAT-ir somata were also significantly enhanced in BHK-hNGF grafted rats relative to control grafted animals. These effects were lost in rats receiving BHK-hNGF grafts for one week and allowed to survive an additional 3 weeks following graft removal. Control grafts did not alter the size of NPY neurons within the striatum. However, the NGF-hNGF grafts significantly increased the size of NPY neurons 1 (13%), 2 (16%) and 4 (13%) weeks post-implantation. Removal of the capsules just prior to sacrifice revealed healthy BHK cells which secreted sufficient levels of hNGF to differentiate PC12A cells. These data indicate that polymer encapsulated cells which were genetically modified to secrete hNGF can influence both cholinergic and noncholinergic neurons within the striatum.

546.10

POLYMER-ENCAPSULATED HUMAN NERVE GROWTH FACTOR-SECRETING FIBROBLASTS PREVENT THE LOSS OF DEGENERATING CHOLINERGIC NEURONS FOLLOWING IMPLANTATION INTO NONHUMAN PRIMATES Dwaine F. Emerich^{1*}, Shelley R. Winn¹, Joseph P. Hammang¹, E. Edward Baetge¹ and Jeffrey H. Kordower² CytoTherapeutics, Inc., 2 Richmond Square, Providence, RI 02906¹; Dept. of Neurological Sciences and Rush Alzheimer's Disease Center, Rush-Presbyterian Medical Center, Chicago, IL 60612².

Basal forebrain cholinergic neurons degenerate in several human dementing illnesses including Alzheimer's disease (AD). Nerve growth factor (NGF) has potent target-derived trophic and tropic effects upon cholinergic basal forebrain neurons and may represent a useful treatment strategy for AD and/or other diseases characterized by basal forebrain-mediated cholinergic deficits. We have developed a polymer encapsulation system that allows for a continuous and site-specific delivery of NGF to the CNS. Baby hamster kidney (BHK) cell lines that constitutively express high levels of human NGF (BHK-hNGF) were developed using the dihydrofolate reductase-based vector system. Polymer devices loaded with BHK-control or BHK-hNGF cells were maintained *in vitro* and hNGF release was quantified with ELISA. BHK cell-containing devices were grafted into the lateral ventricle of four cynomolgus monkeys immediately following a unilateral transection of the fornix. Three control monkeys received non-hNGF-secreting cells and one monkey received a fornix transection only. Control monkeys displayed extensive losses of choline acetyltransferase and p75 NGF receptor-immunoreactive neurons within the medial septum (MS; 53% and 54%) and vertical limb of the diagonal band (VLDB; 21% and 30%) ipsilateral to the lesion. In contrast, monkeys receiving implants of BHK-hNGF cells exhibited a modest loss of cholinergic neurons within the MS (19% and 20%) and VLDB (7%) together with a dense sprouting of cholinergic fibers within the septum. Retrieved capsules contained numerous viable cells which continued to produce hNGF. These results support the use of polymer-encapsulated cell therapy in neurodegenerative diseases such as AD where basal forebrain degeneration is a consistent pathological feature.

546.12

GRAFTS OF POLYMER ENCAPSULATED HUMAN NGF SECRETING CELLS DO NOT ALTER β AMYLOID OR APOLIPOPROTEIN E EXPRESSION IN YOUNG OR AGED MONKEYS. M.A. Burke^{1*}, W.C. Benzing², E.J. Mufson², Y.-T. Liu², J.R. Sladek Jr.³, D.F. Emerich⁴, and J.H. Kordower² ¹Dept. Anatomy and Cell Biology, Univ. Illinois Sch. Med., ²Dept. of Neurological Sciences, Rush-Presbyterian Med. Ctr., Chicago, IL 60612; ³Dept. Neuroscience, Chicago Med. Sch., North Chicago, IL 60064; ⁴CytoTherapeutics, Inc., Providence, RI 02906.

Grafts of polymer encapsulated cells which have been genetically modified to secrete human nerve growth factor (hNGF) rescue axotomized septal neurons for up to 1 month in young and aged monkeys (see adjacent abstracts). Since NGF has been shown to increase β APP production in nonprimates, we examined whether biologically delivered NGF would alter the expression of β amyloid or apolipoprotein E (ApoE)-containing elements in young and aged nonhuman primates. The following groups of monkeys were studied: a) young adult monkeys with NGF grafts (<15 years old; n=2); b) young adult monkeys with control grafts (<15 years old; n=2); c) aged monkeys with NGF grafts (25-29 years old; n=3); d) aged monkeys with control grafts (24-26 years old; n=3); e) intact aged monkeys (23-31 years old; n=10). None of the young adult monkeys displayed β amyloid or ApoE regardless of treatment. Aged monkeys displayed numerous β amyloid containing neuritic plaques within the temporal and parietal neocortex as well as the hippocampus. These animals also displayed numerous ApoE-containing plaques, primarily located within the temporal neocortex. The expression of β amyloid and ApoE was similar in intact aged monkeys and monkeys receiving control grafts or grafts secreting hNGF. Thus, it appears that hNGF can provide trophic support for degenerating cholinergic basal forebrain neurons in young and aged primates without altering some pathological features associated with aging processes.

546.14

CLINICAL RECOVERY AND GRAFT SURVIVAL IN PARKINSONIAN NON-HUMAN PRIMATES AFTER STRIATAL GRAFTING OF FIBROBLASTS GENETICALLY MODIFIED WITH TYROSINE HYDROXYLASE cDNA. K.S. Bankiewicz^{*}, M. Emborg, D. Nagy, S. Leff, R. Mandel, K. Spratt, F. Gage[†], W.W. McLaughlin, M.V. Sofroniew, Somatic Therapy Corporation, 850 Marina Village Pkwy., Alameda CA 94501, #UC San Diego.

Somatic gene therapy uses grafts of genetically modified autologous cells to produce and deliver therapeutic substances to specific sites within the body and eliminates the need for immunosuppression or barrier devices. We are utilizing a process that consists of harvesting autologous cells through a biopsy, followed by *ex vivo* genetic modification of these cells to produce specific therapeutically active proteins, and subsequent grafting of these cells to an appropriate site. 7 MPTP-treated overlesioned hemiparkinsonian monkeys were used for this study. Using MRI guided stereotaxic surgery the 3 monkeys were grafted with autologous fibroblast transfected with retroviral vector (MFGS) carrying a human tyrosine hydroxylase (TH2) cDNA, 2 monkeys were implanted with non-transfected fibroblasts and 2 animals were left non-implanted. Prior to the implantation all animals were behaviorally characterized for 9-12 months using parkinsonian rating scale, apomorphine-induced turning, arm use scale and activity monitors. TH implanted monkeys showed immediate clinical improvement and increase of activity after the implantation which lasted for 4 months, reduction of apo-rotation and they regained functional arm use. Animals were sacrificed at 4 months. Control implanted animals recovered only from apomorphine-induced rotation, while control non-implanted monkeys remained unchanged. MRI scanning detected grafts in the striatum and closure of the blood brain barrier at 2 weeks post-implantation. Histological examination of the implanted animals showed surviving, well vascularized and integrated in the host striatum fibroblast grafts representing over 40% of implanted cellular volume. Immunocytochemistry and in-situ hybridization analysis of the brains are in progress. These results validate potential application of *ex-vivo* gene therapy for neurodegenerative brain disorders.

NON-HUMAN PRIMATE MODEL OF PARKINSON'S DISEASE FOR STUDY OF TROPHIC AND/OR DOPAMINE REPLACEMENT THERAPY. M.E. Emborg, W.W. McLaughlin and K.S. Bankiewicz, Somatix Therapy Corp., Alameda, CA 94501.

Administration of 0.4 mg/kg of MPTP into one internal carotid artery produces hemiparkinsonism in monkeys. In such a model, the side ipsilateral to MPTP administration becomes severely depleted of DA, while the side contralateral serves as a "normal" control. As we previously reported (Bankiewicz KS, et al. Life Sci. 1988), unilateral administration of 0.8 mg/kg results in overlesioned HPD monkeys (HPD+) which display bilateral signs of the PD. In this study, we further characterize HPD+ monkeys using behavioral and in vivo biochemical methods. 17 Rhesus monkeys (age 5-16; weight 3.92-14.86 kg; 6 female, 11 male) were studied during 9-18 months after MPTP lesion. The monkeys received an intracarotid infusion of 2-4 mg of MPTP supplemented by 0.4 mg/kg i.v. to induce HPD+, which still enabled them to sustain themselves. Apomorphine-induced turning, arm use, general activity measurements, clinical recordings using rating scale, in vivo microdialysis and CSF levels of HVA were examined. After the MPTP treatment, all of the monkeys showed progressively bilateral signs (freezing, bradykinesia, decreased defense reaction, posture and gait problems), and hemiparkinsonian signs with predominant use of the arm ipsilateral to the side of MPTP administration (rigidity, action tremor and decreased use of contralateral arm, ipsilateral spontaneous circling and apomorphine-induced contralateral turning). The CSF HVA levels were increased in the first hours after the MPTP administration with subsequent decrease of 40-60% 3 days later. Extracellular levels of dopamine and HVA as measured by microdialysis in caudate and putamen nucleus on the ipsilateral side were not detectable. Local amphetamine administration induced DA and HVA peaks only on the contralateral side, suggesting total lack of any remaining innervation on the ipsilateral side. This side, modelling the end stage of human PD, could be used for grafting DA-producing cells for studying DA replacement therapy, while the partially-lesioned contralateral side, modelling an advanced stage, could be used for studying trophic factor-releasing cells and inducing a trophic reaction.

ISOLATION OF MESENCEPHALIC PROGENITOR CELLS FROM RAT; REGULATION OF THE DEVELOPMENT OF THE DA PHENOTYPE. P.M. Carvey, D.H. Lin, and L.R. Ptak, Dept. Neurological Sciences, Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612.

Reynolds and Weiss (Science 255:1707;1992) reported the isolation and partial characterization of epidermal growth factor (EGF) responsive striatal progenitor cells. Using their procedure, we have isolated mesencephalic progenitor cells. E-14.5 rat mesencephalon was isolated and plated onto 100 x 20 mm petri plates (1300 cells per cm²) that had not been pre-treated with extracellular matrix products. The cells were grown in media containing 20 ng/ml EGF. Less than 0.1% of the cells survived and went on to form clusters of cells if left undisturbed for 14 days. These mitotically active cells have been successfully passed for 8 months. When cultured on poly-L-lysine coated plates containing a complete media (10% FCS), the cells differentiated into glia and neuron-like cells. None of these cells stained positive for tyrosine hydroxylase (TH). Similarly, TH positive cells were not found after exposure to various trophic factors or following co-culture with E14.5 striatum. In contrast, co-culturing progenitor cells with fresh mesencephalon had a profound effect increasing the number of TH staining neurons ($F_{2,69} = 122.97$; $p < 0.01$) relative to mesencephalic mono-cultures. Mitochondrial dehydrogenase activity was unchanged in the co-cultures suggesting that mitotic activity was not responsible for the increase in TH neurons observed. The cultures were also negative for the NE marker DBH. These data suggest that a soluble or a cell contact mediated activity present in mesencephalon was responsible for converting the progenitor cells into a DA neuron phenotype. Like striatal cells, mitotic progenitor cells capable of developing into DA neurons exist within the mesencephalon.

546.19

XENOTRANSPLANTATION OF PORCINE VENTRAL MESENCEPHALIC NEUROBLASTS RESTORES FUNCTION IN PRIMATES WITH CHRONIC MPTP-INDUCED PARKINSONISM. L.H. Burns,^{*1} P. Pakzaban,¹ T.W. Deacon,¹ J. Dinsmore,² O. Isacson,¹ Neuroregeneration Laboratory¹, McLean Hospital, Belmont, MA 02178, and Program in Neuroscience, Harvard Medical School, Boston, MA 02115; Diacrin Inc.,² Charlestown, MA 02129.

To investigate the potential of xenogeneic neuroblasts as an alternative to human cells for therapeutic neural transplantation, we evaluated the long-term survival and function of porcine fetal ventral mesencephalon (VM) cells transplanted into the striatum of parkinsonian monkeys. Four *Macaca fascicularis* were rendered parkinsonian by chronic intermittent low-dose intravenous injections of MPTP over a period of up to 15 months. Average daily locomotor activity, measured by photo-cell beams, decreased to 5 - 25% of normal values and remained unchanged for the 3 months preceding transplantation. Parkinsonian signs included hypokinesia, bradykinesia, rigidity and tremor. During the same period, dopamine fiber density in the striatum, as assessed by the ligand ¹¹C-CFT and PET, decreased to 20 - 30% of pre-MPTP values. Monkeys were transplanted unilaterally in the caudate and putamen with cell suspensions derived from the ventral mesencephalon of E28 porcine fetuses. To prevent xenograft rejection, monkeys were either immunosuppressed with cyclosporine A (CsA) or were implanted with cells pre-treated with anti-porcine MHC class I antibody fragments (Fab). One monkey received otherwise identical cells without any immunosuppression.

At 3 - 4 months after xenotransplantation, the CsA-treated monkey and the 2 Fab-treated monkeys showed increased locomotor activity and increased striatal ¹¹C-CFT signal on PET. The non-immunosuppressed monkey did not show an increase in locomotor activity or dopaminergic PET signal (compared to pre-transplant values). These data indicate that porcine mesencephalic neuroblasts can restore motor function and replenish dopaminergic fibers in parkinsonian primates.

CCK FACILITATES METHAMPHETAMINE-INDUCED DOPAMINE OVERFLOW IN RAT STRIATUM AND FETAL NIGRAL GRAFTS. Y. Wang* and S.L. Pong, Dept. of Pharmacology, National Defense Medical Center, Taiwan.

The purpose of this study was to investigate the electrochemical interactions of cholecystokinin (CCK) and methamphetamine (MA)-induced dopamine (DA) overflows in rat striatum. High-speed chronoamperometric recording techniques using Nafion-coated carbon fiber electrode were used to evaluate extracellular DA concentration in the striatum. CCK-8S, CCK-8US, MA and DA were locally applied directly to the striatum of urethane-anesthetized Sprague-Dawley rats. We found that CCK potentiated MA-induced DA release in the anterior striatum. This reaction is likely mediated through CCK-A receptors because only CCK-8S, but not CCK-8US, enhanced MA reactions. Replacement of Ca²⁺ with Mg²⁺ antagonized this reaction, suggesting that the modulation of MA by CCK is Ca²⁺ dependent. Both MA-induced DA release and CCK modulatory effects were disappeared in the striatum after unilaterally lesioning the medial forebrain bundle with 6-OHDA lesions. The unilaterally lesioned rats were later transplanted with fetal ventral mesencephalon. We previously found that the zone of normalized dopamine clearance was considerably larger than that of normalized release in the anterior striatum after fetal nigral transplantation, which may be contributed to the partial reinnervation from the transplant. In the present study, we found that the modulation of DA release by CCK was regenerated in the zone of normalized release after fetal nigral transplantation. However, CCK did not increase MA-induced DA release in the partially innervated area. In conclusion, these findings suggest that the not only DA release process but also CCK modulatory mechanism were regenerated after fetal nigral transplantation.

FETAL NIGRAL GRAFT-INDUCED RESTORATION OF GABAERGIC NEUROTRANSMISSION IN THE BASAL GANGLIA IN A RAT MODEL OF PARKINSON'S DISEASE. B.A. Flumerfelt*, W. Rushlow, C. Naus and N. Rajakumar, Department of Anatomy, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

The basal ganglia exert their function mainly via disinhibitory GABAergic circuits. However, very little is known about the changes that occur in GABA neurotransmission in Parkinson's disease, and virtually nothing is known about such changes following dopamine supplementation by grafted fetal dopaminergic neurons. In the present study, GAD mRNA levels were compared in neurons of the entopeduncular nucleus (EPN) and the substantia nigra pars reticulata (SNR) in normal, unilaterally 6-hydroxydopamine-lesioned and grafted rats by means of *in situ* hybridization using [³⁵S] labeled cRNA probes. Autoradiographs revealed a moderate elevation of GAD mRNA levels in the ipsilateral SNR, particularly in the lateral half of the nucleus, while the ipsilateral EPN showed a slight increase. Nine months after transplantation of fetal nigral neurons, the GAD mRNA levels remained significantly elevated in the ipsilateral SNR, but the ipsilateral EPN appeared similar to those of normal rats. These data indicate that nigral grafts placed in the striatum differentially influence GAD mRNA levels in the EPN and SNR, and suggest a necessity for additional dopaminergic grafts in the nigra for complete restoration of basal ganglia function. [Supported by the Parkinson's Foundation of Canada].

Fast axonal transport is not influenced by exposure to pulsed electromagnetic fields before or after injury. Betty F. Siskin¹, Janet L. Walker and Jane M. Jacob. Center for Biomed. Engineer. and Dept. of Anat. and Neurobiol., U. Kentucky, Lexington, KY 40506 and Dept. of Anat. Sci., U. Oklahoma HSC, Oklahoma City, OK 73190.

Fast axonal transport (FAXT) is responsible for the bidirectional movement of proteins within the nerve terminal and axon. Anterograde transport by FAXT of neurotransmitter-associated proteins and membranous organelles to nerve terminals occurs at a rate of ~410 mm/d. Pulsed electromagnetic fields (PEMF) have been shown to enhance axonal outgrowth in sciatic nerve when applied before or after injury, although the mechanism of this effect is not known. In this study, we examined the effects of acute PEMF treatments on fast axonal transport rates in the sciatic nerve of young Sprague-Dawley rats under 2 conditions: in uninjured (non-operated) nerves and 1 d after a crush of the nerve behind the knee. Rats were placed between Helmholtz coils for 15 min/d for 2 d preceding isotope injection or for 60 min on the day of isotope injection. While maintaining core body temperature at 37°C, [³H]-proline was stereotactically microinjected into the spinal cord; rats were killed 2.5-5.0 hr later. After tissue solubilization and liquid scintillation spectroscopy, transport profiles indicate that acute treatments with PEMF had no effect on fast transport rates in uninjured or injured sciatic nerves. These studies are in agreement with others indicating that fast axonal transport rates are not altered in response to crush injury. They also show that PEMF effects are not related to fast transport mechanisms. Studies on slow axonal transport using a similar paradigm are underway. Supported by NIH NS 29621-02 (BFS).

THE DIFFUSIBLE FAST AXONALLY TRANSPORTED DRG PROTEINS: DO THEY REPRESENT COMMON OR UNIQUE SECRETORY PRODUCTS? B. Tedeschi¹, S. Mulugeta and R.P. Ciavatta. Departments of Anatomy & Neurobiology and Microbiology & Immunology, East. Virg. Med. Sch., Norfolk, VA 23501.

Fast axonal transport (FT) is believed to represent the translocation of granules/vesicles in the neuronal secretory pathway. In the frog DRG/sciatic nerve preparation, we have previously differentiated the diffusible FT protein subset from the membranous protein subset. In the present study we addressed two questions: (1) Which diffusible DRG FT proteins are unique relative to the secretory products of non-neuronal nerve cells? and (2) Which diffusible DRG FT proteins are unique relative to other neuronal FT proteins? Neuronal or non-neuronal nerve proteins were pulse-labelled with ³⁵S-methionine and time allowed for FT (in the case of neuronal proteins). Radiolabelled diffusible proteins were collected in a bath surrounding nerve and bath/nerve proteins were subsequently analyzed by two-dimensional gel electrophoresis (2D-PAGE) and fluorography. Results showed that: (1) only one (10%) of the diffusible DRG FT proteins exhibited a possible identity with a diffusible non-neuronal sciatic nerve protein and (2) all of the diffusible DRG FT proteins were FT by retinal ganglion cell neurons. These results suggest that diverse neuronal populations may package a similar set of soluble FT proteins and that these diffusible products are quite different from the secretory products of non-neuronal nerve cells.

DISTRIBUTION AND REGULATION OF LOW MOLECULAR WEIGHT GTP BINDING PROTEINS *rab3A* & *rab3B* IN THE RAT BRAIN. F. Nothias*, O. Stettler¹, J-D Vincent and Ph. Vernier. Inst. A. Fessard, CNRS, 91198 Gif-sur-Yvette & INSERM U334, CEA-SHFJ, 91400 Orsay, France.

Rab3A and *B* belong to the ras-related superfamily of small GTP-binding proteins and are mainly present in nervous and endocrine tissues. These proteins appear to be involved in the control of a late step of exocytosis during which vesicles become docked to the plasma membrane. Physiological studies showed that these proteins may differentially regulate tonic and phasic exocytosis. This data prompted us to examine the brain distribution of mRNA encoding *rab3A* and *B*. *In situ* hybridization revealed that both mRNAs are heterogeneously distributed in the brain but overlap in most areas, although *rab3B*-mRNA is generally less abundant, except in the pituitary and olfactory bulb. This distribution was quantitatively ascertained by competitive PCR in the same tissues. In addition, double *in situ* hybridization showed that *rab3A* and *B* mRNAs are essentially colocalized within individual neurons.

During lactation, both *rab3A* and *B* mRNAs are upregulated in the magnocellular hypothalamic system in which increased stimulations are associated with the pulsatile release of oxytocin from the neurohypophysis. During lactation, an increase of *rab3B* mRNA was also observed in the anterior pituitary. Western blots confirmed these results and revealed that *rab3A* and *B* proteins exhibit different apparent molecular weights due to a post-translational modification.

FAST AXONAL TRANSPORT IN CORTICOSPINAL (CS) AXONS OF THE RAT. Daniel L. O'Donoghue¹, Elizabeth G. Lease and Jane M. Jacob. Dept. of Anatomical Sciences, University of Oklahoma HSC, Oklahoma City, OK 73190.

The axonal transport of proteins from the soma to the axon terminal is one of the most important functions of a neuron. In the peripheral nervous system (PNS), the fast transport rate of neurotransmitters and membranous organelles occurs at ~410 mm/d (Ochs, *J. Physiol.* 227:627, 1972). In this study, we directly measure the fast axonal transport rate in the longest axon tract in the central nervous system (CNS), the CS tract. Male Sprague-Dawley rats (4-10 wks old) were anesthetized with Chloroform and their body temperature maintained at 37°C. Intracortical microinjection of [³H]-proline was made into sensory-motor areas containing CS neurons. Rats were killed 3-5 hrs later and the CS tract removed, cut into consecutive 1 mm segments, the non-protein radioactivity removed, and the tissue solubilized. After liquid scintillation spectroscopy, transport profiles indicated that the fast transported wave of radiolabeled proteins moved at ~267 mm/d (n=9). Fast transport rates in adolescent animals (4 wks) were no different than those in 10 wk rats. These data are in agreement with previous studies indicating that transport rates in the CNS are slower than those in the PNS.

SYNAPTAPHYSIN AND SV2 ARE INCORPORATED INTO SYNAPTIC VESICLES VIA DIFFERENT ROUTES IN NGF-TREATED PC12 CELLS. J.-H. Tao-Cheng*. Lab. of Neurobiology, NINDS, NIH, Bethesda, MD 20892.

Transport and sorting of synaptic vesicle (SV)-associated proteins and divergence of SV and dense core granule (DCG) biogenesis have been explained by conflicting models. The present report characterizes the distribution of two such proteins, synaptophysin and SV2, by pre-embedding EM immunocytochemistry (ICC) in NGF-treated PC12 cells.

Two subcellular organelles had striking differences in ICC labeling: (1) DCG, the endocrine granules in PC12 cells, were intensely labeled for SV2 but only weakly for synaptophysin. Throughout the cell body and neurites, 60-80% of all DCG's were labeled for SV2, often with multiple grains of silver enhanced gold particles per DCG; while only 5-10% of DCG's were labeled for synaptophysin, and mostly with a single grain. (2) Pleomorphic, clear vesicles (~50-200 nm) in the shaft of the neurites were intensely labeled for synaptophysin, but minimally for SV2. These vesicles probably are in transit between the cell body and the terminals.

In contrast, in varicosities along the neurites and at neuritic terminals, two other organelles, (1) clusters of SV's and (2) irregular-shaped vesicles, most likely endosomes, were intensely labeled for both synaptophysin and SV2.

These results, combined with previous reports on SV and DCG biogenesis in PC12 cells, suggest that (a) the bulk of synaptophysin is transported through the neurites by way of pleomorphic vesicles, while the bulk of SV2 is transported by DCG's, (b) once they reach their functional destination, the neuritic terminals and the varicosities, both proteins are sorted into synaptic vesicles, probably through local vesicle membrane recycling and via endosomes.

RIBOSOMES BEARING SHORT GAP-43 NASCENT PEPTIDES BIND TO NUCLEAR AND MICROSOMAL SUBCELLULAR FRACTIONS. R. Moore-Batchelder, H. Pestana, and J. Denny*. Division of Life Sciences, Univ. of Texas at San Antonio, San Antonio, TX 78249.

We have transcribed a linearized pGEM3 vector containing a full-length GAP-43 cDNA insert and have translated the purified, uncapped mRNA *in vitro* using reticulocyte lysate and 35S-methionine. A nuclear fraction isolated from cultured PC12 cells and a microsomal fraction isolated from either PC12 cells or from canine pancreas were added to translation mixtures both co-translationally and post-translationally at 30°C. The canine microsomes were specifically rough microsomes. In the co-translational experiment fractions were present during a 1 hour translation that was subsequently blocked either with cycloheximide or puromycin/high salt. In the post-translational experiment fractions were incubated with mixtures for 1 hour after the translations had been blocked with cycloheximide. In all cases there was an enrichment of GAP-43 nascent peptides of molecular weight 22 kDa and below in high-speed Airfuge pellet fractions relative to all larger nascent peptides and full-length GAP-43 and also relative to pellets obtained from translation mixtures that did not receive any subcellular fraction. These results suggest that short GAP-43 nascent peptides are competent for interaction with membranes while longer peptides are not.

ARCHITECTURAL EDITING OF GABA RECEPTOR $\alpha 1$ AND $\beta 3$ SUBUNIT DETERMINE LOCALIZATION IN PC12 AND COS-7 CELLS. N.L. Peterson*, R. Salas and K.J. Angelides. Depts. Cell Biol. and Biochem., Baylor College of Med., Houston, TX 77030.

Several subunits and their isoforms have been identified encoding the γ -amino-butyric acid receptor (GABAR). Assembly of specific subunits leads to different pharmacological properties and cell surface localization. Despite the potential to assemble both homo- or heteromeric receptors in nonneuronal cells, there is emerging evidence that assembly and expression of GABAR subunits in neurons may be restricted. We have examined the sorting, cell surface expression, and localization of the $\alpha 1$ and $\beta 3$ GABAR subunits in PC12 and cos-7 cells for clues of how receptor assembly of specific GABAR subunits affects localization and membrane mobility in neurons. PC12 cells transfected with cDNA encoding the $\alpha 1$ subunit retain the $\alpha 1$ subunit in an intracellular compartment whereas PC12 cells transfected with cDNA encoding the $\beta 3$ subunit sort it to the plasma membrane and form clusters on both cell bodies and processes. After transfection of both $\alpha 1$ and $\beta 3$ in PC12 cells, both proteins are found on the cell surface co-localized in clusters. In contrast to oocytes and epithelial cells, neuron-like cells express at their plasma membranes a more restricted repertoire of GABAR complexes. Moreover, we show that the localization of GABAR in discrete domains can be conferred by the $\beta 3$ subunit. Cos-7 cells, used to study the intracellular localization at higher resolution, sort GABAR subunits similar to PC12 cells. The location of $\alpha 1$ in Cos-7 cells is consistent with an ER pattern suggesting that $\alpha 1$ may contain an ER retention signal. The $\beta 3$ subunit, able to redirect $\alpha 1$ from the intracellular compartment to the cell surface, was not able to rescue a truncated $\alpha 1$ containing only the first two transmembrane domains. These results suggest that neurons likely have a mechanism by which specific complexes are assembled, requiring all the transmembrane domains, and architecturally edited before expression on the cell surface. EFFICIENT EXPRESSION OF FOREIGN PROTEINS IN A HUMAN NEURONAL TISSUE CULTURE SYSTEM. D.G. Cook*, R.S. Turner, V.M.-Y. Lee, & R.W. Doms. Dept Pathology, Univ. of Pennsylvania, Philadelphia, PA 19104

There is a great deal of interest in studying the cell biology of neurons. However, because neuronal cell lines have been difficult to obtain and because large cultures of purified primary neurons are difficult to prepare, many standard cell biological studies have not been feasible. Furthermore, it is often difficult to express foreign genes in neurons. In an effort to overcome these disadvantages, we have characterized vaccinia virus (VV) directed expression of foreign proteins in the human cell line NTera 2 (NT2). Using retinoic acid, NT2 cells differentiate to form large, highly purified (>99%) cultures of mature neurons (NT2-N). We found that NT2-N cells are readily infected by recombinant VV, yet they maintain their polarized morphology and die at a rate matching non-infected controls. To determine if foreign proteins can be expressed and properly processed in NT2-N cells they were infected with recombinant VV expressing the HIV-1 glycoprotein, gp160, under the control of a VV early/late promoter. Gp160 was easily detected 1 to 4 days post-infection by western blot, pulse-labeling, and immunofluorescence microscopy. Gp160 was transported to the Golgi apparatus, efficiently cleaved into gp120 and gp41 subunits, and expressed on the cell surface. Despite efficient expression the infection was non-productive (virus particles were not produced).

The ability of NT2-N neurons to efficiently express foreign proteins, with few of the cytopathic responses normally associated with VV infection, provides a novel opportunity to address a wide array of cell biological questions in a system of pure human neurons.

ENTEROPATHOGENIC *ESCHERCHIA COLI* DEPOLARIZES INFECTED HELA CELLS. H. Yan, D.A. Mathers*, M.A. Stein and B.B. Finlay. Departments of Physiology and Biotechnology, University of British Columbia, Vancouver, BC Canada V6T 1Z3.

Enteropathogenic *Escherichia coli* (EPEC) causes severe diarrhea in children. EPEC attach intimately to gut intestinal epithelial cells and mediate cytoskeletal rearrangements characterized by the formation of pedestal-like structures and localized degeneration of brush border microvilli. We have applied patch-clamp methodology to characterize the electrical events occurring during the early interactions of EPEC with epithelial cells.

HeLa epithelial cells were incubated with EPEC strain E2348/69 for 30 minutes at 37°C and washed extensively. Cells with attached EPEC colonies were used for whole-cell recordings, made at 21-24°C with patch electrodes containing (in mM): 135 KCl 5 NaCl 1 MgCl₂, 10 HEPES and 3 EGTA. Cells were bathed in a saline containing (in mM): 135 NaCl 4 KCl 1.8 CaCl₂, 1 MgCl₂, 10 HEPES and 5 glucose. The mean resting membrane potential (V_{REST}) of HeLa cells infected with EPEC was -24 mV. Cells incubated with supernatant from EPEC cultures, normal culture medium, or an EPEC mutant (*efm14-2-1*) that does not mediate cytoskeletal rearrangements, showed mean V_{REST} values of about -48 mV. The results suggest that membrane depolarization is an important component of the pathogenicity of EPEC.

SORTING AND CELL SURFACE EXPRESSION OF NMDA RECEPTOR SUBUNITS

Biserka Mulac-Jericic, Lefkothea Karaviti* and Kimon J. Angelides, Department of Cell Biology, Baylor College of Medicine, Houston, Texas 77030.

Neurons are highly polarized cells with a complex morphology, where proteins are targeted to discrete regions of the cell surface. At synaptic spines N-methyl-D-aspartate receptors (NMDAR) appear to be clustered at high density mediating the events of glutamate neurotransmission. Molecular cloning has identified several cDNAs encoding NMDAR subunits NR1, NR2A, NR2B, NR2C and NR2D. The NR1 subunit is essential in a heterologous configuration for electrophysiological and pharmacological characteristics of NMDAR. There is emerging evidence that the subunit composition of ligand-gated channels can determine sorting and targeting of the receptors. In order to study how neurons process NMDAR we have transfected COS-7 and neuron-like PC12 cells with cDNA encoding the NR1 subunit. We have used subunit specific antibodies, indirect immunofluorescence, light and confocal microscopy to determine the cellular distribution of the NMDAR subunit in transfected cells. In COS-7 and PC12 cells NR1 is retained intracellularly when expressed alone. The majority of NR1 protein is sequestered in the Golgi compartment and a small fraction is found in lysosomal vesicles. When transfected cells were treated with Brefeldin A to dissociate the Golgi apparatus, NR1 was redistributed into the ER. The presence of NR1 beyond the ER in transfected COS-7 and neuron like PC12 cells strongly suggests that the protein is folded appropriately and has been processed into a transport-competent configuration. The NR1 subunit was not detected on the surface of these transfected cells by immunofluorescence or immunoblotting of biotinylated surface proteins. These results raise the possibility, that the presence of more than one subunit is necessary for cell surface delivery of functional NMDAR and expression of the complex is regulated by availability of the other NMDAR subunits. Supported by grant NS28072 of HFSP.

RNA SIGNALS AT THE CORTICAL SURFACE OF THE ISOLATED MAUTHNER CELL AXON. E. Koenig* and R. Martin. Dept. of Physiology, Univ. at Buffalo, Buffalo, NY 14214 and Electron Microscopy Section, Univ. of Ulm, Ulm, Germany.

Although RNA extracts derived from microscopic samples of isolated Mauthner (M) cell (C) axoplasm contain heavy and light cytoribosomal RNAs, comprising ~25% of the total RNA, ribosomes are not detected in randomly selected EM sections of this axon (Koenig (1979) *Brain Res.* 174:95). Either ribosomes may be in such low density that they are ordinarily overlooked, or they may be restricted in distribution to a particular region normally considered unlikely, such as the cortical domain near the plasma membrane. In order to investigate the latter possibility, we have examined the surface of isolated MC axoplasm, using (1) fluorescence microscopy to evaluate staining with YOYO-1, a fluorescent, cyanine nucleic acid-binding dye, and (2) electron spectroscopic imaging (ESI) to evaluate signals originating from polyphosphates characteristic of ribosomes. YOYO-1 staining of the MC axon shows a complex pattern of irregular strand-like axially oriented arrays on the surface containing strongly fluorescent ribonuclease-sensitive puncta. In preliminary ESI analysis, crazing thin sections of the cortical surface of isolated MC axons show areas exhibiting intense phosphorus signals characteristic of ribosomes, embedded in a homogenous "ribbon-like" structure. These areas, however, are encountered infrequently, which may reflect sampling problems at the ultrastructural level. Subaxolemmal ribosomes suggests a potential link between the actin-based cortical matrix and translational machinery. Supported in part by BNS 9010251 from NSF.

NADPH-DIAPHORASE HISTOCHEMISTRY OF RAT CHOROID PLEXUS. A. Chodobski*, J. Szymdynger-Chodobska, P.R. Monfils, A.Y.-J. Lin, M.P. Rahman, and C.E. Johanson. Program in Neurosurgery, Department of Clinical Neurosciences and Central Research Laboratory, Brown University/R.I. Hospital, Providence, RI 02903.

NADPH-diaphorase (NADPH-d) has been frequently colocalized with neuronal isoform of nitric oxide synthase (NOS), a synthetic enzyme for nitric oxide (NO), and is, therefore, considered as a histochemical marker for the latter enzyme. In the present study, we demonstrate the colocalization of NADPH-d-positive staining with NOS in rat choroid plexus (see accompanying abstract by J. Szymdynger-Chodobska et al.). Rats were perfused transcardially with 4% paraformaldehyde and brains were postfixed for 4 h at 4 °C. Parts of the choroidal tissue were dissected out and incubated at 37 °C for 3 h in PBS (pH 7.6) containing 0.1 mg/ml of nitro blue tetrazolium and 1 mg/kg of NADPH. Triton X-100 was added (0.6%) to improve tissue penetration. NADPH-d-positive nerve fibers were found to accompany anterior choroidal artery and its branches, as well as smaller arteries within the choroidal stroma. Choroidal venules and veins were devoid of NADPH-d staining; however, larger veins draining blood from the inferior part of the choroid plexus, proximal to the basal vein, had NADPH-d-positive innervation. Endothelial cells were stained as well. In addition, a deposition of the reaction product (formazan) was found in the cytosol of choroidal epithelial cells, with nuclei being free of staining. In conclusion, NADPH-d was shown to be colocalized with NOS in the choroid plexus. The presence of NADPH-d in different choroidal cell types suggests the multiple NO-mediated regulatory mechanisms in choroidal tissue. Supported by NIH Grant NS 27601.

OSMOTIC OPENING OF BLOOD-BRAIN BARRIER TO ENDOGENOUS ALBUMIN. A.W. Vorbrodt, D.H. Dobrogowska, and A.S. Lossinsky*. NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Early changes leading to the opening of the blood-brain barrier (BBB) to endogenous albumin were studied using a new quantitative immunocytochemical procedure. Hyperosmolar L(+)-arabinoxyl solution (1.8M) was infused into carotid arteries of rats which were killed 1, 5 and 30 min afterwards. Brain samples were immersion-fixed and embedded at low temperature in Lowicryl K4M. Ultrathin sections were exposed to anti-rat albumin antiserum followed by protein A-gold. The density of immunosignals (gold particles per μm^2) was recorded over four compartments: vascular lumen, endothelial cells (ECs), subendothelial space including basal lamina (BL), and the adjacent neuropil. The labelling density of the vessel lumen was considered to represent 100% of the circulating albumin. Morphometric and quantitative analysis indicated that in control animals, only 0.4-0.6% of the circulating albumin appears in the subendothelial space, whereas as soon as 1 min after infusion, this value increases to 3% followed by a further increase to 25% and 56% after 5 and 30 min respectively. The main routes of albumin escape are through the damaged ECs cytoplasm (including vesicles and penetrating indentations) rather than through modified interendothelial junctions. A slow increase of immunosignals in the adjacent neuropil suggests that the BL represents a serious obstacle for escaping albumin which seems to get trapped in this structure. (Supported by the National Institute on Aging, grant R01-AG 10279-03).

GLYCATION INCREASES THE PERMEABILITY OF PROTEINS ACROSS THE BLOOD NERVE AND BLOOD BRAIN BARRIERS. Joseph F. Poduslo*, Geoffrey L. Curran. Molecular Neurobiology Lab, Mayo Foundation, Rochester, MN 55905.

We have demonstrated increased permeability across the blood nerve barrier (BNB) of albumin after glycation with D-glucose (PNAS 89 (1992) 2218). The generality of this observation was evaluated by measuring the permeability coefficient-surface area product (PS) after correction for the residual plasma volume (V_p) across the BNB, as well as the blood brain barrier (BBB), for nerve growth factor (NGF) and human IgG after *in vitro* glycation with D-glucose, using an i.v. bolus injection technique in the cannulated brachial vein and artery of normal adult rats. Glycated proteins (gNGF and gIgG) had significantly decreased circulating plasma half-lives compared to the non-glycated proteins. The PS across the BNB obtained for gNGF was significantly increased compared to NGF with a 2.0 fold increase observed after 8 weeks of glycation and a 5.1 fold increase at 21 weeks of glycation. The V_p measurement for NGF and gNGF across the BNB was not significantly different at 8 weeks of glycation but was 1.3 fold greater at 21 weeks of glycation. The PS across the BBB for gNGF was 2 fold greater than NGF with a glycation time of 8 weeks and 3.2-3.6 fold greater with a glycation time of 21 weeks for six different brain regions. No changes were observed in the V_p for any of the brain regions for gNGF compared to NGF. The PS across the BNB for gIgG compared to IgG was significantly greater with a 4.1 fold relative increase. The PS across the BBB for gIgG ranged from a 2.8 fold increase for the thalamus to a 5.1 fold increase for the caudate putamen when compared to IgG. No significant differences were observed for the V_p values. These data demonstrate that glycation can enhance the permeability across the BNB and BBB of proteins with widely varying M_r and function. Since the glycation of NGF does not appear to affect its neurotrophic activity, systemic deliver of gNGF might be useful for treating a variety of neurodegenerative diseases. Similarly, the glycation of immunoglobulins might be a convenient procedure for delivery of a variety of antigens into the nervous system. NS14304

IMMUNOHISTOCHEMICAL LOCALIZATION OF NITRIC OXIDE SYNTHASE IN RAT CHOROID PLEXUS. J. Szymdynger-Chodobska*, A. Chodobski, A.Y.-J. Lin, M.P. Rahman, B. Mayer, P.R. Monfils, and C.E. Johanson. Program Neurosurg., Dept. Clin. Neurosci. and Central Res. Lab., Brown Univ./R.I. Hospital, Providence, RI 02903, USA, and Inst. Pharmacol. Toxicol., Univ. Graz, A-8010 Graz, Austria.

We have previously shown that nitric oxide (NO) mediates some hemodynamic actions of angiotensin II (AII) in the choroid plexus. In the present study, we demonstrate by immunohistochemistry the presence of NO synthase (NOS), a synthetic enzyme for NO, in rat choroidal tissue. Anti-NOS antibody was raised in rabbits against purified porcine brain NOS. It recognizes neuronal NOS in several mammalian species, including the rat, and does not cross-react with inducible NOS. Rats were perfused transcardially with 4% paraformaldehyde and brains were postfixed for 4 h at 4 °C. Parts of the choroidal tissue were dissected out and incubated for 68 h at 4 °C with primary antibodies (1:2500). The procedures which followed were performed at room temperature. Biotinylated donkey anti-rabbit IgG was used to detect primary antibody, followed by incubation with streptavidin-biotin-peroxidase complex. To obtain color reaction, diaminobenzidine was used. NOS-positive nerve fibers were found to be associated with the anterior choroidal artery and its branches, as well as with smaller arteries located within the choroidal stroma. Choroidal veins and venules were devoid of NOS-containing innervation. Endothelial cells were not stained, indicating that the antibody does not cross-react with endothelial form of NOS. Choroidal epithelial cells expressed intense, distinctive staining of their cytosol. These results provide anatomical evidence supporting the physiological observations of AII interactions with NO synthesis in the choroid plexus. Supported by NIH Grant NS 27601 and by research funds from the R.I. Hospital.

EFFECTS OF HYPERTONIC SALINE INFUSION ON CEREBRAL PERFUSION IN NORMONATREMIC AND HYPONATREMIC RATS.

S. Adler, D. Williams and J.G. Verbalis*. University of Pittsburgh School of Medicine and Carnegie Mellon University, Pittsburgh, PA 15213.

Rapid increases in plasma sodium (P_{Na}) and osmolality can disrupt the blood brain barrier (BBB). Recent studies from our laboratories have shown that this occurs at lower thresholds in hyponatremic (HN) than in normonatremic (NN) rats. The present experiments studied the effect of similar increases in P_{Na} on cerebral perfusion in HN and NN rats. NN (n=6), acute HN (n=8), and chronic HN (n=10) rats received iv infusions of either 700 mM or 500 mM NaCl. Both cortical and white matter perfusion were measured by arterial spin tagging in a 4.7 Tesla NMR magnet before and at 30, 60, and 90 min during the infusion. P_{Na} increased 22, 20, and 23 mmol/L, respectively, and arterial pressures remained constant throughout. Arterial pCO_2 rose slightly in all groups (from 61 to 63 in NN, 57 to 64 in acute HN, and 47 to 48 mm Hg in chronic HN). Cerebral perfusion increased significantly in both regions in each group, but the increases occurred more rapidly and were greater in the HN rats at all times. For example, by 60 min perfusion had increased in cortex and white matter by 36% and 27% in NN, by 62% and 56% in acute HN, and by 60% and 51% in chronic HN. Because local increases in brain perfusion can affect the BBB, the increased perfusion produced by hypertonic NaCl infusions may contribute to the BBB disruption caused by the induced hyperosmolality, and both of these factors may therefore participate in the demyelination that frequently accompanies overly rapid correction of hyponatremia.

SELECTIVE OPENING OF THE BLOOD-TUMOR BARRIER: ROLE FOR RMP-7 IN CHEMOTHERAPY. T. Inamura, T. Nomura, P.J. Elliott*, R.T. Bartus & K.L. Black. Brain Res. Inst., UCLA Medical Center, Los Angeles, CA 90024 & Alkermes Inc., 64 Sidney St., Cambridge, MA 02139.

Current treatment of brain tumors is limited by the presence of cerebral capillary endothelial cells within the tumor tissue. Such cells have tight junctions which comprise the blood-tumor barrier. Enhanced drug delivery to tumors has been achieved previously by opening these junctions with hyperosmotic agents. However, such regimens have also allowed cytotoxic drugs access to healthy tissue. Recently, we have developed a bradykinin analog, RMP-7, which has been shown to selectively open tight junctions between cerebral endothelial cells.

In the current study, female Wistar rats (170-210g) with striatal RG2 tumors were given a labeled chemotherapeutic agent carboplatin, along with a 15min infusion (3ml/h) of RMP-7 (1ug/kg/min). Using quantitative autoradiography we found that RMP-7 produced a significant ($p<0.01$) two fold increase in carboplatin in the tumor, compared to vehicle-treated rats. No differences between RMP-7 and vehicle-treated groups were found in any other brain region examined. Similar data was obtained with other anti-tumor agents. Furthermore, treatment of other tumor-bearing rats with RMP-7 and chemotherapeutic drugs prolonged the survival time of such animals.

Thus, RMP-7 has the potential to be an adjunct to current neuro-oncology therapy due to (1) its selectivity for tumor cells over normal healthy tissue and (2) the probability that it may reduce the cytotoxic side-effect profile of anti-tumor drugs, by allowing lower therapeutic doses to maintain current (or greater) efficacy.

THE BRADYKININ AGONIST RMP-7 ENHANCES THE PERMEABILITY OF THE BLOOD-BRAIN BARRIER: EVIDENCE FROM ELECTRON MICROSCOPY EXPERIMENTS. E. Sanovich¹, P.M. Friden², R.T. Bartus² and M. Brightman¹. Lab. of Neurobiology, NINDS, NIH, Bethesda, MD 20892¹ and Alkermes, Inc., 64 Sidney Street, Cambridge, MA 02139².

RMP-7, a novel bradykinin agonist, was tested for its ability to open the blood-brain barrier (BBB). Balb C mice were infused for 2 minutes via the jugular vein with La^{3+} (MW 139), in the form of LaCl_3 (5 mM), with or without RMP-7 (5 $\mu\text{g/kg}$). After 10 minutes, the mice were fixed with aldehydes and the brains processed for electron microscopy, so as to trace the pathway opened by RMP-7. Midbrain and cerebral cortex were examined for the presence of La^{3+} in tight junctions (TJ), basal lamina (BL) and perivascular spaces (PVS).

In control animals, La^{3+} did not penetrate the PVS and only occasionally labeled the BL. In contrast, the BL was labeled in more vessels and the PVS around many vessels were penetrated in the RMP-7 group. In some RMP-7 specimens, La^{3+} penetrated deep into the neuropil surrounding the vessel. These observations indicate that RMP-7 permeabilizes the BBB to La^{3+} by an intercellular route. Dextran (MW 3,000) appears to follow the same route. Is transcytosis involved as well?

Labeling of endocytic vesicles by La^{3+} was no greater in the RMP-7-treated mice; transcytosis, therefore, is not responsible for the movement of La^{3+} across the endothelium. In contrast, the number of TJ labeled and the depth of penetration through series of junctions were greater in RMP-7 mice than controls. Thus, RMP-7 may open the barrier by way of TJ. Whether the TJ is the exclusive pathway is being further examined.

CLEARANCE OF ACIDIC AMINO ACIDS FROM CEREBROSPINAL FLUID, USING VENTRICULO-CISTERNAL PERFUSION IN THE ANAESTHETIZED RAT, A DEVELOPMENTAL STUDY. H. Al-Sarraf, J.E. Preston^{*}, M.B. Segal. Sherrington School of Physiology, UMDS, London SE1 7EH, UK.

The acidic amino acids, aspartate and glutamate, are excitatory neurotransmitters in CNS. The clearance of this group of amino acids from cerebrospinal fluid of adult and neonatal (7-day old) rats was investigated. Ventriculo-cisternal perfusions with ^{14}C -amino acids and ^3H -dextran were carried out for up to 90 min. Uptake of the amino acid by the whole brain was measured and the loss to blood was calculated (Davson *et al*, 1982).

	Lost (A)	Brain(B)	Blood (A-B)
Neonate	22.8 \pm 4.8	10.1 \pm 3.0	12.7 \pm 2.1
Adult	64.7 \pm 7.4	7.1 \pm 3.32	57.6 \pm 4.5

The percentage loss of ^{14}C -glutamate from the perfusion fluid during 90 min (A), Loss to brain (B), and to blood (A-B). Values are mean \pm S.E., (n=2-4).

Aspartate followed a similar pattern to glutamate, indicating a greater acidic amino acid efflux from CSF to blood in adult than in neonatal rats. However, there was no significant change in the loss to brain tissue with age ($p>0.05$).

G_s AND G_i LEVELS ARE ALTERED BY AGING IN RAT BRAIN MICROVESSELS. P. Moore and P. Grammas^{*}. Dept. of Pathology, Univ. of Oklahoma HSC, Oklahoma City, OK 73104

Guanine nucleotide-binding regulatory proteins (G proteins) play a central role in receptor-mediated signal transduction. These membrane proteins couple activated receptors to messenger enzymes, including adenylyl cyclase. In aging, altered response to agonists that elevate cAMP may reflect abnormal receptor-effector coupling. The objective of this study was to examine G protein expression in the cerebral microvasculature of aged rats. Microvessels were isolated from the cerebral cortices of young adult (1-3 month) and aged (>18 month) rats and membranes subjected to ADP-ribosylation. Cholera toxin and pertussis toxin were used to identify G_s and G_i respectively, and the two isoforms quantified by autoradiography of SDS-PAGE gels. The results indicated that the level of G_{sa} increased significantly ($P<0.01$) in microvessels from aged rats (65%) while the level of G_{sa} was lower (40%) in aged animals. These results demonstrate differential changes in G protein expression in aged animals and suggest that alterations in signal coupling may underlie some age-related alterations of the blood-brain barrier. (Supported by NS grant 30457, OCAST and the Glenn Foundation).

ASSESSMENT OF BLOOD-BRAIN BARRIER CHOLINE TRANSPORT USING THE *IN SITU* BRAIN PERFUSION TECHNIQUE. DAVID D. ALLEN^{*}. Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

Choline is an important constituent of membrane phospholipids and is a precursor to the neurotransmitter acetylcholine. Previous *in vivo* studies have found only a single low affinity transport system (K_m 200-500 μM) at the blood-brain barrier (BBB), whereas *in vitro* studies using isolated capillaries or cultured endothelial cells have found only a high affinity system (K_m 2-20 μM) or a mixture of the two. To address this discrepancy, the concentration dependence of unidirectional choline transport into brain was determined using the *in situ* rat brain perfusion technique (Takasato *et al*, 1984). Brains were perfused for 60 sec with physiological saline containing 0.0125 μM ^3H -choline and 0-20 mM unlabeled choline. At the end of perfusion, brains received a 15 sec wash with tracer-free fluid to remove extravascular isotope. Under these conditions, the concentration dependence of choline uptake was best described by a model with a single saturable system ($V_{max} = 3.2$ nmol/min/g, $K_m = 39$ μM) and a small nonsaturable uptake component ($K_D = 9.9 \times 10^{-5}$ ml/sec/g). Saturable choline uptake was hemicholinium sensitive and sodium dependent. In summary, the results suggest that saturable choline uptake into brain is mediated by a single, rather high affinity system with a K_m consistent with previous *in vitro* studies ($K_m < 50$ μM). As the K_m is on the same order as plasma choline concentration (5-20 μM), brain choline uptake may be subject to transport saturation and modulation under different physiologic conditions.

DIFFERENTIAL EXPRESSION OF α -ACTIN mRNA AND IMMUNOREACTIVE PROTEIN IN BRAIN MICROVASCULAR PERICYTES AND SMOOTH MUSCLE CELLS. R. J. Boado^{*} and W. M. Pardridge. Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Hypertension has been linked to opening of the blood-brain barrier and may be related to the expression of the smooth muscle (sm) α -actin gene in contractile cells at the brain microvasculature. However, the cellular origin (i.e., endothelial cells, pericytes, sm cells) of the α -actin mRNA in the brain microvasculature is not clearly identified. Therefore, we investigated the abundance of actin mRNA by Northern blot analysis. The relative abundance of the α -actin 1.7 Kb transcript was: cultured pericytes-endothelial primaries (which contain both endothelial cells and pericytes) = freshly isolated microvessels. The α -actin mRNA was absent in a cloned bovine brain endothelial cell line. All samples showed the characteristic 2.1 Kb transcript corresponding to cytoplasmic β and γ isoform mRNA. The cellular distribution of the sm α -actin immunoreactive (IR) protein was studied by immunocytochemistry in cytosol/ isolated brain microvessels with a monoclonal antibody directed to the sm α -isoactin. This antibody reacted strongly with pre-capillary arterioles of microvessels, whereas no immunostaining was observed in either endothelial cells or in pericytes. Conclusion, the α -actin mRNA is expressed in cultured brain microvascular pericytes and in endothelial primaries, but the immunoreactive α -actin protein is not expressed in brain microvascular pericytes *in vivo*. These data suggest that either (a) the α -actin gene is induced in cultured brain pericytes, or (b) the α -actin mRNA in pericytes *in vivo* is subject to translational repression resulting in no detectable α -actin protein under normal physiologic conditions.

548.12

POSSIBLE DETERMINANTS OF VESSEL PHENOTYPES IN MUSCLE GRAFTED TO BRAIN. S. Naito, L. Chang and M. Brightman^{*}. LN., NIH., Bethesda, MD. 20892.

The ability to determine a vessel's phenotype is decreased in adult tissue; some vessels in mature skeletal muscle grafted to mature choroid plexus are of the choroidal, fenestrated (FV) type rather than exclusively of the continuous (CV) muscle type. It is reported here that when the graft is from an E14 fetal rat, about 80% of the vessels are CV, like those of muscle and brain. Only a very few CV can be immunostained for endothelial barrier antigen and are, accordingly, brain derived. By E16, about 70% are FV, like those of host choroid plexus. Thus, between E14 and E16, a purported "conversion" factor that converts invading FV to CV, is diminished. To see whether the FV are extensions of choroidal blood vessels or converted graft vessels, fetal tissue was labeled with bromo-deoxyuridine. VEGF (vascular endothelial growth factor) may also be a vessel type determinant. It is known that VEGF is associated with FV and that its mRNA is in the choroid plexus. By *in situ* hybridization, we find that mRNA to VEGF receptors is in choroid plexus but not in the graft. It is likely, therefore, that the tissue conversion factor, rather than VEGF, determines a vessel's phenotype during regeneration of blood vessels supplying muscle grafts.

ACIDIFICATION DECREASES $[Ca]^{2+}$ IN RAT BRAIN CORTICAL ENDOTHELIAL CELLS D.Freyer, M.Weih, S.Weikert, J.G.Schulz, A.Villringer, U.Dimagl, Dept. of Neurology, Humboldt University Berlin, FRG.

The brain extracellular and intracellular pH changes under various physiological (f.e. neuronal activation) and pathophysiological (f.e. ischemia) conditions. We investigated whether the extra- or intracellular pH affects $[Ca]^{2+}$ in rat brain cortical endothelial cells (DIV 0-14), which might link pH changes to $[Ca]^{2+}$ dependent mechanisms. For imaging of intracellular pH and $[Ca]^{2+}$ we used a confocal laser scanning microscope (Biorad MRC 600) and the fluorescent dyes BCECF-AM and FLUO-3-AM. Acidification of extracellular fluid (pH 7.4 to 6.8) led to a similar decrease of $[Ca]^{2+}$ but smaller decrease of pH than intracellular acidosis induced by the NH_4^+ prepulse technique. The results are summarized in the table:

	FLUO-3 ΔF	BCECF ΔF
means \pm S.D.		
* = p < 0,05 cp. to control		
Extracellular acidosis	-25,3% \pm 10,3% *	-17,4% \pm 13,1% *
	n=37 cells, 2 preparations	n=18 cells, 2 preparations
Intracellular acidosis	-29,3% \pm 11,5% *	-26% \pm 15,7% *
	n=13 cells, 1 preparation	n=20 cells, 3 preparations

We conclude that both extracellular and intracellular acidosis are capable of influencing intracellular free calcium in cortical endothelial cells and may thereby affect subsequent release of vasoactive substances like prostaglandines or nitric oxide. Supported by the DFG (Di 454-4/2).

548.15

BLOOD-BRAIN BARRIER PERMEATION AND *IN VIVO* BRAIN RECEPTOR OCCUPANCY OF THE CALCIUM CHANNEL BLOCKER, SNX-111 (SYNTHETIC ω -CONOPEPTIDE MVIIA). K. Gohil, T.J. Abbruscato, Jr., T. Singh, D. Silva, G. Miljanich, R. Newcomb, L. Nadasdi, and T.P. Davis*, NEUREX Corporation, Menlo Park, CA 94025 and Dept. of Pharmacology, Univ. of Arizona, College of Medicine Tucson, AZ 85724.

The highly charged 25 amino acid peptide, SNX-111, is a potent blocker of N-type calcium channels and is neuroprotective in brain ischemia models when administered i.v. (e.g., ~1mg/kg). The blood-brain barrier (BBB) permeability of SNX-111 and its closely related Met¹²-norLeu¹² analog, SNX-194, was assessed with three models: 1) Permeation through brain capillary endothelium using cultured brain microvessel endothelial cells (BMEC; Banks, et al., *Peptides* 13 (1992)). 2) Amounts in rat brain *in vivo* using reversed phase HPLC after i.v. injection of ¹²⁵I-SNX-111, cardiac perfusion, and solid phase extraction. 3) Brain receptor site occupancy using receptor autoradiography in brain sections from naive rats or rats receiving transient four-vessel occlusion (4VO) following i.v. administration of SNX-111. Permeability of SNX-194 through the BMEC was 0.0007cm/min. *In vivo* brain amounts of SNX-111 were stable between 10 to 20 minutes after injection (0.0032 \pm 0.0009% (cortex) and 0.0062 \pm 0.0029% (midbrain) of injected peptide/g tissue). Brain amounts decay to <0.001%/g tissue 1-2hr after i.v. injection. Assuming a homogeneous distribution these data translate to a maximal brain concentration of 30-50nM after i.v. injection of 10mg/kg. The *in vitro* and *in vivo* data are consistent with the expected BBB permeation for a peptide the size of SNX-111. In brain sections, the most pronounced inhibition of binding of ¹²⁵I-SNX-111 by the injected SNX-111 was in hypothalamus, septum, medial striatum, and ventral hippocampus in 4VO-treated brains. The occupancy of receptor sites after 4VO may be related to the neuroprotective efficacy of SNX-111. In conclusion, despite low BBB permeability, SNX-111 is neuroprotective at moderate i.v. doses due to its high affinity for N-type calcium channels.

THE UPTAKE OF DOPAMINE BY THE CAUDATE NUCLEUS OF PERFUSED GUINEA PIG BRAIN. C.L. Martel*, J.B. Mackic, L.K. Klaidman, M.H. Weiss, J.G. McComb, J.D. Adams and B.V. Zlokovic. Depts. Neurol. Surg. and Pharmacol. and Divn. Neurosurg. CHLA, USC Sch. Med., Los Angeles, CA 90033.

Our studies in the guinea pig, *Cavia porcellus*, have demonstrated that, contrary to the conclusions drawn from studies in rats, [³H]-dopamine ([³H]-DA) does enter the brain by a specific, saturable uptake mechanism which is independent of the enzyme monoamine oxidase-B (MAO-B) and is inhibited by several D₁ and D₂ DA-receptor antagonists. In order to determine the molecular form of DA uptake, a high pressure liquid chromatography analysis was performed according to the method of Kalivas [J. Pharm. Exp. Ther. (1985) 235: 544-550] on the brain tissue of control guinea pigs and guinea pigs perfused for ten minutes with 10 μ M DA. The levels of DA and its two main metabolites, 3, 4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) were quantitated in several different brain regions. In the caudate nucleus of the DA-perfused animals, there was an increase in the DA concentration of more than 75% from control levels, but there was no change in the levels of HVA or DOPAC. In non-striatal brain tissue, there was no significant change in the concentrations of DA or either of its main metabolites. This suggests that DA does indeed cross the blood-brain barrier intact, with minimal metabolic breakdown, but in a regionally selective manner. (Supported by TRDRP grant 2RT0071).

EFFECT OF ENDOTHELIN ON ATPase ACTIVITY IN CEREBRAL CAPILLARY ENDOTHELIUM. N. Kawai, T. Yamamoto, H. Yamamoto, R.M. McCarron and M. Spatz*, Stroke Branch, NINDS, NIH, Bethesda, MD 20892.

Capillary ATPase activity has been thought to control the homeostasis of water-electrolytes in the brain. Endothelin-1 (ET-1) has recently been implicated in changes of blood-brain barrier (BBB) permeability. This reports describes receptor (ET_A)-mediated stimulation of ouabain-sensitive (OS) and ouabain-insensitive (OI) ⁸⁶Rb⁺ uptake (as a measure of Na⁺ K⁺ ATPase activity) by ET-1 and ET-3 in cultured rat brain capillary endothelial cells (BCEC). The uptake of ⁸⁶Rb⁺ (0.2 μ Ci/well) was determined in confluent BCEC (grown in 96-microwell plates) incubated in M199 with HEPES for 5 min at room temperature. A concentration-dependent increase of ⁸⁶Rb⁺ uptake induced by ET-1 or ET-3 [EC₅₀ = 0.73 \pm 0.17 (6) and 12.89 \pm 3.69 (6), respectively] was inhibited by the ET_A receptor antagonist (BQ123) but not by the ET_B receptor antagonist (IRL 1038). Ouabain (ATPase inhibitor) and bumetanide (Na⁺ K⁺ Cl⁻ cotransport inhibitor) decreased ET-1-stimulated ⁸⁶Rb⁺ uptake into BCEC by 35% and 65%, respectively. Complete inhibition was seen with both of these agents. Similar results were observed with PMA, a PKC agonist. Amelioride [5-(N-ethyl-N-isopropyl)], inhibitor of the Na⁺ H⁺ antiporter, decreased both the OS and OI ATPase induced by ET-1, suggesting a linkage of the Na⁺ H⁺ exchanger with Na⁺ K⁺ ATPase and Na⁺ K⁺ Cl⁻ cotransport systems. The inhibition of ET-1-stimulated OS and OI ⁸⁶Rb⁺ uptake with staurosporin (PKC antagonist) indicates that ET-1 induced ATPase activity is mediated by PKC. These results suggest that the effect of ET-1 on capillary OS and OI Na⁺ K⁺ Cl⁻ systems may play a role in water-electrolyte disturbances in brain injury.

IN VITRO AND *IN VIVO* BLOOD-BRAIN BARRIER PERMEABILITY OF MU SELECTIVE, OPIOID ANTAGONIST CTAP AND AGONISTS DPDPE AND BIPHALIN: EVIDENCE FOR IMPROVED PERMEABILITY BY HALOGENATION. T.J. Abbruscato, S.J. Weber*, V.J. Hruby, and T.P. Davis, Departments of Pharmacology and Chemistry, University of Arizona, Tucson, AZ 85724, OREAD Laboratories, Inc., Lawrence, KS 66047

The enhancing effect of halogenation on blood-brain barrier (BBB) permeability was investigated for three receptor selective, opioid peptide ligands: CTAP (D-F-C-Y-D-W-R-T-Pen-T), DPDPE (Y-D-Pen-G-F-D-Pen), and biphalin ((Y-D-A-G-F-NH)₂). A significantly (P<0.01) greater percent of the halogenated peptide compounds reached the perfused mouse brain after 30, 60, 120min by both I.P. and I.V. administration when compared to non-halogenated parent. *In vitro* bovine brain microvessel endothelial cells (BMEC) were used to model the BBB. Permeability coefficients were calculated from passage across the BMEC confluent monolayers. A positive correlation was apparent between *in vitro* BMEC and *in vivo* distribution for halogenated CTAP and DPDPE. Nearly a two fold increase in the permeability coefficient was observed for the halogenated analogues of CTAP, DPDPE, and biphalin. (see data below).

Peptide Analogue	Permeability Coeff.	LP. % Inj	I.V. % Inj
CTAP	4.55 \pm 2.6	0.023	-----
[p-Ci Phe] CTAP	7.60 \pm 2.0	0.036	-----
DPDPE	49.24 \pm 2.18	-----	0.064
[p-Ci Phe ⁴] DPDPE	82.76 \pm 3.46	-----	0.178
Biphalin	55.00 \pm 4.98	-----	0.089
[p-Ci Phe ⁴] Biphalin	92.00 \pm 5.88	-----	-----

These data show that halogenation leads to dramatic improvement in BBB penetration of three structurally distinct opioid ligands. Supported by NIDA #DA-06284

THYROID HORMONES EXPRESS HIGH AFFINITY FOR BOTH THE THYROID HORMONE AND LARGE NEUTRAL AMINO ACID TRANSPORTERS OF THE BLOOD-BRAIN BARRIER. M. Hokari and Q.R. Smith*. Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda MD 20892.

Thyroid hormones are taken up into brain by a saturable transporter at the blood-brain barrier (BBB). This transporter has been suggested to be distinct from that for large neutral amino acids (System L), even though both sets of compounds show marked structural similarities. To examine this further, the kinetics of thyroid hormone and amino acid uptake into brain were examined simultaneously using the *in situ* rat brain perfusion technique (Takasato et al., 1984). Brains were perfused for 10-30 s using physiologic saline containing L-[¹²⁵I]T₃, L-[¹⁴C]leucine and 0.1 mM cold compound. Permeability-area products were calculated from the quantity of tracer accumulated within the nervous system by the end of the perfusion. The results demonstrated that T₃ is taken up into brain with high affinity (V_{max} = 0.16 \pm 0.02 nmol/min/g, K_m = 0.26 \pm 0.03 μ M) by a saturable mechanism that is sensitive to triiodothyroacetic acid (10 μ M) but not to BCH (1 mM) - the defining substrate of the L System. T₃ was also a high affinity inhibitor of the BBB large neutral amino acid transporter (K_i = 1.0 \pm 0.1 μ M). At 30 μ M, T₃ inhibited [¹⁴C]leucine uptake by >95%. The results indicate that [¹²⁵I]T₃ binds with high affinity to both the thyroid hormone and large neutral amino acid transport systems and may be of use in identifying and labeling the carrier proteins.

VIRAL INDUCED DEMYELINATION: A ROLE FOR THE BLOOD-BRAIN BARRIER?

Egleton R.D., Dawson J., Butt A.M., Amor S* & Segal M.B*
Physiology and *Immunology, UMDS, London SE1 7EH, U.K.

In multiple sclerosis (MS), dysfunction of the blood-brain barrier (BBB) has been observed, and may be major factor in this disease. Using the Semliki Forest virus (SFV) model of MS in the Balb-C mouse, we have measured the permeability of the BBB to ^{14}C mannitol during the course of the infection stage, in controls and following treatment with cimetidine, a histamine H_2 antagonist.

SFV animals were perfused at 3, 5 and 10 days post inoculation (PID) with a Ringer/albumin solution containing ^{14}C mannitol and the unidirectional transfer coefficient (Kin) for mannitol calculated

	SFV PID 5	SFV + Cimetidine
Brain	+ 74.20 %	+ 53.50 %
Spinal cord	+ 40.84 %	+ 1.35 % *

Table 1 The % increase of mannitol permeability across the BBB for PID5 and cimetidine treated animals compared to control (* $p < 0.001$, Students t-test compared to PID5).

The histamine H_2 antagonist cimetidine significantly reduced the permeability changes at PID 5. The opening of the BBB as indicated by the increase in the Kin for mannitol corresponds to the viremia and accumulation of virus in the brain as seen by others.

ENDONEURIAL REGULATION OF PERINEURIAL PERMEABILITY: EVIDENCE FROM PARTIAL NERVE TRANSECTION STUDIES. ¹J. R. Steiner, ²A. Weerasuriya and ³M. E. Michel. ¹Division of Basic Sciences, Mercer Univ. School of Medicine, Macon, GA 31207, and ²NINDS, NIH, Bethesda, MD 20892.

The monofascicular mid-thigh portion of the frog sciatic nerve has major contributions from the 7th, 8th and 9th spinal roots. Comparisons of compound action potentials reveal that each of these roots contributes about 30% of the myelinated fibers in the sciatic nerve. The effect of transecting either the 8th, or 8th and 9th, or all three roots on perineurial permeability was examined using an

in vitro technique (Brain Research, 173, 503-511, 1979); the index of permeability was ^{22}Na . The results are graphed as mean \pm S.E. (n = 5 or 6). The initial increase in permeability is probably associated with the clearing of myelin debris from the endoneurium, and the later increase to the absence of fibers in the underlying endoneurium. It is difficult to reconcile these data with the notion that the permeability of the blood-nerve interface is altered in an all or none fashion with an increase in its permeability being considered as a breakdown of its barrier properties. The data are more consistent with the prospect that perineurial permeability is regulated in a graded manner by endoneurial components, which release factors that affect the rate of turnover of perineurial tight junctions (NIH RO1 NS30197).

PRESYNAPTIC MECHANISMS IV

549.1

ARE LONG LATENCY RECURRENT EPSPS RECORDED IN THE IMMATURE HIPPOCAMPUS MONOSYNAPTIC EVENTS? K. Smith and J.W. Swann. The Cain Foundation Laboratories, Department of Pediatrics, Division of Neuroscience, Baylor College of Medicine, Houston, TX, 77030.

The immature hippocampus has a great propensity for generating electrographic seizures. One possible explanation could be that there is an age dependent difference in the recurrent excitatory network. Our laboratory, has been investigating the local network through paired intracellular recording from immature CA_3 neurons. Minislices of CA_3 from immature (9 - 14 days old) rats were bathed in 1.7 mM penicillin to block inhibition. In 152 neuronal pairs (304 cells) 8% revealed monosynaptic interactions. The onset of the epsps ranged from 0.7 - 3.3 msec. Many of our epsps had latencies longer than 2 msec. However, when compared with polysynaptic epsps; they did not fluctuate in latency, their durations were short, they followed one for one at high presynaptic spike frequencies, and the probability of transmission was high. We therefore attempted to determine why some monosynaptic epsps had long latencies. We hypothesized that the long latencies were due to slow conduction velocities in CA_3 recurrent axons. To determine this we investigated the conduction velocity of the Schaffer collateral fibers by extracellular recordings of the presynaptic fiber volley. The experiments were conducted at 33°C in the presents of CNQX and APV. In 6 experiments conduction velocities of 0.14 - 0.33 m/sec were recorded. Based on a mean value of 0.20 m/sec, an action potential would be expected to travel 500 μm in 2.5 msec. Therefore, our results suggest the longer latency epsps are likely to be monosynaptic events and the delays are due to slow conduction velocities in the developing recurrent axons of the hippocampus. (Supported by NIH Grant NS18309).

549.2

Presynaptic influences on the decay of excitatory synaptic currents. S. Mennerick and C.F. Zorumski. Dept. of Psychiatry and Program in Neuroscience, Washington Univ. Med. Sch., St. Louis, MO 63110.

Since synaptic glutamate (Glu) transients are very brief, the decay of excitatory synaptic currents (EPSCs) is thought to represent the average elementary lifetime of a receptor channel bound only once by transmitter molecules. Our results suggest that in hippocampal microcultures under conditions of enhanced transmitter release, decays of evoked non-NMDA EPSCs can reflect prolonged Glu actions. In neurons treated with cyclothiazide (CYZ) to enhance non-NMDA receptor sensitivity, inhibition of Glu uptake with DL-Threo-3-hydroxyaspartate (THA, 30 μM) differentially prolonged currents of large quantal content. The optimal EPSC decay time constant was increased in THA by 12.4 vs 2.7 msec in bath solutions containing 3 mM vs. 0.75 mM Ca^{++} . THA had no effect upon CYZ-treated miniature EPSC decays in cells where evoked responses were prolonged by THA. These results suggest that uptake plays a greater role in clearing Glu after release of many quanta, presumably because of higher or prolonged Glu concentrations. CYZ-treated EPSCs became faster with decreased release even in the absence of THA: (decay = 51.9 msec and 26.2 msec in 3 mM and 0.75 mM Ca^{++}). In cells untreated with CYZ, a subset of slowly decaying EPSCs were preferentially prolonged by THA. Depressing release speeded EPSCs and reduced the THA effect upon slow EPSCs. Comparison of presynaptic versus postsynaptic inhibition of EPSCs indicated that the speeding of EPSCs with reduced release was not due to differences in the changing current amplitude with high and low release. Therefore, diffusion, uptake, and receptor desensitization are insufficiently rapid to limit the decays of evoked EPSCs to those of miniature EPSCs. The results are consistent with studies suggesting that multiple quanta can interact with overlapping or closely spaced postsynaptic receptor domains.

549.3

DIFFERENTIAL REGULATION OF PRESYNAPTIC PLASTICITY BY αCaMKII IN THE CA1 REGION OF HIPPOCAMPAL SLICES. B.G. Freguelli*, A. Smith, A.J. Silva & P.F. Chapman. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724 and *University of Minnesota, Minneapolis, MN 55455.

Paired-pulse facilitation (PPF) and post-tetanic potentiation (PTP) are presynaptic forms of short-term plasticity. We have studied PPF and PTP in mice heterozygous for the α isoform of CaMKII (αCaMKII). These mice, in contrast to homozygous αCaMKII mutants, show no deficiency in long-term potentiation (LTP), the induction of which is postsynaptic in CA1 neurons. Extracellular and whole-cell recordings of PPF and PTP were made from the CA1 region of hippocampal slices, under standard *in vitro* conditions, taken from wild-type mice (WT) and heterozygous mice (HET). Extracellular field recordings revealed a striking deficit in the extent of PPF across 50-250 ms interpulse intervals (IPI) in HET (eg at 100 ms IPI, WT, $158 \pm 7\%$, n=13 slices; HET, $134 \pm 2\%$, n=22, $p < 0.001$) even under conditions of GABA receptor blockade. Whole-cell (-60 mV) recordings in the absence of GABA inhibition confirmed these observations (eg at 100 ms IPI, WT, $185 \pm 11\%$ n=5 cells; HET, $130 \pm 10\%$ n=7, $p < 0.05$). PTP was elicited, in the presence of AP5, by theta burst stimulation (TBS) consisting of two 4 shock, 100 Hz bursts separated by 200ms. To sample PTP, 15 shocks were given at 1 Hz commencing 1 s after the last burst. Surprisingly, TBS elicited PTP which was significantly greater in HET than in WT in both field (WT, $121 \pm 2\%$ n=9; HET, $140 \pm 5\%$ n=10, $p < 0.01$) and whole-cell (WT, $102 \pm 2\%$ n=4; HET, $122 \pm 3\%$ n=5, $p < 0.05$) recordings. These observations reflect a specific impairment of synaptic function since other aspects appear normal. For example, the effects of reductions in extracellular Ca^{2+} were identical in WT and HET slices, as was the ratio of fEPSP slope to fiber volley amplitude. Thus, αCaMKII can modulate synaptic transmission in a manner dependent upon the immediate history of the terminal.

What accounts for the variance of miniature synaptic current amplitude? M. Frerking, S. Borges, and M. Wilson*. Section of Neurobiology, Physiology, and Behavior, University of California, Davis CA 95616.

Isolated amacrine cells from embryonic chick retina form autapses in culture. In the presence of TTX, TEA, and internal Cs^+ , these autapses are capable of Ca^{2+} dependent evoked and spontaneous GABA release. Spontaneous, discrete GABA $_A$ currents (minis) represent, on average, the opening of less than 20 channels. As in other cell types, the mini amplitude distribution is positively skewed; cable filtering is unlikely to account for this skew, since these neurons are electrically compact. To determine how much of the observed variance in the mini distribution is due to the summed properties of individual release sites, we have examined regions of the cell in isolation.

Minis were restricted to a small region of an isolated neuron by focal superfusion of a Ca^{2+} containing saline. Multiple Gaussian peaks are evident in distributions of focally restricted minis in all cells examined, with little variance unaccounted for by uncorrelated noise, and we estimate on the basis of this low variance that the probability of channel opening is between 50 and 100%, implying a small number of receptors per release site. When compared to whole cell mini distributions, focally restricted minis show a reduced variance, mainly due to the absence of large minis; however, both distributions have a similar mode. We calculate that the frequency of mini release is too low to support the possibility that the large events seen in the whole cell distribution are random coincidences. We suggest on this basis that some of the variance seen in the whole cell distribution is not due to the sum of independent events at different release sites. THE EFFECT OF ELECTROTONIC STRUCTURE ON QUANTAL AMPLITUDE AT CENTRAL SYNAPSES. A.A.V. Hill*, G.W. Davis, C. Bigelow, R.K. Murphy. Neuroscience and behavior program, Univ. of Massachusetts at Amherst, MA 01003.

We examined a distributed central synapse in the cricket cercal sensory system. Dual, simultaneous intracellular recordings were made from the lateral and medial dendrites of the cricket interneuron, MGI, while stimulating an identified sensory neuron (SN), 3c. This SN makes synaptic contacts at two electrotonically separated sites, the lateral and medial dendrites of MGI. Thus, an electrode in the lateral dendrite can detect EPSPs that originate from the nearby site and EPSPs that originated from a distant site --the medial dendrite. Therefore, the amplitude histogram contains the true quantal amplitude, q , of nearby synapses and the smaller apparent quantal amplitude of the distant synapses due to the electrotonic decay of potential. Isolation of EPSPs originating solely from each group of release sites was achieved by comparing EPSP amplitudes recorded simultaneously. If the amplitude of an EPSP was much greater in one dendrite than in the other dendrite then the EPSP was assumed to originate from that dendrite. The q of EPSPs that arose near the electrode in either dendrite were of the similar amplitude. Since the input resistances of these two dendrites are comparable, this suggests that the underlying quantal synaptic conductances are very similar. This result shows that the q is uniform for the terminals of a single SN.

We performed compartmental simulations of the distributed synaptic input to MGI. The simulations showed that our method of isolating EPSPs that originated solely on one dendrite was reliable. The simulations also showed that the evoked amplitude histogram, seen from a single electrode, in one dendrite is greatly affected by the presence of synapses located on the other dendrite. We were unable to fit the resulting simulated amplitude histograms with a simple binomial model of release. We suggest that a statistical model, the sum of two binomials, that takes into account the electrotonic structure of the postsynaptic neuron is required.

Comparison of Quantal Analysis Methods at Crayfish, *Drosophila* and Rat Hippocampal Synapses: Measurements of Charge, Amplitude and Direct Counts of Events. B.A. Stewart*, R.L. Cooper, J.M. Wojtowicz, S. Wang and H.L. Atwood. Dept. of Physiology, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A8.

In crayfish neuromuscular synapses low transmitter output permits direct counting of quanta released by stimulation. This is often the preferred method of estimating the quantal content " m ". We have compared this method with two alternative methods: (1) measurements of the peak amplitude and (2) measurements of current area (or charge). These two methods have been used in the past in other preparations but not compared directly. To verify their accuracy we compared all three methods on data sets from the crayfish neuromuscular junction and found consistently that the areas but not the peak amplitudes give accurate results. In the crayfish and larval *Drosophila* preparations extracellular focal macropatch recordings over visible neuromuscular varicosities were used, whereas in the rat, whole cell clamp recordings were used. The deficiency of the amplitude method is most acute when quantal release is not synchronous as in crayfish synapses. In the rat dentate gyrus synapses the area method gave substantially higher estimates of " m " since it included the late, asynchronous release. Another advantage of the area method is a reduced noise level and partial compensation for spatial decrement along dendrites. Finally, the area and peak amplitude methods were compared at the *Drosophila* synapses and excellent agreement between the two was found. These synapses have high output and appear to release transmitter synchronously. We conclude that in general the area method offers an adequate substitute for the direct estimate of quantal content. WHOLE CELL RECORDINGS OF EPSPS IN RAT TRIGEMINAL MOTONEURONES IN-VITRO. J.C. Curtis & K. Appenteng & M-Y Min (SPON: Brain Research Association) Dept. of Physiology, Univ. of Leeds, Leeds, UK.

We have used the whole cell patch recording method to record synaptic activity in rat trigeminal motoneurons in tissue slices (500 μ m thickness) from animals aged 8 days. Electrodes were filled with a potassium gluconate solution and data only accepted from motoneurons when the seal resistance was at least 2 G Ω , access resistance < 50 M Ω and membrane potential at least -50 mV. There was a high incidence of spontaneous activity in the motoneurons. The mean interval between single spontaneous EPSPs in normal ACSF was 100 ms, but this increased to 350 ms in slices bathed in TTX (0.6 μ M). EPSP activity obtained in the presence of TTX was completely abolished by bath application of CNQX (10 μ M). Amplitude distributions of single spontaneously occurring EPSPs recorded in either normal ACSF or in the presence of TTX were skewed and peaky. The mean quantal amplitudes in the different cells ranged from 210 to 405 μ V. Averaged EPSPs elicited by single presynaptic neurones in single motoneurons ranged from 33 - 76 μ V. Examination of individual sweeps comprising the averages revealed that the small averaged EPSPs were due to a high incidence of failures of transmission. The above data suggests that transmission at excitatory synapses at trigeminal motoneurons may be quantal in nature, that the quantal amplitude as determined at the soma may be relatively uniform for glutaminergic inputs onto the motoneurons, and that alterations in the probability of transmitter release are likely to provide a powerful means of modulating transmission at these synapses.

TARGET REGULATION OF THE PROBABILITY OF PRESYNAPTIC RELEASE IN THE CRICKET CNS. G.W. Davis* and C. Bigelow and R.K. Murphy. Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

Our results demonstrate that a single SN is capable of making synapses with different probabilities of release at different target interneurons, MGI and 10-3. A single identified SN was stimulated and at least 500 EPSPs were recorded simultaneously from MGI and 10-3. The simple binomial was fit to each amplitude distribution using the Expectation-Maximization algorithm with four free parameters; the binomial parameters n and p , the quantal size, q , and the variance of the background noise. Goodness of fit was assessed using both chi squared and Kolmogorov-Smirnov analysis. The contacts to MGI had a lower probability of release, p , compared to the terminals from the same SN that contacted 10-3. The difference in p at the terminals of a single SN contacting MGI and 10-3 appears to determine the dynamic properties of these synapses. SN terminals contacting MGI showed paired-pulse facilitation while terminals contacting 10-3 showed paired-pulse depression. The majority of the change in EPSP amplitude during paired-pulse facilitation and depression can be accounted for by changes in p . Furthermore, when transmitter release was reduced in low calcium, high magnesium saline the probability of release at these synapses was reduced and synaptic depression was abolished. The difference in the probability of release and dynamic properties for synapses contacting MGI and 10-3 was consistent for 5 identified SNs that contacted either interneuron alone (N=13). These results indicate that the probability of presynaptic transmitter release is regulated locally, at the synapse by an interaction with the postsynaptic cell. We further hypothesize that such a local regulation of p is responsible for determining the characteristic short term dynamic release properties of these central synapses during development. PRESYNAPTIC GABAERGIC CONTROL OF EXCITATORY AXON ACTIVITY REVEALED BY BLOCK OF GAD. H. Golan* and Y. Grossman. Department of Physiology, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel.

Block of glutamate decarboxylase (GAD) as well as GABA receptor (GABA R) have epileptogenic effect. In order to study the effects of reducing GABA levels in the inhibitory terminal, inhibitory and excitatory postsynaptic potentials (IPSPs, EPSPs) were recorded intracellularly from fibers in the opener muscle of crayfish walking leg. The corresponding synaptic currents, (IPSCs, EPSCs) were recorded by loose patch clamp technique. 90 min exposure to mercaptopropionic acid or aminooxyacetic acid, GAD blockers in this system, reduced IPSP amplitude by 52% (n=6) and conductance by 63.3%. The maximal inhibition of EPSP amplitude decreased by 40% (n=10). Quantal analysis of the IPSCs revealed a decline in the quantal content due to 27% (n=5) reduction in the probability of release at each active zone. Quantal current was not affected. Presynaptic inhibition of EPSCs was reduced by 62%. Reduction in presynaptic inhibitory tonus induced by perfusion with GAD or GABA R blockers (90 min) generated hyperactivity of the excitatory terminal manifested in one of the following responses: doubled EPSC amplitude, increase of potentiation, or spontaneous activity. Our data show that blockage of GABA synthesis reduces pre- and postsynaptic GABA release and inhibition. Lack of tonic GABA input on the excitatory terminal increases its excitability and release. SPONTANEOUS SYNAPTIC CURRENTS IN VISUALIZED RAT HIPPOCAMPAL NEURONS. Z. Xiang* and T. H. Brown. Depts. of Psychol. and Cell. & Mol. Physiol. Yale Univ., New Haven, CT. 06520.

This laboratory has long been interested in the structure and physiology of the mossy-fiber (mf) system of the hippocampus (Brown et al, 1979; Brown and Johnston, 1983; Johnston and Brown, 1983; Barrioneurovo et al, 1986; Griffith et al, 1986; Claiborne et al., 1993; Yu and Brown, 1994). Our recent analysis of the quantal mechanism of mf LTP expression supports the hypothesis of a presynaptic process that increases the mean number of released quanta (Xiang et al, 1994).

Using sharp electrodes, this lab had previously examined spontaneous miniature synaptic potentials and currents in CA3 pyramidal neurons, but the signal-to-noise-ratio was poor. Here we have begun to re-examine spontaneous synaptic activity in CA3 neurons using whole-cell recordings. The cells were directly visualized using infrared (IR) differential interference contrast (DIC) video microscopy, switching from our previous (fixed-stage) inverted configuration (Keenan et al, 1988) to an upright one (40X water-immersion objective).

The recordings were restricted to cells judged to be healthy based on their contrast under video microscopy. We restricted the analysis to events judged to be electrotonically near to recording site based on 10-90 rise time (<1.5 msec). With the soma clamped at about -80, most of the spontaneous events were in the range of 10 - 50 pA, although occasionally we saw very large spontaneous events (>200 pA), even in the presence of 1 μ M tetrodotoxin, which should block evoked release. We are currently trying to characterize the quanta specifically associated with the mf synapses. Supported by NSF, NIH & ONR

COMPUTATION OF LONG-DISTANCE PROPAGATION OF POISSON PROCESS-ELICITED IMPULSES. K. Moradmand and M.D. Goldfinger*. Dept. of Physiology & Biophysics, Wright State University, Dayton, OH 45401-0927.

The Hodgkin-Huxley/Cable theory formalism was used to compute propagating impulses in a 100- μ m-diameter axon ($\lambda=3245\mu$ m) as previously described (1). Computation parameters were: $\Delta x=405.63\mu$ m; $(\Delta x/\lambda)=0.125$; $T=10^\circ\text{C}$. Total axon length was 8.1 cm (25 λ) or 101.4 cm (312.5 λ). The temporal integration step ($=1.0\mu$ sec) provided a single-spike point-to-point conduction velocity averaging 6.61 m/sec (with $c=0.053$ m/sec) except near the sealed ends. The Poisson stimulation train of 0.2 msec-duration, constant-amplitude pulses had a mean rate of 10.6 msec ($\sigma=9.6$ msec; coeff.var.=0.91), single-exponential Intervent Distribution (IID) falling limb, and an Expectation Density (ED) consisting of a maintained noisy ($\pm 1\sigma$) plateau. Poisson stimulation yielded variability in elicited action potential amplitudes. For short interspike intervals (5.2-8. msec), the second-spike peak was attenuated by as much as 37.mV; for 10-15 msec intervals, second-impulse amplitude was slightly (~ 1 .mV) increased. Impulse amplitude did not change for larger intervals. Using paired stimuli, short interspike intervals (5-11 msec) increased in duration and longer interspike intervals (12-16 msec) decreased in duration with propagation distance.

With Poisson stimulation, in the 25 λ cable, the IID consisted of a deadtime, short-interval peak, and monotonic falling limb. The ED consisted of a deadtime, short-interval peak, and noisy-maintained plateau. However, both IID and ED varied with propagation distance: longer propagation distance shifted IID and ED modes to a larger time range, as expected by the slower and variable conduction velocity of the second of a short-interval impulse pair. Over a larger conduction distance (306 λ , ~ 1 m), the IID included a major symmetrical peak, and the ED developed harmonics. These computations confirmed (2) that wide-band impulse codes can change with propagation distance. Ref's.: (1) M.D. Goldfinger, *Biophys. J.*, 50:27, 1986; (2) S.A. George, *Biol. VISUALIZATION OF NERVE TERMINAL STAINING WITH FM1-43 TRIGGERED BY BLACK WIDOW SPIDER VENOM (BWSV).

A.W. Henkel and W. Betz* Dept. of Physiology
University of Colorado Medical School, Denver, CO 80262

Frog motor nerve terminals can be stained with the fluorescent styryl dye FM1-43 in an activity dependent fashion. The dye, evidently, is taken up into vesicles while they undergo cycles of exo- and endocytosis in response to nerve stimulation. BWSV is well known to trigger massive exocytosis at synapses. This action does not depend on free extracellular calcium ions. However, calcium is required for subsequent endocytosis.

Here we show that frog nerve terminals take up FM1-43 when they are exposed to BWSV in the presence of calcium. Frog nerve muscle preparations were pre-incubated in normal frog Ringer containing BWSV (0.3 gland/ml) until the muscles started to twitch (about 30 minutes). FM1-43 (2 μ M) was added for five additional minutes. The muscles were then washed for 1 hour. The FM1-43 staining pattern was indistinguishable from control preparations stimulated via the nerve without BWSV. When the same experiment was performed in the absence of extracellular calcium only a minute quantity of dye was taken up into the nerve terminals and the synapses looked swollen and puffed. These observations support previous electron micrograph data which suggest an important role for calcium in endocytosis of BWSV poisoned nerve terminals.

PAIRED PERFORATED PATCH RECORDINGS IDENTIFY THE TRANSMITTER RELEASED FROM SACCULAR HAIR CELLS.

B. Yazejian*, Z.J. Zhou and A. D. Grinnell, Jerry Lewis Neuromuscular Research Center and Jules Stein Eye Institute, UCLA, 90024-1770.

The transmitter released by saccular hair cells has been suggested to be glutamate but this has never been proven directly. We have used glutamate receptor-rich catfish retinal horizontal cells as detectors of transmitter released from frog saccular hair cells. Simultaneous perforated patch recordings were made of voltage-activated calcium currents from isolated hair cells and of the responses in closely apposed horizontal cells. The magnitudes of the hair cell presynaptic calcium currents were correlated with the amplitudes of the horizontal cell responses. The current responses in the horizontal cells appeared to have a linear current-voltage relationship in the absence of extracellular Mg^{2+} and reversed near the cationic reversal potential. Our results are consistent with the hypothesis that the hair cell transmitter is glutamate or some closely related excitatory amino acid. This approach will allow the identification and characterization of both the hair cell transmitter and the mechanism of its release.

550.2

MODULATION OF PRE-AND POST-SYNAPTIC CURRENTS MEASURED WITH THE PERFORATED PATCH METHOD AT A VERTEBRATE SYNAPSE.

A. D. Grinnell* and B. Yazejian, Jerry Lewis Neuromuscular Research Center, UCLA, 90024-1770.

We have been using double perforated patch recording techniques to study the mechanisms of transmitter release at synapses formed in culture between varicosities on *Xenopus* motor neuron neurites and muscle cells. This system has proven to have many advantageous features in common with the classic squid giant synapse preparation. Most notable of these is the ability to measure directly the presynaptic calcium currents responsible for transmitter release. In addition, we are able to measure the quantal content of evoked release, the dependence of release on the presynaptic calcium current and on the extracellular calcium concentration. Furthermore, we have shown the level of modulation of release and presynaptic calcium current by both adenosine and norepinephrine and the sensitivity of these to applications of omega conotoxin and dihydropyridines. Finally, we have studied the calcium current dependence of depression and facilitation by giving paired presynaptic voltage clamp steps to evoke equal magnitude calcium currents.

ANALYSIS OF CHANGES IN PRESYNAPTIC CURRENTS DURING SLOW DEVELOPING POTENTIATION IN APLYsia. M.V. Storozhuk and S.M. Fredman*. A.A. Bogomoletz Institute of Physiology, Kiev, Ukraine and Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

Brief high frequency stimulation of the A-B neuron synapse in the cerebral ganglion of *Aplysia* evokes a long-lasting increase in synaptic transmission, slow developing potentiation (SDP). Work to date indicates that SDP is due to changes in the presynaptic A neurons. Although there are transient alterations in the action potential following tetanic stimulation (4, 500 msec 20 Hz trains), these changes are poorly correlated with the time course of increases in EPSP amplitudes in B neurons. There is no significant broadening of the falling phase of the A neuron action potential. The input resistance of the B neurons does not change during SDP. Inducing SDP while voltage clamping A neurons reveals a decrease in total outward current. SDP is not due to the inactivation of the early K^+ current, I_A . SDP persists even when I_A is inactivated by clamping A neurons to a holding potential of -35 mV. Usually only 5-15% of the total current changed after high frequency stimulation. As the relative changes are small, it is likely that a specific current is altered. Subtracting the total current during SDP from that during preceding control stimulations reveals an inward difference current that peaked at ~ 12 msec after the start of a step from -35 to +25-30 mV and then decayed. The change in current was time-dependent and slowly diminished after tetanization. This current may be due to either the inactivation of a fast outward current with a voltage-dependence different from that of I_A , or an increase in a high voltage activated Ca^{2+} current. Since SDP can be partially blocked by L-type Ca^{2+} channel antagonists, this latter possibility is presently being investigated.

FACILITATION STUDIES ON CRAYFISH NEUROMUSCULAR SYNAPSES:

EFFECT OF SEROTONIN AND CAFFEINE. K. Judd, L. Crawford, M. Lui and S.J. Veleg*. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The facilitation properties of the largest excitatory neuron innervating the superficial flexor muscles of the crayfish *Procambarus clarkii* were examined by measuring the junction potential sizes (Jp' s) elicited in muscle fibers while stimulating the neuron at 1 and 10 Hz. In Ringers solution, the Jp' s obtained at 10 Hz were larger than those obtained at 1 Hz, and these were stable during 15 minutes of constant stimulation. In a 10^{-5} M solution of serotonin (5-HT) in Ringers, Jp' s obtained at both 1 and 10 Hz were larger than controls, and both were again stable during constant stimulation. In a 25 mM solution of caffeine in Ringers, there was no change from controls in the initial Jp' s recorded at 1 and 10 Hz stimulation, but during the 15 minutes of continuous stimulation the Jp' s decreased by more than 50% of their initial values. Serotonin's presynaptic depolarization, by increasing calcium entry upon stimulation, could enhance the initial Jp' s recorded at 1 and 10 Hz, yet this is not affecting the stability of the facilitation mechanisms. Caffeine's known effect of releasing calcium from internal stores suggest that interfering with the intracellular free calcium concentration is not affecting the initial release of transmitter but over time will have an effect on the stability of the facilitation mechanisms, which are believed to involve residual calcium levels.

550.5

CLOSE PRESYNAPTIC ACTIVE ZONES MAY ENHANCE FACILITATION J.L. Winslow^{1,2}, R.L. Cooper², C.K. Govind³, J. Pearce³, L. Marin², H.L. Atwood^{1,2}. ¹Biomedical Eng., ²Physiology Dept., ³Life Sciences, Scarborough College, U. of Toronto, Toronto, Ont. M5S 1A8.

Voltage activated Ca^{2+} , Ca_v , channels, normally activate neurotransmitter release. Freeze fracture micrographs of crayfish presynaptic active zones, AZs, show Ca_v channels and K_{Ca} channels as prominent intramembrane particles. Reconstructed serial EM sections of varicosities from crayfish opener muscle axons show 0.5 AZs per synapse, with different separations. To evaluate separation effects on facilitation due to spatial summation of Ca^{2+} diffusing from two adjacent zones, we used a computational preparation. We video-digitized a freeze-fractured image of an AZ, then traced the channels. The ratio of Ca_v to K_{Ca} channels was set at 2:1. Using a reaction diffusion model for Ca^{2+} and Ca^{2+} binding proteins (non diffusible buffer) with Ca_v channels arranged as traced, we calculated the 3D concentration of Ca^{2+} for one AZ, then for two separated AZs. With Ca^{2+} diffusion coefficient as in H_2O and no binding sites, all Ca^{2+} diffuses away 0.2 ms after channel closing. With 0.5-1.6 mM total Ca^{2+} binding proteins, residual concentration of Ca^{2+} increases 5-7 times the resting value 0.1 μM with successive stimulation. When two AZs centers are separated by 200 nm, the Ca^{2+} concentration midway between the AZs is sufficient to potentially cause vesicle release. Thus, in single synapses adjacent AZs may promote transmitter release and facilitation. (See Cooper, R.L. et al., this meeting.) Funded by NSERC, MRC, & NCE of Canada.

550.7

EVIDENCE THAT EXCITABILITY CHANGES IN PRESYNAPTIC FIBERS MAY AFFECT PAIRED-PULSE FACILITATION IN HIPPOCAMPAL SLICES J.E. Storm* & R. Lipowsky. *Inst. of Neurophysiol., University of Oslo, Norway.* Facilitation is a widespread synaptic phenomenon, usually attributed to presynaptic mechanisms. Excitatory synapses in hippocampal slices also show facilitation, even during minimal stimulation of afferent fibers, but it has not been extensively tested whether this is an entirely synaptic process, or whether there may also be variable excitation or conduction in the presynaptic axons. If so, this may have implications also for the study of other synaptic processes. Encouraged by suggestions from D. Kullmann and B. McNaughton, we have performed experiments to test these possibilities.

Whole cell recordings were obtained from CA3 and CA1 pyramidal cells in slices from young rats, while paired stimuli of equal, low intensity (Stim.1 = Stim.2; interval 40-60 ms) were given from a small glass pipette. In CA1 cells, stimulation of presynaptic fibres in *str. radiatum*, elicited excitatory postsynaptic currents (EPSCs), which usually showed clear facilitation; i.e. EPSC2 was larger and/or showed fewer failures than EPSC1. To test whether this difference could be partly due to variable axon excitability or conduction, fibres in *str. radiatum* were stimulated in a similar way while recording from CA3 somata, giving short-latency, presumably antidromic, action potentials. In response to paired pulses, these spikes often showed fewer failures to Stim.2 than to Stim.1. This effect persisted even after blocking excitatory and inhibitory synaptic transmission by reducing the $[Ca]/[Mg]$ ratio (0.1 mM $Ca/6.5$ mM Mg) or by adding CNQX and bicuculline. Similar effects were also seen with antidromic stimulation of CA1 cells or by "direct" stimulation close to CA3 or CA1 somata. These results suggest that the initiation and/or conduction of action potentials in hippocampal axons may change during repetitive stimulation, and that these effects may add to and influence paired-pulse facilitation and other synaptic phenomena. [Supported by NFR.]

INCREASE IN NEUROSECRETORY ACTIVE SITES DURING FACILITATION. M.K. Worden, D.A. August, and J.T. Hackett*. Dept. Mol. Physiol. and Biol. Physics. UVa. Health Sci. Ctr., Charlottesville, VA 22908

The classic Del Castillo and Katz model for quantal release has as its basis the statistical parameters "n", the number of active quantal release sites and "p", the probability for release to occur. Unfortunately, these values are subject to spatial and temporal variations which may render them useless. We have used a method (Provan & Miyamoto, 1993) which avoids these problems to measure facilitation of neurosecretion at a lobster neuromuscular junction. Extracellular recording during steady state conditions were made from synaptic sites using macropatch electrodes with tip diameters of 20 μm . The excitatory nerve was stimulated at a constant frequency for each trial in a range between 1 and 20 Hz. Unbiased estimates of quantal release parameters were computed. Both "n" and "p" increased for stimulus frequencies at and above 4 Hz ($p < 0.001$, t-test). Spatial variance in "p" was found to increase up to 4 Hz, and then to reach a plateau. In sum, unbiased estimates of "n" and "p" were obtained and both increased in proportion to stimulus frequency, while the spatial variance in "p" was nearly constant. Facilitation results from an increase in both the active release sites and the probability of quantal release.

550.6

STRUCTURAL CORRELATES OF QUANTAL PARAMETERS AT CRUSTACEAN NEUROMUSCULAR JUNCTIONS. R.L. Cooper*, J.L. Winslow, C.K. Govind*, J. Pearce*, L. Marin & H.L. Atwood. Dept. of Physiology, Med. Sci. & Life Sci. at Scarborough College¹, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A8.

We investigated the role of calcium in determining the probability of transmission and whether "complex" synapses have a higher probability of transmission. Synaptic currents are recorded from single varicosities with a macropatch electrode to determine quantal parameters of synaptic release. Reconstruction of recorded crayfish excitatory terminal varicosities shows complex (more than one active zone) and simple (only one active zone) synapses. Complex synapses have also been observed in a variety of crustacean species at inhibitory, excitatory and presynaptic inhibitory neuromuscular junctions (NMJ). In the reconstructions of serial sectioned macropatched terminals active zones (AZs) of complex synapses are often close together. In freeze fracture replicas, two AZs containing intramembranous particles (Ca_v and K_{Ca} channels) also occur close together. Cooperative interaction of between closely spaced AZs may occur at complex synapses. Thus, $[Ca^{2+}]$, would be greater at sites of vesicle release after an impulse at complex synapses. We propose that the probability of release is higher at sites where AZs are in close apposition and that the number of pairs of close AZs may represent the anatomical correlate of the quantal parameter "n" (number of release sites) at low frequencies of stimulation. At higher frequencies of stimulation, more distant AZs and single AZs may acquire higher probability of release, thus giving the nerve terminal a mechanism for grading synaptic output with frequency (see also Winslow, J.L. et al., this meeting). Funded by MRC, NCE & NSERC of Canada.

550.8

RELEASE PROBABILITY IS CHANGED BY ALTERING EXTRACELLULAR Ca^{2+} , BUT PAIRED PULSE FACILITATION IS NOT, AT PYRAMID-INTERNEURONE SYNAPSES IN NEOCORTICAL SLICES. Alex Thomson*, David C. West and Jim Deuchars. Dept. Physiology, Royal Free Hospital School of Medicine, London NW3 2PF, UK.

Single axon connections between pyramidal cells and interneurons were recorded using pairs of biocytin-filled sharp electrodes in slices of neocortex. Typically, EPSPs elicited in an interneurone by spikes in a single pyramid exhibited profound paired pulse facilitation and a high probability of failures of transmission to single presynaptic spikes in standard medium (2.5mM Ca^{2+}). The effect of raising extracellular Ca^{2+} on the EPSPs elicited in one class of interneurons, ie. bursting, sparsely-medium spiny interneurons, was studied. When extracellular Ca^{2+} was raised to 5mM, the proportion of failures of transmission to the first spike decreased and averaged amplitudes were almost doubled. However, the 2nd EPSP also increased in amplitude and paired pulse facilitation was not reduced. These data contrast strongly with those obtained from pairs of synaptically connected pyramidal neurones. EPSPs elicited in postsynaptic pyramids typically exhibited paired pulse depression that was augmented when extracellular Ca^{2+} was raised. In addition, unlike pyramid-pyramid EPSPs, the time course of EPSPs recorded in this class of interneurons was increased.

550.10

SHORT-TERM PLASTICITY OF EXCITATORY SYNAPSES BETWEEN HIPPOCAMPAL NEURONS IN DISSOCIATED CELL CULTURE.

D. D. Cummings^{1*} and M. A. Dichter¹⁻³ ¹The David Mahoney Institute of Neurological Sciences, ²Dept. of Neurology, University of Pennsylvania School of Medicine and ³Graduate Hospital, Philadelphia, PA 19104.

Excitatory synaptic transmission mediated by either NMDA, non-NMDA, or both receptors in our very low density embryonic hippocampal neuron cultures exhibits paired-pulse depression at interstimulus intervals between 0.1 and 4 seconds in paired whole cell patch clamp recordings. However, paired pulse depression (PPD) is much less predictable at excitatory synapses than at inhibitory synapses (Wilcox, Buchhalter, and Dichter, 1994). Consistent with classical experiments, lowering extracellular Ca from 2.0 to 0.5 mM decreases the probability of PPD and raises the probability of paired pulse facilitation (PPF) at 1 sec. interstimulus intervals. The unexpected occurrence of PPD and post tetanic depression (PTD) in $[Ca]_o = 2.0$ mM in this elemental synaptic preparation and in other CNS preparations (Thomson and West, 1993) suggests that this may be an important biological property of excitatory synapses. Some experiments demonstrate a relative increase in the frequency in mini-EPSCs accompanying PPD or PTD. A correlation between decreased evoked response amplitude and increased mini-EPSC frequency suggests that short-term plasticity of evoked response amplitude may be dissociated from changes in spontaneous release of neurotransmitter. Alternatively, post-synaptic mechanisms such as desensitization of AMPA receptors may mask facilitation of the evoked response. Supported by NS24260 (M.A.D.).

ANESTHETICS PRODUCE DIFFERENTIAL EFFECTS ON EPSP FACILITATION. S.M. Amagasa, A.A. Mikulec, F.A. Monroe and M.B. MacIver* Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

Anesthetic effects on excitatory postsynaptic potential (EPSP) facilitation were studied as a measure of actions on presynaptic release. Effects produced by clinically relevant concentrations of halothane, isoflurane, and thiopental were compared on Schaffer-collateral evoked dendritic EPSPs recorded in CA 1 of hippocampal brain slices. Paired stimulus pulses were used to produce EPSP facilitation. In agreement with previous studies, synaptically evoked discharge of CA 1 neurons was blocked by halothane (1.2 vol %, 1 rat MAC), isoflurane (1.4 vol %), and thiopental (100 μ M). The block produced by the anesthetics was associated with a $22 \pm 1.3\%$, $26 \pm 2.4\%$, and $23.4 \pm 8.5\%$ depression of single-pulse EPSP amplitudes by halothane, isoflurane, and thiopental respectively. Halothane increased EPSP facilitation from control values of 130% to $142 \pm 6.7\%$, while isoflurane and thiopental reduced EPSP facilitation to $123 \pm 3.1\%$ and to $121 \pm 11.3\%$ respectively. Effects on EPSP facilitation demonstrate anesthetic actions on glutamate nerve terminals, since facilitation is known to involve only presynaptic mechanisms. The similar effects on EPSP amplitude but differential effects on facilitation provide further support for a Multisite Agent Specific (MAS) mechanism of anesthetic action.

ECTOPIC ACTION POTENTIALS IN HIPPOCAMPAL AND DENTATE NEURONS UNDER CONTROL CONDITIONS. D.D. Mott, S.F. Stasheff, D.V. Lewis and W.A. Wilson. Depts. of Ped. (Neurology), Neurobiol., Med. and Pharmacol., Duke Univ. and V.A. Med. Ctrs, Durham, N.C. 27710.

We have previously reported that induction of electrographic seizures (EGS) using kindling-like stimulation increased the occurrence of ectopic action potentials (baseline spikes) in CA3 pyramidal cells. These ectopic action potentials appeared to be generated in the axon terminal by a depolarizing GABA response. However, it was also noted that in 37% of the CA3 neurons sampled, ectopic action potentials occurred prior to EGS induction. We now report the presence of ectopic action potentials under control (non-hyperexcitable) conditions in other cell types in both the hippocampus and dentate gyrus.

Intracellular responses were recorded from neurons in the rat hippocampal slice preparation using sharp microelectrodes. Ectopic action potentials were identified as action potentials which arose sharply out of the baseline with no preceding depolarization and continued to occur despite somatic hyperpolarization. Ectopic action potentials were present in 31 out of 160 sampled granule cells (19%). Similarly, ectopic action potentials were observed in area CA1 in both pyramidal cells and fast spiking interneurons in the pyramidal cell layer. In these cells ectopic action potentials occurred both spontaneously and following orthodromic and antidromic stimulation. Evoked ectopic action potentials occurred primarily during the GABA_A IPSP and manipulations designed to reduced GABAergic inhibition blocked ectopic action potentials, demonstrating their dependence on GABAergic potentials.

These results suggest that the occurrence of ectopic action potentials may be more widespread than previously thought and that these action potentials may contribute to cellular responses under normal (non-hyperexcitable) conditions.

TRANSIENT INWARD CURRENT IN CULTURED RAT EMBRYO MUSCLE MIMICKING QUANTAL SECRETION PROCESS.

J. Vautrin, A.E. Schaffner and J.L. Barker.

Lab. of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

Current- and voltage-clamp, whole-cell patch recordings in myotubes and 20 μ m-diameter myoballs from 18-22 day old rat embryos exhibited dihydropyridine, Mg^{2+} - (10mM) and TTX- (1 μ M) sensitive transient inward currents (TICs). TICs were either spontaneous, or evoked, appearing during depolarizing commands, and after both depolarizing and hyperpolarizing pulses. The delay to TIC occurring during the pulse was an hyperbolic function of the stimulating pulse amplitude with a minimum of about 200 μ s. The delay until TIC occurring after a short (0.5-2ms) pulse could be as long as 500ms and its variability increased with its average value. At depolarized holding potentials the peak amplitudes of TICs occurring milliseconds after the end of hyperpolarizing pulses were a direct function both of the duration and the amplitude of the pulse, the gradation suggesting adequate control of the potential by the clamp system. At more hyperpolarized holding potentials the peak amplitude of TICs occurring during (longer) depolarizing pulses remained independent on the membrane potential as if they were unclamped. However, the delay and time course remained dependent of the potential at which these TICs occurred suggesting some control of the potential by the clamp amplifier and that the TIC peak amplitude is not controlled by membrane potential. With short constant liminal pulses, TICs showed all-or-none behavior, as well as discrete fluctuations in amplitude mimicking quantal and subquantal fluctuations in synaptic signals. Intriguingly, both facilitation and depression occurred in paired pulse protocols. How TICs are related to synaptic transmission is a challenge for future study.

ZINC ENHANCES ACTION POTENTIAL INDEPENDENT GABA RELEASE FROM INHIBITORY TERMINALS IN THE DENTATE GYRUS. E. Buhl¹ and L. Mody². ¹MRC Anatomical Neuropharmacology Unit, Oxford University, U.K., and ²Depts. of Anesthesiology/Pain Mgmt. & Neurology, UT Southwestern Med. Ctr., Dallas, TX.

Depending on the developmental stage, zinc is known to exert various effects on GABAergic inhibition. The effects of zinc range from diminishing GABA responsiveness in the absence of the γ -subunit, to enhancing inhibition secondary to its action on the excitability of inhibitory interneurons. We have examined the possibility whether zinc modulates the release of GABA from inhibitory nerve terminals when the excitability of interneurons *per se* is unlikely to be affected.

Recordings were obtained from dentate gyrus granule cells in conventional (400 μ m thick) coronal adult rat brain sections using whole-cell patch clamp techniques. Miniature inhibitory postsynaptic currents (mIPSC) were recorded in the presence of 1 μ M TTX, 10 μ M CNQX and 40 μ M D-AP5, with 130 mM CsCl, 10 mM Hepes, and 2 mM MgCl₂ containing electrodes. During a given recording, access resistance was frequently monitored, and experiments were only selected for analysis if access resistance did not change throughout the recording period. Furthermore, event detection accuracy was ensured by analyzing the frequency and amplitude of events at two different holding potentials. Zinc (100-200 μ M) was applied through bath perfusion, and produced a significant enhancement of mIPSC frequency. In 20% of the recordings, zinc induced dramatic bursts of mIPSCs, causing a 10-20-fold increase in event frequency during burst periods. As expected from the presence of the GABA_A receptor γ -subunit on adult granule cells, zinc had no effect on the decay kinetics, 10-90% rise times, and amplitudes of mIPSCs.

Our findings demonstrate a presynaptic effect of zinc on GABA release most likely occurring at the level of inhibitory terminals of GABAergic neurons. Such modulation of tonic GABA release by zinc, may play an important role in the regulation of excitability in the dentate gyrus.

LONG-TERM POTENTIATION: PHYSIOLOGY VI

551.1

MECHANISMS OF SELECTIVE LONG-TERM POTENTIATION OF EPSCs IN INTERNEURONS OF STRATUM ORIENS IN RAT HIPPOCAMPAL SLICES. M. Ouardouz* and J.-C. Lacaille. Center for Research in Neurological Sciences and Department of Physiology, University of Montréal, Montréal, Qc, Canada H3C 3J7.

Mechanisms of long-term potentiation (LTP) have been extensively studied in hippocampal pyramidal cells, but the involvement of local inhibitory cells remains largely unknown. In the present study, the effects of tetanization were examined on excitatory postsynaptic currents (EPSCs) in different hippocampal interneurons. Rat hippocampal slices (300 μ m thickness) were submerged in a chamber mounted on an upright microscope and CA1 interneurons were identified visually with Nomarski optics in str. oriens (OR-cells) or lacunosum-moleculare (LM-cells). EPSCs evoked by electrical stimulation of afferent fibers (-80 mV, 0.033 Hz) were recorded in whole-cell mode (recording solution in mM: 140 CsCH₃SO₃, 5 NaCl, 1 MgCl₂, 10 HEPES, 1 EGTA, 2 ATP, 0.4 GTP). Following tetanic stimulation (100 Hz, 1s) paired with postsynaptic depolarization (-20 mV), EPSCs in OR-cells were significantly increased in amplitude for 10 min ($137.7 \pm 7.0\%$ of control [mean \pm sem], $n=11$) to 30 min ($129.9 \pm 1.3\%$ of control, $n=5$). Similar stimulation did not potentiate EPSCs in LM-cells ($91.6 \pm 8.2\%$ of control, $n=7$). LTP of EPSCs in OA-cells was blocked by intracellular application of 25 mM BAPTA ($88.2 \pm 7.4\%$ of control, $n=5$), and by bath application of i) 25 μ M AP-5 ($88.3 \pm 4.2\%$ of control, $n=8$), ii) 500 μ M MCPG ($98.6 \pm 8.4\%$ of control, $n=5$), and iii) 100 μ M L-NAME ($83.4 \pm 6.4\%$ of control, $n=5$). These results suggest that excitatory synapses of interneurons in str. oriens display selective long-term potentiation via activation of NMDA and metabotropic glutamate receptors, postsynaptic elevation of Ca^{2+} and NO synthesis. Thus, various inhibitory cells may participate differently in hippocampal long-term potentiation.

FEED-BACK SYNAPTIC PLASTICITY IN HIPPOCAMPAL ST. ORIENS-ALVEUS INHIBITORY NEURONS. G. Maccaferri* and C. J. McBain. Laboratory of Cellular and Molecular Neurophysiology, NICHD National Institutes of Health, Bethesda, MD 20892.

We studied the effect of low (10 min, 1 Hz) and high frequency (4 X 1 s, 100 Hz) stimulation of the st. radiatum on the synaptic responses of st. oriens-alveus (O-A) interneurons. Hippocampal slices were prepared from 15-22 days old rats and whole-cell current-clamp recordings were performed on a total of 17 interneurons in the presence of 1 μ M bicuculline. In addition, the extracellular field potential in the pyramidal cell layer was continuously monitored. Activation of st. radiatum afferents elicited excitatory postsynaptic potentials (EPSP) or action potentials commencing ~2.5 ms after the peak of the field population spike (fPS). Following the recording of stable synaptic responses for 10 minutes at 0.1 Hz, the low-frequency protocol was applied and both EPSP and fPS amplitudes were strongly depressed (~70%) for the entire duration of the recording (up to 30 min). Subsequent treatment with the high-frequency protocol could restore or even potentiate the original baseline response. Identical results were obtained when the recording electrode contained 10 mM EGTA in the absence of Ca^{2+} or when the phosphatase inhibitor microcystin LR (10 μ M) was added. In contrast, bath application of the NMDA receptor antagonist D-AP5 (50 μ M) could prevent both the EPSP and the fPS depression. These data indicate that st. O-A interneurons can undergo long-term depression (LTD) and long-term potentiation (LTP) without requiring an increase of intracellular Ca^{2+} concentration or phosphatase activity. These results, together with the delayed onset of the interneuron EPSP when compared to the fPS peak, demonstrate that the LTD and LTP observed are indirect phenomena driven by the recurrent collaterals of CA1 pyramidal cells.

551.3

LONG TERM POTENTIATION OF RECURRENT INHIBITION ONTO HIPPOCAMPAL CA1 PYRAMIDAL CELLS IN VITRO. H.C.R. Grunze, D.G. Rainnie, E.F. Hearn, R.W. McCarley, R.W. Greene. Harvard Medical School & VAMC, Department of Psychiatry, Brockton MA 02401, USA

Modulation of recurrent inhibition is critical not only for the normal function of highly excitable regions of the brain, especially the limbic system, but may also be important in prevention of excitotoxic damage. Post-mortem data indicate reduced numbers of GABAergic interneurons while MRI data show marked volume reductions in cortical and especially limbic gray matter in schizophrenics, suggesting a possible role of excitotoxic damage in this disorder, and the need for careful study of the dynamics of recurrent inhibition. In the present study, standard extracellular ($n=26$) and intracellular ($n=8$) recordings from *in vitro* brain slices of rat hippocampi showed that recurrent inhibition onto CA1 neurons is enhanced by NMDA-mediated long term potentiation (LTP), and that this LTP persists for periods greater than 20 minutes. The LTP was evoked by a tetanus applied to the Stratum oriens (100 Hz for the extracellular and 400 Hz for the intracellular recordings) and resulted in a mean enhancement of the recurrent inhibitory drive of $19 \pm 9.8\%$ in 23/26 recordings (extracellular recordings) and $32.5 \pm 24.7\%$ in 8/10 neurons (intracellular recordings). Furthermore, this LTP was completely blocked by the NMDA antagonists 2-aminophosphonopropionic acid (APV), MK-801, phencyclidine (PCP) and N-Acetyl-L-aspartyl-L-glutamic acid (NAA-G). Presumably, the tetanic stimulus activated excitatory recurrent CA1 axon collaterals synapsing on inhibitory interneurons that, in turn, elicited the inhibitory postsynaptic potentials (IPSPs) in the recorded CA1 neurons. We thus infer that the LTP (indexed by the increased amplitude of the evoked IPSP) occurs at the excitatory CA1 to inhibitory interneuron synapse. Blocking the LTP of recurrent inhibition may explain the increased behavioral excitability in rats seen on exposure to PCP, whose effects in man mimic positive schizophrenic symptoms.

HOMOSYNAPTIC AND HETEROSYNAPTIC CHANGES IN DRIVING OF DENTATE GYRUS INTERNEURONS FOLLOWING BRIEF TETANIC STIMULATION Richard A. Tomasulo. Departments of Neuroscience and Neurology, University of Virginia, Charlottesville, VA 22908.

The inhibitory circuit within the hippocampal dentate gyrus (DG) can change its net inhibitory efficacy following brief tetanic stimulation of either the perforant path (PP) or the dentate commissural pathway (CP) (J. Neurophysiol. 69:165). To further explore the possible contribution of inhibitory circuit plasticity to information storage, we measured, in urethane-anesthetized rats, changes in interneuron driving that followed conditioning regimens similar to those of the previous study. The primary measure of synaptic drive was the firing latency of DG interneurons isolated with an extracellular tungsten recording electrode. Stimulating electrodes were placed in the ipsilateral angular bundle and the contralateral dentate hilus. Identification criteria included high spontaneous firing rate, short duration action potential, firing to PP stimulation at low latency and threshold, multiple firing, and CP firing latency below 6 msec. Data were collected in 20-minute periods during which we activated the CP and PP inputs alternately. Conditioning regimens were control, PP tetany at spike threshold, PP tetany well above spike threshold, CP tetany, and paired tetany. Paired conditioning was given only after both inputs had been individually conditioned. (Conditioning stimulation: 400Hz, 20 msec.) Both CP and paired tetany consistently reduced CP firing latency ($p = .03$ and $.01$). PP latency decreased to paired and to high-intensity PP tetany, but the mean changes were not significant. Individual cases suggested heterosynaptic interactions. The results indicate limited plasticity of interneuron driving *in vivo* under conditions that alter the E-S relationship and change commissural inhibitory efficacy. We suggest that plasticity of the inhibitory circuit contributes to information storage in the hippocampus. Supported by K08NS01438 from NINDS to RT.

THE RELATIONSHIP BETWEEN SHORT-TERM AND LONG-TERM POTENTIATION OF INHIBITORY SYNAPTIC TRANSMISSION IN RAT VISUAL CORTEX. Y. Komatsu. Dep. of Physiology, Kyoto Prefectural Univ. of Med., Kamigyoku, Kyoto 602, Japan.

High-frequency activation of inhibitory synapses can induce short-term (STP) or long-term potentiation (LTP) of inhibitory synaptic transmission in rat visual cortical cells. To study the relationship between the STP and LTP, inhibitory postsynaptic potentials evoked by layer IV stimulation were recorded from layer V cells of developing rat visual cortex slices where excitatory synaptic transmission was blocked by glutamate receptor antagonists. Strong high-frequency conditioning stimulation of layer IV commonly induced LTP while weak one induced LTP or STP that decayed to control levels over 20-40 minutes. A weak conditioning stimulation, which first elicited STP, elicited LTP when it was applied again after the potentiated responses had returned to the control level (20-30 minutes). After LTP was saturated by repetitive application of strong conditioning stimulation, STP was still induced. These results suggest that different mechanisms are responsible for STP and LTP although they may be partly common.

551.4

LONG-TERM POTENTIATION OF IPSPs IN HIPPOCAMPAL CA1 PYRAMIDAL NEURONS. Z. Xie, S. Yip, and B.R. Sastry. Neuroscience Research Laboratory, Department of Pharmacology & Therapeutics, The University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3

Previous reports from this laboratory showed that tetanic stimulation of the stratum radiatum induced LTP of not only the excitatory postsynaptic potentials (EPSPs) but also of the inhibitory postsynaptic potentials (IPSPs) in CA1 neurons. In the present study, experiments were conducted to further examine LTP of the IPSPs in guinea pig hippocampal CA1 neurons. In control neurons, tetanic stimulation (100 Hz, 1s) of the stratum radiatum caused LTP of the EPSP and the fast IPSP but not of the slow IPSP ($n=8$). In CA1 neurons injected with BAPTA (a Ca^{2+} chelator) ($n=6$) or K-252b (a PKC inhibitor) ($n=8$), the tetanic stimulation induced a larger LTP of the fast IPSP and LTP of the slow IPSP, but did not cause LTP of the EPSP. While tetanic stimulation of the stratum radiatum induced LTPs of the EPSP and the fast IPSP in control neurons, the IPSPs evoked by the stimulation of the alveus were not changed ($n=4$). LTP of the fast IPSP was reduced, and LTP of the slow IPSP was blocked in BAPTA- ($n=6$) or K-252b- ($n=6$) injected CA1 neurons when the tetanus was applied in the presence of APV. In the presence of APV (50 μM) and CNQX (20 μM), stimulation of the stratum radiatum presumably evokes monosynaptic IPSPs. When the tetanic stimulation was given in the presence of these drugs, LTP of the fast, but not of the slow-IPSP, was observed in control as well as BAPTA- or K-252b-injected neurons ($n=6$ each).

These findings suggest that LTP of the IPSPs in CA1 neurons is modulated not only by postsynaptic $[\text{Ca}^{2+}]_i$ and PKC activity but also by presynaptic conditions (changes in interneuron excitability or LTP of excitatory synapses on the interneurons?). There appear to be differences between LTPs of the fast and the slow IPSPs. This study was supported by a grant from the NIH (NS 30959) to B. R. S. and Canadian M. R. C. Studentships to Z. X. and S. Y.

551.6

GABAergic LONGTERM POTENTIATION IN RAT BRAINSTEM SLICES Steven R. Glaum* & Penelope A. Brooks. Dept. Physiology, Royal Free Hospital School of Medicine, London, U.K. & *Dept. Pharmacological & Physiological Sciences, University of Chicago, Chicago, IL. 60637

Whole-cell patch recordings were made in the nucleus tractus solitarius (NTS) in transverse brainstem slices from rats. Monosynaptic GABA_A-receptor mediated inhibitory postsynaptic currents (IPSCs) or potentials (IPSPs) were evoked (0.1-0.2 Hz) by electrical stimulation within and medial to the tractus solitarius in the presence of ionotropic glutamate receptor (GluR) antagonists (10 μM DNQX, 50 μM D-AP5). Low frequency (5-50 Hz) tetanic stimulation resulted in posttetanic- (PTP) (<5 min, $222.4 \pm 18.3\%$ control, $n=39$) and longterm- (LTP) potentiation (≥ 15 min, $175.3 \pm 8.6\%$ at 15 min posttetanus, $n=26$) of the IPSP/Cs. In the majority of cells, a 20Hz tetanus resulted in LTP persisting 20-40 min, but was occasionally observed to persist up to the duration of the recording (~ 2 hr). LTP was not due to alterations in the reversal potential of IPSP/Cs and the IPSP/C could be completely blocked by the GABA_A antagonist bicuculline. Furthermore, current responses to micropressure application of the GABA_A-receptor agonist muscimol were unaltered in cells displaying LTP. Unlike excitatory LTP in the hippocampus, GABAergic LTP was evokable in the presence of the metabotropic GluR antagonist α -methyl-4-carboxyphenylglycine (MCPG, 200 μM). Although we have previously shown that presynaptic GABA_A receptors inhibit GABAergic transmission in the NTS (Brooks et al., J. Physiol. 457:115-129, 1992), paradoxically, induction of LTP was blocked in the presence of the GABA_A-receptor antagonists 2-OH-saclofen (400 μM) or CGP35348 (3-amino-propyl-(diethoxymethyl)) phosphinic acid (100 μM). PTP was unaffected by GABA_A-receptor antagonists. These data suggest that neuronal or terminal excitability of GABAergic interneurons in the NTS is enhanced following brief periods of increased frequency of activation *in vitro*. This phenomenon may be involved in the temporal modulation of autonomic reflex sensitivity observed during certain behavioral states, such as the defense reaction.

551.8

KCL induced LTP in CA3-CA1 cultures: a possible role for NO J.Noel* & A.Malgaroli. Scientific Inst. S.Raffaele, DiBit, Milano, ITALY

LTP of miniature EPSCs (mini) frequency can be elicited in hippocampal CA3-CA1 cultures by local application of Glutamate or Sucrose (0 Mg⁺⁺). We studied the role of NO in this LTP by recording minis in the whole cell configuration (TTx 0.5 μM present). Local application of NO donors (SIN-1, 0.05-10 mM, 60 sec) increased mini frequency in the absence of any stimulated pre or post synaptic activity ($n=9/15$; APV 25 μM)(A). The onset of the effect was always delayed (~ 30 -60 sec lag from SIN-1 washout) and displayed a burst like pattern throughout the experiments. These features and the requirement of high dosage of SIN-1 might result from the absence of concurrent pre-synaptic activity in most of the boutons. We used 90 mM KCl pulses (0.2 sec applications, 3 times with 5 sec intervals) to synchronize pre- and post-synaptic activation. This elicited a strong and reliable LTP (2 to 10 fold increase in mini frequency for more than 60 min, $n=5/6$) (B). Block of postsynaptic Ca^{2+} rise (5-10 mM BAPTA $n=8/8$) prevented mini frequency potentiation, possibly by inhibiting the production of the retrograde messenger(s). We have now begun to test if NO and other putative retrograde messengers can restore LTP in BAPTA blocked cells where presynaptic activity is present and dissociated from the postsynaptic Ca^{++} rise.

551.9

HEME OXYGENASE-2 MUTANT MICE AS MODELS FOR STUDYING EFFECTS OF THE DEPLETION OF ENDOGENOUS CARBON MONOXIDE, A PUTATIVE NEURONAL MESSENGER. K.D. Poss, C. Chen*, and S. Tonegawa. Center for Cancer Research and Dept. of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139.

Recent research has implicated carbon monoxide (CO) as being a retrograde messenger in the mammalian hippocampus. The major physiological supply of CO depends on the activity of microsomal heme oxygenases, of which there are two isoforms. These enzymes degrade heme molecules to release biliverdin, free iron, and CO. We are currently studying heme oxygenase-2 (HO-2), which is highly expressed in many neuronal populations of the brain. Using homologous recombination in embryonic stem cells, we have generated mice with null mutations in HO-2, in order to remove this source of CO postulated to have roles in neuronal activity. Homozygous HO-2 mutants are viable and are indistinguishable from wild-type litter mates upon sight. Our initial experiments will attempt to determine whether or not endogenous CO normally acts as a type of neurotransmitter. Neuroanatomy and synaptic transmission are therefore being studied in the mutant mice. We are also measuring LTP in HO-2 mutants. The possible role of HO-2 and CO in spatial learning will be investigated, by testing HO-2 mutants in tasks such as the Morris water maze. In addition, second messenger systems reported to be modulated by CO are being examined in the mutants, to determine possible mechanisms of CO action.

TAURINE INDUCES A LONG LASTING INCREASE OF SYNAPTIC TRANSMISSION IN RAT HIPPOCAMPAL SLICES. M. Galarreta¹, J. Bustamante², R. Martín del Río¹ and J.M. Solís^{1*}. ¹Depto. Investigación, Hosp. Ramón y Cajal, and ²Depto. Fisiol., Fac. Medicina, U.C.M., Madrid, Spain.

Although taurine is one of the most abundant amino acids in the brain of mammals, its physiological role in the nervous system is not well defined. The best known electrophysiological effect of taurine is to act as a weak agonist on GABA_A receptors. Our purpose has been to study the actions of taurine on evoked synaptic potentials. Experiments were carried out in the CA1 region of rat hippocampal slices continuously perfused in a submerged chamber. The basic observation was that bath application of taurine (10 mM) for 30 min induced, after a transitory decrement, an enhancement of field excitatory postsynaptic potentials (fEPSPs) that lasted after taurine washout (146±9% after 1h washout, n=15). The following features related with this taurine action can be pointed out: 1) fEPSPs increase is dependent on taurine concentration (5-10 mM) and taurine perfusion time (10-30 min), 2) fEPSP potentiation develops in the presence of GABA_A or NMDA antagonists, 3) N-methyltaurine, a taurine analogue, does not induce fEPSP potentiation, 4) during taurine perfusion the afferent volley (AV) also shows a long lasting increase in amplitude, 6) fEPSP enhancement is not fully explained as a function of the AV increase, as it is demonstrated by the AV/fEPSP relations before and after taurine, 7) the taurine-induced potentiation of the AV is also observed in 0 Ca²⁺ 12 mM Mg²⁺, 8) intracellular recordings of evoked EPSPs and monosynaptic evoked IPSPs show long term increases of both EPSPs and IPSPs amplitudes after taurine perfusion, while input resistance does not change significantly. These results could be explained, at least partially, through a taurine effect on glutamatergic and GABAergic presynaptic fibers, and show a new action of taurine consisting in a long lasting enhancement of synaptic transmission. (Supported by F.I.S.S. 93/0565).

IS ADULT CORTICAL PLASTICITY MEDIATED BY INHIBITORY GATING OF LONG-TERM POTENTIATION IN HORIZONTAL PATHWAYS?

J.P. Donoghue*, C.D. Aizenman, G. Hess. Dept. Neurosci., Brown Univ., Providence, RI 02912; Dept. Animal Physiology, Jagiellonian Univ. Krakow, Poland.

Adult sensory and motor cortical representations are capable of rapid reorganization, but neither the mechanism nor the site for this plasticity is clear. Reorganization of motor cortex (MI) has been obtained by local blockade of inhibition within MI, which implicates inhibitory neurons in plasticity and suggests that intrinsic cortical circuits contain necessary components. We investigated whether persistent changes in the functional interactions of MI neurons can arise by long-term potentiation (LTP) of synaptic transmission in horizontal pathways within layers II/III and whether the occurrence of horizontal LTP is gated by cortical inhibitory circuitry. Field potentials (FPs) evoked in horizontal pathways were examined in adult rat MI slices. Focal, transient application of the GABA_A receptor antagonist, bicuculline methiodide (BMI) immediately before theta-burst stimulation (TBS) resulted in LTP. Simultaneous stimulation of horizontal pathways on either side of the recording site yielded larger LTP (34% increase in FP amplitude), with greater reliability (88% of cases), than stimulation of horizontal pathways from one side alone (24% increase; 57% of cases). Nearby recording sites that did not receive BMI expressed no LTP. Intracellular recordings confirmed the long lasting enhancement of EPSPs following TBS (4 of 9 neurons). Next, the hypothesis that activity in vertical pathways can replace the BMI requirement for LTP induction was tested. Combined TBS of the horizontal pathway and the vertical pathway leading from deep layer III to layers II/III produced LTP in the horizontal pathway FP (21%, 94% of cases). The vertical pathway FP usually potentiated as well (15%, 83% of cases). LTP was blocked reversibly by 50 μM APV.

These data demonstrate the potential for LTP in horizontal pathways of MI and suggest that inhibition may gate synaptic modification. This gate may be opened by conjoint activity with vertical connections which presumably decreases local inhibition. The results demonstrate the importance of temporal interactions among cortical pathways for cortical plasticity and also support the conclusion that intrinsic connections form a substrate for cortical reorganization. Support: NS25217.

551.10

A NOVEL CHOLINERGIC INDUCTION OF LONG-TERM POTENTIATION IN RAT HIPPOCAMPUS. J.M. Auerbach* and M. Segal. Dept. of Neurobiology, The Weizmann Institute, Rehovot 76100, Israel.

Long-term potentiation (LTP) is a lasting increase in the efficacy of synaptic transmission and is assumed to underlie plastic changes associated with learning and memory. As acetylcholine (ACh) is known to be involved in cognitive processes of learning and memory, we studied the long lasting effects of ACh on synaptic transmission in submerged hippocampal slices using intra- and extracellular recording techniques. Here we describe a novel action of the muscarinic agonist carbachol (CCh). Submicromolar concentrations of CCh produced a gradually developing, long-lasting increase in the CA1 excitatory postsynaptic potential (e.p.s.p.) and population spike when continuously applied for 20 minutes, while higher concentrations caused an immediate but reversible depression. This potentiation, named muscarinic LTP (LTP_m) was N-methyl-D-aspartate (NMDA) receptor independent, was independent of influx of extracellular calcium, but was dependent on release of calcium from intracellular stores and on the activation of kinases. LTP_m can be induced in the complete absence of synaptic stimulation, as well as in the absence of intact CA1/CA3 connections. Saturation experiments showed that the mechanisms of LTP_m and tetanus-induced LTP converge. These observations provide a direct link between ACh and mechanisms of synaptic plasticity.

551.12

CONDITIONS FOR LTP INDUCTION STUDIED WITH PERFORATED PATCH-CLAMP METHODS IN VISUAL CORTICAL SLICES OF YOUNG RATS. T. Tsumoto* and Y. Yoshimura. Dept. Neurophysiol., Biomedical Research Center, Osaka University Medical School, Suita, 565 Japan.

For induction of long-term potentiation (LTP) of synaptic efficacy, the membrane potential of postsynaptic neurons during synaptic inputs is suggested to be a critical factor. To test this suggestion, we prepared thin slices (140-150 μm thick) of visual cortex of rats aged 9 to 18 days for whole-cell voltage-clamp recordings from layer 2/3 neurons. Nystatin, which makes the membrane of a cell-attached patch electrically permeable (Horn and Marty, J. Gen. Physiol. 92, 145, 1988), was added to the pipette solution at 200 μg/ml. Excitatory postsynaptic currents (EPSCs) evoked by test stimulation applied to an adjacent layer 2/3 neuron at 0.1 Hz were recorded for 5-10 min after an establishment of perforated patch-clamp recording. Then, test stimulation was paired with postsynaptic depolarization at 1 Hz for 1 min. In 11 of the 15 cells in which the membrane potential was depolarized to -20 mV, LTP of EPSCs was induced following pairing. LTP of EPSCs was observed in 5 of the 14 cells depolarized to -40 mV. No LTP was observed when the postsynaptic cells were clamped at -60, -70 or -90 mV. Thus, the induction of LTP may depend on postsynaptic depolarization more than about -40 mV. Significant LTD was not induced in any of the cells tested with pairing stimulation of neighboring 2/3 cells. A question of whether this is also the case in synapses from layer 4 neurons to layer 2/3 neurons is being addressed with similar pairing procedures.

SYNAPTIC TRANSMISSION BETWEEN DESCENDING FIBERS AND LUMBAR MOTONEURONS OF THE FROG: FACILITATION AND LONG-TERM DEPRESSION OF SINGLE-FIBER EPSPS. A.E. Dityatev^{1,2}, V.M. Kozhanov² and H.P. Clamann¹. Dept. of Physiology, Univ. of Bern¹, CH-3012, Switzerland; Inst. of Evolutionary Physiology & Biochemistry², 195271 St. Petersburg, Russia

Twenty-five data sets of motoneuronal EPSPs evoked by intracellular stimulation of descending fibers of the ventral lateral column were analyzed. Reticulospinal fibers (n=13) were identified by stimulation of the reticular formation; the remaining fibers (n=12) were presumably propriospinal. In both subsets of data there was considerable variability of the mean amplitude (from 44 to 4100 μV) and shape of averaged EPSPs (half-width from 4.9 to 23 ms). Amplitude of the propriospinal EPSPs was higher; in 4 cases mean amplitudes were bigger than 1 mV. There was strong positive correlation between rise-time and half-width and negative correlation between the rise-time and amplitude (for EPSPs with amplitude < 1 mV), implying variability in location of synaptic boutons.

When a test stimulus was evoked in a single fiber 40 ms after a conditioned stimulus, it produced weak facilitation of reticulospinal EPSPs (ratio between mean amplitudes of test and conditioned EPSPs was 1.21±0.22). For the propriospinal fibers (mean ratio 1.05±0.21), facilitation was observed in only a half of studied connections. In the remaining synapses, which all had high amplitude EPSPs, there was weak depression of the test EPSP. Stimulation of a descending fiber at 5 Hz produced strong depression of the EPSP in 1-2 min. Recovery time after 5-10 min of stimulation was from 15 to 30 min (n=4) and in one case recovery was not complete 45 min after termination of 5 Hz stimulation. Ratio between amplitudes of test and conditioned EPSPs was not changed but half-width was increased within 5 min after the stimulation. We suggest that presynaptic mechanisms mediate the depression, and the effect is stronger at more proximal synapses. Supported by SNF.

LONG-TERM POTENTIATION AND KINDLING-INDUCED POTENTIATION IN THE FREELY MOVING GUINEA PIG. G.C. Teskey and P.A. Valentine. Behav. Neurosci. Res. Grp., Dept. of Psychology, Univ. of Calgary, Calgary, AB, Canada T2N 1N4.

This study was undertaken to examine both long-term potentiation (LTP) and kindling-induced potentiation (KIP) in the same structures in freely moving guinea pigs. Guinea pigs were chosen because they exhibit a number of differences in electrical kindling as compared to rats. Male and female, mixed strain guinea pigs were chronically implanted with bipolar stimulating and recording electrodes. Animals had stimulating electrodes implanted in either the olfactory bulb (OB) or lateral olfactory tract (LOT) and recording electrodes in the piriform cortex. Following a two week recovery period, a series of baseline input/output (I/O) response curves were generated. These were based on the application of rectangular 200 μ sec pulses at 11 intensities thru the stimulating electrodes. The potentials evoked in the piriform cortex were analyzed for maximum peak and minimum valley amplitudes. LTP experimental animals received high frequency stimulation (HFS) trains once a day for a total of four days. Kindling experimental animals received a total of 10 stimulations, one per day, consisting of 1 msec biphasic square wave pulses at 60 Hz, for 2 seconds. In these animals the resulting afterdischarges (AD's) were recorded and the convulsive behaviour scored. Post-manipulation I/O's were recorded for several weeks. We report potentiation of the piriform evoked responses to HFS and kindling of the LOT but not to HFS and kindling of the OB. Supported by NSERC and AHFMR.

MOSSY FIBER LONG-TERM POTENTIATION IN CONSCIOUS, FREELY MOVING ANIMALS: TIME COURSE AND INDUCTION PARAMETERS. E.J. Barea-Rodriguez*, B.E. Derrick and J. L. Martinez, Jr. Department of Psychology, University of California, Berkeley, CA 94720.

Previously we reported that in the anesthetized animal, mossy fiber long-term potentiation (MF-LTP) is frequency dependent (J. Neurosci., in press), because a minimum of 30 pulses at 100 Hz are needed to induce MF-LTP. In the present study, we investigated the stimulation parameters necessary for the induction of MF-LTP in conscious, freely moving animals with indwelling electrodes. We found that unlike for the anesthetized preparation, 30 pulses at 100Hz did not induce MF-LTP but that seizures were induced. By contrast, when the animals were placed in a novel environment, the administration of two 100 Hz trains induced MF-LTP, without the occurrence of seizures. This potentiation decayed within 24 hrs. We propose that the physiological mechanisms associated with hippocampal theta activity which are present in novel environment, prevent the occurrence of seizures and facilitate the induction of MF-LTP.

GENE EXPRESSION ASSOCIATED WITH HIPPOCAMPAL MOSSY FIBER LONG-TERM POTENTIATION D.T. Rivera*, B.E. Derrick, W. Meilandt, M.R. Rosenzweig and J.L. Martinez, Jr. Departments of Psychology and Cell and Molecular Biology, University of California, Berkeley, CA 94720.

Long-term potentiation (LTP) is a long lasting form of synaptic plasticity that currently is considered a viable model of memory storage in the mammalian brain. Such sustained plastic changes are likely maintained by alterations in gene expression. To study gene expression associated with LTP, we induced mossy fiber LTP unilaterally in anesthetized rats in the presence of the NMDA receptor antagonist (+/-)-CPP, while the contralateral hippocampus was not potentiated and was used as a control. Three hrs after LTP induction, mRNAs were isolated from both hippocampi. A cDNA library was generated from the potentiated hippocampal tissue. This library then was subtracted from cDNAs amplified *in vitro* from the contralateral, non-potentiated, control hippocampus. This subtraction yielded 44 subtracted clones. Partial screening of these clones for LTP-association using Northern blot analysis revealed one clone preferentially hybridized to the same gene expressed in a hippocampus of a separate rat in which mossy fiber LTP was induced. We termed this gene LAG-19 for LTP-associated gene 19. Restriction endonuclease analysis of this gene identified its size as 5600 bp. Thus far, partial DNA sequencing of LAG-19 reveals no homology to published sequences in the Genbank nucleotide database. Future analysis will focus on continued screening and on the identification of other subtracted clones. Supported by DA 04195 (JLM), NSF-DCR 9101951 (DTR), NIDA DA04795 (MRR).

A DEVELOPMENTAL EXAMINATION OF LTP IN FREELY-MOVING RATS. J.D. Bronzino*, R.J. Austin-LaFrance and P.J. Morgane. Dept. of Engineering and Computer Science, Trinity College, Hartford, CT 06106.

This study examined the establishment, maintenance, and decay of LTP across the perforant path/dentate granule cell synapse in freely-moving rats at 15, 30, and 90 days of age. Measures of population spike amplitude (PSA) and population EPSP slope were used to assess the magnitude and duration of LTP obtained from each age group. At 15 days of age, significant potentiation of both EPSP slope and PSA measures was obtained 15 min. after tetanization. This enhancement was maintained without significant change over the first 24 hrs. post-tetanization, after which these measures rose steadily during the 5 day recording period. To determine what percentage of this rise resulted from tetanization and what percentage resulted from normal development, input/output curves were recorded daily from non-tetanized pups as they matured from PND 16-29. Subtraction of developmental increases indicated that tetanization effects decayed to baseline between days 4 and 5 post-tetanization. At both 30 and 90 days of age, significant enhancement of both EPSP slope and PSA measures was obtained 15 min. after tetanization. These levels were significantly below those obtained from 15 day olds and were maintained without significant change for only 3-5 hrs., decaying to baseline within 24 hrs. Results indicate that LTP of both the EPSP slope and PSA can be reliably established in 15-day old rats, and that both the magnitude and duration of this LTP is significantly greater than that obtained from juveniles or adults. The immature functional status of GABAergic interneuronal synaptic contacts with the granule cell population is hypothesized as a possible mechanism underlying both the greater magnitude and longer duration of LTP obtained from 15 day old animals. Supported by NSF Grant # BCS-9208128.

SYNAPTogenesis INDUCED BY HIPPOCAMPAL MOSSY FIBER LONG-TERM POTENTIATION. M.L. Escobar*, E.J. Barea-Rodriguez, J.A. Reyes, B.E. Derrick, and J.L. Martinez, Jr. Department of Psychology, University of California, Berkeley, CA 94720.

Evidence that neural activity may cause the formation of synapses in the adult brain has come from studies of limbic seizures and kindling in the rat hippocampus (TINS 13: 312-318, 1990; J. of Neurosci. 9: 2795-2803, 1991). It has been shown that long term potentiation (LTP) of mossy fiber responses in area CA3 of the rat hippocampus constitutes an opioid receptor-dependent form of hippocampal synaptic plasticity (Brain Res. Bull., 27: 219-223, 1991). In the present study, Timm sulfide silver technique was used to examine whether LTP at the mossy fiber-CA3 synapse affects structural reorganization and synaptic formation in the adult rat hippocampus *in vivo*. Our results show that seven days after LTP induction, a prominent band of Timm's staining is present bilaterally in the infrapyramidal band but is more prominent in the contralateral CA3 (*stratum oriens*). In addition, we found that naloxone (an opioid receptor antagonist) reverses this effect. Stimulation induced increases in Timm's staining, not associated with LTP, was also evident. The increase in Timm's staining which we interpret to be synaptic reorganization, becomes apparent as soon as 1 hour after the LTP induction and is quite pronounced after 7 days. These results indicate that synapses are formed in response to neural activity associated with LTP thus, experience-dependent information storage could involve local, activity-dependent synaptogenesis.

IDENTIFICATION OF A NOVEL G-PROTEIN COUPLED RECEPTOR IN THE VENTRAL TEGMENTUM BY PCR. M.E. Charlton* and R.S. Duman. Laboratory of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Previously we described the PCR based identification of cDNA fragments encoding novel G-protein coupled receptors in the rat brain (Soc. Neuro. 19 Abstract #634.8). PCR of cDNA derived from the ventral tegmentum with degenerate primers to the third and sixth transmembrane domains (Libert *et al.*, *Science* 244:569, 1989) resulted in the amplification of several previously identified (e.g. beta2-adrenergic, dopamine D2, neuromedin K) as well as several novel PCR clones. One of these clones, VT 15-20, was chosen for further study. Sequence analysis revealed that this cDNA fragment is most homologous at the nucleotide and amino acid levels to the IL-8 receptor (approximately 40%). Northern blot analysis of rat spleen RNA detected a single major RNA species of approximately 2.0 kb in length. The relative abundance of this clone was determined by ribonuclease protection assay: levels of VT 15-20 mRNA were highest in the spleen, lung, heart, and liver with lower levels in the thalamus, pons, frontal cortex, and hippocampus. In addition, VT 15-20 mRNA was also detected in neuroblastoma (locus coeruleus-like) and hemopoietic (HL-60) cell lines. The cellular distribution pattern of this clone is being determined by *in situ* hybridization. We are currently in the process of isolating a full length clone encompassing VT-15-20 from a rat spleen cDNA library. Further study will include characterizing the ligand specificity, pharmacology, and regulatory properties of the receptor.

MOLECULAR CLONING OF A NOVEL CANDIDATE G PROTEIN-COUPLED RECEPTOR FROM RAT BRAIN. Z. H. Song*, W. S. Young, M. J. Brownstein and T. J. Bonner. Lab. of Cell Biology, NIMH, NIH, Bethesda, MD 20892

To clone novel G protein-coupled receptors, degenerate primers designed from the regions conserved between SKR6 (a cannabinoid receptor) and edg-1 (a published orphan receptor) yet distinguishing them from other receptors, were used to amplify the DNA prepared from a rat cerebral cortex cDNA library. rCN3, one of the clones generated by PCR, had amino acid sequence features typical of G protein-coupled receptors. Using a radiolabeled PCR fragment of rCN3 as a probe, a full-length cDNA was isolated from the rat cerebral cortex library. This 1.8 kb full-length cDNA of rCN3 contained a 1098 base pair open reading frame, encoding 363 amino acid residues. Sequence analysis demonstrated that rCN3 possesses a number of structural characteristics of rhodopsin-like G protein-coupled membrane receptors, including seven putative hydrophobic transmembrane domains and six connecting loops. Comparing the sequence of rCN3 with other G protein-coupled receptors revealed that rCN3 is similar to GPCR1 and GPCR21 (61% amino acid identity in transmembrane region one through carboxy-terminal), two other published orphan G protein-coupled receptors. Therefore, rCN3, together with GPCR1 and GPCR21, may belong to a novel G protein-coupled receptor subfamily with identical or closely related endogenous ligand. Northern and *in situ* hybridization experiments demonstrated that rCN3 mRNA is present in the rat brain, with particularly high levels of expression in striatum and retrosplenial cortex. The precise physiological role of rCN3 awaits elucidation of its ligand and signal transduction pathways.

CHARACTERIZATION OF THE RAT CEREBELLAR ENDOTHELIN_B (ET_B) RECEPTOR USING THE NOVEL AGONIST [125I]BQ3020 M.E. Jarvis*, A.A. Assal, and G.E. Martin. Rhône-Poulenc Rorer Central Research, Collegeville, PA 19426

The complex binding of radiolabeled endothelin isopeptides (ET-1, ET-2, ET-3) in rat brain has indicated the existence of multiple affinity subtypes of the ET_B receptor. Vasodilation has been associated with an interaction with a "super high affinity" ET receptor subtype whereas vasoconstriction is mediated via a different "high affinity" receptor subtype. Recently, a linear peptide fragment of ET-1, N-acetyl-[Ala^{11,15}]ET-1(6-21) (BQ3020) has been identified as a potent and ET_B-selective agonist. The present studies were conducted in order to characterize the binding of [125I]BQ3020 to the ET_B receptor in rat cerebellum. [125I]BQ3020 (0.1 nM) bound with high specificity (90% of total) and selectivity for the ET_B receptor. ET-1, ET-2, and ET-3 inhibited 0.1 nM [125I]BQ3020 binding with equivalent affinity (K_i values = 55 - 110 pM). The sarafotoxins S6a, S6b, and S6c also potentially inhibited [125I]BQ3020 binding (K_i values = 55 - 2000 pM). The ET_A-selective antagonist, BQ123 (10 μM) did not significantly inhibit [125I]BQ3020 binding. Ligand saturation studies indicated that [125I]BQ3020 bound a single class of recognition sites with very high affinity (K_d = 31 pM) and limited capacity (B_{max} = 570 fmol/mg protein). High affinity 0.1 nM [125I]BQ3020 binding was reduced by 40-50% in the presence of 1 nM guanine nucleotides. ET-1 was found to produce a biphasic inhibition curve in competing for 0.5 nM [125I]BQ3020. This ET-1 inhibition curve was made monophasic and shifted to the right in the presence of 1 mM GTP-γ-S. The guanine nucleotide sensitivity of [125I]BQ3020 binding suggests that the different functional consequences of ET_B receptor activation may be mediated by different affinity states of the receptor.

552.2

IDENTIFICATION OF A PUTATIVE CHEMOKINE RECEPTOR FROM RAT LOCUS COERULEUS BY PCR. S. R. Marsh*, M. E. Charlton, and R. S. Duman. Laboratory of Molecular Psychiatry, Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Studies in our laboratory have examined the molecular and cellular determinants which underlie the function of the locus coeruleus (LC), the major noradrenergic nucleus in brain. One approach is to identify and characterize novel G protein-coupled receptors from this brain region using PCR. cDNA derived from the LC, and other discrete regions of rat brain, was PCR amplified using a set of degenerate primers derived from the conserved third and seventh transmembrane-spanning domains of the IL-8, δ-opioid, angiotensin II, somatostatin, substance P and substance K receptors. The resulting PCR products (ranging from 300 to 1000 bp) were then subcloned and identified by sequencing. Some of these clones corresponded to previously published sequences, such as the SSTR-2 receptor and a D4-like receptor. Another clone (LCR3-12), amplified from LC cDNA, shared properties with other G protein-coupled receptors and was most homologous (52% identical over a 100 amino acid stretch) to the human C-C chemokine receptor type 1 (Neote *et al.*, *Cell* 72, 415, 1993). RNase protection analysis showed high levels of LCR3-12 mRNA in rat spleen and lung, with lower levels in kidney, liver, pons, thalamus, midbrain, olfactory bulb, and cerebellum. Northern blot analysis revealed two primary transcripts of approximately 1.7 and 4.8 kb. Further studies are in progress to isolate a full length cDNA clone for LCR3-12, and then to investigate its ligand-binding and functional properties.

CLONING, CHROMOSOMAL LOCALIZATION AND EXPRESSION MAPPING STUDIES OF HUMAN GENES ENCODING G PROTEIN-COUPLED RECEPTORS. M. Heiber, T. Nguyen, J. Docherty, H. Heng, R. Cheng, A. Marchese, G. Shah, X. Shi, L.-C. Tsui, S. George and B. O'Dowd*. Addiction Res. Found. and Dept. of Pharm., Univ. of Toronto, and The Research Institute, Hospital for Sick Children, Toronto, ON, Canada M5S 1A8

Following the cloning of the opioid receptors (OR) μ, κ and δ, we searched for related receptors. We used oligonucleotides based on the OR to amplify human genomic DNA using PCR, and we have isolated fragments encoding 11 unique GPCR genes. We have obtained full length clones containing 9 of these genes and each of the encoded receptor structures most closely resemble peptide binding GPCR. Two genes designated #11 and #12 shared 70% identity with each other and each shared 40% identity in the transmembrane (TM) regions of the opioid receptors. Gene #11 was mapped to C20 (q13.3) and gene #12 to C10 (q11.2-q21.1). mRNA transcripts from these genes are expressed in the frontal cortex, and *in-situ* hybridization histochemistry revealed expression of gene #12 in the human pituitary and mouse brain demonstrated expression in the PVN of hypothalamus. Gene #33, mapped to C15 (q21.6), encoded a receptor with identity to the OR in the TM regions. Northern analysis revealed #33 transcripts were located in the hippocampus, and *in situ* analysis in the rat brain revealed expression in the dentate gyrus and the CA 1-3 regions of hippocampus. Gene #64, mapped to C6 (q21-22.1), was expressed in the human caudate. Gene #14 mapped to C19 (q13.2-13.3), gene #18 to C17 (q21.1 to 21.3), but neither gene was expressed in brain regions. Gene #53 was mapped to C1 (p36). We predict that the discovery of these receptors represent an advance in the understanding of the functions of peptide transmitter systems in brain.

552.6

CHARACTERIZATION OF CORTICOTROPIN RELEASING FACTOR RECEPTORS FROM HUMAN SMALL CELL LUNG CARCINOMA (SCLC) CELLS. K.D. Dieterich, D.E. Grigoriadis and E.B. DeSouza*. Neurocrine Biosciences, Inc. San Diego, CA 92121.

Numerous peptides, growth factors and receptors have been identified in small cell lung carcinoma (SCLC) cells which account for 25% of bronchogenic neoplasms. We examined the radioligand binding, second messenger and mRNA characteristics of corticotropin releasing factor (CRF) receptors in a variety of human SCLC cell lines and compared their characteristics to CRF receptors in the mouse pituitary tumor cell line AtT-20. The human SCLC cell lines NCI H-69, H-82, H-146, H-209, H-345, H-446, and H-510A all demonstrated specific [125I]Tyr⁰-ovine CRF ([125I]oCRF) binding which was linear with increasing protein concentrations, saturable, reversible and of high affinity. NCI H-82 showed the highest level of specific [125I]oCRF-binding (about 60% of total binding). Scatchard analysis revealed a single class of binding sites in NCI-H82 and AtT-20 cells with K_D values of 263 ± 48 and 285 ± 75 pM and B_{max} values of 74 ± 7 and 70 ± 13 fmol/mg protein, respectively. [125I]oCRF-binding sites on NCI-H82 cells demonstrated pharmacological rank order of potencies for a variety of CRF-related peptides comparable to those seen in AtT-20 cells. Ovine, bovine and rat/human CRF all inhibited the binding with similar K_i values (1 nM) while the peptide antagonist α-helical oCRF had a K_i value of 27-49 nM. VIP, GHRH, secretin and the de-amidated peptide bovine CRF(1-41)OH did not inhibit the binding. [125I]oCRF-binding was inhibited by guanine nucleotides suggesting a coupling of receptors to guanine nucleotide binding proteins. CRF stimulated cAMP production in NCI-H82 and AtT-20 cells with EC₅₀ values of about 2 nM. Northern blot analysis of total RNA revealed the presence of a 2.6kb mRNA band in NCI-H82 cells corresponding to the CRF-R1 variant of the recently cloned human CRF receptor. In summary, the data demonstrate the presence of CRF receptors in SCLC cells with kinetic, pharmacological, second messenger and mRNA characteristics comparable to those in pituitary and brain and suggests the utility of this cell line for CRF-related studies.

552.7

PHARMACOLOGICAL CHARACTERIZATION OF RAT AND HUMAN CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS EXPRESSED IN STABLE CELL LINES. D.E. Grigoriadis*, C.W. Liaw, T. Oltersdorf and E.B. De Souza, Neurocrine Biosciences Inc., San Diego, CA 92121.

Over the past decade, substantial evidence has accumulated from both laboratory and clinical studies implicating corticotropin-releasing factor (CRF) as a physiological mediator of stress responses or stress-induced disorders. Recently, using an expression cloning approach a CRF receptor cDNA was isolated from a human ACTH-secreting pituitary adenoma. Full length human and rat CRF receptor cDNAs were subcloned in the mammalian expression plasmid pCDM-7 amp containing the human cytomegalovirus (CMV) promoter or a modified version of pCDM-7 in which the CMV promoter was replaced with the RSV promoter. These constructs were co-transfected with pSV-2neo into two different cell backgrounds, COS-7 and Ltk-, which do not normally express CRF receptors, using the calcium phosphate precipitation method resulting in the generation of stable cell lines. CRF receptors expressed in these cell lines demonstrated reversible, saturable, high-affinity binding to CRF with the pharmacological and functional characteristics comparable to those found in a variety of animal or human tissues. [¹²⁵I]CRF bound to a single population of binding sites in Ltk- cells transfected with human and rat CRF receptors with apparent affinities (K_D) of 130 and 168 pM and receptor densities of 97 and 588 fmol/mg protein respectively. The pharmacological rank order of potencies of CRF and related peptides was identical to the established profile for the CRF receptor in the rat frontal cortex. In addition, CRF receptors transfected into these cell lines were coupled to a guanine nucleotide binding protein and when incubated with CRF, could stimulate the production of cAMP from these cells with an EC₅₀ of approximately 1 nM. Furthermore, CRF-stimulated cAMP production could be inhibited by specific and selective peptide antagonists to the CRF receptor. The stable expression of CRF receptors in clonal cell lines represents an unique opportunity for the discovery of non-peptide agonists or antagonists to the human receptor for the possible treatment of CRF-mediated disorders.

552.9

PRESENCE OF CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS ON HUMAN PERIPHERAL BLOOD CELLS AND MONOCYTE LINES. P.J. Reynolds, D.E. Grigoriadis, T.W. Lovenberg*, T.T. Wong, D.P. Behan, E.B. DeSouza, and P.J. Conlon, Neurocrine Biosciences, Inc. San Diego, CA 92121.

Corticotropin releasing factor (CRF), a 41-amino acid peptide, plays a significant role in integrating the stress-related and inflammatory responses to immunological agents such as viruses, bacteria, or tumor cells through its coordinated actions in the nervous, endocrine and immune systems. In addition to its effects on the hypothalamus-pituitary-adrenal (HPA) axis, CRF has recently been reported to exacerbate inflammatory responses. *In vitro* CRF has been described to enhance pro-inflammatory cytokine production. *In vivo*, anti-CRF antibody treatment was shown to lessen the recruitment of cells to an inflammatory site. In an effort to better understand the mechanism(s) of action whereby CRF may be involved in inflammation, CRF-receptor binding studies were carried out on immune cell populations. Specific, saturable high affinity binding of CRF to human peripheral blood cells was observed. CRF-receptors were also detected on the human monocyte-like cell lines THP-1 and U937. No appreciable CRF binding was seen on HuVec cells and the human promyelocytic cell line HL-60. The presence of the CRF receptor was confirmed on peripheral blood mononuclear cells and monocyte lines using RT-PCR. Given that peripheral mononuclear cells express CRF receptors, further studies are underway to determine which immune cell populations express CRF receptors, and whether these receptors are modulated during an immune response; and if so, is receptor modulation due to pro-inflammatory cytokine production? These studies are likely to further our understanding of the role of CRF in inflammation.

EVIDENCE OF FUNCTIONAL GROWTH HORMONE-RELEASING FACTOR RECEPTORS IN RAT HYPOTHALAMUS. L. Boulanger* and P. Gaudreau, Neuroendocrinology Laboratory, Notre-Dame Hospital Research Center and University of Montreal, Montreal, Canada, H2L 4M1.

Recent reports suggest the existence of GRF receptors mediating endocrine and behavioral actions of this peptide, in the hypothalamus. Our goals were to characterize GRF binding sites in hypothalamus homogenates and to determine if this binding leads, as in the anterior pituitary, to the stimulation of adenylate cyclase (AC) activity. In our assay conditions (Tris buffer pH 7.4 containing MgCl₂, EDTA, sucrose, diprotine and BSA, ≈ 200 µg prot./tube, 1 h, 4°C), [¹²⁵I-Tyr¹⁰]hGRF(1-44)NH₂ was stable and specific binding represented 40-50% of the total binding. This binding was temperature and time-dependent, reversible and saturable. The affinity was hGRF(1-29)NH₂ > Nα-Ac-[His¹,D-Arg²] >> [Ala¹] ≈ [Ala²] ≈ [Ala¹⁰]. VIP and PACAP were inactive at 0.1 µM. In our AC assay conditions (Lefrançois and Gaudreau, J. Chromatogr., 1993), hGRF(1-29)NH₂ elicited a concentration-dependent production of cAMP. Although the efficacy of GRF was much lower in the hypothalamus than in the pituitary, its potency was similar in both tissues (EC₅₀ ≈ 40 nM). The antagonist, Nα-Ac-[His¹,D-Arg²]GRF(1-29)NH₂ did not stimulate AC activity, but substantially inhibited the response to hGRF(1-29)NH₂. Although these results support the existence of functional hypothalamic GRF receptors, they still have to be localized to establish their involvement in the regulation of GRF secretion and control of appetite.

COLORIMETRIC ASSAY FOR RAPID SCREENING OF CRF RECEPTOR LIGANDS. C.W. Liaw, D.E. Grigoriadis, E.B. De Souza, T. Oltersdorf* Neurocrine Biosciences, Inc. San Diego, CA 92121.

Corticotropin releasing factor (CRF) is the primary regulator of ACTH secretion and other pro-opiomelanocortin-derived peptides from the anterior pituitary gland. The receptor for corticotropin releasing factor is known to be coupled to G_s and transduces its signal through stimulation of cAMP production. Here we describe the characterization of several stable rat and human CRF receptor-expressing LVIP2.0Zc cell lines which also contain an exogenous cyclic AMP responsive β-galactosidase reporter gene construct. CRF receptor activity was assayed by measuring the induction of β-galactosidase in response to CRF. Rat/human and bovine CRF stimulated β-galactosidase activity in a dose dependent manner with EC₅₀ values of ~0.1 nM; the biologically weak deamidated analog of bovine CRF was ~500-fold less potent. The pharmacological specificity of the interaction was further demonstrated by the dose-dependent inhibition of CRF-stimulated β-galactosidase activity by CRF receptor antagonist, [D-Phe¹²,Nle^{21,38},Ala³²] r/hCRF(12-41). The magnitude of the maximal response to CRF varied among individual cell lines. This variation was independent of the level of CRF receptor expression, but reflected differences in the intrinsic activity of adenylate cyclase. In contrast to most cyclic AMP assay systems, the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine decreased the CRF induced β-galactosidase activity when used in the context of the assay regimen described here. Since the assay can be easily performed in a high throughput 96-well plate format, these cell lines provide an efficient way for the identification of CRF receptor agonists and antagonists.

CORTICOTROPIN RELEASING FACTOR-BINDING PROTEIN IN HUMAN BRAIN: IDENTIFICATION AND CHARACTERIZATION IN ALZHEIMER'S DISEASE. D.P. Behan, J.C. Troncoso, N. Ling*, and E.B. De Souza, Neurocrine Biosciences, Inc. San Diego, CA 92121 (D.P.B. and E.B.D.S.) and Neuropathology Lab, Johns Hopkins University School of Medicine, Baltimore, MD 21205 (J.C.T.).

Corticotropin releasing factor (CRF), a 41-amino acid peptide, has been implicated in cognitive function and in neurologic illness such as Alzheimer's disease (AD). Overall, large deficits in CRF and a reciprocal up-regulation of CRF receptors in brain areas affected in AD have been observed. A membrane-associated form of a binding protein with high affinity for CRF (CRF-binding protein; CRF-BP) and the ability to inactivate CRF has recently been identified in brain areas (cerebral cortex, amygdala and hippocampus) that are affected in AD and are involved in learning and memory processes. The present study was designed to characterize and quantify CRF and CRF-BP in postmortem brain samples of Alzheimer's patients and age-matched controls. CRF-BP levels were measured in NP-40 solubilized membranes of occipital, parietal, frontal and temporal cerebral cortex using a specific two-site ligand immunoradiometric assay. CRF-BP levels in cerebral cortex ranged from 300 - 700 ng/g wet weight and approximately 70% - 85% of the total CRF-BP activity was membrane associated. Pharmacological characterization of the CRF-BP activity solubilized from cerebral cortex revealed a rank order of binding potency [human CRF > α-helical ovine CRF(9-41) > human CRF(6-33) >> ovine CRF] identical to that seen for recombinant human CRF-BP. As previously reported, CRF levels were decreased (>50% reductions) in all areas of the cerebral cortex examined in AD as compared to age-matched controls; no significant alterations in the pharmacological characteristics or levels of CRF-BP were noted in the same tissue samples between groups. In summary, these data provide evidence for the presence of CRF-BP in normal and AD brain tissue and suggest that deficits in CRF may be due to decreased CRF synthesis and/or increased degradation rather than neuronal loss or that CRF-BP is mainly confined to a separate group of non-CRF neurons which are spared in dementia.

CELLULAR UPTAKE OF INTRACEREBROVENTRICULARLY INJECTED ANTISENSE OLIGODEOXYNUCLEOTIDES INTERNALLY LABELED WITH BIOTIN OR DIGOXIGENIN. F. Yee*, H. Ericson, D.J. Reis and C. Wahlestedt, Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell University Medical College, New York, NY 10021.

Recently, we have demonstrated that intracerebroventricular (icv) administration of antisense oligodeoxynucleotides (ODNs) specific for the rat neuropeptide Y (NPY) - Y1 receptor and N-methyl-D-aspartate (NMDA)-R1 receptor subunit resulted in decreases of the respective binding levels (Wahlestedt, *et al.*, *Science*, 259:528, 1993; Wahlestedt *et al.*, *Nature*, 363:260, 1993). In addition, treatment with the NPY-Y1 antisense ODNs was shown to produce anxiety-like effects, and treatment with the NMDA-R1 antisense ODNs reduced focal ischemic infarctions in rats.

In contrast, the intracellular fate of icv injected ODNs has not been well characterized. In the present study, we used biotin or digoxigenin to label the rat NPY-Y1 and NMDA-R1 receptor antisense ODNs at an internal position, and examined their cellular uptake at several timepoints (*i.e.* 15 min, 1, 2, 4 and 6 hrs) after icv administration. Because the biotin antibody detected endogenous biotin in addition to the biotinylated antisense ODNs, we used digoxigenin to label the antisense ODNs. We found the most intensely stained cells near the injection site, along with labeling of the vasculature and surrounding cells, which were mainly in ventral cortical regions.

The stability of the icv injected antisense ODNs were examined by performing recovery experiments, and a portion of the intact digoxigeninated antisense ODNs were detected in the cytoplasmic and nuclear fractions of rat brain extracts.

EXPRESSION OF PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE RECEPTOR SUBTYPES IN SUPERIOR CERVICAL GANGLION NEURONS. K. M. Braas* and V. May. Dept. of Anatomy & Neurobiology, Univ. of Vermont Coll. of Medicine, Burlington, VT 05405.

Pituitary adenylate cyclase activating polypeptides (PACAP) belong to the vasoactive intestinal polypeptide (VIP)/secretin/glucagon family of bioactive peptides. The PACAP type I receptor is specific for PACAP, while the type II receptor displays similar affinity for PACAP and VIP. Splice variants of the type I PACAP receptor differentially stimulate adenylate cyclase and phospholipase C. The PACAP peptides exerted potent regulation of superior cervical ganglion (SCG) neuropeptide Y (NPY) and catecholamine (CA) expression. PACAP38 and PACAP27 stimulated sustained secretion of NPY and CA from cultured rat SCG neurons; neurosecretory responses to PACAP were approximately 100-fold more potent than to VIP. To identify the population of responsive SCG neurons, binding was determined using biotinylated PACAP38. Over 60% of the SCG neurons were labeled and may be responsive to PACAP regulation. To distinguish the expression of type I PACAP receptor isoforms, the presence or absence of either one or two 84 bp cassettes was examined using reverse transcription and polymerase chain reaction (RT-PCR) with mRNA from fetal, neonatal, adult and cultured SCG cells. The predominant molecular form of PACAP receptor mRNA identified by RT-PCR contained one 84 bp cassette; further hybridization studies are necessary to identify the specific insert. No PCR products were observed using primers specific for the VIP (type II) receptor. These studies demonstrate that SCG neurons express specific type I PACAP receptor mRNA, bind PACAP and respond to PACAP stimulation. Supported by HD-27468.

XENOPUS OOCYTES INJECTED WITH RAT BRAIN POLY (A⁺) RNA EXPRESS ADRENOMEDULLIN-SENSITIVE RECEPTORS. Y. Uezono*, H. Kobayashi*, T. Nagatomo*, H. Yamashita*, A. Wada* and F. Izumi. Depts. of Pharmacol. and *1st Physiol., Sch. of Med., Univ. of Occup. and Environ. Health, Kitakyushu 807; #Dept. of Pharmacol., Miyazaki Medical College, Kiyotake 889-16, Japan.

Adrenomedullin (AM), a 52 amino acid peptide, has been recently discovered from human pheochromocytoma which has a hypotensive effect via an elevation of cAMP. AM is localized in several tissues other than pheochromocytoma such as brain, lung, kidney and structurally homologous to the calcitonin gene-related peptide (CGRP) and amylin, the peptides known to exert their effects via increasing cAMP. Little is known, however, about the receptors for AM. We have reported that the protein encoded by the cystic fibrosis transmembrane conductance regulator gene (CFTR), the Cl⁻ channel activated by A-kinase, can be used as a sensitive reporter for cAMP changes in *Xenopus* oocytes (Receptors and Channels 1:233 (1993)). In the present study to see whether brain expresses the AM receptors, we injected cRNA for the CFTR along with poly (A⁺) RNA from rat brain into oocytes. Three days after injection, rat AM resulted in a concentration-dependent increase in Cl⁻ current via CFTR channels with the maximal response at 10⁻⁷M. In the same oocyte, both CGRP and amylin 10⁻⁷M also caused CFTR currents. The potencies for the CFTR currents of the three peptides were CGRP > AM >> amylin. The present results suggest this is a novel method for functional expression cloning of the receptors; although it is not known whether all three peptides have their own receptors or share several types of common receptors.

TRANSIENT CEREBRAL ISCHEMIA INDUCES OVEREXPRESSION OF OXYTOCIN RECEPTORS IN THE GERBIL HIPPOCAMPUS. M. Dubois-Dauphin*, C. Bouras, and P. Vallet. Dept. of Physiology, University Medical Center, 1211 Geneva, Dept. of Psychiatry, Div. of Morphology, 1225 Geneva, Switzerland.

Using an iodinated oxytocin (OT) antagonist and light microscopy autoradiography, oxytocin receptors were detected in the brain of adult male gerbils following transient cerebral ischemia (6 min.). Either immediately or 10, 30, 100 hrs later, the animals (3/series) were reanesthetized and their brain quickly removed and frozen in isopentane. Section were incubated with 0.05 nM of [¹²⁵I]-labelled-d(CH₂)₅[Tyr(Me)², Thr⁴, Tyr-NH₂⁹] OVT with or without an excess of OT in order to determine the non specific binding. In control animals, specific binding occurred in various regions of the brain (bed nucleus of the stria terminalis, amygdaloid nuclei, anterior periventricular hypothalamus, subiculum, dorsal motor nucleus of the vagus nerve). In the hippocampus, binding sites were localised in *stratum oriens* and *stratum radiatum*. The labelling covers uniformly these layers suggesting that oxytocin receptors could endow glial cells rather than interneurons. Hippocampal pyramidal cell layers were devoid of binding sites. After 10-100 hours of survival following ischemia, a marked increase of the density of oxytocin binding sites was detected in the *stratum oriens* dorsal to the CA1 pyramidal layer in the anterior hippocampus. A delayed neuronal death with a drastic loss of neurons was observed in the CA1 layer after 48 hours of survival following ischemia. Concomitantly, an increase of GFAP immunoreactivity was observed in this region and in the *stratum oriens* as well. Thus, the increase in the density of oxytocin receptors in the *stratum oriens* following transient cerebral ischemia appears to be associated with glial cells and could be related to neuronal death occurring in the pyramidal CA1 layer.

DISTINCT RECOGNITION RESIDUES FOR BENZODIAZEPINE AND PEPTIDIC CCK RECEPTOR ANTAGONISTS DETERMINED BY SITE DIRECTED MUTAGENESIS. E. Malatynska, R.J. Knapp, D.Stropova, P. Peterson, E. Yarga, H.I. Yamamura and W.R. Roeske*. University of Arizona Dpt. of Pharmacology, Tucson, AZ 85724.

CCK-B receptor antagonists are important as anxiolytics, neuroleptics, antinociceptive and antisatiety drugs. This abstract describes the possible recognition sites for CCK receptor antagonists with different chemical structure. The rat CCK-B receptor cDNA was obtained by PCR using primers derived from the sequence first described by Wank et al. (PNAS 89:8691, 1992). The cDNA was cloned in the pCRII vector and then transferred to pSV-Sport1 expression vector. COS-7 cells transfected with this recombinant vector expressed high levels (B_{max} = 210 fmol/mg protein) of the CCK-B receptors. The expressed receptor was fully functional since SNF 8702 (CCK-B selective ligand) increased free cytoplasmic calcium levels with an A₅₀ value of 66 pM. Here we used the recombinant rat CCK-B/pSV-Sport1 vector to produce single amino acid mutation of Val³⁴⁹ residue located on VIth TMD to Leu using the unique site elimination method. Selectivity of the benzodiazepine derivatives L365,260 for CCK-B and L364,718 for CCK-A receptors results from the presence of Val³⁴⁹ or Leu at this position, respectively (Beinborn et al., 1993). It was tested here whether this residue is also important for peptidic CCK-B receptor antagonist. For Val³⁴⁹ CCK-B receptor the IC₅₀ values of L364,718, L365,260 and PD134308 (peptoid) were as follows 617 nM, 253 nM and 18 nM, respectively. These values agree with CCK-B receptor antagonists profile. For mutant Leu³⁴⁹ CCK receptor the IC₅₀ values of L364,718 (96.4 nM) and L365,260 (424.2 nM) were inverted while the IC₅₀ value for PD134308 (26 nM) was unchanged. Thus, the antagonist profile for the benzodiazepine derivatives switch to that of CCK-A receptor while the affinity for PD134308 remains as that of CCK-B receptor. The conclusion of this study is that benzodiazepine and peptidic CCK antagonists have distinct recognition residues.

552.16

CLONING THE GUINEA PIG CALCITONIN RECEPTOR. A. Sarkar* and I.M. Dickerson. Dept. Phys. and Biophys., Univ. Miami Sch. Med., Miami, FL.

Calcitonin is a 32 amino acid peptide hormone which interacts with both central and peripheral calcitonin receptors. The calcitonin receptor is a member of the class of 7-transmembrane G protein-coupled receptors. The deduced amino acid sequences of rat, human and porcine calcitonin receptors were aligned. From this alignment, degenerate oligonucleotide primers were designed for the polymerase chain reaction (PCR). The primers were denoted CTR-1, CTR-2, and CTR-3. CTR-1 is the upstream PCR primer located in the proposed N-terminal extracellular domain. CTR-1 is a 27mer and is 2048-fold degenerate. CTR-2 is the downstream PCR primer located just prior to the first transmembrane domain, and is a 131,072-fold degenerate 27mer. CTR-3 is the primer for reverse transcription, located between the proposed transmembrane loops II and III and is a 30mer with 2048-fold degeneracy. Reverse transcription was performed on guinea pig kidney and cerebral poly A⁺ mRNA using CTR-3 as a primer. An aliquot of the reverse transcription reaction was used as template for the PCR reaction in which CTR-1 and CTR-2 served as primers. The resulting PCR products were cloned into the plasmid pAMP-1 (GIBCO-BRL). DNA was isolated from 24 colonies, and digested with restriction enzymes that flank the cloning region. The subcloned PCR products were the expected size of 222bp. Twenty-four individual subclones representing kidney and cerebral PCR amplified products were selected for sequencing. DNA sequencing revealed that all clones were identical, with >90% identity to previously cloned calcitonin receptors. This indicates that the guinea pig, like the human and pig, may contain a single calcitonin receptor isotype, unlike the rat, which contains two calcitonin receptors isotypes. Our subcloned PCR product is denoted ppp.CTR. Northern Blots probed with ppp.CTR insert identified a 4.0 Kb RNA, in agreement with the size reported for the porcine and human calcitonin receptor RNA. The sequence of the calcitonin receptor will be compared to the known calcitonin receptors, and the pharmacological properties of the guinea pig calcitonin receptor will be determined.

PHARMACOLOGICAL CHARACTERIZATION OF BRAIN OXYTOCIN RECEPTORS (OTRs) IN RATS. L.M. Flanagan-Cato* and S. J. Fluharty, Depts. of Psychology, Animal Biology, Pharmacology, and Institute of Neurological Sciences, University of Pennsylvania, Phil., PA 19104

Brain OTRs have been implicated in a variety of behaviors, e.g. sexual and parental. Previous characterizations of peripheral OTRs have suggested diverse binding properties of OTRs in reproductive tissues. Little is known, however, about the functional properties of rat brain OTRs. In the present studies, the pharmacological profile of rat brain OTRs was assessed. Brains from 10-day old rats were homogenized and the membranes prepared for incubation with the radioligand [¹²⁵I]-ornithine vasotocin ([¹²⁵I]-OVTA). Saturation isotherm studies with Scatchard analysis determined the density and affinity of brain [¹²⁵I]-OVTA binding sites (B_{max} = 24 fmol/mg protein; K_D = 50 pM). The specificity of binding was confirmed by competition with unlabelled OT (K_D = 2.01 ± 0.08 nM, n = 5). The rank order potency of brain OTR agonist binding was OT > AVP > Thr⁴Gly⁷-OT (n = 3). OT binding was best fit with a two-site model, with approximately 50% high affinity sites (K_D = 0.19 pM), and 50% low affinity sites (K_D = 10.80 nM). Preliminary studies using nonhydrolyzable analog of GTP, GTPγS, resulted in monophasic OT binding with only the low affinity component, which indicates that brain OTRs, like their peripheral counterparts, are coupled with G-proteins. *Supported by NS23986 and MH43787.

HUMAN Y-79 RETINOBLASTOMA CELLS EXPRESS PACAP RECEPTORS. M.C. Olanas^{*1}, M.G. Ennas², S. Petruzzelli³ and P. Onali¹, Dept. Neurosciences¹, Dept. Cyto-morphol.², Inst. Internal Medicine³, University of Cagliari, Cagliari, Italy.

Recently, the presence of receptors for pituitary adenylate cyclase activating peptide (PACAP) has been demonstrated in the retinas of different mammalian species (Onali & Olanas, Brain Res. 641, 132, 1994). In the present study we report that in human Y-79 retinoblastoma cells PACAP-38 and PACAP-27 are potent stimulators of adenylyl cyclase activity with EC₅₀ values of about 20 and 150 pM, respectively. VIP is much less potent (EC₅₀ = 40 nM) than PACAPs, whereas secretin (1 µM) is inactive. The adenylyl cyclase stimulation by PACAP-38 is potently counteracted by the specific PACAP receptor antagonists PACAP 6-38 and PACAP 6-27. Cytochemical studies using biotinylated PACAP-38 demonstrate the diffuse presence of PACAP binding sites in Y-79 cells. These results support the idea that PACAP may act as a neurotransmitter in the retina and indicate that Y-79 retinoblastoma cells may represent an useful model for studying the possible effects of the peptide on retinal cell function and differentiation.

VIP AND PACAP BIND WITH HIGH AFFINITY TO HUMAN GLIOBLASTOMA CELLS. T.W. Moody^{*}, S. Jakowlew, P. Chung, M. Fridkin and J. Gosses, Biomarkers and Prevention Research Branch, National Cancer Institute, Rockville, MD 20850; Department of Organic Chemistry, Weizmann Institute of Science, Rehovot, Israel; and Department of Chemical Pathology, Sackler School of Medicine, Tel Aviv, Israel.

Human glioblastoma cells contain peptide (Bombesin/GRP) (BB/GRP) and growth factor (epidermal growth factor) (EGF) receptors. The actions of BB and EGF are reversed by synthetic antagonists such as (Psi)¹²⁴, Leu¹⁴BB and monoclonal antibody (mAb) 108 respectively. Here the effects of vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase activating peptide (PACAP) were investigated. ¹²⁵I-VIP bound with high affinity to U-138 cells and specific ¹²⁵I-VIP binding was inhibited with high affinity by VIP. PACAP and VIPhybrid (IC₅₀ values of 5, 10 and 500 nM respectively). In contrast, specific ¹²⁵I-PACAP-27 binding was inhibited with high affinity by PACAP and PACAP(6-38) (IC₅₀ = 10 and 30 nM) but not VIP (IC₅₀ = 1000 nM). These data suggest that ¹²⁵I-PACAP may bind to PACAP type-I (PACAP) and ¹²⁵I-VIP may bind to PACAP type-II (VIP) receptors. Northern analysis of poly A⁺ mRNA from U-138 cells indicated major 5.5, 2.4 and 1.3 bands using a VIP receptor cDNA probe. VIP and PACAP elevated cAMP and the increase in cAMP caused by VIP was reversed by VIPhybrid whereas the increase in cAMP caused by PACAP was reversed by PACAP(6-38). The effects of VIP and PACAP on the growth of U-138 cells will be discussed. These data suggest that VIPhybrid and PACAP(6-38) function as VIP and PACAP receptor antagonists respectively on glioblastoma cells.

PEPTIDES: PHYSIOLOGICAL EFFECTS II

HYPOTHALAMIC AND EXTRAHYPOTHALAMIC CORTICOTROPIN-RELEASING HORMONE mRNA EXPRESSION IN COLD STRESSED RATS. S. Makino¹, K. Fukuhara², M. A. Smith³, and P. W. Gold¹.

Clinical Neuroendocrinology Branch¹, Biological Psychiatry Branch³, NIMH; Clinical Neuroscience Branch², NINDS; National Institutes of Health, Bethesda, MD 20892.

Exposure to cold is a potent stimulus of the hypothalamo-pituitary-thyroid axis. Yet it is still controversial whether cold stress activates the hypothalamo-pituitary-adrenal (HPA) axis. On the other hand, the regulation of extrahypothalamic corticotropin-releasing hormone (CRH) in the stressful situations needs to be elucidated. To address these issues, we exposed rats to cold (-3°C) continuously for 0.5, 1, 3, 6, 24 hours and 5 days, and examined CRH mRNA expression in the paraventricular nucleus (PVN), central nucleus of the amygdala (CEA) and bed nucleus of the stria terminalis (BNST) by using *in situ* hybridization histochemistry. Plasma levels of corticosterone increased transiently at 0.5 h, then returned to normal by 1 h. CRH mRNA in the PVN and POMC mRNA in the anterior pituitary did not change up to 5 days. This indicates that cold stress may transiently induce CRH or ACTH secretion, but may not be enough to stimulate CRH or ACTH synthesis. By contrast, CRH mRNA in the CEA and dorsolateral subdivision of the BNST decreased at 6 and 24 hours exposure to cold (maximally decreased by 25% and 45% at 24 h compared to control in the CEA and BNST, respectively). These data suggest that (1) cold is a mild stressor, if any, of the HPA axis, (2) but that cold stress can modulate extrahypothalamic CRH.

CRF-INDUCED EXCITATION OF NEURONAL FIRING RATES IN LOCUS COERULEUS NEURONS IS ATTENUATED BY SYSTEMIC ADMINISTRATION OF APRAZOLAM. J.C. Landry, Z.N. Stowe, M.J. Owens, P.M. Plotsky^{*} and C.B. Nemeroff. Laboratory of Neuropsychopharmacology, Dept. of Psychiatry and Beh. Sciences, Emory Univ. Sch. of Medicine, Atlanta, GA 30322.

Corticotropin-releasing factor (CRF) neurons are believed to integrate the endocrine, autonomic, immunologic, and behavioral responses of mammals to stress. Investigations have shown that both direct and intracerebroventricular (ICV) administration of CRF excites LC neurons. Benzodiazepines (BZD) have been shown to decrease LC neuronal firing rates after direct, ICV, or systemic administration. However, only systemic administration of BZD attenuates sensory-evoked activity of LC neurons. In the present study, the effects of ICV CRF on LC neuronal firing rates and responsiveness to GABA were assessed. Furthermore, the effects of systemic administration of alprazolam on CRF-induced excitation and GABA-induced inhibition were studied. Individual extracellular neuronal recordings were obtained from spontaneously active LC neurons (n=17) in chloral hydrate anesthetized (400 mg/kg, i.p.) male rats (250-350 gm). ICV CRF (5 µg) produced an increase in firing rate that peaked at 20-30 minutes post injection; recordings were continued for up to 60 minutes. Systemic administration of alprazolam (0.25 mg/kg; [n=3]; 0.5 mg/kg, [n=5], i.p.) attenuated CRF-induced excitation. At 0.5 mg/kg of alprazolam, the CRF-induced excitation was reduced by 31.8% (n=5). Throughout the experiment, GABA (0.25 M, pH 3.7) was iontophoretically (5-30 nA) applied in a 30 second pulse every 90 seconds. All neurons studied were inhibited by direct application of GABA. Interestingly, no significant change in GABA-induced inhibition was observed either after ICV CRF or systemic alprazolam administration.

These findings are consistent with the action of systemic BZD to attenuate increases in LC neuronal firing rates associated with stimulation. The ability of alprazolam to attenuate CRF-induced excitations of LC neurons supports the hypothesis suggesting that CRF may mediate LC responses to stress and that alprazolam may exert a portion of its therapeutic effect via actions on CRF. Supported by Daland Fellowship from American Philosophical Society to ZNS and NIMH MH 42088 to CBN.

553.3

CORTICOTROPIN-RELEASING FACTOR (CRF) INCREASES HIGH-VOLTAGE ACTIVATED (HVA) CALCIUM CURRENTS IN ACUTELY DISSOCIATED NEURONS OF THE CENTRAL AMYGDALA (CeA). B.Yu^{*} and P. Shinnick-Gallagher. Dept. of Pharmacology & Toxicology, Univ. of Texas Medical Branch, Galveston, TX 77555

Since CRF and the CeA mediate certain stress responses in the brain, we tested CRF on calcium currents in CeA neurons. When held at -80 mV, HVA currents peaked at +10 mV and averaged 298pA ± 17 (n=106) in 3 mM [Ca²⁺]_o. Nifedipine (5 µM) inhibited 53% ± 4 of peak current (held at -40 mV). However, not every CeA neuron possessed L-type HVA currents. ω-CTX GVIA (1-2 µM) inhibited 24% ± 5 of the peak I_{Ca}, indicating N-type currents were present, while ω-CTX MVIIIC (200 nM) inhibited 30 ± 4% of the peak I_{Ca}, suggesting the presence of Q-type currents. No P-type current was recorded since ω-Agatoxin (100-200 nM) did not reduce I_{Ca}. These data suggest that the HVA calcium currents of CeA neurons are comprised of N-, L-, and Q- but not P-type of calcium currents. CRF (1-400 nM) enhanced HVA calcium currents in approximately 50% CeA neurons recorded. However, in the remaining neurons, CRF had no effect. CRF enhanced both peak and steady state HVA calcium currents. CRF (50 nM) increased the peak HVA 23 ± 4% (n=9). No shift was observed in the peak of the current-voltage relationship. The CRF-induced increase in HVA calcium currents is concentration-dependent and the estimated EC₅₀ is 9.7 nM. The CRF receptor antagonist (α-helical CRF₄₁₋₅₁, 3 µM), which did not alter calcium currents itself, blocked the CRF-induced increase of HVA calcium currents. These data suggest that CRF enhances calcium currents through a receptor mechanism and could thereby facilitate neuronal communication through CeA neurons during the stress response. (supported by NS 29265).

INTRACISTERNAL (IC) CRF ANTAGONIST INCREASES GASTRIC VAGAL EFFERENT DISCHARGE (GVED) IN URETHANE-ANESTHETIZED RATS. H.P. Kosoyan, J.Y. Wei, M. Gunion^{*} & Y. Taché. CURE/Gastroenteric Biol. Ctr., VA Wadsworth Med. Ctr. & Dept. of Med. & Brain Res. Inst., UCLA, Los Angeles, CA 90073.

We previously showed that IC CRF (21 and 63 pmol) decreases GVED by 17.4 and 24.0% respectively in rats. Urethane induced an increase of hypothalamic CRF transcripts and secretion and low basal activity of GVED. Aim: To assess the influence of the new CRF antagonist, [D¹Phe¹², Nle²¹⁻³⁸, C³⁹-MeLeu³⁹]rCRF₁₋₄₁ given IC on GVED in urethane-anesthetized rats. Method: Male SD rats (280-320 g) were injected with urethane (1.5 g/kg, im) and implanted with a catheter into the cisterna magna for IC(15 µl) injection. A strand of the ventral gastric branch of the vagus was cut distally to record multi-unit efferent discharge. Nerve signals were sent to a window discriminator and counted on computer. Maximum 1 min peak changes from basal GVED were calculated and expressed as Mean ± SEM peak changes from baseline. IC injections of distilled water (15 µl, pH=7.0, 37°C) and CRF antagonist (25 µg/rat) over 15-30 sec were performed at 10-35 min intervals and thereafter CRF was injected IC. Results: IC vehicle (n=11) had no significant effect on basal GVED (101.6 ± 1.4%, p>0.05) while IC injection of CRF antagonist increases GVED to 143.6 ± 3.8% (n=8). The excitatory response peaked within 15 ± 3.2 min (n=8), and lasted more than 2 h. CRF (21 pmol/rat) injected IC at 5 min, 95 ± 5 min, 125 ± 5 min and 176 ± 35 min after the CRF antagonist had no significant effect on GVED, while the injection of CRF (63 pmol/rat) at 185 ± 15 min after the CRF antagonist produced a significant inhibition of GVED to 82.2 ± 5.4% (n=4). Conclusions: These results suggest that IC [D¹Phe¹², Nle²¹⁻³⁸, C³⁹-MeLeu³⁹]rCRF₁₋₄₁ antagonizes both endogenous and exogenous CRF and urethane-induced tonic inhibition of GVED through brain CRF pathways. (Supported by NIH grants NS28433 & DK30110).

SOMATOSTATIN EFFECT ON GUINEA-PIG DORSAL THALAMIC NEURONS IN VITRO. R. Rai* and R. Lindas, Dept. of Physiology & Biophysics, New York University Medical Center, 550 First Avenue, New York, NY 10016.

Spontaneous and voltage-evoked electroresponsiveness were examined using sharp microelectrode intracellular recordings in dorsal thalamus neurons in guinea-pig slices. A few minutes following bath application of 2μM somatostatin superfusion, a characteristic increase in low-threshold calcium spike activity was noticed in specific thalamic nuclei. The results could be observed, at the spontaneous-electrical-activity level, as a marked tendency towards intrinsic oscillation, often occurring from a membrane potential similar to the initial non-oscillating level, where low-threshold activity was only observed after membrane hyperpolarization in the order of 5 to 10 mV. In other cases the increase of oscillatory activity would occur on depolarizations or hyperpolarizations of a few millivolts from the initial resting-potential level. The results suggest that such changes in the resting level of the cell, which are either too small, or in the wrong direction, to affect directly the level of voltage-dependent inactivation of the type-T calcium channels responsible for such low-threshold activity were not the decisive factor effecting the excitability changes.

Similar results were obtained by testing neuronal excitability directly, via transmembrane current pulses delivered from different holding potentials. In somatostatin the voltage dependence for low-threshold calcium-spiking initiation was found to decrease by close to 30% with reference to the normal voltage level at which low-threshold spikes are generated. The results suggest that the level at which low-threshold calcium spikes is triggered in thalamic neurons may be regulated by means other than transmembrane voltage. Somatostatin did not affect all thalamic neurons, moreover cells that responded were localized in a group probably related to somatostatin innervations.

The results indicate that neuropeptides may exercise regulation of intrinsic membrane properties onto well-defined sets of thalamic nuclei without affecting others, and so, may modulate global brain activity by acting on the thalamocortical system in a manner different from that generated by conventional synaptic input. NIH/NS13742.

EFFECTS OF CYSTEAMINE ON REGIONAL CHOLINE ACETYLTRANSFERASE ACTIVITY IN RATS. K. Kuki, H. Kaneda, Y. Komurasaki, K. Sakai* and K. Maeda, Dept. of Psychiatry, Kobe Univ. Sch. of Med., Kobe 650, Japan.

It is well-known that somatostatin (SS), one of brain neuropeptides, is decreased in cerebrospinal fluid or postmortem brain with Alzheimer's disease. Dysfunction of cholinergic system in Alzheimer's disease is also reported. The relation between SS and cholinergic system is not obvious yet in Alzheimer's disease. In this study, we investigated the effects of cysteamine, which depleted brain SS contents, on regional choline acetyltransferase (CAT) activity in rats.

Male Wistar rats (300-350 g) were used. Cysteamine was dissolved in saline and adjusted to pH 7.4. 90, 150, 300 mg/kg cysteamine and saline for controls were injected intraperitoneously (n=5). Four hours later, rats were decapitated and the brains were dissected into the olfactory bulb (Ob), anterior cortex (Ac), temporal cortex (Tc), posterior cortex (Pc), hippocampus (Hc) and striatum (St) with Glowinski's method. SS and neuropeptide Y (NPY) contents of each region were measured by radioimmunoassay and CAT activity by Fonnum's method. Statistical analysis was performed by student t-test.

As a result, SS contents in the hippocampus were only decreased significantly (Mean ± SE of % of controls were 33.8 ± 16.2, 39.7 ± 12.9, 18.4 ± 2.4 % at 90, 150, 300 mg/kg, p < 0.05). However, NPY contents and CAT activity did not have changes in any regions.

Our results suggest that cysteamine may not have effects on CAT activity directly in the brain regions and the decrease of hippocampal SS contents may not, too.

DOPAMINE-INDUCED INHIBITION IS ATTENUATED BY IONTOPHORETICALLY APPLIED NEUROTENSIN IN THE NUCLEUS ACCUMBENS OF RATS - IN VIVO STUDY. Z.N. Stowe*, J.C. Landry, Z.L. Tang, and C.B. Nemeroff, Laboratory of Neuropsychopharmacology, Dept. of Psychiatry and Beh. Sciences, Emory Univ. Sch. of Medicine, Atlanta, GA 30322.

Neurotensin (NT), an endogenous tridecapeptide, possesses a pharmacobehavioral profile that is similar to antipsychotic drugs. Previous electrophysiological data suggest that both direct and intracerebroventricular (ICV) application of NT produces predominantly excitatory responses in dopamine (DA) neurons in the ventral tegmental area (VTA). Direct administration of NT consistently antagonized DA-induced inhibitions in the VTA. In contrast, McCarthy et al (Gen. Pharmacol. 10: 331-333; 1979) found that iontophoretic application of NT either had no effect or inhibited the firing rate of DA-sensitive neurons in the nucleus accumbens (NAS). The effects of iontophoretically applied NT on DA-induced inhibitions in individual neurons in the NAS were studied. Extracellular neuronal recordings were obtained from spontaneously active neurons in the NAS in chloral hydrate anesthetized (400 mg/kg, i.p.) male rats (250-350 gm). DA-sensitivity was confirmed via iontophoretic application (15-35 nA) of DA (0.1M, pH 4.0). A total of 12 neurons were included in the data analysis [percent change = -26.3 ± 12.4]. Direct iontophoresis (25-40 nA) of NT (0.5mM, pH 6.0) did not produce any significant alteration in firing rates (n=9) [percent change = -0.46 ± 18.7]. However, direct application of NT antagonized DA-induced inhibition in all neurons tested (n=6).

These findings provide electrophysiologic evidence that NT antagonizes the effects of DA in the NAS. These findings support the hypothesis that NT receptor agonists may prove to be useful adjuncts in the treatment of psychotic symptoms, purportedly related to excessive mesolimbic DA tone. SOMATOSTATIN (SS) EFFECTS ON CYTOSOLIC CALCIUM CONCENTRATION ([Ca²⁺]_i) IN PC12 CELLS.

G. Traina, S. Cannistraro and P. Bagnoli*, Dept. of Environmental Sciences, Tuscia University, 01100 Viterbo and Dept. of Physiology and Biochemistry, University of Pisa, 56123 Pisa, Italy.

Recent findings suggest that, among neuropeptides, SS plays an important role in the modulation of nerve cell functional activity. The control of [Ca²⁺]_i has long been recognized as a fundamental mechanism of cell activation. In the present study, the effects of SS on [Ca²⁺]_i have been studied by conventional fluorimetry in PC12 cells loaded with Fura-2 in the presence of 2mM Ca²⁺. In all the experiments, the application of either Ca²⁺ ionophores or high K⁺ concentration has been used to increase the [Ca²⁺]_i. Our results can be summarized as follows: i) the application of the tetradecapeptide form of SS, SS-14 (10⁻⁹-10⁻⁶M), induces a dose-dependent decrease of [Ca²⁺]_i; ii) similar effects are induced by the application of SS analogs (SMS 201-995; D-Trp,D-Cys-SS; D-Trp-SS; MK 678; CGP 23996); iii) pretreatment with a SS antagonist (Cyclo-SS) prevents the effects of SS-14 application. These observations suggest that SS may modulate nerve cell functional activity by a specific inhibition of Ca²⁺ channels. In addition, experiments with selective blockers of different voltage-dependent Ca²⁺ channels (D 600, Ω conotoxin, GVIA, nifedipine, nifedipine) suggest that this inhibition is mediated by Ca²⁺ channels of the L-type.

SELECTIVE EFFECTS OF NEUROTENSIN IN THE PREFRONTAL CORTEX FOLLOWING DOPAMINERGIC STIMULATION IN THE NUCLEUS ACCUMBENS. D. McGrath*, J. Arnold, A. Drumheller and F.B. Jolicoeur, Departments of Psychiatry and Pharmacology, Faculty of Medicine, Univ. of Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4

Neurotensin has been shown to markedly reduce the behavioral hyperactivity which appears 2 hr after intra-accumbens administration of the potent dopamine receptor agonist, 2-amino-6,7-dihydroxy-1,2,3,4 tetrahydronaphthalene (ADTN) (Jolicoeur et al, Neuropeptides 6:143,1985). In order to better characterize this finding, the effects of bilateral intra-accumbens administration of ADTN (12.5μg) on concentrations of norepinephrine (NE) dopamine (DA), its metabolites DOPAC and HVA, serotonin (5-HT) and its metabolite 5-HIAA were examined in terminal regions of dopaminergic fibers, including prefrontal cortex, amygdala, septum, globus pallidus, striatum and the nucleus accumbens itself. Following ADTN administration, neurochemical changes were assessed at 2 hr, when animals displayed a marked hyperactivity. Results indicate that intra-accumbens administration of ADTN results, 2 hr later in significant decreases in concentrations of NE, DA, DOPAC and HVA as well as of 5-HT and 5-HIAA in all regions. In a follow-up experiment, neurotensin (3.5μg) was injected intraventricularly 20 min prior to the neurochemical determinations performed at 2 hr after intra-accumbens administration of ADTN. Except for the prefrontal cortex, neurotensin accentuated the observed neurochemical changes in all regions. In the prefrontal cortex, neurotensin also further reduced concentrations of NE, 5-HT and 5-HIAA; however, the peptide systematically reversed the decreases in DA, DOPAC and HVA produced by ADTN in this region. These findings suggest that: a) dopaminergic stimulation in the accumbens results in widespread and enduring neurochemical changes; and b) neurotensin appears to have a selective neurochemical action in the prefrontal cortex in these circumstances.

NEUROTENSIN EXCITATION OF SEROTONERGIC NEURONS IN THE RAT DORSAL RAPHE NUCLEUS IN VITRO.

T. Jolas* and G.K. Aghajanian, Depts. of Psychiatry & Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Immunohistochemical and autoradiographic studies have shown that neurotensin (NT) and its receptors are heavily represented in the dorsal raphe nucleus (DRN), especially in its ventral part. The purpose of the present study was to test, in brain slices containing the DRN, the influence of NT on the activity of serotonergic (5-HT) neurons. The cells were identified by the ability of the α₁-agonist phenylephrine (PE) to induce firing, and serotonin to reduce this effect. In extracellular recordings, after washout of PE, NT (10 nM - 10 μM) induced a dose-dependent increase of the firing rate of 5-HT neurons (EC₅₀ ~ 150 nM; maximum effect ~ 1 μM). This response was not homogeneous since excitations were mainly observed in the ventral part of the DRN. The response to NT desensitized rapidly for some 5-HT neurons whereas it was very prolonged for others. Calyculin A, a phosphatase inhibitor, increased the desensitization of the NT response, suggesting a phosphorylation step in this phenomenon. In the presence of PE, the NT response was occluded, possibly due to shared transduction mechanisms. In intracellular recordings using KCl (2 M) electrodes, NT induced a depolarization with little or no apparent change in membrane resistance.

In conclusion, NT has an excitatory effect on 5-HT neurons in the DRN which desensitizes rapidly in some cells; this desensitization may involve receptor phosphorylation since it is enhanced by the phosphatase inhibitor calyculin A.

NEUROTENSIN REVERSES LOCOMOTOR INHIBITION PRODUCED BY MICROINJECTIONS OF GBR-12909 INTO THE MEDIAL PREFRONTAL CORTEX. R. A. Radcliffe and V. G. Erwin*, School of Pharmacy, University of Colorado Health Sciences Center, Denver, CO 80262

It has been postulated that increased dopamine (DA) activity in the medial prefrontal cortex (mPFC) exerts an inhibitory influence over DA release in the nucleus accumbens leading to a reduction in locomotor activity. In addition, it has been demonstrated that neurotensin (NT) modulates DA-stimulated cell activity in the mPFC (Beauregard, M. *et al.*, *Neuroscience*, 47:613-619, 1992). Thus, experiments were designed to test two hypotheses: 1) that an increase of DA in the mPFC causes locomotor inhibition and 2) that NT modulates DA-influenced locomotor activity in the mPFC. Bilateral cannula guides were implanted into the mPFC in pentobarbital/chloral hydrate anesthetized LS/1BG mice. Open field behavior was monitored in 5 minute blocks for a total of 30 minutes 24 hours post surgery in an automated open field apparatus (Omnitech). The distance traveled within the first 15 minutes after injection of drug was the measure used for analysis. The subjects, naive to the apparatus, were injected bilaterally with either GBR-12909, a selective DA uptake blocker, neurotensin, or a combination of the drugs. Drugs were delivered in a volume of 100 nl per side over a 30 second period and were prepared in normal saline. GBR-12909, in doses ranging from 30 fmols to 1 nmol per side, produced a U-shaped dose response curve. A maximum inhibition of 47% of saline-injected control values was observed at a dose of 3 pmols. The highest dose tested of GBR-12909 (1 nmol) caused the animals to become significantly activated to ca. 129% of control values. Higher doses of GBR-12909 could not be tested owing to the insolubility of the drug at higher concentrations. Doses of NT from 0.01 fmols to 1 nmol were tested and found to have no dose-related effect on locomotor activity. NT, when co-injected with 3 pmols GBR-12909, dose-dependently reversed the inhibitory effect of GBR-12909. A dose of 3 pmols NT completely abolished the locomotor inhibition produced by GBR-12909. In conclusion, these results are consistent with the hypothesis that the DAergic system of the mPFC regulates locomotor activity. Furthermore, these results suggest that NT modulation of DA function in the mPFC may be important for the regulation of locomotor activity. CHOLECYSTOKININ- AND NEUROTENSIN-EVOKED CATIONIC CURRENTS IN SUBSTANTIA NIGRA DOPAMINERGIC NEURONS ARE MEDIATED BY IP₃-INDUCED CALCIUM RELEASE. T. Wu¹ and H. L. Wang*, Dept. of Physiology, Chang Gung College of Medicine and Technology, Kwei-San, Tao-Yuan. ¹ Dept. of Neurology, Chang Gung Memorial Hospital, Taipei, Taiwan, R.O.C

To understand the ionic and molecular mechanisms by which sulfated cholecystokinin octapeptide (CCK-8) and neurotensin (NT) modulate the electrical activity of substantia nigra (SN) dopaminergic (DA) neurons, whole-cell patch-clamp recordings were used to study electrophysiological effects of CCK-8 and NT on acutely isolated SN DA neurons. Both CCK-8 and NT excite SN DA neurons via increasing a nonselective cationic conductance. CCK-8- and NT-evoked inward currents were inhibited by the intracellular perfusion of GDP-beta-S (1 mM). In DA neurons internally perfused with GTP-gamma-S (0.5 mM), the inward currents produced by CCK-8 and NT became irreversible. Pretreating DA neurons with 500 ng/ml pertussis toxin (PTX) did not significantly affect the ability of both peptides to induce cationic currents. Intracellular application of heparin (2 mg/ml), an inositol (1,4,5) trisphosphate (IP₃) receptor antagonist, and buffering intracellular calcium with the Ca²⁺-chelator BAPTA (10 mM) suppressed cationic currents evoked by CCK-8 and NT. Dialyzing DA neurons with protein kinase C (PKC) inhibitors, staurosporine and PKC(19-31), failed to prevent CCK-8 and NT from generating cationic currents. It is concluded that PTX-insensitive G-proteins mediate neuropeptide-induced enhancement of cationic conductance of SN DA neurons. The coupling mechanism via G-proteins is likely to involve the generation of IP₃, and subsequent IP₃-evoked Ca²⁺ release from the intracellular store results in activating the nonselective cationic conductance.

EFFECTS OF A SYSTEMICALLY ADMINISTERED NEUROTENSIN PEPTIDE AGONIST ON DA AND DOPAC TURNOVER IN THE RAT NUCLEUS ACCUMBENS AND STRIATUM. L.W. Cooke*, M.J. Hyde, D. Wustrow, M.D. Davis Neuroscience Section, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105.

Recently, novel analogues of neurotensin have been synthesized which, unlike native neurotensin, are capable of producing changes in locomotor activity and brain neurochemical turnover when administered i.p. and s.c. (*Neurosci. Abs.* 123.14, 1992). These modified peptides appear to have greater stability in circulation and/or efficiency in crossing the blood brain barrier. This study evaluated the effect of one of these stable peptide agonists, a modified C-terminal hexapeptide of neurotensin, (Me)-Arg-Lys-Pro-Trp-tLeu-Leu (MNT 8-13) on dopamine (DA) and DOPAC overflow in the nucleus accumbens and striatum of urethane-anesthetized rats as measured by intracerebral microdialysis (ICMD). In untreated animals, MNT 8-13 (2.5mg/kg s.c.) produced variable changes in DA and DOPAC in both regions. However, in those animals pre-treated with pargyline (50mg/kg i.p.), DA levels increased 69% in the nucleus accumbens and 30% in the striatum, while DOPAC values remained relatively unchanged following MNT 8-13 injection. We conclude that under certain conditions, stable neurotensin analogues are able to preferentially modulate DA turnover in the mesolimbic system of rats following peripheral administration.

NEUROTENSIN (NT), N-ACETYL-L-ASPARTYLGLUTAMATE (NAAG) AND BETA-ENDORPHIN (BE) MODULATE BASAL AND NMDA-STIMULATED [³H]DA RELEASE FROM SLICES OF GUINEA PIG NUCLEUS ACCUMBENS (NAC), PREFRONTAL CORTEX (PFC) AND STRIATUM (STR). J.K. Weatherspoon*, A. Frank and L.L. Werling, Dept. of Pharmacology, The George Washington University Medical Center, Washington, DC 20037.

Dopaminergic activity is thought to be disturbed in schizophrenia; positive symptoms may be associated with hyperactivity in nucleus accumbens, while negative symptoms may be due to hypoactivity in frontal cortex. The striatum, although not involved in the symptomatology of schizophrenia, is the substrate for unwanted side effects of typical antipsychotic medication. We sought to identify potential endogenous regulators of DA release that might produce differential effects in these brain areas. Using a superfusion system, we tested the peptides NT (0.1nM-1μM), NAAG (5-500μM) and BE (0.1nM-1μM) for their effects on basal and 100μM NMDA-stimulated [³H]DA release in slices prepared from guinea pig brain. NT enhanced basal release in NAC, PFC and STR at all concentrations tested. NT (maximally at 10-100nM) also potentiated 100μM NMDA-stimulated [³H]DA release in a biphasic manner from all regions. NAAG enhanced basal [³H]DA release in NAC, PFC and STR but to a lesser extent than NMDA. BE enhanced basal [³H]DA release in STR and NAC (PFC not yet tested) but to a lesser extent than NMDA. NAAG (5-500μM) or BE (0.1nM-1μM) did not enhance 100μM NMDA-stimulated [³H]DA release in these regions. These results suggest that NT, NAAG and BE may all be endogenous regulators of DAergic neurotransmission and therefore may be potential therapeutic targets for antipsychotic drug development. Supported by NARSAD and NIDA.

THE NEUROCHEMICAL AND BEHAVIORAL PHARMACOLOGY OF SYSTEMICALLY ACTIVE REDUCED BOND NEUROTENSIN(8-13) MIMETICS. D.J. Wustrow, L.D. Wise, M.D. Davis*, L.C. Cooke, H.C. Akunne, A.E. Corbin, J.N. Wiley and T.G. Heffner, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, Michigan 48105.

The C-terminal hexapeptide fragment of neurotensin (NT(8-13)) has been shown to bind to the neurotensin receptor and retain full agonist activity. Structure-activity studies on a variety of NT(8-13) mimetics resulted in the discovery of compounds which behaved as NT receptor agonists *in vitro*, and had a variety of behavioral effects consistent with NT agonist activity when administered systemically. The reduced bond isostere PD 149760 was shown to have high affinity for the NT receptor found in new born mouse brain (K_i = 1.13nM) and was effective at inhibiting calcium mobilization (EC₅₀ = 362nM). Its putative prodrug PD 149163 effectively inhibited spontaneous locomotor activity in the mouse (ED₅₀ = 0.2 mg/kg IP) and acetic acid induced stretching (ED₅₀ = 0.05 mg/kg IP). A related analog, PD 147113 was also shown to have potent systemic activity in the acetic acid induced stretching paradigm (ED₅₀ = 0.08 mg/kg IP). These effects were not reversed by naloxone or by the NT antagonist SR 48692. PD 147113 also increased the firing rate of A-10 DA cells *in vitro* at a concentration of 10 nM and elevated DOPAC overflow in the nucleus accumbens as measured by intracerebral microdialysis *in vivo* (2 mg/kg SC). PD 149163 and PD 147113 also inhibited feeding in the rat (ED₅₀ = 0.2 mg/kg IP). These findings demonstrate systemically active NT agonists may have utility as antipsychotic, analgesic or anorectic agents.

553.16

SUBSTANCE P (SP) AND THE μ SELECTIVE OPIOID AGONIST, DAMGO, ARE PHYSIOLOGICAL ANTAGONISTS WITHIN THE VENTRAL PALLIDUM (VP). I. Mitrovic* and T.C. Napier, Department of Pharmacology, Loyola University Chicago, Stritch School of Medicine, Maywood, IL, 60153.

It has been demonstrated with various paradigms that SP and opioids are likely physiological antagonists (e.g., SP antagonists block behavioral symptoms of morphine withdrawal; enkephalins attenuate pain by blocking release of SP). Axons from the nucleus accumbens (NA) neurons that contain SP and enkephalin-like immunoreactivity synapse on the VP neurons. Both SP and μ opioid receptors are found within the VP. Our previous work demonstrated that SP increases and opioids decrease firing rate of the VP neurons. To ascertain possible interactions between opioids and SP within the VP, the present study employed single neuron extracellular recordings and microiontophoresis of DAMGO (10mM) and SP (1mM) in chloral hydrate anesthetized rats. Sixty-one VP neurons were tested with both compounds. Forty-eight percent of these were sensitive to DAMGO, and 49% to SP. As observed previously, microiontophoretically applied DAMGO decreased, and SP increased, neuronal activity. Thirty-three percent of the neurons tested were sensitive to both SP and DAMGO, and 30% to one peptide only. Ejection currents ranging between 5-35nA were used to generate current-response curves for both compounds. E_{max} for DAMGO was 41% below the baseline firing with an E₅₀ at 15nA. SP E_{max} was 47% above the baseline and the E₅₀ 20nA. A near-threshold current of SP, co-iontophoresed with multiple current levels of DAMGO, reduced DAMGO-induced responses to the pretreatment firing rates. Similar treatments with DAMGO attenuated neuronal responses to SP. This study 1) verified opposite roles of SP and μ opioid agonists in regulation of neuronal activity within the VP, 2) suggests colocalization of opioid and SP receptors (implying convergence of enkephalinergic and SP-ergic projections from NA on to single VP neuron), and 3) implicates physiological antagonism between SP and opioids within the VP. Work supported by DA0525 to TCN.

MODULATION OF INTRACELLULAR CALCIUM BY BRADYKININ IN N1E-115 CELLS. Jay S. Coggan* and Stuart H. Thompson. Hopkins Marine Station, Department of Biological Sciences, Stanford University, Pacific Grove, CA 93950.

Murine N1E-115 neuroblastoma cells release calcium from IP₃-sensitive internal stores in response to bradykinin (BK), but not the selective B1 receptor agonist des-arg⁹ BK. This suggests that the B2 receptor type is expressed. Low concentrations (<500 pM) of BK elicit responses that are slow in onset (20-30 sec), long in duration (2-4 min) and exhibit low frequency calcium oscillations (20-50 sec periods). When N-methyl-D-glucamine is substituted for extracellular Na in order to block Na/Ca exchange, the calcium oscillations in response to BK (500 pM) have shorter periods but are less profound. High concentrations of BK (> 1 nM) result in rapidly rising calcium concentrations which smoothly decay to baseline within one minute in the continued presence of agonist. Short duration application of BK (30 sec.) elicits similar calcium transients, but responses to subsequent applications exhibit marked desensitization. In the absence of extracellular calcium, the responses to bradykinin display the same characteristics. Trace averages from several cells indicate that there is no difference between responses in the presence or absence of extracellular calcium. Calcium influx, therefore, is not associated with the release of calcium from intracellular stores in response to BK. Supported by NIH NS14519.

EVIDENCE FOR A NEUROGENIC COMPONENT IN BRADYKININ B1 RECEPTOR-MEDIATED PLASMA EXTRAVASATION DURING TURPENTINE INFLAMMATION IN THE RAT. M.J.K. Walker and M.N. Perkins*. Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN, U.K.

Although bradykinin (BK) B1 receptors are not involved in the acute activation of nociceptive neurones, several studies have demonstrated that following persistent inflammation B1 receptors are induced and contribute to inflammatory pain. The B1 receptor agonist, des-Arg⁹ BK, is inactive in naive animals, but it has been found to increase nociceptive responses following an inflammatory insult in rats. In addition to the sensitisation and activation of nociceptive afferents, kinins also mediate other symptoms of inflammation including oedema formation. The experiments presented here have investigated whether B1 receptors induced during inflammation also mediate plasma extravasation (PE). PE was examined in rats that had been injected with 50% turpentine into a single hind paw 72 hours prior to testing, and was measured as the extravasation of ¹²⁵I-BSA following intraplantar injections of des-Arg⁹ BK. Des-Arg⁹ BK (100-300 pmol/paw) induced a significant increase in PE in both the ipsilateral and contralateral hind paws of turpentine-treated, but not naive rats. An increase in PE was observed 60 min., but not at 5 or 30 min. following des-Arg⁹ BK administration. This effect was reversed by the selective B1 antagonist, des-Arg⁹-Leu⁸ BK. A neurogenic component of des-Arg⁹ BK-mediated PE was revealed by pre-treating rats with capsaicin in order to deplete C-fibres. Capsaicin pre-treatment reversed the B1-mediated PE, but had no effect on the baseline extravasation in controls. Inhibition of des-Arg⁹ BK-mediated PE by co-administration of a NK1 receptor antagonist, CP 99994, suggests that B1 receptor-mediated PE involves the activation of C-fibres and the release of substance P. These results are consistent with a systemic induction of B1 receptors following local persistent inflammation. They also suggest that B1 receptor activation initiates a chain of events which ends with a neurogenically-mediated PE.

EFFECTS OF THE TACHYKININ NK₂ RECEPTOR ANTAGONIST SR48968 ON RAT SPINAL MOTONEURONES. G. Baranaukas*, A. Nistri, Biophys. Lab., Int. Sch. Adv. Studies (SISSA), Via Beirut 4, 34013 Trieste, Italy.

Several studies suggest the existence of the tachykinin NK₂ receptor subtype in the rat spinal cord. To clarify this issue and to study the possible involvement of NK₂ receptors in synaptic transmission, the specific NK₂ receptor antagonist SR48968 was used during intracellular recording from functionally-identified lumbar motoneurons (rest potential 74±2 mV, mean±s.e.m.) of the neonatal rat (P6-12) spinal cord continuously superfused *in vitro* at room temperature. All drugs were bath-applied. In all cells SR48968 (0.5 μM) had no effect on resting membrane potential or resistance but it did reduce the depolarisation (50±10%; n=5), the increase in input resistance (10±5%; n=5) and the baseline synaptic activity induced by the specific NK₂ receptor agonist [BAla¹]NKA₄₋₁₀ (200 nM). SR48968 did not affect analogous changes produced by substance P-methylester (200 nM) and [MePhe⁷]NKB (200 nM), specific agonists for NK₁ and NK₃ receptors, respectively. For synaptic transmission studies two different types of dorsal root stimulation was used to recruit either Aβ fibers alone or C fibers as well. Additionally, 1 Hz trains (25 s) were employed to elicit slowly incrementing depolarizations with slow recovery (windups). In the presence of SR48968 no change in response amplitude for all three types of stimulation was detected, although a modest reduction (16%) in the duration of the depolarization tail following windup was noted. Our study confirms the existence of SR48968 sensitive NK₂ receptors in rat spinal cord and suggests that they play a relatively minor role in synaptic transmission from dorsal root afferents to motoneurons. Supported by CNR and INFN.

BRADYKININ-INDUCED OSCILLATIONS OF CYTOSOLIC CA²⁺ ACTIVITY AND OF MEMBRANE POTENTIAL IN RAT GLIOMA CELLS. G. Reetz and G. Reiser*. Institute of Physiological Chemistry, University of Tübingen, Hoppe-Seyler Str. 4, 72076 Tübingen, Germany.

In fura-2 loaded rat glioma cells (C6-4-2) continuously superfused with bradykinin (bk), rhythmic membrane hyperpolarisations and [Ca²⁺]_i oscillations (1/min) were observed.

The initial [Ca²⁺]_i response to bk resulted from InsP₃-induced Ca²⁺ release, whereas the subsequent oscillations were dependent on both InsP₃-sensitive Ca²⁺ stores and Ca²⁺ influx. Simultaneous intracellular recording of the membrane potential showed that the oscillation of [Ca²⁺]_i and of the membrane potential were synchronous. The oscillations were affected by the K⁺ equilibrium potential and by blocking of K⁺(Ca²⁺) channels. This indicates a potentiation of Ca²⁺ influx by membrane hyperpolarisation due to activation of K⁺(Ca²⁺) channels. Mn²⁺ quench experiments gave additional evidence for influx of Ca²⁺.

We conclude that Ca²⁺ is periodically released from Ca²⁺ stores and subsequently opens K⁺(Ca²⁺) channels. The stores are refilled by the Ca²⁺-ATPase and by influx of Ca²⁺ across the cell membrane, augmented by membrane hyperpolarisation. The oscillations were also influenced by hypotonic and by hypertonic medium. Thus cell volume probably serves as a negative feedback regulator during the falling phase of [Ca²⁺]_i. These experiments are discussed with respect to physiological functions of glial cells in volume regulation during ischemia or stroke.

CHARACTERIZATION OF A NOVEL HYPERPOLARIZING RESPONSE TO SUBSTANCE P IN FERRET SENSORY NEURONS. M.S. Jafri and D. Weinreich*. Dept. Pharmacol. & Exp. Ther., Univ. Maryland Sch. Medicine, Baltimore, MD 21201.

Substance P (SP) depolarizes some primary afferent neurons situated in trigeminal or dorsal root ganglia. This study represents the first characterization of a hyperpolarizing response to SP recorded in primary afferent neurons, those located in the nodose ganglion.

In intact and in acutely dissociated neurons, 100 nM SP hyperpolarized the membrane potential by ~10% (-7.0 ± 0.7 mV) and decreased the membrane input resistance by ~30% (-6.1 ± 1.3 MΩ). The hyperpolarization or outward current produced by SP was recorded in 105 of 132 cells (80%) and was dose-dependent (EC₅₀ = 68 nM). The SP effect was reversibly blocked by 10 nM CP96,345, an NK-1 antagonist and was mimicked by 100 nM ASMSP, an NK-1 agonist. The response was not affected by 100 nM SR48968, an NK-2 antagonist. The SP effect was reversibly abolished by lowering extracellular Ca²⁺ (<10 μM) and reversibly blocked by the K⁺-channel blockers apamin, 4-aminopyridine, Ba²⁺, Cs⁺, and TEA. E_{rev} for the SP current was -85 ± 2 mV and varied with [K⁺]_o in a Nernstian fashion (slope = 55 mV/10-fold Δ[K⁺]_o). Our results show that SP activates an NK-1 receptor coupled to a Ca²⁺-dependent outward K⁺ current. We have observed SP-like immunoreactivity associated with ferret nodose neurons and therefore propose that SP receptors on these neurons may function as inhibitory autoreceptors.

IS THE GALANIN-INDUCED INCREASE IN POTASSIUM CONDUCTANCE AND DECREASE IN BARIUM CURRENTS OCCURRING IN MUDPUPPY PARASYMPATHETIC NEURONS MEDIATED BY TWO DIFFERENT RECEPTORS? L. A. Merriam*, J. M. Mulvaney and R. L. Parsons. Dept. of Anatomy and Neurobiology, Univ. of Vermont, Burlington, VT 05405.

Galanin increases an inwardly rectifying potassium conductance (G_K) and decreases voltage-dependent barium currents (I_{ba}) in mudpuppy parasympathetic neurons. In the present study, we have determined the concentration dependence of galanin and sensitivity to pertussis toxin and the chimeric ligand galantide to determine whether galanin's actions are mediated by the activation of a single receptor or different receptors. All experiments were done on dissociated neurons from the cardiac ganglion of the mudpuppy *Necturus maculosus* using the perforated patch mode of the whole cell voltage clamp technique. We found that the EC₅₀ for the activation of G_K (~44 nM) is 100-fold greater than the EC₅₀ for the inhibition of I_{ba} (~0.4 nM). Pretreatment with PTX (~10 μg/ml for 24-36 hrs) inhibited both actions of galanin. Galantide (10⁻⁹-10⁻⁶M) antagonized the increase in potassium conductance by 10⁻⁶M galanin without any measurable agonist action. In contrast, galantide (10⁻⁸-10⁻⁶M) produced a concentration-dependent decrease in I_{ba}. I_{ba} could be further decreased by 10⁻⁷M galanin in the presence of galantide. These results suggest that although activation of a G protein is involved in both actions of galanin, two different galanin receptors may mediate the increase in potassium conductance and decrease in I_{ba} in mudpuppy neurons. BARORECEPTOR REFLEX MODULATION BY THE GALANIN FRAGMENT (1-15). Z. Díaz, J.A. Narváez*, P.B. Hedlund, J.A. Aguirre, N. Yanaihara, S. González-Barón and K. Fuxe. Dept. of Physiology, Faculty of Medicine, University of Málaga, Spain; Lab. of Bio-Organic Chemistry, School of Pharmaceutical Sci. University of Shizuoka, Japan and Dept. of Neuroscience, Karolinska Institutet, 104 01 Stockholm, Sweden.

Recently we have reported that the galanin (1-15) [GAL (1-15)] administered centrally elicits dose-related vasopressor responses and counteracts the vaso-depressor responses induced by galanin (1-29) [GAL (1-29)]. For a better understanding of the role of the galanin peptide family on central cardiovascular control we have studied the modulation of the baroreflex responses (BRR) by both galanin molecules. Groups of anaesthetized rats received injections in the lateral ventricle (i.v.t.) of 0.1 nmol of GAL (1-15), 0.3 nmol of GAL (1-29), 3 nmol of GAL (1-29) or aCSF alone (control group) by means of an automatic injection pump (30 μ l/3 min). BRR was elicited before and after i.v.t. injections by intravenous bolus injections of few different doses of L-phenylephrine (LPE) (33 to 6.25 μ g/kg b.w.) administered in a random manner. Mean arterial pressure (MAP) and heart rate (HR) changes were recorded from a catheter in the femoral artery. BRR sensitivity was evaluated from the slope of the regression lines related to the maximal reflex bradycardia due to the transient hypertension induced by LPE. GAL (1-29) did not induce any statistical changes in the slopes compared with the controls at any dose tested. However, i.v.t. injection of 0.1 nmol of GAL (1-15) produces a decrease of BRR sensitivity ($p < 0.02$) when compared with the control of the GAL (1-29) groups ($p < 0.05$). The blocking effect of BRR by GAL (1-15) might explain in part its vasopressor action and may indicate a major role for this galanin fragment in central cardiovascular regulation could be suggested possibly acting on specific receptor subtypes for N-terminal fragments of galanin.

100-FOLD MORE POTENT VIP AGONIST AND ANTAGONIST A. Davidson*, G. Lilling, R. Glazer, A. Ticher, I.E. Ashkenazi, S. Rubinraut, M. Fridkin, D.E. Brenneman and I. Gozes Sackler Med. Sch., Tel Aviv Univ.; Weizmann Inst. Rehovot, Israel; SDMP, LDN, NICHD, NIH, Bethesda, MD 20892.

Vasoactive intestinal peptide (VIP), a regulator of neuronal survival, is found in brain areas associated with the control of memory and biological rhythms. To distinguish VIP receptors that mediate distinct VIP functions, potent analogues were designed. Using the replacement of Met₁₇ with Nle and the addition of stearyl moiety, an analogue was devised that exhibited a 100-fold greater potency than VIP in the promotion of neuronal survival of spinal cord neurons. This agonist increased neuronal survival via a cAMP-independent mechanism. Identical modification of a VIP hybrid antagonist (neurotensin₁₋₆VIP₇₋₂₈) also resulted in a 100-fold greater potency in blocking VIP-mediated increases in neuronal survival. Blockade of circadian activity rhythms was limited to VIP antagonists that could inhibit VIP-mediated increases in cAMP. In addition to these lipophilic peptides providing a means for receptor discrimination, these compounds offer a new strategy in the treatment of neurodegenerative diseases or disturbances in biological rhythms.

EFFECTS OF BRAIN-DERIVED PEPTIDES ON SYNAPTIC TRANSMISSION IN THE HIPPOCAMPUS H. Xiong*, J.M. Wojtowicz and A. Baskys. Depts. of Physiology and Psychiatry, Univ. of Toronto and Clarke Inst. of Psychiatry, Toronto, Ontario M5S 1A8, Canada

We have demonstrated previously that a neuroprotective drug Cerebrolysin™ (CB) (EBEWE Pharmaceuticals, Austria) exerts a profound depressant action on synaptic transmission in rat hippocampal slices via GABA_A receptors (Soc. Neurosci. Abstr. 19:1525, 1993). However, this GABA_A effect accounts for only ~40% of the CB-induced depression, suggesting that other mechanisms may also be involved. The aim of this study is to test our hypothesis that CB may also act on opioid receptors.

Evoked field potentials (FPs) were recorded in the CA1 of rat hippocampal slices. Bath application of CB (10 μ M/ml) reduced the initial slope (mV/ms) of the FPs to $26.4 \pm 3.6\%$ of control ($n=19$, $p < 0.01$, \pm s.e.m.), followed by a long-lasting enhancement (0.5 - 2 hrs.) to $117.2 \pm 5.9\%$ of control ($n=19$, $p < 0.01$). Application of broad spectrum opioid receptor antagonist naloxone attenuated this CB-induced depression in a dose dependent manner, suggesting involvement of opioid receptors in the mediation of CB-induced depression. To find the possible agonist component in the CB mixture, the effects of DAMGO (Mu selective) and Dynorphin A (1-8) (DYN, kappa selective, also high affinity for delta subtype) peptides on synaptic transmission in the CA1 were tested and compared with the effects of CB. Preliminary results have shown that DYN (1 - 3 μ M) reduced FP initial slope to $60.4 \pm 10.2\%$ of control ($n=13$, $p < 0.01$), followed by an enhancement ($113.1 \pm 7.9\%$ of control, $p = 0.06$). In contrast, DAMGO (2 - 4 μ M) caused a small reduction of FP slope ($83.6 \pm 4.6\%$ of control, $n=9$, $p > 0.05$). The results shown that both DYN and CB had similar effects with respect to time course and enhancement, suggesting that CB may contain kappa and/or delta receptor agonist components. These components may play a role in preventing brain damage and cognitive impairment.

AN IN VITRO INVESTIGATION OF THE EFFECTS OF ORG 2766 ON MEDIAL VESTIBULAR NUCLEUS NEURONS IN GUINEA PIG. D.P.D. Gilchrist, C.L. Darlington* and P.E. Smith. Dept. of Psychology and Neuroscience Research Centre, University of Otago, Dunedin, New Zealand.

Vestibular compensation is a process of behavioural recovery that follows removal of the peripheral vestibular receptors in one inner ear. The spontaneous recovery is correlated to a return of resting activity in medial vestibular nucleus (MVN) neurons on the ipsilateral side to the lesion. In behavioural studies systemic administration of adrenocorticotrophic hormone fragment 4-10 (ACTH-(4-10)) can accelerate the compensation process. ACTH-(4-10) may produce its effects by acting directly on MVN neurons, as these neurons respond to ACTH-(4-10) *in vitro* at concentrations ranging from 10^{-10} to 10^{-14} M. Our own recent behavioural studies have shown that the synthetic ACTH-(4-9) analogue, Org 2766, can accelerate compensation at smaller doses than ACTH-(4-10). The present study investigated the effect of Org 2766 on MVN neurons *in vitro*. Using standard electrophysiological techniques MVN neurons in coronal brainstem slices from guinea pig were recorded before and after superfusion with Org 2766 at concentrations of 10^{-8} , 10^{-10} and 10^{-12} M. The mean resting rate of all neurons recorded was 11.65 Hz ($n=49$). No neurons responded to Org 2766 at a concentration of 10^{-8} M (6/6). At a concentration of 10^{-10} M only 25 % (5/20) of neurons responded to Org 2766 superfusion. At a concentration of 10^{-12} M 33% (4/12) of neurons responded. For those neurons that did respond to Org 2766, the predominant response was a decrease in firing. Although the direction of the response to Org 2766 is the same as for ACTH-(4-10), the size of the response and the number of cells that have responded is comparatively small. In some cases the resting activity did not return to the control level indicating the concentration may have been toxic. Since Org 2766 produces its effects at smaller doses than ACTH-(4-10) in behavioural studies, it will be necessary to continue the *in vitro* investigations using lower concentrations of Org 2766. Alternatively the finding may indicate that although Org 2766 and ACTH-(4-10) produce a similar effect in a behaving animal, the site of action may differ.

A SYNTHETIC PEPTIDE DERIVED FROM LAMININ MODULATES THE ELECTRICAL PROPERTIES OF NEURONS

G. Hager¹, P. Liesi², H. Pawelzik¹, L. Trachsel¹ and W. Ziegglansberger¹. ¹Max-Planck-Institute of Psychiatry, Clin. Institute, Clin. Neuropharmacology, D-80804 Munich FRG; ²Lab. of Molecular and Cellular Neurobiol., National Institute on Alcohol Abuse and Alcoholism, NIH, 12501 Washington Avenue, Rockville, MD 20852

The ECM-molecule laminin plays a role in brain development as well as in neurodegeneration and regeneration in the mature CNS.

We investigated the effect of a synthetic decapeptide derived from a neurite-outgrowth-promoting domain of the B2-chain of laminin (P20) on the electrical properties of neocortical pyramidal neurons. 30 pyramidal neurons were recorded intracellularly in *in vitro* slice preparations from adult rat neocortex and stimulated synaptically or by depolarising current pulses. 19 neurons were treated with P20 and 11 neurons with a control-peptide of the same molecular size.

In the presence of P20, 85 % of the neurons tested showed a significant increase in input resistance (R_N). In 60% of them R_N increased by more than 20%. The strong rise in direct excitability was associated with an increase in inward rectification. The peak conductance of the IPSP was slightly reduced in 60% of the neurons. In 10 out of 19 neurons spreading depressions occurred terminating the recording period. No significant changes were observed during the application of the control-peptide.

Our results indicate that the synthetic peptide derived from a neurite-outgrowth-promoting domain of the B2-chain of laminin alters the electrical properties of neocortical neurons, making them more excitable. Laminin or related smaller peptides may have neuromodulatory functions in the adult CNS.

CENTRAL NON-OPIOID MOTOR EFFECTS OF DYNORPHINS: ANTAGONISM BY NMDA RECEPTOR ANTAGONISTS. V. K. Shukla, S. Lemaire* and M. Dumont. Dept. of Pharmacology, University of Ottawa, Ottawa, K1H 8M5, CANADA.

Central administration of Dyn A(1-13) and related peptides in mice produced dose dependent non-opioid motor effects characterized by wild running, jumping, circling and barrel rolling. Animals showed one or more of these effects within 10 min after i.c.v. administration of these peptides. The doses which produced motor effects in 50 % mice (ED_{50}) with Dyn A(1-13), Dyn A(1-17), Dyn A(1-8), Dyn Ia, Dyn A(2-13), [Ala¹]Dyn A(1-13) and Dyn A(6-10) were 14.40, 14.32, 40.08, 3.08, 28.82, 26.00 and > 100 nmol/mouse, respectively. Dyn A(1-13) (20 nmol/mouse)-induced motor effects were completely blocked by the co-administration of NMDA antagonist, dextrorphan (0.2-0.6 nmol/mouse). Co-administration of other NMDA antagonists (nmol/mouse) like dextromethorphan (0.2-1), MK-801 (0.1-0.3), CPP (0.075-0.3) and HA-966 (0.5-8) also partly blocked Dyn A(1-13)-induced motor effects. All the NMDA antagonist tested were less effective at doses exceeding the peak protection levels because of their intrinsic *per se* toxicity. The results indicate that the NMDA receptor is involved in the non-opioid motor effects of Dyn and related peptides. Supported by the Medical Research Council of Canada.

MELANOTROPIC AND OPIOID PEPTIDE EFFECTS ON NORADRENERGIC NEURONS IN THE CAUDAL DORSOMEDIAL MEDULLA. J.A. Carr* and K.J. Gregg. Dept. Biol. Sci., Texas Tech Univ., Lubbock, TX 79409-3131

We used an *in-vitro* approach to investigate the influence of opiate and melanotropic peptides on the activity of noradrenergic neurons in the A2 area of the caudal brainstem of the rat. [Nle⁴, D-Phe⁷]α-MSH (NDP-MSH) had no effect on the synthetic activity of noradrenergic neurons in the A2 as gauged by *in-vitro* L-DOPA accumulation in caudal dorsomedial medulla (CDMM) explants. NDP-MSH reduced the norepinephrine (NE) content of explants treated with NSD-1015 but had no effect on basal or K⁺-stimulated release of endogenous NE from CDMM slices *in vitro*. β-endorphin (βE) reduced K⁺-induced release of NE from CDMM slices and naloxone attenuated this effect. The μ-opioid agonist [D-Ala², N-Me-Phe⁴, Gly-ol⁵]-enkephalin (DAGO) had no effect on basal NE release but significantly reduced K⁺-stimulated NE release from CDMM slices. These results suggest that activation of μ-opioid receptors inhibits depolarization-induced NE release from noradrenergic nerve terminals in the CDMM. Melanotropin receptors do not modulate NE release, but may influence NE metabolism in the CDMM. Supported by a grant from the Howard Hughes Medical Institute through the Undergraduate Biological Sciences Education Program and a grant from the TTU Research Enhancement Fund.

Pancreastatin Stimulates Cobalt Uptake by Hippocampal Neurons. C. S. Toomim* & W. R. Millington. Division of Molecular Biology and Biochemistry, Univ. of Missouri-Kansas City, Kansas City, MO 64108.

Pancreastatin, a 49 amino acid peptide derived from chromogranin A, is widely distributed in neural and endocrine tissues. Pancreastatin modulates the secretion of insulin and other endocrine hormones; however, no evidence of its function in brain exists to date. We tested whether pancreastatin activates hippocampal neurons by using a histochemical assay which measures cobalt uptake through calcium permeable channels in tissue slices (Pruss et al. *Neuron* 7:509, 1991). Our initial experiments confirmed that kainic acid, a glutamate receptor agonist, produced a dose-dependent accumulation (1-100 μM) of cobalt in hippocampal neurons of the dentate gyrus and Ammon's horn (CA). Co-incubation with the glutamate receptor antagonist, kynurenic acid (5mM) blocked the response completely.

Pancreastatin also produced a concentration related activation of cobalt uptake, albeit at considerably lower concentrations (0.5, 1, 10 or 100nM) than kainate. The regional distributions of pancreastatin and kainate responsive neurons were similar; Pancreastatin (500pM) stimulated cobalt uptake in areas CA1 and CA2, whereas higher concentrations (1-100nM) also promoted cobalt uptake into CA3 and pyramidal and hilar cells of the dentate gyrus. At low concentrations, cobalt uptake was visible only in small portions of the dendrites, whereas, at higher concentrations, the cell bodies were also labelled. Interestingly, pancreastatin stimulated cobalt uptake was also blocked by kynurenic acid (100μM) suggesting that a glutamate receptor may be involved in the response. These data demonstrate that pancreastatin activates hippocampal neurons, suggesting that it may function as a neurotransmitter. Supported by the Scientific Education Partnership of the Marion Merrell Dow Foundation.

ENDOTHELIN-1 ACTIVATES CHEMOSENSORY TYPE I CELLS AND POTENTIATES THE HYPOXIC RESPONSE IN RABBIT CAROTID BODY. J. Chen, L. He, B. Dinger and S.J. Fidone*. Dept. of Physiol., Univ. of Utah Sch. of Med., Salt Lake City, UT 84108

Endothelin (ET) and ET mRNA have been localized to diverse structures in the central and peripheral nervous systems, and ET has been demonstrated to evoke release of catecholamines (CA) from adrenal chromaffin cells and corpus striata. In many tissues, the effects of ET are mediated by G-protein coupled receptors which initiate the hydrolysis of phosphatidylinositol. In the present study, we have examined the effects of ET-1 on inositol-phosphate (IPn) formation, CA release and carotid sinus nerve activity elicited from *in vitro* superfused rabbit carotid bodies where vascular effects are eliminated. Submicromolar and micromolar concentrations (0.01, 0.1, 0.5 and 1.0 μM) of ET-1 elevated the accumulation of IPn 1.3-, 2.1-, 4.7- and 5.3-fold (p<0.01), respectively. Similar concentrations (0.1 and 1.0 μM) of ET-1 potentiated the hypoxia-evoked release of CA by 1.36- and 2.16-fold (p<0.05), respectively. Finally, CSN activity evoked by hypoxic superfusion solutions (equilibrated with 20% O₂) was elevated by 31.2% ± 5.8% (X ± SEM, p<0.001) in the presence of 1 μM ET-1. In preliminary experiments, ET-3 appeared to be less potent with respect to IPn formation, CA release and CSN discharge. The data suggest that ET actions are mediated by elevated intracellular Ca²⁺ concentrations and protein kinase C in chemosensory type I cells. Endothelins may act as physiological antagonists to atrial natriuretic peptide and nitric oxide, which are endogenous to the carotid body and exert powerful inhibitory influences on the carotid chemoreponse. Supported by USPHS grants NS12636 and NS07938.

PRESYNAPTIC DELIVERY OF CGRP BY TRANSFECTED PC12 CELL CO-CULTURES. E. S. Schweitzer*, C.-J. Jeng, and Susan J. H. Tao-Cheng**. Dept. of Anatomy & Cell Biology, UCLA Medical School, Los Angeles, CA 90024 and **Laboratory of Neurobiology, NINDS, NIH, Bethesda, MD 20892.

In order to examine the role of CGRP in synapse formation and maintenance, we have engineered PC12 cells to synthesize and secrete CGRP from regulated (presynaptic) secretory vesicles. We have previously shown that the transgenic CGRP co-localizes with norepinephrine-containing vesicles on density gradient fractionation, and is secreted upon depolarization of the PC12 cells in the presence of calcium. We have now shown by immunoelectron microscopy that the CGRP is contained exclusively in dense-core vesicles in both undifferentiated and NGF-treated PC12 cells. CGRP is absent from the synaptophysin- and SV2-rich small clear vesicles. The CGRP in the dense-core vesicles is therefore presumably the source of the CGRP secreted from the cells upon stimulation.

We have now co-cultured wild-type and CGRP-expressing PC12 cells with C2 myotubes, to examine the effect of the CGRP on the induction of ACh receptors and the formation of ACh receptor clusters. Preliminary evidence indicates that the location of the ACh receptor clusters on the surface of the myotubes is correlated with the presence of PC12 cell presynaptic terminals. We are examining these co-cultures for evidence of a specific effect of CGRP on the rate or extent of ACh receptor clustering.

PITUITARY ADENYLATE CYCLASE ACTIVATING PEPTIDE (PACAP) STIMULATES cAMP-DEPENDENT TRANSCRIPTION AND PROMOTES SURVIVAL OF CEREBELLAR GRANULE NEURONS "IN VITRO". F. Rene, F. Barthel, J.M. Felix, J.L. Roberts, A.C. Gore*, and J.P. Loeffler. Lab. of Physiology, URA 1446, 21 rue Rene Descartes, 670 Strasbourg Cedex France. *Mt. Sinai Medical Center, New York, NY 10029-6574.

We have studied the effects of PACAP on the survival and on the transcriptional regulation of rat cerebellar granule cells in culture. Incorporation studies using (3H)leucine and (3H)uridine demonstrated that PACAP acted as a survival factor for cerebellar granule neurons which were prepared from 8 or 11-day-old rats respectively. This neurotrophic effect appears to result from PACAP receptor isoforms that activate the adenylate cyclase rather than phospholipase C. Indeed, the survival effect is mimicked by Forskolin (5x10⁻⁶M) but not by TPA (10⁻⁷M). To investigate this mechanism, we chose to analyze long term effects at the transcriptional level. We used a chloramphenicol acetyl transferase (CAT) reporter gene driven by the minimal cAMP responsive element (CRE: TGACGTCA). We have shown that after transfection into cerebellar neurons, this construct is efficiently stimulated by PACAP27 (10⁻⁸M) or PACAP38 (10⁻⁸M). This induction is mediated by the cAMP regulatory pathway. Indeed, cAMP measurements have shown that the activation of PACAP receptors increases cAMP level in a dose-dependent manner. Further co-transfection studies with mutated PKA regulatory subunits have shown that induction of CRE/TK-CAT by PACAP was suppressed when the cAMP-dependent protein kinase (PKA) was inactivated with a dominant inhibitory mutant of this kinase. Finally, by using a yeast transcriptional activator GAL4-CREB fusion protein, we demonstrated that the transcriptional effect of PACAP is mediated by the transacting factor CREB. In summary, we demonstrated that PACAP is a survival factor for cultured cerebellar granule neurons and these trophic effects may depend on transcriptional regulation primarily mediated by cAMP.

BINDING OF THE NEMATODE FMRFamide-LIKE NEUROPEPTIDE, SDPNFLRFamide, TO PANAGRELLUS REDIVIVUS MEMBRANES. J.P. Davis, J.W. Bowman, T.G. Geary, A.R. Friedman, M.J. Larsen, D.E. Lowery* and D.P. Thompson. Upjohn Laboratories, Kalamazoo, MI 49001.

SDPNFLRFamide (PF1), originally isolated from the free-living nematode *P. redivivus*, induces profound flaccid paralysis in neuromuscular segments of the parasitic nematode, *Ascaris suum*, at 1-10 nM. We conducted binding studies to characterize the receptor(s) for this peptide using [³H]PF1 (134 Ci/mmol) and membrane preparations from *P. redivivus* (whole worm) and *A. suum* (muscle, hypodermis, ovaries). Among the *A. suum* tissue preparations, a low level of specific binding was detectable only in the hypodermal membranes. Scatchard analysis of [³H]PF1 binding to *P. redivivus* membranes indicated both a high and low affinity binding site for this peptide. The high affinity site is characterized by a K_d of 2.7 nM and B_{max} of 8.5 fmol/mg protein. K_d and B_{max} values of 23.3 nM and 58.3 fmol/mg protein, respectively, were obtained for the low affinity site. Specific binding in these studies accounted for 40% of the total bound, and total binding was 1% of the label added. Competition binding studies revealed that, in the *P. redivivus* membrane preparation, the affinity of PF1 is equal to that of SADPNFLRFamide (PF2), another neuropeptide isolated from *P. redivivus* that has inhibitory effects on *A. suum* muscle.

554.19

NEUROMUSCULAR EFFECTS OF NEMATODE FMRFAMIDE-LIKE PEPTIDES IN *ASCARIS SUUM*. J.W. Bowman, D.P. Thompson, A.R. Friedman, C.A. Winterrowd, A.K. Ichhpurani, K.L. Blair* and T.G. Geary. The Upjohn Co., Kalamazoo, MI 49001.

FMRFamide (Phe-Met-Arg-Phe-NH₂) related peptides (FaRPs) are widely distributed in invertebrates, but have not yet been found in vertebrates. Several unique FaRPs have been identified in nematodes, including the free-living organisms *Caenorhabditis elegans* and *Panagrellus redivivus* and the parasitic species *Ascaris suum*. We investigated the physiology of one of the peptides isolated from the free-living worms, PF1 (SDPNFLRFamide), and also confirmed reports that two *A. suum* FMRFamide-like peptides, AF1 and AF2, have a biphasic effect (relaxation followed by excitation) on muscle strips prepared from this parasite. We show that an intact nerve cord (dorsal or ventral) is required for this response. In contrast, PF1 is strictly inhibitory in *A. suum* muscle strips (with or without nerve tissue) and does not require Cl⁻. Inhibitors of nitric oxide synthase (NOS) blocked the effects of PF1 on this preparation. We detected NOS activity in whole *P. redivivus* and in *A. suum* hypodermis tissue and identified a specific binding site for [³H]PF1 in these tissues. We propose that PF1 acts on the hypodermis to release NO and thus inhibit muscle activity in *A. suum*.

554.20

STRUCTURE-ACTIVITY RELATIONSHIPS OF NEMATODE FMRFAMIDE-LIKE NEUROPEPTIDES IN *ASCARIS SUUM*. D.P. Thompson*, A.R. Friedman, J.W. Bowman, T.G. Geary, M.F. Kellman, M.L. Ware, E. Bullock and A.K. Ichhpurani. Upjohn Laboratories, Kalamazoo, MI 49001.

We examined the structure-activity relationships of two FMRFamide-like neuropeptides found in nematodes, AF1 (KNEFIRFamide) and PF1 (SDPNFLRFamide). We substituted alanine for each amino acid to generate a series of analogs that could pinpoint residues important for biological activity. We also tested a series of PF1 analogs in which each amino acid was replaced with its *D*-isomer. Truncated AF1 and PF1 analogs were similarly analyzed. Activity was measured in an *Ascaris suum* muscle strip preparation.

For both AF1 and PF1, elimination of the C-terminal amide abolished activity. In the AF1 series, N-terminal deletions or extensions had unfavorable effects on potency. Ala substitution at any position markedly reduced potency. KNAFIRFamide and KNEFARFamide showed only inhibitory effects, lacking the pronounced excitatory phase characteristic of AF1. For the PF1 analogs, ala substitution in the 4 N-terminal positions had little effect on activity. A similar pattern was found for the *D*-isomers, except that SD(*D*)PNFLRFamide and SDP(*D*)NFLRFamide were inactive. Substitution in either series in the C-terminal half was generally deleterious with the exception of SDPNFARFamide, which was at least as active as PF1, and SDPN(*D*)FLRFamide, which showed excitatory activity, completely opposite of the effects of PF1.

CATECHOLAMINE RECEPTORS VI

EFFECTS OF AGING AND ALCOHOL CONSUMPTION ON DOPAMINE D1 RECEPTORS IN MULTIPLE BRAIN REGIONS OF FISCHER 344 RATS. J. M. Woods* and M. J. Druse-Manteuffel. Molecular & Cellular Biochem. Loyola U. Med. School, Maywood, IL 60153.

We examined the separate and combined effects of chronic alcohol consumption and aging on dopamine D1 receptors in the rostral and caudal striatum, nucleus accumbens, frontal cortex, ventral pallidum and globus pallidus of Fischer 344 rats. [³H]-SCH 23390 was used to radiolabel dopamine D1 receptors on twenty micron brain sections. Brains were obtained from 5, 14 and 24 month Fischer 344 rats that were pair-fed a control or ethanol-containing liquid diet on a chronic basis prior to sacrifice. The relative density of [³H]-SCH 23390 binding was determined using the NIH Image program.

The results of these experiments demonstrated an age-related decrease in dopamine D1 receptors in both the rostral and caudal striatum and in the frontal cortex. This age-related decline was typically found in both control and ethanol-fed rats. In comparison to control rats, binding was significantly decreased in the ventral pallidum of ethanol-fed rats. No significant differences were found in the K_D for [³H]-SCH 23390 binding.

This research was supported by the USPHS - AAO8451.

555.2

EFFECTS OF AGING AND ALCOHOL CONSUMPTION ON DOPAMINE D2 RECEPTORS IN BRAIN REGIONS OF FISCHER 344 RATS. M. J. Druse-Manteuffel* and N. Tajuddin. Molecular & Cellular Biochem. Loyola U. Med. Sch., Maywood, IL 60153.

The present study examined dopamine D2 receptors in multiple brain areas of 5, 14 and 24 month Fischer 344 rats that were pair-fed a control or ethanol-containing liquid diet prior to sacrifice. Additional rats consumed the control liquid diet ad libitum. The brain areas examined include the rostral and caudal striatum, nucleus accumbens, substantia nigra, ventral pallidum and globus pallidus. [³H]-Spiperone was used to radiolabel dopamine D2 receptors on twenty micron brain sections. Binding was determined using the NIH Image program.

These experiments demonstrated an age-related decrease in dopamine D2 receptors in the rostral striatum of both control and ethanol-fed rats. There was also an age-related decrease in D2 receptors in the caudal striatum. Although [³H]-spiperone binding to D2 receptors was comparable in most brain areas of control and age-matched ethanol-fed rats, binding in the ventral pallidum of the ethanol group was generally lower. No significant age or alcohol-related differences were found in the K_D. There were also no significant difference in D2 receptors in age-matched control rats that consumed the liquid diets on a pair-fed or ad libitum basis.

This research was supported by the USPHS - AAO8451.

555.3

EFFECTS OF PRENATAL IV COCAINE AND GENDER ON D₁ AND D₂ RECEPTORS IN THE STRIATUM AND NUCLEUS ACCUMBENS. D.R. Wallace*, C.F. Mactutus and R.M. Booze. Dept. of Pharmacology, College of Medicine and College of Pharmacy, University of Kentucky, Lexington, KY 40536.

The effect of maternal cocaine treatment on the density of D₁ and D₂ receptors was examined in the striatum and nucleus accumbens of male and female offspring. Intravenous cocaine injections were given on gestational days 8-14 (3 mg/kg X 1 daily) and on gestational days 15-20 (3 mg/kg X 2 daily; Mactutus *et al.*, *NTT*:1994). Pups (Sprague-Dawley) were sacrificed on postnatal day 35 and striatum/nucleus accumbens tissue removed and frozen (tissue homogenates) or whole brains were blocked and frozen (receptor autoradiography). Binding analysis for D₂ receptor density was performed with [³H]-epidipride (0.5 nM) and D₁ receptor density was determined by [³H]-(+)-7-OH-DPAT (5 nM). All analyses were carried out at room temperature (21±1°C) for 90 minutes and terminated either by rapid filtration (homogenates) or by two successive 2 minute washes in ice-cold buffer (autoradiography). Densities of both D₁ and D₂ receptors, as determined by quantitative densitometry, were based on appropriate standards which were co-exposed with tissue sections. Overall, female pups demonstrated a 52% higher density of striatal D₁ receptors, relative to male pups. A significant drug effect (F_{1,8}=80; p<0.003) was apparent when analyzing D₁ receptors in the striatum. Dopamine D₂ receptor density was unchanged in the nucleus accumbens. These results suggest that prenatal cocaine administration alters D₁ receptor density across gender and region, and moreover, that a gender difference exists with females exhibiting a higher density of striatal D₁ receptors in comparison to males. Prenatal IV cocaine-induced alterations of presynaptic striatal D₁ receptors could result in significant gender-related differences in D₁ receptor-modulated dopamine release/synthesis. EFFECTS OF QUINOLINIC ACID LESIONS ON THE DISTRIBUTION OF D3 RECEPTORS IN RAT BRAIN. Catherine Chen*, W.D. Essman, S. McElligott, M.P. Kung, H. Kung and P. McGonigle. Depts. of Pharmacology and Radiology, University of Pennsylvania, Phila., PA 19104.

Quinolinic acid lesions of the cell bodies in the nucleus accumbens (NAc) were used to examine the cellular localization of D3 receptors in the rat brain. A unilateral injection of quinolinic acid (150 nmol/0.5 µl) was administered into the NAc (ML+1.5; AP+1.5 from bregma; DV-6.8 from the dura) at a rate of 0.1 µl/min. The contralateral NAc received a vehicle injection. Eight days later, the animals were sacrificed and coronal sections were processed for histology and quantitative autoradiography. D3 and D2 receptors were labelled with [¹²⁵I]-7-Trans-OH-PIPAT and [¹²⁵I]-NCQ-298, respectively. A marked loss of neuronal perikarya was observed in the shell and core of the NAc surrounding the site of injection. The density of D3 receptors was reduced in both the shell (dorsal - 60±8%; ventral - 43±4%) and the core (dorsal - 54±10%; ventral - 42±6%) of the NAc. Quinolinic acid has been shown to eliminate GABAergic efferent neurons at this dose, suggesting that D3 receptors are on the cell bodies or dendrites of these cells. The density of D2 receptors in the NAc was not altered by the lesion, indicating that D2 and D3 receptors are not co-localized on these cells. The density of D3 receptors was also reduced in the ipsilateral substantia nigra pars compacta (45±11%) and the ventral tegmental area. This result suggests that D3 receptors are also located on the terminals of striatonigral fibers originating in the NAc. The D1 receptor has a similar cell body and terminal localization, suggesting that D1 and D3 receptors may be co-expressed by some cells in the NAc. (Supported by USPHS GM 34781 and NS-24538)

REPEATED COCAINE ADMINISTRATION INCREASES DOPAMINE RECEPTOR-REGULATED ADENYLYL CYCLASE ACTIVITY IN RAT CAUDATE PUTAMEN. E.M. Unterwald*, J.J. Fillmore, and M.J. Kreek. The Rockefeller University, New York, NY 10021.

Cocaine binds to the dopamine transporter and prevents the reuptake of dopamine into presynaptic dopaminergic terminals. Repeated daily cocaine administration to rats for 14 days has been shown to upregulate dopamine D₁ receptors (Unterwald et al., 1994). Adenylyl cyclase activity was measured to investigate the functional consequences of cocaine-induced dopamine receptor changes. Male Fischer rats were injected three times daily at one-hour intervals with saline or cocaine HCl (15 mg/kg, ip) for 1, 7, or 14 days. The ability of dopamine and SKF-82958, a selective D₁ receptor agonist, to stimulate adenylyl cyclase in the rostral portion of the caudate putamen was examined using a cAMP radioligand binding assay in crude membrane preparations. Dopamine, 10⁻⁸ to 10⁻⁴ M, produced a dose-dependent increase in cAMP formation with a maximum stimulation of 207 ± 2.7% over basal levels in saline-injected rats. Administration of cocaine did not significantly effect dopamine-stimulated cyclase activity. SKF-82958, 10⁻⁸ to 10⁻⁴ M, produced a dose-dependent increase in cAMP formation with a maximum stimulation of 192 ± 5.9% over basal levels. Administration of cocaine for 1 or 7 days did not significantly alter SKF-82958-stimulated cyclase activity. However, 14 days of cocaine administration significantly increased the stimulation of cyclase activity by SKF-82958. These findings suggest that chronic, repeated cocaine administration results in an enhancement of D₁ receptor-mediated effector function in the rostral caudate putamen. EXPRESSION OF D₁ RECEPTOR-MEDIATED INHIBITION OF MIDBRAIN DA NEURONS REQUIRES CO-ACTIVATION OF POSTSYNAPTIC D₂ RECEPTORS. P.L. Smith, W.-X. Shi, B.S. Bunney*. Depts of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

We previously reported that low doses of the D₁ antagonist SCH23390 partially but significantly reversed *α*-amphetamine-induced inhibition of substantia nigra dopamine (DA) neurons in paralyzed rats (low cerveau isolé preparation) and suggested that D₁ receptors are involved in the feedback control of DA neurons. However, we also showed that the D₁ agonist SKF38393 alone had no consistent effect on DA cells. Since *α*-amphetamine by releasing DA activates both D₁ and D₂ receptors and SKF38393 acts on only D₁ receptors, we hypothesized that the expression of the D₁-mediated effect on DA neurons may require co-activation of D₂ receptors. To test this hypothesis, we examined the effect of SKF38393 in animals pretreated with the D₂ agonist quinpirole. Quinpirole potently inhibited DA neurons. To avoid a complete inhibition, low doses of quinpirole (<40 µg/kg, i.v.) were first used to produce a partial inhibition. In most of these cells (8/9), however, SKF38393 (20 mg/kg, i.v.) produced no effect on the remaining activity of the cell. Considering the fact that DA autoreceptors are much more sensitive to a DA agonist than postsynaptic DA receptors, we further postulated that a D₁-mediated effect depends on activation of postsynaptic D₂ receptors and that the doses of quinpirole used were not high enough to activate those receptors. To examine this possibility, we injected quinpirole slowly to desensitize DA autoreceptors. By doing this, we were able to inject 40 µg/kg or more of quinpirole while keeping the cell active. In most of these cells (8/9), SKF38393 clearly produced a further inhibition of firing, which could be completely reversed by SCH23390 (20-80 µg/kg, i.v.). These results suggest that activation of D₁ receptors has an inhibitory effect on DA neurons and the expression of this effect requires co-activation of D₂ receptors most likely located on non-DA neurons. DOPAMINE RELEASE FROM HUMAN CEREBRAL CORTEX SLICES IS MODULATED BY D₂-TYPE AUTORECEPTORS. E. Fedele, *P. Severi, *A. Ruelle and M. Raiteri*. Institute of Pharmacology and Pharmacognosy, University of Genova, Viale Cembrano 4, 16148 Genova and *Division of Neurosurgery, Galliera Hospital, Via A. Volta 8, 16128 Genova, Italy.

In this study we have investigated the existence and the pharmacological profile of dopamine autoreceptors in superfused, electrically-stimulated slices of human neocortex prelabeled with [³H]DA. Human cerebral cortex tissue was obtained from patients undergoing neurosurgery to remove subcortical tumours. Samples of frontal (1), parietal (2) and temporal (4) cortex from 5 males and 2 females (aged 32-57 years) were used. [³H]DA release was elicited using a continuous electrical stimulation protocol (3 Hz, 2 ms, 24 mA). Full concentration-response curves for agonist(s), either in the presence or in the absence of (-)sulpiride, along with the appropriate controls were done on cerebral tissue obtained from a single patient. Since no significant differences both in the evoked overflows and in the drugs' effects have been observed among the various cortical region, the data from the different experiments were pooled. Quinpirole (0.01 - 10 µM) was able to inhibit [³H]DA overflow in a concentration-dependent manner, the EC₅₀ being 25 nM and the maximal effect, reached at 10 µM, approx. 80%. On the contrary, SKF 38393 was devoid of any significant effect up to 10 µM. The concentration-response curve of quinpirole was shifted to the right in the presence of (-)sulpiride (0.1 and 1 µM). The calculated apparent pA₂ value was 8.26 (8.51 at 1 µM and 8.02 at 0.1 µM). (-)Sulpiride (1 µM) did not affect on its own [³H]DA release. In conclusion, this study represent the first demonstration that in human brain the release of dopamine from mesocortical nerve terminals is controlled by receptors sensitive to D₂ receptor ligands thus indicating the presence of presynaptic autoreceptors of the D₂ type which, however, do not seem, under our experimental conditions, to be tonically activated by the released neurotransmitter. DOPAMINE-INDUCED DEPOLARIZATION OF MEDIAL PREFRONTAL CORTICAL NEURONS. W.-X. Shi* and B.S. Bunney. Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510

Dopamine (DA) innervation in the prefrontal cortex (PFC) is particularly sensitive to stress and has a powerful influence on subcortical DA systems. Malfunction of this system has been suggested to play a critical role in the pathogenesis of schizophrenia. To understand how DA may act in the PFC, we made whole cell recordings from rat medial PFC neurons in an interface brain slice preparation. Confirming the result of a previous intracellular study (Penit-Soria et al., *Brain Research* 254:263-274, 1987), we found that DA dose-dependently (1-200 µM) depolarized most mPFC neurons located in layers V and VI (30/34, ranging from 2.5 to 15 mV). This effect of DA persisted in the medium containing TTX (1 µg/ml, n=3) or zero Ca²⁺ and 4 mM Mg²⁺ (n=2), suggesting a direct effect of DA on the recorded cell. Using electrodes containing Lucifer Yellow (0.1%), nine DA-responding neurons were intracellularly labeled, six of them were identified as pyramidal neurons and three as non-pyramidal neurons, suggesting that DA affects both projection and interneurons in the PFC. Surprisingly, however, the depolarizing effect of DA was not mimicked by either the D₁ agonist SKF38393 (1-10 µM, n=4) or the D₂ agonist quinpirole (1-10 µM, n=5) or the mixture of the two (n=2). The mixed D₁/D₂ agonist apomorphine (10 µM) also produced no effect on PFC neurons (n=3). Furthermore, neither the D₁ antagonist SCH23393 (10-30 µM, n=7) nor the D₂ antagonist eticlopride (10 µM, n=2) blocked the effect of DA. These preliminary results suggest that the depolarizing effect of DA seen in PFC neurons is not mediated by the known DA receptors that should be sensitive to the DA active agents used above. Whether DA produces this effect by acting on a new type of DA receptor or non-specifically on other transmitter receptors remains to be determined. Supported by PHS award MH28849, the NPF, the NARSAD, and the State of Connecticut.

THE D₂ RECEPTOR AGONIST QUINPIROLE EXCITES NEURONS OF THE GLOBUS PALLIDUS IN FREELY-MOVING RATS. K. C. Hooper*, D. A. Banks, and G. V. Rebec. Program in Neural Science and Dept. of Psychology, Indiana University, Bloomington, IN 47405.

We have previously shown that selective stimulation of D₂ receptors by systemic administration of the D₂ agonist quinpirole (LY-171555) inhibits the activity of neurons in the striatum of awake, behaving rats (Hooper et al., *Soc. Neurosci. Abstr.* 1992 18:995).

To assess how this change in striatal activity affects neuronal activity in the globus pallidus, an output nucleus of the basal ganglia that receives an inhibitory projection from the striatum, we monitored single-unit activity in the globus pallidus of freely-moving male rats in response to the systemic administration of quinpirole at a dose known to inhibit striatal activity (1.0 mg/kg). Our results indicate that quinpirole excites neurons in the globus pallidus of awake rats. This effect probably occurs through a disinhibitory mechanism since GABAergic striatal cells, which project to the globus pallidus, are inhibited by quinpirole. Consistent with this view, preliminary data indicate that the quinpirole-induced excitation of pallidal neurons is reversed by eticlopride, a D₂ receptor antagonist.

Supported by USPHS Grant DA 02451.

SYNERGISTIC ACTIVATION OF DOPAMINE SOMATODENDRITIC AUTORECEPTORS BY PRAMIPEXOLE, A D₃-PREFERRING AGONIST, AND U-91356A, A D₂-PREFERRING AGONIST. M.F. Pierce*, M.W. Smith, S.R. Haadsma-Svensson, and W.E. Hoffmann. CNS Diseases Research, The Upjohn Company, Kalamazoo, Michigan, 49001 USA.

Membranes from CHO cell lines expressing D₁, D₂, D₃, and D₄ receptors were used to demonstrate preferential affinities of dopamine agonists U-91356A and pramipexole to D₂ and D₃ receptors, respectively, whereas apomorphine bound with good affinity to all subtypes. Using dye-filled glass microelectrodes, DA neurons in SNPC were identified by classical electrophysiological/neuroanatomical criteria (Bunney et al., *JPET* 155:560, 1973). Apomorphine (ED₅₀ = 13 µg/kg i.v.), pramipexole (ED₅₀ = 66 µg/kg i.v.), and U-91356A (ED₅₀ = 32 µg/kg i.v.) all depressed DA neuronal cell firing in the SNPC. U-99194A, the D₃-selective antagonist (J. Neurotransm. 94:11-19, 1993), selectively bound to D₃ receptors, and more effectively blocked apomorphine than it blocked either U-91356A or pramipexole. Pramipexole and U-91356A were combined in solution such that their final concentration in the mixture was inversely proportional to their relative individual potencies. The resulting potency (ED₅₀ = 15 mg/kg) was equal to that for apomorphine and greater than for either compound alone. Moreover, U-99194A more effectively antagonized the pramipexole/U-91356A combination than it did either of the compounds given alone. It is concluded that there is a D₂-D₃ synergism at the somatodendritic autoreceptor level.

555.11

SELECTIVE DOPAMINE D3 RECEPTOR ACTIVATION BY 7-OH-DPAT INDUCES HYPMOTILITY AND DECREASES STRIATAL DOPAMINE RELEASE BUT NOT METABOLISM IN AWAKE RATS. R.B. Gainetdinov, T.D. Solnikova, T.V. Grekhova and K.S. Bayevsky. Institute of Pharmacology RAMS, Baltiyskaya 8, Moscow 125315, Russia

We have previously found a rather good correlation ($r=0.75, p<0.02$) between the abilities of acute typical and atypical neuroleptics to affect preferentially dopamine (DA) metabolism or release in the rat dorsal striatum *in vivo* and their relative potencies at D2 and D3 receptor. The present microdialysis study in awake Wistar rats with selective DA D3 agonist 7-OH-DPAT (KID3 - 0.78 nM; KID2 - 61 nM for CHO cells; Levesque et al., 1992, PNAS 89:8155) gives a further support for the hypothesis that DA D3 but not D2 autoreceptors are responsible for the presynaptic regulation of DA release in rat striatum. Using quantitative microdialysis "point of no net flux" method we were able to estimate the interstitial free concentration (IFC) of 7-OH-DPAT in the dorsal striatum. 7-OH-DPAT as well as DA, DOPAC and HVA were detected by HPLC/ED. In 20 min after i.p. administration of 7-OH-DPAT in dose 6mg/kg its IFC reached maximum: 1918±299 nM (n=4). The marked decrease of DA release (to 20-30% of basal) and metabolism (to about 50%) was also observed. Due to approximately linear dependence of the dose-dialysate concentration observed it may be inferred that 7-OH-DPAT dose of 0.05 mg/kg gives IFC which would not exceed 16 nM. Importantly, that 7-OH-DPAT in this dose produced significant decrease of DA release (to about 60%), but failed to affect metabolites level in the rat striatum, whereas in dose 0.25 mg/kg (calculated IFC 80 nM) decreased, both DA release and metabolism approximately to 30 and 70%, respectively. The threshold dose for the significant decrease of DA release was 0.025 mg/kg (calculated IFC 8 nM), while even in a dose 0.01 mg/kg (calculated IFC 3.2 nM) the drug induced hypomotility. In conclusion, 7-OH-DPAT at the dose range well below the affinity to DA D2 receptor induces hypomotility and decreases DA release but not its metabolism in the dorsal striatum of awake rats.

555.13

INTERACTIONS BETWEEN D₂-PREFERRING AGONISTS AND ANTAGONISTS IN BIOCHEMICAL AND BEHAVIORAL MODELS IN RATS. K.A. Svensson¹, N. Waters², M.P. Stone¹, J.E. Myers¹ and A. Carlsson². ¹CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001, and ²University of Göteborg, Göteborg, Sweden.

Behavioral experiments in rats show that the D₂-preferring agonists (+)-7-OH-DPAT and pramipexole were highly efficacious in reducing exploratory activity as compared to D₂ agonists. In the same animals, the accumulation of DOPA or the release of dopamine in various brain regions was not affected by the ED₅₀ dose causing reduced locomotor activity. In contrast, for the more D₂-preferring agonists, such as apomorphine, (+)-3PPP, and quinpirole, there was a closer correlation between doses that reduce locomotor activity and doses that reduce DOPA accumulation and dopamine release. A similar trend was also observed for the D₂-selective compound U-91356. The data suggest that the D₂-selective agonists, in contrast to the more D₂-selective agonists, are able to reduce locomotor activity at doses that do not affect dopamine release and/or synthesis. Furthermore, these data are in line with the hypothesis that the D₂ receptor is postsynaptic with an inhibitory influence on rat locomotor activity. Our present work focuses on the interaction between D₂-preferring agonists and antagonists on behavioral and neurochemical parameters in order to shed further light on the possible functional role of the D₂ receptor.

555.15

EFFECTS OF THE D₂-PREFERRING DOPAMINE AGONIST PRAMIPEXOLE ON REGIONAL BRAIN ENERGY METABOLISM AND THEIR RELATIONSHIP TO DISTRIBUTION OF ³H-PRAMIPEXOLE BINDING SITES. M. Camacho-Ochoa¹, D.L. Evans, E.L. Walker, S. Mattichak, and M.F. Piercey. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

In studies with cloned subtypes of the D2 receptor subfamily, Pramipexole (PPX) has higher affinity for the D₂ as compared to the D₂ and D₄ subtypes, and none for D₁ receptors (Neurosci Abs 19:80, 1993). Using Sokoloff's quantitative 2-deoxyglucose (2DG) autoradiography method (J Neurochem 28:897, 1977), PPX, 0.3 mg/kg, i.v., increased energy metabolism in several basal ganglia regions (substantia nigra, subthalamic nucleus), but increased it even more in sensory and motor cortex. No significant effects were observed in mesolimbic DA areas (n. accumbens, olfactory tubercle, islets of Calleja, VTA), or in primary areas of nigrostriatal innervation (caudate, globus pallidus). Receptor binding autoradiography was used to evaluate distribution of ³H-PPX (5 nM, 62 Ci/mmol) binding sites within rat brain. Talipexole, 10 µM, was used to evaluate nonspecific binding. ³H-PPX binding sites were found in the islets of Calleja, an area dominated by D₂ receptors (PNAS 89:8155, 1992), nucleus accumbens, and olfactory tubercle, as well as in the caudate nucleus, a DA postsynaptic area high in D₂ receptors, but in which D₂ pharmacological effects also occur (Neurosci Abs 19:80, 1993). ³H-PPX binding sites were low in VTA and substantia nigra, areas rich in DA cell bodies, and in sensory and motor cortex. Thus, increases in energy metabolism occurred in areas low in ³H-PPX binding sites, but not in areas with the highest ³H-binding site concentrations. The data emphasize the ability of 2DG autoradiography to measure downstream functional effects of pharmacological agents.

555.12

MODULATION OF MESOLIMBIC, MESOCORTICAL AND NIGROSTRIATAL DOPAMINE RELEASE AND SYNTHESIS BY DOPAMINE D₃ AUTORECEPTORS: INFLUENCE OF THE SELECTIVE D₃ ANTAGONIST, S 14297. A. Gobert^{*}, J.-M. Rivet, V. Audinot, J.-L. Peglion and M.J. Millan. Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, France.

Dopaminergic autoreceptors control the activity of ascending dopaminergic pathways. Here, we employed the novel, selective D₃ antagonist, S 14297, to evaluate the potential contribution of D₃ receptors to this action. As a measure of synthesis, the ratio of the levels of the dopamine metabolite, DOPAC, were compared to those of dopamine (DA) in the cortex, nucleus accumbens, olfactory bulb and striatum of (male) rats. For determination of DA release, its levels were measured in dialysates of the nucleus accumbens and striatum of freely-moving rats. Doses are in mg/kg, s.c.. The selective D₃ agonists, 7-OH-DPAT (0.0025 - 0.04) and quinpirole (0.01 - 0.63) potentially increased DA:DOPAC ratios whereas the mildly preferential D₂ agonist, pibedilil was weakly active (0.16 - 10.0). Further, across these and other agonists, for each tissue, correlation coefficients for potency in decreasing synthesis were higher with affinity at cloned D₃ receptors ($r = 0.81 - 0.91$) than cloned D₂ receptors ($r = 0.65 - 0.79$) and were very high with potency in evoking hypothermia (0.96 - 0.98). S 14297, which slightly enhanced turnover of DA alone, dose-dependently (0.31 - 10.0) prevented the influence of 7-OH-DPAT (0.16) upon DA turnover. In contrast, its stereoisomer, S 17777, which displays 20-fold lower affinity at D₃ sites, was inactive. 7-OH-DPAT (0.16) greatly (~80%) reduced dialysate levels of DA in the accumbens and striatum. This action was markedly inhibited by S 14297 (1.25) which, alone, failed to modify levels of DA. S 17777 (20.0) was inactive. In conclusion, D₃ autoreceptors inhibit synthesis and release of DA in ascending dopaminergic projections and S 14297 acts as an antagonist at these sites. These data support a role of D₃ receptors in the modulation of mood and in the pathogenesis of psychiatric and motor disorders.

555.14

S 14297, A SELECTIVE, POTENT AND STEREORESOLVED LIGAND ANTAGONIST AT HUMAN D₃ RECEPTORS ABOLISHES 7-OH-DPAT-INDUCED HYPOTHERMIA IN THE RAT. V. Audinot, J.-L. Peglion, J.-M. Rivet^{*}, J. Vian, J.-F. Prost, M. Spedding and M.J. Millan, Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, France.

Evaluation of the functional significance of dopamine D₃ receptors has been hindered by the lack of a selective antagonist and by the absence of a model of their activation *in vivo*. This study addressed these questions employing the novel naphthofuran, (+)-S 14297. At cloned, human D₃ or D₂ receptors transfected into CHO cells, using [¹²⁵I]-iodosulpiride as a radioligand, S 14297 showed high selectivity and potency at D₃ vs D₂ sites: Kis (nM) = 13 and 297 as compared to its (-)-isomer, S 17777 (406 and 3544), AJ 76 (70 and 154), haloperidol (2 and 0.5) and the agonists, 7-OH-DPAT (2 and 103), quinpirole (6 and 265) and pibedilil (243 and 126). Scatchard analysis suggested S 14297 to bind competitively; Kd/Bmax (+ 30 nM, S 14297) = 3.6 nM/2.2 pmoles/mg protein vs (without S 14297) 1.0/2.1. In (male) rats, 7-OH-DPAT (0.01 - 0.63 mg/kg, s.c.) elicited hypothermia, an action potentially mimicked by quinpirole (0.04 - 2.5) whereas pibedilil (0.63 - 10.0) was weakly active. For a total of 8 agonists, potency correlated powerfully with affinity at D₃ receptors (0.84) but not D₂ receptors (0.49). S 14297 (0.04 - 1.25), but not S 17777 (> 10.0), mimicked haloperidol (0.01 - 0.16) and AJ 76 (0.16 - 2.5) in abolishing hypothermia induced by 7-OH-DPAT (0.16). Across 8 antagonists, the correlation was very high for D₃ affinity (0.97) but less pronounced for D₂ affinity (0.82). S 14297 (up to 20.0 mg/kg, s.c.) elicited neither catalepsy nor prolactin secretion indicating a lack of D₂ antagonist properties *in vivo*. Further, antagonist potency in eliciting prolactin secretion correlated better with affinity at D₂ (0.98) than D₃ (0.81) sites. The affinity of S 14297 at diverse monoaminergic receptors was > 80-fold lower than at D₃ receptors. In conclusion, D₃ receptors mediate hypothermia in the rat and S 14297 is as a selective, potent and stereoresolved antagonist of D₃ receptors *in vivo*.

555.16

EFFECTS OF THE DOPAMINE D3 SELECTIVE AGONIST R-(+)-7-OH-DPAT IN THE INTRACRANIAL SELF-STIMULATION (ICSS) PARADIGM. T. Kling-Petersen¹, E. Ljung¹, N. Waters¹ and K. Svensson². ¹Dept. of Pharmacology, Medicinaregatan 7, 413 90 Göteborg, Sweden and ²CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001, USA.

The dopamine D3 selective agonist R-(+)-7-OH-DPAT produced a significant increase in reward thresholds over a wide dose range (0.094 - 96.0 nmol/kg, s.c.) similar to the effects seen with the classical D2 antagonist haloperidol (0.005 - 0.16 mg/kg, i.p.) when tested in rats trained to self-stimulate in a rate-intensity brain stimulation reward paradigm. At higher doses, 7-OH-DPAT produced a significant facilitation of reward thresholds.

7-OH-DPAT, at doses that per se produced a increase in reward threshold, significantly enhanced d-amphetamines facilitatory effect on brain stimulation reward when administered in combination with d-amphetamine (0.25 or 1.0 mg/kg, s.c.). This is in contrast to haloperidol that antagonize the facilitatory effects of d-amphetamine.

The data from the ICSS model corroborate earlier observations that 7-OH-DPAT is capable of producing hypolocomotion over a wide dose range (Svensson, K. et al, J Neural Transm, 95, 71, 1994) without the concomitant reduction of brain dopamine release and synthesis seen after D2 selective agonists. The data support the hypothesis that the functional D3 receptor is a postsynaptic receptor with a psychomotor inhibitory function in the rat.

555.17

CHARACTERIZATION OF A SELECTIVE DOPAMINE D3 RECEPTOR AGONIST LIGAND, [3H]PD 128907. H.C. Akunne¹, P. Towers², G.J. Ellis², D. Dykstra³, H. Wikstrom³, L. Wise⁴, T. Heffner¹ and T. Pugsley¹. ¹Pharm/Chem, Parke-Davis Pharm. Res., Div. of Warner-Lambert Co., Ann Arbor, MI, 48105 USA; ²Cardiff Lab, Amersham Corp, Forest Farm, Cardiff, Wales CF4 &YT and ³Dept Of Med Chem, Univ of Groningen, NL-9713 AW Groningen, Netherlands.

A selective dopamine (DA) D3 receptor agonist ligand, PD 128907 [(+)-trans-3,4,4a,10b-tetrahydro-4-propyl-2H,5H[1]benzopyrano[4,3b]-1,4-oxazin-9-ol] exhibits about a 1000-fold selectivity for human D3 receptors (K_i , 1 nM) versus human D2 receptors (K_i , 1183 nM) using [³H]spiperone as the ligand. Binding studies with [³H]PD 128907, prepared as a selective probe for the D3 receptor, showed saturable, high affinity binding in human D3 receptors expressed in CHO-K1 cells with a K_d of 0.99 nM and a binding density (B_{max}) of 826 fmol/mg protein (in the absence of Na⁺). Under the same conditions, there was no specific binding in CHO-K1 cells expressing human D2 receptors. [³H]PD 128907 binding in all these studies was monophasic with the Hill coefficients close to unity. The K_d and B_{max} in the rat olfactory tubercle membranes, presumably rich in D3 receptors, were 1.3 nM and 116 fmol/mg protein respectively; while in the rat striatal membranes, the K_d was 3.8 nM and the B_{max} was 298 fmol/mg protein. There was no specific binding in the rat striatal membranes in the presence of 120 mM NaCl (a condition that inhibits binding to the D2 receptor); in comparison the binding parameters were not significantly different in olfactory tubercle and CHO-K1-D3 cell membranes in the presence or absence of NaCl. This suggests that [³H]PD 128907 labels D3 receptors specifically in the presence of NaCl without MgCl₂. The rank order of potency for inhibition of [³H]PD 128907 binding with reference DA agents was consistent with the pharmacology for D3 receptors. This highly selective new ligand possesses high specific activity, high specific binding activity with low non-specific binding and therefore should be useful for characterizing further the DA D3 receptors.

Olanzapine compared to clozapine and haloperidol as dopamine and serotonin receptor antagonists in rats. Susan K. Hemrick-Luecke*, Frank P. Bymaster and Ray W. Fuller. Lilly Research Laboratories, Eli Lilly and Co., Lilly Corporate Center, Indianapolis, IN 46285 U.S.A.

Receptor occupancy in rats was estimated by the ability of test drugs (given ip) to counteract effects of EEDQ (N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline), which irreversibly inactivates dopamine D1 and D2 receptors as well as serotonin (5HT_{2A}) receptors. EEDQ (10 mg/kg, sc) increased striatal concentrations of 3,4-dihydroxyphenyl-acetic acid (DOPAC) at 24 hrs. Haloperidol at 0.3 mg/kg increased striatal DOPAC concentrations at 1 hr and antagonized the prolonged EEDQ increase in DOPAC as well as the EEDQ-induced decrease in radioligand binding to D2 receptors. Haloperidol at doses up to 3 mg/kg did not block the effects of EEDQ on radioligand binding to striatal D1 or cortical 5HT_{2A} receptors. Clozapine increased striatal DOPAC at 10 mg/kg, but a higher dose (60 mg/kg) only partially antagonized the EEDQ-induced increase in DOPAC. Clozapine was more potent in antagonizing the EEDQ-induced decrease in cortical 5HT_{2A} receptors as compared to striatal D1 or D2 receptors. Olanzapine increased striatal DOPAC at 1 mg/kg, whereas a higher dose (10 mg/kg) was needed to block the EEDQ-induced increase in DOPAC. Olanzapine blocked EEDQ-induced decreases in radioligand binding to striatal D2 and cortical 5HT_{2A} receptors at lower doses than required to block effects on striatal D1 receptors. Neuroendocrine measurements are compatible with these findings. Haloperidol antagonized the dopamine D2 receptor-mediated increase in rat serum corticosterone by pergolide, with an ED₅₀ of 0.18 mg/kg, whereas the ED₅₀ values for olanzapine and clozapine were 3 mg/kg and >10 mg/kg. The quipazine-induced rise in serum corticosterone, a 5HT_{2A} receptor-mediated effect, was blocked by olanzapine and clozapine with ED₅₀ values of 0.57 mg/kg and 2.6 mg/kg but not by haloperidol (at 1 mg/kg). These data show that olanzapine, an atypical antipsychotic drug candidate, has lower occupancy of dopamine D1 and D2 receptors than of 5HT_{2A} receptors *in vivo*. In this respect, olanzapine is like clozapine, but in all cases, olanzapine was more potent than clozapine.

REGIONAL BRAIN GLUCOSE METABOLISM FOLLOWING α_2 ADRENERGIC BLOCKADE IN BIPOLAR MALES. Mark E. Schmidt, John A. Matochik*, Robert C. Risinger, Philip Mitchell, William Z. Potter. Section on Clinical Pharmacology, NIMH, Bethesda, MD, 20892.

Several medications used to treat mood disorders have indirect effects on the α_2 adrenergic receptor. Moreover, altered regulation of this receptor has been postulated to play a pathophysiologic role in depression. Comparing FDG PET scans before and after an infusion of the α_2 antagonist idazoxan (IDX) may provide a possible measure of central α_2 function. Using this method, we hope to test hypotheses regarding α_2 function in psychiatric disorders and therapeutics. Six males with Bipolar Mood Disorder underwent FDG scans before and after infusion of IDX, 200 mcg/kg. 5 templates comprised of 62 regions of interest (ROIs) were applied to 5 matching transaxial planes from each PET scan. Baseline global metabolism was significantly lower ($p < .01$) in the patient group (9.57 ± 1.51) compared to a control group of 13 normal males (11.71 ± 1.14). Absolute metabolic rate significantly increased in 13 ROIs including 6 prefrontal and 4 occipital ROIs ($p < .05$). There was a trend for an increase in global metabolic rate after IDX ($p < .10$). In comparison, healthy males showed no effect on global metabolic rate, also showed significant increases in occipital ROIs, but showed no change or a significant decrease in metabolism in frontal ROIs. While preliminary, our finding of lower baseline global metabolism replicates previous findings in bipolar depressed patients. The regional findings suggest common responses to α_2 blockade in occipital regions but group differences notably in prefrontal cortex.

POSSIBLE INVOLVEMENT OF DOPAMINE D3 AUTORECEPTORS IN THE BEHAVIORAL EFFECTS OF PD 128907. A.E. Corbin*, J.N. Wiley and T.G. Heffner. Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, MI 48105.

PD 128907 has been described as a dopamine (DA) D3 receptor agonist-like compound (D3 K_i = 1.1 nM, D2 K_i = 1183 nM, D1 K_i > 10000 nM; DeMattos et al., Soc Neurosci Abstr, 19, 77, 1993). Previous studies in rats have shown that PD 128907 inhibited DOPA accumulation (ibid.) and decreased striatal DA release as measured by microdialysis (Cooke et al., Soc Neurosci Abstr, 19, 77, 1993). The present studies show that PD 128907 reduces spontaneous locomotor activity (LMA) in mice (ED₅₀ = 0.75 mg/kg ip) and rats (ED₅₀ = 0.03 mg/kg sc). However, at higher doses, LMA inhibition diminishes in rats, a profile similar to the DA D2 agonist apomorphine and the DA D3 agonist-like compound (+)-7-OH-DPAT. Doses of PD 128907 that reduce LMA in rats also reduce DOPA accumulation in the GBL/NSD model (ED₅₀s = 0.014 and 0.37 mg/kg sc in mesolimbic area and striatum) and reduce DA overflow in awake rats in the microdialysis model (28-52% decreases at 0.03-0.1 mg/kg sc). PD 128907 dose-dependently reverses the LMA stimulation produced by the indirect DA agonist amphetamine in mice (ED₅₀ = 0.3 mg/kg ip) and rats (ED₅₀ = 0.01 mg/kg sc). At higher doses, PD 128907 produces stereotyped behavior (sniffing at 1 mg/kg sc) and reverses the behavioral sedation produced by the DA depleting agent reserpine (ED₅₀ = 6.3 mg/kg sc). The high D3 potency of PD 128907 suggests that at low doses, this drug may be acting at D3 receptors to inhibit spontaneous as well as amphetamine-stimulated LMA. The correlation of decreased DA synthesis and release with these low dose behavioral effects of PD 128907 suggests mediation by presynaptic D3 receptors. High dose studies reveal DA agonist-like effects which may be mediated by stimulatory actions at D2 receptors or D2 and D3 receptors.

LEVODOPA BUT NOT BROMOCRIPTINE INDUCES TRE- AND CRE-BINDING ACTIVITIES IN THE RAT STRIATUM.

K. Kashiwara¹*, T. Ishihara², K. Akiyama², Y. Shiro¹, T. Morimasa¹, T. Shomori¹. Department of ¹Neurology and ²Psychiatry, Okayama Univ. Medical School, 2-5-1 Shikata-cho, Okayama 700, Japan.

Long-term treatment of Parkinson's disease with levodopa is associated with a high incidence of adverse effects such as wearing-off phenomenon and dyskinesia. Bromocriptine, on the other hand, has been reported to produce these effects less frequently. In order to elucidate the effects of levodopa and bromocriptine on transcription factors, which may produce long-lasting changes in the responsibility of central dopaminergic system, we examined the effect of these compounds on 12-O-tetra-decanoylphorbol 13-acetate-responsive element (TRE)- and cyclic AMP-responsive element (CRE)-binding activities by using gel-mobility assay. Administration of levodopa (100 mg/kg; ip) with benserazide (50 mg/kg; ip) to rat increased both TRE- and CRE-binding activities in the dorso-lateral aspect of the caudate-putamen. Bromocriptine (2.5, 5mg/kg) did not induce TRE- and CRE-binding activities. As has been reported on *c-fos* expression in the dopamine depleted striatum, levodopa, a mixed D-1/D-2 dopamine receptor agonist, but not bromocriptine, a D-2 agonist, may induce TRE- and CRE-binding activities.

555.22

EFFECTS OF ADRENOCEPTOR AGONISTS ON ELECTRICAL SLOW WAVES AND PHASIC CONTRACTIONS OF CAT COLON CIRCULAR MUSCLE. K. Venkova and J. Krier*. Dept. Physiol., Michigan State Univ., East Lansing, MI 48823

The effects of isoproterenol, phenylephrine and norepinephrine on spontaneous electrical slow waves (ESW) and associated phasic contractions (PC) of colon circular muscle were studied using intracellular microelectrode recordings and isometric force measurements. Atropine (0.5 μ M) and hexamethonium (1 μ M) were present to prevent interaction with cholinergic neurons. ESW consist of an upstroke phase followed by a plateau and repolarization. Muscle cells near the submucosal border had resting membrane potential of 71 ± 2 mV. ESW had a mean rate of upstroke depolarization of 308 ± 33 mV/s, an amplitude of 32 ± 3 mV, duration of 6-20 s and a rate of repolarization of 60 ± 6 mV/s. The frequency of ESW and PC ranged between 4-6 cycles per min. Isoproterenol (0.1-1 μ M) reduced the duration of ESW and the amplitude of PC by 51% and 83%, respectively. Phenylephrine (0.05-0.5 μ M) increased the duration of ESW and the amplitude of PC by 40.5% and 34%, respectively. Norepinephrine (0.01-0.5 μ M) resembled the effect of phenylephrine, increasing the duration of ESW by 20% and the amplitude of PC by 28%. All adrenoceptor agonists did not change the resting membrane potential, the amplitudes of ESW, the frequency of ESW and PC and the rate of upstroke depolarization and repolarization of the ESW. The effects of isoprenaline were blocked by propranolol (1 μ M) and the effects of phenylephrine and norepinephrine were blocked by phentolamine (3 μ M). Propranolol potentiated the excitatory effects of norepinephrine. Nitrendipine (1-10 μ M) and verapamil (1-10 μ M), antagonists of L-type Ca²⁺ channels, reduced the duration of ESW to 2.5-3 s and suppressed PC. Under these conditions, isoprenaline, phenylephrine or norepinephrine did not affect ESW and PC. The data indicate that ESW and PC of colon circular muscle are regulated by α - and β -adrenoceptors. The data suggest that adrenoceptor agonists cause changes in the duration of ESW and the amplitude of the associated PC by interacting with L-type Ca channels. (NIH-DK-29920)

556.1

INCREASED NITRIC OXIDE SYNTHASE ACTIVITY BY SIN-1 AND SODIUM NITROPRUSSIDE IN INTACT NEURONAL CELLS. J. Hu* and E.E. El-Fakahany. Division of Neuroscience Research in Psychiatry, University of Minnesota Medical School, Minneapolis, MN 55455.

It has been shown that nitric oxide (NO) regulates NO synthase activity through negative feedback in cytosolic enzyme preparations in a variety of cell types. We tested the effects of the NO-generating compounds *S*-nitroso-*N*-acetyl-penicillamine (SNAP), 3-morpholinodimethylamine (SIN-1) and sodium nitroprusside (SNP) on NO synthase activity in intact neuroblastoma N1E-115 cells. SIN-1 and SNP at concentrations which elicit almost complete inhibition of NO synthase activity in cytosolic enzyme preparations of these cells only inhibited about 30% of the enzyme activity in intact cells, as measured by the conversion of [³H]-arginine into [³H]-citrulline during incubation for 45 min. Surprisingly, SIN-1 and SNP stimulated [³H]-citrulline formation when cells were incubated with the compounds for > 1.5 hours. Neither inhibitory nor stimulatory effects of SNAP on NO synthase were observed in the intact N1E-115 cells. This is in contrast to the inhibitory effects of SNAP in cytosolic preparations of the enzyme. Measurement of the activity of lactate dehydrogenase indicated that there was no parallel increase in cell permeability in response to SIN-1 or SNP. The stimulation by SIN-1 and SNP of NO synthase activity was completely blocked by 3 mM EGTA, suggesting that an influx of Ca²⁺ is activated by the compounds in intact N1E-115 cells. Moreover, hemoglobin, superoxide dismutase and deferoxamine attenuated the effects of SIN-1, but not those of SNP, on [³H]-citrulline formation. Our results demonstrate that NO-generating compounds might somehow enhance Ca²⁺ influx, resulting in an up-regulation of NO synthase activity. These effects might be dependent on the chemical nature of the NO species released by the compounds.

556.3

SIMPLE GUANIDINE ANTAGONISTS OF NITRIC OXIDE SYNTHASE. J. E. Macdonald,*D. W. Reif, A. Wallace, Fisons Pharmaceuticals Divisional Research and Development, PO Box 1710, Rochester NY 14603

The role of nitric oxide synthases (NOS) in the function of the nervous system under normal and ischemia/reperfusion conditions is a topic of great interest. The current known antagonists of NOS are limited in that they lack selectivity between the brain, endothelium and macrophage NOS isoforms. Thus, selective antagonists would be useful tools to elucidate the role of the three NOS isoforms. Using the [³H]-L-arginine to [³H]-L-citrulline conversion assay (PNAS 87, 682-685, (1990)), compounds were assayed for inhibition of rat cerebellar, mouse macrophage, and human endothelial NOS. In our initial search for novel antagonists of NOS, we speculated that simple guanidines would be a reasonable starting point. The screening results for a series of substituted guanidines will be presented. Briefly, we have discovered small simple guanidines which inhibit the NOSs in the micromolar range (similar to methylarginine and nitroarginine), but are not selective versus a particular isoform. We will present results which will demonstrate that all of the NOS isoforms are inhibited by small cyclic guanidines and that inhibition is very dependent upon the size of the molecule.

556.5

PHOTONEURAL REGULATION OF RAT PINEAL NITRIC OXIDE SYNTHASE N.C. Schaad*, Jiri Vanecek and P.E. Schulz. Div. of Clinical Psychopharmacology, Dept of Psychiatry of the University of Geneva, 1225 Chêne-Bourg, Switzerland

Nitric oxide (NO) appears to play a role in the regulation of cGMP synthesis in the rat pineal gland. Pineal nitric oxide synthase (NOS) is dependent on calcium for its activity, and all its biochemical characteristics are similar to the constitutive form of the enzyme present in the cerebellum. The factors regulating the expression of the constitutive form of NOS in the central nervous system remain largely unknown. We report here a photoneural regulation of NOS activity in the rat pineal gland. In the absence of the adrenergic stimulation following constant light exposure (LL) or denervation (bilateral superior cervical ganglionectomy), pineal NOS activity is markedly reduced. A maximal drop is measured after 8 days in LL (-80% versus control). When rats are housed back in normal light:dark conditions (LD 12:12), pineal NOS activity returns to normal after 4 days. A partial decrease in pineal NOS activity is also observed when rats are placed for 8 days in LD 18:6 or shorter dark phases indicating that pineal NOS activity reflects the length of the dark phase. Because it is known that norepinephrine (NE) is released at night from the nerve endings in the pineal gland and this release is blocked by exposure to light, our data suggest that NOS is controlled by adrenergic mechanisms. Our observation may also explain the lack of cyclic GMP response to NE observed in animals housed in constant light.

556.2

TRANSMITTER MODULATION OF NMDA-ACTIVATED NITRIC OXIDE SYNTHASE (NOS) ACTIVITY IN RAT FRONTAL CORTEX. S. Alagarsamy* and K. M. Johnson. The Department of Pharmacology and Toxicology, The University of Texas Medical Branch, Galveston, TX 77555-1031.

We have previously reported that activation of classical N-methyl-D-aspartate (NMDA) receptors can stimulate NOS activity in the frontal cortex. In this study we focused on other transmitters that may activate NOS or modulate the NMDA-activation of NOS. We found that of the transmitters examined, glutamate and acetylcholine (ACh) receptor agonists were the only ones to affect NOS activity. Glutamate stimulated NOS activity and this response is blocked by NMDA antagonists, but was unaffected by non-NMDA antagonists. These data are substantiated by the fact that AMPA, kainic acid (KA) and quisqualic acid (Quis) did not increase NOS activity, even in the presence of diazoxide which prevents desensitization of the glutamate receptors, suggesting that the glutamate response was due to activation of the NMDA receptor in this preparation.

Norepinephrine, dopamine and γ -aminobutyric acid (GABA) had no effect on either the basal or NMDA-activated NOS. However, while the basal NOS activity was unaffected by ACh agonists, 1 mM carbamylcholine chloride, a mixed ACh agonist, inhibited the NMDA response completely. This inhibition was not reversed by atropine, nor was it mimicked by muscarine. Nicotine (30 μ M) inhibited the NMDA response, but this inhibition was not complete, perhaps due to receptor desensitization. The inhibitory effect of nicotine was insensitive to hexamethonium and d-tubocurarine. Complete pharmacological characterization of this apparent novel nicotinic mechanism is currently under investigation. Supported by DA-02073.

556.4

ISOLATION OF NITRIC OXIDE SYNTHASE (NOS) IN THE RAT UTERUS. Y. Jaing, A.K. Singh, M.S. Kannan, D.E. Johnson and R.L. Shew*. Departments of Veterinary Diagnostic Medicine & Veterinary Pathobiology, Pediatrics, Cell Biology & Neuroanatomy, University of Minnesota, St. Paul, MN 55108 and Minneapolis, MN 55455

The presence of NADPH-diaphorase-positive nerves in the rat uterus, and the role of nitric oxide (NO) during pregnancy, suggest that neurons containing NO may be important in regulating myometrial activity, uterine blood flow and other reproductive functions. NOS was isolated from the uterus of adult female rats by diethylaminoethyl (DEAE) column and further purified by 2',5'-ADP agarose. The chromatographic properties revealed two isoenzymes, NOS₁ and NOS₂. The molecular weights of both isoenzymes was approximately 155 Kd by SDS PAGE which was similar to NOS₁ and NOS₂ from rat brain. The enzymes required NADPH, Ca²⁺ and calmodulin as cofactors. However, in the absence of calmodulin and/or calcium NOS₁ was reduced by 96%, while NOS₂ was reduced by 70%. This maximal enzyme activity was similar for brain. These results demonstrate that the rat uterus contains NOS and the fundamental kinetic constants, K_m and V_{max}, are similar to brain NOS. The uterine NOS is NADPH-dependent and different enzyme isoforms are suggested by the calmodulin-dependence and trifluoroperazine-dependence of both uterine and brain NOS₁.

556.6

INDUCIBLE NITRIC OXIDE SYNTHASE IN CA1 NEURONS. I. Divac* and J. Regidor. Department of Medical Physiology, University of Copenhagen, Denmark, and Department of Morphology, University of Las Palmas de Gran Canaria, Spain.

Our results, obtained in collaboration with several colleagues, have shown that NADPH-diaphorase activity can be induced in the pyramidal CA1 neurons of the hippocampus by different agents. The effective agents are: electrical stimulation, mild stress, and direct injury of the hippocampus, either in vitro by slicing or in vivo by saline injections. After the induction, we found in hippocampal tissue an increased formation of cyclic GMP, indicating that the induced molecule has NOS enzymatic function. The induction of NADPH-diaphorase activity in CA1 neurons following intrahippocampal injections of saline can be abolished by pretreatment with anti-inflammatory drugs, dexamethasone or indomethacin, but not by a NOS inhibitor, L-NAME. Surprisingly, an antibody raised against the constitutive neuronal NOS did not stain the CA1 neurons which are demonstrably stained for NADPH-diaphorase. We conclude tentatively that a molecule, different from the constitutive NOS with both NADPH-diaphorase and NOS activities, can be induced in some neurons.

556.7

DISTRIBUTION OF NITRIC OXIDE SYNTHASE (NOS) IN RAT CENTRAL NERVOUS SYSTEM (CNS): A COMPARATIVE STUDY OF QUANTITATIVE AUTORADIOGRAPHY AND ENZYME ACTIVITY. S. Maayani*, G. R. Holstein, and P. Fernandez. Departments of Anesthesiology (S.M., P.F.) Neurology and Anatomy/Cell Biology (G.R.H.), Mount Sinai Medical Center, New York, NY 10029.

NOS is a ubiquitous enzyme in mammalian CNS. However, a quantitative assessment of its distribution is lacking. We have developed a novel method for quantitative autoradiography of [3 H]-nitroarginine binding. Data obtained with this method have been compared to the distribution of enzyme activity across rat CNS measured by the citrulline assay. The (100 μ M) nitroarginine-sensitive NOS activity was assessed (24°C, 10 min, 0.25–40 μ M [3 H]-arginine) in three preparations: a crude homogenate and cytosolic and particulate fractions derived from it. Quantitative autoradiography of (100 μ M) arginine-sensitive [3 H]-nitroarginine binding was done under the same NOS assay conditions with 50 nM [3 H]-nitroarginine, in 20 μ m coronal cryostat sections of rat brain.

Km values appeared to be constant across the rat CNS (1–3 μ M) while the Vmax (fmol/min mg tissue) varied substantially: the highest was observed in the cerebellum (100) and the lowest was found in the spinal cord (10). 20–40% of NOS activity was found in the particulate fraction, indicating an uneven distribution of the enzyme within cell compartments. Areas of highest binding included the olfactory tubercle, amygdala, fornix, substantia nigra, periaqueductal gray, and the cerebellar cortex. Intermediate binding levels were obtained in piriform cortex, hippocampus, septal nuclei, hypothalamus, globus pallidus, and the superior colliculus. Low binding was observed in frontal and parietal cortices, and the caudo-putamen. Arginine-sensitive [3 H]-nitroarginine binding varied between 65% of total binding (olfactory tubercle) to none (caudoputamen).

This combination of two quantitative methods for assessing NOS is proposed as a powerful tool to study the enzyme in mammalian CNS.

556.9

NITRIC OXIDE SYNTHASE ACTIVITY IS INCREASED IN BRAIN IN EXPERIMENTAL HEPATIC ENCEPHALOPATHY V.L. Raghavendra Rao, R. Audet and R.F. Butterworth* Neuroscience Res. Unit, Hôp. St-Luc (Univ. Montreal), 1058 St-Denis St., Montreal, Que.

Glutamatergic synaptic dysfunction has been proposed as a causal factor in hepatic encephalopathy. Increased glutamate release (Butterworth et al., *J. Neurochem.* 56, 1481, 1991) and decreased glutamate binding to NMDA receptors (Peterson et al., *J. Neurochem.* 55, 386, 1990) were previously reported in the brains of portacaval shunted rats. Such changes could lead to alterations in the second messenger systems coupled to glutamate receptors. As NMDA receptors have been shown to act via the nitric oxide/cGMP second messenger system, we studied the activities of nitric oxide synthase (NOS), in the brains of rats following portacaval anastomosis. Our results demonstrate that the activities of this enzyme were significantly increased in cerebral cortex (by 65%, $p < 0.01$), cerebellum (by 54%, $p < 0.01$), hippocampus (by 88%, $p < 0.01$) and striatum (by 64%, $p < 0.01$) of shunted rats compared to sham-operated controls. As the arginine transport is a prerequisite for nitric oxide production, we also studied [3 H]arginine transport into the cerebellar and cortical synaptosomes prepared from the brains of portacaval shunted and sham operated rats. [3 H]arginine uptake was significantly increased (by 45–55%, $p < 0.01$) in both cortex and cerebellum. Alterations of the NOS system and the resultant increased production of nitric oxide and cGMP in brain could be of pathophysiological significance in hepatic encephalopathy. (Supported by MRC Canada).

NITRIC OXIDE (NO) GAS ENHANCES TRITIATED NOREPINEPHRINE ([3 H]NE) RELEASE FROM RAT HIPPOCAMPAL SLICES. A.K. Stout* and J. J. Woodward, Department of Pharmacology and Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond VA 23298.

Previous studies in our lab have shown that NO gas enhances N-methyl-D-aspartate (NMDA)-stimulated release of preloaded [3 H]NE from rat brain slices in a dose-dependent, oxygen-sensitive, and cyclic GMP-independent manner. In this study we have attempted to determine the mechanism for the enhancement of neurotransmitter release seen with NO. NO-enhanced transmitter release was not due to buffer acidification or generation of NO degradation products, since reducing buffer pH below 7.3 inhibited NMDA-stimulated [3 H]NE release and nitrite or nitrate ions (3–100 μ M) had no significant effect on release. Carbon monoxide (10–300 μ M), another diatomic gas with properties similar to NO including heme binding and guanylate cyclase activation, had no significant effect on depolarization-induced [3 H]NE release. The NO effect was probably not due to mono-ADP-ribosylation of cellular proteins, since the ADP-ribosyltransferase inhibitors nicotinamide (10 μ M–10 mM) and luminol (1 μ M–1 mM) did not diminish the enhancement of transmitter release seen with NO. The NE reuptake inhibitor desmethylinipramine (10 nM–10 μ M) neither mimicked nor blocked the effect of NO, suggesting that NO was not acting via inhibition or reversal of the NE transporter. The metabolic inhibitors sodium azide (0.1–3 mM), potassium cyanide (0.1–3 mM), and 2,4-dinitrophenol (1 μ M–1 mM) all dose-dependently enhanced NMDA-stimulated [3 H]NE release similar to NO. These results suggest that NO may enhance neurotransmitter release by inhibiting cellular respiration and altering calcium homeostasis. Supported by NIAAA AA08089 and NIDA Training Grant DA 07027.

556.8

LOCALIZATION AND BIOCHEMISTRY OF NADPH-DIAPHORASE IN THE DEVELOPING CHICK RETINA: REGULATION BY CALCIUM IONS AND INHIBITION BY ARGININE ANALOGS R. Paes-de-Carvalho*, M.H. de Faria, J.L.M. do Nascimento and J.N. Hokoc. Dep. Neurobiologia UFF and Inst. Biofisica C. Chagas Filho, UFRJ, Rio de Janeiro, Brazil.

NADPH-diaphorase (ND) activity, reported to be identical to Nitric Oxide Synthase (NOS), is found in specific groups of neurons in the CNS. Here we studied ND activity and localization in the developing chick retina. Enzyme activity was measured by spectrophotometry after incubating retinal homogenates with NADPH and Nitro blue Tetrazolium in Tris 50 mM pH 8.1 at 37°C. ND histochemistry, performed incubating 4% paraformaldehyde-fixed cryostat tissue sections with the same compounds, revealed the presence of stained cells in retinas since 8 days of development (E8). An adult pattern was observed at E14, when photoreceptors and amacrine cells were ND positive. ND was detected biochemically in homogenates of E8, E11 and E14 retinas when we observed a 50% stimulation by Ca^{++} and 70% inhibition by L-NG-Nitroarginine (NARG). The stimulation by Ca^{++} decreased at E17 and was not significant in post-hatched retinas. Inhibition curves obtained with increasing concentrations of NARG and L-Ne-(1-iminoethyl) ornithine (NIO) in the presence and absence of Ca^{++} suggested the presence of Ca^{++} -dependent and independent isoforms of NOS in the retina. The results showed that the ND biochemical assay is a simple and sensitive method for studying NOS activity and that different isoforms of NOS are expressed in populations of chick retinal cells during development. (supported by CNPq and PROPP-UFF).

NITRIC OXIDE AND CYCLIC GMP ACTIVATE LOCUS COERULEUS NEURONS IN RAT BRAIN SLICES: ROLE OF CYCLIC GMP-DEPENDENT PROTEIN KINASE

J. H. Kogan*, J. Pineda and G. K. Aghajanian. Depts. of Cell. & Mol. Physiology, Psychiatry, & Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06508.

Nitric oxide (NO) has recently been shown to be a diffusible second messenger capable of stimulating soluble guanylate cyclase. Since the noradrenergic nucleus locus coeruleus (LC) is rich in the α_1 and β_1 subunits of soluble guanylate cyclase (Furuyama et al., *Mol. Brain Res.* 20, 1993) we investigated the role of the NO/cyclic GMP pathway in the LC. Extracellular electrophysiological recordings demonstrated that bath-applied 8-bromo-cyclic GMP (8Br-cGMP, 1 mM) caused a gradual excitation of LC neurons; a more rapid response occurred when cyclic GMP (100 μ M) was introduced via patch pipettes. Similarly, during extracellular recordings, the NO donors sodium nitroprusside (SNP, 1 mM) and S-nitroso-N-acetylpenicillamine (SNAP, 1 mM) excited LC neurons. The SNP excitation could be occluded by a prior application of 8Br-cGMP indicating that SNP was acting through the NO/cyclic GMP pathway. Furthermore, H-8 (100 μ M), a protein kinase inhibitor with a relatively high affinity for cyclic GMP-dependent protein kinase (PKG), antagonized both the SNP and the 8Br-cGMP activation of LC neurons consistent with an action through PKG. These results suggest that there may be a physiological role for the NO/cyclic GMP pathway in the LC.

556.12

CHARACTERIZATION OF NITRIC OXIDE-INDUCED [3 H]NOREPINEPHRINE RELEASE FROM HIPPOCAMPAL SLICES. G. Lonart* and K.M. Johnson. Dept. of Pharmacol. and Toxicol. Univ. of Texas Med. Branch, Galveston, TX 77555

We have previously reported that a long exposure to hydroxylamine, a nitric oxide (NO) generator, induced a tetrodotoxin-insensitive, Ca^{2+} -dependent release of [3 H]norepinephrine ([3 H]NE) from rat hippocampal slices (Lonart et al., *Eur. J. Pharmacol.*, 1992). These data suggested that NO induced the release of [3 H]NE directly from the noradrenergic terminals via exocytosis. However, we recently made observations which suggest the involvement of both NO-induced glutamate (Glu) release and non-classical [3 H]NE release via reverse NE transport. When we applied only a 10 min pulse of 100 μ M hydroxylamine, which evoked a 10-fold increase in the [3 H]NE efflux, this response was reduced by about 80% by both 0.5 μ M tetrodotoxin and 1 mM kynurenate, a Na^+ -channel blocker and a non-selective ionotropic glutamate receptor antagonist, respectively. Ten μ M CNQX and 100 μ M GYKI 52446, competitive and non-competitive AMPA/kainate receptor antagonists, respectively, reduced the hydroxylamine-evoked response by about 50%. The NMDA receptor antagonists AP-5 and MK-801 reduced the hydroxylamine response only at concentrations which also inhibited [3 H]NE transport in hippocampal synaptosomes. However, CGS 19755, another NMDA receptor antagonist which had no effect on the [3 H]NE transport, did not influence the hydroxylamine-induced [3 H]NE efflux. Ten μ M desipramine or 10 μ M nomifensine, potent inhibitors of norepinephrine transport, reduced the hydroxylamine-evoked [3 H]NE efflux from hippocampal slices by about 80%. S-nitroso-L-cysteine, another NO generator (300 to 3,000 μ M), stimulated the efflux of both [3 H]Glu and [3 H]NE from hippocampal synaptosomes. These data suggest that moderate NO stimuli can evoke [3 H]NE efflux both directly from the noradrenergic terminals and indirectly via releasing glutamate. LIPOPOLYSACCHARIDE INHIBITS THE PRODUCTION OF NITRIC OXIDE IN RAT PHEOCHROMOCYTOMA CELLS. G. Cao*, R.L. Prior*, J.G. Strain* and J.A. Joseph*. *USDA-ARS, HNRC at Tufts Univ. Boston, MA 02111 and *Dept. of Nutri. Sci., Univ. of Conn. Storrs, CT 06296

Nitric oxide (NO) is a recently recognized messenger molecule mediating diverse functions including vasodilation, neurotransmission, and antimicrobial and antitumor activities. NO is produced from L-arginine by NO synthase which has two isoforms, i.e. the constitutive NO synthase (cNOS) and inducible NO synthase (iNOS). The iNOS can be induced by bacterial lipopolysaccharide (LPS), phorbol esters, and some cytokines like TNF- α , IFN- γ and IL-1 β . However, the mechanism involved in the negative regulation of the NO production is not clear. Here, we report an inhibition of 43% and 50% in nitrite production in U-10 cells, a variant of PC-12 rat pheochromocytoma cells, by adding 1 or 10 μ g/ml LPS, respectively in the culture media for 3 days. Nitrite production was also inhibited by 43% in control cells not exposed to LPS but incubated with 0.5 mM N^G-methyl-L-arginine acetate, a compound that specifically and competitively inhibits NOS. The results suggested that the NO produced in these U-10 cells was from cNOS and could be negatively regulated by LPS.

DOES CARBON MONOXIDE REGULATE CYCLIC GMP LEVELS IN THE RAT BRAIN IN VIVO? J.T. Laitinen* and K.S.M. Laitinen. Depts. of Physiol. and Pharmacol. & Toxicol., Univ. of Kuopio, POB 1627, FIN-70211 Kuopio, Finland.

Microdialysis method combined with a specific RIA was used to study in vivo regulation of brain cGMP levels by the putative gaseous messengers nitric oxide (NO) and carbon monoxide (CO). Anesthetized rats were implanted with the microdialysis probes in the frontal cortex (FC) or the cerebellum (CB). Basal cGMP production was similar in both regions but we observed marked differences in responses to the NO-donor sodium nitroprusside (SNP) or to CO. Most notably, SNP maximally elevated cGMP 3-fold in the FC but 90-fold in the CB. Perfusion with CO-saturated ACSF stimulated cortical cGMP levels transiently and reversibly but elicited an irreversible and delayed response in the CB. Perfusion with the NO-synthase inhibitor L-NAME (2 mM) suppressed cerebellar cGMP by 75 % but exhibited no potency in the FC. Quite opposite, local perfusion with the heme oxygenase (HO) inhibitor zinc protoporphyrin IX (ZnPP) (100 μ M) suppressed basal cortical cGMP by 50 % but was without effect in the CB, suggesting that CO, generated by HO activity, might regulate cortical cGMP production in vivo. As ZnPP may have actions independent of HO inhibition, we have begun to address these questions by using more specific tools, including a microassay for HO activity in discrete brain regions, as well as antisense oligodeoxynucleotide targeting of HO gene in vivo. These tools are hoped to reveal whether endogenously produced CO participates in the maintenance of cortical cGMP levels in vivo.

REGULATION OF THE cAMP RESPONSE ELEMENT BINDING PROTEIN (CREB) IN THE LOCUS COERULEUS (LC) AND NUCLEUS ACCUMBENS (NAc) BY DRUGS OF ABUSE. K.L. Wadnell*, D.S. Russell, D.W. Self, M.J.D. Miserendino, C. Konradi*, S.E. Hyman*, and E.J. Nestler. Laboratory of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale School of Medicine, New Haven, CT 06508; *Massachusetts General Hospital, Charlestown, MA 02129.

We have shown previously that chronic administration of morphine or cocaine alters certain G proteins and components of the cAMP intracellular messenger system. These changes occur in specific brain regions known from behavioral and pharmacological studies to mediate aspects of drug addiction (see *Neuron*, 11:995, 1993). We are currently investigating the molecular mechanisms involved in these adaptations by focusing on regulation of the transcription factor CREB in the LC and NAc. Morphine administration regulates CREB phosphorylation in the LC, as would be expected given morphine regulation of the cAMP pathway (*J. Neurochem.* 58:1168, 1992). CREB has been thought to be constitutively expressed in the brain, however we have found that chronic morphine increases levels of CREB immunoreactivity in the LC. Interestingly, in the NAc, chronic morphine decreases CREB immunoreactivity. Preliminary evidence suggests that chronic cocaine also influences CREB levels in this brain region. In order to test whether CREB is directly involved in the observed changes in signal transduction proteins, we are infusing antisense PS-oligonucleotides to CREB into the NAc. Chronic (5 day) antisense injections downregulate CREB immunoreactivity by approximately 50%; this decrease in CREB appears to be associated with regulation of protein kinase A and G α , as well as Fos-like proteins as would be expected. These studies should further elucidate the role of CREB in morphine and cocaine regulation of intracellular target proteins implicated in drug addiction.

CARBON MONOXIDE AS A NEUROTRANSMITTER: A SIMPLE, SENSITIVE, SPECIFIC RADIOMETRIC ASSAY FOR HEME OXYGENASE. E.E. Thompson* and S.H. Snyder. The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Heme oxygenase (HO) catalyses the oxidation of heme to biliverdin and carbon monoxide (CO). Since CO can activate soluble guanylate cyclase, it is likely that HO plays a role in cGMP mediated signal transduction. To better study the role of HO in signal transduction, we have developed a new assay for HO which uses ⁵⁵Fe-labelled heme as substrate. As HO cleaves the heme ring to release Fe²⁺, this assay directly measures released ⁵⁵Fe²⁺ bound to transferrin attached to Sepharose beads. As little as one pmol of ⁵⁵Fe²⁺ is readily detected, providing a sensitivity 50 to 100 times greater than conventional assays based on the absorbance of bilirubin formed from biliverdin by biliverdin reductase. The assay is specific, as no known brain enzyme other than HO releases Fe²⁺ from heme. The assay is simple to perform. Assays are conducted in the presence of the Sepharose-transferrin beads which are counted directly after incubation, centrifugation and washing. Thus, 100 to 200 assays can be performed in an hour. This assay permits detection of HO activity in very small brain samples and microwell samples of cell culture.

MORPHINE ATTENUATES FORSKOLIN-INDUCED PREPROENKEPHALIN mRNA IN RAT STRIATUM: A QUANTITATIVE *IN SITU* HYBRIDIZATION STUDY. J.N. Simpson* and J.E. McGinty. Department of Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, NC 27858-4354.

Activation of the adenylate cyclase/cAMP second messenger system leads to an increase in preproenkephalin (PPE) and prodynorphin (PPD) gene expression. Because opiate receptors are negatively coupled to adenylate cyclase, pro-opioid gene expression may be negatively influenced by opiate receptor agonists. We previously demonstrated an increase in striatal PPE and PPD mRNA levels as well as an increase in striatal phospho-CREB and FOS immunoreactivity following intracerebroventricular (ICV) administration of forskolin (Simpson and McGinty, *Neuroreport*, June, 1994). In a preliminary experiment, medial striatal PPE and PPD mRNA levels were measured in rats which received either unilateral ICV injection of H₂O-soluble forskolin (FSK, 10 mM/10 μ l dH₂O) 1 h following a systemic injection of morphine sulfate (MOR, 25 mg/kg, n = 4) or unilateral ICV FSK only (n = 4). In the MOR/FSK group, a booster injection of MOR (10 mg/kg) was given 2 h after ICV FSK. The mRNA hybridization signal in the striatum ipsilateral to ICV FSK was compared with hybridization signal in the contralateral striatum. FSK induction of PPE, but not PPD, mRNA was significantly attenuated by MOR. In a separate experiment, levels of striatal pro-opioid and *zif/268* mRNA were examined 4 h following ICV FSK (10 mM/10 μ l saline, n = 5) or ICV saline (10 μ l, n = 5). FSK significantly induced PPE, PPD, and *zif/268* mRNA in the medial striatum. The finding that striatal *zif/268* mRNA is induced by FSK supports previous reports that the promoter region of the *zif/268* gene contains a CRE-like element. Results of a current study confirming morphine effects on forskolin-induced pro-opioid mRNA in the rat striatum as well as morphine effects on forskolin-induced *zif/268* mRNA will be presented. Supported by DA 05470 (JNS) and DA 03982 (JFM).

Molecular basis of dopamine-glutamate interactions in the rat striatum. C. Konradi¹*, X.-M. Li², R. L. Cole¹ and S. E. Hyman¹. ¹Laboratory for Molecular and Developmental Neuroscience, Massachusetts General Hospital, Harvard Medical School, Charlestown, MA 02129 and ²Department of Psychiatry, University of Saskatchewan, Saskatoon, S7N 0W0 Canada.

Abnormalities in dopamine neurotransmission have been implicated in the pathogenesis of neuropsychiatric disorders including Parkinson's disease and schizophrenia. The goal of our studies is to elucidate the influence of glutamate on dopamine-mediated gene regulation in striatum. Knowledge of dopamine-glutamate interactions may provide novel targets of drug therapy.

We have previously demonstrated regulation of AP-1 binding proteins in rat striatum by dopamine agonists and antagonists. In addition, we and others have observed that D1 and D2 dopamine receptor-mediated *c-fos* expression is inhibited by pretreatment with the NMDA receptor antagonist MK-801. Conversely, in primary striatal cultures, low levels of glutamate that are insufficient to induce *c-fos* expression, significantly enhance dopamine mediated *c-fos* expression and AP-1 binding activity. This effect appears to be mediated by Ca²⁺. Dopamine markedly induces cAMP in these cultures, while glutamate has no effect on cAMP levels. In addition, the Ca²⁺ ionophore A23187 was able to mimic the effects of glutamate. These data suggest that interactions between Ca²⁺ and the cAMP pathway may be critical in the regulation of striatal gene expression in response to dopaminergic drugs.

INDUCTION OF A NEWLY SYNTHESIZED CREB/ATF PROTEIN COMPLEX AFTER DOPAMINERGIC STIMULATION IN RAT PRIMARY STRIATAL CULTURES. R.L. Cole*, C. Konradi and S.E. Hyman. Molecular and Developmental Neuroscience, Massachusetts General Hospital, Harvard Medical School, Boston MA 02115.

Chronic administration of the psychostimulant drugs cocaine and amphetamine results in slow onset, long term behavioral changes including sensitization, tolerance, and most significantly, a profound state of dependence. Our previous studies have focused on the initial events regulating the prodynorphin gene which is robustly and selectively induced by chronic (but not acute) administration of amphetamine in both dorsal and ventral rat striatum. To investigate the molecular mechanisms of gene regulation by dopamine in striatal neurons we have utilized rat primary striatal cultures. We have previously reported that in gel-shifts CREB binds to three functional CRE elements within the dynorphin promoter, which have been termed dynCRE1 (-1660/-1553), dynCRE2 (-1630/-1623) and dynCRE3 (-1546/-1539), and is phosphorylated in response to dopamine stimulation. We now report that, in addition, a lower molecular weight complex is induced. The appearance of this complex is blocked by pre-treatment with the protein synthesis inhibitors cycloheximide and anisomycin prior to dopamine stimulation, suggesting protein synthesis dependence. In supershift analysis, the new protein complex is recognized by a CREB antiserum, implying that the new complex may contain CREB protein heterodimerizing with a newly synthesized protein. This raises the intriguing possibility that switching of dimerization partners may be a critical mechanism regulating CREB activity, thus altering its effects on gene expression, either positively or negatively. However, this protein complex may also represent a homodimer of a newly-synthesized protein in the CREB/ATF family, which cross reacts with the CREB antiserum. This would suggest that novel transcription complexes are induced by striatal neurons after dopamine stimulation. Changes in the composition of transcription factor complexes and/or the appearance of new transcription factors are likely to be key events in the regulation of gene expression following chronic psychostimulant administration.

556.20

GLUCOCORTICOIDS ATTENUATE KAINATE-INDUCED AP1 DNA BINDING ACTIVITY IN RAT BRAIN. T.M. Unluf and R.S. Jope. Dept. of Psychiatry and Behavioral Neurobiology, University of Alabama at Birmingham, Birmingham, AL 35294.

Glucocorticoids, which are produced by the adrenal glands, play a vital role in enabling mammals adapt to stress. This process is facilitated by glucocorticoids binding to their receptors in the cytosol of target cells and translocating these receptors into the nucleus where they function as transcription factors and modulate gene expression. Persistent high levels of glucocorticoids, however, can have profound deleterious effects, the mechanisms of which are not clearly understood.

In order to elucidate the mechanism by which glucocorticoids affect neuronal signal transduction pathways, this laboratory has shown that depletion of circulating glucocorticoid levels in rats by adrenalectomy increases the induction of immediate early genes (IEG), genes whose expressions are altered minutes after a stimulus has been initiated and whose expressions are regulated by the AP1 transcription factor. AP1 consists of homodimers (Jun-Jun) or heterodimers (e.g. Jun-Fos). Furthermore, this laboratory has also shown that dexamethasone (1mg/kg) significantly reduced kainate-induced AP1 activation in rat brain without altering the levels of IEG proteins.

To determine if endogenous glucocorticoid levels affect kainate-induced AP1 activation, rats were treated with kainate (12 mg/kg) for 1.5hr prior to sacrifice either in the morning (6:30 A.M.) or in the afternoon (2:30 P.M.), when glucocorticoid levels are low or high, respectively, and AP1 activity was measured in the cortex and hippocampus using a gel mobility shift assay and a radiolabeled oligonucleotide containing the AP1 binding site (TGACTCA). We found that kainate-induced AP1 activity was higher in the morning than in the evening (4 fold vs 1.8 fold over control) in the cortex but was the same at both times in the hippocampus. Since circulating glucocorticoid levels are higher in the afternoon than in the morning the reduced kainate-induced AP1 activation in the afternoon may be due to these high circulating glucocorticoid levels.

BEHAVIORAL PHARMACOLOGY II

557.1

BEHAVIORAL AND BIOCHEMICAL PROPERTIES OF GABA AND BENZODIAZEPINE RECEPTORS IN CBA AND C57 MICE. S. Liljequist* and G. Cebers. Dept of Clinical Neuroscience, Drug Dependence Res, Karolinska Institute, S-17176 Stockholm, Sweden.

C57Bl/6 male mice show "normal" habituation in a locomotor activity test situation, whereas CBA/Ca show no habituation. CBA mice also display increased latency in a passive avoidance situation and an increased sensitivity to the convulsive actions of the GABAergic antagonist picrotoxin. Receptor binding studies revealed no differences in benzodiazepine (BDZ) binding properties or in the ability of various BDZ receptor ligands to inhibit BDZ binding. Neither was there any differences in GABA- or pentobarbital-produced enhancement of BDZ binding. However, the binding of ³⁵TBPS (2 nM) was about 30% higher in forebrain microsacs of CBA mice as compared to C57 whereas no strain differences were noted in midazolam- or DMCM-produced modulation of ³⁵TBPS binding. Further experiments revealed no differences in GABA-produced influx of ³⁶chlorine. However, midazolam-induced enhancement of ³⁶chlorine influx was significantly higher in forebrain microsacs of C57 mice as compared to CBA mice. In contrast, the DMCM-produced a more marked reduction of GABA stimulated ³⁶chlorine in forebrain microsacs of CBA as compared to C57. Our current data indicate that genetic differences in the GABA/BDZ receptor system may explain at least some of the previously observed genetic differences in the behavioral actions of GABA receptor ligands in CBA and C57 animals.

557.2

FELBAMATE, A NOVEL ANTIEPILEPTIC AGENT, DOES NOT AFFECT COGNITION IN RODENTS R.D. Smith*, M.E. Grzelak & V.L. Coffin. Schering-Plough Research Institute, Kenilworth NJ 07033.

Felbamate (2-phenyl-1,3-propanediol dicarbamate; Felbatol, Taloxa) is a novel anticonvulsive agent recently approved by the FDA for treatment of epilepsy in the U.S. While the mechanism of action of felbamate has not been fully elucidated, recent evidence has accumulated to indicate that felbamate may act at the strychnine-insensitive glycine-binding site on the NMDA receptor complex. Since the NMDA receptor has been implicated in cognitive processes (i.e., LTP), the current study was designed to investigate the potential effects of felbamate on cognition.

Doses of felbamate up to 1000mg/kg sc did not produce deleterious effects in either mice or rats in passive-avoidance responding (PAR). In contrast, the noncompetitive NMDA antagonist MK-801 (dizocilpine) produced performance deficits at doses from 0.1 to 1.0mg/kg in both rats and mice. Both drugs prevented NMDA-induced convulsions (ED50=20.3 and 0.82, respectively). The therapeutic index (ratio of deficit-producing to anticonvulsant doses in ED50s) for dizocilpine was less than one-fold, while felbamate had a greater than 50-fold separation. Taken together, these results indicate that felbamate does not produce cognitive deficits at doses more than 50 times the dose needed to block seizure activity in rodents.

Animal	Therapeutic Ratio ^a	
	dizocilpine	felbamate
Test-time after drug administration		
rat (24h)	0.119	>50
mouse (24h)	0.078	>50
mouse (1h)	0.354	>50

^aDose producing PAR deficit/Dose to block NMDA-induced seizure

INHERITABLE INDIVIDUAL-SPECIFIC BEHAVIORAL FEATURES OF RATS AND EFFECTS OF PROPOFOL R. Dirksen¹, B. Ellenbroek², and A.R. Cools². Inst. of Anesthesiology¹, and Dept. Psychoneuropharmacology², University of Nijmegen, Nijmegen 6500HB, the Netherlands.

Inheritable differences in the physiological state of the brain that direct the display of behavior include those in the GABA transmission. This transmission is essential to effects of various general anesthetics, including propofol. The present study uses the 14th generation of pharmacogenetically selected APO-UNSUS and APO-SUS rats to evaluate whether the neurobiological profile of individual-specific features affects the response to propofol. We assessed the duration of abolishment of purposeful movements (APM) and the incidence of propofol-evoked behavior after three different doses i.v., each injected at a one week interval. One week later, the rats were anesthetized with urethane, and the effects of i.v. propofol on withdrawal reflexes, heart rate and blood pressures were measured. The induction of APM and magnitude of reflex inhibition representing the anesthetic type of effect were not different for the two types of rats. APO-UNSUS rats showed a greater heart rate variability and their systolic blood pressures were lower than APO-SUS rats. Propofol reduced heart rate variables stronger in APO-UNSUS rats, whereas blood pressures variables were reduced to a greater extent in APO-SUS rats. Cardiovascular responses serve to indicate the sensitivity of an individual to an anesthetic in clinical conditions, and the marked interindividual differences occurred at the same magnitude of anesthetic response. Drug-induced behavior differed among the two types of rats. APO-SUS rats showed a higher incidence of involuntary muscular contractions and vacuous chewing with tongue protrusion than the APO-UNSUS rats, whereas their incidence of grooming behavior was lower. The difference in these adverse reactions may relate to the mirror image in functionality of GABA transmission in the striato-nigro-collicular pathway for the two types of rats. Translated to the human condition, personality may affect the severity of side-effects of propofol.

557.4

STEREOSPECIFIC REQUIREMENTS FOR BINDING AND TRANSDUCTION OF BEHAVIORAL EFFECTS AT DIAZEPAM-INSENSITIVE GABA_A RECEPTORS IN PIGEONS. J.B. Acri, G. Wong, J.M. Wilkin*. Drug Devel. Grp., Psychobiology Section, NIDA-IRP-ARC, NIH, Baltimore, MD 21224 and Laboratory of Neuroscience, NIDDK, NIH, Bethesda, MD 20814.

There is a positive correlation between binding at diazepam-insensitive (DI) benzodiazepine receptors and substitution for the discriminative stimulus effects of flumazenil (FLU) in pigeons. These experiments examined the binding affinities and discriminative stimulus effects of two benzodiazepine partial agonists (bretazenil and Ro 14-5974) and their R-enantiomers, Ro 18-2598 and Ro 14-7527, at diazepam-sensitive (DS) and DI receptors. The ability of compounds to substitute for the discriminative stimulus effects of FLU and midazolam (MDZ) were determined, to differentiate DS- from DI-mediated effects, with comparison to the full DS agonist, Ro 19-0528. Compounds were also tested for their ability to block MDZ effects. S-enantiomers bretazenil, Ro 14-5974, and Ro 19-0528 bound to both DI and DS receptors with nanomolar affinities, whereas R-enantiomers did not bind to either DI or DS receptors (K_i > 1000 nM). Consistent with DI binding affinity, bretazenil and Ro 14-5974 fully substituted for the discriminative stimulus effects of FLU, and Ro 19-0528 partially substituted. Bretazenil and Ro 14-5974 partially substituted for the discriminative stimulus effects of MDZ, and Ro 19-0528 fully substituted, consistent with actions as partial and full DS agonists. Both bretazenil and Ro 14-5974 partially blocked the discriminative stimulus effects of MDZ. The R-enantiomers did not engender FLU or MDZ responding, and did not block the discriminative stimulus effects of MDZ. Results indicated a stereospecific requirement for DI binding and transduction of behavioral effects, consistent with DI receptor-mediation of the discriminative stimulus effects of FLU. Further, this is the first report of DI effects for a full DS agonist, Ro 19-0528, and a non-parallel FLU substitution curve for this compound suggests the possibility of unique behavioral interactions that remain to be elucidated.

557.5

EVIDENCE FOR AN INVERSE AGONIST ACTION OF RITANSERIN ON ASSOCIATIVE LEARNING IN THE RABBIT. S. Welsh*, A. G. Romano, K. J. Simansky and J. A. Harvey, Department of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Drugs classified as partial agonists at 5-HT₂ receptors (e.g., LSD) have been demonstrated to enhance associative learning as measured by acquisition of the rabbit's nictitating membrane (NM) response. We have now examined the effects of the 5-HT₂ antagonist, ritanserin, on acquisition of the NM response and on its ability to antagonize the effects of LSD. Classical conditioning of the NM response was accomplished by pairing both light and tone CSs with a corneal airpuff US. Ritanserin (0.032 to 3.2 mg/kg, s.c.) given 1 hr prior to each conditioning session, significantly retarded acquisition of CRs in a dose-dependent manner. LSD (0.013 mg/kg, i.v.) given 20 minutes prior to each session significantly enhanced the acquisition of CRs. This enhanced acquisition of CRs produced by LSD was completely blocked by a dose of ritanserin (0.5 mg/kg) which when given alone had an intermediate effect in retarding CR acquisition. The ability of ritanserin to block the effects of LSD suggests that LSD produces an enhancement of learning through an action at the 5-HT₂ receptor. Control experiments indicated that ritanserin (0.5 mg/kg) given alone had no effect on nonassociative determinants of responding such as sensitization, pseudoconditioning or altered baseline rates. This dose of ritanserin did alter stimulus processing. There was a more than 10 dB elevation of the CS intensity threshold for eliciting CRs. Ritanserin had no effect on the US intensity threshold for eliciting URs but did significantly decrease the amplitude of the elicited UR. The results of these studies lead us to conclude that ritanserin blocks learning through an inverse agonist action at the 5-HT₂ receptor. Therefore, these data suggest that the activity of the serotonergic systems in brain are normally required for optimal learning. This research was supported by MH 16841.

MODULATION BY INOSITOL OF CHOLINERGIC AND SEROTONERGIC-INDUCED SEIZURES IN LITHIUM TREATED RATS. M.B. Williams* and R.S. Jope, Dept. of Psychiatry and Behavioral Neurobiology, Univ. of Alabama at Birmingham, Birmingham, AL 35294

Lithium's inhibitory effect on inositol monophosphatase of the PI pathway was suggested to be involved in the mechanism of action of lithium, the treatment for bipolar affective disorder (Berridge et al, 1982). Inositol depletion occurs following toxic but not therapeutic doses of lithium. However, supplemental inositol attenuated seizures induced by acute lithium plus pilocarpine (PILO) (Tricklebank et al, 1991; Kofman et al, 1993). We used EEG measurements of seizures produced by PILO given to lithium-pretreated rats (acute or chronic) and determined the effect of myo- and epi-inositol on seizure latency. Myo-inositol (0.55 mmole, icv) dose-dependently increased latency to seizures induced by acute lithium (3 mmole/kg, ip) plus PILO (30 mg/kg, sc). Epi-inositol, which is not utilized for PI synthesis, blocked seizures in 50% of tested rats. In chronic lithium treated rats, inositol did not block seizures produced by PILO. Similarly to its effect on muscarinic agonists, lithium increased the response to R(-)-DOI, a selective 5HT₂ (PI-linked) agonist (Williams and Jope, 1994). While DOI (8 mg/kg, i.p.) alone was not convulsive, lithium plus DOI evoked seizures. Myo-inositol (icv) blocked seizures in some rats treated with lithium and DOI.

POSSIBLE ROLE FOR THE 5-HT1B/D RECEPTOR IN THE MEDIATION OF ANTIDEPRESSANT-LIKE EFFECTS IN THE MOUSE TAIL SUSPENSION TEST. M. F. O'Neill, A. G. Fernández and J.M. Palacios*, Laboratorios Almirall, Cardener 68-74, Barcelona 08024, Spain.

The ability of many antidepressant treatments to increase synaptic concentrations of serotonin is believed to be the mechanism by which they exert their clinically beneficial effects. It is uncertain, however, via which receptor subtype(s) the increased concentrations of serotonin subsequently act. Several studies have suggested that agonists at 5-HT1B receptors such as RU 24969 demonstrate antidepressant-like actions in rodent tests. We set out to determine if RU 24969 could reduce immobility in the mouse tail suspension test and to compare the effects of two recently described compounds; WAY 100135 and GR 127935, selective antagonists at 5-HT1A and 5-HT1B receptors respectively, on the effects of this and other antidepressant treatments. All drugs were administered s.c. RU 24969 significantly decreased immobility at a dose of 3mg/kg. Neither antagonist alone had any effect in this test up to doses of 10mg/kg. WAY100135 (10mg/kg) had no effect on the decrease in immobility induced by paroxetine (1mg/kg) or RU 24969 (3mg/kg) while GR 127935 (10mg/kg) not only blocked the effects of the 5-HT1B agonist but also blocked the effects of paroxetine (1mg/kg) and imipramine (10mg/kg) in the TST. In conclusion, these results indicate that the 5-HT1B/D receptor may be involved in the mediation of the behavioural action of antidepressant agents.

FAILURE OF ACEA 1021 TO SERVE AS A DISCRIMINATIVE STIMULUS IN RATS. K.L. Shelton* and R.L. Balster, Medical College of Virginia, Department of Pharmacology and Toxicology, Richmond, VA 23298-0613

NMDA antagonists have shown promise as treatments for a number of neurological disorders. However, one of the problems of NMDA antagonists, particularly those such as PCP which act by blocking the receptor associated ion channel, is their production of PCP-like psychological effects and abuse liability. Nonetheless, behavioral studies have shown potentially important differences among the different types of site-selective NMDA antagonists. To further examine the behavioral effects of glutamate antagonists, we attempted to train the novel quinoxalinedione glutamate antagonist, 5-nitro-6,7-dichloro-1,2,3,4-tetrahydroquinoxaline-2,3-dione (ACEA 1021), which has *in vitro* selectivity as an antagonist at the glycine modulatory site on the NMDA receptor, as a discriminative stimulus in rats. Fifteen adult, male Sprague-Dawley rats were used as subjects. The rats were initially trained to respond under a fixed ratio-1 schedule on both levers of a standard two-lever operant conditioning chamber for 45-mg food pellet reinforcers. After responding had stabilized under FR-1 conditions, discrimination training began. One lever was designated the saline lever and the other lever as the drug lever. Rats were injected once per day, 30 minutes prior to the training session with either 10 mg/kg ACEA 1021 or vehicle in a double alternation sequence (i.e. drug, drug, sal, sal). Over sessions, the FR requirement was gradually increased until a FR-16 schedule was in effect. After 60 training sessions, only one subject had reached the acquisition criteria of 9 out of 10 consecutive sessions during which the first FR had been emitted on the correct lever and 90% or more of the animal's total responses were on the correct lever. For 7 of the subjects, the training dose of ACEA 1021 was then increased to 15.6 mg/kg. After 60 additional training sessions, none of these animals had reached acquisition criteria. It has been shown that nearly all drugs with abuse liability can be trained as a discriminative stimulus in animals. The inability to train ACEA 1021 as a discriminative stimulus despite prolonged training at doses that decreased response rates compared to saline, provides evidence that its interoceptive stimulus properties are weak at best and it may therefore have low potential for abuse. Research supported by grants DA-01442 and AA-05357

IMIPRAMINE, CLOMIPRAMINE AND FLUOXETINE SHOW SIMILAR EFFICACY, BUT A DISTINCT MECHANISM OF ACTION IN THE LEARNED HELPLESSNESS PARADIGM. Gambiarra C*, Ghiglietti O., De Montis M.G. and Tagliamonte A., Institute of Pharmacology, University of Siena, Siena, Italy.

The clinical efficacy of antidepressant drugs which act selectively upon the serotonergic system supports the hypothesis of the relevant role of serotonin in the pathogenesis of depression. Selective inhibitors of 5-HT uptake, as well as agonists of 5-HT_{1A} receptors, are active in some animal models of depression. Thus, in the present study we compared the effects of a long-term exposure to imipramine (IMI), clomipramine (CMI) and fluoxetine (FLU) on the learned helplessness (LH) model of depression. Experiments were carried out on male Sprague-Dawley rats. IMI (10 mg/kg i.p. twice a day), CMI (10 mg/kg i.p. twice a day) and FLU (10 mg/kg i.p. once daily) were administered for 15 days. Animals received 80 unavoidable electric shocks (1 mA) on the tail 2 h after the last treatment, and were tested for escape 24 h later. IMI, CMI and FLU showed the same efficacy in preventing the behavioral effects of repeated unavoidable stress. The acute inhibition of D₁ dopamine receptor activity (as obtained by injecting SCH 23390) completely prevented the effects of IMI, and only partially those of FLU. On the other hand, SCH 23390 antagonized the efficacy of CMI only in 50% of the animals. Moreover, the preventive effect of FLU and CMI was completely antagonized by the acute administration of pindolol (a 5-HT_{1A} antagonist), which failed to affect IMI antidepressant activity. Since pindolol also inhibits β -adrenoceptors, propranolol (a β -blocker which does not compete with endogenous 5-HT) was acutely tested on IMI, CMI and FLU treated rats, and showed no effect. It was concluded that: a) β -adrenoceptors are not involved in the LH prevention by the three compounds tested; b) IMI prevents LH development through the selective activation of D₁ dopamine receptors; c) FLU and CMI act mainly at the level of 5-HT_{1A} receptor system.

EFFECTS OF 5-HT₃ ANTAGONISTS AND 5-HT_{1A} AGONISTS ON FIXED-CONSECUTIVE-NUMBER PERFORMANCE IN RATS. P.C. Mele, J.H. McDonough, P.J. Winsauer and C.G. Franz, Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20889-5603.

Similarities and differences in the behavioral effects of 5-HT₃ antagonists and 5-HT_{1A} agonists have been reported. The present study compared drugs from these classes in rats responding under a fixed-consecutive-number (FCN) schedule of reinforcement. The FCN schedule required 20 consecutive responses on one lever before a response on a second lever resulted in delivery of milk reinforcers during daily 30-min sessions. The selective 5-HT₃ antagonists ondansetron (0.001-3 mg/kg, i.p., 15 min pre-session) and zacopride (0.01-10 mg/kg, i.p., 15 min pre-session) failed to alter either rates or accuracies of responding significantly. The mixed D2/5-HT₃ antagonist metoclopramide (1-3 mg/kg, i.p., 30 min pre-session) and the selective 5-HT_{1A} agonist 8-OH-DPAT (0.032-0.32 mg/kg, s.c., 15 min pre-session) dose-dependently reduced rates and accuracies of responding. The partial 5-HT_{1A} agonist buspirone (0.3-10 mg/kg, i.p., 15 min pre-session) decreased response rates substantially but reduced accuracies only minimally. Within-session patterns of responding differed across drugs: 8-OH-DPAT disrupted responding early in the session and this was followed by recovery; metoclopramide reduced or eliminated responding after a period of unaffected or less affected responding early in the session; buspirone eliminated responding throughout the session. Selective 5-HT₃ antagonists and 5-HT_{1A} agonists differentially altered FCN performance in rats. Within each class, selective versus nonselective drugs could be distinguished.

557.11

EFFECTS OF CORTICOSTERONE AND DEXAMETHASONE ON SCHEDULE-INDUCED POLYDIPSIA IN ADRENALECTOMIZED RATS. F. Cirulli^{1,2*}, H. van Oers¹, E. R. De Kloet³ and S. Levine¹. ¹Dept. of Psychiatry, Stanford Univ. Sch. of Med., Stanford, CA 94305; ²Lab. Fisiopatologia O. S., Istituto Superiore di Sanità, I00161 Rome, Italy; ³Div. of Medical Pharmacology, Cent Bio-Pharm Sci., Univ. of Leiden, 2300 RA Leiden, The Netherlands.

Removal of circulating glucocorticoids by adrenalectomy prevents the normal acquisition of schedule-induced polydipsia (SIP), while corticosterone (CORT) administration reinstates this behavior in adrenalectomized (ADX) rats. These studies investigated which glucocorticoid (GC) receptor is responsible for mediating CORT effects on SIP. In Experiment I the effects of dexamethasone (DEX) and CORT on the acquisition of SIP were studied. DEX and CORT pellets (respectively 15 mg and 200 mg) were implanted subcutaneously in ADX rats. CORT but not DEX replacement was able to reinstate SIP in ADX rats. Because DEX binds almost exclusively to glucocorticoid receptors (GRs), while CORT binds to both GRs and mineralocorticoid receptors (MRs), results from Experiment I indicate that GRs alone are not sufficient for SIP acquisition. In Experiment II CORT pellets of different concentrations (1, 10, 50, 200 mg) were implanted in ADX rats in order to distinguish whether MRs alone, or a combination of GRs and MRs is required for SIP reinstatement. Results from Experiment II showed that the 1 and 10 mg CORT pellets were not able to reinstate SIP in adrenalectomized rats, while animals implanted with 50 or 200 mg pellets did show the behavior. These results indicate that occupancy of both MRs and GRs is required for SIP acquisition.

THE CCK₁ RECEPTOR ANTAGONIST DEVAZEPIDE DECREASES RETENTION OF IMMOBILITY BY A GLUCOCORTICOID RELATED MECHANISM IN THE FORCED-SWIM TEST IN RATS. M. Ruiz-Gayo, F. Hernandez and J.A. Puentes*. Dept. of Pharmacology, Sch. of Pharmacy, Univ. Complutense, Ciudad Universitaria, 28040 Madrid, Spain

Post-stress occupancy of glucocorticoid receptors has been shown to influence information storage. This is a fact that seems to facilitate the manifestation of "depressive" signs in rats that suffer a second stressful session. Cholecystokinin (CCK) has been proposed as a second rank order modulator of the hypothalamus-pituitary-adrenal axis. With the aim to study whether endogenous CCK plays a role in behavioral patterns regulated by glucocorticoids, the effects of both CCK₁ (MK-329, devazepide) and CCK₂ (L-365,260) receptor antagonist on the retention of immobility in the forced-swim test were studied in rats.

Male Wistar rats, weighing 120-150 g, were forced to swim during 15 min into a methacrylate cylinder (18 cm diameter, 25 cm high) containing a water depth of 18 cm at 25°C. 24 hr later, animals were reintroduced during 5 min period. Drugs were dissolved in polyethylenglycol 200-ethanol (95/5) and given subcutaneously just before first swimming trial.

Devazepide (0.3 mg/kg), but not L-365,260 (1 mg/kg), was found to reduce the duration of immobility as compared to control in the 5-min retest session. As previously reported, the same effect was observed when the drug tested was the glucocorticoid γ_1 receptor antagonist RU-486 (mifepristone). Interestingly, the effect of devazepide was not only reversed by the CCK receptor agonist CCK₁ (40 μ g/kg), but also by the selective glucocorticoid γ_1 receptor agonist dexamethasone (0.03 mg/kg).

These results suggest that CCK₁, by acting upon CCK₁ receptors, may be involved in the behavioral response to stress through a glucocorticoid related mechanism.

557.15

THE NITRIC OXIDE SYNTHASE INHIBITOR, N(G)-MONOMETHYL-L-ARGININE IN THE MPOA INCREASES SEMINAL EMISSIONS IN RESTRAINED SUPINE RATS AND REDUCES THE INCIDENCE OF COPULATION IN A COPULATION TEST. J. Moses* & E. M. Hull. Department of Psychology, State University of New York at Buffalo, Buffalo, NY 14260.

The nitric oxide synthase inhibitor N(G)-monomethyl-L-arginine (NMMA; 25, 50, 100, 200 and 400 μ g) was microinjected into the medial preoptic area (MPOA) of male rats. In a test of ex copula genital reflexes, restrained supine rats exhibited a dose-dependent increase in seminal emissions which was significant at the 400 μ g dose. This effect was not mimicked by the inactive isomer N(G)-monomethyl-D-arginine. In a subsequent copulation test, animals in the NMMA (400 μ g) condition were significantly less likely to successfully initiate copulation than were animals in the vehicle condition. The results suggest that nitric oxide in the MPOA contributes to the regulation of male sexual behavior.

557.12

3 α -ANDROSTANEDIOL INHIBITION OF SEXUAL RECEPTIVITY AND NOCICEPTION: EVIDENCE FOR A GABAERGIC MECHANISM. C.A. Frye*, K.R. Van Keuren & M.S. Erskine. Department of Biology, Boston University, 5 Cummington Street, Boston, MA 02215

Many steroids can act via intracellular receptors and at the GABA receptor complex (GBR). Progesterone (P) or its metabolites may initiate sexual receptivity and 5 α -reduced androgens, particularly 3 α -Androstenediol (3 α -Diol), may terminate estrus in part via actions at the GBR. To investigate this hypothesis ovariectomized (ovx) rats (N=50) received 3 α -Diol (0.6, 3.0, 6.0 and 7.5 mg/kg) or vehicle (10% (v/v) ethanol:propylene glycol) at 1000h (0h), and 2 SC injections of estradiol (E₂: 1 μ g/0.2 ml in 10% ethanol) at 1300 (3h) and 1900 (9h) daily for 2 days. P (0.5, 1.0, 2.0 and 4.0 mg/kg) or sesame oil vehicle was given at 1430h after 2 days of 3 α -Diol and E₂. Behavioral testing was carried out at 1830h, 48-49 hours after the first injection of E₂ and 4 hours after injection of P. 3 α -Diol (3.0 and 6.0 mg/kg) significantly attenuated P's (2.0 and 4.0 mg/kg) facilitation of sexual behavior (Lordosis Quotient, Lordosis Rating, Proceptivity). P and 3 α -Diol both produced analgesia as assessed via the radiant heat tailflick method. 3 α -Diol at 3.0 mg/kg inhibited P-induced receptivity, uniformly produced maximum analgesia, and dramatically increased GABA-stimulated chloride flux into cortical synaptosomes. As 3 α -Diol binds poorly to its intracellular receptor, these data suggest that 3 α -Diol may act via the GBR to inhibit sexual receptivity and promote analgesia.

THE EFFECTS OF THE NEUROSTEROID, PREGNENOLONE SULFATE, ON SPONTANEOUS LOCOMOTOR ACTIVITY, SPATIAL LEARNING AND MEMORY. D.M. Kinsella, M. Kavaliers, K.-P. Ossenkopp and R. Shivers*. Neuroscience Program, University of Western Ontario, London, Canada.

The sulfated neurosteroid Pregnenolone Sulfate (PS) has been shown to have a variety of behavioral effects. Recently evidence has been presented that PS affects cognitive processes. The present study examined the effects of PS on spatial learning and memory in adult male rats. PS (0.5 and 1.0 mg/kg) and vehicle treated rats were tested in a Morris water maze task, where they had to learn the position of a hidden platform. PS treated rats were found to learn the task significantly faster than the saline vehicle controls, although the vehicle group had significantly better retention. The effects of PS on locomotor activity and swimming behavior were also examined. In a multivariate analysis of locomotor behavior, PS was found to cause a dose-dependent increase in activity. There were, however, no significant effects on swimming behavior. These results suggest that PS may affect spatial learning and locomotor activity. Supported by an NSERC to KPO and MK.

THE EFFECTS OF THE NOS INHIBITORS, 7-NITROINDAZOLE AND L-NITRO-ARGININE-METHYL ESTER, ON THE SEDATIVE/HYPNOTIC AND ANTINOCICEPTIVE EFFECTS OF PROPOFOL AND ETOMIDATE. S. Harris, S. La Marca and R.W. Dunn*. Ohmeda Inc., Pharmaceutical Products Division, 100 Mountain Ave., Murray Hill, NJ 07974.

It has previously been shown in rats that L-Nitro-Arginine-Methyl Ester (L-NAME) reduced the requirement for the inhalational anesthetic halothane (Johns et al., *Anesthesiology*, 77:779, 1992). Therefore, we examined the sedative/hypnotic and antinociceptive effects of intravenous (iv) anesthetics alone and in the presence of NOS inhibitors [L-NAME and 7-Nitroindazole (7-NI), iv]. ED₅₀ values for anesthetic potency of propofol (P) and etomidate (E), as measured by the loss of righting (LOR) in rats, were determined to be 3.7 and 0.3 mg/kg, iv, respectively. Intravenous administration of L-NAME was devoid of anesthetic effects (10-1000 mg/kg, iv) while 7-NI produced a dose-dependent LOR with an ED₅₀ of 20.4 mg/kg. However, pretreatment (30 min) with either L-NAME (100 mg/kg, iv) or a sub-anesthetic dose of 7-NI (10 mg/kg, iv) had no significant effect on the anesthetic potency of P (3.1 and 4.3 mg/kg, respectively) or E (0.34 and 0.56 mg/kg, respectively). Therefore, NOS inhibition did not reduce the requirement of the iv anesthetics tested. In addition, at the ED₅₀ dose for LOR, both P (5 mg/kg) and E (1.23 mg/kg) lacked antinociceptive activity in the tail flick assay. At higher doses, P and E significantly increased tail flick latencies with antinociceptive A₅₀ values equal to 11.1 and 5.4 mg/kg, iv, respectively. Pretreatment with either L-NAME (30 min) or 7-NI (15 min) at doses devoid of antinociceptive effects in rats (100 and 10 mg/kg, respectively), had no effect on E tail flick latency. However, L-NAME but not 7-NI, significantly reduced the A₅₀ for P by 37% to 7.0 mg/kg, iv. These data show that NOS inhibition by either L-NAME or 7-NI has no effect on the anesthetic potency of P or E, but that the antinociception produced by anesthetic doses of propofol is enhanced by pretreatment with L-NAME.

ASSESSMENT OF DRUG-INDUCED REBOUND USING A THREE-LEVER DRUG-DISCRIMINATION TASK. W. F. Caul*, R. J. Barrett, E. M. Huffman, and J. R. Stadler. Department of Psychology and V. A. Medical Center, Vanderbilt University, Nashville, TN 37240.

Our previous research, using a two-lever drug-drug discrimination task, has shown that time-dependent, bidirectional changes in choice responding occur following administration of drug (e.g., Barrett et al., Psychopharm., 1992). Because one limitation of the two-lever procedure is that it is not possible to identify cue states that differ from those associated with the training drugs, in the present study animals were trained on a three-lever task to discriminate among two drugs and vehicle.

Rats were trained over a 10-month period using a VI schedule of food reinforcement to discriminate among 0.5 mg/kg amphetamine, distilled water, and 0.03 mg/kg haloperidol. The dose-response functions for responding on each lever indicate that animals were responding on the basis of a continuum of dopaminergic activity. Subsequent to a large (10 mg/kg) dose of amphetamine, predominant responding shifted from the amphetamine lever at 4 hr, to the water lever at 8 hr, and then to the haloperidol lever at 20 and 24 hrs.

558.3

DISCRIMINATIVE STIMULUS EFFECTS OF CAFFEINE IN METHAMPHETAMINE-TRAINED SQUIRREL MONKEYS. D. M. Grech*, R. D. Spealman and J. Bergman, New England Regional Primate Research Center, Harvard Medical School, Southborough, MA 01772-9102.

The behavioral effects of caffeine were studied alone and in combination with methamphetamine (MA) in squirrel monkeys trained to distinguish 0.30 mg/kg MA from saline using conventional drug discrimination procedures. In initial experiments, caffeine (3-56 mg/kg) substituted for MA to varying extents in four of seven monkeys, resulting in 67-100% MA-lever responding. However, the MA-like discriminative stimulus effects of caffeine diminished over successive determinations and could not be reinstated regardless of dose. Pretreatment with caffeine (3 and 10 mg/kg) did not systematically alter the discriminative stimulus effects of MA; on the other hand, pretreatment with a normally ineffective dose of MA did partially restore caffeine's MA-like effects (50-90% MA-lever responding). These findings suggest that, although caffeine and MA generally have dissimilar discriminative stimulus effects, their behavioral actions may overlap to a limited extent. EFFECT OF FOURPHIT, AN IRREVERSIBLE INHIBITOR OF STIMULANT BINDING, ON COCAINE-INDUCED BEHAVIORS. M. Schweri*, B. de Costa, and K. Rice. Div. Basic Med. Sciences, Mercer U. Sch. Med., Macon, GA 31207 and NIDDK, Bethesda, MD 20892.

We have shown previously that 20 mg/kg (i.v.) Fourphit HCl (4-isothiocyanato-1-[1-phenylcyclohexyl]piperidine; FPH), an irreversible inhibitor of [³H]methylphenidate binding to the stimulant recognition site on the dopamine transporter, decreases the total, ambulatory, and non-ambulatory activity caused by a low dose (15 mg/kg, i.p.) of cocaine-HCl (COC) 24 hrs after treatment with FPH. The present work examined the effect of the same dose of FPH on the behavioral response to a higher dose of COC (40 mg/kg, i.p.). After overnight acclimatization in individual activity monitor cages, male Sprague-Dawley rats were injected with FPH or vehicle (VEH; 20% EtOH/saline), then challenged 24 hrs later with 40 mg/kg (i.p.) COC. Activity counts recorded after COC injection were analysed by 2-way (time x treatment) ANOVA with repeated measures after square root transformation. Significant time x treatment interactions were obtained for the total (p<.05) and ambulatory (p<.02) activity counts recorded at three consecutive 25 min intervals, starting at 10 min after COC administration. Analysis by t-test showed that FPH-treated rats were significantly less active than VEH controls during the first measurement interval. Although FPH had no effect on nonambulatory activity (often used as a measure of stereotypy), differences in particular stereotypic behaviors were found: FPH-treated rats exhibited more thigmotaxis (p<.03) and less rearing (p<.04) after COC than controls. The data show that FPH has a significant effect on behaviors caused by a higher dose of COC. (Supported by NIDA #DA06305 and NINDS #NS28584).

LOW DOPAMINERGIC AND HIGH CHOLINERGIC FUNCTION IN CAUDATE NUCLEUS DURING ETHANOL WITHDRAWAL. V.S. Belagode, I.L. Rivera, and C.M. Harris,* NYCOM, Old Westbury, NY 11568.

Rats (n=4) were given ethanol liquid diet for 1-5 weeks. After a final dose (4g/kg, po), microdialysis probes were inserted into the caudate n. Samples of perfusate collected during intoxication, withdrawal and reintoxication were analyzed by HPLC with electrochemical detection. Average dopamine, DOPAC and HVA concentrations declined to minimal values by 18-24 hours of withdrawal and increased 30% on reintoxication with ethanol (4g/kg, po). Withdrawal signs included trembling and muscle rigidity. Another group was given ethanol (10%, by gavage, n=7) for 4 days, or isocaloric sucrose (n=3 controls). Withdrawal scores in the ethanol group (24.9±0.7) were higher than controls (15.8±0.6). L-dopa (20 mg/kg, ip) did not affect these scores, but atropine (3mg/kg, ip) reduced withdrawal scores to the control range, relieved muscle rigidity and tremors and improved performance of a motor task. These data support the hypothesis that abnormal motor function during withdrawal is due to deficient dopaminergic function in basal ganglia which may be relieved by removing a tonic inhibitory cholinergic influence. Supported by DA06873 to CMH.

558.4

EFFECTS OF α-METHYL-D-TYROSINE AND RESERPINE ON DA LEVELS AND AMPHETAMINE-INDUCED BEHAVIORS OF EEDQ-TREATED RATS. C.A. Bolanos, M.A. Duke, S.A. McDougall*, and C.A. Crawford. Department of Psychology, California State University, San Bernardino, CA 92407 and Neuropsychiatric Institute, University of California, Los Angeles, CA 90024

EEDQ irreversibly binds to DA receptors and decreases striatal DA levels. In spite of these actions, EEDQ does not affect the apomorphine-induced behaviors of rat pups, but marginally depresses amphetamine-induced behaviors. To further assess these findings, EEDQ-pretreated rat pups were given the DA synthesis inhibitors α-methyl-D-tyrosine (AMPT) or reserpine prior to behavioral testing with amphetamine. More precisely, 16-day-old rat pups were injected with EEDQ (7.5 mg/kg) and then injected, one day later, with either reserpine (5 mg/kg), AMPT (200 mg/kg), or saline. Amphetamine (1.0 mg/kg) and saline-induced activity were then assessed across a 4-day span. An HPLC was used to measure DA levels after EEDQ, AMPT, and reserpine treatment. Results showed that amphetamine's activity enhancing effects were not blocked by EEDQ, but they were attenuated by AMPT and reserpine. EEDQ did not potentiate AMPT's or reserpine's behavioral actions. This was surprising, since EEDQ as well as AMPT and reserpine significantly reduced the DA levels of 17-day-old rats. In general, these results suggest that EEDQ's presynaptic actions are not of great behavioral significance for the preweanling rat.

MODULATION OF DOPAMINE RECEPTOR AGONIST INDUCED ROTATIONAL BEHAVIOUR BY PLG AND ITS NOVEL ANALOGUE PAOPA. D. Whan, R.K. Mishra* & R.L. Johnson. McMaster Univ., Hamilton, Ont. & Dept. of Medicinal Chemistry, Univ. of Minnesota, Minneapolis, Mn.

The interaction of L-prolyl-L-leucylglycinamide (PLG) and its novel synthetic analogue 3-(R)-[N-(L-prolyl)amino]-2-oxo-1-pyrrolidineacetamide (PAOPA) with central dopamine receptors *in vivo* was investigated in 6-hydroxydopamine lesioned rats. PLG maximally potentiated apomorphine-induced rotations at a dose of 1.0 mg/kg (intraperitoneal injection, i.p.) and 100.0 ng (intrastriatal injection, i.s.). PAOPA was 100 fold more potent than PLG, inducing maximal potentiation at dosages of 10.0 µg/kg (i.p.) and 1.0 ng (i.s.). Co-administered intrastriatal injections of PLG and PAOPA (100.0 ng and 1.0 ng respectively) enhanced the agonist induced rotations by 25%. Concurrent intraperitoneal injections of PLG and PAOPA (1.0 mg/kg and 10.0 µg/kg respectively) similarly increased the rotational response by 50%. PAOPA also potentiated both SK&F 38393 and quinpirole induced contralateral rotations. PAOPA maximally mediated its effects via D₂ dopamine receptors as PAOPA produced an 85% increase in quinpirole (D₂ agonist) induced rotations. In contrast, PAOPA yielded a modest 14% increase in SK&F 38393 (D₁ agonist) induced rotations. Haloperidol blocked these peptide potentiated apomorphine rotations and those induced by quinpirole regardless of the route of administration (i.p. or i.s.). SCH 23390 blocked the SK&F 38393 induced rotations potentiated by PAOPA. Thus PAOPA, with greater potency than PLG to modulate the effects of dopamine agonists, is of therapeutic importance in the treatment of Parkinson's disease and the dyskinetic syndromes. (Supported by NIH Grant NS 20036.)

DIZOCLIPINE (MK-801)-INDUCED BEHAVIOR IN RATS IS INHIBITED BY NEUROLEPTIC DRUGS AND POTENTIATED BY ACIVICIN. P. Andiné*, R. Axelsson and M. Sandberg. Departments of Clinical Neuroscience, Section of Psychiatry, Sahlgrenska University Hospital, and Anatomy and Cell Biology, Institute of Neurobiology, University of Göteborg, S-413 90 Göteborg, Sweden.

N-Methyl-D-aspartate (NMDA) receptor antagonists are psychotomimetics offering the most schizophrenia-like drug-induced syndrome in humans. The NMDA antagonist dizocilpine (MK-801) causes a typical behavior in rats which is used as an experimental model for psychosis. We used adult Sprague-Dawley rats and observed them from 15-75 min after intraperitoneal administration of MK-801 (0.05-1.0 mg/kg). They were scored for locomotion, stereotyped sniffing and ataxia every 5 min throughout the experiment. MK-801 caused increased locomotion and stereotyped sniffing in lower doses and also ataxia in higher doses. Female rats were much more susceptible to MK-801 than males. Neuroleptic drugs, administered in a single-dose 30 min before MK-801, offered a potent reduction of MK-801 behavior, with a total inhibition at doses (haloperidol 1.0 mg/kg, perphenazine 2.0 mg/kg, chlorpromazine 10 mg/kg, remoxipride 20 micromoles/kg) that correspond to their antipsychotic potency in patients. An enhancement of MK-801 behavior was found in male rats pretreated with acivicin (100 mg/kg), an inhibitor of the putative amino acid reuptake enzyme gamma-glutamyl transferase. In vitro, acivicin did not influence extracellular (ec) glutamate, however, it increased ec glutathione. Glutathione may cause NMDA receptor blockade via redox interaction and thereby an enhancement of MK-801 behavior. In conclusion, MK-801-induced behavior in rats is aggravated by gamma-glutamyl transferase inhibition and abolished by neuroleptics.

DIFFERENTIAL REGULATION AND BEHAVIORAL EFFECTS OF THE MODE OF STIMULATION OF DOPAMINE D₁ RECEPTORS IN MPTP-EXPOSED PARKINSONIAN PRIMATES. P.J. Blanchet*, R. Grondin, P.J. Bédard, K. Shiosakiti, D.R. Britton† and J.W. Keibabian‡. Centre de Recherche en Neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Canada; †Neuroscience Research (D-47U), Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, Illinois; and ‡Research Biochemicals International, Natick, Mass.

The contribution and optimal mode of stimulation of dopamine (DA) D₁ receptors in the treatment of Parkinson's disease (PD) remain poorly defined. In one experiment, the long-acting, selective D₁ agonist A-77636 ((1R,3S) 3-(1'-adamantyl)-1-aminomethyl-3,4-dihydro-5,6-dihydroxy-1H-2-benzopyran hydrochloride) (Keibabian et al., EJP 1992; 229: 203) was administered once daily for 1 week at doses extending from 0.5 to 10 mg/kg s.c. to 4 MPTP-exposed, parkinsonian cynomolgous monkeys with levodopa-induced dyskinesia (LID). Following the first dose (0.5 mg/kg), all monkeys quickly showed a definite antiparkinson response for at least 8-12 hrs with increased ambulation persisting overnight. Only mild dyskinesia and stereotypies were seen. A second dose the next day was not as effective, and the level of motor activity progressively declined in 3 animals but remained above baseline values during the last 5 days of treatment, in spite of the administration of higher doses. In another paradigm, the short-acting, full D₁ agonist SKF 82958 (6-chloro-7,8-dihydroxy-3-allyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrobromide) was administered to 3 drug-naïve, MPTP-exposed, parkinsonian cynomolgous monkeys at a dose of 1 mg/kg s.c. thrice daily for 4 weeks. Parkinson features were quickly relieved in all animals for 35-60 minutes following each dose. However, after several days of treatment and especially in the last 2 weeks of the protocol, the drug response significantly shortened (20-30 min) in all animals and choreiform dyskinesia developed in 2 while peak response was maintained. These data clearly show that selective D₁ receptor stimulation can effectively relieve parkinson features and lead to dyskinesia similar to LID in this primate model of PD. However, this DA receptor subtype seems exquisitely prone to downregulation. Prolonged D₁ receptor occupancy should be avoided. The mechanisms for such pharmacological behavior and ways to prevent it must be explored further. [Supported by FRSC and MRC (Canada)]

DIFFERENTIAL REINFORCEMENT OF IMMOBILITY IN AMPHETAMINE-TREATED RATS: IMPLICATIONS FOR UNDERSTANDING TOLERANCE. D. L. Wolgin* and J. V. Wade. Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL 33431

The purpose of this study was to determine whether amphetamine-treated rats can learn to suppress stereotyped head movements. Rats implanted with cannulas were reinforced with intraoral infusions of milk for holding their heads stationary within a narrow area defined by intersecting photobeams mounted in the horizontal and vertical planes. Concurrent interruption of these photobeams activated an infusion pump, which delivered milk at the rate of 2 cc/min for the duration of the interruption.

Four of six rats given chronic injections of amphetamine (2 mg/kg) learned to hold their heads within the intersecting photobeams. The amount of milk ingested as a result of these infusions increased over trials at a rate that was comparable to that of bottle-fed rats. Analysis of the temporal distribution of photobeam interruptions revealed a highly fragmented pattern that differed markedly from the sustained pattern found in saline controls. These results support the view that tolerance to amphetamine hypophagia involves an instrumentally learned behavioral adaptation.

THE EFFECTS OF DOPAMINERGIC AGONISTS ON DELAYED MATCHING-TO-SAMPLE (DMTS) PERFORMANCE UNDER THERMAL NEUTRAL AND COLD STRESS CONDITIONS.

D. Shurtleff*, J.R. Thomas, S.T. Ahlers, and J. Schrot. Naval Medical Research Institute, Bethesda, MD 20889-5607.

Dopaminergic drugs have been shown to be important in the modulation of working memory. This study examined the role of the D₂/D₃ agonist quinpirol (0.025-0.10 mg/kg) and the D₁ agonist SKF 38393 (1.0-4.0 mg/kg) on working memory in rats using a DMTS procedure. Each DMTS trial required rats to respond to one of two cued levers, which initiated a variable delay of 1-16 sec. Following the delay, rats were reinforced for correctly responding to the previously cued lever. Under thermal neutral conditions (22°C) following saline, rats' matching accuracy showed a characteristic decline as the delay interval increased. Consistent with previous research and relative to 22°C, matching at 2°C (cold) was reduced. Quinpirol at 22°C improved matching following .025 mg/kg but reduced matching accuracy at higher doses. Quinpirol did not prevent the cold-induced decline in matching. SKF 38393 did not reduce matching accuracy at 22°C and did not affect matching accuracy at 2°C. Drug and cold effect results include the analysis of changes in slope (retention) and y-intercept (stimulus encoding) of the matching accuracy gradient. These data suggest that D₂/D₃ receptors are more important in modulating working memory than the D₁ receptor, and these receptors may not be directly involved in cold-induced working memory deficits.

558.10

BEHAVIORAL AND BIOCHEMICAL STUDIES ON THE INTERACTION OF THE NMDA ANTAGONIST MK-801 AND THE D₂ ANTAGONIST HALOPERIDOL. H. Dai*, R.J. Carey. VA Medical Center, Research Service 151, Syracuse, NY 13210

Thirty two male rats were assigned to four groups and were given saline, MK-801 (0.3 mg/kg), haloperidol (0.5 mg/kg) and MK-801/haloperidol combined treatments. The behavioral data of locomotor activity showed that the NMDA antagonist MK-801 induced hyperactivity, haloperidol induced hypoactivity but that the activity of the combined MK-801/haloperidol group was identical to the saline animals in both total locomotion distance and the within session habituation pattern. On the other hand, the *Ex vivo* biochemical data revealed no significant effect by MK-801 on dopamine metabolism, nor did MK-801 modify haloperidol effects on dopamine metabolite turnover ratios. None of the drug treatments had an effect on brain serotonin metabolism. Haloperidol, however, significantly increased serum 5-HT level. No drug treatment affected plasma catecholamine or plasma corticosterone levels. Taken together all these results supports the hypothesis that the effect of MK-801 on behavior is independent of biochemical changes in dopaminergic transmission.

A HIGH DOSE OF THE SELECTIVE D₂ AGONIST QUINPIROLE IS POSTSYNAPTICALLY MEDIATED. R.A.V. Fox*, C.L. Zuch and D.A. Cory-Slechta. Dept. of Environmental Medicine, University of Rochester School of Medicine, Rochester, NY 14642.

Utilizing a drug discrimination paradigm, this laboratory demonstrated that the stimulus properties of a low dose (0.05 mg/kg) of the selective D₂ agonist quinpirole (QUIN) are mediated by D₂ presynaptic autoreceptors (Widzowski and Cory-Slechta, 1993, JPET, 266, 526-534). The current study examined the hypothesis that the stimulus properties of a high dose of QUIN (0.20 mg/kg) would be mediated by postsynaptic D₂ receptors, resulting in a pattern of responding to pharmacological treatments opposite to that noted in the previous study. The findings were consistent with that premise. D₁ receptor blockade with SCH23390 produced full substitution for 0.05 QUIN, but only saline responding in 0.20 QUIN-trained rats. Also, alpha-methyl-paratyrosine depletion of catecholamines produced drug lever responding (DLR) in the 0.05 QUIN group but not in the 0.20 QUIN group. Low doses of apomorphine (up to 0.167 mg/kg), produced 70% DLR in the 0.05 QUIN group, but only 25% in the 0.20 QUIN group. Higher doses of apomorphine, which substitute for D₁ agonists (Cory-Slechta, D.A., 1989, JPET, 250, 800-809), produced only 35-40% DLR in the 0.20 QUIN group. DLR was not produced in either group by the D₁ agonist SKF82958. Taken together, these data are consistent with a postsynaptic mediation of the stimulus properties of a high dose (0.20 mg/kg) of QUIN. Moreover, pretreatment with the D₁ antagonist SCH23390 decreased DLR in the 0.20 group to 43%, suggesting postsynaptic D₁-D₂ interactions.

ASSESSMENT OF THE BEHAVIORAL PROFILES OF CONVENTIONAL AND ATYPICAL ANTIPSYCHOTIC DRUGS IN RODENTS. J.G. Wettstein*, S. Roux and R.D. Porsolt. I.T.E.M.-LABO, 93 ave Fontainebleau, 94276 Le Kremlin-Bicêtre, France.

The effects of a reference neuroleptic, haloperidol, were compared with those of three atypical antipsychotic agents (clozapine, DuP 734 and risperidone) and a 5-HT₂ antagonist, ritanserin, in a number of procedures. Drugs were first examined in mice over a wide dose-range using a primary observation method in order to target the doses for other studies. Haloperidol (0.125-2 mg/kg) was distinctly active in all procedures and produced marked catalepsy. Risperidone was more potent than the other compounds in many of the procedures, often having activity at doses well below 1 mg/kg. Neither clozapine (1.0-16 mg/kg) nor DuP 734 (0.5-8 mg/kg) induced catalepsy in rats yet both drugs appeared to antagonize amphetamine-induced hyperactivity at doses less effective against amphetamine- or apomorphine-induced stereotypies in mice. Clozapine and DuP 734, along with ritanserin, also clearly blocked mescaline-induced scratching. Ritanserin (2-16 mg/kg), in general, did not have a behavioral profile like those of the other four drugs. All compounds also differed with respect to their actions as antagonists of PCP-induced stereotypies and SKF 10047-induced hyperactivity in rats. In view of the clinical findings currently available with these drugs, it appears highly useful to employ a series of methods in order to identify novel antipsychotics that differ from haloperidol. Absence of cataleptogenic activity and selective antagonism of amphetamine-induced hyperactivity would appear to be useful criteria.

The noncompetitive NMDA receptor antagonist (+)dizocilpine fails to prevent sensitization to apomorphine-induced rotational behavior in rats with nigrostriatal lesions. S. Ganther* and A. Mayer, Dept of Neurology, Oregon Health Sciences University, Portland, Oregon, 97201.

Sensitization to CNS stimulants is well described and is reportedly prevented by the noncompetitive NMDA receptor antagonist (+)dizocilpine (MK-801). We sought to determine if MK-801 pretreatment prevents sensitization to apomorphine (APO)-induced rotational behavior in rats with unilateral nigrostriatal lesions. Six rats were lesioned with 6-OHDA, and beginning 2 weeks later, received 8 daily doses of MK-801 (0.1 mg/kg, ip) followed 30 min later by APO (0.1 mg/kg, sc). Three and 5 days later, single doses of the D₁ agonist SKF38393 (2 mg/kg) & APO (0.1 mg/kg, day 5) were administered without MK-801 pretreatment. Despite MK-801 pretreatment, the rotational behavior increased over the protocol (for doses 1, 4, and 8, total and peak/5 min rotations were 104 and 24, 407 and 92, and 576 and 85, respectively, $p < .05$). The dose of SKF induced 1624 rotations. MK-801 enhanced APO rotations; in comparison with dose 8, APO alone induced 449 rotations ($p = 0.05$).

In a separate experiment, 3 rats received MK-801 + APO on postlesion day 14, and 3 days later, received 2 mg/kg SKF 38393; as reported by Morelli et al, SKF 38393 failed to induce rotational behavior. These data suggest that in contrast to sensitization in unlesioned animals, lesioned animals sensitize to APO despite NMDA channel blockade.

558.17

POTENTIATION OF THE DIHYDREXIDINE DISCRIMINATIVE STIMULUS BY PHOSPHODIESTERASE INHIBITION AND THE EFFECT OF RECEPTOR RESERVE ON D₁ AGONIST SUBSTITUTION. Q.D. Walker¹, D.M. Black¹, D.A. Eckerman¹, D.E. Nichols² and R.B. Mailman¹. Curriculum in Toxicol., Univ. of N. Carolina¹, Chapel Hill, NC 27599, and Dept. Med. Chem., Purdue Univ.², West Lafayette, IN 47907.

In rats, administration of the full D₁ agonist dihydrexidine (DHX, 2 mg/kg) induces robust discriminative stimulus (DS) effects that are mediated selectively by D₁ receptor stimulation. We investigated whether the DHX cue was also mediated by increased intracellular concentrations of cAMP. The phosphodiesterase inhibitor rolipram (0, 7.5, 15, or 30 µg/kg) was administered either alone or in combination with doses of DHX (0.25 or 0.5 mg/kg) or SKF38393 (1.0 or 2.0 mg/kg) that induce little drug appropriate responding. Rolipram (15 µg/kg) and DHX (0.25 mg/kg) induced 0 and 7% DHX lever responding, respectively, when administered alone, but 50% when coadministered. Rolipram also synergistically increased SKF38393 substitution. Coadministration of rolipram (30 µg/kg) and SKF38393 (2.0 mg/kg) induced 63% drug lever selection, although the compounds induced only 15 and 20% drug lever selection, respectively, when administered alone. The second series of experiments tested the hypothesis that D₁ receptor reserve explains the complete substitution of the partial agonist SKF38393 for the DHX cue. EEDQ (10 mg/kg) was administered with a receptor protectant cocktail (prazosin, ketanserin, remoxipride) to decrease D₁ receptor number by about 50%. Forty-eight hr after EEDQ, rats were administered doses of either DHX (2 mg/kg) or SKF38393 (8 mg/kg) that substituted > 90% prior to EEDQ treatment. Administration of EEDQ significantly decreased the substitution of SKF38393 (93% vs. 26%) but did not affect substitution of DHX (98% vs. 74%). These results suggest that D₁ receptors coupled to adenylate cyclase mediate the DS effects of DHX and that SKF38393 substitutes for DHX by occupying a greater proportion of the receptor population than does DHX.

Effect of NO synthase inhibition on behavioral changes induced by a single administration of methamphetamine
Tomohiro Abekawa*, Tetsuro Ohmori and Tsukasa Koyama
Department of Psychiatry and Neurology, Hokkaido University School of Medicine, Sapporo, Japan

The present study examined the effects of nitric oxide synthesis inhibition on behavioral changes induced by a single administration of methamphetamine (MA). Rats received one subcutaneous injection of MA (3.22 mg free base/kg). Nitric oxide synthase inhibitor, N^ω-nitro-L-arginine methyl ester, LNAME (10, 30 and 60 mg/kg) were administered intraperitoneally 1 hr prior to injection of MA or saline. MA increased locomotion-stereotypy rating scores and motor activity counts measured by an infrared sensor. LNAME (30 and 60 mg/kg) administered 1 hr prior to MA significantly decreased the level of locomotion stereotypy rating and motor activity induced by MA. The results suggest that NO synthesis is involved in the full expression of behavioral effects of MA.

QUINOLINIC ACID-INDUCED LESION OF THE SUBSTANTIA NIGRA PARS RETICULATA: BEHAVIOURAL AND NEUROCHEMICAL EFFECTS. B. Zadow*, M. Bubser and W.J. Schmidt, Department of Neuropharmacology, University of Tübingen, D-72074 Tübingen, Germany.

As one of the major output structures of the basal ganglia (BG) the substantia nigra pars reticulata (SNr) is part of the motor loop through the BG and thus is involved in the performance of motor behaviour. The SNr receives information from the striatum and sends inhibitory GABAergic projections to the thalamus and the deeper layers of the superior colliculus. The present study investigated the role of the SNr in mediating motor behaviour in male Sprague Dawley rats. The SNr was bilaterally lesioned with the excitotoxin quinolinic acid (2 x 30 nmol/0.5 µl/side). Locomotor activity and exploration were tested in an open field with holeboard and sniffing stereotypy was tested in an experimental chamber (Schmidt, W.J., 1986, Psychopharmacology 90: 123-130). Both locomotor- and sniffing activity were increased after SNr lesions, whereas exploration was not changed. The histological verification of the SNr lesions demonstrated that in most cases a part of the substantia nigra pars compacta was also lesioned. The levels of dopamine (DA) and its metabolites (DOPAC, HVA) in the anterior and posterior striatum and in the nucleus accumbens were analysed post mortem with HPLC with electrochemical detection. DA and DOPAC were reduced in all three structures, whereas HVA was only reduced in the anterior striatum. The metabolism of dopamine (measured as DOPAC/DA and HVA/DA) was increased in the anterior and posterior striatum. These increases correlated significantly with the increases in locomotor- and sniffing activity. In conclusion, bilateral lesions of the SNr and thus reduced activity of this structure results in an increase of motor activity. This increase may be explained by the deficient inhibitory effects of the SNr on the thalamus and the superior colliculus, but also by the increased dopamine metabolism in the striatum. Supported by BMFT 01KL9008/0 and SFB 307/A4.

ROLE OF NMDA AND NON-NMDA RECEPTORS IN SPINAL TRANSMISSION OF THE EXERCISE PRESSOR REFLEX. C.M. Adreani, J.M. Hill, and M.P. Kaufman, C.L. Stebbins*. Cardiovasc. Med., Univ. of Calif., Davis, CA 95616.

Much evidence suggests that glutamate plays a role in the spinal transmission of the reflex autonomic responses to static contraction. Previously we measured the reflex increase in arterial pressure evoked by static contraction of the hindlimb muscles in chloralose-anesthetized cats before and after glutamatergic receptor blockade in the lumbosacral cord. The reflex pressor response to contraction was unaffected by NMDA receptor blockade (AP-5), but was significantly attenuated by non-NMDA receptor blockade (CNQX). Recently, NMDA antagonists have been shown to block the responses of dorsal horn cells to noxious input in decerebrate, but not in chloralose-anesthetized cats (Radhakrishnan and Henry, 1993). This finding raises the possibility that the absence of an effect mediated by NMDA receptors on the pressor response to static contraction could have been due to chloralose. We, therefore, investigated the effect of glutamatergic receptor blockade on the reflex ventilatory and cardiovascular responses to contraction in decerebrate unanesthetized cats. We found that intrathecal injection of 500 µg AP-5, onto the lumbosacral cord attenuated the reflex increase in heart rate due to static contraction ($\Delta 36 \pm 4$ to $\Delta 21 \pm 4$ bpm; $p < 0.05$), but had no effect on the pressor and ventilatory responses to contraction ($n=10$). Subsequent intrathecal injection of 90 µg CNQX attenuated ($p < 0.05$) the pressor ($\Delta 40 \pm 6$ to $\Delta 14 \pm 6$ mmHg), heart rate ($\Delta 36 \pm 4$ to $\Delta 13 \pm 3$ bpm), and ventilatory ($\Delta 359 \pm 116$ to $\Delta 105 \pm 44$ ml/min) responses to contraction. Our results suggest that non-NMDA receptors are involved in the pressor and ventilatory responses to static contraction, and that both NMDA and non-NMDA receptors are involved in the chronotropic response.

SYSTEMIC 2-DEOXY-D-GLUCOSE LEADS TO EXCITATION OF ADRENAL MEDULLARY SYMPATHETIC PREGANGLIONIC NEURONS. S.F. Morrison*. Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Adrenal medullary release of epinephrine and the subsequent stimulation of glycogenolysis and gluconeogenesis are important components of the physiological response to hypoglycemia. To determine the central pathways controlling catecholamine secretion by the adrenal medulla, the responses of adrenal medullary sympathetic preganglionic neurons (AdSPNs) to 2-deoxy-D-glucose (2-DG) administration (200mg/kg, iv.) were studied in urethane/chloralose-anesthetized, artificially-ventilated rats. AdSPNs were identified by their antidromic responses to adrenal nerve stimulation and their unique orthodromic responses to stimulation in the rostral ventrolateral medulla (RVLM). Ten minutes after 2-DG injection, the basal discharge rate of AdSPNs had increased ($p < 0.001$) from 5.8 Hz (control) to 9.2 Hz. Subsequent bilateral microinjection of muscimol (25 nmol) into the RVLM eliminated the 2-DG-induced increase in AdSPN discharge, although a low level of AdSPN discharge remained. The increase in AdSPN discharge following 2-DG was not different in animals with transections of the neuraxis rostral to the superior colliculus. These results suggest that activation of AdSPNs is a brainstem-mediated component of the neural response to the blockade of glucose utilization by 2-DG and that RVLM neurons may be necessary for this response. Supported by NIH HL47196.

SPINAL NITRIC OXIDE IS INVOLVED IN THE VASOPRESSOR ACTION. S.Y. Kim, H.C. Koh, K.W. Sung and S.B. Lee*. Dept. Pharmacology, Catholic University Medical College, 505 Banpo-dong, Socho-gu 137-701 and Dept. Pharmacology, Hanyang University Medical College, Seoul, KOREA.

Anatomic studies have localized nitric oxide (NO) synthase activity in the spinal cord intermediolateral column. The present study was designed to investigate a possible role of the spinal NO in the central regulation of blood pressure (BP). Experiments were carried out in urethane-anesthetized, d-tubocurarine-paralyzed and artificially ventilated male Wistar rats. Intrathecal (i.t.) administration of drugs were made using the injector cannula (33 G stainless steel) through the guide cannula (PE 10) which was inserted intrathecally at the thoracic level through a puncture of the atlantooccipital membrane. I.t. injection of a NO donor, sodium nitroprusside (SNP; 1, 5 and 15 nmol) produced dose-dependent increases in BP. The vasopressor effect of SNP (15 nmol, i.t.) was completely blocked by pretreatment with the N-methyl-D-aspartic acid (NMDA) receptor antagonist, D,L-2-amino-5-phosphonopentanoic acid (10 nmol, i.t.). The pretreatment with the non-NMDA receptor antagonist kynurenic acid (250 nmol, i.t.) also attenuated the vasopressor effect of SNP (15 nmol, i.t.). In addition, i.t. injection of an inhibitor of NO synthase, N^G-nitro-L-arginine methyl ester (20, 100 and 1000 nmol) evoked dose-dependent decreases in BP. These results suggest that NO generated in spinal cord plays a role in the facilitatory regulation of BP. This vasopressor action of the spinal NO seems to be tonically active and to be mediated via its interaction with the glutamatergic system in the spinal cord.

SPINAL RELEASE OF SUBSTANCE P DURING MUSCLE CONTRACTION: EFFECT OF 5-HT_{1A} RECEPTOR ACTIVATION. A.C.L. Nobrega, A.F. McIntyre, A. Ally, L.B. Wilson*. Harry S. Moss Heart Center, University of Texas Southwestern Medical Center, Dallas, TX 75235-9034

Static muscle contraction increases mean arterial pressure (MAP) and substance P (SP) release in the dorsal horn of the spinal cord. Activation of 5-HT_{1A} receptors in this region attenuates the reflex pressor response to contraction. This study evaluated the effect of microdialysis of 8-hydroxy-2-(di-n-propylamino)tetralin (DPAT; 5-HT_{1A} agonist) into the L₇ dorsal horn on the release of SP during contraction using anesthetized cats. Ipsilateral to the muscle to be contracted, all ventral and dorsal roots from L₅ to S₂ were severed, except the L₇ dorsal root. Static contraction of the triceps surae muscle was induced by alternate electrical stimulation of the distal ends of L₇ and S₁ ventral roots for 5 min (3X motor threshold; 30 Hz; 0.1-0.3 ms). The dialysates from two probes, placed in the L₇ dorsal horn region ipsilateral to the contracting muscle, were analyzed for SP-like immunoreactivity (SP-LI) using a radioimmunoassay. DPAT (10 mM; $n=8$) attenuated the MAP response to contraction (control = 38 ± 11 ; DPAT = 10 ± 3 mmHg; $P < 0.05$). Likewise, the heart rate response was also blunted (control = 13 ± 3 ; DPAT = 7 ± 3 bpm; $P < 0.05$). However, the SP-LI values during contraction were unaffected by DPAT (control = 0.492 ± 0.026 ; DPAT = 0.501 ± 0.034 fmol/100 µL; $P > 0.05$). These results suggest that the modulation of the pressor response to contraction by 5-HT_{1A} receptors in the dorsal horn is not mediated through inhibition of SP release.

SPINAL NMDA RECEPTOR MEDIATES c-fos EXPRESSION FOLLOWING HYPOTENSION IN THE CONSCIOUS RAT. Huang, W. and West, M.J.* Department of Medicine, University of Queensland, Prince Charles Hospital, Brisbane, QLD 4032, Australia.

Recent studies show that baroreflex induced vasoconstrictor responses following hypotension are attenuated by the administration of NMDA receptor antagonist AP5. We have examined the effect of intrathecal AP5 on spinal cord c-fos expression induced by hypotension in conscious rats. AP5 or saline were administered intrathecally prior to a 90 minute infusion of sodium nitroprusside which lowered blood pressure by 30 mmHg. Animals were subsequently killed under general anaesthesia and the medulla and spinal cord processed for demonstration of c-fos protein using immunocytochemistry. C-fos neuronal immunoreactivity (Fos-IR) was observed in the rostral and caudal ventrolateral medulla and nucleus tractus solitarius and in the intermediolateral cell column (IML) of the spinal cord with the highest segmental concentration in segments T7-T10. At the level of the intrathecal administration of AP5, T9, there was a significant reduction in Fos-IR cells in the IML in animals given AP5 compared to those given saline (125 ± 6.9 /segment ($n=3$) vs 235 ± 6.5 ($n=2$), $p < 0.05$). There were no differences between treated and control animals in the medulla or other segments of the spinal cord. The results show that (i) following hypotension, cells in IML of segments T7-T10 show maximal expression of Fos-IR and (ii) AP5 inhibits c-fos expression. We conclude that spinal NMDA receptors in IML of spinal cord are involved in central baroreflex control of the circulation.

SECOND MESSENGER MODULATION OF MEMBRANE POTENTIAL OSCILLATIONS IN SYMPATHETIC PREGANGLIONIC NEURONS. D. Spanswick, M.L.H.J. Hermes and L.P. Renaud*. Neuroscience Unit, Loeb Research Institute, Ottawa Civic Hospital, Ottawa, Canada K1Y 4E9.

The presence of spontaneous oscillations in sympathetic preganglionic neurons (SPNs) endows these neurons with the ability for rhythmogenesis, which can be manifested as burst firing, tonic single spike discharge or combinations of these. This activity is thought to reflect electrotonic coupling between SPNs, the oscillation representing an action potential discharged in a neighbouring neuron. Furthermore, these oscillations and rhythmic activity are subject to modulation by neurotransmitters such as serotonin and noradrenaline (Logan et al., '93). We have utilized whole-cell recording techniques in a spinal cord slice preparation to further investigate factors involved in the regulation of rhythmogenesis in SPNs, in particular the effects of elevating intracellular calcium and cAMP.

Superfusion of the membrane permeable analog of cAMP, 8-Bromo-cAMP (5-25 µM), completely blocked spontaneous oscillations in SPNs. 8-Bromo-cAMP also inhibited oscillations or short latency depolarizations (SLD) evoked by stimulation of the ventral roots. These effects of 8-Bromo-cAMP could be reversed by superfusion of the glutamate metabotropic receptor agonist ACPD (100 µM). The spontaneous oscillations were relatively unaffected by ryanodine (10 µM). Superfusion of caffeine (10-20 µM) induced oscillations and rhythmic activity in previously silent SPNs. Stimulation of the ventral roots in these neurons evoked a SLD which was enhanced in the presence of caffeine.

These data suggest that rhythmogenesis in SPNs is subject to regulation being induced by intracellular calcium release and inhibited by stimulation of cAMP production (Supported by The Heart and Stroke Foundation of Canada).

MEDULLARY STIMULATION CAN EVOKE IPSPs IN SYMPATHETIC PREGANGLIONIC NEURONES IN THE BRAINSTEM-SPINAL CORD PREPARATION. Susan A. Deuchars*, S.F. Morrison, K.M. Spyer and M.P. Gilbey. Royal Free Hospital School of Medicine, Rowland Hill Street, London. NW3 2PF U.K.

In the neonatal rat brainstem-spinal cord preparation using whole cell patch recordings, we have shown that stimulation of the rostral ventrolateral medulla can elicit multiphasic EPSPs in sympathetic preganglionic neurones (SPNs) mediated by both non-NMDA and NMDA receptors (Marks and Morrison, *J. Physiol.* 473, 155P, 1993). Here we report that medullary stimulation can also evoke IPSPs in SPNs. SPNs were identified on the basis of their antidromic activation following stimulation of the ventral root and their morphology and location within the spinal cord. Stimulation of the ventrolateral medulla (twin, 1ms pulses; 6 ms apart; 50-100 μ A) elicited IPSPs in ten SPNs at holding potentials more positive than -50 mV. The mean latency to onset of these responses was 34.4 ± 4.1 ms (mean \pm S.E.M.) while the average amplitude at membrane potentials of -40 mV was 5.77 ± 1.0 mV. These IPSPs persisted in the presence of the excitatory amino acid receptor antagonists 6-cyano-7-nitroquinoxaline-2,3-dione and D,L-2-amino-5-phosphonopentanoic acid in all but the SPNs tested. Indeed, sometimes blockade of the EPSP was necessary to reveal an IPSP. In the presence of these antagonists, hyperpolarising the neurones decreased the amplitude of the IPSPs until reversal occurred at membrane potentials more negative than -60 mV. On two occasions bath applications of 5 μ M bicuculline blocked the evoked IPSP. These results indicate that medullary stimulation can evoke IPSPs in SPNs which involve activation of GABA receptors.

ADULT AND NEONATAL SYMPATHECTOMY WITH ANTI-DBH IMMUNOTOXIN. M.J. Picklo*, J.D. Amlicke, R.G. Wiley, D.A. Lappi, D.M. Roden, D. Robertson. Depts. of Pharmacology, Medicine, and Neurology, Vanderbilt University and DVAMC, Nashville, TN 37232 and Whittier Institute, La Jolla, CA 92037.

The anti-dopamine beta-hydroxylase immunotoxin (DHIT) is a recently developed noradrenergic lesioning tool. In the following study, we examined the degree of sympathetomy achieved in adult and neonatal rats given DHIT peripherally. 30 μ g of DHIT was injected i.v. into anesthetized, adult, male Sprague-Dawley rats. Three weeks later animals were anesthetized and cannulas placed into the femoral artery and vein for blood pressure and heart rate recording and drug administration. Plasma was drawn before and after tyramine (300 μ g/kg) administration to examine basal and tyramine evoked norepinephrine levels. DHIT treated animals had significantly less basal (33%) and tyramine stimulated (20%) plasma norepinephrine levels than controls. Plasma epinephrine was unchanged. Basal blood pressure and heart rate were not significantly changed. One day old neonatal rats were injected subcutaneously with 4 μ g of DHIT and sacrificed at 1, 3, 6, and 13 days afterward. Nissl staining of superior cervical ganglia from day three animals showed an almost complete lack of large neuronal cell bodies. Cardiac ventricles and adrenal glands were assayed for catecholamine content. Ventricular norepinephrine levels fell to 60% of controls at day one and dropped to 2% of controls by day 13. Adrenal norepinephrine levels fell to 70% at day one and to 2% by day 13. Adrenal epinephrine levels were 70% of control at day one and fell to 5% by day 13. DHIT is potent in creating adult and neonatal sympathetomy. Sequential doses of DHIT may be necessary to lesion remaining neurons and adrenal chromaffin cells in adults. The ability of a single dose of DHIT to deplete adrenal catecholamines in neonates is an advantage over previous sympathetomy methods.

559.11

MEMBRANE PROPERTIES OF SYMPATHETIC GANGLION CELLS IN GENETICALLY HYPERTENSIVE OR HYPERACTIVE RATS. A.P. Gokin*^{1,2} and C.J. Forehand*. ¹Bogomoletz Inst. of Physiol., Kiev, Ukraine, 252024 ²Dept. of Anat. and Neurobiol., Univ. of Vermont, Burlington, VT, 05405.

Increased sympathetic nerve activity in the spontaneously hypertensive rat (SHR) may be partially due to alteration of the membrane properties of postganglionic neurons. Since the SHR also exhibits significant behavioral hyperactivity to stress, the relationship of neuronal alterations in SHR to the hypertensive phenotype is uncertain. To determine whether the decreased accommodation observed in SHR ganglion cells (Yarowski and Weinrich, *Hyperten.* 7:268, '85) is associated with hypertension, we examined active and passive membrane properties of cells in four inbred rat strains (WKY, SHR, WKHT and WKHA). The SHR is both hypertensive and hyperactive; WKY is neither. The WKHA is hyperactive, but not hypertensive; the WKHT is hypertensive, but not hyperactive.

Membrane properties were examined in 55 SHR, 44 WKY, 42 WKHT, and 40 WKHA superior cervical ganglion cells. No significant differences were observed in resting membrane potential, input resistance, the after hyperpolarization, or threshold for action potential generation among the four strains. In contrast, the number of action potentials generated during a 1 nA, 400 msec depolarizing pulse was significantly greater in both hypertensive strains (4.3 ± 0.69 , SHR; 6.0 ± 0.89 , WKHT) relative to the WKY (2.9 ± 0.56); the WKHA ganglion cells generated an intermediate number of action potentials (3.6 ± 0.63). The decreased ganglion cell accommodation in the hypertensive strains reflects an overall difference in the number of neurons in each population that exhibited a non-phasic response (≥ 4 action potentials) to the 400 msec stimulus: 21% in the WKY, 26% in the WKHA, 33% in the SHR and 48% in the WKHT.

CARDIAC AND RESPIRATORY MODULATION OF NEONATAL POSTGANGLIONIC SYMPATHETIC ACTIVITY. B.W. Hundley, P.M. Gootman, A.L. Sica*. Dept. of Physiology, SUNY-Hlth. Sci. Ctr., Bklyn, NY 11203.

The major aim of the present investigation was to determine whether sympathetic components of peroneal nerves (PN) were modulated by cardiac- and/or respiratory-related rhythms in an age-related manner and whether such relationships were influenced by vagal afferent and/or chemoreceptor inputs. In Saffan-anesthetized, paralyzed and artificially ventilated (100% O₂) piglets aged 1-40 days, different branches of PN were recorded along with C5 phrenic (PHR) root activity, AoP, EKG, and EEG. Age-related differences were observed for both types of modulation which were independent of vagal afferent inputs. Piglets < 1 wk old exhibited very little spontaneous PN activity related to either cardiac or respiratory rhythms. However, respiration-related activity in PN discharges of 1 wk old swine was easily elicited by ventilation with a hypoxic gas mixture (10% O₂, balance N₂). Spontaneous PN activity of piglets > 2 wks of age exhibited respiratory-related discharge, which were facilitated by hypoxia. Modulation by cardiac rhythm was revealed by coherence spectral analyses as indicated by significant coherence estimates over the 3-5 Hz range; such coupling was stronger in older piglets. Hypoxia significantly increased coherence regardless of age. The results indicate that cardiac and respiratory modulation of postganglionic sympathetic activity is delayed postnatally compared to preganglionic recordings. (Gootman et al. *Am. J. Physiol.* 1991, 261:R1147). (Supported by NIH grant HD-28931).

INSPIRATORY COMPONENT OF SPLANCHNIC SYMPATHETIC NERVE ACTIVITY IS RESISTANT TO THE SYMPATHOLYTIC DRUG CLONIDINE. N. Koshiya* and P.G. Guyenet. Department of Pharmacology, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Splanchnic sympathetic nerve (SND) and phrenic nerve discharges (PND), and arterial pressure (AP) were recorded in urethane-anesthetized, vagotomized, aortic deafferented, paralyzed and artificially ventilated Sprague-Dawley rats (n=7). SND and PND were rectified, analog integrated at 30 ms reset-interval and digitized. Distribution of the SND in the central respiratory cycle was analyzed by means of PND burst-triggered averaging. During control period, mean AP was 106 ± 10 mmHg (mean \pm SEM); SND distributed throughout the respiratory cycle with increased activity in inspiratory/early-inspiratory phase and peak activity in the post-inspiratory phase.

Clonidine was given i.v. at small (15-30 μ g/kg, n=6) and/or large doses (200-250 μ g/kg, n=7). Small dose of clonidine produced brief hypertension (<30 sec, 150 ± 9 mmHg peak) followed by moderate hypotension (89 ± 3 mmHg) which was accompanied by a reduction in SND ($-63 \pm 11\%$ control value). Large dose of clonidine produced sustained hypertension (>10 min, 173 ± 3 mmHg) accompanied by silence of SND. During the sustained hypertension, the vasodilator sodium nitroprusside was administered i.v. (80-150 μ g/kg). The nitroprusside-induced hypotension retrieved a component of SND which was barosensitive but resistant to clonidine. During those hypotensive periods (both after small dose of clonidine and during nitroprusside-induced hypotension after large dose of clonidine), SND was largely attenuated in expiratory phase and, in most cases (6 out of 7), SND showed single inspiratory peak with very small activities in the post-inspiratory/expiratory period. In 2 cases, despite the substantial decrease in total SND, the amplitude of the remaining inspiratory peak was virtually unchanged from the control level.

These results suggest that the sympatholytic drug clonidine works on the sympatho-respiratory coupling differentially throughout the respiratory cycle, and the central inspiration-related component of SND is the least sensitive to the drug.

THE LOCATION AND MORPHOLOGY OF CARDIAC GANGLIA NEURONS IN THE HUMAN HEART. S. Singh*, M. A. Mostafa, R. D. Wurster. Neuroscience Program, Department of Physiology, Loyola University of Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

The parasympathetic innervation of the human heart consists of preganglionic neurons located in the brain stem that project via the vagus nerve to postganglionic neurons located in the cardiac ganglia. Previous studies on the location and morphology of neurons in the cardiac ganglia have been limited to animal models, to discrete regions of the heart, or to early developmental stages. Therefore, the purpose of this study was to determine the location and morphology of the cardiac ganglia neurons throughout the human heart and at several stages of development. We have mapped the location of the cardiac ganglia neurons using standard histological procedures. Our results indicate that the cardiac ganglia are clustered in two prominent epicardial fat pads in the atria of the heart; one in the right atrium below the pulmonary veins and the other near the junction of the inter-atrial sulcus and atrio-ventricular groove. Smaller clusters of ganglia are interspersed throughout other areas of the atria, including the regions above the coronary sulcus and below the left pulmonary veins.

Image analysis techniques have been used to determine if the morphology of the cardiac ganglia neurons is related to heart size changes as occur during development. Morphometric variables for the nucleolus, nucleus, soma of the neuron, as well as the cardiac ganglia were used to evaluate this possibility. Results indicate that the size of the neuronal soma and cardiac ganglia increases concomitantly with increases in heart size. The ratio of the cytoplasm to the nucleus also increases with heart size. The changes in the size of the neuron and ganglia may reflect changes in the innervation of the developing heart muscle.

SUBSTANCE P AND CGRP DEPOLARIZE PARASYMPATHETIC POSTGANGLIONIC NEURONS IN THE GUINEA PIG CARDIAC GANGLION. J. C. Hardwick*, G. M. Mawe, and R. L. Parsons. Department of Anatomy & Neurobiology, University of Vermont, Burlington VT 05405.

Increasing evidence suggests that parasympathetic ganglia are sites of complex synaptic integration rather than simple relay stations. The present study was done to establish whether afferent input to parasympathetic neurons of mammalian cardiac ganglia may provide another mode of synaptic modulation. Whole mount preparations from the guinea pig heart were utilized to localize afferent inputs by immunohistochemistry and to record voltage responses of individual neurons *in situ*. Immunohistochemical analysis demonstrated that most parasympathetic neurons were surrounded by fibers immunoreactive for both substance P (SP) and CGRP. Intracellular recordings were obtained from individual parasympathetic neurons maintained in an oxygenated Krebs's solution at 37°C. Action potentials could be elicited both by intracellular current injection and stimulation of interganglionic fiber bundles. In some cells, high frequency (5-10 Hz) interganglionic fiber stimulation produced a slowly developing depolarization of 4-10 mV which lasted for 5-30 sec. These depolarizing events were unchanged in the presence of 100 μ M hexamethonium and 1 μ M atropine but were significantly diminished by superfusion with calcium-free solution. A prolonged depolarization was also produced by local application of capsaicin (1 mM), which releases both SP and CGRP from afferent terminals. Direct application of either SP or CGRP (100 μ M) by pressure ejection depolarized these neurons. This peptide-induced depolarization was often associated with a decrease in input resistance and an increase in excitability. We suggest that the slowly developing depolarization produced by interganglionic fiber stimulation is due to the release of SP and/or CGRP from afferent terminals. Further, we suggest that afferent input to the cardiac ganglia may be involved in local reflex modulation of the parasympathetic cardiac neurons. GUANETHIDINE EVOKES VASODILATATION IN MESENTERIC ARTERY BY ACTING ON SENSORY NERVES. Z.L. Zheng, K. Shimamura, T.L. Anthony and D.L. Kreulen*. Department of Physiology, West Virginia University, Morgantown, WV, 26506.

Capsaicin-sensitive sensory nerves mediate an endothelium-independent, NANC vasodilatation in guinea-pig mesenteric arteries. This vasodilatation is potentiated by previous administration of guanethidine (30 μ M) presumably through depletion of vasoconstrictor neurotransmitters from sympathetic nerves. Our current hypothesis is that guanethidine also releases transmitter(s) from capsaicin-sensitive sensory nerves and thereby invokes vasodilatation. To test this hypothesis, segments of endothelium-denuded mesenteric arteries (5-8 mm long, 200 μ m wide) were suspended in tissue baths (50ml) containing normal Krebs solution and stretched to L_0 . Each vessel was precontracted with methoxamine (30 μ M). Administration of sodium nitroprusside evoked a 100% relaxation of these vessels. Administration of guanethidine (30 μ M) evoked a 73 \pm 5% relaxation of the precontracted vessels. Pretreatment with capsaicin (10 μ M) reduced the guanethidine-induced vasodilations to 13 \pm 7%. Similarly, 100 μ M nitric oxide synthase inhibitor N(1)-Nitro-L-Arginine (NOLA) reduced the guanethidine-induced vasodilations to 22 \pm 7%. The NOLA-mediated effects could be almost completely reversed with hydroxyguanine (HOG, 10 μ M), an intermediate of nitric oxide, but not L-arginine (1 mM). To determine whether this effect of guanethidine on sensory nerves was dependent on transport, the vessels were pretreated with cocaine (5 μ M) for 5 min or ouabain (25 μ M) for 15 min. Cocaine decreased the guanethidine-induced vasodilations to 35 \pm 14%. Likewise, ouabain diminished the guanethidine-induced vasodilatation to 9 \pm 5%. The guanethidine vasodilatation were not affected by propranolol (100 μ M), 6-hydroxydopamine (6-OHDA, 30 μ M) or tetrodotoxin (TTX, 10 μ M). Support: NIH-HL27781.

REGULATION OF AUTONOMIC FUNCTIONS: CARDIOVASCULAR

560.1

POSSIBLE ROLE OF THE FUNDUS STRIATI VP RECEPTORS IN BLOOD PRESSURE (BP) CONTROL. P. Krémárik, K. Cooper* and Q.J. Pittman. Neuroscience Research Group, University of Calgary, Calgary, Alberta, T2N 4N1, CANADA.

Vasopressin, given intracerebrally to rats, can induce motor disturbances, increases in BP and antipyresis. The possibility the highly concentrated vasopressin (VP)-binding sites in the fundus striati (FStr) could participate in these effects was investigated using chronically implanted cannulas into this area. A uni or bilateral injection in the FStr of 100pmol/1 μ l VP did not induce motor disturbances (scored visually) after the first and even the second injection, 24 hours later. The body temperature recorded simultaneously (i.p. minimeter) was not altered by the VP injections. After a bilateral injection of 100pmol/0.25 μ l VP in the FStr, the fever induced by an i.p. injection of the lipopolysaccharide of *E. Coli* (50 μ g/kg) or by interleukin 1 β (0.1 μ g/kg) was not affected. In contrast, a bilateral injection of 100pmol/0.25 μ l VP into urethane anesthetized rats, induced an increase in BP (19.1 \pm 2.24 mmHg, $p < 0.001$) compared with saline controls while the heart rate was not modified ($p > 0.4$). This increase in BP was blocked by a V1 antagonist; OT and a V2 agonist were ineffective.

This study suggests then that the VP receptors in the FStr could intervene in the regulation of the BP together with other regions known to be implicated in such a role.

PHYSIOLOGICAL STUDIES OF MYENTERIC NEURONS FROM HYPERTENSIVE RATS SUGGEST A COMMON PROGENITOR TO SYMPATHO-ADRENAL DERIVED AND SOME ENTERIC NEURONS. B. Jubelin, D.E. Richardson* and M. D. Gershon. Dept of Anatomy & Cell Biology, P&S, Columbia Univ., NY, NY., 10032, *Dept of Neurosurgery, Tulane Medical Center, New-Orleans, La, 70112.

Our previous studies showed that: 1) sympathetic neurons from genetically hypertensive (SH) rats, unlike their controls (WKY, SD), do not accommodate long-term depolarizing pulses and thus fire repetitively; 2) A sub-population of myenteric neurons shows co-expression of dopamine β -hydroxylase (DBH) and calbindin, suggesting that enteric and sympathetic neurons may be derived from common precursors. We thus decided to examine the electrical membrane properties of enteric neurons in the SH rats, to see if the lack of accommodative properties was also characteristic of myenteric neurons. Enteric neurons from the myenteric plexus are characterized as S or AH neurons. Besides morphological differences, these neurons are separated on the basis of their electrical membrane properties. AH neurons usually fire one or two action potentials (AP), show a typical Ca^{++} shoulder during repolarization and a characteristic after-hyperpolarization (AHP) following the AP. S neurons fire repetitively and do not show a Ca^{++} shoulder or an AHP. Most myenteric neurons in the SH rats show identical electrical membrane properties to their controls, but a subpopulation (approx 40%) of AH neurons show repetitive firing upon long-duration depolarizing pulses. They still show the Ca^{++} shoulder and the AHP, which is of longer duration since multiple AP allow more Ca^{++} to enter. These neurons were identified during the experiment and labeled for calbindin and DBH: there is no specific label for the repetitively firing sub-population of AH neurons.

In conclusion, similar abnormal electrical behaviors in sympathetic and enteric neurons support the concept of a common progenitor, but the absence of a common cellular markers leaves open the possibility that this fact reflects a default common to all neurons of the SH rats, irrespective of their lineage. Supported by NIH grants NS 12969 and NS 15547 and by awards from the PMAF and the CHF.

560.2

AUTONOMIC STRUCTURES IN RAT BRAIN SHOW INCREASED NUMBERS OF C-FOS POSITIVE CELLS DURING CLONIDINE WITHDRAWAL. R.L. Stornetta*, M. Fisher and P.G. Guyenet. Dept. of Pharmacology, University of Virginia, Health Sciences Center, Charlottesville, VA 22908.

Animals and humans become dependent on clonidine (clo) following chronic administration of this α_2 -adrenergic receptor (AR) agonist as revealed by either spontaneous or antagonist induced behavioral and autonomic withdrawal symptoms. The present study sought to determine whether specific autonomic areas of brainstem might be involved in clo withdrawal using the presence of c-fos nuclear protein as an indication of cell activation.

17 male Sprague Dawley rats were briefly anesthetized with ether and implanted subcutaneously in the back of the neck with Alzet osmotic minipumps containing either saline(sal) or clo (300 μ g/kg/day). Animals were returned to their home cages and after 7-10 days were injected i.p. with either saline or the α_2 -AR antagonist atipamezole (at) (1.5 mg/kg) and 2.5 hours later were deeply anesthetized with Nembutal i.p. and perfused with 4% paraformaldehyde. Brains were extracted, cryoprotected for 12-48 hrs and cut on a cryostat in 20 μ m sections. Sections were incubated in c-fos antibody (Santa Cruz) and reacted for immunoreactivity using a standard avidin-biotin protocol with VIP as the colorimetric substrate (Vector). Rats were run in the experimental protocol in 4 groups of 4 or 5. The groups consisted of 3 control rats (sal+sal, sal+at, clo+at) and 1 or 2 experimental rats (clo+at).

All experimental rats showed behavioral symptoms of withdrawal such as whole body shakes, paw shaking and increased digging and escape behaviors while none of the control rats exhibited these behaviors. An increase in the number of c-fos positive cells in the clo + at (withdrawing rats) was noted in many brainstem autonomic structures including rostral ventrolateral medulla (RVL), locus coeruleus(LC), nucleus of the solitary tract and raphe pallidus. This increase was quantified for RVL (41.6 \pm 4.4 cells/section in clo+at; 5.0 \pm 0.8 in clo+sal, 8.2 \pm 1.0 in sal+at and 7.3 \pm 1.4 in sal+sal) and LC (32.8 \pm 4.0 cells/section in clo+at; 3.8 \pm 0.9 in clo+sal, 4.9 \pm 0.7 in sal+at and 4.4 \pm 0.7 in sal+sal). The increase in neuronal activity in brainstem autonomic areas could explain the rebound hypertension observed during clonidine withdrawal.

CARDIOVASCULAR EFFECTS ELICITED BY MICROINJECTIONS OF NEUROPEPTIDE FF (NPFF, MORPHINE MODULATORY PEPTIDE) IN THE NUCLEUS TRACTUS SOLITARIUS. J.H. Jhamandas*, K. Harris and K.H. Jhamandas. Department of Medicine (Neurology) & Division of Neuroscience, University of Alberta, Edmonton, Alberta and Department of Pharmacology & Toxicology, Queen's University, Kingston, Ontario, Canada.

Nucleus tractus solitarius (NTS), termination site of baroreceptor afferents is enriched in both NPFF immunoreactivity and binding sites. The function of NPFF in this area is unclear. We have examined the potential of NPFF to influence blood pressure in the urethane anesthetized rat following microinjection of the peptide in the NTS. Unilateral injections of NPFF (0.2-1.0 nmols, 50-150 nL) produced elevation in blood pressure. The peptide induced response had a finite latency and outlasted the injection. Following a pressor response, higher doses of peptide had to be injected to produce a similar response, suggesting a desensitization to its action. We also observed similar profile of pressor responses following unilateral injections of the NPFF analog (IDME)Y8Fa (0.2-1.0 nmols, 50-150 nL) within the NTS. Naloxone (2-4 mg/kg) administered intravenously failed to influence the effect of NPFF analog. Sites within the NTS where NPFF elicited the most consistent effect included medial and dorsomedial NTS at and just rostral to the level of area postrema. These results suggest that in the NTS, NPFF may serve to modulate cardiovascular function.

Supported by the Medical Research Council of Canada.

CHARACTERIZATION OF BRAINSTEM CIRCUITS FOLLOWING ELECTRICAL STIMULATION OF THE CENTRAL NUCLEUS OF THE AMYGDALA (CNA): A COMBINED C-FOS AND RETROGRADE TRACING STUDY. T. Petrov*, J.H. Jhamandas, T.L. Krukoff. Depts. of Anatomy and Cell Biology and Medicine (Neurology), Univ. of Alberta, Edmonton, Alberta, Canada T6G 2H7.

We have previously shown that electrical stimulation of the CNA induces expression of Fos (the protein product of the immediate early gene *c-fos*) in catecholaminergic (CA) neurons in the ventrolateral medulla (VLM) and the nucleus of the solitary tract (NTS). In this study we electrically stimulated the CNA and examined: 1) the connectivity of activated VLM neurons with the NTS, 2) the connectivity of activated NTS neurons with the VLM, 3) the proportion of activated CA neurons that project to the VLM or NTS respectively.

Rhodamine-labelled latex microspheres (R-LLM) were stereotactically injected into the NTS or VLM of rats. Six days later, the ipsilateral CNA was electrically stimulated for 60 min (25-50 μ A, 10 sec pulsed trains, 20 Hz, 100 μ sec) under urethane anaesthesia. In control animals the electrode was positioned in the CNA without delivery of current. Brains were then processed for Fos and tyrosine hydroxylase (TH) immunocytochemistry. In the experimental animals increased number of profiles that contained R-LLM were Fos immunoreactive (IR) in the ipsilateral VLM and NTS. 1) In the VLM 30% of the Fos IR cells projected to the NTS. 2) In the NTS 12% of the Fos IR cells projected to the VLM. 3) Of the CNA activated, R-LLM containing neurons, 17% in the VLM and 3% in the NTS were also TH IR.

The results indicate that local brainstem circuits between the VLM and NTS may be involved in mediating CNA-induced activation of medullary neurons. CA and non-CA autonomic cells may participate in a reciprocal activation of NTS and VLM neurons.

ALTERATION OF THE CARDIAC BAROREFLEX APPEARS LATE DURING PREGNANCY IN CONSCIOUS RABBITS. V.L. Brooks* and R.R. Quesnell. Dept. of Physiology, Oregon Health Sciences University, Portland, OR 97201.

There is evidence that reflex increases in heart rate (HR) and other effectors are reduced during pregnancy. The present study tested the hypothesis that the change in the baroreflex occurs early in pregnancy, coincident with increases in the steroid hormones estrogen and progesterone. Rabbits were instrumented with abdominal aortic and vena caval catheters. When the animals were nonpregnant (n=8), the relationship between arterial pressure (BP) and HR was determined by first decreasing BP with infusion of increasing doses of nitroprusside (3.6, 12.24, 48 μ g·kg⁻¹·min⁻¹) and then by increasing BP with phenylephrine (0.5, 1.2, 4.8 μ g·kg⁻¹·min⁻¹). The cardiac baroreflex was reassessed in the same animals (n=3-7) after about 1, 2, 3 and 4 wk of pregnancy (term is 31 days). Differences in the baroreflex curves between pregnant and nonpregnant rabbits were determined by comparing with ANOVA parameters generated by logistic analysis. BP was 65 \pm 2 mmHg in nonpregnant rabbits and was not significantly different in pregnant rabbits. HR increased (p < 0.01) from 142 \pm 2 in nonpregnant animals to 174 \pm 6 and 186 \pm 4 bpm after 3 and 4 wk of pregnancy. Baroreflex relationships between BP and HR were not altered after 1, 2 and 3 wks of pregnancy. However, maximal reflex gain decreased from -28 \pm 5 to -6 \pm 1 bpm/mmHg after 4 wk of pregnancy (p < 0.01). These results indicate that the cardiac baroreflex is not altered until the end of pregnancy, and suggest that increases in estrogen and progesterone do not mediate the change that occurs. Supported by NIH Grant HL 39923 and MRF of Oregon.

560.4

COMPARISON OF HEMORRHAGE- AND NITROPRUSSIDE-INDUCED Fos EXPRESSION IN BRAINSTEM NEURONS THAT PROJECT TO THE PARAVENTRICULAR NUCLEUS (PVN). K.H. Harris*, D. MacTavish, T.L. Krukoff and J.H. Jhamandas. Depts. of Medicine (Neurology); Anatomy & Cell Biology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2B7

We previously reported that hemorrhage-induced hypotension activates neurons in the nucleus of the solitary tract (NTS) and ventrolateral medulla (VLM) that project to the PVN. In the present study, Fos-immunoreactivity (FI) was used to compare the activation of PVN-projecting brainstem neurons in response to hemorrhage- and sodium nitroprusside (SN)-induced hypotension. Under anesthesia, rats received injections of rhodamine-labelled latex microspheres into the PVN and were instrumented with arterial and venous cannulae. One week later, conscious rats (n=6) were hemorrhaged (5-6 ml) to lower and maintain arterial pressure (AP) to 30-50% of resting AP for 1.5 h. A separate group (n=6) received SN intravenously (4 mg/kg, 0.5 ml) to lower and maintain the AP to 30-50% of baseline for 1.5 h. A comparable number of neurons with FI were observed at all levels of the NTS and VLM following both hypotensive stimuli. The only exception was the NTS, at the level of area postrema, where greater FI was found following SN-induced hypotension. In sham, controls, few neurons with FI were found. At all levels of the NTS, SN-induced hypotension led to FI in a significantly greater number of retrogradely labelled cells (40-50%) than in hemorrhaged animals (18-30%). These results show that both hemorrhage- and SN-induced hypotension activate medullary neurons in the NTS and VLM which project to the PVN. Moreover, quantitative analysis of FI following the two hypotensive stimuli suggests that a change in blood volume accompanying hemorrhage is not a significant factor in the activation of NTS and VLM neurons. Supported by the MRC and Heart & Stroke Foundation of Canada.

ACUTE BLOOD PRESSURE CHANGE ELICITS HIPPOCAMPAL THETA RHYTHM AND BEHAVIOURAL AROUSAL IN THE UNRESTRAINED CONSCIOUS RABBIT Ying-Hui Yu* and W.W. Blessing. Centre for Neuroscience, Flinders University, Bedford Park, SA 5042, Australia.

Acute changes in arterial blood pressure (AP) cause arousal from sleep in lambs (Fewell and Johnson, Brain Res. 311 1984 259, Horne et al. Am. J. Physiol. 256 1989 H434), a response mediated via arterial baroreceptors. Arousal is accompanied by desynchronization of the neocortical EEG, but no studies have reported the effect of blood pressure changes on hippocampal theta rhythm. In staged operations in New Zealand White rabbits (3-3.2 kg), anesthetized with 1% halothane, we implanted mono- and bipolar EEG electrode in the skull and the dorsal hippocampus, a cuff occluder around the thoracic inferior vena cava, and cannulae in an external jugular vein and a common carotid artery. The lines were kept open by constant infusion of heparinized solution. The rabbit remained in a cage with a swivel on the roof for freely accessing electric and fluid channels. The EEG and AP signals were recorded with MacLab (AD Instruments). The rabbit's behaviour was recorded with a videocamera. AP was reduced by inflation of the IVC cuff, and increased by phenylephrine (3-10 μ g/kg i.v.). Changing AP beyond a threshold (approx 60 mmHg) in either direction caused hippocampal theta rhythm (7-10 Hz), sometimes followed by behavioral arousal. Our data suggest that major alteration in baroreceptor inputs affects arousal state.

NITROGLYCERIN-INDUCED FOS-LIKE IMMUNOREACTIVITY AND AP-1 EXPRESSION IN RAT BRAIN. C. Tassorelli*, A.V. Prasad, A.H. Siddiqui and S.A. Joseph. Neurosurgery, University of Rochester, Rochester, NY 14642.

Nitroglycerin (NTG) is a well known vasodilator, commonly used in the treatment of angina pectoris. A less diffuse, but very intriguing clinical application of NTG is the diagnosis of primary vascular headache, as it consistently induces a spontaneous-like migraine attack in predisposed subjects. Recent findings have shown that NTG is capable of inducing the release of different neurotransmitters, such as noradrenaline and calcitonin gene-related peptide, in the central nervous system (CNS). These findings have suggested that NTG may act, at least partially, through a centrally-mediated mechanism, rather than as a pure direct vasodilator.

The proto-oncogene *c-fos* encodes a nuclear protein Fos, whose expression in certain brain regions can be induced by a variety of stimuli. For this reason, the immunohistochemical analysis of Fos-like immunoreactivity has been proposed as a highly sensitive method for the metabolic mapping of polysynaptic pathways in the brain. Moreover, Fos contributes to the formation of the protein activator AP-1, which, in turn, triggers the transcription of specific downstream genes, ultimately cooperating in the regulation of target genes that may underlie cellular adaptive responses.

The aim of the present study was to evaluate, in the rat, the possible CNS effects of systemic NTG by means of the induction of *c-fos* activation and AP-1 expression. The activation of *c-fos* was evaluated by immunocytochemical detection of Fos-like immunoreactive neurons, while AP-1 expression was detected by electromobility-shift assay (EMSA).

The results obtained by a time course study and immunocytochemical analysis reveal the existence of significant differences in both the localization and number of positive neuronal elements expressing Fos. The results obtained by EMSA following NTG injection demonstrate AP-1 expression as early as the second hour post-administration. These data strongly suggest that NTG can induce a selective activation of specific CNS nuclei. (supported by NIH grant NS213323)

MORPHOLOGY OF SYMPATHETIC GANGLION NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS. C. Cameron* and K.G. Ruit. Department of Anatomy and Cell Biology, University of North Dakota School of Medicine, Grand Forks, ND 58202.

Increases in levels of nerve growth factor (NGF) in the walls of muscular arteries has been hypothesized as a contributing factor in the development of hypertension in genetically hypertensive rats (SHR). Our previous studies of the trophic effects of NGF on sympathetic ganglion neurons prompted us to hypothesize that significant changes in components of the autonomic nervous system may also be contributing to the development of hypertension.

Superior cervical ganglion (SCG) neurons in 6-7 week-old SHR and normotensive Wistar-Kyoto (WKY) rats were intracellularly filled with a 5% solution of Lucifer yellow in order to visualize the dendritic arborizations of these neurons. Each intracellularly filled neuron was drawn by camera lucida, and cell body size, total dendritic length, and number of primary dendrites were determined and compared between groups.

Preliminary experiments show that although SHR ganglion neurons tended to be larger and have greater total dendritic lengths, the differences were not statistically significant. In addition, the number of primary dendrites elaborated by these neurons did not differ. An interesting observation we have made in SHRs, however, is that there is extensive dye-coupling between neurons of the SCG not seen in the WKYs. Previous investigators have shown that there is enhanced synaptic transmission through the SCG of the SHR. Our present evidence suggests that this may not be the result of large-scale changes in SCG neuron dendritic architecture and preganglionic innervation, but possibly as a result of the establishment of local ganglionic electrical connections.

SPINAL AUTONOMIC REFLEX ARCS. M. Anwar*, K. Otake, E.P. Mui, and D.A. Ruggiero, Div. Neurobiol., Dept. Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

Somatovisceral reflex arcs mediate cardiopulmonary adjustments to pain and exercise. The structural underpinnings of short intraspinal reflex pathways were sought using axonal transport techniques in chloral hydrate (0.5mg/kg)-anesthetized adult and 8-12 day-old neonatal Sprague-Dawley rats. **Study 1. Do first order axonal muscle afferents project to spinal autonomic motoneurons?** Ten 1µl deposits of a 10% solution of Dextran-Lucifer Yellow (DLY) were slowly injected, bilaterally, into the longissimus muscle. Following 6-8 day survival periods, thoracolumbar spinal segments were sectioned and processed immunocytochemically for DLY. Transganglionic transport of DLY labeled first order muscle afferents in the thoracic spinal cord: lamina VII and lamina VIII of ventral horn; bypassing the intermediolateral cell column (IML) in mature (n=6) and young (n=3) animals. **Study 2. Do neurons in the dorsal horn project to autonomic motor nuclei?** Iontophoretic deposits of *Phaseolus vulgaris* leucoagglutinin (n=13) centered on lateral loci in upper thoracic (T1-2) or thoraco-lumbar (T11-12 or L1-2) spinal segments transported, intrasegmentally, to the IML and nucleus intercalatus with ipsilateral predominance. A larger medial fiber trajectory decussated in the dorsal gray commissure and terminated within a mirror locus in the dorsal horn on the contralateral side. Deposits confined to medial loci in the dorsal horn terminated in laminae VII and X and the ventral horn, bypassing the IML. We conclude: Intraspinal-autonomic circuits may provide an anatomical substrate for the early reflex component of the exercise pressor reflex. The direct spinal-autonomic reflex arc may be reinforced by way of a multisynaptic commissural pathway. Direct pathways from the dorsal horn to spinal preganglionic motoneurons may explain retention of the capacity for cardiovascular reflex adjustments to peripheral stimulation following spinal cord transection. (HL18974, NS28200)

TRIGEMINALLY MEDIATED ALTERATIONS OF NORMAL CARDIO-RESPIRATORY RHYTHMS DURING TRANSNASAL APPLICATION OF CARBON DIOXIDE. P. Yavari, W.M. Panneton, and J.H. Haring*, Dept. of Anatomy & Neurobiol., St. Louis Univ. School of Medicine, St. Louis, MO 63104.

Psychophysical studies in humans have shown that nasal stimulation with carbon dioxide (CO₂) is perceived as painful; physiological studies in the rat have shown that such effects may be mediated through the medullary dorsal horn. Since the medullary dorsal horn is also a probable site for the mediation of the "diving response", we have studied the cardiorespiratory responses in the rat which result from applying CO₂ across the nasal mucosa. The animals were anesthetized with intraperitoneal injections of a mixture of chloralose-urethane. Cannulas were inserted into the femoral vein and artery for the delivery of drugs and recording of blood pressure, respectively. Other tubing was placed in the trachea for breathing and into the nasopharynx for drawing air over the nasal mucosa. The stimulus was 100% CO₂ applied to the nares and slowly drawn through the nose by gentle suction applied to the nasopharyngeal tube. Such stimulation caused an abrupt drop in heart rate, and in the majority of the experiments, apnea and an elevation of blood pressure. In other experiments the application of CO₂ caused deep breathing and hyperventilation (no apnea) or arrhythmic breathing with apneic periods. The bradycardia was not the result of activating baroreceptors since it persisted even in those cases where prazosin, an alpha-1 adrenergic blocker, was used to prevent the increase in blood pressure. The CO₂-induced bradycardia was vagally mediated since it could be completely abolished after intravenous atropine. The nasal application of the local anesthetic procaine resulted in a blockade of up to 90% of the responses, suggesting that the responses are trigeminally mediated. These CO₂ induced responses previously have not been reported and resemble those of the diving response. Supported by NIH grant HL38471.

A MODEL OF AUTONOMIC DYSREFLEXIA IN THE RAT. G. Sansone*, R. Bianca, R. Cueva-Rolon, L. Gomez, C. Beyer, B. Whipple, and B.R. Komisaruk, Institute of Animal Behavior, Rutgers University, Newark, NJ 07102

The present study ascertained whether increases in heart rate (HR) and blood pressure (BP) that are produced by vaginocervical stimulation (VS, 500 g) persist after spinal cord transection. Three groups of rats were used: spinal transection at a) T7 (n=13), or b) L5 (n=13), or c) a sham-operated control group (SH, n=10). In the SH group, VS produced significant increases in HR (78.0 ± 8.3 [sem] beats per minute [bpm]) and BP (37.8 ± 8.1 mmHg), confirming earlier studies. In the L5 group, VS continued to increase HR (20.4 ± 9.8 bpm), but the effect of increasing BP was abolished. By contrast, in the T7 group, while VS significantly increased BP (31.3 mmHg ± 8.6), it produced a significant decrease in HR (-42.0 ± 11.9 bpm). These results can be accounted for by the human model of autonomic dysreflexia. The T7 transection blocks the reflexive VS-induced increase in heart rate. At the same time, it leaves intact the baroreceptor-vagal inhibitory drive to the heart that results from the VS-induced increase in BP. By contrast, the L5 transection permits the stimulatory drive from VS to the heart via the hypogastric nerve, which enters the spinal cord above the transection. However, the low level of transection blocks the ability of VS to increase blood pressure via local reflexes.

NEURONS IN THE INSULAR CORTEX ARE RESPONSIVE TO MUSCULAR CONTRACTION AND HAVE SYMPATHETIC AND/OR CARDIAC-RELATED DISCHARGE. T.G. Waldrop* and G.A. Iwamoto. Depts. of Physiology & Biophysics, Veterinary Biosciences and Neuroscience Program, University of Illinois, Urbana, IL 61801.

Recent studies have shown that stimulation of the insular cortex elicits cardiovascular responses; this cortical region is known to have connections with several brain sites involved in cardiovascular regulation. The purpose of the present study was to characterize the basal discharge patterns of neurons in the insular cortex and to determine if feedback from contracting muscles impinges upon these neurons. Extracellular recordings of single unit activity were made from insular cortex neurons in anesthetized cats whose lungs were artificially ventilated with a phrenic-triggered ventilator. Static and rhythmic contractions of the hindlimb muscles were elicited by stimulation of the distal cut end of L₁ and S₁ ventral roots. Signal averaging techniques revealed that many of the insular cortex neurons had a basal discharge correlated temporally to the cardiac cycle and/or sympathetic nerve discharge. In addition, contractions of hindlimb muscles altered the discharge frequency of many of the neurons located in the insular cortex; the discharge rate of most of the responsive neurons was decreased by muscular contraction. The activity of most of these neurons was not altered by baroreceptor stimulation elicited by a phenylephrine-induced rise in arterial pressure. The present findings indicate that the peripheral feedback reflex originating in active skeletal muscles during exercise alters the discharge of insular cortex neurons. These results indicate that the insular cortex may be involved in the modulation of cardiovascular responses elicited during exercise. (Support by HL 06296, 37400 & 38726).

A GLUTAMATERGIC RELAY FOR THE DIVING RESPONSE IN THE MEDULLARY DORSAL HORN OF THE MUSKRAT. W.M. Panneton* and P. Yavari, Dept. of Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Stimulating the upper respiratory tract, including the nasal cavity, can induce powerful cardiorespiratory responses. Such responses include an apnea, bradycardia, and a selective peripheral vasoconstriction; these responses together resemble those of the diving response. In the present experiments, the nasal cavity was stimulated using ammonia vapors to induce the diving response while 100-150 nanoliter injections of either 2% lidocaine or 40mM kynurenate were made in the medullary dorsal horn (MDH) to block the responses. Muskrats were tranquilized with ketamine hydrochloride and anesthetized with a mixture of alpha chloralose-urethane administered intravenously. The femoral artery was cannulated for the recording of blood pressure, a tube was inserted into the trachea for respiration, and another tube was inserted into the nasopharynx for gently sucking ammonia vapors through the nasal cavity. In animals which showed consistent responses to ammonia vapors either lidocaine or kynurenate injections were made in the MDH to block the response. Effective bilateral lidocaine injections were limited to rostral, ventral parts of the MDH. The distribution of effective kynurenate injections mimicked those using lidocaine. Since kynurenate does not affect fibers of passage, the effective sites probably localize the area where the stimulated primary afferent fibers from the nose synapse upon secondary trigeminal neurons mediating the diving response. Furthermore, the results using kynurenate suggest that a transmitter used at this synapse is glutamate. Supported by NIH grant HL38471.

CARDIOVASCULAR EFFECTS OF NITRIC OXIDE ON BRAINSTEM NUCLEI OF RATS. C. J. Tseng,* H. Y. Liu, H. C. Lin and C. S. Tung. Dept of Medical Education and Research, Kaohsiung Veterans General Hospital, Kaohsiung; Dept of Pharmacology and Physiology, National Defense Medical Center, Taipei, Taiwan, R.O.C.

Nitric oxide (NO) has been reported as second messenger or neuromodulator in vivo. In this study, we evaluated the cardiovascular effects of NO in the nucleus tractus solitarius (NTS), rostral ventrolateral medulla (RVLM) and area postrema (AP) of male Sprague-Dawley (SD), Wistar-Kyoto (WKY) and spontaneously hypertensive rats (SHR) respectively. Unilateral microinjection (60 nl) of L-arginine (L-Arg, 1-100 nmol) into the NTS and RVLM produced a prominent dose-related decrease in heart rate and blood pressure. The depressor and bradycardic effect of L-Arg were significantly attenuated by the pretreatment of NO synthase inhibitor - N^G-monomethyl-L-arginine (L-NMMA). The depressor effect of L-Arg in the NTS of SHR was less sensitive than the WKY. Furthermore, the cardiovascular effects of L-Arg was potentiated via intravenous injection of the lipopolysaccharide (LPS). In addition, a simultaneously inhibition of sympathetic nerve activity was noted during the period of L-Arg induced depressor effect in the NTS. However, there is no significant cardiovascular effect of L-Arg in the AP. These results suggest that NO is involved in the central cardiovascular regulation. The depressor effect of L-Arg in the NTS might be through the inhibition of sympathetic nerve activity.

Pharmacological characterization of the 10 Hz Sympathetic Nerve Discharge Frequency. ME Clement* and RB McCall. The Upjohn Company, Kalamazoo, MI.

Most of the power in the discharge frequency of sympathetic nerve in baroreceptor denervated decerebrate or urethane-anesthetized cats concentrates in a 2-6 Hz band and a narrower frequency band around the 10 Hz range. Barman and Gebber have shown that chemical inactivation of the midline medullary raphe with muscimol eliminates the 10 Hz peak, while stimulation of this area can induce the 10 Hz rhythm. Our laboratory has recently examined the effect of a number of pharmacologic agents on the frequency distribution of sympathetic activity. We found that systemic administration of the GABA antagonist picrotoxin (0.01-1 mg/kg) selectively increased the power in the 10 Hz band in a dose dependent manner. Incremental doses of picrotoxin also tended to shift the 10 Hz peak to higher frequency. Low doses of 8-OH-DPAT (1-3 µg/kg) selectively inhibited the 10 Hz power band in a dose dependent manner. The inhibitory effects of 8-OH-DPAT could be reversed by the 5-HT antagonist spiperone. The putative 5-HT_{1A} antagonist WAY-100135 (0.01-0.1 mg/kg) did not reverse 8-OH-DPAT but did inhibit 10 Hz activity when given alone. The 5-HT antagonist methysergide (0.01-1 mg/kg) caused a dose dependent shift in the 10 Hz band to lower frequencies. Chlorimipramine, a 5-HT uptake inhibitor, also eliminated the 10 Hz peak in SND, but did not block stimulation induced 10 Hz activity. These data suggest that 5-HT and GABA modulate the level of excitability of the central oscillator responsible for the generation of the sympathetic 10 Hz frequency.

CATECHOLAMINE AND NADPH-DIAPHORASE NEURONS ARE SEPARATE IN HUMAN AND RAT MEDULLA AND ARE NOT CO-ACTIVATED. I. L. Smithson, P. J. Zollman, J. D. Schmelzer, P. A. Low and E. E. Benarroch*. Neurophysiology Laboratory, Mayo Clinic, Rochester, MN 55905.

Catecholamine- and nitric oxide (NO)-producing neurons occupy cardiorespiratory regions of the nucleus of the tractus solitarius (NTS) and ventrolateral medulla (VLM). Selective involvement of these neurons may underlie clinical disorders of cardiorespiratory control. We sought to determine 1) the distribution of NADPH-diaphorase (NADPH-d) and tyrosine hydroxylase (TH)-reactive neurons in the NTS and VLM of human medulla and 2) the pattern of activation of these neurons in response to stimuli in the rat. Human medulla obtained within 12-48 hr of death were fixed and sectioned (50 µm). Sections were processed for both TH and NADPH-d. These markers were localized in topographically related but distinct neurons in human NTS and VLM. Rats were anesthetized and ventilated; mean arterial pressure (MAP), heart rate, and arterial blood gases were continuously monitored. The rats were subjected to hypovolemic hypotension or hypoxemia for approximately 60 min. Animals were perfused and 30 µm sections were processed for cFos (antibody provided by Dr F. Sharp) and for TH- or NADPH-d. cFos reactivity overlapped with that of TH- but not NADPH-d labeled neurons in NTS and VLM. Thus, in humans, as well as in rats, TH- and NADPH-d neurons are distinct but interacting populations. Selective involvement of these two neuronal groups may underlie human disorders of central cardiorespiratory control.

REGULATION OF AUTONOMIC FUNCTIONS: CNS PATHWAYS AND TRANSMITTERS

561.1

SUBNUCLEAR DISTRIBUTION OF DOPAMINE RECEPTOR SUBTYPES IN THE HUMAN NUCLEUS OF THE SOLITARY TRACT AND OTHER SELECTED BRAINSTEM NUCLEI. T.M. HYDE*, A.M. MURRAY, M.E. KNABLE, M.M. HERMAN, C.F. SPURNEY, AND J.E. KLEINMAN. Clinical Brain Disorders Branch, IRP, NIMH, Washington, D.C. 20032.

The nucleus of the solitary tract (NTS), dorsal motor nucleus of the vagus (DMN), and area postrema (AP) are interrelated structures important in the modulation of visceral function, including those mechanisms underlying nausea and vomiting. Neuroleptics, probably acting on dopamine receptors, have potent antiemetic actions. In order to establish and characterize the role of medullary dopamine receptor subtypes in the neural control of nausea and vomiting, we studied the distribution of D1-D5 receptors. Fresh frozen human brainstem sections from normal controls, n=9, sectioned at 20 µ and slide mounted, were incubated with [³H]raclopride for D2 and D3 receptors, [¹²⁵I]epidepride for D2, D3, and D4 receptors, [³H]SCH23390 for D1 and D5 receptors, and [³H]emonaipride for D2, D3, and D4 receptors, and apposed to ultrafilm for computerized image analysis. Dopamine receptors were most densely distributed over the medial and intermediate subnuclei of the NTS and the DMN. Moderate binding was noted over the dorsal, ventromedial, and substantia gelatinosa subnuclei. The medial region of the NTS receives a dense projection from the subdiaphragmatic vagus. Dopamine receptors in this region of the NTS, as well as in the DMN, probably act as a central site of antiemetic action of neuroleptics.

561.2

LOCAL PROJECTIONS OF THE NUCLEUS OF THE SOLITARY TRACT TO THE DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE PIGEON. M.L. Berk* and K.H. Gerlach. Dept. of Anatomy, Cell and Neurobiology, Marshall Univ. Sch. of Med., Huntington, WV 25755.

The pairing of sensory and motor representation of a specific organ within certain levels of the avian nucleus of the solitary tract (NTS) and dorsal motor nucleus of the vagus (DMNX) could facilitate vago-vagal reflexes. The present study investigated the existence and peptide content of local NTS projections to DMNX that could subserve esophageal reflexes. Fluorescein-latex beads were injected into an anterior DMNX subnucleus, which innervates the esophagus. Retrogradely labeled NTS cells were observed ipsilaterally and contralaterally and were most dense in medial tier NTS subnuclei, which are recipients of vagal afferents from the alimentary tract. The combination of retrograde labeling and immunofluorescence techniques revealed many bombesin, enkephalin, and neurotensin immunoreactive medial tier NTS cells that were double-labeled. Many of the enkephalin and neurotensin containing double-labeled cells were located in medial tier NTS subnuclei that are the major recipients of esophageal afferents and thereby could subserve as interneurons in esophageal reflexes. Bombesin double-labeled cells were found in medial tier NTS subnuclei that are major targets of gastric afferents. These bombesin containing cells that project to the anterior DMNX may serve to integrate esophageal and gastric functions. On-going experiments will attempt to verify the axonal projections of these medial tier NTS cell groups to esophageal DMNX motoneurons by combining anterograde axonal tracing with retrograde labeling techniques. Support NSF R11-8922106

561.3

DISTRIBUTION OF BOMBESIN-LIKE IMMUNOREACTIVITY IN THE NUCLEUS OF THE SOLITARY TRACT (NTS) AND DORSAL MOTOR NUCLEUS (DMN) IN HUMANS. R.B. Lynn¹, R.R. Miselis², and T.M. Hyde³. ¹Dept. of Med., Thomas Jefferson Univ., Phila. PA 19107; ²Dept. of Animal Biol., Univ. of Penn., Phila. PA, 19104; ³Clin. Brain Disorders Branch, NIMH, IRP, Wash., D.C. 20032

Bombesin, also referred to as gastrin releasing peptide (14-27), has important autonomic and behavioral effects when injected into the NTS/DMN complex in rats. Bombesin-like immunoreactive (Bb-LI) labeling is abundant in the rat NTS/DMN complex, but has not been described in the human medulla. Four normal human medulla were flash frozen and subsequently thawed and fixed. Frozen sections (40µ) through the caudal NTS were stained using primary antiserum to bombesin (Incstar) and the ABC technique. The heaviest Bb-LI labeling, probably representing fiber/terminals, was found at the level of the obex, diffusely in the medial and intermediate subnuclei of the NTS and in the medial portion of the DMN. Lighter but significant labeling was noted in the dorsal, interstitial, ventromedial and commissural subnuclei of the NTS and the lateral portion of the DMN. The substantia gelatinosa and the tractus of the NTS appeared void of Bb-LI staining. Rare Bb-LI labeled cell bodies were scattered within the NTS. Bb-LI staining was also noted in the A1 region and the spinal trigeminal nucleus. In controls, all Bb-LI staining was abolished by preabsorption of the primary antiserum with bombesin peptide. This distribution of labeling is very similar to the pattern of labeling in the non-colchicine treated rat. The anatomic similarities between human and rat suggest that bombesin has similar functions in the visceral neuraxis of these two species. Support: KO8 DK02094(1); GM27739(2); IRP-NIMH(3).

561.5

GLUTAMATE-IMMUNOREACTIVE NEURONES AND AXON TERMINALS OF THE NUCLEUS TRACTUS SOLITARIUS (NTS): DEMONSTRATION OF GLUTAMATE IN VAGAL SENSORY AFFERENTS.

R.M. Sykes, D. Jordan*, K.M. Syver and P.N. Jzsa Dept. Physiology, Royal Free Hosp. Sch. Med., Rowland Hill St., London, NW3 2PF, U.K.

Although there is a growing body of literature regarding the actions of glutamate in the NTS very little is known about the anatomy and organization of the glutamatergic neuronal structures in this region. Using post-embedding immunocytochemical techniques glutamate-containing neurones and axonal boutons have been examined at both the light and electron microscopic level. Furthermore, by combining this technique with anterograde labelling this study begins to examine the origins of glutamate-immunoreactive axon terminals observed in the NTS.

Light microscopic examination of semi-thin plastic sections revealed glutamate-immunoreactive neurones throughout the NTS and gracile nucleus with a distinctive organization at intermediate levels where groups of immunoreactive perikarya were observed. Axonal boutons were also labelled. These were found throughout all subnuclei providing a very dense and apparently homogeneous innervation.

Ultrastructural examination of glutamate immunogold-labelled sections identified a population of axonal boutons which displayed common morphological features and formed exclusively asymmetric synaptic specializations. The major post-synaptic targets of these boutons were small to medium-sized dendrites. Glutamate immunocytochemistry of sections containing anterograde labelling following the injection of horseradish peroxidase into the nodose ganglion revealed that these axons contribute to the population of glutamate-immunoreactive axonal boutons in the NTS.

TRANSSYNAPTIC DOUBLE LABELING WITHIN THE VISCERAL NEURAXIS WITH UNIQUELY MARKED STRAINS OF PSEUDO-RABIES VIRUS (PRV). R.R. Miselis*, M. Yang, A. Robbins, M. Whealy and L. Enquist, Animal Biol., Vet. Med., Univ. of Penn., Phila., PA 19104, DuPont-Merck, Wilmington, DE 19880, and Mol. Biol., Princeton Univ., Princeton, NJ 08544

Using recombinant DNA techniques two strains of PRV were made that expressed unique proteins. Cells infected with one or both viruses could be easily distinguished by immunofluorescent techniques. BaBlu was derived from the Bartha strain and expressed E. coli beta-galactosidase. PRV 41/91 was derived from the Becker strain with a gE gene deletion for reduced virulence and expressed a novel protein from a hybrid gene of the PRV gC gene and the Herpes simplex gC gene. The viruses were injected separately into either the esophagus and stomach or stomach and cecum of rats to determine if they would spread trans-synaptically into the same second or third order neurons in the CNS. Double labeling of the same neurons did not occur in the primary motor nuclei for the different viscera but did occur in some neurons of the nucleus of the solitary tract, ventrolateral medulla, parapyramidal area, paraganglionic reticular formation, raphe magnus and the A5, A6 and sub A6 catecholaminergic areas - known afferent sources to the above primary motor nuclei. The double labeling provides anatomical evidence that some second and third order afferents can simultaneously modulate final common paths to different viscera and thereby serve an integratory or coordinating function. Supported by GM27739 and DuPont-Merck.

561.4

GABA NEURONS IN THE NUCLEI OF THE SOLITARY TRACT RECEIVE SYNAPTIC INPUT FROM TERMINALS OF CENTRAL AMYGDALOID NEURONS. D.M. Cestari*, E.J. Van Bockstaele, J. Chan and V.M. Pickel, Dept. of Neurology and Neuroscience, Cornell Univ. Med. Coll., New York, NY 10021.

Direct applications of GABA agonists within the nuclei of the solitary tracts (NTS) is known to enhance sympathetic activities in a manner similar to that seen following stimulation of the central nucleus of the amygdala (CNA). We examined whether GABA immunoreactive neurons within the NTS received direct synaptic input from efferents derived from the CNA. The anterograde tracers, *phaseolus vulgaris* leucoagglutinin (PHA-L) or biotinylated dextran amine (BDA) were iontophoresed into the CNA of adult rats. These animals were sacrificed after survival periods of 10 - 14 days and single sections through the brainstem were processed for immunoperoxidase and gold silver labeling of the anterograde tracers or GABA, respectively. Anterograde labeling was maximally observed using BDA. Anterogradely labeled varicose processes in the medial and commissural NTS were established as unmyelinated axons and axon terminals by electron microscopy. The terminals formed almost exclusively symmetric synapses with soma and large dendrites, many of which were GABA immunoreactive. Despite the GABA-like symmetry of the anterogradely labeled terminals, the majority were not dually labeled. However, GABA labeling was abundantly seen in other neighboring axon terminals. These also were presynaptic to GABA dendrites. We conclude that stress induced autonomic activation may be mediated through an inhibitory pathway from the CNA to GABA neurons in the NTS. (NIH grants MH48776 and HL18974).

561.6

TRANSNEURONAL LABELING OF NEURONS IN THE BRAIN AFTER INJECTION OF PSEUDORABIES VIRUS (PRV) INTO THE RAT PHARYNX. X. Bao, E.B. Wiedner, and S.M. Altschuler*, Children's Hospital of Phila., Univ. of Pa. Sch. of Med., Phila., PA 19104.

The initiation and control of swallowing is dependent on premotor neurons (PMNs) located primarily in NTS. The subnuclear location and connectivity of PMNs innervating the pharynx were determined using a Bartha strain of PRV. In 15 rats, PRV injections were made into the pharynx. Following a 48-96 h survival, brain sections were processed immunocytochemically for PRV. Neuronal labeling was limited to the semicompact formation (sc) of the NA for a survival time of 48 h. At 56-62 h survivals, PRV-labeled 2nd order neurons (PMNs) were localized to the interstitial (ist) and intermediate (int) subnuclei of NTS. At longer survivals, neuronal labeling occurred in adjacent subnuclei of the NTS, raphe nucleus, A5, hypothalamus, and forebrain. Pharyngeal PMNs are localized to the istNTS and intNTS, the sites of termination of superior laryngeal nerve afferents, and have direct synaptic contact with scNA motoneurons. The pattern of labeling at longer survivals suggests widespread CNS control over pharyngeal motility. Supported by NIH grant DK-44487.

561.8

SYMPATHETIC NERVE FIBERS IN THE SUBDIAPHRAGMATIC VAGUS NERVE OF THE RAT SEEN WITH FLUOROGOLD, CT-HRP OR PSEUDORABIES VIRUS. M. Yang*, X. Zhao and R.R. Miselis, Animal Biology, Phila., PA 19104

To identify the source, number and the level of entry of sympathetic nerve fibers in the vagus nerve one of three retrograde tracers was injected into the subdiaphragmatic vagus nerve trunks of the rat. We examined the upper sympathetic ganglia, the nodose ganglion, and the dorsal motor nucleus of the vagus (DMV) in the same animals. We find a small number of labeled postganglionic neurons in the sympathetic trunk ganglia (g): an average of 6 neurons in the superior cervical g. (SCG), 30 in the cervicothoracic g. (CTG) and 25 in the other thoracic g. In addition there are preganglionic parasympathetic catecholaminergic nerve fibers originating from tyrosine hydroxylase containing neurons in the caudal DMV (approximately 324). Rough ratios of postganglionics in the vagus to the total number of postganglionic neurons in the sympathetic g. are 0.12% for the SCG and 0.54% for the CTG. This is a minor contribution by this unusual and perhaps developmentally aberrant path. Many more labeled neurons are seen in the prevertebral g. when the stomach is injected. Since sympathetic fibers enter the vagus as high as the caudal pole of the nodose g. and within the thoracic cavity, it would take a cervical vagotomy at the cranial pole of the nodose g. to ablate all parasympathetic innervation to visceral organs without disrupting sympathetic nerve fibers in the vagus nerve. Supported by GM27739.

561.9

DICHOTOMOUS MODULATION OF VAGAL MOTONEURON ACTIVITY BY THE HYPOTHALAMUS. X. Zhang*, R. Fogel and W.E. Rehean. Div. Gastroenterology, Henry Ford Health Sciences Center, Detroit, MI 48202

Recent evidence suggests that the hypothalamus may play an important role in stress-related gastrointestinal disorders. Stimulation of the paraventricular nucleus of the hypothalamus (PVH) can induce gastric erosion and motility changes that can be eliminated by vagotomy, suggesting that the PVH effect involves neurons in the dorsal motor nucleus of the vagus (DMNV). Little is known, however, about the potentially important PVH influence on DMNV neurons. To address this issue, we used glass micropipettes containing 2% Neurobiotin to record the response of individual gastric- and intestine-sensitive DMNV neurons to PVH stimulation. The stomach and duodenum of 15 rats were separately cannulated to permit distention with normal saline. Stimulating electrodes were placed around the subdiaphragmatic and gastric branches of the vagus nerve. Stimulating electrodes were also placed in the PVH. Following physiological characterization each neuron was injected with the tracer and reconstructed using the Eutectic Neuron Tracing System. A total of 18 DMNV neurons were successfully labeled. Most of these neurons were inhibited by intestinal and/or gastric distention. PVH stimulation, however, inhibited 6 and excited 8 of the distention-sensitive DMNV cells (PVH stimulation did not affect the activity of the remaining 4 neurons). Interestingly, our data suggested that a given DMNV neuron's response to PVH stimulation may be related to certain morphologic features. We noted that those DMNV neurons that were inhibited by PVH stimulation tended to exhibit a higher density of dendritic swellings than the neurons that were excited by this stimulus ($p = 0.068$). These preliminary results suggest that PVH neurons may project to two distinct subsets of gastrointestinal DMNV neurons. These two groups appear to receive similar input from the intestine, but opposing inputs from the hypothalamus. Supported in part by NS30083 and DC01074.

Dorsal Motor Nucleus Neurons Recorded in Vitro are Activated by Pancreatic Polypeptide Under Conditions of Synaptic Blockade

Richard C. Rogers* and Gerlinda E. Hermann, Dept. of Physiology, The Ohio State University College of Medicine, Columbus, OH 43210

Pancreatic Polypeptide (PP), when injected directly into the dorsal vagal complex, strongly augments gastric acid secretion and gastric motility by increasing vagal cholinergic activation of the stomach [AJP; 265:G1169-1176, 1993]. The adjacent abstract suggests that this increase in vagal excitation of the stomach might come about as the result of direct activation of dorsal vagal complex neurons. To test this hypothesis, brainstem slices of the medulla were prepared for extracellular recording using an interface slice chamber. 400 micron thick slices were incubated in a modified Krebs Solution at 34° C. under a 95% O₂, 5% CO₂ atmosphere. The DMN was easily identified visually and DMN-area neurons were recorded. Recorded cells maintained spontaneous [5 to 5 Hz] activity under conditions of synaptic blockade [low Ca⁺⁺/ high Mg⁺⁺], a feature typical of DMN neurons. The application of a pulse of PP to the perfusion chamber [peak chamber PP concentration of 0.5 micromolar to 50 nanomolar] produced dramatic increases in DMN activity under normal as well as under synaptic blockade conditions. These results support the concept of PP as a peripheral hormone which control digestion by directly altering the excitability of vagal reflex control neurons. Supported by NS 30803.

561.13

EXOGENOUS CCK ACTIVATES CATECHOLAMINERGIC NEURONS IN THE CAUDAL MEDULLA THAT INNERVATE THE HYPOTHALAMUS.

L. Rinaman*, G.E. Hoffman, J. Dobanics, E.M. Stricker, and J.G. Verbalis. Depts. of Neuroscience, Neurobiology, & Medicine, University of Pittsburgh, PA 15260.

Immunocytochemical localization of the protein product of the proto-oncogene cFos allows anatomical identification of physiologically activated neurons. Peripheral administration of CCK octapeptide in rats inhibits gastric motility and feeding, stimulates pituitary secretion of oxytocin, and produces robust expression of cFos immunoreactivity in restricted areas of the caudal medulla and forebrain. The present study used triple-labeling methods to determine whether CCK activates the catecholaminergic neurons in the caudal medulla that innervate the paraventricular nucleus of the hypothalamus (PVN). Male Sprague-Dawley rats were anesthetized, and Fluorogold (FG) retrograde tracer was iontophoresed into the PVN unilaterally under stereotaxic guidance. After 2 weeks, rats were injected with CCK (100 µg/kg, ip), anesthetized 1 hr later, and perfused with fixative containing 4% paraformaldehyde with lysine and sodium meta-periodate. Brain sections were incubated in rabbit anti-cFos (Oncogene Sciences, 1:50K), and blue-black nuclear cFos labeling was produced using Elite Vectastain reagents and a nickel-DAB reaction product. Sections were then incubated in rabbit anti-FG (Chemicon, 1:50K), and green fluorescent FG labeling was produced using Elite Vectastain reagents and BODIPY-streptavidin conjugate (Molecular Probes). Finally, sections were incubated in mouse anti-tyrosine hydroxylase (TH; Incstar, 1:100K), and red fluorescent TH labeling was produced using a modified alkaline phosphatase method (CAS Inc). In rats with precise PVN injections (n=10), approximately 70% of the FG-labeled neurons in the nucleus of the solitary tract and ventrolateral medulla expressed cFos. Of these activated PVN-projecting neurons, approximately 60% were catecholaminergic. These data indicate that catecholaminergic pathways transmit vagal sensory information from the caudal medulla to the hypothalamus, and support the hypothesis that these pathways participate in the neuroendocrine, physiological, and behavioral effects of CCK-induced gastric vagal stimulation. Supported by NIH grants NS28477 and MH25140 (MERIT award).

Pancreatic Polypeptide Increases the Activity of Dorsal Vagal Complex Neurons in vivo

Dana M. McTigue* and Richard C. Rogers. Dept. of Physiology, College of Medicine, Ohio State University, Columbus, OH 43210

Pancreatic polypeptide (PP), a hormone released during digestion, has been shown to alter vagal control of the stomach by acting at the dorsal vagal complex (DVC) within the brainstem. This area contains fenestrated capillaries through which the circulating hormone gains access. In the present studies, we examined the effect of PP on neuronal activity in the DVC using extracellular recording in anesthetized rats. Cells within the DVC were identified in two ways: vagal stimulation to identify NTS vs DMN neurons or gastric inflation to identify On vs Off cells (neurons that increase or decrease firing rate during inflation, respectively). The results obtained indicate that over 65% of On cells and Off cells were stimulated by PP while none were inhibited. Furthermore, 60% of NTS cells were stimulated by PP. Preliminary studies examining DMN neurons demonstrate that 30% are inhibited while the rest were unaffected. These studies indicate that in general, gastric related DVC neurons are potentially stimulated by PP. When the entire population of DVC neurons is studied, more complex effects may be observed. The long-lasting stimulation of gastric related DVC neurons may provide a mechanism for the observed increases in gastric activity following PP administration. (NS 30803 to RCR)

2-DEOXY-D-GLUCOSE (2DG) INDUCES C-FOS IN CENTRAL AND PERIPHERAL CATECHOLAMINE (CA) SYSTEMS. S. Ritter* and I. Llewellyn-Smith. College of Veterinary Medicine, Washington State University, Pullman, WA, U.S.A. 99164, and Department of Medicine, Flinders Medical Centre, Adelaide, S.A. 5042, Australia.

2DG is a glucose analogue that competitively inhibits glucose utilization. Responses to 2DG include increased feeding and adrenal medullary secretion and induction of Fos-like immunoreactivity (FLI) in the brain and adrenal medulla. Previous studies have shown that 2DG-induced feeding is impaired by lesion of brain CA systems and by pharmacological reduction of CA neurotransmission. In this experiment, 2DG was administered systemically and immunocytochemistry used to determine whether *c-fos* was induced in hindbrain neurons which express tyrosine hydroxylase (TH). Results show that 2DG induces FLI in some, but not all, TH-containing neurons in the A1/C1 and A2/C2 regions and in many neurons not containing TH. 2DG also induced FLI in a subpopulation of sympathetic preganglionic neurons retrogradely labelled by injection of the B subunit of cholera toxin into the adrenal medulla. Results identify specific subpopulations of brain CA and preganglionic neurons activated by glucoprivation.

PANCREATIC POLYPEPTIDE (PP) AND PEPTIDE YY (PYY) mRNA IN THE BRAINSTEM OF RATS DETECTED BY REVERSE-TRANSCRIPTASE PCR (RT-PCR). D.C. Whitcomb*, A.M. Puccio, J.M. Leifer, G. Finley, G. D. Ehrlich and A.F. Syed, Depts Medicine, Pathology and Neuroscience, Univ. Pittsburgh, Pittsburgh, PA 15261.

PP and PYY are circulating gut hormones that regulate digestion. Receptors for PP and PYY are present in the brainstem on both sides of the blood-brain barrier (BBB). When PP and PYY are microinjected into certain areas of the dorsal medulla inside the BBB, they produce potent gastrointestinal effects. We hypothesized that PP and PYY are produced by cells within the CNS that project to areas with high densities of receptors, despite the failure to consistently demonstrate these peptides by radioimmunoassay and immunohistochemistry. Objective: to determine if PP and PYY mRNA are present in the brain, using RT-PCR. Methods: Total RNA was extracted from the dorsal pons and medulla of the rat brain, pancreas and distal 10 cm of ileum using the Trisol method (Biotec, Houston, TX). First strand cDNA was generated using a Moloney Murine Leukemia Virus reverse transcriptase reaction. Five ng of cDNA products were incubated with the PP or PYY primers and Taq DNA polymerase along with controls and standards for 35 cycles. The products were separated directly on Nu-Sieve agarose gels. The identity of the PCR products was tested by Southern blot. Results: PP and PYY mRNA were detected in the dorsal medulla of the rat brain using the RT-PCR. The PP primers yielded a single band identical in size to the PP mRNA isolated from the pancreas. For PYY, two bands were amplified from brain mRNA, corresponding to predicted PYY mRNA fragments with alternate splicing. The relative density of the two PYY bands differed between brain and ileum. Southern blots labeled with ³²P-PP or ³²P-PYY cDNA probes demonstrated that the amplified PCR products hybridized with the appropriate cDNA. Conclusion: PP and PYY mRNA are present in the brainstem of rats. This supports the hypothesis that PP and PYY receptors in areas of the brain that are inaccessible to circulating hormones may have physiologic relevance.

561.15

CAUDAL RAPHE STIMULATION EVOKES SEROTONIN (5-HT) RELEASE INTO DIALYSATES OF THE DORSAL VAGAL COMPLEX IN FED, BUT NOT FASTED RATS - GLUTAMATERGIC MEDIATION R.L. Stephens Jr., Dept. of Physiology, The Ohio State University, Columbus, Ohio 43210.

The dorsal vagal complex (DVC) is the central relay station coordinating sensory & motor control of autonomic function. The caudal raphe nuclei is the source of the dense serotonergic innervation of the DVC. 5-HT augments the effect of TRH on gastric function at the DVC. Regulatory mechanisms of 5-HT release into regions of the dorsal medulla containing the DVC in anesthetized rats were explored. Basal 5-HT release was enhanced in fed as compared to 24-hr fasted rats. In addition, stimulation of the raphe obscurus with kainic acid produced a marked release of 5-HT into dialysates of the dorsal medulla of fed but not 24-hr fasted rats [Mean 5-HT release (pgrams/15min; n = 5-8)]:

	BASAL 5-HT						nRO KAINATE (423 pmoles/10nl)							
	FAST	3	8	5	3	2	4	1	2	0	0	0	0	0
FED	16	17	15	9	15	15	15	149	363	106	76	47	84	50

Gastric distension of fasted animals did not evoke 5-HT release after nRO-stimulation. However, probe infusion of kynurenic acid (1 mM) in fed animals attenuated nRO-stimulated serotonin release. Given the vagal sensitivity of nRO-stimulated 5-HT release in this system, the results suggest that activation of glutamatergic vagal afferents may facilitate serotonin release into the DVC. TOPOGRAPHY OF SOMATOSENSORY INPUT TO THE RAT PARABRACHIAL COMPLEX: A SITE FOR SOMATO-VISCERAL INTEGRATION? K. Feil* and H. Herbert. Dept. Animal Physiol., Univ. of Tübingen, Auf der Morgenstelle 28, D-72076 Tübingen, Germany.

The parabrachial (PB) and Kölliker-Fuse nucleus (KF) receive - in addition to viscerosensory afferents from the solitary nucleus - strong somatosensory inputs from the dorsal horn of the spinal cord and the spinal trigeminal nuclei (Sp5). In the present study we examined, in detail, the spino- and trigeminoparabrachial projections by means of the anterograde transport of PHA-L. Our results show that the organization of spinal and trigeminal pathways to the PB/KF is more complex than previously thought.

Spinal dorsal horn neurons (lamina I-II) of cervical segments project to the ventral portion of the external lateral PB, while those of thoraco-lumbar segments project almost exclusively to the dorsal lateral and central lateral PB. Neurons in lamina V and the lateral reticulated area of all spinal segments project to the internal lateral PB while those of the cervical segments project in addition to the KF.

Trigeminal neurons in the superficial layers of the Sp5, pars caudalis and interpolaris, project strongly to the KF and to the ventral portion of the external lateral PB. In contrast, neurons of the paratrigeminal nucleus project specifically to the ventral lateral PB.

Our data demonstrate that the somatosensory input to the PB/KF is somatotopically organized. We thus conclude that the spino- and trigeminoparabrachial afferents consist of parallel pathways which convey and process either somatosensory information from different parts of the body, or somatosensory information of different qualities, or even both. It is assumed, that the pathways from the spinal cord and the Sp5 through the PB to various forebrain and medullary nuclei represent neural circuits which are involved in somato-visceral processing.

EFFECT OF SEPTAL LESIONS IN THE SALIVARY SECRETION INDUCED BY INTRACEREBROVENTRICULAR (ICV) INJECTION OF PILOCARPINE IN RATS. A. Renzi, W.A. Saad*, L.A.A. Camargo, J.E.N. Silveira and J.V. Menani. Dept. of Physiol. Sci., School Odontol., Paulista State University - UNESP, 14801-903, Araraquara, SP, Brazil.

Electrolytic lesions of the lateral hypothalamus or the anteroventral third ventricle reduces the salivary secretion induced by ICV injection of pilocarpine in rats. In this work we investigated the effect of septal (medial + lateral) electrolytic lesion (2 mA x 20 s) on the increase of the salivary secretion induced by ICV (lateral ventricle) injection of pilocarpine in anesthetized rats. The salivary flux was measured by pre-weighed cotton balls inserted in the mouth. Twelve hours or five days (acute lesion) and fifteen or twenty five days (chronic lesion) after the lesion, the saliva was collected 7 min before (control) and 7 min after ICV injection of pilocarpine (120 ug/ul). ICV injection of pilocarpine in sham rats increases the salivary flux (430 ± 26 mg/7 min) compared to control (18 ± 5 mg/7 min). Septal lesion reduces (99 ± 20, 138 ± 17, 210 ± 25 and 327 ± 42 mg/min, respectively) the salivatory effect of ICV pilocarpine, but not the basal salivary flux (20 ± 5 mg/7 min). These results suggests the septal lesion participates in the salivary secretion produced by ICV injection of pilocarpine in rats.

EFFERENT PROJECTIONS OF THE NUCLEUS PARAGIGANTOCELLULARIS IN THE RAT: A PHA-L TRACING STUDY Y. Zhu*, S. Chen and G. Aston-Jones, Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann Univ., Philadelphia, PA 19102.

Previous studies have shown that the nucleus paragigantocellularis lateralis (PGi) strongly innervates the nucleus locus coeruleus (LC) and sympathetic nuclei of the spinal cord. However, other efferents of the PGi have not been systematically examined. In the present study, Phaseolus vulgaris-leucoagglutinin (PHA-L) was used to comprehensively map PGi efferents in the rat. Multiple deposits of PHA-L were iontophoresed into the PGi. After 7-10 days, animals were perfused and processed for PHA-L immunostaining. Dense PHA-L terminal labeling was seen in the intermediolateral cell column and intermediomedial areas of the spinal cord, A1/C1 areas of the ventral medulla, the nucleus of the solitary tract, dorsal motor nucleus of the vagus (X), the hypoglossal nucleus (XII), the LC, medial and lateral parabrachial nuclei, Kölliker-Fuse nucleus, the periaqueductal gray, the interstitial nucleus of the medial longitudinal fasciculus, deep superior colliculus and thalamic intralaminar nuclei. Fewer fibers and terminals were seen in the nucleus prepositus, facial nucleus (VII), A5 area, Barrington's nucleus, dorsal raphe nucleus, lateral hypothalamus and septum. Scattered fibers and terminals were also seen in the hippocampus and subiculum. PHA-L labeling was generally bilateral, but with a ipsilateral predominance. The present study shows that PGi sends divergent efferents to several brain areas, many of which were previously found to project to the PGi. Supported by PHS grant NS 24698.

DESCENDING PATHWAYS FROM THE RAT PARABRACHIAL AND KÖLLIKER-FUSE NUCLEUS: RELATION OF TERMINAL AXONS, AND MEDULLARY MONOAMINERGIC CELL GROUPS. H. Herbert* and F. Weber. Dept. Animal Physiol., Univ. of Tübingen, Auf der Morgenstelle 28, D-72076 Tübingen, Germany.

In the present study we analyzed pathways from the parabrachial and Kölliker-Fuse nucleus (PB/KF) to ponto-medullary and spinal nuclei which might participate in mediating the PB/KF cardiovascular, respiratory, and antinociceptive responses. We combined the anterograde transport of PHA-L with immunocytochemistry for noradrenergic (A1-A5), adrenergic (C1-C3), and serotonergic cells (B1-B3).

After large PHA-L injections into the lateroventral aspects of the PB/KF complex a dense plexus of terminal fibers was consistently found in the ventrolateral and caudal commissural solitary nucleus (NTS), along the ventrolateral medulla (VLM), and in the lateral facial nucleus. Smaller numbers of fibers were seen in the gigantocellular reticular nucleus, in the nucleus raphe magnus, and in the spinal trigeminal nuclei. In the spinal cord, terminal axons were found in the intermediolateral and intermediomedial cell column and in the phrenic nucleus.

In the caudal commissural NTS labeled PB/KF axons were codistributed with A2 cells. However, in the light microscope only few potential synaptic contacts could be observed. In the rostral VLM the majority of terminal fibers was located within the pool of C1 cells. Many axonal boutons were seen closely apposed to C1 somata and dendrites, indicating axo-somatic and axo-dendritic contacts. In the caudal VLM, efferent PB/KF fibers were only seen dorsal to the pool of A1 cells where they intermingled with dorsally travelling A1 dendrites. Medullary areas which contain the B1-B3 cells receive only minor projections from the PB/KF. Nevertheless, labeled axonal varicosities were often found in close apposition to serotonergic somata and dendrites.

Our results demonstrate that the PB/KF complex has strong projections to medullary and spinal autonomic, respiratory, and antinociceptive centers. Therefore, these pathways seem to be involved in the central neural control of these functions. (Supported by DFG He 1842/3-2)

CORTICAL EFFERENT PROJECTIONS TO SPINAL CORD AUTONOMIC CENTERS IN THE RAT. K.G. Ruit* and M. Bennett. Department of Anatomy and Cell Biology, University of North Dakota School of Medicine, Grand Forks, ND 58202.

Anatomical evidence for the cortical innervation of autonomic preganglionic neurons within the spinal cord is sparse and, in some cases, contradictory because of a lack of systematic approaches to the question and by limitations imposed by tracing techniques. The present study was designed to focus on regions of the cortex known to have a "visceral motor" function and determine their spinal connections using an effective "long-tract" anterograde tracer.

In adult Sprague-Dawley rats, biotinylated dextran (10,000 MW) was injected by iontophoresis into one of three regions of the medial frontal cortex (MFC)—the anterior cingulate (AC), prefrontal (PL), and infralimbic (IL) areas. After a 21 day survival period the brain and spinal cord were removed, sectioned, reacted using ABC histochemistry, and visualized by light microscopy.

Results of preliminary experiments show that injections in more dorsal regions of the MFC (AC and PL) resulted in terminal labelling within ventral laminae of the thoracic dorsal horn and within gray matter adjacent to the central canal. Injections in ventral regions of the MFC (IL) resulted in terminal labelling adjacent to the central canal and within the intermediolateral cell column. Both of these regions of the thoracic spinal gray matter contain sympathetic preganglionic neurons that form the "final common pathway" out of the central nervous system for the innervation of visceral effectors. Cortical connections with spinal autonomic centers may be important for regulating visceral components of emotion or responses to stress.

GLP-1 AND ITS RECEPTORS IN THE CENTRAL NERVOUS SYSTEM: POWERFULL REGULATORS OF AUTONOMIC FUNCTIONS IN THE RAT BRAIN. M. Tang-Christensen, R. Göke, M. Møller and S. P. Sheikh*. Dept. Clin.Biochem. 7642, National University Hospital, Rigshospitalet Copenhagen and Dept. of Medical Anatomy, MAI-B, Panum Inst., Denmark.

Glucagon like peptide-1(7-36)amide (GLP-1), is a gut hormone known to play an important role as an incretin in the entero-insular axis. Since GLP-1 immunoreactivity and specific receptors are present in the rat brain, we investigated the biological effects following central GLP-1 administration. GLP-1 was injected directly into the lateral ventricle of brain-cannulated rats, and food and water intake were measured. In cannulated rats with access to food 180 min during a 24 h period, but with free access to water, GLP-1 produced a strong dose-dependent inhibition of both food and water intake. At doses of 1 and 10 µg of GLP-1, food intake was significantly suppressed to $46 \pm 12\%$ (n=9) and $23 \pm 6\%$ (n=10) of control animals (n=15). To investigate the effect of GLP-1 on water homeostasis, the urine output of freely feeding rats was measured following intracerebral injection of GLP-1. The urine output was considerably increased by GLP-1 in a dose-dependent manner. At doses of 10 and 1 µg of GLP-1 urine output was increased 4.51 ± 0.68 (n=14) times respectively 2.16 ± 0.37 (n=10) times of control (n=34). Measurement of sodium and potassium concentration in the urine-samples revealed GLP-1 as a natriureticum. These significant effects on both food and water intake and urinary output suggests an important role for GLP-1 or a structurally related peptide as a neurotransmitter in regulation of both ingestive behaviour and salt and water homeostasis.

REGULATION OF AUTONOMIC FUNCTIONS: GASTROINTESTINAL

CELIAC GANGLIONIC AND VAGAL PROJECTIONS TO THE RAT DUODENUM COMPARED USING DiI/DiA DUAL LABELING AND CONFOCAL MICROSCOPY. Z. Cheng and T.L. Powley*. Purdue University, West Lafayette, IN 47907.

The duodenum receives strong autonomic projections. The patterns of these inputs are still incompletely known. To label both branches of the ANS concurrently, male rats were injected bilaterally in the dorsal motor nucleus of the vagus with DiA and then one to two weeks later in the left celiac ganglion with DiI, after prior sectioning of the abdominal splanchnics. Five days before sacrifice, the animals received i.p. Fluoro-gold injections to label the enteric nervous system. After perfusion, the duodenum was separated into muscularis externa and submucosal wholemounts and processed for confocal microscopy. In contrast to the vagal pattern of dense networks of fibers and varicosities innervating the myenteric ganglia, sympathetic fibers tend to course superficially around the perimeter of the ganglia. These celiac fibers provide fine collaterals within some ganglia but form relatively few varicose contacts. Celiac fibers also form lattices of axons between the longitudinal and circular muscle layers. These lattices are comprised of axons and interstitial cells paralleling the two muscle sheets. Other fibers penetrate into one or the other muscle layers and arborize in varicose endings. These intramuscular efferents parallel the muscle fibers of the respective layers. In the submucosa, the sympathetic efferents form extensive networks of endings both on blood vessels and on interstitial cell complexes. They also supply varicose endings to submucosal ganglia. Single vagal varicosities, as well as rings and baskets of vagal endings, occur in apparent contact with those myenteric neurons which retrogradely label from the celiac ganglion. Thus, a novel and particularly direct interaction between the two ANS divisions may be vagal control of the enteric neurons projecting centripetally to the celiac ganglion. DIFFERENT VAGAL EFFERENT PROJECTION PATTERNS IN STOMACH, DUODENUM AND CECUM. J.B. Kelly*, M.C. Holst and T.L. Powley. Purdue University, West Lafayette, IN 47907.

In a recent survey of vagal motor fibers in the gastrointestinal tract, we observed that vagal efferents collateralize extensively, providing a dense network of endings within enteric plexuses (cf. Boyd et al., Neurosci. Abst. 19:962, 1993). The present inventory of these inputs was designed to characterize and compare efferent patterns in three prominent GI organs distinguished both by projections from different motor neuron pools within the dorsal motor nucleus of the vagus and by their specialized functions. Male rats received one or more iontophoretic injections of PHA-L in the dorsal motor nucleus of the vagus and were perfused 21 days later. Whole mounts of stomachs, small intestines, and ceca, as well as frontal sections of the medullas (56µm), were prepared immunohistochemically (Vector ABC Elite Kit). Cuprolinic blue was used to counterstain both enteric neurons and the medulla. Individual motor fibers were identified as they entered the target organs and then traced and digitized in their entirety (Eutectics Neuron Tracing System). In the stomach, vagal efferents enter from the lesser curvature and ramify so extensively, both radially and longitudinally, that single myenteric ganglia (and many individual neurons) receive multiple overlapping, convergent inputs. The proximal duodenum is innervated by two distinctive types of vagal fibers which frequently converge on the same ganglion. One is a longitudinally projecting axon, and the other a radially coursing axon. In the cecum, vagal fibers enter from the mesenteric attachment and fan out through the myenteric plexus to form contiguous radial fields without extensive overlap. Fibers in all three organs have large projection fields, but variations in the amount of ramification and ratio of longitudinal to radial orientation produce differences in the amount of convergence observed in the enteric ganglia of the organs. NIH DK27627 and NIMH MH01023.

562.3

TAXONOMY OF VAGAL AFFERENT PROJECTIONS TO THE GASTROINTESTINAL TRACT. F.B. Wang* and T.L. Powley. Purdue University, West Lafayette, IN 47907.

Vagal afferents have critical roles in the control of gastrointestinal function, but their morphologies and innervation patterns have only been characterized in limited areas. To survey these afferents, including a comparison of their (a) regional morphologies, (b) projection field sizes, and (c) regional densities, male SD rats were given unilateral intracranial motor rootlet rhizotomies (adapted from Walls et al., Neurosci. Abst., 19:816, 1993) and then injected in the ipsilateral nodose ganglion with WGA-HRP or DiI. All rats had i.p. Fluoro-gold injections to counterstain enteric neurons and verify the rhizotomy. Animals were perfused and processed with TMB (WGA-HRP) or for confocal microscopy (DiI). The entire stomach and cecum as well as samples of the duodenum, jejunum, ileum and colon were prepared as whole mounts and/or transverse thick sections. Individual fibers were followed to reconstruct their peripheral arbors. Vagal afferents terminate as free nerve endings which aggregate in polymorphic clusters. These fibers often branch extensively, sometimes distributing separate collaterals to different tissues. Prominent intramuscular and intraganglionic specializations occur, and these vary in distinct regions. Different areas of the GI tract are distinguished by contrasting patterns of intramuscular endings varying (1) in density from almost none to very heavy and (2) in distribution from predominantly in the longitudinal muscle, to predominantly in the circular, to in both layers. Overall, innervation of the muscularis externa and myenteric plexus is densest in the stomach and proximal duodenum and falls progressively along the small intestine. Sensory innervation of the cecum is relatively extensive, and vagal afferents are even found in the distal colon. The polymorphic and polytopic patterns distinguishing different regions may explain the mechano- and chemoreceptive functions of the different organs. NIH DK27627 and NIMH MH01023.

562.4

DISTENSION INDUCED EXPRESSION OF C-FOS IN MYENTERIC PLEXUS OF GUINEA PIG SMALL INTESTINE. R.C. Ritter* and M. Costa. Dept. of VCAPP, Washington State University, Pullman, WA 99164 and Dept. of Human Physiology, School of Medicine, The Flinders University of South Australia, Bedford Park, S.A.

Distension of the small intestine activates enteric reflexes which involve sensory and motor neurons within the myenteric plexus. In order to identify enteric neurons that respond to a distending stimulus, we examined the myenteric plexus for expression of the immediate early gene, c-fos, following distension. Three cm segments of the jejunum or upper ileum were placed in a 37°C Krebs' buffer as open tubes, or closed sacs. Sacs were distended with 0.4 ml Krebs' buffer or left non-distended. Distension resulted widespread expression of fos-like immunoreactivity (Fos-li) in nuclei of myenteric neurons. Neuronal nuclei expressing Fos-li were much less numerous in myenteric plexus of open tubes and non-distended sacs. Application of tetrodotoxin (1µM) in the bath and lumen reduced expression of Fos-li following distension. These results indicate that distension leads to increased expression of c-fos in the nuclei of myenteric neurons as a result of increased neuronal activity. *R.C. Ritter was Visiting Professor and Senior International Fellow at Flinders University during the conduct of these experiments.

ACTIONS OF CALCITONIN GENE-RELATED-PEPTIDE (CGRP) ON GUINEA PIG GALLBLADDER NEURONES. G. M. Mawe¹ and A. P. Gokint². ¹Department of Anatomy and Neurobiology, Univ. of Vermont, Burlington, VT, USA 05401; ²Bogomoletz Institute of Physiology, Kiev, Ukraine, 252024

CGRP is co-expressed with substance P in varicose, sensory nerve fibers surrounding neurons in gallbladder ganglia. Furthermore, these peptides are released from gallbladder preparations in response to capsaicin. To assess CGRP's action in gallbladder ganglia, intracellular recordings were made from 94 neurons in intact preparations, and CGRP was applied by pressure microejection (0.01-0.1 mM, 20 PSI, 0.1 - 3.0 sec). CGRP caused a 67.0 ± 3.4 sec depolarization with an amplitude of 5.0 ± 0.4 mV that had a reversal potential near 0 mV. The response was associated with a 23.2 ± 1.8 % decrease in input resistance. The magnitude of the depolarizing response was dependent on the duration of CGRP application, and was diminished in a low Na⁺ bathing solution. During the depolarizing response, neurons had increased excitability, manifested as an increase in number of spikes per current pulse, and activation of anodal break action potentials. These results indicate that CGRP, along with substance P, may mediate slow EPSPs in gallbladder ganglia, and that its depolarizing action is due predominantly to opening of cation channels. Supported by NS26995.

562.7

ACTIVATION OF THE RAPHE PALLIDUS NEURONES INCREASES SERUM INSULIN LEVELS THROUGH VAGAL PATHWAYS. H. Yano^{*}, V. L. W. Go, and Y. Taché. CURE, VA Med. Ctr., Brain Res. Inst. and Dept Medicine, UCLA, Los Angeles, CA 90073

Chemical stimulation of medullary raphe neurons induces gastric secretion, motility, cytoprotection and ulcer formation through vagal pathways in urethane-anesthetized rats. The effect of excitation of raphe pallidus (Rpa) neurons on the endocrine pancreatic secretion was examined. **Methods:** Rats (280-350 g) were anesthetized with pentobarbital, a PE-50 cannula was inserted into the jugular vein for taking blood samples and a double-lumen cannula was placed into the forestomach for measuring gastric acid secretion. Serum insulin and glucagon levels were tested using Linco RIA kits. **Results:** Microinjection of kainic acid (10 ng/50 nl) into the Rpa induced an increase in serum insulin level. Values before and 30, 60 and 90 min after microinjection were 0.34 ± 0.02 , 0.54 ± 0.06 , 0.60 ± 0.06 and 0.99 ± 0.13 ng/ml respectively (n=8). All values after Rpa stimulation were statistically significant from the basal level. In the same rats, stimulated gastric acid secretion was also observed (basal: 2.3 ± 0.55 ; 30 min after Rpa stimulation: 26.1 ± 8.6 μ mol/15 min). Microinjection outside of the Rpa had no effect. Serum glucagon level (basal: 48.8 ± 4.3 pg/ml) significantly increased only 90 min after the Rpa stimulation (86.6 ± 11.2 pg/ml). The increases of gastric acid secretion and serum insulin levels were completely prevented by bilateral cervical vagotomy whereas the increase in glucagon levels was only slightly but not significantly reduced. **Conclusion:** Chemical stimulation of Rpa stimulates not only gastric function but also endocrine pancreatic secretion through vagal pathways.

SEROTONIN INHIBITS, BUT 8-OH-DPAT STIMULATES, GASTRIC ACID SECRETION THROUGH VAGAL-INDEPENDENT MECHANISMS. K.J. LePard^{*}, S. Gidener and R.L. Stephens Jr., Department of Physiology, The Ohio State University, Columbus, OH 43210.

Serotonin (5HT) is a neuroendocrine component of the gastrointestinal tract. 5HT_{1A} receptors have been demonstrated autoradiographically in high density in the rat stomach. However, the physiologic role of 5HT_{1A} receptors in the stomach is not known. Thus, the effect of the selective 5HT_{1A} agonist, 8-OH-DPAT, on gastric secretory function was compared to 5HT. In acute, urethane-anesthetized rats with gastric fistula, acid secretion was stimulated by pentagastrin (24 μ g/kg/hr, i.v.). After 90 minutes, either 5HT or 8-OH-DPAT (3.5 μ moles/kg, i.v.) was given. 5HT inhibited, but 8-OH-DPAT stimulated, gastric acid secretion [mean \pm SEM, % change: 5HT (n=8), -47 ± 11 ; 8-OH-DPAT (n=7), $+71 \pm 42$; p<0.05]. Bilateral, cervical vagotomy did not reverse the effect of either 5HT or 8-OH-DPAT on acid secretion. In addition, the enhancement of acid by 8-OH-DPAT was spiperone-sensitive. Hence, the data suggests that selective activation of 5-HT_{1A} receptors may augment gastric secretory function. Supported by NIH DK 42880.

562.6

EXCITATION OF RAPHE PALLIDUS-INDUCED GASTRIC EROSION IS MEDIATED BY TRH IN DORSAL MOTOR NUCLEUS OF VAGUS NERVE (DMN) IN RATS. H. Kaneko, H. Yang, G. Sobue^{*}, and Y. Taché. CURE/VA Wadsworth Medical Center and Department of Medicine and Brain Research Institute, UCLA, Los Angeles, CA 90073, and Fourth Department of Internal Medicine, Aichi Medical University, Aichi, 480-11, Japan.

Medullary raphe neurons that contain thyrotropin-releasing hormone (TRH) projecting to the dorsal vagal complex are involved in the brain stem regulation of gastric function. We examined whether excitation of raphe pallidus (Rpa)-induced gastric mucosal lesions is mediated by TRH in the DMN in urethane-anesthetized rats. **Methods:** Gastric acid secretion was measured every 10 min after microinjection (30 nl) of vehicle (0.1M phosphate buffer) or kainic acid (KA: 1.5-12 ng) into the Rpa in either vehicle or indomethacin (5 mg/kg, ip, -60 min) pretreated rats. In other groups, indomethacin pretreated rats were killed 4 h after microinjection of KA (12 ng) into the Rpa, and the percentage of corpus mucosal lesions was determined by computerized image analyzer. The effect of TRH-antibody 8964 (1.3 μ g) or control antibody (purified IgG from non immune rabbit serum: 1.3 μ g) into the bi- or unilateral DMN and atropine (0.3 mg/kg, sc, -30 min) before microinjection of KA into the Rpa on gastric lesions were also studied. **Results:** KA into the Rpa stimulated dose-dependently gastric acid secretion (net output μ mol/60 min: 1.5 ng: 50.7 ± 11.5 ; 3 ng: 60.9 ± 7.6 ; 12 ng: 82.9 ± 16.6 , n=5), which was not modified by indomethacin (μ mol/60 min: 1.5 ng: 46.3 ± 7.0 ; 3 ng: 52.2 ± 9.8 ; 12 ng: 75.1 ± 15.6 , n=5). KA (12 ng) into the Rpa in indomethacin treated rats produced 2.7 ± 0.3 % of lesions which were blocked by 99.6%, 93.6%, and 81.1% in atropine, bilateral, and unilateral microinjection of TRH-antibody into the DMN pretreatment, respectively. KA outside of the Rpa and TRH-antibody outside of the DMN had no effect. **Conclusion:** Rpa neurons activated by KA induced gastric erosion through TRH release in the DMN which stimulated vagal cholinergic pathways.

562.8

EXTRINSIC DENERVATION INCREASES FOS-LIKE IMMUNOREACTIVITY IN THE SUBMUCOSAL AND MYENTERIC GANGLIA OF GUINEA PIG ILEUM. A.M. Yunker^{*} and J.J. Galligan. Dept. Pharmacology and Toxicology and Neuroscience Program, Michigan State University, E. Lansing, MI 48824

Gastrointestinal functions are normally controlled by interactions of enteric neurons found within the wall of the gut, and by extrinsic sympathetic, parasympathetic, and sensory nerves. However, normal digestion can occur after extrinsic denervation, suggesting enteric neurons can assume functions previously regulated by extrinsic nerves. Antiserum raised against Fos protein was used to determine if specific enteric neurons are altered following loss of extrinsic nerves. As Fos protein is related to neuronal activity, increased Fos protein-like immunoreactivity (Fos-ir) would be indicative of changes in nuclear events following denervation. One week after denervation of a loop of ileum, 9 \pm 1 Fos-ir nuclei/submucosal ganglion and 110 \pm 8 Fos-ir nuclei/myenteric ganglion were observed. These values were significantly greater (p < 0.05) than those from unoperated segments from the same animals, as 3 \pm 0.3 Fos-ir nuclei/submucosal ganglia and 12 \pm 6 Fos-ir nuclei/myenteric ganglia were observed. This difference was unlikely due to surgical trauma, as there was no difference (p > 0.05) in the number of Fos-ir nuclei in the submucosal plexus (2 \pm 1 Fos-ir nuclei/ganglion) or myenteric plexus (17 \pm 6 Fos-ir nuclei/ganglion) in sham-denervated segments as compared to controls (2 \pm 1 Fos-ir nuclei/submucosal ganglion, 17 \pm 7 Fos-ir nuclei/myenteric ganglion). Although significantly more (p < 0.05) nuclei contained Fos-ir 7 and 10 weeks after surgical denervation as compared to preparations from unoperated segments, the number of nuclei/ganglion decreased in both submucosal and myenteric ganglia, possibly as a result of regrowth of extrinsic nerves. Finally, no differences were observed in Fos-ir in control and denervated preparations 24 weeks after surgery. These data suggest that most, if not all, enteric neurons are altered following loss of extrinsic nerves. Some of these changes may be part of the adaptive process that allows enteric neurons to function in the absence of extrinsic innervation. (Supported by DK 40210 and NS 07279)

GASTRIC MUCOSAL EROSIONS PRODUCED BY NMDA INFUSIONS INTO THE LATERAL HYPOTHALAMUS: EFFECTS OF SELECTIVE KNIFE CUTS. C.V. Grijalva^{*}, J. Landeira-Fernandez and Stacey Nuccion. Department of Psychology, Univ. of California, Los Angeles 90024.

Bilateral infusions of N-methyl-D-aspartate (NMDA) into the lateral hypothalamus (LH), which interrupt intrinsic neurons, produce gastric erosions in rats (Grijalva, Rios-Jimenes & Landeira-Fernandez. *Soc. Neurosci. Abst.* 19, part 2: 1993, 959). The present study attempted to determine the pathways mediating this effect. In order to interrupt axonal transmission, knife cuts (KC) were made in different planes adjacent to the LH. In separate groups of rats, KC were made anterior, posterior or lateral to the LH just prior to bilateral NMDA infusions (20 μ g/ μ l). The incidence of gastric erosions was measured 24 h after NMDA infusions. Animals receiving Sham KC and infused with NMDA exhibited significantly more gastric erosions than those infused with PBS control (p < .05). Lateral parasagittal KC blocked the occurrence of gastric erosions produced by NMDA, whereas anterior coronal KC significantly increased the incidence of erosions produced by NMDA (p < .005). Posterior coronal KC did not significantly alter the incidence of gastric erosions produced by NMDA. These results suggest that intrinsic LH neurons with gastric function project axons laterally and probably descend through the internal capsule to brainstem medullary nuclei. The results of the anterior KC suggest that the LH sends and/or receives inhibitory projections from neural structures (possibly the amygdaloid complex) anterior to the plane of the KC. (supported by UCLA research grant PZ-06 and CNPq)

EFFECTS OF PITUITARY ADENYLATE CYCLASE-ACTIVATING POLYPEPTIDE (PACAP) ON GASTRIC MOTOR FUNCTION IN THE BRAINSTEM OF THE RAT. P.J. Hornby¹, G. Légradi², A. Arimura², and Z.K. Krowicki¹. ¹Dept. of Pharmacology, LSU Medical Center, New Orleans, LA 70112 and ²U.S.-Japan Biomedical Research Laboratories, Tulane Univ. Hebert Ctr., Belle Chasse, LA 70037.

PACAP-like immunoreactive cell bodies and fibers exist in the brainstem nuclei known for regulatory effects upon autonomic functions (Légradi and Arimura, Soc. Neurosci. Abstr., 732, 1993). These findings prompted us to investigate the effect of PACAP38 (1, 10, and 100 pmol; 30 nl) and saline (30 nl) in the dorsal vagal complex (DVC), the nucleus raphe obscurus (NRO) and in the vicinity of the nucleus ambiguus (NA) of alpha-chloralose-anesthetized rats on intragastric pressure (IGP), pyloric and greater curvature motility, heart rate, and blood pressure. Increases in gastric motility upon microinjection of L-glutamate (15 nmol; 30 nl) were used as an indicator of the location of the tip of the micropipette. Overall, PACAP dose-dependently increased the indices of gastric motor function; however, this attained statistical significance only for the increases in IGP at the highest dose of PACAP (100 pmol), as follows: in the DVC (N=5), the increase in IGP was $1.08 \pm 0.35 \text{ cm}^2$ ($P < 0.01$ vs. saline); in the NRO (N=5), the increase in IGP was $0.54 \pm 0.12 \text{ cm}^2$ ($P < 0.001$ vs. saline); in the region of NA (N=5), the increase in IGP was $0.5 \pm 0.2 \text{ cm}^2$ ($P < 0.05$ vs. saline). In the region of NA, PACAP (100 pmol) decreased heart rate by $6 \pm 3 \text{ bpm}$ ($P < 0.05$ vs. saline). These data indicate that PACAP is a stimulator of IGP in the brainstem nuclei of the rat. Supported by PHS grant DK42714.

MUCOSAL EXCITATORY INFLUENCE ON ANATOMICALLY IDENTIFIED NEURONS IN THE MYENTERIC PLEXUS OF THE GUINEA-PIG ILEUM. W.A.A. Kunze, J.C. Bornstein, J.B. Furness and H.M. Young.* Departments of Physiology and Anatomy & Cell Biology, University of Melbourne, Parkville, Victoria, Australia 3052.

To examine the influence of input from the mucosa on S neurons of the myenteric plexus, we compared the discharge properties of neurons very close to the mucosa with those whose somata lay further away. Opened segments of guinea-pig ileum were superfused with oxygenated physiological saline at 37°C; contractions were minimised by addition of 3 μM nifedipine. The myenteric plexus was exposed for half the area of each segment by removal of overlying mucosa, submucosa, and circular smooth muscle. Intact mucosa was circumferentially adjacent to the exposed plexus. Neurons were impaled with conventional microelectrodes filled with 1M KCl and 4% neurobiotinTM (Vector) and subsequently visualised using Texas Red fluorescence. Twenty-three neurons were recorded adjacent (<500 μm) to, and 13 far (>500 μm) from the mucosa. Twelve adjacent neurons, but only one far neuron discharged tonically throughout 500 ms depolarising current pulses, whereas 11 adjacent and 12 far neurons fired phasically. None of the tonic neurons projected orally (6 of 7 had anal projections), but 3 of 8 phasic neurons impaled >500 μm from the mucosa projected orally. The results indicate that input from the mucosa may preferentially enhance the excitability of orally projecting S neurons.

DUAL ANTAGONISTIC EFFECTS OF VAGAL AFFERENTS AND EFFERENTS ON JEJUNAL ALANINE ABSORPTION. C.F. Nassar, W.S. Hamdan, K.A. Barada, A.M. Taha, S.F. Atweh*, S.J. Jabbur and N.E. Saade*. Fac. Med. American University of Beirut, Lebanon.

The role of the vagus nerve in the regulation of water and electrolyte transport across the small intestine is well documented. However, there is lack of adequate information on its role in amino acid absorption. This study was thus undertaken to characterize the role of the vagus nerve in intestinal amino acid absorption, using selective chemical stimulation or block of various groups of vagal afferents and efferents, and the single-pass perfusion technique. Application of capsaicin (cp) to the isolated intact cervical vagi produced a 14% decrease of alanine absorption while similar application to the distal parts of cut vagi produced a 28% inhibition of alanine absorption. Chronic destruction of the cp sensitive vagal afferents resulted in 40% increase of alanine absorption. On the other hand selective activation of preganglionic vagal neurons by microinjection of kainic acid into the dorsal motor nucleus of the vagus produced a 48% increase in jejunal alanine absorption; this increase was abolished by previous treatment of the injected rats by atropine.

These results suggest that cp sensitive vagal afferents exert an inhibitory effect (direct and reflex) upon jejunal alanine absorption while cholinergic muscarinic vagal efferents exert an opposite facilitatory effect. (Supported by grants from the L.N.C.S.R. and U.R.B.).

CONSTITUTIVE AND INDUCIBLE NUCLEAR ONCOPROTEINS IN THE ENTERIC NERVOUS SYSTEM OF THE GUINEA PIG ILEUM. E.J. Parr and K.A. Sharkey*. Neuroscience Research Group, The University of Calgary, Calgary, AB, Canada T2N 4N1.

Constitutive c-Myc and c-Fos antigens are detectable in the nuclei of all enteric neurons of the guinea pig ileum. We have demonstrated that they make suitable markers to count enteric neurons in double-labelled preparations as well as providing a method to distinguish neurons from glia.

We have also investigated inducible nuclear oncoproteins in the guinea pig enteric nervous system. Inducible nuclear c-Fos, JunB and c-Jun immunoreactivity was found to be elicited in neurons by *in vitro* incubation of ileal segments in media containing 50mM K⁺ or 20 μM veratridine as depolarizing stimuli. The neurons expressing activity-related c-Fos antigens included all major immunohistochemically defined subgroups of the submucous plexus. However, in incubated ileal segments, smooth muscle cells and substantial numbers of glia as well as submucous neurons containing VIP-immunoreactivity expressed nuclear c-Fos-immunoreactivity in the absence of a depolarizing stimulus. We conclude that these immediate early genes appear to be regulated by neuronal activity in most or all subgroups of neurons but *in vitro* isolation of ileal segments is sufficient to induce expression of these genes in many cell types by as yet unidentified stimuli.

NEURAL CONTROL OF GASTRIC ACID SECRETION: ANATOMICAL DEMONSTRATION OF VAGAL INPUT TO GASTRIN RELEASING PEPTIDE (GRP) CONTAINING ENTERIC NEURONS. H.R. Berthoud* and Q. Lin. Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA 70808.

The prevailing theory of vagal control of gastric acid secretion suggests the presence of at least two stimulatory pathways. One is a direct cholinergic input to the parietal cells, the other involves the release of gastrin from mucosal endocrine cells that is partially driven by GRP containing vagal postganglionic enteric neurons. Additionally, there may be vagal inhibitory input mediated by somatostatin cells. In order to anatomically and neurochemically characterize this vago-enteric interface, we started to examine the relationship between DiA labeled vagal preganglionic terminals and immunocytochemically characterized enteric neurons and their projections.

The percentage of GRP-positive myenteric neurons is gradually decreasing from about 40% in the fundus or forestomach, to 25% in the corpus and only about 10% in the pyloric antrum. Dense networks of GRP-positive varicose terminal fibers were found around gastric glands in myenteric ganglia, and more sparsely within the external smooth muscle layers. In the corpus and antrum, 34% and 35%, respectively, of the GRP-positive neurons receive vagal efferent contacts. Conversely, of all the vagally contacted neurons, 33% and 16% were GRP-positive in the corpus and antrum, respectively. Vagal contacts with enteric neurons of other neurochemical phenotypes and with somatostatin cells, as well as possible contacts of DiI-labeled vagal afferent fibers within such neurons, are currently being analyzed. In conclusion, there is a significant number of GRP-positive enteric neurons that receive vagal preganglionic input, supporting a role of GRP in vagally controlled gastrin and gastric acid secretion and possibly other functions. Supported by NIH grant DK47348.

ELECTROPHYSIOLOGICAL EFFECTS AND IMMUNOCYTOCHEMICAL LOCALIZATION OF PACAP IN GUINEA PIG PANCREATIC GANGLIA. M.-T. Liu, A. Arimura, M.D. Gershon, and A. Kirchgessner*. Dept. of Anat. & Cell Biol., Columbia University, New York, NY 10032.

Intracellular recordings were used to examine the actions of pituitary adenylate cyclase-activating peptide (PACAP) on morphologically identified neurons in the guinea pig pancreas. In addition, the distribution of PACAP immunoreactivity in the pancreas was examined using an antibody that recognizes PACAP-27 and -38. Pancreatic neurons were classified as tonic, phasic, or nonspiking based on their physiological activity. PACAP-38 applied by pressure microejection evoked excitatory responses in phasic pancreatic neurons. The responses consisted of membrane depolarization in association with increased input resistance and repetitive spike discharge. Nonspiking neurons became excitable after application of PACAP. Most of the phasic pancreatic neurons that responded to PACAP had filamentous processes that were densely surrounded by VIP-immunoreactive terminals. PACAP immunoreactivity was observed in nerve fibers and in varicose terminals that covered a subset of pancreatic neurons. PACAP immunoreactive pancreatic neurons were not observed; however, they were observed in myenteric ganglia in the adjacent duodenum. The effects of PACAP and distribution of PACAP immunoreactive nerve fibers on pancreatic neurons suggest that PACAP is a neuromodulator. The possibility that PACAP immunoreactive axons are of enteric origin is being studied. Supported by grants NS27645 and NS01582.

DETECTION OF INSPIRATORY RESISTIVE LOADS IN HUMANS TRAINED TO BREATHE WITH DIAPHRAGM OR INTERCOSTAL MUSCLES. S.M. Reynolds*, W.R. Revelette, and D.T. Frazier. Department of Physiology, University of Kentucky Medical Center, Lexington, KY 40536-0084.

We recently recorded cerebral evoked potentials in response to inspiratory occlusion in humans trained to breathe with their diaphragm or intercostal muscles (*Neurosci. Abst.* 19:764, 1993). The amplitude of the evoked signal during intercostal breathing was significantly greater than that for any other condition. One explanation for this could be that the greater amplitude is related to the greater number of group I afferents in intercostal muscles compared with that of the diaphragm. The objective of the present study was to determine whether differences for the detection threshold of added resistive loads during free breathing (FB), diaphragm breathing (DB), and intercostal breathing (IB) exist. Assuming a correlation between perception of added loads to breathing and evoked potential amplitude exists, we hypothesized that the threshold for detection during intercostal breathing would be lower than that for diaphragm breathing. Respiration was used to monitor abdominal and rib cage motion. Subjects were provided visual feedback by watching the output of each band on an oscilloscope. Nineteen inspiratory resistive loads (26-3.54 cmH₂O/L/sec) were presented to ten subjects for a single breath under three conditions (FB, DB, IB). The detection threshold (mean \pm SEM) was 0.53 ± 0.09 for FB, 0.62 ± 0.11 for DB, and 0.54 ± 0.09 for IB. There was no statistically significant difference between these means. There appears to be no significant correlation between evoked potential amplitude elicited by inspiratory occlusion and detection threshold for resistive loads across the breathing conditions. (Supported by NIH Grant # PO1 40369)

METABOLIC AND RESPIRATORY RESPONSES TO MILD EXERCISE IN PATIENTS WITH CFS. DL Cordero*, JG Pareja, MT Bergen, WN Tapp and BH Natelson. Neurobehavioral Unit, DVA, East Orange, NJ 07018.

To identify patients with Chronic Fatigue Syndrome (CFS), our lab has been studying the physiological responses that CFS patients exhibit during and after treadmill exercise. Seven non-medicated CFS patients and seven sex-matched controls screened for their level of fitness were recruited for this study. Subjects walked on a motorized treadmill at 2.5 mph for 4 minutes and then sat for 4 minutes, this pattern repeated 4 times. Physiological variables were collected from an ECG machine and a metabolic breath analyzer. Although initial baseline heart rate, tidal volume, minute volume, respiratory rate, VO₂ and RQ were not different between groups, there was a significant difference in end-tidal CO₂ during the initial resting stage (CFS: 32.61 ± 0.88 mmHg, controls: 35.73 ± 0.50 , mean \pm SEM, $p < .01$). For the entire test, ANOVA revealed significant group differences for respiratory rate and ventilation, which were higher for CFS patients, and end-tidal CO₂, which was lower for CFS patients (all $p < .05$). The decreased end-tidal CO₂ at rest does not correlate with hyperventilation and so may reflect either a physiological abnormality or pre-test hyperventilation.

IDENTIFICATION OF HUMAN BRAIN REGIONS UNDERLYING RESPONSES TO INSPIRATORY LOADING WITH FUNCTIONAL MAGNETIC RESONANCE IMAGING. O. Omidvar, D. Gozal, K.A.T. Kirlaw, G.M. Hathout, R. Hamilton, J. Zhang*, R.B. Lufkin and R.M. Harper. Depts. of Anatomy & Cell Biology and Radiology, UCLA School of Medicine, Los Angeles, CA 90024-1763.

In man, locations of putative brain sites mediating responses to respiratory loading are unknown. To examine this issue, we employed a 1.5 Tesla MR scanner, and used SPGR pulse sequences (TR: 72 msec; TE: 45 msec; flip angle: 30°; FOV: 26 cm; slice thickness: 5 mm; 128 x 256 x 1 NEX). Mid-sagittal and axial images across the rostral pons were acquired in 8 healthy volunteers during two-way valve unloaded breathing, and while applying a 30 cm H₂O resistor to the inspiratory port. Digital image subtraction and ROI analysis revealed significant increases in image intensity in discrete regions of the dorsal medulla, pons, and cerebellum, as well as bilaterally, in the inferior colliculi, putamen, and internal capsule. With continuous loading, signal increases progressively diminished over time. Upon cessation of stimulus, ROI signal gradually returned to baseline. We conclude that inspiratory loading elicits consistent regional activation of discrete brain locations. We speculate that temporal changes in signal intensity may indicate respiratory afterdischarge and habituation phenomena.

ACTIVE AND PASSIVE CHEST INFLATION DIFFERENTIALLY MODIFY ABDOMINAL EXPIRATORY ACTIVITY. B. Bishop*, F. Cerny, L. Puckree, J. Darbee, D. Allen. Depts. of Physiology, and of PT and Exercise Science, State Univ. of NY at Buffalo, Buffalo, NY 14214

When supine, abdominal muscles are silent. However, they are active in expiration during an expiratory threshold load (ETL) or during continuous positive airway pressure (CPAP). We questioned how the sensory inputs of these two loads are integrated. Both loads change end-expiratory lung volume (EELV), and hence, vagal-volume feedback, but CPAP modifies feedback from chest wall receptors as well. EELV was passively increased to 25% and 50% of inspiratory capacity (IC) by rapidly reducing pressure in a full chest cuirass. EELV was actively increased by impeding expiration with a water column. We measured changes in breathing pattern and in expiratory activity in surface EMGs from external oblique (EO) and internal oblique (IO) abdominal muscles during ETLs of 5, 10 and 15 cm H₂O in 5 supine subjects (Ss). We used a "Respirace" to record EELV changes; and a pneumotach to assess V_E, T_E, and T_E. An increase in ETL evoked deeper, slower breathing, and higher peak expiratory activity in IO and EO, with minimal change in burst duration. Breathing was not altered by inflation to 25% IC. Inflation to 50% IC increased V_E without changing timing, and in 2 Ss evoked expiratory activity in IO. Combined ETL and CPAP evoked no additional changes in breathing pattern or burst duration, but did elevate the EO and IO expiratory peaks more than either load alone. Thus, feedback during the combined loads had additive effects on the output of the central pattern generator, but not on that of the central rhythm generator.

563.4

SCALP TOPOGRAPHY OF RREP ELICITED BY EXPIRATORY OCCLUSION IN ADULTS. C.A. Smith-Hammond*, C. Sapienza, D. Dalziel and P.W. Davenport. Dept. of Physiol. Sci., JHMC, University of Florida, Gainesville, Florida, 32610.

Respiratory related evoked potentials (RREP) was previously only recorded with inspiratory loads. It was hypothesized that a RREP can be recorded using expiratory occlusion. Adults were studied semi-reclined at rest, screened from the experimenter and apparatus. They respired through a mouthpiece and non-rebreathing valve. The expiratory occlusion was produced using a pressure activated valve with a 2 msec closure time. Early expiration was interrupted with an occlusion for 350 msec. EEG activity was recorded from F₇, F₈, C₃, C₄, C_{3'}, C_{4'}, T₃, T₄, P₃, P₄, T₃, T₄, C₂ and P₂ referenced to the joined earlobes. Two occlusion trials of 80 occlusions were separated by a control trial on 80 no-load presentations. The EEG activity was computer averaged on-line and saved on disk. Expiratory occlusion elicited an evoked potential was found in all subjects. An initial positive peak (P₁) was the only consistent peak observed in all subjects and was present in electrodes C₃, C₄, C_{3'}, C_{4'}, P₃, P₄, C₂ and P₂. This evoked potential was reproducible in both occlusion trials. The mean P₁ peak latency was measured 42 msec. No activity was consistently observed in the frontal electrodes. No peaks were observed with control R₀. These results support the hypothesis that a RREP can be recorded with an expiratory load. The distribution of the P₁ peak is consistent a bilateral sensory cortex origin. The positive peak is similar to the P₁ peak found with inspiratory occlusion suggesting that this expiratory positive peak is the initial respiratory mechanoreceptor mediated activation of the sensory cortex. Supported by NIH/NHLBI grant HL48792.

563.6

LOCALIZATION OF POTENTIAL HUMAN BRAIN REGIONS MEDIATING RESPONSES TO EXPIRATORY LOADING USING FUNCTIONAL MAGNETIC RESONANCE IMAGING. D. Gozal*, O. Omidvar, G.M. Hathout, K.A.T. Kirlaw, R. Hamilton, R.B. Lufkin, and R.M. Harper. Depts. of Anatomy & Cell Biology and Radiology, UCLA School of Medicine, Los Angeles, CA 90024-1763.

Functional MRI provides a noninvasive tool to assess spatial and temporal characteristics of neural response to respiratory stimuli. We attempted to identify human brain regions which may underlie the ventilatory response to increased expiratory resistance. To study this issue, we employed a 1.5 Tesla MR scanner, and used SPGR pulse sequences (TR: 72 msec; TE: 45 msec; flip angle: 30°; FOV: 26 cm; slice thickness: 5 mm; 128 x 256 x 1 NEX). Mid-sagittal and axial images across the rostral pons were acquired in 5 healthy volunteers during two-way valve unloaded breathing, and while applying a 30 cm H₂O resistor to the expiratory port. Digital image subtraction and ROI analysis revealed significant increases in image intensity in discrete regions of dorsal medulla, and the ventral and dorsal rostral pons. With continuous loading, increases in signal progressively diminished over time. Upon cessation of the stimulus, ROI signals immediately returned to baseline. We conclude that expiratory loading elicits consistent regional activation of discrete brain locations which differ from those which uniformly activate during inspiratory loading. We speculate that temporal changes in signal intensity may indicate either a switch to oxidative neural metabolism or habituation phenomena.

NUCLEUS AMBIGUUS AND THE VENTRAL RESPIRATORY GROUP: A CORRELATIVE ANATOMICAL STUDY OF THE RAT AND HUMAN VENTROLATERAL MEDULLA OBLONGATA. H. H. Ellenberger* and D. A. Hopkins. Department of Anatomy and Neurobiology, Dalhousie University, Halifax N.S., Canada, B3H 4H7.

The nucleus ambiguus (NA) and ventral respiratory group (VRG) in the ventrolateral medulla of the human brainstem were characterized by an anatomical comparison with homologous neuron populations in the rat ventrolateral medulla oblongata. To identify these neuron populations, we performed parallel immunohistochemical labeling studies on rat and human brainstem tissue using antibodies to choline acetyltransferase (ChAT) to label NA motoneurons, and parvalbumin (PV) to label presumptive bulbospinal VRG neurons (*Cox & Halliday, Neurosci Lett., 160:101-105, 1993*). Anatomical subdivisions of NA in the rat were identified in transverse and sagittal sections of ChAT-immunoreacted tissue. ChAT-immunoreactive neurons in the ventrolateral medulla of the human brainstem were distributed in locations and patterns that were comparable to those in the rat NA. In particular, the compact division of NA formed a distinct dorsal column in both species. By combining PV immunohistochemistry with retrograde labeling after Fluoro-Gold injections into the C4 spinal cord, we have shown that most bulbospinal VRG neurons are PV-immunoreactive in rats. Our comparison of the location and distribution of PV-immunoreactive neurons in the ventrolateral medulla of the human and rat brainstem suggests the presence of a human homologue of the rat bulbospinal VRG neuronal population.

Supported by MRC grants MT12212 (HHE) and MT7369 (DAH) and a grant from The Scottish Rite Charitable Foundation (DAH).

SOMATIC AND VISCERAL AFFERENTS: THERMORECEPTION

564.1

RESPONSES OF PRIMATE CUTANEOUS NOCICEPTORS EVOKED BY NOXIOUS COLD. D.A. Simone*, H.D. Gilchrist† and K.C. Kajander†. [†]Neurosci. Res. in Psychiatry and [‡]Depts. of Oral Science and Cell Biology & Neuroanatomy, Univ. of Minnesota, Minneapolis, MN 55455.

Unlike heat pain, the peripheral neural mechanisms underlying sensation of cold pain are poorly understood. Although many studies have examined responses of cutaneous nociceptors to noxious heat and stimulus-response functions have been well described, responses of nociceptors to cold stimuli have not been well characterized. We have examined responses of cutaneous nociceptors to controlled noxious cold stimuli. Single fiber recordings were made from the saphenous nerve in anesthetized monkeys. Nociceptors were located by mildly pinching the skin and receptive fields mapped using von Frey filaments. Conduction velocity, mechanical threshold (von Frey), and responses to thermal stimuli were assessed. Heat stimuli of 39-51°C (5 sec duration) and cold stimuli of 30 to -14°C (5 or 10 sec duration) were applied from a base temperature of 32°C and delivered in ascending or descending order.

Recordings were made from 9 Aδ and 6 C-fiber nociceptors. Mechanical thresholds for Aδ and C-fibers ranged from 5.5-149.3 mN and from 0.61-19.6 mN, respectively. Under normal conditions only one A-fiber was excited by noxious heat. In contrast, all were excited by noxious cold stimuli with a mean response threshold of -4.2°C (range: 8° to -12°C). 7 of 9 A-fibers had a response threshold below 0°C. All C-fiber nociceptors were excited by both noxious heat and cold stimuli. The mean response threshold to cold was 15.3°C and thresholds ranged from 30° to -2°C. Unlike Aδ fibers, 5 of 6 C-fibers exhibited response thresholds ≥ 0°C. Responses of both A- and C-fibers typically increased monotonically as stimulus temperature decreased. It is concluded that: 1) Aδ and C "mechanonociceptors" are excited by noxious cold and 2) C nociceptors contribute to cold pain at temperatures above 0°C, while both Aδ and C nociceptors contribute to pain sensation evoked by temperatures below 0°C. Supported by NS31223 and NS29567.

RESPONSE CHARACTERISTICS OF REGENERATING COLD-SENSITIVE CORNEAL C-FIBERS. S.Monroe* & D.L. Tanelian. Dept. of Anesthesiology and Pain Mgt, UT Southwestern Med. Ctr., Dallas, TX 75235-9068.

To date, there has been no quantitative, systematic, study of the electrophysiology of regenerating cold receptors. This study, therefore, examines the changes in cold-receptor neural activity following a circular wound (5 mm dia, 200 um deep) on the surface of the rabbit cornea. This is a well studied wounding model, in which neural regeneration has been anatomically quantified. Extracellular recordings were obtained from a total of 90 single cold fibers, at 1, 3, 10, 20, or 30 days following wounding. Conduction velocities for regenerating cold-fibers were similar to those recorded from normal fibers, 0.65 +/- .03 and 0.96 +/- 0.22 M/sec, respectively. The adapting temperature was 35°C in all experiments. Thermal sensitivity for each fiber was determined using a series of temperature steps, 0.2°C ranging from 35 to 34°C, and 2°C steps ranging from 35 to 24°C. The rate of temperature change ranged from 0.2 to 1°C/sec. At the adapting temperature, the tonic activity of the regenerating cold-fibers was not significantly different from normals. On day 1, regenerating fibers showed decreased responsiveness to cooling (p<.05). At days 3 and 10 post wounding, action potential rates in response to cooling were enhanced by 180 - 200% of normal (p < .05) and returned to pre-injury values by 20 to 30 days post wounding. There was no difference in the slope of the rate of cooling vs action potential frequency at any time point from pre-injury through the 30 day regeneration period, suggesting that the cold transduction mechanism itself was not altered during regeneration. Beuerman & Rozsa (1984), using the same experimental wound in rabbit corneas, reported elevated neurite density between 3 to 14 days post wounding. This data, in combination with our electrophysiological study, suggest that the elevated responsiveness of regenerating fibers may be a result of increased transducer numbers, as opposed to alteration in the transduction mechanism. Supported by NIH grant NS28646 and Sid W. Richardson Foundation.

THERMOSENSITIVITY OF CULTURED TRIGEMINAL NEURONS T.K. Baumann*^{1,2} and M.E. Martenson¹, Division of Neurosurgery¹ & Department of Pharmacology², Oregon Health Sciences University, Portland, OR 97201

Little is known about the membrane mechanisms involved in thermal transduction because the sensory endings are inaccessible for direct study *in vivo* or in isolated tissues. However, thermo-sensitive membranes may be exposed in culture. To examine the thermal response properties of cultured somatosensory neurons we have built a miniature heat stimulator (Baumann et al., Biophys. J. 66: 442, 1994) which can stimulate individual cells. Whole-cell, patch-clamp recording techniques were used to study the thermosensitivity of cultured adult rat, rabbit, and cat trigeminal ganglion neurons. Triangular or rectangular heat stimuli (up to 20°C in amplitude, 3 to 10 s in duration) were applied every 10 to 30 s from a baseline temperature of 25 to 29°C. Responses were non-uniform, but largely reproducible. A proportion of neurons responded to heating with a depolarization and action potential discharge. Others showed the opposite behavior; they were inhibited by heating and discharged action potentials upon heat removal. Some neurons showed no overt response to changes in temperature. Following exposure to high temperatures, some neurons developed spontaneous action potential discharge, some became inexcitable. We conclude that cultured trigeminal ganglion neurons show features of thermoreceptors and heat nociceptors and may provide a useful model for studying thermal transduction mechanisms. (Supported by NSF grant IBN 92-11545.)

564.4

RATE DEPENDENCE OF COLD TRANSDUCTION IN CORNEAL C-FIBER COLD RECEPTORS. D.L. Tanelian* & S.Monroe. Dept. of Anesthesiology and Pain Mgt, UT Southwestern Med. Ctr., Dallas, TX 75235-9068.

The component of thermal energy change (i.e. rate, magnitude) which the cold receptor transducer responds to remains in question. In this study ramps and sinusoidal temperature changes were used to investigate the dependency of neural activation and adaptation on the rate and magnitude of temperature change. Single unit extracellular recordings were obtained from 54 cold units in 22 rabbits. The adapting temperature was 35°C in all experiments. Thermal sensitivity for each fiber was determined using a series of temperature steps, 0.2°C ranging from 35 to 34°C, and 2°C steps ranging from 35 to 24°C. The rate of temperature change (dT/dt) ranged from 0.2 to 1°C/sec for ramps. For sinusoids the frequency ranged from 0.07 to 0.005 Hz at a median temperature of 35°C with a +/-5°C change in amplitude. Action potential frequency (AP) was proportional to the magnitude (ΔT, 0 to -9°C) and rate (dT/dt, .2 to 1 °C/sec) of temperature change. The action potential acceleration (dAP/dt) and rate of change of adaptation were proportional to dT/dt and independent of ΔT. Sinusoidal stimulation showed that AP always peaked prior to reaching maximal ΔT, indicating that the thermal transducer mechanism does not depend on ΔT. Conversely, and more logically, AP and dAP/dt always peaked just following maximal dT/dt. Additionally, phase analysis of the sinusoidal ΔT vs AP showed the best phase correlation, at all frequencies, to be between dT/dt and dAP/dt, suggesting that it is the rate of change in temperature that is being transduced in cold receptors. We hypothesize that dAP/dt correlates better than AP with dT/dt because dAP/dt may be a reflection of cold receptor generator potential. Further studies are being done to investigate the effects of adapting temperature upon these receptor processes. Supported by NIH NS28646 and the Sid W. Richardson Foundation.

SPATIAL LOCALIZATION OF THERMAL STIMULI, AND ITS RELATIONSHIP TO DERMATOMIC ORGANIZATION. D.K. Lee, S.L.B. McGillis, and J.D. Greenspan*. Dept. of Neurosurgery, SUNY Health Science Center, Syracuse, NY 13210, USA.

Fourteen healthy subjects (4 males, 10 females) were asked to localize a thermal stimulus applied to their left distal forearm. For these experiments, two thermal stimulating probes (1.2cm diameter each) were strapped to the forearm, separated by approximately 8cm. Each trial consisted of a tone, followed by a temperature change at one of the probes. The subject then indicated at which of the two probes he/she felt the temperature change. Stimulators were oriented in one of three ways: 1) longitudinally within the C6 dermatome, 2) longitudinally within the region overlapping the C8/T1 dermatomes, and 3) transversely with one probe on the C6 and one probe on the C8/T1 dermatomes. Every day, all orientations were used, in different orders on different days. For each orientation, one block of 20 trials provided 10 stimuli at either probe. For six days, warming stimuli were used (change from 35° to 40°C), and for three days, cooling stimuli were used (change from 32° to 27°C).

For any given stimulus orientation, cooling stimuli were localized significantly better than warming stimuli. For both warming and cooling, the transversely oriented probes (across dermatomes) provided significantly better localization than the longitudinally oriented probes. Thus, the anisotropy that is well described for tactile spatial acuity is also present for thermal localization. These results suggest that cutaneous spatial information is integrated similarly for both tactile and thermal stimuli, but differently within vs. across dermatomes.

SOMATIC AND VISCERAL AFFERENTS: ANATOMY AND PHYSIOLOGY OF MECHANORECEPTION

565.1

SYNAPTIC CONTACTS BETWEEN JAW-MUSCLE SPINDLE AFFERENTS AND TRIGEMINOTHALAMIC NEURONS: A COMBINED RETROGRADE HRP AND INTRACELLULAR BIOTINAMIDE STUDY. Pifu Luo and Dean Dessem*, U. Maryland Dental Sch., Baltimore, MD 21201

Trigeminothalamic neurons were identified by retrograde HRP labeling from the VPM of the thalamus in rats. HRP-labeled neurons were found contralaterally in the supratrigeminal region (Vsup), the trigeminal principal sensory nucleus, the ventrolateral part of the trigeminal subnucleus oralis, the spinal trigeminal subnuclei interpolaris and caudalis, the reticular formation and an area ventral to the trigeminal motor nucleus (Vmo) and medial to the trigeminal principal sensory nucleus (AVM). Jaw-muscle spindle afferents were physiologically identified and intracellularly injected with biotinamide. Axon collaterals and boutons from jaw-muscle spindle afferents were found in: Vmo; Vsup; the dorsomedial part of the trigeminal principal sensory nucleus (Vpdm); the dorsomedial part of the spinal trigeminal subnuclei oralis, interpolaris (Vidm) and caudalis; the parvocellular reticular formation (PCrt) and the mesencephalic trigeminal nucleus. Trigeminothalamic neurons in Vsup, Vpdm, Vidm, PCrt and AVM were associated with boutons from intracellularly-stained spindle afferents. Trigeminothalamic neurons in Vsup, Vpdm, Vidm, and PCrt were closely apposed by up to 14 intracellularly-labeled boutons from jaw-muscle spindle afferents suggesting a powerful input to some trigeminothalamic neurons. Ultrastructural examination of Vpdm and the caudolateral part of Vsup demonstrate that the dendrites and somata of retrogradely labeled trigeminothalamic neurons are contacted by intracellularly labelled boutons in addition to unlabeled type "S" and "F" boutons. These data demonstrate that muscle spindle sensory feedback projects to the contralateral thalamus via multiple regions of the trigeminal system. Supported by NIH DE10132.

QUANTITATIVE ANALYSES OF WHISKER AND NON-WHISKER PRIMARY AFFERENTS STAINED IN THEIR ENTIRETY. P.J. Shortland*, P.M.E. Waite, J.A. DeMaro & M.F. Jacquin. Anatomy, St. Louis Univ., St. Louis MO 63104; Anat., Univ. New South Wales, Sydney 2033 Australia; Neurol., Washington Univ. Sch. Med., St. Louis MO 63110.

Prior studies suggest that some categories of A- β primary afferents have distinct morphologies in the brainstem, and that single fibers give rise to collaterals with different shapes in different trigeminal subnuclei. However, conclusions are based on relatively few and incompletely stained fibers and limited statistical rigor. Here, 86 fibers were stained with Neurobiotin in rats to provide repeated within-animal inter-subnucleus comparisons, as well as between-animal intra-subnucleus comparisons, of numeric features of collaterals associated with a vibrissa, guard hairs, hairy skin or oral structures. Qualitative features were as described before. Multiple analysis of variance and post-hoc group comparisons (Scheffe') indicated that fibers differed between subnuclei on 3 measures: collaterals were most numerous in interpolaris, arbors were largest in caudalis, and arbors were less circular in caudalis than in oralis and principalis. When subnucleus and peripheral receptor association were compared, the only reliable difference pertained to interpolaris, where vibrissa fibers gave rise to more collaterals than guard hair or oral afferents. There were no indications that a particular fiber category was disproportionately represented at particular sites along the rostrocaudal axis, although most fibers adhered to an onion-leaf topography in caudalis. Moreover, when analyses were restricted to individual subnuclei, no differences were revealed between fiber categories. Peripheral receptor association and adaptation rate failed to predict arbor dimensions, arbor circularity and bouton number in every subnucleus. We confirm that arbor location is predicted by receptive field location, but that collateral number and structure are predicted only to a limited extent by subnucleus and never by peripheral receptor. TONGUE ADAPTATION TEMPERATURE INFLUENCES THE DYNAMIC AND STATIC RESPONSES OF LINGUAL NERVE FIBERS TO THERMAL STIMULATION. Robert F. Lundy Jr* and Robert J. Contreras. The Florida State University, Program in Neuroscience, Tallahassee, FL, 32306-1051.

Previous studies have investigated the response characteristics of thermal-sensitive neurons to small temperature changes at varying adaptation temperatures in the cutaneous skin of many species including humans. The present study repeated as well as extended this line of investigation to the oral cavity. Phase 1 examined the effects of tongue adaptation temperature (35 vs. 25 °C) on the neural responses of 32 lingual nerve fibers to: (1) a 1 °C/s temperature decrease until reaching a plateau of 10 °C, and (2) menthol stimulation for 40 s. In Phase 1, two groups of fibers were identified on the basis of response latency, peak sensitivity, and range of sensitivity after adaptation to 35 °C water. In addition, the effect of menthol in the oral cavity is highly dependent upon adaptation temperature. All menthol concentrations were effective when adaptation and stimulus temperature was 35 °C. Phase 2 examined the response of 8 thermal-sensitive fibers to a 2 °C temperature decrease (at 1 °C/s) after adaptation to several different tongue temperatures. Similar to other cutaneous areas, the mean change in response rate of thermal-sensitive neurons as a function of adaptation temperature resembled a bell shaped curve with a maximal discharge at approximately 29 °C. In the present study, the change in response rate seemed to be linearly related to baseline rate since large response rates were associated with high baseline activity.

565.2

A CIRCUIT MODEL FOR WHISKER RECEPTIVE FIELDS IN NUCLEUS PRINCIPALIS. M.F. Jacquin*, J.J.A. Arends, P.J. Shortland, D.W. Doherty, J.A. DeMaro & T.A. Woolsey. Anatomy & Neurobiology, St. Louis Univ. Sch. Med., St. Louis MO 63104; Neurology & Neurological Surgery, Washington Univ. Sch. Med., St. Louis MO 63110.

There is a paucity of data on the brainstem link in the whisker-barrel neuraxis: trigeminal nucleus principalis (PrV). A circuit model has been developed to guide research aimed at explaining PrV cell responses. We view the primary afferent inputs to PrV, and the dendrites in PrV, as a complementary set of somatotopic and overlapping columns. Regions of overlap are not revealed by histochemical or glucose uptake methods due to their low sensitivity or processing that suppresses transmission at border zones. Available data suggest that: adjacent whisker primary afferents interdigitate in PrV's transverse plane, dendrites from thalamic-projecting and GABAergic cells in PrV span multiple columns, spinal V and cortical inputs to PrV are point-to-point, and most PrV cells have 1-whisker receptive fields. The model must then include local and higher-order modulatory mechanisms. One possible scenario is that the B1 whisker receptive field, say, is produced in the B1 column by neighboring (e.g. B2) whisker activation of GABAergic cells in the B2 column via primary afferent, spinal V and cortico-V projections, which then inhibit transmission of B2 primary afferent inputs to more distal B1 dendrites extending into the B2 column. Spinal V and cortical inputs to the B1 column end on more proximal dendrites to amplify responses to the B1 whisker. Many predictions follow; for example: cells in the B1 column should receive synaptic inputs from B1 and B2 primary afferents, as well as from spinal V's B1 column via local circuit axons, and from the B1 barrel via the cortico-V pathway. GABA cells in PrV's B2 column should terminate on distal dendrites of B1 cells and receive inputs from B2 primary afferents, as well as from spinal V's B2 column and from the B2 barrel. THE POSSIBLE INPUTS OF GABA-IMMUNOREACTIVE NEURONS IN THE CUNEATE NUCLEUS OF THE RAT. C.Y. Wen*, J.H. Lue, K.N. Chen and J.Y. Shieh. Dept. of Anat., College of Med., Nat'l Taiwan Univ., R.O.C.

After chloral hydrate anaesthesia, the rat were injected 0.2ul of 2% of wheat germ agglutinin conjugated with horseradish peroxidase (Sigma, WGA-HRP) into the forelimb area of the primary somatosensory cortex in six rats or into the brachial plexus in another six rats to label respectively the corticocuneate terminals (CCTs) and the primary afferent terminals (PATs). 24 to 36 h survival, the animals were perfused fixed with a mixture of aldehydes (containing 0.5% glutaraldehyde and 4 % paraformaldehyde in 0.5M phosphate buffer) under slightly overdose of chloral hydrate. Vibratome sections of the cuneate region were cut and incubated with anti-GABA antiserum (Incstar) to label the GABA-immunoreactive (GABA-IR) neurons. Some of ultrathin sections, which were proved to have definite synapse between PAT and GABA-IR terminals, with anti-glutamate antiserum (Sigma). The results showed that: (1) the labeled CCTs made predominantly contact with dendrites of the GABA immunonegative neurons. On the other hand, the PATs made direct contact to the profiles of the GABA-IR neurons, (2) some GABA-IR boutons were found to form axosomatic and axodendritic synapse other GABA-IR neurons, (3) triple labeling of the same sections for the GABA, the PAT and the glutamate-IR terminals revealed that PATs, which were glutamate positive, were presynaptic to the dendrites of GABA-IR neurons, while a few none-PAT glutamate-IR terminals, which were unlabeled by WGA-HRP, synapsed with the dendrites and the somata of the GABA-IR neurons. MECHANISTIC MODELS FOR TACTILE NEURAL CODING OF SHAPE.

M.A. Srinivasan* and K. Dandekar, Dept. of Mechanical Engineering and Research Lab. of Electronics, MIT, Cambridge, MA 02139.

The relationship between the biomechanics of primate fingertip and the responses of slowly adapting mechanoreceptors (SA-I) in the tactile sensing of object shape was investigated. Finite element analysis was performed on a progressively realistic series of mechanistic models of the primate fingertip under a variety of shape stimuli. The external shape of the models ranged from a circular cylinder of about the same diameter as typical primate fingertips to realistic 3-dimensional fingertips. The latter were generated from video images of accurate epoxy copies of monkey and human fingertips at various known orientations, obtained by using a videomicroscopy system. The internal geometry consisted of a central rigid bone enclosed by either a homogeneous or a layered material. The stresses, strains and deformations calculated from the models were correlated with data from both biomechanical experiments on fingertip deformations and neurophysiological experiments on the responses of SA-I.

In all the models, the strain energy density and the maximum compressive strain were the leading contenders to be the *relevant stimulus* for SA-I. Because the models took into account the curvature and finiteness of the primate finger, the predictions of SA-I population responses to rectangular gratings indented into the fingerpad were more realistic than the predictions from previously proposed flat, semi-infinite model (Phillips and Johnson, J. Neurophys., 46(6), 1981). Although these population responses were radically different from the previous predictions, the spatial response profiles matched the neural data as well as before. In addition, the new models predicted that the spatial response profile of a receptor was strongly dependent on its location with respect to the center of contact region on the fingerpad. Analysis of the nonlinear mechanics of contact between the models and cylindrical indentors of various radii demonstrated good correlation between strain measures at the receptor site and corresponding neural response. A VARIABLE THRESHOLD MECHANORECEPTOR MODEL. F.J. Looft*, S.S. Hsiao*, and K.O. Johnson*. Dept. of Elec. and Comp. Eng., Worcester Polytechnic Institute, Worcester, MA 01609 and *Krieger Mind/Brain Inst. and Dept. of Neurosciences, Johns Hopkins University, Baltimore, MD 21205.

The responses of primary mechanoreceptive (SA, RA and PC) afferents in macaque monkeys were studied using a sinusoidal vibratory stimulus and a two-pulse condition-test paradigm (CT). The CT experiments consisted of presenting either a mechanical or electrical conditioning pulse followed by a mechanical test pulse. For sub-threshold conditioning pulses and CT delays 2 msec and greater, the mechanical test pulse amplitude required to elicit an action potential was essentially invariant - a result that would occur if there was no residual membrane depolarization. By comparison, the use of a supra-threshold conditioning pulse required a significantly increased test pulse amplitude to generate an action potential. Supra-threshold CT experiments showed that threshold recovery following an action potential is closely fit by a two-exponential decay function that has fast (1-5 msec) and slow (15-40 msec) time constants. These results suggest that a previous mechanoreceptive model [J. Physiol. 323:43-64, 1982] was flawed since these authors had assumed that threshold is reset immediately following an action potential and that there is a substantial residual membrane depolarization following sub-threshold stimuli. A revised mechanoreceptive model in which threshold recovery was modeled by an exponential decay resulted in significant improvements in fits to the responses of mechanoreceptive afferents to sinusoidal stimuli. In addition to effectively modeling the statistical regularity of the impulse trains, the variable threshold model also properly predicts the initial increase followed by a subsequent decrease in impulse phase retardation with increasing stimulus frequency. Finally, the model predicts that the neural responses are only slightly affected by noise bandwidth or absolute refractory period and are moderately sensitive to the shape of the generator potential.

ACTIVITY-DEPENDENT CHANGES IN CONDUCTION LATENCY: A PROBE OF MODAL SPECIFICITY OF MECHANOSENSITIVE AFFERENTS IN RAT. S.S. Waikar, J.G. Thalhammer*, S.A. Raymond, D.S. Chang, and G.R. Strichartz, Anesthesia Research Laboratories, Brigham & Women's Hospital, Harvard Medical School, Boston, MA 02115.

Impulse activity in axons generates aftereffects on membrane excitability that can alter the conduction velocity of subsequently conducted impulses. We used computerized stimulus patterns to assess *in vivo* activity-dependent changes in conduction latency of functionally identified rat cutaneous afferents from the posterior tibial branch of the sciatic nerve. We measured several different parameters of activity dependence: super- and subnormality, a decrease or increase in conduction latency following conditioning with a single preceding impulse; depression, an increase in conduction latency during tetani; and recovery, the time to return to baseline conduction latency following these tetani. Taken together, these parameters generate a "profile" of the activity dependence of a fiber's conduction latency. We have shown previously that such profiles of nociceptor and cold receptor afferents correlate with modality; our current work extends this investigation to mechanosensitive afferents. We wished to determine whether diameter-matched afferents (inferred from matched resting conduction velocity) of two different types of functionally identified mechanoreceptors differed in activity dependence of conduction latency.

Axons of Pacinian corpuscles (PC; n=3) and rapid adapting mechanoreceptors (RA; n=6) of the glabrous skin were examined for activity-dependent changes in conduction latency using a standardized stimulus protocol. Five of the six isolated RAs exhibited subnormality, i.e., the second of two impulses initiated within 5 msec of another conducted less rapidly than the first. By contrast, only one PC exhibited subnormality. PC and RA latency changes differed significantly during 20 separated bursts of 10 stimuli at 200 Hz in the mean normalized difference between the first and second impulse latency: in all three PCs the latency of the second impulse of the burst was supernormal, while in six of seven RAs the latency was subnormal ($p < .05$). Our data suggest that differences in function among mechanoreceptors in the glabrous skin may extend into their axons' conduction properties. (NIH USPHS GM 35647)

RESPONSES OF CUTANEOUS MECHANORECEPTOR AFFERENTS TO STEP AND SINUSOIDAL SKIN DISPLACEMENTS. J. C. Makous*¹ and S. J. Bolanowski^{1,2}.

¹Institute for Sensory Research and ²Department of Bioengineering and Neuroscience, Syracuse University, Syracuse, NY 13244-5290

Neural activity was recorded from more than 100 nerve fibers innervating the glabrous skin of the cat hind-paw. Action potentials from individual nerve fibers of the medial plantar nerve were monitored in response to sinusoidal displacements of the skin ranging in frequency from 1 to 500 Hz and in amplitude from threshold to 250 μ m. The same fibers were also characterized in response to step indentations (2 ms rise-time) of the skin over a similar range of intensities. In addition, receptive fields were mapped with von Frey hairs, and conduction velocities were measured. Fibers were characterized on the basis of these responses and were classified as slowly adapting (SAI, SAII), rapidly adapting (RA) or Pacinian corpuscle (PC) afferents. Vibratory stimulation revealed frequency characteristics of the RA and SA fibers that often spanned the range of 1 to 200 Hz. The PC fibers were typically tuned with a peak sensitivity near 250 Hz. The SA fibers showed a transient and a sustained response to steps, whereas the RA and PC fibers showed only transient responses to steps. Peri-stimulus-time histograms revealed that, at the highest amplitudes of stimulation (> 25 dB above threshold), the step-responses showed periodicity of firing for the majority of fibers studied. Interval histograms demonstrated that the periodicity ranged from about 3 to 35 ms depending upon the fiber type. The PC and RA fibers tended to have shorter inter-spike intervals in response to the steps than the SA fibers. Supported by NINCDS RO1-DC00380.

565.8

ADAPTATION OF MECHANORECEPTIVE AFFERENTS TO CONTINUOUS SINUSOIDAL VIBRATION. Y.Y. Leung, S.S. Hsiao and K.O. Johnson*. Kreiger Mind/Brain Inst. & Dept. of Neuroscience, Johns Hopkins Univ., Balt. MD. 21205.

The effects of stimulus duration, amplitude and frequency of an adapting sinusoidal stimulus on thresholds of rapidly adapting (RA), slowly adapting (SA) and Pacinian (PC) mechanoreceptive afferents were studied. Recordings were made from median and ulnar nerves of 3 anaesthetized monkeys while vibration was delivered via a 1 mm diameter probe glued to the skin. Experimental trials consisted of an adaptation period containing the adapting vibratory stimulus and a recovery period in which no adapting stimulus is applied. During both periods, a sinusoidal test stimulus was presented once every 4 secs to track changes in absolute and entrainment thresholds. This testing rate was determined to have minimal effects on thresholds. The amplitude of the test stimulus was systematically varied between tests to evoke between 0 and 1 impulse per stimulus cycle for the duration of each test stimulus. Adapting and test stimulus frequencies of 10, 30, and 60 Hz were used for SAs; 30, 60 and 100 Hz for RAs; and 60, 100, and 300 Hz for PCs for a total of 9 combinations of test and adapting frequencies for each afferent type. Amplitudes of the adapting stimulus ranged from 2 to 30 times absolute threshold and were applied for durations of 1, 2, 4 or 8 min.

All afferents (6 SAs, 8 RAs, and 5 PCs) exhibit increases in thresholds with increases in either the adapting stimulus amplitude or frequency; there is about a 1 to 10 elevation in threshold over the range of frequencies and amplitudes studied. SA and RA thresholds increase and recover rapidly ($\tau = 10-30$ sec) during both the adapting and recovery periods with stimulus durations greater than 1 min having no effect on the time constants nor on the level of adaptation. PC afferents adapt slowly ($\tau > 5$ min) with the thresholds of some PCs still increasing after 8 min of stimulation. The PCs exhibit variable recovery time constants (30 sec to 6 min) and often have a small residual elevation in thresholds 50 min after the adapting stimulus was discontinued.

TACTILE SIGNALS GENERATED BY A TOOL USED TO DISCRIMINATE THE SOFTNESS OF OBJECTS. R.H. LaMotte*, J. Zhang and J. Yan, Department of Anesthesiology, Yale University School of Medicine, 333 Cedar Street, New Haven, CT 06510.

Subjects were 90-100% correct in ranking the softness of 9 rubber disks that differed in compliance (1.8 to 10.9 um/g) either by indenting each specimen with the fingerpad, or by tapping each with a stylus held between two fingers. In order to study the role of tactile signals, the back of a finger was rigidly mounted to a load cell. One end of the stylus indented the volar distal pad with a base force of 20 g-wt, maintained by a servocontrolled motor, and the other end tapped with a specimen held by the experimenter. Subjects were able to discriminate between hard (≤ 1.8 um/g-wt) vs. soft (≥ 7.7) specimens and a "medium soft" standard of 4.0 um/g-wt when the velocity of tapping was held approximately constant. The perceptions of softness felt "natural" as did a tap-evoked sensation produced when a previously recorded force trace from a specimen was "played back" through the motor. Subjects were unable to discern whether a "live" or a "played-back" trace was delivered. It was found that perceived softness depended primarily on the slope of the initial segment of the rising phase of the force trace which, for hard specimens, changed little with moderate variations in tapping force and velocity in comparison with that for softer specimens. The perceived softness of softer specimens decreased with increasing tap velocity suggesting that, for these specimens, passive touch without independent information about velocity may not be sufficient for reliable discriminations of softness. It is hypothesized that the greater the initial force rate, the more likely that rapidly-adapting as opposed to slowly-adapting mechanoreceptors will be engaged and convey the tactile signals associated with the perceived softness of objects. (Supported by ONR URI grant# N00014-92-J-1814)

INTERLAMELLAR FLUID DYNAMICS OF THE PACINIAN CORPUSCLE (PC). B. Pietras* and S.J. Bolanowski. Institute for Sensory Research and Bioengineering and Neuroscience, Syracuse University, Syracuse, NY 13244.

Receptor potentials recorded from isolated PCs in response to sinusoidal vibrations have been shown to have non-linear asymmetrical input-output functions and U-shaped frequency characteristics. The PC's accessory capsule was studied both experimentally and theoretically to determine its mechanical contribution to the observed non-linear receptor potential. During compression of the accessory capsule, a shear stress is created and inter-lamellar fluid flows with velocity components orthogonal to the direction of displacement. The viscosity of the fluid imparts a resistance to the shear stress which arises as a force parallel to the compression. Inter-lamellar fluid is considered to be incompressible and, at the velocities considered here, to have a resistive force proportional to its velocity. Measurements of reactive force in response to sinusoidal displacements have shown that the reactive force is linear and increases with increasing frequency and amplitude. Furthermore, the reactive force can be described by a first-order linear differential equation of the form $f(x,t) = kx + c \, dx/dt$. A series of first-order linear differential equations was used to compute the inter-lamellar fluid velocities and lamellar displacements for a range of frequencies, stimulus amplitudes, and probe sizes. Computational simulations of the inter-lamellar fluid flow in response to sinusoidal displacement of the surface of the capsule shows that the multi-layered structure linearizes the inter-lamellar fluid velocity, thus linearizing the inter-lamellar compressive force. Video analysis of PCs subjected to a static stress shows that the stress load is carried by the outermost lamellae. Indeed, it is only during a highly time-dependent displacement of the surface (frequencies above 40 Hz) that a strain is observed below the outermost lamellae. Video analysis and computational simulations also show that the multi-layered capsule acts as a mechanical high-pass filter. Furthermore, the compressive strain and reactive forces increase with stimulus frequency. Thus the non-linear asymmetrical input-output function and the U-shaped frequency response cannot be mechanical in origin and must arise from intrinsic neural properties of the neurite. A SECOND SYSTEM FOR INNOCUOUS MECHANORECEPTION IN THE HUMAN SKIN. H. Olsson, N. Kadu, J. Wessberg and Å.B. Vallbo. (SPON: European Neuroscience Association). Department of Physiology, Göteborg University, Medicinargatan 11, S-413 90 Göteborg, Sweden.

In various mammals many unmyelinated (C) afferents respond to light touch. In man on the other hand, C-fibers with sensory functions have been identified almost exclusively with the senses of pain and temperature. For that reason it has been suggested that an older and slowly conducting system for innocuous mechanoreception has faded away during the evolution.

Using the microneurography technique we have now found low threshold mechanoreceptors with conduction velocities within the unmyelinated region to be frequent in the hairy skin of the human forearm. The impulse rate associated with clearly innocuous mechanical stimulus amounted to 100 imp/s, leaving no doubt that light touch was the adequate stimulus. The thresholds to v Frey hairs ranged between 0.01 and 8 g with a median value of 0.25 g. The conduction velocity assessed using electrical or mechanical stimulation ranged between 0.7 and 1.0 m/s. For some units the receptive fields were explored in detail using a scanning method. The fields were found to be fairly large (10 mm x 5 mm) and composed of multiple areas of different sensitivity.

Our study showed that low threshold mechanoreceptors are common in the hairy skin of the human forearm. It suggests that the human body is provided with a widespread system for innocuous mechanoreception subserved by C-fibers.

INHERENT FIRING PATTERNS OF MUSCLE AFFERENT AXON TERMINALS ARE GRADUALLY LOST IN CHRONIC NEUROMAS.

J.B. Munson and R.D. Johnson. Depts. of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

We have previously shown that following transection and cross-regeneration of cat medial gastrocnemius (MG) muscle nerve into the sural nerve skin territory, large diameter muscle afferent fibers retained their stretch-sensitive and slowly-adapting firing patterns despite the presence of a foreign target devoid of muscle receptors. We have also shown that in short-term 6-day neuromas, even the sprouts of axotomized muscle afferents retained these native firing patterns. Since the characteristic patterns were evident for at least 2 years in skin, we designed the present study to determine if these firing patterns could be obtained from muscle afferent sprouts in long-term neuromas.

In adult cats, the MG nerve was transected and the proximal end sutured into a blind-ending Gore-Tex sleeve. Following a recovery period of 3-16 months, the mechanosensitivity of sprouted afferents was tested by recording from dorsal root filaments while mechanically stimulating the neuroma. Compared to afferents from 6-day neuromas, afferents from long-term neuromas were significantly more difficult to mechanically activate and showed a progressive decrease in conduction velocity, stretch-sensitivity, and slow-adaptation properties.

We suggest that the rescue of these physiological properties may be dependent on trophic factors present in peripheral targets such as muscle and skin but absent in chronic neuromas. Supported by NS15913 and NS27511.

STRETCH SENSITIVITY OF SA2 MECHANORECEPTORS IN ISOLATED RAT SKIN. Peter Grigg*. Department of Physiology University of Massachusetts Medical School, Worcester MA 01655

SA2 mechanoreceptors were recorded in a preparation of skin (approx. 20 mm square) isolated from the hindlimb of rats and studied in vitro. Responses of afferents were recorded from filaments of the femoral nerve. The skin was subjected to pure in-plane stretching, by pulling on 12 tabs that were cut along its edges (3 tabs / side). Each tab was coupled to a miniature tensile load cell, and was actuated with a miniature linear actuator. Loads measured at the tabs were used to calculate tensile and shear stresses in the skin. Deformations of the skin were measured by optically tracking a set of opaque markers that were fixed to the skin surface. While there were many afferents with rapidly adapting responses to in-plane skin stretching, relatively few SA2s were observed in these preparations. The SA2s were readily activated by stretching the skin. Their responses were strongly determined by uniaxial stresses or strains. There was no strong relationship with shear stresses or strains. Biaxial stresses and strains were ineffective stimuli. Supported by NIH grant NS-10783

A NOVEL METHOD FOR SELECTIVE ELECTRICAL STIMULATION OF SMALL DIAMETER NERVE FIBERS. J.C. Petruska* and R.D. Johnson. Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

There is a good deal of evidence that the small diameter nerve fibers in peripheral nerves, the thinly myelinated A-delta fibers and unmyelinated C fibers, display a high degree of central and peripheral plasticity in response to injury to the nervous system. The electrophysiological investigation of specific spinal cord input from these fibers is difficult because standard electrical stimuli recruit large myelinated fibers before small fibers. We have designed the following method for selectively stimulating small fibers.

In urethane-anesthetized rats, the caudal cutaneous sural and sciatic nerves were surgically isolated. A lumbar laminectomy was performed to isolate dorsal root filaments for recording. A bipolar Ag/AgCl electrode was placed around the sural nerve for stimulation of various fiber groups. Specially fabricated Ag/AgCl ring electrodes producing differential current densities were placed around the sciatic nerve. Using an arbitrary-waveform constant-current stimulus isolator and a modified triangular stimulus waveform, an anodal polarization block of sural-activated large A fibers was achieved at the sciatic site, allowing only the smallest A-delta and/or C fibers to conduct through to the dorsal root filaments.

This method could be used to study the input from small fibers into the spinal cord and/or the peripheral target tissue without the contamination by large myelinated fibers. Supported by NS 27511.

SHORT-TERM CHANGES IN EFFICACY OF CORTICOCORTICAL EPSPs IN RACCOON PRIMARY SOMATOSENSORY CORTEX. P. Zarzecki and P. Isvan, MRC Group in Sensory-Motor Physiology, Depart. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Neurons in the cortical representation of glabrous skin of raccoon digits receive input from their "on-focus" digit by direct thalamocortical connections. Weaker and less common inputs from "off-focus" digits are probably relayed by a corticocortical pathway from the heterogeneous zone a few mm rostral to the glabrous zone. "Off-focus" inputs quickly become more effective during short-term cortical plasticity, a change that could come about from altered function of corticocortical synapses.

Our purpose was to test for short-term plasticity in the corticocortical pathway from the heterogeneous zone to the glabrous zone. Neurons were recorded intracellularly in the representation of glabrous skin in primary somatosensory cortex of raccoons anesthetized with Nembutal. Short latency corticocortical EPSPs were recorded following electrical stimulation (5 Hz) of the heterogeneous zone. Corticocortical synaptic responses were paired with simultaneous depolarizing current steps (up to 3 nA, 100 ms duration) injected intracellularly. Pairings of EPSPs with depolarizing current steps (50 pairings at 5 Hz) caused enhancement of corticocortical EPSPs lasting beyond the period of pairing. Enhanced EPSPs that were subthreshold before pairing usually evoked spike discharges after pairing. The effect was short-term (1 to 2 min), reversible, and reproducible in repeated pairing cycles. Thus, corticocortical EPSPs that could be relaying "off-focus" somatosensory inputs can be enhanced by occurring during depolarization of the target neuron by another input. Remaining questions are whether somatosensory EPSPs are also enhanced after corticocortical EPSPs are paired with current steps, and whether any such effects on somatosensory responses are restricted to "off-focus" inputs.

Supported by the Medical Research Council of Canada.

SEQUENCE OF EVENTS IN THE DEVELOPMENT OF LAMINATION, INTRINSIC AND EXTRINSIC CONNECTIONS IN FERRET SOMATOSENSORY CORTEX. S.L. Juliano, R.V. Sonty, S. Palmer, P. Awenowicz, Depts. of Anatomy & Neuroscience, USUHS, Bethesda, MD.

Despite the relative immaturity of ferret nervous system at birth, we previously demonstrated that axons of thalamic neurons reach the somatosensory cortex by PND 1, and are organized into distinct clusters by PND 5. Horizontal connections, in contrast, do not display a clustered organization until PND 28. To more precisely define the development of intrinsic and extrinsic connections in relation to laminar development, we used slices of ferret brains aged PND 1-28. After injections of fluorescein-labeled dextran the slices were maintained in an oxygenated chamber to allow for transport of the tracer. On PND 1-3, injections into the deeper layers of cortex, or subcortical white matter, led to a slim radial column of labeled cells that extended from the upper portion of the cortical plate to the base of the ventricular zone. The labeled radial column contained both radial glia and neurons migrating to their proper positions within the neocortex. The cells within the column did not extend axons into the cortex, although horizontally-running fibers were seen beneath layer 6. In contrast, injections into the superficial cortical plate led to labeled neurons that extended their axons tangentially. Comparison with the locations of cells labeled with BRDU and born from E22-E38, indicate that neurons destined to occupy all cortical layers are present in the cortex by PND 1. At PND 1, injections into the white matter labeled thalamocortical axons that terminated in crude clusters within the neocortex. With increasing age, the deeper injections lose their radial character and by PND 14 many axons extend into all cortical layers. After injections into more superficial cortical sites, a continuous band of labeled cells can be seen in layers 2-3. By PND 28, injections into the upper layers results in discrete clusters of labeled cells in layers 2-3. Supported by NS24014.

FACTORS THAT INFLUENCE NEURONAL RESPONSE VARIABILITY IN SOMATOSENSORY CORTEX: THE ROLE OF NMDA RECEPTORS.

D. Prince, B. Whitsel, M. Tommerdahl, O. Favorov, Departments of Biomedical Engineering and Physiology, University of North Carolina, Chapel Hill, NC 27599.

Potentials evoked in rat sensorimotor cortical slices by single-site stimulation of the white matter were examined (i) to determine the effects of stimulus frequency and intensity on intertrial response variability (hereafter referred to as response variability) in SI neurons, and (ii) to evaluate the prediction that response variability is an indicator of the degree of cortical NMDA receptor activation (Lee and Whitsel, 1992). Evoked potentials (EPs) were recorded for 50 to 100 consecutive stimulus presentations at a given stimulus frequency and intensity (frequencies between 0.2 - 5 Hz and intensities between 1.0 - 3.5 times the minimum intensity required to evoke a response). Magnitude of the EP for each trial was determined by integrating the EP over the duration of its post-synaptic component; response variability was calculated as the coefficient of variation of the EP magnitude for all responses recorded for each stimulus condition. To ascertain the contribution of the NMDA receptor population to response variability, some experiments were performed following application of ketamine, a selective NMDA receptor antagonist. A direct relationship was found between response variability and stimulus intensity. As intensity was increased, variability decreased linearly, and the slope increased over the range 0.2 to 5 Hz. The relationship between response variability and stimulus intensity and the effects of stimulus frequency on this relationship were observed more clearly at more superficial sites in SI cortex (those containing the highest density of NMDA receptors). Moreover, blocking NMDA receptors with a selective antagonist decreased the dependency of response variability on stimulus intensity in a dose-dependent manner. This work was supported in part by NIMH RO1 MH48654 and the Whitehall Foundation.

QUANTITATIVE ANALYSIS OF DEVELOPING INTRINSIC CONNECTIONS IN THE CAT SOMATOSENSORY CORTEX. R.V. Sonty and S.L. Juliano, Depts. of Anatomy & Neuroscience, USUHS, Bethesda, MD 20814.

Clustered intrinsic connections in the cat somatosensory cortex (SSC) develop from an initially diffuse network in the early postnatal period. Although the shift from relative homogeneity to intermittent clusters can be observed visually, the transition is not easy to define. As a result we found it important to quantify the developmental sequence of events to more clearly identify the changes that occur in intrinsic cortical development. To do this, confocal images were obtained from coronal or horizontal sections taken through Dil-labeled kitten SSC at various postnatal ages. Several statistical tests were conducted in order to analyze the clustering of retrogradely labeled neurons and the distribution of tangential fibers emanating from the injection site. For some tests, individual sections were drawn to indicate labeled neurons. We analyzed neuronal clustering using spatial point process analysis. The null hypotheses stated that the distribution of labeled neurons at each age, did not differ from CSR (complete spatial randomness). Quadrat counts showed a change from a random distribution on PND3 ($p=0.786$) to a clustered one on PND6 ($p=0.001$). A refined nearest neighbor analysis confirmed conversion from a random distribution on PND3 ($p=0.43$) to a clustered distribution on PND6 ($p=0.01$). Other tests (dispersion indices, density recovery profiles, etc.) verified the transformation of a diffuse organization of neurons to a clustered one. Coronal sections on PND15 confirmed a patchy distribution of intrinsic connections resembling the adult distribution. The numbers of labeled neurons were significantly higher in clusters than in the intercluster zones ($p<0.001$) on PND6. Profile plots (reflecting axonal distributions) revealed a significant periodicity (center-to-center $\sim 750\mu\text{m}$) on PND6. We demonstrate that the study of local circuit development in the cerebral cortex is amenable to formal statistical analyses. Support: PHS NS24014.

DYNAMIC PATTERNS IN COLUMNAR DISTRIBUTION OF SYNAPTIC ZINC IN DEVELOPING RAT SOMATOSENSORY CORTEX. R.H. Dyck, N.L. Ruff, and D.D.M. O'Leary, Molecular Neurobiology Lab, The Salk Institute, La Jolla, CA 92037.

A subset of excitatory synapses in the mammalian telencephalon contain zinc within synaptic vesicles of their terminal boutons. In this study we describe the normal distribution of zinc in the somatosensory cortex of rats during postnatal development.

In the adult rat, specific staining for zinc is lowest in lamina 4 but demarcates the barrel pattern by staining at highest levels in the barrel septa. This pattern of zinc staining gradually arises during postnatal development as a result of complex tangential and laminar redistributions during the first 4 weeks. Zinc staining in somatosensory cortex was minimal at birth (P0). From P0 to P4, levels of zinc gradually increased across cortical laminae in a deep to superficial gradient, but a barrel-related pattern was not evident. Subsequently, the increase in the density of zinc staining within layer 4 was heterogeneous across its tangential extent. By P7 the highest levels of zinc clearly demarcated the barrel fields, but by heavily staining the barrel hollow and lightly staining the barrel septa. During the second and third weeks, zinc staining was reduced within barrel hollows with a distinct spatiotemporal pattern. For example, an adult-like pattern of zinc staining was attained by P12 in the posteromedial barrel subfield but not until P21 in the anterolateral division.

Thus, the distribution of excitatory inputs, defined by synaptic zinc, undergoes distinct spatiotemporal changes during the first 3 postnatal weeks. This process may reflect a differential maturation of the functional organization within barrel cortex.

NMDA RECEPTOR EXPRESSION IN THE RAT TRIGEMINAL PATHWAY TO BARREL FIELD CORTEX DURING DEVELOPMENT. V. Remy and E.E. Ebner, Institute for Developmental Neuroscience, Kennedy Center, Vanderbilt University, Nashville, TN 37203

Polyclonal antibodies against the C-terminal and N-terminal domains of the NMDAR1 subunit were produced to analyze changes in expression of NMDA receptors during normal postnatal development of the trigeminal pathway relays to rat barrel field cortex. At P-0 there is already substantial expression of NMDAR1 subunit in the trigeminal (V) complex, the VPM, POM + intralaminar thalamic nuclei, and in barrel field cortex. From birth to P-180 there is relatively high level of NMDAR1 expression in the V complex, with slight variations in the intensity of staining detectable as a peak at P-30 and a gradual slight reduction from P-30 to P-180. Around P-40 a single row of intensely immunoreactive cells is noteworthy along the line between the spinal V tract and nucleus. The VPM nucleus is uniquely outlined by its intense staining from P-3 to P-40 when it blends with the moderate subunit density seen throughout the mature thalamus. POM has a more gradual onset to peak densities at P-21 that are always less intense than VPM. Intra-laminar nuclei, especially CL, peak even later at P-35, retaining scattered cells that express high levels of NMDAR1 for up to 12 months. Overall staining intensity in the barrel cortex increases from P-3 to P-21, when staining appears more diffuse due to a transient expression of NMDAR1 by astrocytes, which appear vividly in fiber tracts such as the corpus callosum and fornix. At P-30, NMDAR1 is only marginally lower than P-21, but at P-35 & P-40 neurons in layers IV + VI show markedly decreased expression. Analysis of the most intensely labeled pyramidal cells in layer V of the barrel cortex shows very intense staining at P-3 & P-7 which reduces through P-14, P-21 & P-30. The expression in these cells again goes up at P-35 where they remain for as long as 12 months. These differences are currently being quantified by Western & Northern blots + *in situ* hybridization. LOCALIZATION OF NMDAR1 SUBUNIT IN RAT LAYER IV BARREL CELLS. F.F. Ebner*, S.-M. Lu, V. Rema, W. Huang, M. Armstrong-James & A. Banerjee, Inst. for Dev. Neuroscience, Kennedy Center, Vanderbilt University, Nashville, TN 37203.

NMDAR1 subunits were localized with immunocytochemical methods in sections cut tangential to the cortical surface. In layer IV barrels, a striking pattern of NMDAR1 immunoreactivity was created by the presence of a small number of densely labeled, large somata in the periphery of the barrels whose dendrites point toward the center of the barrel. These cells have intensely staining puncta, roughly 1 μ m in diameter, on their soma and dendrites, plus diffuse cytoplasmic labeling. Since NMDAR1 can form functional NMDA channels, the aggregates on the cell membrane suggest that the puncta are active glutamate receptor sites. These cells exhibit multipolar dendritic morphology and few spines suggesting that they are aspiny, GABAergic, stellate cells. The distribution of these cells and their high content of NMDAR1 further suggest that they may be extraordinarily sensitive to changes in sensory activity levels arising from the whiskers and from other barrels. These cells are surrounded by many other cells containing far lower levels of reaction product that is seen almost exclusively in their cell body. In addition to layer IV cells, each barrel contained a few clusters of densely labeled, small, circular profiles that we interpreted as cross-sections through some of the apical dendrite bundles of layer V cells. Stimulus-Dependent Expression of the Immediate-Early Genes *c-fos* and *zif268* in the Whisker-to-Barrel Pathway of the Rat.

P. Melzer* and H. Steiner, Laboratory of Cerebral Metabolism (P.M.) and Section of Neuroanatomy (H.S.), NIMH, Bethesda, MD 20892.

Recent studies in the rat whisker-to-barrel pathway have shown that the expression of the immediate-early genes *c-fos* and *zif268* is decreased in barrel cortex, when the corresponding whiskers had been clipped (Steiner & Gerfen, in press). Here we report that stimulation of one whisker in the freely moving albino rat increases the expression of the two genes in the appropriate barrel, and that the magnitude of *zif268* expression is dependent on the amplitude of whisker deflection. The rats were anesthetized with halothane, and a metal piece (6.0 mm long, 0.4 mm in diameter) was glued on left whisker C2 about 15 mm above the skin; all other whiskers on that side were clipped. The whiskers on the right side were left intact. Thirty minutes later, each rat was exposed to a pulsating magnetic field at one of nine strengths from 0 to 15.7 mT for 10 minutes. After an additional 10 minutes, the rats were sacrificed, and the brains were removed and frozen at -55° C. Twelve μ m-thick sections, cut either coronally or, with cortical flat mounts, parallel to the pia, were hybridized with [³²S]cDNA probes for the mRNAs of *c-fos* and *zif268*. Superimposing autoradiograms on sections stained for cytochrome oxidase activity showed a localized increase in the expression of the two genes in the C2 barrel contralateral to stimulation. The expression of *zif268* in barrel C2 was increased above control levels at field strengths higher than 8.0 mT. The increase in immediate-early gene expression in the barrel representing the stimulated whisker follicle and its dependence on stimulus intensity suggest that the products of these genes are associated with neuronal processing of sensory information in the whisker-to-barrel pathway.

THE ROLE OF RAT SUPRAGRANULAR CORTEX IN LAYER IV PLASTICITY AFTER WHISKER-PAIRING. W. Huang*, M. Armstrong-James, S.-M. Lu, M.E. Diamond, F.F. Ebner, Inst. for Dev. Neurosci., Kennedy Ctr., Vanderbilt Univ., Nashville, TN 37203

Neurons in rat SI barrel cortex have been reported to develop biased receptive fields (RF) after days to weeks of experience with all but 2 whiskers trimmed on one side of the face ("whisker-pairing"). This type of adult plasticity or "bias" occurred in the superficial and deep layer neurons after only 24 hours of whisker pairing, a time prior to any change in layer IV neuron RFs. These results raised the question of whether early-altered neurons in the superficial layers are required for the later layer IV plasticity. Epidural application of NMDA (150 mM for 15 m) selectively destroyed neurons in layers II and III over the barrel field cortex. Fourteen days after the lesion, neurons of layers IV, V, VI still exhibit center (D2 whisker) and surround (D1, D3, C2 and E2 whiskers) RFs under urethane anesthesia. We started whisker pairing 7 days after the cortical lesion, when all but 2 whiskers were cut on one side (leaving either D2 + D1 or D2 + D3). The trimming was repeated every other day for 5 days. On day 7 layer IV neurons in the D2 barrel failed to show the expected bias toward the paired (ie., intact) whisker. In contrast, deep layer neurons in the same radial penetrations developed the bias. These results indicate that the superficial layers of SI cortex must be intact for normal plasticity in layer IV. We are studying now whether this apparent delay in layer IV plasticity is permanent after long periods of whisker pairing. (supported by NS-25907)

CHARACTERIZATION OF A FUNCTIONAL WHISKER REPRESENTATION IN RAT BARREL CORTEX: OPTICAL IMAGING OF INTRINSIC SIGNALS VS. SINGLE-UNIT RECORDINGS. R.D. Frostig*, S.A. Masino, M.C. Kwon, Dept. of Psychobiology, University of California, Irvine, CA 92717.

The whisker-to-barrel system provides the opportunity to stimulate an independent sensory unit in the periphery and measure the extent of its cortical representation. To achieve this goal, we compared the functional representation of a whisker obtained with optical imaging of intrinsic signals to that obtained with single-unit recording. Specifically, we compared the area which exhibits stimulus-related intrinsic signal responses to the area which exhibits stimulus-related neuronal responses.

We first determined the functional representation of the whisker in barrel cortex by imaging through a thinned skull during stimulation of an individual whisker for one second at 5 Hz. After imaging, we removed the skull and proceeded with closely spaced single-unit recordings guided by the imaged representation of the whisker while delivering identical whisker stimulation.

Although the largest change in the intrinsic signals are found within a localized area which we defined as the functional representation of the whisker (Masino et al, PNAS, 90: 9998-10002, 1993), there is a widespread area beyond the functional representation which exhibits a stimulus-related change in intrinsic signals. When we compared the area of the stimulus-related neuronal responses to the area of the stimulus-related intrinsic signal responses we found that the two were similar. Both response areas spread over a radial distance of approximately 2 mm from the center of the imaged representation. However, the spread of single-unit activity was not uniform; there was a significant decrease in single-unit responses starting at and extending beyond the border of the localized functional representation determined with imaging. These results demonstrate an extensive response area activated by stimulation of a single whisker as assessed by both techniques, and highlight the correspondence between intrinsic signals and underlying single-unit response characteristics. Supported by the Beckman Foundation and NIH grant MH-50362.

EFFECTS OF WHISKER TRIMMING ON GABA_A RECEPTOR BINDING IN DEVELOPING RAT WHISKER BARREL CORTEX. E. Salazar, S.C. Carpenter, R.L. Miller, T.A. Austin and J.L. Fuchs*, Dept. Biological Sciences, University of North Texas, Denton TX 76203.

Sensory deprivation affects GABAergic systems in adult neocortex (e.g., Hendry et al. '90; Akhtar & Land '91), but little is known about the role of this predominant inhibitory system in shaping the developing neocortex. The present study investigates developmental effects of sensory deprivation on GABA_A receptors in rat whisker barrel cortex. Either the middle row or the outer rows of vibrissae were kept trimmed. In [³H]muscimol autoradiographs of tangential sections from rats trimmed from birth (P0) to 6 wks, [³H]muscimol binding declined in deprived relative to nondeprived barrel rows (10.3%; $p < 0.028$, $n = 6$), confirming a previous report (Fuchs '93). This deprivation effect was not yet present by P10 ($n = 7$), indicating that neonatal deprivation did not interfere with the transient developmental peak in [³H]muscimol binding. In rats trimmed as adults (6-12 wks; $n = 4$), the decrease was notably smaller than in rats trimmed from P0 to 6 wks, suggesting the presence of a developmental "sensitive" period. Preliminary observations suggest that if whiskers are trimmed from P0 to 6 wks followed by 10 wks of recovery, the deprivation effect persists, compatible with electrophysiological evidence for long-lasting decreases in inhibition following a similar period of whisker trimming (Simons & Land '87).

Our observations extend previous reports that sensory deprivation can lead to a decline in GABAergic systems, and suggest that some of these effects may have a developmental sensitive period. GABAergic down-regulation might be compensatory, disinhibiting the reduced excitatory sensory input. Such a role could be particularly important during the refinement of synaptic circuitry. NONSPECIFIC SHORT-TERM ELECTRICAL STIMULATION OF A SINGLE FOREPAW DIGIT INCREASES THE PHYSIOLOGICAL REPRESENTATION OF THAT DIGIT IN LAYER IV OF RAT BARREL FIELD CORTEX: AN EXTRACELLULAR RECORDING STUDY. C.X. Li*, R.S. Waters, C.A. McCandlish, E.J. Johnson, Dept. of Anatomy and Neurobiology, UT, Memphis, Col. of Medicine, Memphis, TN 38163

Limited differential sensory experience can alter the physiological organization of the glabrous representation of the forepaw in the forepaw barrel subfield (FBS) cortex in rat layer IV (see companion abstract, Waters et al.). To determine whether nonspecific short-term electrical stimulation can also alter the physiological representation of the forepaw, we examined barrel cortex prior to and immediately after a short period of electrical stimulation.

Adult rats were anesthetized with Nembutal, head was stabilized, skull was opened over SI, dura was removed, and cortex was covered with warmed silicon fluid. Carbon fiber electrodes were used to map the representation of digit two (D2), D3, D4 prior to and immediately after electrical stimulation of the D3. Pulses of direct current (amplitude: 80-120 μ A, duration: 100 μ sec, interval: 1 Hz) were applied to the tip of D3 for 2 hr. Following the period of electrical stimulation, the cortex was immediately remapped. The following results were obtained:

1. Following electrical stimulation, the area of cortex served by D3 increased by approximately 10%.
2. These results suggest that brief periods of electrical stimulation are sufficient to immediately alter the physiological representation of the stimulated digits. These results bear directly on the role of afferent input on cortical organization. (Supported by USPHS GR NS-25824, NSF Grant BNS 88-02766)

566.13

DIFFERENTIAL SENSORY EXPERIENCE ALTERS THE REPRESENTATION OF THE FOREPAW IN FOREPAW BARREL SUBFIELD (FBS) CORTEX IN RAT. R.S. Waters*, C.X. Li, S.C. Fowler, C.A. McCandlish. Dept. of Anatomy and Neurobiology, UT, Memphis, Col. of Medicine, Memphis, TN 38163; * Dept. of Psychology, Uni. of Mississippi, Oxford, MS 38677.

The relationship between the representation of the forepaw and the barrel-like structures in the forepaw barrel subfield (FBS) in rat SI cortex offer an excellent model system to study the differential effects of sensory experience on cortical structure and function. We describe results of physiological mapping and morphological analysis of FBS in rats trained on a sensory-motor task.

Adult rats, water deprived, were trained to depress a 9mm disk to receive simultaneous liquid reinforcement. Training lasted approximately 15 min per/day for a period time of 18-30 days. Following training, animals were anesthetized with Nembutal, the head was stabilized, the skull was opened over SI, dura was removed, and the cortex was covered with warmed silicon fluid. Carbon fiber electrodes were used to map the forepaw representation in SI cortex in both hemispheres. Lesions were made to identify specific recording sites and to relate the electrophysiological map with the morphological map in FBS. Following physiological mapping, the cortex was removed, hemispheres were flattened and cut tangentially. Tissue was stained with cytochrome oxidase (CO). The following results were obtained:

1. Sensory-motor training resulted in an average increase of 24% in the area of cortex represented by glabrous digit tips in trained as compared to untrained hemispheres.
2. No morphological differences within the FBS were observed between trained and untrained hemispheres.
3. Limited sensory-motor experience is sufficient to alter the physiological map without a noticeable change in the morphological map in FBS.

ACUTE CHANGES OF THE RECEPTIVE FIELDS AND NEURONAL ACTIVITIES OF THE VPL THALAMIC NEURONS FOLLOWING EITHER TEMPORARY OR PERMANENT DEAFFERENTATION OF SINGLE DIGITS OF ANESTHETIZED RATS. J.H. Sohn*, J.O. Son, H.C. Shin*, S.A. Raymond* & H.J. Park. Dept. Psychol., Chungnam Natl. Univ. Taejeon, Korea, Dept. Physiol., College Med., Hallym Univ. Chunchon, Korea #200-702, Dept. Anesthesia Res* Labs, Brigham & Women's Hospital, Harvard Med. School, Boston, MA, USA.

To investigate whether either temporary (TD) or permanent (PD) deafferentation produces reorganization of sensory maps in the forepaw area of the ventral posterior thalamus, we made single or multiple unit recordings from neurons in VPL thalamus of urethane anesthetized rats. Neuronal responses to subcutaneous electrical stimulation to the receptive field (RF), a forepaw digit, and to other digits were quantitated by analyzing post-stimulus time histograms. After determining stable RF and evoked unit responses for 30 min of control period, either TD or PD of a RF (single digit) was carried out by lidocaine injection (2%) or amputation, respectively. Ten of 12 VPL units showed a reversible block of original RF (ORF) after TD and exhibited a new RF (NRF) located neighbouring digits. NRFs were initially observed at 23.8±3.1 min after TD and they disappeared at 57.3±6.1 min after TD. The NRF showed much weaker responsiveness to the peripheral activation than the ORF did (maximum 43.5±13.6% of the ORF (133.8 Hz/stimulus, n=8) at 28.0±4.4 min after TD). Onset response latencies from the NRF (9.3±0.7-15.4±0.8 ms) were slightly longer than those from the ORF (7.9±0.4-15.4±1.0 ms). Seven VPL units were subject to PD study and they exhibited NRF digits located next to the ORF digits. NRF appeared at 14.7±6.2 min after PD and lasted up to 40-80 min of experimental period (58.6±6.7 min). The NRF showed weaker responsiveness to the peripheral activation than the ORF did (maximum 66.8±22.5% of the ORF (119.7±26.1 Hz/stimulus) at 34.4±9.1 min after PD). Response latencies from the NRF (10.5±0.8-20.6±1.8 ms) were slightly longer than those from the ORF (8.9±0.7-18.6±2.3 ms). These results demonstrate that either temporary or permanent deafferentation of single digit induces a marked reorganization of the somatosensory map within minutes in the VPL thalamus. (KRF 93)

DISTINCTIVE PATTERNS OF BURSTING IN NEURONAL ACTIVITY FROM SOMATOSENSORY CORTEX OF AWAKE CATS. A.A. Myasnikov*, H.H. Webster and R.W. Dykes. Departement de physiologie, Université De Montréal, Montréal, Québec H3C 3J7.

Recent studies show that differences in the membrane characteristics of cortical neurons allow cortical neurons to be distinguished on the basis of the shape and temporal pattern of their action potentials. These characteristics may allow their identification in behaving animals. To examine this possibility in the somatosensory cortex, we obtained extracellular digital records from neurons in awake, quietly resting cats using tungsten-in-glass microelectrodes. Neurons were characterized by their action potential waveforms, receptive field characteristics and other electrophysiological attributes. Analysis of their spontaneous activity showed some cells to have distinctive bursting patterns. Cells of one class had multiple peaks in their autocorrelograms, many impulses per burst and nearly constant interburst intervals. A second had only one peak in their autocorrelograms, short bursts, and increasingly longer intervals within the burst. Other cells lacked any temporal dependence between spikes.

EARLY TACTILE EXPERIENCE ALTERS THE CUTANEOUS FOREPAW REPRESENTATION IN THE PRIMARY SOMATOSENSORY CORTEX OF THE RAT.

O. Cog, Y. Zennou-Azogui, C. Xerri*. Lab. Neurobiology of Functional Restorations, University of Provence, 13397 Marseilles, France.

Earlier anatomical, biochemical and behavioral studies have shown that subject-environment interactions have significant effects on brain structure and learning capabilities. Moreover, it is well established that the cutaneous representations of the primary somatosensory (SI) cortex display a remarkable plasticity and can be reshaped through an experience-dependent process involving spatio-temporal coactivation of inputs. We have designed experiments to evaluate the influence of early differential tactile experience on the organization of the cutaneous "maps" of the SI cortex in the rat. Long-Evans female rats were housed under different tactile environments (standard, impoverished, enriched) for 1 month from the time of weaning. Their forepaw representation within SI was then reconstructed by using microelectrode mapping. The "standard" rats were housed in groups of 3, in a conventional environment. The "impoverished" rats were also exposed to a conventional environment, but each animal was housed in a separate cage. The "enriched" animals were housed in larger cages, in groups of 12 and were provided with objects of different shapes, sizes and textures. Preliminary results suggest that: 1) the skin territories more likely to be stimulated (protuberant skin surfaces) are best represented within the SI cortex; 2) early tactile enrichment through object manipulation and contact with mates improves the spatial resolution (smaller cortical receptive fields, RFs) of the cutaneous forepaw representation; 3) tactile impoverishment results in a degradation of the forepaw representation that is characterized by larger RFs, many double RFs, and by the emergence of non-cutaneous small "islands" within the cutaneous map. These results indicate that early tactile experience plays a critical role in the development and maintenance of the cutaneous cortical representations.

566.16

DEAFFERENTATION CHANGES THE DISTRIBUTION AND ORGANIZATION OF THE BURSTING PATTERNS OF NEURONS IN SOMATOSENSORY CORTEX OF AWAKE CATS. R.W. Dykes*, H.H. Webster, A.A. Myasnikov and I. Salimi. Dept. de physiologie et Centre de recherche, Dept. de psychiatrie, Hôpital Sacré-Cœur, Université de Montréal, Montréal, Québec H3C 3J7.

After identifying specific classes of neurons in the cat somatosensory cortex based on the structure of their spontaneous activity, these same classes were sought in somatosensory cortex that had undergone a large deafferentation by transection of the radial, median and ulnar nerves. Recordings made from several days to two weeks after the surgery showed an increased probability of encountering neurons with a pattern of short bursts and a decreased probability of encountering neurons with long bursts. This change suggests that deafferentation leads to less structure in the ongoing activity within deprived cortex. We hypothesize that this results from a reduction of the strength of corticocortical and corticothalamic feedback loops impinging on the deprived area.

566.18

NEOCORTICAL AND THALAMIC PLASTICITY FOLLOWING NEONATAL DEAFFERENTATION IN RATS. D.M. Liu*, D.T. Ross, J. Nissarov, and P.J. Hand. Institute of Neurological Science, University of Pennsylvania, PA 19104.

One critical issue involving activity-dependent neocortical plasticity is the relative contribution of intracortical and subcortical structures to representational changes. Our previous study showed that neonatal removal of all whiskers except C3 produced a prominent enlargement of 2DG functional representation of spared C3 (SC3) in SI cortex. In this study, we used the same model to investigate the plasticity at the cortical and subcortical level. SC3 preparation resulted in a significant expansion of 2DG functional representation in both SI cortex (303.3±35.8%) and ventrobasal thalamus (112.2±35.2%) but not in the brainstem trigeminal complex. However, we only found a 99.5±17.6% enlargement of barrel size as revealed by CO staining. Presumably the striking representational enlargement was only partly due to a structural changes in SI cortex. To test the hypothesis that GABAergic disinhibition may involve in this additional expansion, we performed GAD immunocytochemistry in the SC3 model. Preliminary results showed that the pattern of GAD positive labeling in control barrel cortex is well organized and homogenous. In contrast, the boundary of each barrel in deafferented barrel cortex is disorganized and the GAD positive cell density of adjacent barrels is significant attenuated by 39.5±6.0% as compared with SC3 region. These results suggest the GAD expression may be activity-dependent and its down regulation following deafferentation may reflect a decreased lateral GABAergic inhibition that contributes to the observed neocortical plasticity. FUNCTIONAL MAPPING OF HUMAN SOMATOSENSORY CORTEX WITH ECHO PLANAR MAGNETIC RESONANCE IMAGING. K. Sakai¹*, E. Watanabe², Y. Onodera³, H. Itagaki³, E. Yamamoto³, H. Koizumi³ and Y. Miyashita¹. ¹Dept. Physiol., Sch. Med., Univ. Tokyo, Tokyo 113, ²Dept. Neurosurg., Tokyo Metro. Police Hospital, Tokyo 102, and ³Central Research Lab., Hitachi, Ltd., Tokyo 185, Japan.

Somatotopical organization of the human somatosensory cortex was analyzed with echo planar imaging (EPI) at 1.5 T, utilizing deoxyhemoglobin as an endogenous contrast medium. Scrubbing stimulation at a frequency of 3 Hz was applied to one of three cutaneous areas: toes, fingertips, and tongue tip. Each measuring session consisted of resting (40 s), stimulation (30 s), and resting (40 s) periods. Sagittal EPI slices of 10- or 15-mm thickness (data acquisition time, 60 ms per slice; in-plane resolution, 2 x 4 mm²) were obtained every 2 s continuously in a single session. A spin echo image of the corresponding sagittal slice was taken just before and after several sessions. Statistical significance of signal changes was assessed with Student's t-test for each voxel. We found focal bands of increased signals (1.5 to 8 %) during stimulation periods, with rise time of 2 to 6 s. These activated bands were identified on the contralateral postcentral gyrus. The cortical responses from the three stimulation sites were anatomically distinct and organized medially-to-laterally in the order of toes, fingertips, and tongue tip.

MOTOROTOPIC ORGANIZATION OF HUMAN CORTICAL 20-Hz OSCILLATIONS. R. Salmelin*, R. Hari, M. Hämäläinen, and M. Kajola. Low Temp. Lab., Helsinki Univ. of Technology, 02150 Espoo, and Neuromag Ltd., 00510 Helsinki, Finland.

In humans, the spectral distribution of cortical spontaneous rhythms ('alpha', 'mu', 'tau') is dominated by frequencies around 10 and 20 Hz. The reactivity and source areas of cortical somatomotor rhythms associated with self-paced left- and right-sided index finger, toe, and mouth movements were studied non-invasively in eight healthy subjects employing a 122-channel whole-head neuro-magnetometer.

Following the complete suppression during movements, the rhythms manifested a marked increase above the base level, particularly in the 20-Hz range. Sources of the enhanced 20-Hz activity were found in mesial cortex for toe movements and about 5 cm and 8 cm from vertex (measured along the cortex) for hand and mouth movements, respectively, apparently tracking the representation of the moving body parts in the motor cortex. The reactive 10-Hz rhythms, on the contrary, concentrated at about 6 cm from vertex, close to the hand area in the somatosensory cortex, for all tasks.

The 10- and 20-Hz somatomotor rhythms seem to have separate spatial distribution and distinct functional roles in motor tasks, with the 20-Hz range manifesting motorotopic organization.

RELATIONSHIP BETWEEN RREP AMPLITUDE AND RESISTIVE LOAD MAGNITUDE IN CHILDREN. P.W. Davenport*, C. Smith-Hammond, D. Dalziel and I. Colrain. Dept. of Physiol. Sci., JHMHC, University of Florida, Gainesville, Florida, 32610

Respiratory related evoked potentials (RREP) recorded from C₂-C₃ and C₂-C₄ have been elicited by occlusion of inspiration. The initial positive peak (P_i) is believed to represent the sensory cortical response to the activation of the afferents transducing the inspiratory load. It was hypothesized that the P_i peak amplitude is proportional to the inspiratory load magnitude in children. Children were studied semi-reclined at rest. They respired through a mouthpiece and non-rebreathing valve connected to a loading manifold. EEG activity was recorded from C₂-C₃ and C₂-C₄. The resistive (R) load magnitudes were 2.0, 9.0, 21.0 cm H₂O/lsec⁻¹ and occlusion. Control evoked potentials are obtained by interruption of inspiration with the no-load, R₀, port open. The EEG activity was averaged on-line and stored with computer system. Each trial consisted of 80 load presentations. Each load magnitude and the control no-load were applied 20 times each in an trial. There were 4 trials. The P_i peak amplitude and latency was measured. No P_i peak was observed with control R₀. The P_i peak was found with all R loads and occlusion. The mean P_i latencies were C₂-C₃=38.2, C₂-C₄=38.4 msec and there were no significant differences between R load magnitudes. The P_i amplitude increased with increasing R load magnitude for both electrode pairs. Inspiratory occlusion and resistive loads produce mechanical changes to inspiratory transduced by respiratory mechanoreceptors and project to the sensory cortex. These results support the hypothesis that graded increases in inspiratory load are correlated with increased activation on sensory cortical neurons. Supported by ALAF grant UF #92092907.

POTENTIAL HUMAN SOMATOSENSORY AREA III (SIII) AND ITS MODULATION BY ATTENTION. J.V. Pardo*, J. T. Lee. Psychiatry PET Unit, Psychiatry Service, VAMC, and the Division of Neuroscience Research, Department of Psychiatry, University of Minnesota, Minneapolis, MN.

PET and MEG have recently helped to define human SI (along the Rolandic Sulcus) and SII (parietal operculum). By analogy to the organization of non-human somatosensory cortices, Caselli has posited the existence of human SIII and SIV. Human SIII and SIV are hypothesized to compose a ventrolateral somatosensory associative cortex whose damage causes tactile agnosia.

Ten healthy volunteers participated in a somatosensory processing task while cerebral blood flow was measured with the H₂¹⁵O bolus autoradiographic technique and PET. In the somatosensory attention condition, subjects monitored their finger, lip, or great toe for pauses in a series of taps (3 Hz) from a von Frey hair and maintained passive visual fixation. In the visual attention condition, subjects fixated attentively looking for rare, transient dimmings of the fixation mark while ignoring the taps on their finger, lip, or toe. The somatosensory attention condition produced activation in a region of the contralateral supramarginal gyrus (Brodmann 40) consistent with the predicted location of human SIII. Finger, lip, and toe responses in SIII were closely mapped together and were modulated significantly by attention.

FUNCTIONAL MAGNETIC RESONANCE IMAGING OF HUMAN CORTEX ACTIVATED DURING SOMATOSENSORY AND MOTOR STIMULATION. K.D. Davis*, M.L. Wood*, C.A. Stewart*, E.T. Kiriakopoulos*, J.J.S. Barton* and D.J. Mikulis*. ¹Division of Neurosurgery, ²Department of Radiology, and the ³Division of Neurology, University of Toronto, and the ⁴Eye Research Institute of Canada, The Toronto Hospital, Toronto, Ontario, Canada M5T 2S8.

Functional magnetic resonance imaging (fMRI) techniques have recently been developed to identify cortical areas activated during specific tasks. We have further modified these techniques to identify regions in the cortex activated during simple somatosensory and/or motor tasks.

All data were collected from normal subjects. Images were obtained with a 1.5T MRI scanner. Each protocol typically consisted of alternating sets of 6 images during a task and 6 images at rest or during a control task for a total of 72 images. Typical imaging parameters were: 4mm axial cortical slice, TR=68ms, TE=40ms, bandwidth=4.92KHz, ~6sec/image, FOV=30x22cm, 256x128 matrix, 45° flip angle. Somatosensory-related activity was evoked with either 1) electrical stimuli applied to the median nerve with a TENS-type stimulator to evoke strong paraesthesia in the distribution of the nerve, or 2) natural tactile stimuli (eg, light brush) of the skin. For comparative purposes, scans were also obtained during a sequential motor/sensory task (e.g., thumb to finger opposition with contact). Activated regions were determined based on a pixel by pixel statistical analysis (t-test) of the mean intensity signal differences during the task and controls.

Natural tactile stimuli activated large areas of S1 and M1. Electrical stimuli that evoked paraesthesias activated discrete areas of S1. During simple motor tasks, S1, M1 and MII were activated. Within activated areas, the mean intensity signal followed the expected sawtooth pattern indicative of cortical activation. These data indicate that fMRI can be used to identify and confirm the functioning of sensory and motor cortical areas active during simple tasks.

SOMATOSENSORY CORTICAL REPRESENTATION OF EACH FINGERTIP IS DISTINGUISHABLE IN INDIVIDUAL SUBJECTS, USING MULTI-SLICE FUNCTIONAL MRI. B.R. Krauss¹, P.A. Gelnar¹, N.M. Szeverenyi², C.J. Hodge¹*, A.V. Apkarian¹, Depts. Neurosurgery¹ and Radiology², SUNY HSC, Syracuse, NY.

Functional magnetic resonance imaging (fMRI) has the potential to achieve greater spatial resolution than PET and SPECT. We tested the ability of fMRI to resolve individual finger representations within the somatosensory cortices (SI and SII) by applying a vibratory stimulus to single digits during one imaging session.

A 1.5 Tesla MRI system with a within slice pixel size of 1.6 X 1.6 mm, a single surface coil, and an echo planar acquisition sequence were used to image changes in activity in the middle third of the cerebral cortex contralateral to experimentally applied stimuli. In each session vibratory and proprioceptive stimuli were applied to D1, D2, and D5, the control was rest. Eight 6.0 mm slices were imaged during 6 stimulus-control cycles in each session. Five images/slice were obtained during stimulus or control. T-maps were superimposed on high resolution MR images.

The vibratory cortical activation maps for all three digits exhibited significant activation (t-map clusters containing 9 or more pixels all with p<0.05) in SI and SII. The regions activated by D1, D2 and D5 in SI were spatially distinct when measured both by the center of gravity and by the pixel which exhibited the largest increase in intensity within the activated cluster. In SI, the activated regions for D1 and D2 were spatially closest while the activated regions for D1 and D5 were more distant. The proprioceptive cortical activations were less localized than the vibratory activations.

This demonstrates that fMRI can distinguish the cortical representation of individual fingers in single subjects. Therefore, the spatial resolution of fMRI is higher than that of PET or SPECT.

SPATIAL MAPPING OF PAIN AND MOTOR ACTIVATION IN HUMAN CEREBRAL CORTEX WITH fMRI AT 4 TESLA. Michael J. Iadarola*, Han Wen, Robert C. Coghill, Steven D. Wolff and Robert S. Balaban. Neurobiology and Anesthesiology Branch, NIDR and Laboratory of Cardiac Energetics, NHLBI, NIH, Bethesda, MD USA.

A high resolution gradient recalled echo fMRI method was developed to visualize neuronal activity induced by thermal nociceptive stimuli and motor tasks. Changes in neural activity reflected by blood flow and blood oxygenation level differences (in flow effects and T2* effect, respectively) were obtained in 4, 5 or 8 mm thick transaxial slices with repetitive 13 sec scans that provided good contrast and were registered to high resolution anatomical scan. In both cases, activated voxels were discretely organized such that the activity generally traced the gyral borders and overlapped somewhat into the sulcus. The appearance of the signal was consistent with it originating from marginal or central gyral veins of medium caliber and possibly their collaterals. Multislice acquisitions indicated that the nociceptive signal (from heating the tip of the thumb) occurred over 4-8 mm in the axial dimension and was contiguous between slices. The motor task (repetitive flexion of the last joint of the thumb) yielded a more extensive signal. For example, in 9 successive 5 mm slices starting from the superficial cerebral cortex to the level of the corpus callosum, contiguous activity (associated with the posterior bank of the precentral gyrus/central sulcus) could be traced through adjacent 3 slices. One slice contained the major locus of activity. In the coronal plane the activity was very discretely distributed as well. These data suggest that a prominent portion of the signal increase arises from the venous compartment and that the signal provides functionally relevant and anatomically discrete information.

TRANSFORMATION OF TACTILE SPATIAL FORM WITHIN A CORTICAL COLUMN IN AREA 3b OF THE MACAQUE. J.J. DiCarlo*, S.S. Hsiao, and K.O. Johnson. Krieger Mind/Brain Inst. and Dept. of Neuroscience, Johns Hopkins Univ., Baltimore, MD 21205.

Multi-electrode (7 elect., 400 μ m spacing) recordings were made in area 3b from both hemispheres of an awake Macaque monkey. The electrodes were positioned such that isolated neurons had receptive field centers on the same spatial location of the monkey's distal finger pad. Typically this allowed simultaneous recording from 3-5 neurons located along a perpendicular to the cortical surface, which were assumed to be within a single cortical column. The monkey performed a visual task while embossed letters and oriented bars were repeatedly scanned at a controlled force (30 gm) and velocity (40 mm/sec) across the distal finger pad. The locations of the penetrations were confirmed using standard histological techniques.

Two-hundred and forty-four neurons (65 recording sets) were studied using the letter and bar stimuli. The neural responses to the embossed letters were used to construct two-dimensional spatial event plots (SEPs). A structural analysis of the SEPs shows neurons recorded in the central layers tend to be more isomorphic (similar in structure to the stimulus letters) and more responsive (higher impulse rates) than neurons in both supra- and infragranular layers. Cross-correlation analysis on 225 simultaneously recorded pairs of neurons suggests monosynaptic excitatory connections between 34% and common input to 16% of the pairs. In general, among pairs exhibiting monosynaptic excitatory connections, the SEPs of the "sender" neuron are more isomorphic than those of the "receiver" neuron. The overall pattern of functional connectivity is consistent with anatomical studies; there are monosynaptic connections from the central layers of cortex to supragranular and infragranular layers and monosynaptic connections from supra- to infragranular layers. Together, these results support the hypothesis that local, columnar cortical processing of spatial form proceeds from layer 4 to supra- and infragranular layers and that this processing results in a significant transformation of spatial form.

VIBROTACTILE SENSITIVITY IN PATIENTS WITH CARPAL TUNNEL SYNDROME (CTS). C.M. Checkosky* and S.J. Bolanowski. Institute for Sensory Research and Department of Bioengineering and Neuroscience, Syracuse University, Syracuse, NY 13244.

CTS is commonly diagnosed by neurologic examination and electrophysiological evaluation. However, many investigators have recently advocated the use of vibrotactile testing as an early diagnostic tool. The rationale for this stems from the idea that the large-diameter sensory fibers are affected first in nerve compression, possibly resulting in elevated vibrotactile thresholds. More recently, however, it was shown that vibrotactile thresholds are elevated during coincident pain (Apkarian et al., Soc Neurosci Abstr: 1992). The purpose of this study was to assess vibrotactile sensitivity in CTS quantitatively using strictly controlled laboratory conditions and psychophysical techniques, and to determine whether elevated thresholds correlate with the presence of pain. Detection thresholds were measured on 20 patients (36 hands) clinically diagnosed with CTS. Bursts of vibratory stimuli were delivered to the thenar eminence of the affected hands (stimulus frequencies, 1, 10 and 300 Hz; contactor sizes, 0.008 cm² and 2.9 cm²). The subjects also rated the amount of pain that was present at the beginning of each testing session. Thresholds were compared to normative data in the literature and to thresholds obtained on a within-subject control site, the hypothenar. No elevations in threshold were found on affected areas in 19 hands during all testing sessions when compared to controls. Thus, the testing of vibrotactile thresholds for CTS may not be warranted. In 11 testing sessions elevated thresholds were obtained on affected areas where the subjects reported the presence of pain. These results indicate that elevated thresholds in CTS may actually be the result of the presence of pain. Supported by NIH, DC00098.

NEURAL BASIS FOR TACTILE ROUGHNESS PERCEPTION: THE RELATIVE CONTRIBUTIONS OF SLOWLY ADAPTING AND RAPIDLY ADAPTING AFFERENTS. D.T. Blake, S.S. Hsiao*, and K.O. Johnson. Krieger Mind/Brain Inst. and Dept. of Neuroscience, Johns Hopkins Univ. Baltimore, MD. 21205

Psychophysical and neurophysiological studies were done to assess the relative contributions of slowly adapting (SA) and rapidly adapting (RA) peripheral afferents to tactile roughness perception. The stimuli consist of 18 embossed surfaces composed of tetragonal dot patterns with constant, 3.5 mm center-to-center spacings, variable diameters (250, 700, 1050, 1600, 2050 and 2500 μ m) and variable heights (280, 350, 680 μ m). Dot diameter and height are shown to have differential effects on the responses of SA and RA afferents. It is postulated that differentially stimulating these afferents will allow us to determine the relative contributions of SA and RA afferents to roughness perception.

Psychophysical reports from 15 subjects show that both dot diameter and dot height have significant effects on roughness perception. Decreases in dot diameter and increases in dot height both cause increases in perceived roughness with dot height having a larger effect at small diameters: narrow dots feel more than two times as rough at 680 than at 280 μ m, while wide dots feel equally smooth at all dot heights. Neurophysiological recordings from 12 SA and 14 RA afferents from the ulnar and median nerves of 3 Macaque monkeys were made using the same dot patterns. The neural responses, which are plotted as two-dimensional spatial event plots, are analyzed using a measure of spatial variation in firing rates (*J. Neurosci.* 12:3414-3426, 1992.). In accordance with previous results (Can. J. Physiol. and Pharm., in press), only the SA afferents systematically match the psychophysics. While both SA and RA spatial variation measures are mildly affected by dot diameter, only the SAs are affected by dot height. These results strongly suggest that RA afferents do not contribute to tactile roughness and that SA afferents alone form the neural basis for tactile roughness.

SHORT- AND LONG-LATENCY SOMATOSENSORY EVOKED FIELDS REFLECT DIFFERENT ASPECTS OF TACTILE INFORMATION PROCESSING. N. Forss, R. Salmelin, V. Jousmäki and R. Hari*. Low Temperature Laboratory, Helsinki University of Technology., 02150 Espoo, Finland.

We recorded whole-head somatosensory evoked fields (SEFs) from 7 healthy subjects to airpuff (dorsum of the middle finger) and electric (median nerve at the wrist) stimuli; the interstimulus interval (ISI) was 3 s. The early (20 - 60 ms) SEFs to both stimuli originated in the contralateral first somatosensory cortex (SI) and the late (> 85 ms) SEFs bilaterally in the second somatosensory cortices (SII). An additional source was active at 70 - 110 ms in the contralateral parietal posterior cortex (PPC) in the wall of the postcentral fissure. Only SI responses were markedly smaller in amplitude and longer in latency to airpuffs than to electric stimuli.

In an odd-ball paradigm, 'standard' electric stimuli were delivered to the thumb and 'deviants' (15%) to the little finger, or *vice versa* (ISI 0.5 s). In SI, the deviants elicited similar responses irrespective of whether they were presented alone or among standards. In contrast, SEFs from SII, and especially those from PPC, were clearly larger to deviants presented without the intervening standards.

The early and late SEFs apparently reflect different aspects of tactile information processing. SII and PPC seem to be more integrative and less stimulus-specific in function than the SI cortex.

HUMAN PERFORMANCE ON DELAYED TACTILE DISCRIMINATION TASKS. R. Sinclair*, J. Pruett, and H. Burton. Department of Anatomy & Neurobiology, Washington University Sch. Med., St. Louis, MO 63110.

Human subjects identified either the higher of two vibrotactile stimuli differing in frequency or the rougher of two tactile gratings differing in groove width. Stimuli were presented under computer control by a feedback regulated vibrator or a servo operated surface stimulator previously described. On each trial stimulus pairs were separated by a ~0.5 to 30 second interval. For both vibrotactile and textured stimuli, percent correct decreased and reaction times increased as a function of increased delay interval length. Engagement in a distracting backwards counting task impaired performance relative to unfilled intervals, for delays greater than 5 seconds. For delays of 0.5 and 5 seconds, performance was unaffected by interference. Results are consistent with initial reliance on a fading sensory "trace" and, then, use of coded stimulus information at longer delays. Similar performance decay functions have been reported for visual and auditory stimuli. Preliminary analysis suggests that performance depended on order of stimulus presentation, e.g., rough-smooth grating presentation order was better discriminated than smooth-rough. A possible neural correlate of this order effect has been previously reported (Sinclair & Burton, 1988). These results establish parameters of vibrotactile and textured stimuli for use in animal studies of the neurophysiological basis of tactile memory. (Supported by NS 31005)

RESPONSES IN AREAS SII AND 7B RECORDED DURING A SPATIAL AND CROSS-MODAL TACTILE ATTENTION TASK. H. Burton*, K. C. Whang, and R. J. Sinclair. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Two rhesus macaques performed a task that manipulated attention across tactile space and between tactile and auditory modalities. The task involved three concurrent stimuli: two tactile vibrations presented to the hands and an analogous auditory tone. The monkeys were cued in a blockwise fashion to discriminate between target and distractor amplitude patterns at one of the three stimulus positions at a time. This enabled us to measure neural responses to physically identical stimulus arrays under conditions differing only by cue. An asynchrony between stimuli allowed us to separate components of the response. Psychophysical tests using 80% valid probability cues verified that the monkeys used the cue to direct their attentive resources selectively.

We surveyed 371 cells in areas SII and 7b. Of these, 170 were held long enough for us to record replicate blocks under each attentional condition (for a total of 420 trials per cell), and 85 satisfied an additional *F*-ratio criterion representing task-relatedness and stability of response. Excitatory responses to the transient phases of the tactile stimuli were the most common response pattern, but there were notable exceptions. In SII, a subset of cells was excited by the sustained phases of the stimuli but inhibited by the transients. In 7b, bimodal tactile and visual responses were common, and a few cells showed consistent directional selectivity across modalities. Bilateral tactile receptive fields were found in both areas. In many cases, the response to the first stimulus was followed by a diminished response to the second. These temporal order effects may be related to the phenomenon of tactile masking. (Supported by NS 31005)

RESPONSES OF NEURONS IN PRIMARY SOMATOSENSORY CORTEX TO PREHENSION OF OBJECTS OF DEFINED GEOMETRY. E.P. Gardner*, S. Ghosh, and C.E. Kops. Dept. of Physiology and Biophysics, NYU Medical Center, New York, NY 10016

These experiments measure the responses of cortical neurons when monkeys actively grasp and manipulate objects of defined geometry. The monkey is presented with a set of knobs of specified shape (large and small spheres, cylinders, cubes and rectangular blocks) which he is trained to grasp and lift. Visual cues delivered on the screen of a video monitor indicate which knob should be grasped. The monkey's hand movements are videotaped using two genlocked cameras, and stored together with extracellular spike records of cortical neurons on a VHS recorder. QuickTime movies are made from JPEG compressed video and electrophysiological data on a Macintosh Quadra computer, to allow frame-by-frame correlation of hand position with neuronal firing patterns. These experiments indicate differences in information processing in anterior and posterior portions of S-I cortex. In anterior S-I, where neurons have small receptive fields on single digits, the cell's firing patterns correlate with hand displacement across the knob. These neurons appear most strongly activated when the edges of the cylindrical or rectangular knobs contact the receptive field, and are less responsive when the hand moves over the gently curved spherical surfaces. In posterior S-I, where receptive fields cover multiple digits, some neurons appear to differentiate the surface curvature of individual objects. Other neurons are silenced upon hand contact with the knobs, regardless of shape, and resume tonic activity when the hand is removed. We postulate that neurons in posterior S-I may play a role in global appreciation of the entire object, rather than in perception of specific features of single surfaces. (Supported by NIH: NS11862).

DIVERGENCE OF THALAMIC INNERVATION TO AREA3b OF THE MONKEY SOMATOSENSORY CORTEX. E. Rausell¹*, A. Viñuela², M. Molinari³, and E.G. Jones⁴. Automa University, 28029 Madrid, Spain^{1,2}; Catholic University, 00168 Roma, Italy³; and University of California Irvine, CA 92717⁴.

In the monkey somatosensory system, the extent of divergence and overlap in the projections of individual thalamic cells with the same or different receptive fields has not been established.

Pairs of non-overlapping small injections of fast blue (FB) and diamidino yellow (DY) were made in area 3b at sites where neurons had overlapping (four cases) or non overlapping (five cases) receptive fields. Double labeled neurons were found when the injections were 600 μ m or less apart. The probability for ventrobasal (VB) neurons to be double labeled while varying the distance between injections was calculated. Linear regression analysis of the relative percentage of double labeled neurons with respect to separation between the dyes gave a figure of 627 μ m. This can be taken as an approximation to the diameter of the area of arborization of thalamocortical axons in layer IV.

In VB, there was much intermingling of FB and DY labeled cells even with injections separated by greater than 1,000 μ m. A variable number of clusters of neurons were retrogradely labeled. The number of cells retrogradely labeled with a single dye within a cluster was proportional to the extent of the cortical injection. Separation of injections by less than 600 μ m resulted in intermingled FB, DY and double labeled neurons within the same cluster. Separation greater than 600 μ m resulted in less intermingling, a tendency for neurons labeled with different dyes to be segregated in neighboring clusters, and no double labeled neurons.

These findings have implications for somatosensory cortical mapping and as a potential basis for activity dependent plasticity of representational maps.

567.14

RANDOMIZATION ANALYSIS OF BLOCKWISE VARIABILITY AND THE APPEARANCE OF ATTENTION EFFECTS. K. C. Whang* and H. Burton. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Cells in areas SII and 7b were observed under three different attention treatments, two cued to tactile stimuli and one cued to an auditory stimulus, with each treatment presented in replicated blocks of trials. 40% of the cells showed firing rate differences of 20% or greater between left and right tactile treatments or between tactile and auditory treatments. There was no consistency, however, in the directions of these effects. Across the population that we sampled, both spatial and cross-modal attention effects averaged to zero.

Randomization analyses were applied to determine whether the magnitudes of these observed effects were greater than would be expected by chance alone. The partition of our data set based on our three true treatments was compared to reference distributions generated by random partitioning by block or by trial of the same data set. These analyses showed that the observed attention effects were not significantly greater than would be expected by chance and, furthermore, that there was a significant serial correlation between observations within blocks. The assumption of independent observations made by conventional analyses of variance or *t*-tests is therefore inappropriate.

Analyses of variance using hierarchical error terms corroborated these findings. While a conventional analysis found 75% of the cells to show attention effects significant to $p < .05$, an analysis that made no assumption of independence within blocks found only 6% to be significant. Time series plots reveal random drifts in activity underlying the serial correlation effect. (Supported by NS 31005)

TWO TYPES OF VIBRATORY RESPONSIVE PACINIAN-LIKE NEURONS IN MONKEY PRIMARY SOMATOSENSORY CORTEX (SI) STUDIED DURING ACTIVE HAND MOVEMENTS. M.A. Lebedev* and R.J. Nelson. Department of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, 875 Monroe Avenue, Memphis, TN 38163.

Some SI neurons respond to vibrotactile stimulation of their receptive fields with vibration-entrained responses (Mountcastle et al., *J. Neurophysiol.* 32:452, 1969). Previously, we described changes in entrained activity that occurred prior to voluntary movements (Lebedev and Nelson, *Neurosci. Abst.* 18:503, 1992). In this study, we examined vibration-induced activity of two types of Pacinian-like SI neurons. They were recorded extracellularly from four monkeys that made ballistic wrist flexions and extensions in response to palmar vibration (27, 57, or 127 Hz) that served as the go-cue. Animals held a steady position for a period (≥ 500 ms) preceding the go-cue. The paradigm met NIH animal utilization guidelines. To date, 31 SI neurons (2, 6, 20 and 3 from areas 3a, 3b, 1 and 2) have been considered to be Pacinian-like because each responded better to the highest of the three vibratory stimulus frequencies.

Two types of Pacinian-like SI neurons were found: (1) those that were strongly vibration-entrained ($N=19$), and (2) those that were not ($N=12$). Entrainment was evident by peaks at multiples of the vibratory period in interspike interval (ISI) and expectation density histograms. Joint interval analyses (Perkel et al., *Biophys. J.* 7:391, 1967) revealed negative serial correlations of ISIs for the entrained but not for non-entrained neurons. Negative serial correlations are typical for driven neurons. Type 1 neurons often had short ISIs (2-3 ms) that corresponded to discharge doublets and triplets. The spike trains of Type 2 neurons had unique temporal properties (e.g., the shape of ISI distribution). However, these attributes were not related to the temporal characteristics of the vibration. For both types, the activity patterns resulting from vibratory stimulation of the neurons' receptive fields changed prior to movement onset although the stimulus remained on and no change in hand position was detected.

These two classes of SI Pacinian-like neurons may represent different stages of cortical processing of the information coming from Pacinian corpuscles. Supported by USAF Gr AFOSR 91-0333.

MODULATION OF REACTION TIME BY STIMULUS INTENSITY AND DELAY DURING DIFFERENT ATTENTIONAL STATES. J. Shenasa* and C.E. Chapman. CRSN, Université de Montréal, Canada

As part of a long range goal to investigate the influence of attention on central neural responses to tactile stimuli, a monkey was trained to perform two discrimination tasks: to discriminate either an increase in light intensity (visual), or an increase in the roughness of textured surfaces presented to the immobile digit tips (tactile). The standard textured surface consisted of raised dots with a 2 mm spatial period (SP). The increase in roughness was achieved by increasing the SP to 4.1 or 5.1 mm. Instructional cues indicated whether the animal should direct its attention towards one or both modalities. Trial types were presented in a quasi-random order via the laboratory computer. Results from psychophysical data show that, for the visual task, the animal's mean reaction time (RT) decreased with an increase in either stimulus intensity or delay ($p < 0.01$), with the latter effects being most prominent with the smallest increment in light intensity ($p < 0.001$). The influence of the change in intensity on RT was mostly observed at the shortest visual delay (< 1 sec.). In the texture discrimination task, RT also decreased with increasing stimulus "intensity" (4.1 vs 5.1 mm SP, $p < 0.01$). In contrast to the visual task, however, tactile RT increased with an increase in the stimulus delay ($p < 0.05$). These trends were present for both the directed and the divided attention conditions. It is suggested that the RT for discriminating a change in the visual stimulus is a monotonically increasing saturating function of the stimulus delay. The additive effect of stimulus intensity is most pronounced at shorter delays, i.e. far from the region of saturation. The differential modulation of RT by stimulus delay in the visual and tactile tasks is likely related to the different states of the animal's attention towards these tasks. Supported by the MRC, the FRSQ and the GRSNC (FCAR).

INFLUENCE OF SCANNING VELOCITY ON TEXTURE-RELATED RESPONSES IN THE PRIMARY SOMATOSENSORY CORTEX (SI) DURING THE PERFORMANCE OF A PASSIVE TEXTURE DISCRIMINATION TASK. F. Tremblay* and C.E. Chapman. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Canada.

Psychophysical studies have shown that the ability to scale and discriminate textures by touch is little affected by large variations in scanning velocity. Yet, the signal carried by the cutaneous afferents that subserves texture is strongly modified by changes in scanning velocity. To maintain perceptual constancy, the brain needs to interpret, or perhaps even recode, the peripheral neural input to take into account the peripheral conditions. In the present study, we have addressed this issue by looking at how changes in velocity influence the discharge of texture-related units in SI of monkeys trained to perform a passive texture discrimination task. The task required the monkey to stay immobile while surfaces (smooth or smooth/rough) were displaced under its digit tips using a rotating drum activated by a DC motor. Selected units were tested using two to four different motor speeds. Out of a total of 180 cells with a digital cutaneous field, 56 (31%) were classified as texture-related (significant change in discharge over the second half of the surface, rough vs. smooth, at the slowest speed). Correlations performed on 21/56 units, revealed that 48% (n=10) showed a positive linear relationship between unit discharge and velocity ($p < 0.01$), while 52% (n=11) showed no relationship. An additional 5 units showed a texture-related response that was only apparent at faster motor speeds. These results suggest that there are some SI cells that do reflect changes in velocity in their texture-related discharge, but that a significant proportion of SI cells signal texture independently of scanning velocity. The latter cell type might play an important role in maintaining perceptual constancy of texture when scanning conditions are changing. (funded by the MRC and the FRSQ).

DISCHARGE PROPERTIES OF NEURONES IN THE SOMATOSENSORY FIELDS OF THE LATERAL SULCUS DURING PASSIVE TEXTURE DISCRIMINATION IN THE AWAKE MONKEY. W. Jiang* and C. E. Chapman. CRSN, Université de Montréal, Canada.

We investigated the role of neurones in the upper bank of the lateral sulcus, tentatively the second somatosensory cortex, in discriminating a change in texture of surfaces passively applied to the fingertips of the monkey. Unitary discharge was recorded from 1 monkey trained to discriminate a standard surface (raised dots, 2 mm spatial period (SP) over the entire length) from 3 other surfaces in which, over the second half, the SP was proportionally increased (3, 4 or 5 mm; surfaces physically continuous). The monkey indicated the presence or absence of the change of each surface by, respectively, pulling or pushing a lever with the opposite hand to obtain a juice reward. 54 out of 64 neurones tested had a cutaneous receptive field (RF) that included the scanning digit tips; no RF was found in 10 units although 6 of these discharged vigorously during active hand movements. The discharge of 51/64 cells was modified during the presentation of the texture surfaces (44 increased, 7 decreased). Texture-related modulation of discharge was observed in 15 (28%) of the cutaneous units: 9 displayed proportional changes in their discharge frequency to the SP increase, while the mean discharge rate of the other 6 changed in a single step fashion and so signalled the difference but not the SP. A further 15 cells with varied RF properties (10 cutaneous, 5 no RF) showed a change in discharge at the time that the fingertips contacted the mid-point of the surface irrespective of whether or not a change occurred. While it is evident that some neurones in this area encode specific details of peripheral tactile stimuli (e.g., SP), others are less tightly coupled to the periphery. Together, the results suggest that the somatosensory fields of the lateral sulcus are involved in a higher level of the signal processing hierarchy underlying the sensory decision process required in the present discrimination task. Supported by the MRC and FRSQ.

PAIN MODULATION: PHARMACOLOGY VI

568.1

INTRATHECAL TREATMENT WITH ANTISENSE OLIGODEOXYNUCLEOTIDES TO THE NMDA-RECEPTOR SHOW EFFECTS IN NOCICEPTIVE TESTS IN RAT. M. Rydh-Rinder, L. Alari, M.P. Sandberg, O.-G. Berge*, C.-J. Dalsgaard, C. Wahlestedt, Astra Pain Control AB, Novum Unit, S-141 57 HUDDINGE, SWEDEN

The NMDA receptor has been shown to be involved in transmission and modulation of nociceptive information in the spinal cord. Molecular cloning has recently revealed the existence of five different receptor subtypes termed NR1 and NR2A-D. Functional NMDA-receptors can be reconstituted using the NR1 subunit in combination with any one of the four NR2 subunits. The different combinations differ in expression patterns in the CNS and in their pharmacological properties. We have studied the effect in nociceptive tests of administration of intrathecal antisense oligodeoxynucleotides (ODN) to the NR1 subunit in rats. **METHOD:** Rats (n=18) were divided into three groups: 1) NR1-antisense 2) Mismatch probe 3) Saline 0.9%. Three injections were made on day one, three and five. On day six, tail flick, hot plate and formalin tests were performed. The behaviour was scored by means of a computer program with five behavioural categories where time was continuously recorded 60 minutes after injection; rest and activity with/without paw protection and active pain behaviour (licking, biting). Number of paw jerks were also registered. After testing the animals were killed and the spinal cords were collected on dry ice for radioligand binding experiments. **RESULTS:** In the hot plate test the time latency was significantly prolonged in the antisense-treated group compared to controls. In the tail flick test the tendency was the same although no significance was obtained. In the formalin test the total number of paw jerks were markedly reduced in the antisense group and active pain behaviour was also affected. No motor disturbances were observed in any of the groups. Autoradiography with CGP39653 binding in spinal cord sections from all three groups was undertaken. **CONCLUSION:** This study shows that antisense ODN may be a useful tool in understanding the role of different receptors and their subtypes in complex events such as spinal nociceptive transmission.

568.3

THALAMIC N-METHYL-D-ASPARTATE (NMDA) RECEPTORS ARE INVOLVED IN THE DEVELOPMENT AND MAINTENANCE OF HYPERALGESIA FOLLOWING UNILATERAL HINDPAW INFLAMMATION. R. Kolhekar* and G.F. Gebhart, Dept. of Pharmacology, Univ. of Iowa, Iowa City, 52242.

Effects of inter-thalamic injection of an NMDA receptor antagonist, D,L-amino-5-phosphonopivalic acid (D-APV) on the thermal and mechanical hyperalgesia induced by hindlimb intraplantar injection of carrageenan in the rat were studied in the "acute phase" (within 3 hrs) and the "subacute phase" (24 hrs) after carrageenan administration.

Male Sprague-Dawley rats were injected in the left hindpaw with 2mg carrageenan. Carrageenan produced inflammation and thermal and mechanical hyperalgesia within 3 hours of injection. Two consecutive doses spaced 30 min apart of either D-APV (5 nmol) or saline were injected into the hindlimb representation area in the thalamus (0.5 μ l). Treatment with D-APV, but not saline, in the contralateral but not in the ipsilateral thalamus significantly reduced both the acute mechanical and thermal hyperalgesia. There was no effect on the non-inflamed hindpaw. Rats treated with D-APV in the acute phase failed to develop thermal and mechanical hyperalgesia in the subacute phase. In contrast, rats treated with saline or with D-APV in the ipsilateral thalamus in the acute phase demonstrated significant thermal and mechanical hyperalgesia in the subacute phase.

Taken together, these results suggest an involvement of thalamic NMDA receptors in the development and maintenance of hyperalgesia associated with inflammation in a model of chronic pain.

568.2

ROLE FOR NMDA RECEPTORS IN THE DEVELOPMENT OF MECHANICAL HYPERALGESIA PRODUCED BY CAPSAICIN IN RATS. H.D. Gilchrist* and D.A. Simone. Neuroscience Research in Psychiatry, University of Minnesota, Minneapolis, MN 55455.

Intradermal injection of capsaicin (CAP) has been used as a model for cutaneous hyperalgesia in humans. When injected into the skin, CAP produced hyperalgesia to heat and mechanical stimuli. Furthermore, it was shown that hyperalgesia following CAP correlated with an enhanced excitability of dorsal horn neurons. In order to study underlying pharmacological mechanisms of CAP mediated hyperalgesia, a similar model was developed in rat and discussed previously (Soc. Neurosci. Abst., 396.19, 1993). Briefly, rats received one intraplantar injection of CAP into the plantar surface of one hindpaw. CAP (1-30 μ g) produced a dose-dependent decrease in withdrawal latency to heat and increased the frequency of withdrawal responses to mechanical stimuli (von Frey monofilaments). In the present study, we investigated the role of spinal NMDA receptors in the development of hyperalgesia following CAP.

A chronic intrathecal (I.T.) catheter was surgically placed at the level of the lumbar enlargement. I.T. pretreatment with the competitive NMDA receptor antagonist AP-5 (2, 6, or 8 μ g in 5 μ l), administered 10 min prior to intraplantar CAP (10 μ g in 10 μ l), dose-dependently attenuated the normally enhanced withdrawal responses evoked by mechanical stimuli without altering hyperalgesia to heat stimuli. This suggests that spinal NMDA receptors are necessary for the development of mechanical hyperalgesia following CAP in rat. It is also concluded that in this model, hyperalgesia to heat may involve alternate mechanisms, such as sensitization of peripheral nociceptors. Data will be discussed in terms of the contributions of spinal NMDA as well as non-NMDA receptors to the development of hyperalgesia produced by CAP. Supported by NRS A05592 and the Minnesota Medical Foundation.

NMDA AND NK1 RECEPTOR ANTAGONISTS ACT ADDITIVELY TO REDUCE BEHAVIORAL HYPERALGESIA IN RATS WITH UNILATERAL INFLAMMATION. K. Ren* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies suggest that both N-methyl-D-aspartate (NMDA) and neurokinin 1 (NK1) receptors are involved in spinal nociceptive transmission. To assess the interaction between NMDA and NK1 receptor systems on nociceptive responses of rats with complete Freund's adjuvant-induced hindpaw inflammation/hyperalgesia, an isobolographic analysis was performed using selective antagonists against NMDA or NK1 receptors. Thermal hyperalgesia, determined by a reduction of paw withdrawal latency to a heat stimulus, was induced by a single injection of complete Freund's adjuvant (1:1 emulsion, 100 μ g *Mycobacterium*) into the hindpaw of rats. The drugs were given intrathecally. Dextrophan, a non-competitive NMDA receptor antagonist, attenuated hyperalgesia dose-dependently with a maximal $\approx 80\%$ reversal of hyperalgesia. WIN-51,708 and CP-96,345, nonpeptide NK1 receptor antagonists, also attenuated hyperalgesia when they were given alone. WIN-51,708 appeared to be about 8-fold more potent than CP-96,345. A combination of Dextrophan and WIN-51,708 was then given at a fixed ratio. The ED₅₀ value obtained from co-administration of the drugs was found to be not significantly different from the isobolographic line generated by individual ED₅₀ values of the two receptor antagonists. These results suggest that although both NMDA and NK1 receptor systems play a role in inflammation-induced hyperalgesia, the two systems appear to act independently.

568.5

NMDA AND MUSCARINIC ANTAGONISTS IN THE ROSTRO-VENTRAL MEDULLA INHIBIT MORPHINE ANALGESIA IN THE PERIAQUEDUCTAL GRAY IN RATS. M. Spinella*, L.A. Schaefer, M.L. Cooper and R.J. Bodnar. Dept. of Psychology and Neuropsychology Doctoral Program, Queens Col., CUNY, Flushing, NY 11367.

Supraspinal morphine analgesia in the periaqueductal gray (PAG) is modulated by mu and delta opioid receptors and by 5HT₂ and 5HT₁ receptors in the rostro-ventral medulla (RVM). Since NMDA and muscarinic receptors in the RVM have been implicated in nociception, the present study evaluated whether NMDA (MK-801, AP7) or muscarinic (scopolamine, pirenzepine) antagonists in the RVM altered PAG morphine analgesia on the tail-flick and jump tests. PAG morphine (2.5 ug) analgesia was dose-dependently reduced by MK-801 (0.03-3 ug: 50-100%) and AP7 (0.01-1 ug: 30-70%) in the RVM on both tests. RVM injections of MK-801, but not AP7 reduced basal nociception. PAG morphine analgesia was dose-dependently reduced by the muscarinic antagonist, scopolamine (0.5-5 ug: 70%) and less so by the M₁ antagonist, pirenzepine (0.05-5 ug: 35-50%). Both muscarinic antagonists reduced basal latencies, but not jump thresholds. These data implicate NMDA and muscarinic receptors in the complex modulation of PAG morphine analgesia by the RVM.

AGE-RELATED CHANGES IN THE NEUROCHEMICAL MEDIATION AND THE MAGNITUDE OF SWIM STRESS-INDUCED ANALGESIA IN MICE W.F. Sternberg* and J.C. Liebeskind. Department of Psychology, University of California, Los Angeles, CA 90024.

Organismic variables have been shown to play a modulatory role in the expression of endogenous pain control mechanisms. This study assessed lifespan changes in the magnitude and neurochemical mediation of cold-water swim stress-induced analgesia (SSIA) in male and female young and old Swiss-Webster mice. We have previously shown that this swim stressor produces non-opioid analgesia on the hot-plate test in both male and female mice, and this analgesia is mediated by the NMDA receptor in young adult males, but not in similarly aged females (Mogil et al., *Pain*, 53, 17-25, 1993). In the present study, male and female young (32 days of age) and old (approximately 15 months of age) mice were tested for their analgesic response to a 3-min swim in water maintained at 15°C. In 32 day old animals, male and female mice exhibited analgesia following the swim stressor that was antagonized by MK-801 (0.075 mg/kg; i.p.), and was therefore NMDA-mediated, in both sexes. Thus, prepubescent females display primarily NMDA-mediated SSIA, whereas we previously reported that sexually mature females do not (Mogil et al., *ibid*). In the 15-month old animals, MK-801 did not antagonize SSIA in either sex. Thus, a qualitative difference in SSIA mediation is noted across the lifespan in male mice, as well as females. Analgesic magnitude increased significantly in male mice with aging, but not in females. These findings indicate that ontogenetic stage can contribute significantly to the expression of SSIA, and should be taken into consideration in future studies on SSIA mechanisms. SPINAL ACTIONS OF MEDETOMIDINE AND XYLAZINE ON RESPONSES TO EXCITATORY AMINO ACIDS AND PERIPHERAL STIMULATION. J. F. Herrero and P. M. Headley. The Medical School, Bristol BS8 1TD, U.K. SPON: BRAIN RESEARCH ASSOCIATION.

α_2 -adrenoceptor agonists, including medetomidine (Med) and xylazine (Xyl), are analgesic in animals and man (for review see Pertovaara, A. 1993, *Prog. Neurobiol.* 40, 691). They affect spinal nociception, but the underlying mechanisms are not clear. We have now examined whether this effect is related to an interaction with excitatory amino acids (EAA) and is selective for nociceptive responses. Experiments were performed on spinalized Wistar rats anaesthetized with α -chloralose. Multibarrel pipettes were used for recording single neuron activity. Xyl (10 to 160 μ g/kg) and Med (1.25 to 10 μ g/kg) were injected i.v. in a log₂ regime, and their effects tested on responses elicited by cycles of 2 EAA (NMDA, AMPA or kainate) and 2 peripheral stimuli (noxious pinch, noxious heat or innocuous vibration) in different combinations.

Xyl significantly depressed responses to kainate (ID₅₀=60 μ g/kg), whereas NMDA and AMPA were very little affected. Med, however, produced a non-selective depression of all three EAA, being more potent on kainate and NMDA (ID₅₀=6 μ g/kg) than on AMPA (35% reduction with 10 μ g/kg). Both Xyl and Med depressed nociceptive pinch and heat responses, leaving innocuous vibration responses unaffected. The ID₅₀ for Xyl was 70 μ g/kg for pinch and 170 μ g/kg for heat, and, for Med, 10 μ g/kg for pinch and 2 μ g/kg for heat. Spontaneous activity was not modified by Xyl and was only depressed with 10 μ g/kg of Med. All these effects were reversed or prevented by Atipamezole (80 μ g/kg). The results indicate that at doses of Med and Xyl that cause spinal antinociception, EAA responses are reduced. The pattern of EAA reduction does not, however, correlate clearly with the antinociception. Supported by the Wellcome Trust.

SELECTIVITY OF NMDA AND NON-NMDA EXCITATORY AMINO ACID ANTAGONISTS FOR NOCICEPTION EVOKED BY ACTIVATION OF C OR A δ NOCICEPTORS IN RATS. D.C. Yeomans*, J. Youngwerth, and H. K. Proudfoot. Dept. of Pharmacology, U. Illinois at Chicago, Chicago, Illinois 60612.

Excitatory Amino Acids (EAAs) are contained in and released from nociceptive primary afferents. Although EAAs are apparently contained in all nociceptive afferent types, the EAA receptors that mediate the nociceptive responses produced by activating these afferents have not been determined.

In this experiment, we determined the effects of intrathecal (i.t.) administration of the NMDA antagonist AP5 and the AMPA/Kainate antagonist DNQX on nociception produced by activation of A δ or C nociceptors. Administration of AP5 produced a selective, dose-dependent increase in latencies to foot withdrawal responses evoked by low noxious skin heating rates, but did not affect responses produced by high skin heating rates in doses that did not alter motor activity. These results indicate that activation of C-nociceptors produces nociception mediated in part by NMDA receptors. In contrast, intrathecal DNQX increased latencies for both high and low heating rates. These results suggest that EAAs released from both A δ and C nociceptors act on non-NMDA receptors to produce nociception. Supported by USPHS Grants DA08256 (DCY) and DA03980 (HKP).

568.8

PERIPHERAL ADMINISTRATION OF EXCITATORY AMINO ACIDS MODULATE NOCICEPTIVE BEHAVIOR IN RATS. D.L. Jackson*, J.D. Richardson, K.M. Hargreaves. Depts. of Rest. Sciences and Pharmacology, Minneapolis, MN.

While it has been demonstrated that certain primary afferent neurons in a neonatal rat spinal cord-tail preparation are activated by peripherally administered glutamate (Ault and Hildebrand, *Agents Actions* 1993; 39:C142-144), relatively little is known about the peripheral actions of EAAs in the intact adult animal. To evaluate possible peripheral mechanisms of nociceptive modulation by EAAs, male Sprague-Dawley rats were tested for thermal hyperalgesia by placing them in a clear plastic chamber with an infrared heat source aimed through the glass floor of the chamber at the treated hindpaw (Pain 1988; 32:77-88). Paw withdrawal latencies were detected by a photocell and recorded by an observer blinded to treatment allocation. Following the collection of baseline withdrawal latencies, rats received 100 μ l ipl injections of L- or D-glutamate (10 nmol), aspartate (100 nmol), or saline vehicle. Post-injection latencies were measured at 15 and 60 minutes. Data were analyzed by ANOVA and Duncan's test and expressed as means \pm s.e.m. L-glutamate reduced latencies at 15 minutes relative to the saline control (-19.9 \pm 5.6% vs. +9.5 \pm 8.3%; p<0.05). The stereoisomer, D-glutamate, had no effect on latencies at this time point (+10.8 \pm 12.7%). This is in contrast to the observed increase in latency at both 15 and 60 minutes following the ipl injection of aspartate relative to control (15 min = +42.1 \pm 14.1% vs. -4.4 \pm 11.2%; p<0.05; and 60 min = +54.0 \pm 15.0% vs. +1.8 \pm 14.2%; p<0.05). Collectively, these results support the hypothesis that the EAAs glutamate and aspartate can differentially modulate nociceptive behavior when injected into normal tissue. This research was funded by K16-DE0027, DE09860, DE10093, and a Howard Hughes Medical Institute Predoctoral Fellowship (JDR).

568.10

ANTAGONISTS AT THE GLYCINE MODULATORY SITE OF THE NMDA RECEPTOR COMPLEX REVERSE INFLAMMATION-INDUCED MECHANICAL HYPERALGESIA IN THE RAT.

J.M.A. Laird*, G.S. Mason, R.J. Hargreaves & R.G. Hill Dept. of Pharmacology, Merck, Sharp & Dohme Research Labs., Harlow, CM20 2QR, U.K.

Intraplantar injection of carrageenan (CARRA) in one hind paw in the rat produces inflammation associated with decreased thresholds to noxious mechanical and thermal stimuli applied to the inflamed paw (hyperalgesia). The effects on this mechanical hyperalgesia of L-695,902 and L-701,324, structurally distinct antagonists at the glycine site on the NMDA receptor, and of L-687,414, a low efficacy partial agonist that acts as a functional antagonist at the NMDA/glycine site, were compared.

Mechanical thresholds were measured in both hind paws of male SD rats using an Ugo-Basile algometer 1 hr before and 3 hrs after CARRA or saline was injected into one hind paw. Test compound or vehicle was given i.p. 1 hr before the final test. Dose-response curves for each compound were constructed in separate experiments. All 3 compounds produced dose-dependent and statistically significant (p < 0.05) reversal of mechanical hyperalgesia in the CARRA injected paw with minimum effective doses (M.E.D.s) as follows: L-695,902 = 50, L-701,324 = 3 and L-687,414 = 100 mg/kg. L-695,902 and L-701,324 also produced a dose-dependent and statistically significant (p < 0.05) increase in mechanical threshold in the non-injected paw (analgesia) with M.E.D.s of 20 and 10 mg/kg respectively. In contrast, L-687,414 had no effect on the threshold of the non-injected paw.

We conclude that both antagonists and partial agonists at the NMDA receptor glycine site reverse inflammation-induced mechanical hyperalgesia, but that NMDA receptor glycine site antagonists also affect the response to noxious stimuli applied to normal tissue.

568.11

PAIN REDUCTION BY INTRATHECAL ADMINISTRATION OF GLYCINE.
R.K. SIMPSON*, M.M. GONDO, C.S. ROBERTSON, AND J.C. GOODMAN,
Neurosurgery Department, Baylor College of Medicine, Houston, TX 77030.

Glycine, the primary inhibitory neurotransmitter of the spinal cord, is found in high concentration within segmental interneuron pools. Glycine is released during epidural spinal cord stimulation, an effective method of treating chronic pain. We hypothesize that the pain is attenuated by glycine.

Neuropathic rats were created by unilateral partial ligation of the proximal sciatic nerve with 4 absorbable chromic sutures place 1 mm apart. A PE-10 catheter was placed into the cisterna magna and directed toward the lumbar enlargement. Twelve days after ligation these rats were treated with intrathecal infusion of glycine, strychnine, MK-801, and 5,7-DKA, at a concentration of 0.1 μ mol for 2 hours and at a rate of 5-10 μ l/min. Pain scores were calculated using the Randall-Selitto technique of mechanonociceptive stimulation and compared to rats receiving artificial CSF. Significant differences, as calculated by ANOVA, were defined as $p < 0.05$. Each spinal cord and nerve was evaluated using standard neurohistopathologic techniques.

Our results showed that the force necessary to produce a pain response, or movement of the neuropathic limb, was increased from 70 gr to approximately 120 gr. In contrast, strychnine lowered the threshold from approximately 70 gr to 40 gr. Neither MK-801 or 5,7-DKA alone had significant influence on the pain response.

When glycine and strychnine were administered together, the effect of glycine on pain was blocked. When administered with glycine, MK-801 or 5,7-DKA did not block the reduction in the pain response to glycine.

We suggest that the amelioration of mechanonociceptive induced pain is mediated, in part, by glycine primarily at the strychnine sensitive glycine receptor.

568.13

SPINAL STRYCHNINE INCREASES RESPONSES OF NOCICEPTIVE DORSAL HORN NEURONS TO LOW THRESHOLD INPUT AND LENGTHENS AFTERDISCHARGE. L.S. Sorkin* and S. Puig, Anesthesiol. Research Lab, Univ. of Calif. @ San Diego, La Jolla CA 92093-0818

Hyperesthesia following many neurogenic injuries is associated with inhibitory interneuronal loss. Pharmacologic blockade of glycine receptors results in tactile evoked allodynia. It has been proposed that this is due to loss of "auto-inhibition" of low threshold (LT) input to wide dynamic range (WDR) cells via an inhibitory interneuron. This study determined if spinal strychnine (STR) results in excessive responsiveness of dorsal horn neurons.

Dialysis probes were placed in the dorsal horn of chloralose-anesthetized cats and extracellular recordings made from WDR cells in close proximity to the probes. Artificial CSF was perfused and baseline responses to a range of mechanical stimuli measured. The perfusate was changed to STR (1 mM), STR + an NMDA antagonist (2 mM AP7) or STR + a non-NMDA antagonist (1 mM CNQX) and the receptive field properties redetermined.

Exposure to STR resulted in a greatly enhanced high frequency response to LT input (especially hair). The firing pattern was usually one of irregular bursting. The response to high threshold input also increased, but to a lesser degree. The high threshold response was usually followed by a prolonged afterdischarge (several min). This was seen less frequently after LT input. Receptive field size also increased substantially. In most cases, basal firing rates were unaffected. Preliminary results indicate that this enhanced responsiveness was blocked by co-administration of AP7 and that CNQX reduced evoked activity while leaving the afterdischarge relatively intact.

These results support the hypothesis that removal of tonic glycine inhibition leads to excessive activity in WDR neurons which is mediated by activity at a local NMDA receptor. [This study was supported by NS 11255]

DEXTROMETHORPHAN SUPPRESSES THE FORMALIN-INDUCED INCREASE IN SPINAL CORD C-FOS mRNA. K.J. Elliott*, M. Brodsky, A. Hynansky, K.M. Foley and C.E. Inturrisi, Dept. Pharmacology, Cornell U. Med. Coll., NY, NY and Memorial Sloan-Kettering Cancer Center, NY, NY 10021.

Dextromethorphan (DM) is a clinically available oral antitussive and NMDA receptor antagonist with the ability to attenuate neuronal "wind-up" (Dickenson et al., 1991). We have found that pretreatment with DM (6, 20 or 60 mg/kg sc) suppresses formalin-induced nociceptive behaviors in a dose-dependent manner. Nociception turns on the expression of the immediate early genes (IEG) including c-fos proto-oncogene. Formalin injection (20 μ l) to the right hindpaw of BALB/c mice produces a reliable induction of c-fos mRNA of almost 100% in the right spinal dorsal horn (SDH) as assessed with quantitative solution hybridization at 30 minutes post injection. No change in c-fos mRNA was detected in the contralateral SDH, nucleus raphe magnus, periaqueductal grey, medial thalamus, or sensorimotor cortex. Pretreatment with DM at 60 mg/kg sc thirty minutes prior to formalin resulted in a suppression of c-fos induction, so that c-fos mRNA levels in SDH of animals receiving DM prior to formalin did not differ from controls. These data indicate that DM suppresses formalin nociceptive behavior and one of the biochemical consequences of formalin nociception, i.e., induction of c-fos mRNA. Supported by the VZV Research Foundation (KJE) and DA01457, DA07274, DA00198 and CA32897.

568.12

ROLE OF NMDA RECEPTOR AND NITRIC OXIDE (NO) IN THE FACILITATION BY INTRATHECAL (IT) NMDA OF LIMB WITHDRAWALS EVOKED BY GRADED NOXIOUS HEAT IN CONSCIOUS RATS. E. Carstens*, Neurobiology, Physiology & Behavior, Univ. of California, Davis, CA 95616.

Secondary hyperalgesia is thought to be mediated by hyperexcitability of nociceptive spinal neurons via (a) glutamate release from nociceptors to (b) activate postsynaptic NMDA receptors to (c) allow Ca^{++} influx to (d) effect persistent cellular changes. In behavioral studies, hyperalgesia is seen as a reduced threshold for nociceptive responses such as the tail-flick. We investigated if IT NMDA enhances suprathreshold and threshold responses using a quantitative measure of limb withdrawal response (WR) magnitude, and if this is prevented by NMDA receptor/channel blockers (APV, MK801, respectively) or the alternate substrate for NO synthase (L-NAME).

One wk after implanting IT catheters, the ventral hindpaw was fixed to a thermode to deliver an ascending series of 5 s heat pulses (40-52°C, 2° steps; 2 min interval). The normalized area of integrated limb flexor EMGs gave a measure of WR magnitude across temperatures (stimulus-response function=SRF). Two paradigms were used: (1) One SRF was generated with (a) no drug (control), (b) 3 μ l NMDA (100 pmol) given IT prior to each heat stimulus, or (c) 10 μ l bolus of IT APV (pmol- μ mol), MK801 (μ mol) or L-NAME (μ mol), followed by (b). (2) Two SRFs were generated, the first with no drug (control) and the second 20 min later with (b), (c), (d) each heat stimulus preceded by IT NaCl (0.9%), or (e) APV, MK801 or L-NAME followed by (d).

In the 2-SRF paradigm, NMDA significantly increased WR magnitude at 40-48°C vs. controls, reducing the SRF threshold and slope. This was not prevented by APV, MK801 or L-NAME. In these cases or when NaCl or MK801 + NaCl were given, the second SRF was shifted toward significantly higher temperatures. Thus, WRs appear to be sensitized during the second SRF. This sensitization may confound any effect of NMDA on the second SRF.

In the 1-SRF paradigm, NMDA significantly reduced the threshold of the SRF compared to controls. This was prevented in rats pretreated with APV, MK801 and L-NAME. These data support the idea that the NMDA receptor and NO are involved in the development of hyperexcitability in spinal neurons mediating the WR.

ADRENAL MEDULLARY TRANSPLANTS ATTENUATE NMDA-INDUCED HYPERALGESIA AND ALLODYNIA. J. Siegan*, A.T. Hama, J. Sagen, Dept. of Anatomy and Cell Biology, Univ. of Illinois at Chicago, Chicago, IL 60612

Excitatory amino acids, via activation of the NMDA receptor, are implicated in the persistence of pathological pain. Recent work in our laboratory indicates that the transplantation of adrenal medullary chromaffin cells into the spinal cord subarachnoid space can alleviate chronic pain syndromes in animal models. The purpose of this study was to determine whether adrenal medullary transplants act via modifying spinal NMDA hyperexcitability. For this study intrathecal catheters were implanted into the spinal subarachnoid space of rats. Rats also received either adrenal medullary transplants or control striated muscle transplants via laminectomy at the level of the lumbar enlargement. Abnormal pain responses to several doses of intrathecally administered NMDA were determined using behavioral tests for tactile allodynia and mechanical and thermal hyperalgesia. Results indicated that NMDA produced allodynia and hyperalgesia in control transplanted animals in a dose related fashion. In contrast, the dose response to NMDA was significantly shifted rightward in animals with adrenal medullary transplants, and hyperalgesia and allodynia were completely alleviated in the lower dose ranges of NMDA in these animals. The beneficial effects of the transplants were not decreased by naloxone, but were partially attenuated by phentolamine, indicating a limited role for catecholamines released by the transplanted cells. However, this did not completely account for the effects of the transplants. In summary, these results suggest that adrenal medullary transplants may intervene in the cascade of hyperexcitability initiated by the activation of NMDA receptors in pathological pain syndromes. Supported by NIH grant NS25054.

THE N-METHYL-D-ASPARTATE RECEPTOR ANTAGONIST DEXTROMETHORPHAN SELECTIVELY REDUCES TEMPORAL SUMMATION OF SECOND PAIN IN MAN. D.D. Price*, J. Mao, H. Frenk and D.J. Mayer, Dept. Anesthesiology, Medical College of Virginia, Richmond, VA 23298

Slow temporal summation of second pain is thought to be a psychophysical correlate of temporal summation of C afferent-mediated responses of dorsal horn nociceptive neurons, termed *windup*. Windup has been shown to be mediated by N-methyl-D-aspartate (NMDA) receptor activation within the spinal cord of experimental animals. We thus tested whether a NMDA receptor antagonist would reduce slow temporal summation of second pain in man. Oral doses of dextromethorphan (DM), a common cough suppressant and NMDA receptor antagonist, and their vehicle control were given on a double blind basis to normal volunteer human subjects who rated intensities of first and second pain in response to repeated painful electric shocks and repeated 52° C heat pulses. Doses of 30 and 45 mg but not 15 mg (in a single bolus) were effective in attenuating temporal summation of second pain as compared to vehicle controls (Wilcoxon signed-ranks tests, $P < 0.03$). By contrast, neither first pain nor second pain evoked by the first stimulus in a train of stimuli were affected by any of these doses of DM ($P > 0.05$). These results further confirm temporal summation of second pain as a psychophysical correlate of windup by providing evidence that DM selectively reduces temporal summation of second pain, as has been shown for windup.

NMDA MEDIATED EXCITABILITY CHANGES OF SOMATIC AND VISCERO-SOMATIC NOCICEPTIVE REFLEXES IN THE SPINAL CORD. F. Cervero*, J.M.A. Laird & P. G. de la Rubia. Dept. Fisiología y Farmacología, Fac. Medicina, Univ. Alcalá de Henares, Madrid, Spain.

Repetitive stimulation of somatic nociceptors evokes progressive increases in the excitability of spinal neurones ("wind up"). Some forms of nociceptive stimulation are also reported to evoke long lasting potentiation of somatic reflexes. These changes are believed to be mediated by the activation of NMDA receptors on spinal neurones. In this study we have investigated afferent-induced excitability changes of nociceptive viscerosomatic reflexes and the role of spinal NMDA receptors in their generation.

Experiments were conducted on decerebrated and spinalised rabbits. Reflex activity was recorded from the first lumbar nerve in response to supramaximal electrical stimulation of the ipsilateral second lumbar nerve (somatic reflex) or of the splanchnic nerves (viscero-somatic reflex). Changes in the excitability of these reflexes during repetitive afferent stimulation at 1Hz ("wind up") and up to 5 minutes after (reflex potentiation) were studied as were the effects of intravenous administration of the NMDA receptor antagonist ketamine at doses between 1 and 30 mg/kg.

"Wind up" was consistently evoked in somatic reflexes but less so in viscerosomatic reflexes. Potentiation of viscerosomatic reflexes was rarely seen and often these reflexes were depressed by repetitive stimulation of visceral afferents. Ketamine caused a dose-dependant decrease of both somatic and viscerosomatic reflexes and a reduction in the magnitude of "wind up". We conclude that there are important differences in the spinal organization of somatic and viscerosomatic nociceptive reflexes and that NMDA receptors influence the baseline levels of reflex excitability in the spinal cord as well as the dynamic components of the reflexes.

SYSTEMIC TREATMENT WITH MEMANTINE REDUCES MECHANICAL ALLODYNIA IN A RAT MODEL OF PERIPHERAL NEUROPATHY. G. Hargett*, A. Friedman and S.M. Carlton. Dept. of Anatomy and Neurosciences, Marine Biomedical Inst. UTMB, Galveston, TX 77555

A recently developed animal model of peripheral neuropathy is characterized by mechanical allodynia which develops within days and lasts for 3 months following the injury. The goal of the present study was to determine whether treatment with the non-competitive NMDA antagonist Memantine (MEM) had therapeutic and/or prophylactic effects in relieving mechanical allodynia observed in this animal model.

Acute delivery: In 5 groups of rats (Sprague-Dawley, 125-175gm) a dose-response curve was established. Following baseline testing with von Frey hairs on the ventral surface of each foot and performance on a rotarod, animals were anesthetized and the L5 and L6 spinal nerves tightly ligated with 6-0 silk. Animals were retested on days 1,3,5,7; on day 7, they (n = 5 to 9 per group) were injected IP with saline or either 0.1, 5.0, 10 or 20mg/kg of MEM. The animals were retested for mechanical allodynia and motor performance at 1,2,4,6,8 and 24 hrs post-injection.

Chronic delivery: To determine therapeutic effects, MEM was chronically administered via IP Alzet pumps (#2ML1, delivers 10µl/hr/7 days), implanted on day 7 postsurgery. The pumps delivered MEM at a continuous rate of 4mg/kg/hr for 1 week. To determine prophylactic effects, rats were implanted with IP pumps 2 days prior to surgery for the nerve ligation. All animals were retested every day (7-14 day survival) for withdrawal responses to von frey hairs and rotarod performance.

Acute IP injections of MEM demonstrated that saline and 0.1mg/kg MEM had no effect on behavior. 5.0mg/kg MEM significantly attenuated mechanical allodynia at 1hr post-injection with no motor impairment. Although 10 and 20mg/kg effectively attenuated mechanical allodynia at 1,2 and 4hrs, the animals displayed hyperactivity. No effect was observed on the contralateral control paw. Preliminary studies concerning chronic treatment with 4mg/kg/hr via pumps (n=3) demonstrated a therapeutic effect with no abnormal motor signs. However, this same dose had no obvious prophylactic effect. Results indicate that NMDA receptors play an important role in the expression of allodynia and MEM may be used as a successful treatment for neuropathic pain. (Supported by NS11255 and NS27910.)

568.18

BEHAVIORAL AND ELECTROPHYSIOLOGICAL EFFECTS OF MEMANTINE IN A PRIMATE MODEL OF PERIPHERAL NEUROPATHY. S.M. Carlton*, H. Rees, K. Gondesens, M. Tsuruoka and W.D. Willis. Dept. of Anatomy and Neurosciences, Marine Biomedical Inst. UTMB, Galveston, TX 77555

The development of animal models mimicking painful peripheral neuropathies allows investigation of underlying mechanisms with the expectation that this will lead to improved clinical treatment. NMDA receptor activation is an important mechanism contributing to neuropathic pain. The present study addresses the efficacy of Memantine (MEM), a non-competitive NMDA antagonist, in attenuating behavioral and electrophysiological abnormalities previously documented in a monkey model of peripheral neuropathy.

In an anesthetized monkey (*Macaca fascicularis*), one L7 spinal nerve was tightly ligated, a sham operation was performed on the contralateral side. Compared to pre-surgery levels, the animal demonstrated an increased sensitivity to mechanical stimulation (allodynia) with von Frey hairs and brushing with a camel hair brush 5 days post-surgery. On subsequent days, MEM was delivered in a bolus either IM (5 and 10mg), subcutaneous (15mg) or orally (30 and 50mg). The first test period of each day established the baseline; following administration of MEM, testing was repeated at hourly intervals. The most effective route in attenuating allodynia in the EXP foot was IM or oral administration; the subcutaneous injection did not have any effect. Responses on the control foot were not affected by any route.

In 3 normal primates, 100mM MEM administered through a dialysis fiber in the dorsal horn did not change spontaneous activity of STT cells (n=3), but resulted in decreased responses to brush (+14%), press (+55%), pinch (+40%) and heat (+49%). 10mM MEM administered to 1 neuropathic animal resulted in a similar decrease in 2 STT cells: brush (+11%), press (+26%), pinch (+35%) and heat (+53%). Responses to von frey filaments were also decreased by 27%. These results suggest MEM affects processing by STT cells and may be a suitable therapeutic drug for the treatment of neuropathic pain. (Supported by NS11255 and NS27910.)

MODULATION OF ALTERED NMDA RECEPTOR BINDING BY SPINAL ADRENAL MEDULLARY TRANSPLANTS IN ANIMALS WITH PAINFUL PERIPHERAL NEUROPATHY. A.T. Hama*, J.R. Unnerstall and J. Sagen. Dept. Anatomy and Cell Biol., Univ. IL at Chicago, Chicago, IL 60612.

The sequence of events that leads to neuropathic pain may include activation of the N-methyl-D-aspartate (NMDA) receptor-ion channel complex since pretreatment with competitive as well as noncompetitive NMDA receptor antagonists prevents nerve injury-induced abnormal pain. Earlier studies in our laboratory have shown that spinal adrenal medullary tissue transplants reduce neuropathic pain over an extended period of time. The effects of adrenal tissue transplants on spinal NMDA receptor binding was investigated using a new high-affinity glutamate binding site antagonist, CGP-39653. Saturation studies in spinal cord revealed that [³H]CGP-39653 binding affinity was similar to cerebral cortex but B_{max} was lower. Neuropathic pain was induced in rats by loose ligation of the right sciatic nerve (Bennett and Xie, 1988). Two weeks following nerve surgery, either adrenal medullary or control striated muscle tissue pieces were implanted in the subarachnoid space above lumbar spinal cord. One week following implantation, membrane preparations were made from spinal lumbar regions L₁-L₆, the spinal cord split in half down the dorsoventral axis and homogenized separately. Animals that received control transplants showed decreased [³H]CGP-39653 specific binding ipsilaterally to nerve ligation, compared to the contralateral side and unoperated controls. In contrast, adrenal medullary transplants bilaterally increased [³H]CGP-39653 binding, bringing binding on the nerve-injured side back to near normal control levels. These results suggest that adrenal medullary transplants reduce neuropathic pain by equilibrating abnormal excitatory amino acid transmission in the spinal cord. Supported by NIH grant NS25054.

DO GLIA-NEURONAL INTERACTIONS GENERATE SENSORY EVOKED POTENTIALS? R. Galambos* and G. Juhász. Eötvös Loránd Univ., 1088-N, Budapest, Hungary

We will state and discuss the proposition that cortical evoked potentials are generated when neurons interact with glial cells across extracellular space. The evidence is as follows. First, glial research by Kuffler, Nichols, Dowling, Newman, and dozens of others validates the claim that the major evoked potential of the eye, the retinal b-wave, is produced this way. Second, the b-wave of freely-moving rats (stimulated through a light emitting diode implanted above an eye) approximately doubles in amplitude during slow wave sleep; similar plastic changes takes place in the visual cortical evoked potential recorded at the same time. Third, when the rat receives paired flashes, the refractory periods measured for b-wave and for cortical responses are both prolonged, but not identically. b-waves begin when synapses activated by rods and cones perturb [K⁺]_o and initiate potassium currents within Müller (glial) cell cytoplasm. The evidence that cortical astrocytes similarly optimize [K⁺]_o is still indirect, but nothing uncovered so far seems to rule the possibility out.

SCLERAL DISTRIBUTION OF ERG B-WAVE AND OSCILLATORY POTENTIALS (OPs). P. Lachapelle¹, J. Benoit¹ & C. Casanova². Depts of Ophthalmology, ¹McGill University - Montreal Children's Hospital, Montréal, Qué., Canada H3H 1P3 and ²Université de Sherbrooke, Sherbrooke, Qué., Canada J1H 5N4.

Previous studies reporting the scleral distribution of the ERG made use of a bipolar recording approach a method which could have masked the existence of localised ERG dipoles. We investigated this issue in (n=10) anesthetized, paralyzed and artificially ventilated New Zealand rabbits. Scleral ERGs (1-1000 Hz) and OPs (100-1000 Hz) were recorded with a 0.5 mm tungsten electrode with reference and ground electrodes positioned in the mouth and neck muscles respectively. The anterior portion of the globe was dominated by a positive b-wave whose amplitude was maximal at the cornea. It was gradually replaced by a slow negative wave (inversion at 5-6 mm posterior to the limbus) onto which were superimposed large oscillations. These new ERG components, never reported in bipolar recordings, reached a maximum at 7-8 mm posterior to the limbus. FFT analysis performed at this scleral location indicated that: 1- the negative wave is not an inverted b-wave and 2- the large oscillations are, given their frequency domain, enhanced OPs. This was confirmed with the analysis of the tracings obtained with the OPs specific bandwidth (100-1000Hz). It showed that the OPs reached their maximal amplitude (85% larger than corneal OPs) some 7-8 mm posterior to the limbus. Our results indicate that the OPs are the most consistent retinal potentials since they are found at all scleral locations while the b-wave appears to be limited to the anterior portion of the eye. Furthermore in showing that maximal OPs are obtained in b-wave free locations suggests that the two retinal generators (b-wave and OPs) may interact in an inhibitory fashion. Funded by MRC MT12153.

STIMULATION OF RETINAL DOPAMINE D2 RECEPTORS AFFECTS AMPLITUDES OF THE B BUT NOT A WAVES OF THE RABBIT ELECTRORETINOGRAM (ERG)

L. Boumghar, D. Belliveau, F.B. Jolicoeur* and C. Casanova. Departments of Ophthalmology and Physiology-Biophysics and Departments of Psychiatry and Pharmacology* Faculty of Medicine, Univ. of Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4

The two classical sub-types of dopamine receptors, D1 and D2, are present in the retina. We have shown that stimulation of both receptors with the mixed D1 and D2 agonist apomorphine results in marked reductions in amplitudes of both a and b waves of the rabbit ERG. In order to better delineate the subtype of dopamine receptor responsible for these findings, we have examined the effects of R-norpropylapomorphine (NPA), a purported selective D-2 agonist, on retinal electrophysiology in rabbits. Experiments were carried out in anesthetized adult pigmented rabbits. A corneal electrode was inserted near the limbus to record the ERG. Responses were evoked by a diffuse flash (Grass PS2) and averaged 25 times. Three intensity levels were tested. NPA was injected intravitreally at various concentrations (0.01-10 µg in 100 µl). Our results indicate that the intravitreal injection of NPA reduced, in a dose related fashion, the amplitude of the ERG b wave (up to 40%) in both scotopic and photopic conditions without significant changes in the implicit time. No effects were seen at the level of the a-wave. These results suggest that the D2 receptor is implicated in modulation of the b-wave, whereas the D1 receptor is involved in the modulation of the a-wave.

EXPRESSION OF METABOTROPIC GLUTAMATE RECEPTOR mRNAs IN ADULT RAT RETINA. E. Hartvelt* and J. H. Brandstätter.

Max-Planck-Institut für Hirnforschung, Neuroanat. Abt., Frankfurt, Germany.

Glutamate is an important transmitter in the vertebrate retina and recently a series of ionotropic and metabotropic glutamate receptors has been cloned and characterized. Whereas most of the glutamatergic neurotransmission in the retina seems to be mediated by ionotropic receptors, the extent of involvement of metabotropic receptors in retinal function is unclear. We have therefore investigated the expression patterns of six metabotropic glutamate receptors (mGluR1-mGluR6) by *in situ* hybridization. Retina sections were hybridized with ³⁵S-labeled oligonucleotide probes and thereafter exposed to photo-sensitive emulsion for up to 12 weeks.

mGluR1: expressed by virtually all cells in the ganglion cell layer (GCL) and by some cells with their somata in the inner third of the inner nuclear layer (INL), most likely amacrine cells. *mGluR2*: expressed by some cells in the GCL and by some amacrine cells in the INL. *mGluR3*: not expressed at detectable levels. *mGluR4*: expressed by cells in the GCL and the INL, similar pattern to that seen for mGluR1. *mGluR5*: expressed by cells with their somata in the outer third of the INL, possibly horizontal cells. *mGluR6*: expressed by cells with their somata located in the outer half of the INL, consistent with the recent suggestion by Nakajima et al. (1993) that this receptor corresponds to the physiologically and pharmacologically defined APB-receptor that mediates synaptic input from photoreceptors to ON-bipolar cells. Taken together, metabotropic glutamate receptors show a considerably more widespread pattern of expression in the retina than suggested from physiological experiments. We are currently extending this investigation by examining the expression of the recently cloned mGluR7 and improving the cellular resolution by *in situ* hybridization of dissociated cells. ONTOGENESIS OF ACETYLCHOLINESTERASE (AChE) IN THE DEVELOPING OPOSSUM RETINA. Camargo¹, L.M.C.; Faria², A.C. and J.N. Hokoç². ¹Depto.Histologia & Embriologia (ICB); ²Instituto de Biofísica Carlos Chagas Fz, Universidade Federal do Rio de Janeiro, 21949-900, BRAZIL.

We have previously shown that the differentiation of cholinergic neurons in the opossum retina was detected around 15 postnatal days (P15). In this work, we follow the pattern of expression of AChE, the hydrolyzing enzyme for acetylcholine, during the development of the opossum retina, applying the Hedreen method (1985). The onset of AChE activity was seen in the P10 opossum, in cell bodies present in the ganglion cell layer (GCL). This activity is detected before the emergence of the inner plexiform layer (IPL) and before the appearance of cholinergic neurons, much earlier than the onset of synaptogenesis in the IPL (P22). Between P25-P33, the histochemistry reaction becomes more intense, but is still restricted to cell bodies in the GCL. Only after P45 AChE positive bands in the IPL (strata 1, 3 and 4/5) and somata in the inner nuclear layer (INL) could be seen. In P50, when the retina matures, the AChE-histochemistry reveals the adult pattern, i.e., cell bodies in the GCL and INL, labeled bands in the IPL and OPL. Since AChE could be detected so early during opossum retinal development, a question arises whether AChE takes part on cellular proliferation and/or differentiation in the retina.

MULTIPLE SITES OF S-LAMININ SYNTHESIS IN THE MATURE RAT RETINA. Y.P. Wang¹, J.K.T. Wang^{1,*}, W.J. Brunken², and D.D. Hunter¹

¹Neuroscience Program, Tufts University School of Medicine, Boston, Mass. 02111;

²Biology Department, Boston College, Chestnut Hill, Mass. 02167

Components of the extracellular matrix (ECM) have been implicated in such diverse phenomena as differentiation, neurite outgrowth, and synapse formation. We have previously shown that one such ECM component—s-laminin—is present in the retina during development, and that s-laminin may be involved in photoreceptor differentiation. S-laminin expression remains in the mature retina, especially in the interphotoreceptor matrix (IPM); however, the function and sites of synthesis of s-laminin in the mature retina remain unclear. We have examined the expression of s-laminin RNA and protein in the mature retina to begin to address these issues.

In situ hybridization—using both ³⁵S- and digoxigenin-labeled cRNA probes—demonstrates several sites of synthesis for s-laminin RNA in the mature rat retina. One, the inner nuclear layer, may represent the site of synthesis of s-laminin that is eventually deposited in the IPM. A second prominent site of s-laminin RNA, the retinal ganglion cell layer (GCL), is somewhat surprising: we had previously found little s-laminin protein in this layer when we examined unfixed sections of mature retina. In the absence of fixation, our antibodies detect largely the ECM-associated s-laminin (including in the IPM); notably, these same antibodies, when used on fixed tissue, reveal cellular s-laminin immunoreactivity in the GCL. The presence of s-laminin immunoreactivity under these conditions supports our hypothesis that the GCL is one site for s-laminin synthesis. We are currently testing whether cells in the GCL deposit the s-laminin that they produce in the retina, and whether they ship this s-laminin to their synaptic targets.

IMMUNOLocalization OF THE INOSITOL TRISPHOSPHATE RECEPTOR IN THE CATFISH RETINA. M.A. Micci* and B.N. Christensen. Dept. Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77555.

Inositol 1,4,5-trisphosphate (InsP₃) mobilizes calcium from intracellular stores by binding to specific receptors. In the brain, InsP₃ receptors are concentrated in cerebellar Purkinje cells where they have been biochemically characterized.

Immunocytochemical localization in retinas from rat, turtle and goldfish reveals a characteristic distribution of the InsP₃ receptor at the synaptic layer. For this reason, it has been proposed that the InsP₃ sensitive calcium store may be involved in transmitter release within the retina.

Here, we used an affinity-purified rabbit polyclonal antibody against the 19-mr C-terminal of the mouse cerebellar InsP₃ receptor to determine: 1) whether the antibody to the mammalian InsP₃ receptor can bind the fish receptor in the cerebellum and retina; and 2) the distribution of the receptor in this retina. Since the distribution of the InsP₃ receptor has been described in the rat retina, we used this retina as a control for our antibody.

Observation of catfish retina frozen sections in the confocal microscope revealed that the InsP₃ receptor is localized to the inner nuclear layer with some positive staining also visible at the outer and inner limiting membrane. Immunocytochemistry on dissociated retina cells further demonstrated that the receptor is mainly localized in the cone horizontal cells and in the Müller glia cells.

These data reveal a distribution of the InsP₃ receptor in the catfish retina different from that observed in other vertebrates that may be suggestive of a different function of InsP₃-sensitive calcium stores in this retina.

We have previously demonstrated that a rise in intracellular calcium can occur via influx through voltage-sensitive calcium channels and glutamate-gated channels. In addition, catfish cone horizontal cells contain a calcium store sensitive to ryanodine and caffeine. The presence of InsP₃ provides for yet another source of calcium that may be important for the regulation of calcium-dependent metabolic pathways. Supported by grant NEI-01897.

IDENTIFICATION OF CELL TYPES AND CELLULAR COMPARTMENTS CONTAINING NITRIC OXIDE SYNTHASE IN THE TIGER SALAMANDER RETINA. S. Barnes, R.W. Turner*, K.A. Sharkey and D.E. Kurenniy. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

NADPH-diaphorase histochemistry in retinal sections revealed staining within rod and cone photoreceptor ellipsoids, in pockets external to the photoreceptor cell bodies and in the outer plexiform layer (OPL).

NADPH-diaphorase positive puncta were found also throughout the inner plexiform layer (IPL), possibly representing synaptic terminals of bipolar, amacrine or ganglion cells. Lighter staining was associated with retinal glial cells (Müller cells; counterstained for GFAP) and the axon hillocks and surface of the somata of ganglion cells. NADPH-diaphorase histochemistry performed on enzymatically isolated retinal cells indicated that the distal portions of Müller cells and bipolar cell Landolt clubs account for at least part of the NADPH-diaphorase activity surrounding the photoreceptors. No reaction product was observed when NAD or NADP were used in place of NADPH showing that the reaction required NADPH-dependent electron transfer. NO-synthase localization was detected with polyclonal antibodies directed against rat brain NO-synthase and was consistent with NADPH-diaphorase activity. Labelling was detected in photoreceptor ellipsoids and around their inner segments, in the OPL, Müller cells, a few inner nuclear layer cells, and within the IPL but primarily at the border between sublamina a and b. These results suggest that NO may have several roles in visual processing in the retina.

Anti-NOS antibodies were kindly provided by B. Mayer, Universität Graz.

GABA RAISES INTRACELLULAR CALCIUM IN NEURONS OF DEVELOPING RABBIT RETINA. B. Huang,* D. Redburn

Dept. Neurobiology and Anatomy, Univ. Texas-Houston Med. Sch., Houston, TX 77030.

Previous studies in this laboratory have shown that horizontal cells of the rabbit retina are transiently GABAergic during early post-natal development and that lesioning these horizontal cells or blocking GABA receptors with antagonists interrupt cone synaptogenesis. In order to determine the mechanism by which GABA might exert these effects, we have used a Ca^{2+} fluorescence assay to explore the effects of GABA on calcium flux in developing retinal neurons.

Cells from neonatal rabbit retina were freshly isolated and then loaded with fluo-3 AM. When challenged with 100 μ M GABA, intracellular Ca^{2+} increased in certain populations of retinal neurons. This GABA-induced Ca^{2+} response began to appear in retinal cells of postnatal day 3 and was most prominent on day 5. Both picrotoxin and bicuculline blocked the response, indicating that GABA_A receptors were involved. Based on these results, we propose that during postnatal retinal development GABA may exert its trophic action on retinal synaptogenesis through membrane depolarization and a rise in intracellular Ca^{2+} .

CIRCADIAN RHYTHMS IN THE QUAIL RETINA: MODULATION BY LIGHT AND DOPAMINE

ME Kelly, NF Buelow, and RB Barlow*
Institute for Sensory Research, Syracuse Univ., NY 13244

The Japanese quail exhibits a circadian rhythm in retinal sensitivity.¹ Rhythmic shifting of rod-cone dominance with time of day appears to be intensity dependent. Circadian rhythms in dark-adapted eyes are readily detectable for photopic stimuli: rods dominate retinal sensitivity at night while cones dominate during the day. Surprisingly, for scotopic stimuli, rods dominate retinal sensitivity regardless of time of day, thus abolishing circadian rhythms of sensitivity.

How does the circadian clock shift rod-cone dominance during the day but not at night? We hypothesize that dopamine blocks rod signals to intense stimuli during the day and thereby shifts the retina to the cone-dominated state. Retinal dopamine levels are high during the day and low at night in constant dark making dopamine an obvious candidate for modulating retinal sensitivity.² Dopamine agonists and antagonists alter the rhythms of retinal sensitivity, and light adaptation can disrupt the normal rod dominance at night.^{1,2} Preliminary results suggest light and dopamine are independent modulators of the ocular clock in the Japanese quail.

RAPID CHANGES IN THE SIZE OF NERVE DOMINANCE AGGREGATES IN PRIMATE SOMATOSENSORY CORTEX AFTER NERVE INJURY. A. Silva, S.K. Rasey, and J.T. Wall*

Department of Anatomy, Medical College of Ohio, Toledo, OH 43699.

The area 3b cortex of primates contains band- and patch-like aggregates of neurons that are dominantly activated by cutaneous inputs from the ulnar, radial, and median nerves to the hand. The ulnar nerve innervates about 43% of the hand surface, and normally provides dominant inputs to about 38% of the area 3b hand cortex. This study evaluated whether ulnar nerve dominance aggregates change in size over the first several minutes to hours after wrist level transection of the radial and median nerves. Acutely after injury, cortical aggregates of the ulnar nerve rapidly expand from a normal mean area of about 4.9 mm² to a mean area of about 7.1 mm². Due to this change, ulnar inputs rapidly gain access to about 59% of the area 3b hand cortex, or about 1.5 times the normal cortical space. These size changes are initiated within minutes after injury. The extent and spatial distribution of these changes provide an image of central substrates that were available for decompression of ulnar nerve dominance aggregates at the time of injury. Previous evaluations of radial nerve dominance aggregates after acute transection of the ulnar and median nerves show that these aggregates rapidly gain access to a cortical space that is about 3 times the normal cortical space. Thus, dominance aggregates of different nerves undergo rapid size changes of variable extents. It is suggested that this variability is dependent on differences in the patterns of central connections that are rapidly impacted by the different injuries, and on differences in the patterns of central substrates that can be rapidly accessed by the uninjured nerve. REORGANIZATION OF MOVEMENT REPRESENTATIONS IN PRIMARY MOTOR CORTEX OF ADULT SQUIRREL MONKEYS FOLLOWING DISTAL FORELIMB RESTRICTION. G.W. Milliken*, E.J. Plautz, G.A. Gardner, R. Raiszadeh, & R.J. Nudo. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77030.

The consequences of distal forelimb restriction on the functional topography of primary motor cortex (area 4) were examined in normal adult squirrel monkeys. Using intracortical microstimulation techniques, a detailed map of the movement representations of the hand, wrist, and arm contralateral to the preferred hand was derived (Nudo, et al., *J. Neurosci.*, 12:2918, 1992). After a post operative recovery period the preferred forelimb was placed in a cast that effectively restricted movements of the hand and wrist. Movement maps of the distal forelimb representation were re-derived at 3 month intervals.

In each case, post-restriction maps revealed significant changes in movement representations. The results show that within 6 months, finger representations decreased while wrist representations increased in total area extent. In contrast, the movement representations of control animals that did not undergo forelimb restriction remained relatively unchanged. These results demonstrate that distal forelimb movement representations are alterable through *disuse* and that the changes associated with forelimb restriction are progressive over several months. Taken together with our previous findings that forelimb representations are alterable through *increased use*, these studies lend further support to the idea that movement representations in primary motor cortex are shaped by experiential factors related to use.

MENTAL MOVEMENT EXERCISES PREVENT MOTOR DISTURBANCES AFTER IMMOBILIZATION OF A LIMB.

A. Pascual-Leone*, T. Blanco, M.P. Lopez, B. Romero, A. Deltoro, A. Pascual-Leone Pascual, M.D. Catalá. Neurobiology Unit, Physiology Dept. Univ. Valencia, SPAIN

We studied the effects of mental movements and isometric contractions on motor consequences of complete immobilization of forearm, hand, and fingers in a cast for 5 days.

We divided randomly 12 volunteers into group 1 who simply wore the cast, group 2 who performed isometric muscle contractions, and group 3 who performed mental finger exercises while wearing the cast. We tested subjects before cast placement and 1 hr. and 4-8 hrs after cast removal. We recorded maximal voluntary force for grip and thumb-index opposition, serial choice reaction time with individual digits, performance of a sequence of finger movements, Grooved Pegboard performance, H-reflex in flexor carpi radialis (FCR), and cortical output maps to abductor pollicis brevis, first dorsal interosseus, and FCR generated by transcranial magnetic stimulation. After cast removal, group 1 showed poorer performance in all tasks. This effect was less pronounced in group 2 and absent in group 3. Cortical output maps decreased in size in group 1 but remained unchanged in groups 2 and 3. H-reflexes were stable in all subjects.

Isometric contractions and specially mental exercises decrease the motor disability after limb immobilization by preventing the modulation of cortical outputs to immobilized muscles.

ROLE OF SPONTANEOUS ELECTRICAL ACTIVITY IN MOTOR CORTEX REORGANIZATION INDUCED BY FACIAL NERVE TRANSECTION IN ADULT RATS. S. S. Suzuki*, T. Shitama, Y. Harada¹ and N. Nagamura.

Biosignaling Dept., Natnl Inst. Biosci. and Human Technol., Tsukuba 305, and ¹ Dept. Physiol., Nippon Med. Sch., Tokyo 113, Japan

The motor cortical maps in adult mammals are reported to reorganize following various manipulations including peripheral denervation (Donoghue et al. 1990), repetitive intracortical microstimulation (ICMS) (Nudo et al. 1990) and local disinhibition by intracortical bicuculline infusion (Jacobs and Donoghue 1991). These studies suggest that differential activities in competing regions within the primary motor cortex (MI) mediate the reorganization of motor representations. The present experiment examined this hypothesis by recording multiple unit activity (MUA) from vibrissal and other regions of MI before and after facial nerve transection.

Three to seven microelectrodes were placed at low threshold depths of the right MI in ketamine-anesthetized rats. The same microelectrodes were used for ICMS and MUA recording. Multisite MUA, ICMS-evoked movements and electromyograms of left facial, neck and forelimb muscles were recorded before and after transection of the buccal and mandibular branches of the left facial nerve. The MUA at sites where ICMS had evoked vibrissal movements was greatly reduced, compared with other sites, immediately after the transection and remained so up to several hours. This result suggests that the differential neural activities in the vibrissal and other MI regions might play a role in MI map reorganization. The MUA reduction in the vibrissal regions of MI may be due to a decrease in vibrissal (trigeminal) afferent tone resulting from the motor nerve transection.

CORRELATION DIMENSION AND LYAPUNOV EXPONENT CALCULATIONS FOR NEURAL ACTIVITY RECORDED IN PRIMATES DURING VOLUNTARY TWO-DIMENSIONAL HAND MOVEMENT WITH INSTRUCTED DELAY Gyöngyi Gaál* Dept of Neuroscience, Brown University, Providence, RI 02912

In addition to linear methods, such as Fourier transforms, autocorrelations and crosscorrelations, nonlinear dynamical analysis methods were used to examine multichannel cortical activity in order to characterize the spatio-temporal dynamics of the cortical network during movement performance (Gaál et al., 1994, submitted to J. Neurophysiology). Oscillatory local field potentials (LFP) proved to be nondirectional in a planar directional hand movement task using instructed delay, while units showed directional selectivity (Donoghue et al., 1994, this volume). Therefore both LFP and extracellular unit activity were subjected to correlation dimension (CD) and largest Lyapunov exponent (LE) calculations using MTRCHAOS and MTRYAP Version 1.0 developed by M. Rosenstein (Rosenstein et al., 1993; Physica D 65) as well as Chaos Data Analyzer distributed by the American Physics Institute. Both LFP and unit data turned out to be higher dimensional than results of previous relevant calculations performed by other researchers. Two methods were used to verify the reliability of our methods: 1) phase-randomized surrogate data served as controls for brain-derived data; and 2) data from Lorenz and Rössler systems of equations and extracellular activity of four point spiking neurons driven by Lorenz and Rössler signals were used to test the CD and LE algorithms. The high correlation dimension values obtained indicate that no simple set of equations can be derived to model the system. New methods, such as complexity calculations (Rapp et al., J. Neurosci, 1994) have to be used to further investigate extracellular spiking activity.

THE POTENTIAL FUNCTIONAL ROLE OF REVERBERATING SYNFIRES CHAINS DEVELOPING IN RANDOMLY CONNECTED NEURAL NETWORKS

Martin Arndt¹, Ad Aertsen^{1,2} and Moshe Abeles³. ¹Inst. für Neuroinformatik, Ruhr-Univ. Bochum, FRG; ²Center for Brain Research, Weizmann Inst. of Science, Rehovot, Israel; ³Hebrew Univ., Jerusalem, Israel

Over the past few years, several types of synchronized neural activities have been observed in different cortical areas. This gave rise to a theoretical debate on the potential role of such synchronizations for cortical function. Experimental results on the abundance and behavioral dependence of precise spatio-temporal spike patterns in the prefrontal cortex of awake behaving monkey (Abeles et al. 1993) support the hypothesis, that 'synfire volleys' propagate through the cortex in 'reverberating synfire chains' (RSC): feedforward networks with additional feedback connections.

To get insight into the possible functional role of such RSCs, we investigated their development in a model neural network (see also Bienenstock, 1991). An initially randomly connected network of excitatory and inhibitory neurons with poisson-distributed coupling strength was repeatedly stimulated by a single synchronized spike event, adjusted to activate only a small fraction of the neurons in the network. The global dynamics of the resulting activity spread through the network can be described analytically following Anninos et al. (1970). Concomitantly, the synaptic connectivity changes gradually as a result of interaction with a 'competitive learning rule'. This development leads eventually to the formation of RSCs. Moreover, interconnections between different RSCs develop, depending on the spatio-temporal structure of the corresponding stimuli. The path through the network defined by the RSC, may be interpreted functionally as a trace of auto- and hetero-associations. Thus, the space-time composition of the RSC's and their interconnections provide a natural implementation of stimulus context memory.

THE PROFILE OF VOLTAGE-DEPENDENT CONDUCTANCES IN NEOCORTICAL LAYER I NEURONS. J.A. White*, T. Budde, and A.R. Kay. Dept. of Biological Sciences, Univ. of Iowa, Iowa City, IA 52242 U.S.A.

Layer I of the mammalian neocortex contains >90% GABAergic interneurons and a very low neuronal density. Presumably because of this low density, it has proven to be extremely difficult to record from layer I cells. As a consequence, nothing is known about these neurons' intrinsic firing properties or the complement of ion channels underlying these properties.

We studied membrane currents in acutely dissociated layer I neurons obtained from mature Long-Evans rats by trimming layer I from neocortical slices and subjecting the pieces to enzymatic digestion. Inward currents exhibited by layer I neurons included a fast-inactivating Na⁺ current and a high-threshold Ca²⁺ current. No evidence was found of a persistent Na⁺ current, TTX-resistant Na⁺ current, or low-threshold Ca²⁺ current. Outward currents included a delayed K⁺ current, an A-current, and a Ca²⁺-activated K⁺ current.

The ion channel profile in layer I cells differs from those reported previously in pyramidal or nonpyramidal neurons from lower layers. Unlike nonpyramidal cells, mature layer I cells express an A-current. Unlike pyramidal cells, layer I cells do not exhibit a low-threshold Ca²⁺ current. Possible consequences of this particular complement of ion channels will be discussed.

QUANTITATIVE HOMUNCULUS: GRAPHICAL REPRESENTATION OF DENSITY INFORMATION ON A SURFACE. D.C. Fain, D. Rosenbluth, A.H. Barr, and J.M. Allman*. Computation and Neural Systems, Caltech 139-74, Pasadena CA 91125

In many situations, the data collected in experiments is in the form of scalar data taken at many points distributed on a 2D surface in 3-space. Two familiar examples are two-point discrimination data on the body surface and estimates of the relative representation area on the sensory and motor cortex of various parts of the body. The visualization of such data is problematic and in many situations researchers have resorted to artists' renditions of the data as in the classic picture of the sensorimotor homunculus. We describe a method which takes density information on a surface and produces a deformed surface whose characteristics accurately represent the density data on the original surface. This technique yields a 3D model which may then be projected into the plane from various viewing angles using standard computer graphical rendering techniques.

We use constrained optimization techniques to arrive at a new surface which has uniform density (a hard constraint) and is as close in curvature to the original surface as possible (a soft constraint).

We would like to stress the widespread applicability of this tool within neuroscience as an aid in the visualization of increasingly complex data. One particularly promising application is to the representation of plasticity of the sensory cortex using animation of deformations of a surface.

THEORETICAL IMPLICATION ON JOINT MOVEMENTS REPRESENTATION BY POPULATIONS OF MOTOR CORTICAL NEURONS. S. Tanaka*, Dept. Electrical Engineering, Sophia Univ., Tokyo 102, Japan.

It has been shown that the discharge rate of neurons in the arm area of the monkey motor cortex varies with the movement direction of the arm (e.g. Georgopoulos et al. 1988). Further, the discharge rate has been shown to be modulated by the position of the arm (Caminiti et al. 1990, 1991). Although these results suggest that the motor cortex represents certain aspects of the arm movement, it is still unclear whether a neuronal population codes the movement of the whole arm, which requires the synergistic activation of the muscles of the arm.

In this study the coding of the voluntary movement in the motor cortex and the transmission of the command through the corticospinal system are analyzed theoretically and numerically without using the population vector hypothesis. It is shown that the amount of the shift of the preferred direction of the motor cortical neurons, which has been observed in the experiments by Caminiti et al. (1990a, b, 1991), can be estimated as a function of the posture of a simplified model arm. In the estimation, it requires several populations in the arm area of the motor cortex, which represent the movements of the different joints or agonist-antagonist pairs of the muscles of the arm. The present model shows further that, if the motor cortex receives the feedback information on the rotation of the joint angles, the populations can make the appropriate coding of the joint movements.

These results suggest that there are several populations of neurons in the motor cortex arm area and that each population codes the movement of the corresponding joint of the arm.

PHYSIOLOGICAL SUBGROUPS OF NONPYRAMIDAL CELLS IN LAYER II/III OF RAT FRONTAL CORTEX. Y. Kawaguchi*. Lab. for Neural Circuits, Bio-Mimetic Control Research Center, RIKEN, Rokuban, Atsuta-ku, Nagoya 456 Japan.

Physiological and morphological properties of nonpyramidal cells in layer II/III of frontal cortex of young rats were studied in vitro by whole cell recording and intracellular staining of biocytin. Layer II/III nonpyramidal cells could be divided into four subgroups by their firing patterns in response to depolarizing pulses and patterns of dendritic and axonal arborizations. (1) Fast-spiking (FS) cells had shorter-duration action potentials and constant spike frequencies during an episode of discharges. FS cells had local or horizontal axonal arbors which did not enter layer I. FS cells contained chandelier cells and GABAergic parvalbumin cells. (2) Late-spiking (LS) cells exhibited slowly-developing ramp depolarizations near threshold. LS cells were neurogliaform cells. (3) Low-threshold spike (LTS) cells had low-threshold spikes with larger amplitude and longer duration. The main axons of LTS cells ascended, and the collaterals entered into layer I. (4) Although the remaining cells (regular-spiking (RS) nonpyramidal cells) did not have clearly distinguishable electrophysiological properties, RS cells are tentatively classified into two types. (4a) RS type 1 (RS-1) cells induced depolarizing fast notches with smaller amplitude by depolarization from hyperpolarized potentials. RS-1 cells had vertically elongated axonal fields, extending from layer I to V, sometimes to layer VI. This type contained bipolar cells. (4b) RS type 2 (RS-2) cells extended axonal branches vertically, ascending to layer I. RS-2 cells also contained a chandelier cell. These suggest that each subgroup may differentially contribute to the laminar and columnar circuitry of cortex.

PYRAMIDAL MOTOR EVOKED POTENTIALS EVOKED BY CORTICAL STIMULATION IN RATS. Y.G. Park*, J. W. Chang, J.H. Kim and S.S. Chung. Dept. of Neurosurgery, Yonsei Univ. College of Med, Seoul, Korea

Motor evoked potential (MEP) produced by cortical surface stimulation has recently evolved as a new clinical and experimental tool to monitor the integrity of motor pathways. The original concept using MEPs was based on the assumption that synchronized compound action potentials evoked by electrical stimulation of pyramidal neurons in the motor cortex were conducted along the corticospinal tracts in the spinal cord. It was, however, found that MEPs recorded in the spinal cord were mainly produced by activation of reticular systems in the brain stem due to spread of stimulus current applied on the motor cortex, especially in non-primates with small brain.

The purpose of this study was, therefore, to selectively monitor MEPs evoked by cortical neurons in the rat. A small surface electrode with a diameter of 1.5mm and another electrode protruded 1.5mm from the surface electrode were used as an anode and cathode, respectively. The evoked responses were recorded on the spinal cord using bipolar electrodes. The potentials monitored were cerebral cortex in their origin since the potentials were abolished when the pyramidal tract was selectively lesioned at the internal capsule. The intracord recording of these potentials revealed that the amplitude was highest at the ventralmost area of the dorsal column where the corticospinal tract was located. Latencies of these potentials were much longer than the latencies of the non-pyramidal MEP. Amplitudes, latencies and wave forms of these potentials were studied following intravenous injection of various general anesthetics to examine the effect of these drugs on MEPs.

MOTOR CORTEX: HUMAN STUDIES

MULTIPLE MOVEMENTS MAY BE RELIABLY DIFFERENTIATED USING fMRI, PROVIDING ORGANIZATIONAL PERSPECTIVES ON BRAIN FUNCTION. T.W. Kjaer*, J.A. Hertz, P. Jezard, T.P. Pons, B.J. Richmond. Lab. of Neuropsychology, NIMH/NIH, Bethesda MD, USA; Nordita, Copenhagen, Denmark; Lab. of Cardiac Energetics, NHLBI/NIH, Bethesda, MD, USA.

We have investigated the differentiability of activation in the human brain during several randomly-interleaved self-paced motor tasks, as revealed in functional magnetic resonance imaging (fMRI). We used a neural network as a distribution-free technique to classify the tasks on the basis of the fMRI signal. This approach directly estimates probabilities of multiple conditions from an fMRI picture (or any area within it). It does not make a priori assumptions about the distribution of the signal or the relative signal strength for different conditions. Discriminability is computed as the information carried in the image about the condition set.

Different sets of fMRI-amplitude data from 4 motor tasks were analyzed. The analyses were carried out at 6 spatial scales, from individual voxels to the full picture. In some cases, the data were preprocessed using principal components. In general, information was found to be encoded across many different voxels. However some voxels were found to be completely independent of their neighbors. Hence spatial smearing of fMRI data (by intentional smoothing) appears undesirable.

To determine whether the overall discriminability of a set of conditions was due only to the discriminability of a few of them, we repeated the analyses for subsets of the conditions and compared the information carried about these subsets with that conveyed about the entire condition set. In this way we found areas in the lower part of the frontal lobe where the information in the signal was larger for 4 conditions than for any subset of 2 conditions. Another area at the fronto-parietal junction only permits differentiation between pairs of conditions. For these areas, there is no information in the pictures about added conditions. On the basis of these results, we conjecture that the first set of areas could be involved in planning movements and the second in specific movement components.

Elettronica Stato Solido, CNR, 00156 Roma, Italy; ⁴1st. Tecnologie Avanzate Biomediche, 66100 Chieti; Italy; ⁵Div. Neurol., Ospedale "Fatebenefratelli", Roma; ⁶I.R.C.C.S., "Santa Lucia", Roma, Italy

Neuromagnetic fields elicited from the left hemisphere of five healthy right-handed subjects were investigated under three different experimental conditions run in random order every 5-8 s: electrical stimulation of the right index finger (task S), voluntary movement of the right index finger (M), and "interference" condition (M+S). The M+S condition consisted of voluntary movements triggering the S at the very beginning of the electromyogram of the active muscle. The activity of the sources corresponding to the main components of the task SEFs and movement-related fields was mapped and localized by means of a moving dipole model. The gating effect was measured by S-((M+S)-M).

In all the subjects investigated the gating effect was observed starting at approx. 30 ms after movement onset and lasting for the whole period of the ongoing movement. The site of the early gating effect (mostly centripetal) was found to be more anteriorly located than the later (mostly centripetal) gating effect. The task SEFs were found to be larger (significantly after 40 ms) than the control SEFs elicited in a basal condition.

The results are discussed in terms of the timing, the mechanism (centrifugal and centripetal), locus and selectivity of the somatosensory gating. The interesting corollary finding about larger task SEFs as compared to the control SEFs is interpreted in terms of specific attentional influences upon the components after 40 ms.

Functional MRI of the Lateral Premotor Area during Simple and Complex Finger Movements. S.-G. Kim, G. Tagaris, X. Hu, R. Menon, J. Strupp, A. Golub*, K. Ugurbil, J. Ashe. Ctr. for Magn. Reson. Res. Univ. of Minnesota, Minneapolis, MN 55455 and Brain Sciences Center, VAMC, Minneapolis, MN 55417.

Imaging studies in human subjects and single cell recording in animals have shown that the premotor motor is activated during visuomotor tasks. We tested the hypothesis that the activation of the premotor cortex is modulated by the complexity of the motor output, using functional magnetic resonance imaging at 4 Tesla.

Five healthy human subjects participated in these experiments. They performed visually instructed finger-thumb opposition movements in two different tasks. In task I ("simple") fingers were moved sequentially, while in task II ("complex") the order in which the fingers were moved was randomized. The rate of finger movement (1.25 Hz) and fingers to be used were instructed by a flashing light placed in front of the subject. Three-slice high speed gradient echo planar images (30 ms echo time and 3.1x3.1x10.0 mm³ resolution) were acquired before, during, after each of tasks.

All subjects showed activation in the contralateral premotor area during both tasks. However, the area of activation was significantly greater during the complex task. This suggests that when the premotor cortex is activated during visuomotor tasks, the area of activation is related to the complexity of the motor behavior.

CORONAL FMRI STUDY OF CEREBELLAR AND CEREBRAL ACTIVATION BY FINGER TAPPING. 1,3 T Nordahl, 2 M Buonocore, 2 L Gao, 3 J Eberling*, 1 R Maddock. ¹Department of Psychiatry and ²Radiology, UC Davis Medical Center, Sacramento, CA 95817, ³Lawrence Berkeley Laboratory, Berkeley, CA 94720.

Several fMRI studies have noted motor and sensory cortical blood flow changes with finger tapping contralateral to the side of the tapping hand. Sabatini et al. 1993 using 133 Xenon blood flow found contralateral primary sensorimotor area, supplementary motor area, and ipsilateral cerebellum were activated during right and left finger movements performed at fast frequency. We thus sought to study similar fast finger tapping with coronal multi-slice echo-planar fMRI (EPI) as this can image cerebellar and cerebral regions simultaneously and detect subtle temporal differences in flow. High resolution fast spin echo images were obtained to more precisely identify the location of activation. 3D phase contrast angiography was performed to locate vessels. Echo planar flash (TR=2000, TE=40) and spin echo (TR=2000, TE=95) images were acquired as multislice, multirepetition acquisition. Scan parameters were 64X64 matrix, 22 cm FOV, 6 mm slice thickness, and 2 mm gap. Following baseline scans (16 images), subjects performed sequential finger tapping at their highest rate. Alternation period was 16 seconds (8 images), repeated 8 full cycles. Ten coronal slices were taken. Correlation maps were obtained using box car response template with temporal offsets of 0, TR, ..., 5TR. Threshold value for display of correlation was set at 0.2 or 0.3. Talairach atlas was used to identify regions. Activation was detected in the contralateral cerebellum (precentral gyrus, postcentral gyrus) and matched homunculus localization of the hand. Cerebellar activation on the dominant side had a correlation greater than 0.3 while the nondominant side had 0.2 to 0.3 typically. Cerebellar activation peak preceded the cortical peak by 1000±500 ms. This data is consistent with known findings and may give temporal distinction in regional activation.

571.5

DOES THE CORTEX PROCESS POSTURAL ADJUSTMENTS ASSOCIATED WITH BALLISTIC MOVEMENTS? E. Palmer*, E. Cafarelli, P. Ashby. Playfair Neuroscience Unit, Toronto Western Hospital, Toronto, Canada.

When seated human subjects rapidly abduct one arm in response to a tone, EMG activity occurs in the deltoid of that arm, and, almost simultaneously, in the contralateral latissimus dorsi. The contralateral activity is assumed to be an "associated postural adjustment". When subjects abducted the left arm rapidly, magnetic stimulation over the left motor cortex delayed the onset of the EMG burst in the right latissimus dorsi relative to the initial burst in the left deltoid. When subjects abducted the right arm rapidly, magnetic stimulation over the right motor cortex delayed the onset of the initial EMG burst in the right deltoid relative to the burst in the left latissimus dorsi. In each case, the delay was greatest when the stimulus was given just before the burst was expected to occur. The inhibition of voluntary movements by transcranial stimulation was not associated with a reduction in the excitability of spinal motoneurons. We postulate that both the focal ballistic movement and the associated postural adjustment are preprogrammed, held in memory until the "go" signal and then released through both motor cortices to spinal neurons.

RESPONSES TO TRANSCRANIAL MAGNETIC STIMULATION DURING FATIGUING MAXIMUM VOLUNTARY CONTRACTION W.B. McKay*, S.M. Tuel, A.M. Sherwood, M.R. Dimitrijevic, Div. Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, Texas

Sustained maximum voluntary contraction (MVC) is a widely used paradigm for the study of fatigue mechanisms. Cortical motor output was measured by surface recorded motor evoked potentials (MEPs) resulting from transcranial magnetic stimulation (TMS) of the motor cortex. TMS at 80% of maximum (2.0 Tesla) was delivered over the Cz scalp EEG location. MEPs and M-waves from supramaximal peroneal nerve stimulation (PNS) were recorded at 15 second intervals before and during MVC of ankle dorsiflexors in six healthy human subjects. The subjects were asked to maintain MVC of the right ankle dorsiflexors until the force developed decreased to 50% of its initial value. During ankle dorsiflexor MVC, MEP amplitudes in right and left quadriceps, hamstring, anterior tibial and triceps surae muscles increased compared to pre-contraction values with the largest increase occurring in the exercised anterior tibial muscle ($p < 0.05$). Also, MEP amplitudes in the contracted anterior tibial muscle were maintained while its voluntary activity amplitude and median EMG frequency and force of contraction decreased. Anterior tibial muscle M-wave amplitudes did not change but twitch forces decreased during the contraction. The results show that motor cortex output for single TMS delivery does not decrease while voluntary force generation and EMG do decrease during sustained MVC.

571.9

VIBRATORY, MOTOR AND TRANSCRANIAL MAGNETIC STIMULATION IN HUMANS PRODUCE A LOCALIZED CHANGE IN CEREBRAL OXYGENATION DEMONSTRATED WITH NEAR INFRARED SPECTROSCOPY H. Obrig, S. Brandt, B. Meyer, G.D. Borasio*, U. Dirnagl, A. Villringer Depts. of Neurology Humboldt-Univ., Berlin and *Ludwig-Maximilians-Univ., Munich; FRG We examined the potential of Near Infrared Spectroscopy (NIRS) to detect localized concentration changes of oxygenated and deoxygenated hemoglobin ([oxy-Hb], [deoxy-Hb], [total-Hb]=[oxy-Hb]+[deoxy-Hb]) with a non-invasive near infrared spectroscopy monitor (NIRO-500, Hamamatsu). The following stimuli were tested: (1) a sequential motor task, (2) magnetic stimulation, (3) vibratory stimulation and (4) electrical median nerve stimulation. Optodes were positioned according to a modified 10/20 system, in 3 experiments optode position was assessed by T1-weighted-MRI.

(1) In 20 subjects a finger opposition task ipsi- and contralateral to optode position over left primary motor cortex was repeatedly performed and averaged time-locked to movement onset. A clear rise of [oxy-Hb] and [total-Hb] accompanied by a decrease of [deoxy-Hb] was detected exhibiting a pronounced contralateral predominance.

(2) In 5 subjects transcranial magnetic stimulation was applied over the mid-point between the optodes resulting in a contralateral finger movement. Voluntary movement of the same finger was performed in the same experiment. Magnetic stimulation and voluntary finger movement resulted in similar changes of NIRS-parameters. (3) A localized response to a vibratory stimulus was elicited over primary somatosensory cortex, whereas (4) electrical stimulation of median nerve did not show a clear response. The experiments show that NIRS is able to detect rather small changes of local cerebral oxygenation, though optode positioning remains a problem. Supported by the DFG V937/1-1

MOTOR EVOKED POTENTIALS (MEPs) TO PAIRED TRANSCRANIAL MAGNETIC STIMULI SHOW DIFFERENCES DURING REST, ACTIVATION AND POST-EXERCISE FACILITATION. A. Samii*, M. Hallett, S. Grill and E.M. Wassermann, Human Motor Control Section, NINDS, Bethesda, MD 20892

A TMS pulse to the motor cortex at an intensity of 1.1 x threshold inhibits the MEP produced by a second pulse at intervals (ISIs) from about 40 to 90 ms (Valls-Solé et al., 1992). Both voluntary muscle activation and the post-exercise state in resting muscles increase MEP amplitude and might be expected to reduce this inhibition.

We studied paired stimuli under conditions of rest and activation and after exercise in the wrist extensors of 2 subjects. 10 stimulus pairs at 1.1 x resting motor threshold were given at ISIs from 20 to 150 ms under conditions of rest and 10% maximal force. 8-10 stimulus pairs were given at ISIs of 90 ms in 1 subject and at 70 ms in the other, 500 ms after 10 sec periods of 20% maximal isometric exercise.

In both subjects activation caused a large increase in the amplitude of the first MEP and a progressive decrease of inhibition at ISIs greater than about 100 ms which was not seen at rest. Post-exercise facilitation caused a significantly smaller increase in the amplitude of the first MEP in both subjects, but complete reversal of the inhibition of the second MEP in one subject and frank facilitation of the second MEP in the other. Post-exercise facilitation has a weaker facilitatory effect on the first MEP, but it can cause facilitation or a greater reduction in inhibition after the MEP than voluntary activation.

LOCALIZATION OF rCBF INCREASES IN HUMAN FRONTAL CORTEX AND CEREBELLUM IN VOLUNTARY INDEX FLEXION MOVEMENTS. R. J. Seitz*, J. Missimer, G. Schlaug, R. P. Maguire, U. Knorr, K. L. Leenders. Dept. of Neurology, University of Düsseldorf, Germany, Paul-Scherrer-Institute, Villigen, Switzerland.

Controversy in human mapping studies of unilateral movements relates to bilaterality, quantitation, and spatial extent of the activations. We used quantitative measurements of regional cerebral blood flow (rCBF) with [15O]-butanol and positron emission tomography for mapping of simple finger movements. Ten healthy, right-handed volunteers performed self-paced index flexions with their right hand at 1.9 +/- 0.9 (SD) Hz. The rCBF images (image resolution: 9 mm FWHM) were analyzed by use of the CBA (Seitz et al., J Cereb Blood Flow Metab 10: 443, 1990) and the SPM (Friston et al., J Cereb Blood Flow Metab 11: 690, 1991).

CBA analysis showed significant mean rCBF increases ($p < 0.01$, uncorrected) in the left motor cortex (44 %) and the right parasagittal part of the anterior neocerebellum (38%). At an uncorrected $p < 0.05$ there was also a mean rCBF increase (30%) in the left frontomesial cortex. Smoothing of the images with 10 mm resulted in a three-fold increase of the activation areas and a reduction of the mean rCBF increases that was maximal (17%) in the frontomesial cortex. After smoothing of the images with 20 mm and using SPM significant mean rCBF increases ($p < 0.001$, uncorrected) occurred in the left motor cortex, left frontomesial cortex, and in the right parasagittal part of the anterior neocerebellum.

We demonstrated that ballistic index flexions of the dominant hand induce significant rCBF increases contralateral in frontal cortex and ipsilateral in cerebellum. Quantitation depended on the methods used.

571.10

MEG EVALUATION OF MOTOR FUNCTION: A COMPARISON OF EVENT-RELATED FIELDS AND EVENT-RELATED DESYNCHRONIZATIONS J.J. Davis*, J.D. Lewine, C.C. Wood, C. Edgar, R. Thoma, and W.W. Orrison. MSI Facility, VAMC, 2100 Ridgecrest Drive, SE, Albuquerque, NM, 87108, and *Los Alamos National Laboratory, M-715, Los Alamos, NM, 87545.

Pfurtscheller and colleagues have previously demonstrated that movements of the digits of the hand induce changes in the power spectra of electroencephalographic data recorded over contralateral parietal regions. In particular, an event related desynchronization (ERD) (and associated reduction in power) is seen in the mu-band of the power spectra. Similar changes are observable in the magnetoencephalogram (MEG). Via signal averaging of continuous data epochs time-locked to movement onset, it is possible to extract an alternative type of information in the form of an average event-related field. Dipole modeling of these data provide for identification of the primary motor cortical area associated with digit movements. In this study we sought to compare spatial patterns of MEG event-related de-synchronization and average event-related fields associated with movement. Available data indicate that ERDs are most prominent at the locations of the maxima and minima of the event-related field. This implies common neural generators for the two types of signals. Pfurtscheller and colleagues have demonstrated that neural network analysis of neuroelectric ERD data allows for good single-trial classification of contra- versus ipsilateral movements. Our preliminary data indicate that neuromagnetic ERD data provide for better network classification than that reported by Pfurtscheller for neuroelectric data. Interestingly, even better results are obtained via examination of single trial waveforms, as opposed to ERD parameters.

SPATIAL AND TEMPORAL DISTURBANCES IN PATIENTS WITH PARIETAL LESIONS WITH AND WITHOUT IDEOMOTOR APRAXIA.H. Heftner*, P. Weiss, S. Meermagen, C. Dohle, H. Kuhlmann and H.-J. Freund
Department of Neurology, Univ. of Duesseldorf, 40225 Duesseldorf, Germany.

Lesions of the parietal cortex lead to severe motor disorders, known as apraxia for left and hemineglect for right hemispheric lesions. In a prospective study, 6 patients with left parietal lesions (4 with and 2 without ideomotor apraxia) and 6 patients with right parietal lesions were tested for spatial and temporal errors and the presence of a neglect component during arm movements. Movement trajectories were recorded by a Selspot II® system and a video camera. During the first set of experiments patients had to produce horizontal, vertical, and circular arm movement components in their personal space, out of which 5 simple movement sequences (SMS) were composed. These 5 SMS had to be produced after reading aloud the instructions ('reading'), after verbal instructions ('instruction'), and after the experimenter had demonstrated the movement ('imitation'). The 5 SMS and the 3 modes of instruction were randomized for each side. For all patients the same sequence was used. In patients with left parietal lesions, significantly more spatial (direction reversions) and sequencing errors (wrong order of movement components) of the movement trajectory were observed in comparison to the right parietal lesioned patients. More omissions or repetitions of movement components revealed aspects of motor neglect or preservation in the patients with right parietal lesions. During the second set of experiments, the patients had to grasp a 10 cm long stylus (lying horizontally in front of them) after eye opening without previous visual feedback. Whether hand inversion (HI) or hand eversion (HE) is used for grasping depends on the angle of the stylus in relation to the sagittal plane resulting in a (HI/HE) probability curve. In normals, the HI/HE-probability varied within a small range of 20 degrees only. In both parietal groups, especially in the left hemispheric patients with apraxia, this angle range was significantly enlarged up to more than 100 degrees in comparison to the controls.

We conclude, that the right parietal cortex is mainly involved in the decision "what to do" and the left parietal cortex in the problem "how to do" a motor task. Thus, normal motor behavior affords an intensive interaction between both parietal cortices.

OCULOMOTOR: BRAINSTEM AND MUSCLE

DOWNSTREAM AND UPSTREAM MODELS OF IBN ACTIVITY DURING GAZE SHIFTS IN THE HEAD-FREE CAT AND MONKEY. K.E.Cullen*, C.G. Rey and D. Guitton, Montreal Neurological Inst. McGill Univ., Montreal, Canada.

Our recent studies in the cat (Cullen et al. 1993) have demonstrated that IBN discharges are best correlated, not with the metrics of the movement of the eye in the head but, with the movement of the visual axis in space (gaze) during rapid orienting coordinated eye and head movements. To further address whether cat and monkey IBNs carry gaze or eye related signals, we carried out a dynamic analysis of IBN discharge. The hypothesis that the discharge of IBNs reflects an upstream input signal which encodes a non-linear representation of motor error (Van Gisbergen et al. 1981) was first tested. For our neurons, discharges head-free or head-fixed were significantly less well predicted by a quasi-linear expression of eye or gaze motor-error, than by simple downstream dynamic models which incorporated eye or gaze velocity and a firing rate bias term. For downstream models, we found that gaze velocity was better at predicting IBN activity than eye velocity. The estimated firing rate based on a model using gaze velocity produced significantly better fits of the actual firing rate than that which was based on eye velocity ($\approx 30\%$ less RMS). Adding a bias term to the gaze and eye velocity models improved the fit of both models. Interestingly, the value of the bias estimated for the gaze model was comparable to that which we determined for head-fixed saccades, while the value estimated for the eye model was significantly larger. Since the bias term could reflect the physiological "resting discharge" of the IBN, the necessity of increasing the bias value to predict IBN firing with eye velocity as an input further suggests that gaze velocity is more relevant than eye velocity in describing the discharge of IBNs during gaze shifts. We also tried more complex downstream models. The best downstream fits were obtained using a quasi-linear expression of eye or gaze velocity that included a bias and a pole term for which initial conditions were fitted as parameters. For a significant number of the primate neurons studied, these estimated initial conditions were correlated with the metrics of the eye and/or gaze movements.

INTERACTION BETWEEN VERTICAL EYE POSITION-RELATED NEURONS IN AND AROUND THE INTERSTITIAL NUCLEUS OF CAJAL ON BOTH SIDES. Y. Iwamoto*, S. Chimoto, E. Nambu, K. Yoshida. Dpt. Physiology, Inst. Basic Med. Sci., Univ. of Tsukuba, Tsukuba, 305 Japan

We have recently shown that many neurons in and around the interstitial nucleus of Cajal (INC) that project contralaterally carry vertical eye position signals. In the present study, we recorded activity of vertical eye position-related INC neurons and examined electrophysiologically their axonal course and synaptic nature in the alert cat. For 11 downward-on and 5 upward-on neurons, depth profiles of threshold and latency for antidromic activation were studied by tracking in and around the contralateral (c-) INC. These neurons were activated from not only c-INC but a region 1-2 mm dorsal to c-INC. The latency became longer as the stimulation site moved ventrally, showing that the stem axon coursed ventrally toward c-INC. Double or triple low-threshold peaks and latency variation were observed in 4 downward-on and 2 upward-on neurons when stimuli were applied to c-INC, indicating the existence of branches. Stimulation of the midline region suggested that axons of these neurons projected through the posterior commissure (PC). Stimulation of c-INC and the more dorsal region inhibited spike generation of 7 downward-on and 2 upward-on neurons that were not antidromically activated. The latency of inhibition ranged from 0.7 to 1.4 msec. Effective stimulation sites seemed to be distributed along the course of fibers from PC. Results suggest that these non-commissural INC neurons receive monosynaptic inhibitory connections from commissural INC neurons on the contralateral side, most likely from those having an opposite on-direction.

AN EEG-BASED BRAIN-COMPUTER INTERFACE: USE BY INDIVIDUALS WITH ALS. D.J. McFarland*, L. McCane, T. Vaughan, and J.R. Wolpaw, Wadsworth Labs, NY State Dept Health and SUNY, Albany, NY 12201.

Humans can learn to control the amplitude of EEG activity recorded over sensorimotor cortex (e.g., the 8-12 Hz mu rhythm) and use it to move a cursor to a target on a video screen (Electroenceph clin Neurophysiol 78:252-259, 1991 and in press). Brain-computer interface technology may provide a new communication channel for those with severe motor disabilities. We are using high-resolution EEG frequency and topographic analysis to improve this technology and are investigating its applicability to individuals with specific disorders.

After initial evaluation of the EEG and its relationships to sensorimotor activity, subjects learn to control cursor movement while 64 channels of EEG are stored for offline analysis aimed at improving the algorithm that converts EEG activity into cursor movement.

In initial studies, individuals with early-stage amyotrophic lateral sclerosis (ALS) were able to learn to control cursor movement. If this control persists as the disease progresses, EEG-based communication could prove of considerable value in the later stages, when useful voluntary movement is largely or totally gone. 572.2

HISTOLOGICAL IDENTIFICATION OF PREMOTOR NEURONS FOR HORIZONTAL SACCADIC IN MONKEY AND MAN BY PARVALBUMIN STAINING. A.K.E. Horn* and J.A. Büttner-Ennever, Inst. Neuropathology, LMU Munich, 80337 Munich, F.R.G.

The premotor excitatory (EBN) and inhibitory burst neurons (IBN) are essential for horizontal saccades. In the monkey, EBNs are located in the ipsilateral paramedian pontine reticular formation (PPRF), the IBNs more caudally in the contralateral dorsal paraventricular nucleus (pgd). For a neuropathological analysis of degenerative changes in saccadic disorders of patients the histological identification of EBN- and IBN-areas in man is important. Here we show that this is possible by using parvalbumin (PAV) as a histological marker. First, in monkeys EBNs and IBNs were retrogradely filled by injections of WGA-HRP or cholera-genotoxin into the abducens nucleus (VI) or tetanus toxin fragment C into the lateral rectus muscle and shown by double-labelling to contain PAV. Then, human brainstem sections were immunoreacted for PAV, and by comparing the PAV-staining pattern to that in the monkey the homologue burst neuron areas were defined in man. In the PPRF EBNs were confined to the nucleus reticularis pontis caudalis (nrpc), and did not extend further rostrally into nucleus reticularis pontis oralis (nrpo). All retrogradely labelled cells in the nrpc and pgd were PAV-positive, and ca. 70% of the PAV-positive cells were retrogradely labelled. Both, the EBN-area and IBN-area, were high-lighted by their PAV-content and could be outlined in man as well. EBN: the medial part (2.5mm width) of the nrpc immediate rostrally (250µm) to the omnipause neurons extending 2.2mm rostrally, IBN: the medial part of the pgd immediate ventrocaudally to VI extending 1.8mm caudally. The location of the burst neuron areas, and probably even the EBNs and IBNs themselves, with PAV will help the analysis of clinical cases of slow saccades. This work was supported by the DFG (SFB 220).

572.4

'EYE-NECK' RETICULAR NEURONS CONTROL ORIENTING GAZE SHIFTS BUT NOT GAZE-STABILIZING VESTIBULAR REFLEXES. T. Kitama, A. Grantyn*, A. Barthoz, LPPA, C.N.R.S.- Collège de France, Paris, France.

Previously we defined a class of reticular formation neurons (RFN) controlling eye-neck synergies during orienting. Studies by others in decerebrate cats suggested that some RFNs can be involved in the control of both active orienting head movements and of gaze-stabilizing vestibulo-colic reflex (VCR). In the present work a possibility that one and the same RFN can participate in these two antagonistic functions has been evaluated in alert animals.

RFNs, some of them identified as reticulospinal neurons, were recorded in the caudal pontine and rostral bulbar RF. Orienting-related 'eye-neck' neurons (EN-RFNs) were identified by their phasic-sustained or quasi-tonic discharges correlated with visually triggered eye movements and with activation of ipsilateral neck muscle EMG. They were tested during horizontal sinusoidal rotation (0.2-1.0 Hz; 2.0-21.5°) in dark and in light. None of EN-RFNs showed any modulation during VCR or VOR. They were active only during ipsilaterally directed anticompany movements: quick phases, shifts of the ocular beating field and associated EMG activity. Firing rate correlations with these motor events were qualitatively the same as during visually triggered gaze shifts. In the control sample of RFNs 'unrelated' to orienting movements the fraction of cells modulated by passive rotation (15%) was similar to that reported in decerebrate cats.

Synaptic inputs to EN-RFNs and to RFNs 'unrelated' to orienting were tested by stimulation of the superior colliculus (SC) and the vestibular nerves (VN). Monosynaptic excitatory input from the contralateral SC was found in 92% of EN-RFNs vs 75% of 'unrelated' RFNs. Only 2 out of 17 tested EN-RFNs showed early excitatory responses to VN (latencies 1.25-10.0 ms), in contrast to 30/42 (71%) 'unrelated' neurons. The tecto-vestibular convergence was therefore very rare in EN-RFNs.

The study points to a segregation of reticular neurons controlling orienting eye and head movements from those mediating compensatory reflexes during natural vestibular stimulation. Rhombencephalic vestibulo-reticular input to orienting-related EN-RFNs appears to be negligible, as compared to tectal input. Activity of these neurons during rotation-induced anticompany gaze shifts must therefore require contributions of excitatory pathways from higher order structures.

MOVEMENT FIELD PROPERTIES OF SACCADE-RELATED BURST CELLS IN THE MESENCEPHALIC RETICULAR FORMATION (MRF). V.L. Silakov* and D. M. Waitzman, Newington VAMC, 555 Willard Ave, Newington, CT 06111.

The movement field properties and the discharge dynamics of 206 MRF neurons located lateral to the oculomotor complex have been studied in 2 awake behaving monkeys performing visually guided saccades. At least two major classes of neurons can be distinguished. One group, the long lead burst neurons, has a build up of activity which begins 150 msec before saccades, an accelerated burst just before the saccade, this burst declines during the saccade, and the tail of activity may continue for 50 msec after saccade end. The optimal saccade vector for these cells is primarily contraversive with a vertical component. The movement fields for these cells are large and open-ended. These cells are located in the more ventral and caudal portions of the MRF. A second group of cells is distinguished by a tightly coupled burst of activity which starts 20-30 msec before, peaks just prior to, and declines sharply during visually guided saccades with little post saccadic activity (i.e. clipped cells). These tightly coupled cells can have either large (open-ended) or small (closed) movement fields. While many of these cells have omnidirectional discharges, the optimal saccade vector for these cells is again contralateral with a pronounced vertical component. These cells are located in the more dorsal and rostral portions of the MRF. The correlation of cell type with histologic location suggests at least two physiologically distinct regions of the MRF.

572.7

THE TIMING OF SACCADE-RELATED RESPONSES OF BRAINSTEM OMNIPAUSE NEURONS IN CAT. M. Paré* and D. Guitton, Montreal Neurological Institute and McGill Univ., Montreal H3A 2B4, Canada.

Recent evidence (Paré and Guitton 1994) suggests that fixation neurons (FNs) in the superior colliculus project onto brainstem omnipause neurons (OPNs). Both cell types pause for eye saccades in monkey and gaze saccades in cat and it is of interest to determine whether they share other discharge properties. We recorded OPNs during visually-guided horizontal gaze shifts in the head-fixed and head-free cat and quantitatively analysed the temporal relation of their discharge relative to parameters of eye or gaze saccades. 1. Cat OPNs ceased firing, on average, 25ms before saccade start. They resumed firing, on average, 6ms before saccade end. Some cells were reactivated after saccade end. Consequently, as already reported, the pause duration was well correlated with saccade duration ($r > 0.9$) but the slope of this relation was always less than one - a similar relation holds for monkey FNs (Munoz and Wurtz 1993). The slope increased linearly with the associated correlation coefficient, indicating that OPNs whose pauses are temporally well correlated to saccades have equal onset and end times. 2. Monkey FNs are reactivated sooner for contraversive saccades compared to ipsiversive ones. The timing of the majority of our cat OPNs also depended on saccade direction: two thirds of the cells had significant left-right differences in pause end time. 3. Pause end time was twice as variable as pause onset time; the inverse has been observed for monkey FNs. 4. OPN tonic discharge rate influenced pause timing: the higher a neuron's firing rate, the closer to saccade start it stopped discharging. 5. Pause end time did not depend on any saccade parameters. On average, OPNs were reactivated at either ~ 1 deg of gaze error or ~ 100 deg/s. In 1 and 2, OPNs and FNs have similar discharge characteristics. This suggests that OPNs are segregated into two lateralized populations of cells each receiving inputs from contralateral FNs. However, the timing characteristics of OPNs are also clearly influenced by extra-FN inputs.

MOTONEURONS OF EXTRAOCULAR MUSCLES CODE DIRECTIONS IN VESTIBULAR COORDINATES. V. Henn*, Y. Suzuki, D. Straumann, B.J.M. Hess, K. Hepp, Neurology Dept, University Hospital, CH-8091 Zürich, Switzerland

Extracellular activity of motoneurons was recorded in alert rhesus monkeys. They were put into different static roll positions to induce ocular counterrolling, while they made spontaneous eye movements. This provided a database of eye positions of about ± 40 deg in the horizontal, ± 30 deg in the vertical, and ± 8 deg in the torsional direction. Three-dimensional eye positions during fixation periods were related to steady-state firing rates of neurons, and on-directions were calculated by multiple linear regression analysis. On-directions were compared to anatomically defined pulling directions of extraocular muscles and to orientations of semicircular canals. In the rhesus monkey only the lateral canals show an approximate correspondence with lateral recti muscle action planes. Average on-directions of 52 motoneurons were more closely related to canal than to muscle coordinates.

Results support the notion that vestibular coordinates provide a common reference frame for directional coding also in the oculomotor system (see Suzuki et al, this vol).

572.6

EFFECTS OF REVERSIBLE LESIONS OF THE CENTRAL MESENCEPHALIC RETICULAR FORMATION (cMRF) ON PRIMATE SACCADIC EYE MOVEMENTS. D. M. Waitzman* and V. L. Silakov, Newington VAMC, 555 Willard Avenue, Newington, CT 06111.

Recent studies suggest that the cMRF participates in the generation of saccades, but its exact role remains unclear (Waitzman, *Soc. Neurosci. Abstr.*, 1992). Visually guided saccadic eye movements of one awake rhesus monkey were recorded using a scleral search coil before, during and after the injection of 2% lidocaine (1 - 5 μ l) and muscimol (1 - 3 μ g) into the cMRF. Fifteen injections of lidocaine, 5 injections of muscimol, and 4 injections of saline were placed at a series of sites (containing saccade associated, multi-unit activity) which were at 1 mm increments along the rostral-caudal axis, 2 mm lateral to the oculomotor complex. Within 2 minutes of injection of either lidocaine or muscimol, contraversive horizontal and vertical saccades were hypometric, while ipsiversive saccades were hypermetric. The primary position of gaze was shifted 3° down and to the ipsilateral side. The trajectories of vertical and oblique saccades were markedly curved toward the ipsilateral side. Injections 2 mm above or below the cMRF produced no effects on saccades. The effects on saccade trajectory suggest that the cMRF participates in the descending control of the horizontal component of movement, while changes in saccadic accuracy suggest the cMRF participates in the feedback control of saccade amplitude. The shift in the primary position of the eyes implies that activity of cMRF neurons is used in the maintenance of the primary position of the eyes. 572.8

EFFECTS OF BOTULINUM NEUROTOXIN TYPE A ON MUSCLE PROPERTIES AND OCULAR MOTONEURON DISCHARGE CHARACTERISTICS IN THE ALERT CAT. B. Moreno-López, R.R. de la Cruz*, A.M. Pastor and J.M. Delgado-García, Lab. de Neurociencia, Fac. de Biología, Univ. de Sevilla, E-41012, Spain.

Botulinum neurotoxin A (BoNT) is a useful tool for the study of motoneuron-muscle interactions, since it produces a functional disconnection by blocking the release of acetylcholine at the neuromuscular junction. Are there any retrograde effects on the discharge characteristics of motoneurons when their target muscle is paralysed with BoNT? To address this question, adult cats were prepared for the chronic recording of eye movements, lateral rectus muscle potentials and abducens motoneuron electrical activity. After control recordings, BoNT was injected into the lateral rectus muscle at either 3 or 0.3 ng/Kg. Both doses produced in a few hours the paralysis of abducting eye movements that paralleled the disappearance of muscle field potentials induced by the electrical stimulation of the VIth nerve. The time course of these changes was shorter for the high BoNT dose and the recovery lasted longer. On the contrary, only the high dose produced significant alterations in the discharge characteristics of abducens motoneurons. Thus, motoneurons lost their typical tonic-burst firing that accompanies eye fixations and saccades. Instead they showed a sustained low firing rate (15-50 spikes/s) and barely entered into cut-off even for the fastest eye movements in the off-direction. Firing modulation for both spontaneous and vestibularly-induced eye movements was extremely weak yielding low sensitivities to both eye position and velocity. The signalling deficits of motoneurons for off-directed eye movements were deeper than those for the on-direction. Accordingly, the scatterplots of firing rate versus eye position or velocity showed that two rather than one regression line fitted better the data and corresponded to the data partition into on- and off-directions of movement. The low dose of BoNT produced only subtle changes in the firing of some motoneurons despite total muscle paralysis. These data suggest that the firing alterations found result of a direct action of BoNT on motoneurons and not only due to the target disconnection.

572.10

THREE-DIMENSIONAL EYE MOVEMENTS EVOKED BY ELECTRICAL MICRO-STIMULATION OF THE TROCHLEAR NERVE IN ALERT RHESUS MONKEYS. Y. Suzuki*, D. Straumann, K. Hepp, V. Henn, Neurology Department University Hospital Zürich, CH-8091 Switzerland.

In the rhesus monkey, anatomical coordinates of vertical and oblique eye muscles show major deviations from orthogonality and are therefore not well aligned with semicircular canals. We electrically stimulated the trochlear nerve (0.25ms negative pulses, 20-80 μ A, 0.5-1kHz over 9-70ms), while the alert animal made spontaneous eye movements covering the whole oculomotor range, and measured the evoked eye movements in 3 dimensions. This allowed to test the following hypotheses:

(A) The eye moves in alignment with the anatomical pulling direction of the superior oblique muscle, if the eye plant is organized as an isotropic passive element, where muscle force translates into movement independent of other muscles.

(B) The eye moves along a direction taking into account the equilibrium direction of all other eye muscles.

Results show that movements occurred along a trajectory approximately 45 deg between vertical and torsional planes, thus closely corresponding to the ipsi-lateral anterior canal sensitivity vector, but not to the muscle pulling direction of the superior oblique muscle. This falsifies hypothesis (A). We conclude that extraocular motoneurons code movement in vestibular, not in muscle coordinates in alert condition (see Henn et al, this vol).

SYNAPTIC CONNECTIONS OF ASCENDING TRACT OF DEITERS AND ABDUCENS INTERNUCLEAR INPUTS TO MEDIAL RECTUS MOTONEURONES IN THE CAT OCULOMOTOR NUCLEUS. L.T. Neuvén* and R.F. Spencer. Dept. of Anatomy, Med. Coll. of Virginia, Richmond, VA 23298.

The synaptic connections of abducens internuclear (Abd IN) and ascending tract of Deiters (ATD) neurones with medial rectus (MR) motoneurons in the cat oculomotor nucleus have been examined by light and electron microscopy following injections of biocytin into the abducens and vestibular nuclei, respectively. Both Abd IN and ATD endings contained spheroidal synaptic vesicles and established asymmetrical synaptic contacts with single postsynaptic profiles. Abd IN and ATD synaptic endings were similar in size ($1.68 \mu m^2$ and $1.62 \mu m^2$, respectively). The majority (54%) of Abd IN synaptic endings, however, established synaptic connections with distal dendrites, whereas most ATD synaptic endings contacted proximal dendrites (49%) or somata (30%). In contrast to Abd IN synaptic endings, which typically were associated with only a modest postsynaptic densification at sites of synaptic contacts, ATD synaptic endings frequently exhibited either subjunctional dense bodies in association with axodendritic synaptic endings or subsurface cistern that were associated with axosomatic synaptic endings. The more proximal location of ATD synaptic endings is consistent with the faster rise time and earlier reversal to polarizing currents of ATD EPSPs in comparison to those evoked by the Abd IN pathway as determined electrophysiologically. Given that the ATD pathway conveys only a weak eye position signal, the findings in this study suggest that the ATD pathway may function to reduce the threshold for the activation of MR motoneurons by the Abd IN input related to conjugate horizontal eye movements, possibly as a mean of counteracting the effects of other inputs that are related to vergence eye movements.

TRANSNEURONAL TRANSPORT OF BIOCYTIN THROUGH ABDUCENS MOTONEURONS OUTLINES THE INTERNUCLEAR AND VESTIBULAR PATHWAYS IN TELEOST FISH. R. Baker, E. Marsh and R.F. Spencer*. Dept. of Physiology and Biophysics, NYU Medical Center, New York, NY 10016 and Dept. of Anatomy, Medical College of Virginia, Richmond, VA 23298.

Selective application of biocytin crystals to the Vth nerve in divergent species of teleosts reveals rostral and caudal subgroups of abducens motoneurons with intensely labeled somatodendritic trees spanning the entire mediolateral extent of the hindbrain. Located immediately dorso-medial to each sub-group and in about a 1:2 ratio are internuclear neurons whose axons ascend dorsally in the medulla, pass through the ipsi-MLF to cross the midline, and then project rostrally in the dorsomedial quadrant of the contra-MLF where they terminate onto and occasionally also label medial rectus motoneurons. In those species with rhythmically conjugate horizontal scanning eye movements (e.g. goldfish, catfish vs. sculpin, sunfish) the bipartite motoneuronal/internuclear somata position is observed medial in the hindbrain and this location appears to be independent of either the optic axis or location of the eye in the orbit. However, even when the abducens complex is located most laterally, adjacent to the vestibular nucleus (e.g. midshipman), the medially directed dendrites not only reach but also cross the midline. In all cases, labeled dendrites from each motoneuronal subgroup extensively interdigitate with those of the adjacent internuclear populations suggesting a similar embryonic origin of all neurons in rhombomeres 5 and 6. Transneuronal biocytin transport also marks the pathway and location of contralateral excitatory vestibular neurons in the descending octaval nucleus including occasionally the axons of vestibular neurons that project to medial rectus motoneurons. Electron microscopy of the oculomotor and abducens motor nuclei in goldfish reveals numerous axosomatic and axodendritic synaptic endings showing membrane specializations characterizing chemical and gap junctions. Therefore, the extensive electrotonic coupling and transneuronal transport of biocytin prevalent in some teleosts, like toadfish and midshipman, suggest the possibility of fully describing both the visual and vestibular pathways specific to each extraocular subdivision.

572.12

BILATERAL PROJECTION OF SINGLE MOTOR NEURONS INVOLVED IN VISUOMOTOR CONTROL, A DOUBLE LABELLING STUDY IN THE RAT. P.M. Young (SPON: Brain Research Association). Department of Psychology, University of Central Lancashire, Preston PR1 2HE, UK.

Preliminary retrograde double labelling studies have identified oculomotor nucleus motoneurons projecting bilateral axonal collaterals through the retrorubral fields. This study was designed to combine retrograde / anterograde tracers in delineating these projections. Twenty male Wistar rats (220 - 330g b. wt.) were anaesthetised with tribromoethanol, and individual extraocular muscles, bilaterally, were injected (0.05 - 0.2 μl) through 50 μm tip diameter glass micropipettes connected to a 1 μl Hamilton syringe, with either Fluorogold (FG), Dil, Fast Blue (FB), PHA-L, Biotinylated Dextran Amine (BDA) or cholera toxin - horseradish peroxidase (CTB). Survival times ranged from 48-96 hours, and following perfusion 80 μm frozen sections were appropriately processed. Tetramethylbenzidine diaminobenzidine and Vector VIP were used as chromogens with PHA-L, BDA and CTB. Fluorescent tracers were viewed with a Leitz Diaplan. These studies showed only very occasional bilateral innervation of functional pairs of extraocular muscles. A more common configuration would be, for example, for a ventromedially and rostrally located oculomotor neuron, retrogradely labelled following an injection to the ipsilateral left inferior rectus, to also send an axon collateral to terminate in association with the contralateral third nerve fascicles retrogradely labelled in turn following an injection of tracer to the right inferior rectus muscle. The results demonstrate the anatomical bases of muscle linkages carried out at the simplest level of individual neurons. A primitive system overlain and increased in sophistication by the complex interconnections of premotor afferents.

572.14

SIMULATION OF MOTOR UNIT RECRUITMENT IN EXTRA-OCULAR MUSCLE. Paul Dean*. Dept. of Psychology, University of Sheffield, Sheffield S10 2TN, England.

Understanding the recruitment pattern of extraocular motor units is important for constructing distributed models of oculomotor control. Recruitment in the abducens nucleus was simulated using data relating steady-state horizontal eye position to (a) the firing rates of oculomotoneurons (eg Robinson and Keller, *Biblio. Ophthal.* 82: 7, 1972), and (b) the total active force developed in the lateral rectus muscle (e.g. Miller and Robinson, *Comp. Biomed. Res.* 17: 436, 1984). The purpose was to determine the distribution of motor unit strengths that would fit both sets of data over the oculomotor range.

The lateral rectus was represented as 100 motor units, initially of identical strength. For a given position of the eye, the force developed by each unit was calculated, and the sum of unit forces compared with the active force in the entire muscle as measured experimentally. The properties of the active units were then adjusted to reduce the size of any resultant error, in a manner related to gradient descent methods for neural-net training. The simulated eye muscle was 'trained' in this fashion for a series of eye positions drawn at random from the oculomotor range until performance stabilised. Plots of motor unit strength against oculomotoneuron threshold revealed a U-shaped pattern, with the strongest units being recruited at both extremes of the oculomotor range, and the weakest units recruited in the middle. The pattern remained qualitatively unaltered over a range of assumptions about the distribution of oculomotoneuron parameters, and the relation between motoneuron firing rate and unit force.

One part of the U-shaped pattern is similar to that observed in spinal motoneurons, where stronger units tend to have higher recruitment thresholds, whereas the other part is consistent with evidence from single motor-unit stimulation studies (Shall and Goldberg, *Brain Res.* 587: 291, 1992) suggesting that in eye muscles the stronger units are recruited first. The pattern as a whole may reflect the functional need for precise control of eye position in the middle of the oculomotor range.

OCULOMOTOR: PERFORMANCE AND MODELING OF SACCADDES

573.1

CHARACTERISTICS OF ANTI-SACCADDES IN MONKEY. H. Sanchez, N. Amador, C. Salumbides, M. Schlag-Rey* & J. Schlag. Brain Research Institute, UCLA, Los Angeles, Ca. 90024.

The performance of anti-saccades (AS) - saccades directed opposite to a visual target - entails the inhibition of reflexive foveation and the coordinate computation of a goal specified by instruction, i.e. not pointed to by the visual event. Normal humans (with intact frontal lobe) can readily do it. How do monkeys compare to humans? Long-term behavioral data were obtained from 2 monkeys trained in a task interleaving AS with normal, pro-saccade (PS) trials. The instruction to make AS or PS was given on each trial by the shape of the initial fixation point (respectively a square or a point) lasting 400 - 900ms. Upon its offset, the directional cue (always a point) was briefly flashed (10, 20, or 200ms) in one of 8 directions, at a distance of 10° to 30° from the fixation point.

Compared to PS, AS were slower, less accurate saccades, affected by an upward drift in darkness, but not more so than ordinary memory saccades. Mean latencies of AS were in the same range for both monkeys (~210 ms), greater than PS latencies for one monkey, as expected, but shorter for the other one. This latter result may be related to the prior training experience of that monkey.

As in humans, directional errors were unrepressed PS, but many were followed by corrective AS, some with almost no intersaccadic delay. Back-to-back saccades subsided as performance improved.

Thus, monkeys can be taught to repress their natural tendency to look at any visual stimulus flashed on a screen. They can also learn a rule for directing gaze to a blank site radially opposite to a visible target. (Supported by USPHS grants EY02305 and EY05879).

573.2

IMPROVED TEMPORAL DISCRIMINATION OF TWO BRIEF FLASHES AT THE SAME RETINAL LOCATION JUST BEFORE A SACCADDE. R.H.D. Cai*, M. Schlag-Rey & J. Schlag. Brain Research Institute, UCLA, Los Angeles, Ca. 90024.

Just before a saccade, there is a period (about 100 ms) when the timing of an incoming visual signal and the current internal representation of eye position seem mismatched. As a result, 2 flashes at the same retinal localization appear to be at different places. Could this illusory spatial mislocalization improve the temporal discrimination of 2 stimuli flashed in rapid succession?

Horizontal eye movements were recorded with an Ober2 eye-orbit scanner in 2 human subjects, head fixed in the dark. Subjects were instructed to make a saccade to a 10-ms light spot flashed 10° rightward from the point of fixation. During the latency period, another 4-ms light spot was flashed twice at 12° to the right of the point of fixation. Flash separation varied from 10 to 100 ms. Subjects were to report after each trial, whether they saw 1 or 2 flashes, and when seeing 2, whether they were at the same or different places. The frequency of reporting 2 flashes increased as the pair of flashes occurred closer to the saccade onset. The frequency of reporting two flashes at different locations increased in parallel. We suggest that the improvement in temporal discrimination was due to the impact of the eye position signal on visual input. (Supported by USHHS grant T32 GM08375 and USPHS grant EY05879)

BEHAVIORAL INHIBITION OF SACCADDES: A STUDY USING THE COUNTERMANDING PARADIGM. D.P. Hanes* & J.D. Schall. Dept. Psychology, Vanderbilt University, Nashville, TN 37240

How the brain regulates saccade initiation is not known. For useful neural correlates to be identified, novel behavioral methods are needed that systematically manipulate saccade production. To manipulate the initiation of saccades, we implemented a countermanding paradigm (Lappin and Eriksen, 1966, *J Exp Psych*, 72:805) in two rhesus monkeys. After fixation of a central spot, a target appeared at 1 of 2 locations. At the same time the fixation spot disappeared, signaling the monkeys to generate a saccade to the target. On 25% of the trials the fixation spot reappeared after a delay, signalling the monkey to withhold the saccade. The stop-signal delay ranged from 25-225 ms. With short stop-signal delays monkeys withheld saccades to the peripheral target, and with longer stop-signal delays monkeys increasingly failed to withhold the saccade. We observed a few trials in which monkeys generated a saccade falling short of the target, and on those trials a return saccade was usually made. The probability of saccade generation as a function of stop-signal delay increased monotonically with stop-signal delay in a sigmoid fashion (best fit logistic equation, $r^2 = 0.97$). The hypothesis that generation of the saccade is determined by a race between a go and a stop process provides a means of analyzing this inhibition function to estimate the covert latency of response to the stop signal (Logan and Cowan, 1984, *Psych Rev*, 91:295). For each stop-signal delay the stop-signal response time was estimated as the point on the cumulative distribution of go trial saccade latencies corresponding to the proportion of stop-signal trials in which a saccade was generated for that stop-signal delay. Stop-signal response time decreased with increasing stop-signal delay from 140 ms at a 25 ms delay to 30 ms at a 225 ms delay. The average stop-signal reaction time for both monkeys was 80 ms. This countermanding paradigm will be useful to study the neural mechanisms that regulate saccade initiation. (Supported by R01-EY08890 and T32-EY07135)

BIMODAL LATENCY DISTRIBUTION OF AVERAGING SACCADDES IN MONKEY. I. Chou*, M.A. Sommer and P.H. Schiller. Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Saccades made to a visual target can have a bimodal latency distribution, the first mode of which is termed "express". If more than one target is presented, express saccades are suppressed (Schiller *et al.*, 1987). It has also been reported that saccades occurring during the simultaneous presentation of two targets can be "averaging" and terminate between the targets. In this study, we examined whether averaging saccades can exhibit bimodal latency distributions. Two rhesus monkeys with implanted scleral search coils were used. At the start of a trial, a fixation spot was presented. After a randomized amount of time, this spot was extinguished and either one (80% of trials) or two (20%) targets were turned on at 6 deg. ecc. For the two target condition, separations varied from 3 to 8.5 deg. of arc. Saccadic latencies and their endpoints in space were analyzed. Whenever a distinct averaging saccade population appeared, these saccades had bimodal latencies. As the separation of the paired targets was increased, the probability of averaging saccades declined and saccadic accuracy improved. Also, as saccades became less "averaging" and more "target directed", the express mode was markedly reduced. This study shows that express saccades can be made when two nearby targets are presented simultaneously, but they tend to land at averaged positions where there is no actual visual stimulus.

573.7

EXPRESS AND REGULAR SACCADIC REACTION TIMES GENERATED BY CONTINUOUS, STOCHASTIC DYNAMICS. K. Kopecz and C.C.A.M. Gielens. Lab. Med. Phys. & Biophys. Univ. Nijmegen. The Netherlands.

The existence of an *express* (E) and a *regular* (R) mode in distributions of saccadic reaction times (SRT) is now a widely accepted fact (review, Fischer & Weber, *Beh. Brain Sci.*:16, 1993). The E-mode is often observed in the gap paradigm, where the offset of an attention attractor precedes target onset. These results led to the notion of "engaged" and "disengaged" attention. Without inducing E-saccades, gap conditions also lead to a reduction of mean regular SRTs (Saslow, *J. Opt. Soc. Am.*:57, 1967).

We have put the intuitions about the relation of SRTs to states of attention into a quantitative model. We assume that: (1) The attentional state can be mapped onto one, continuous variable, $a(t)$. (2) Aside from conduction delays, the total SRT is determined by a "processing time", which is mapped onto a relaxation of $a(t)$, governed by stochastic dynamics of the form $\dot{a} = f(a) + \xi(t)$, down to a threshold. $\xi(t)$ is a Gaussian white-noise. (3) Two behaviorally relevant "signals" act parametrically onto the attentional system: a *warning*- and a *go*-signal. Without these signals the dynamics is *bistable*, reflecting the states of engaged and disengaged attention. Due to noise, the system switches spontaneously between the two states, so that they are visited with a certain probability. During the gap interval the system is still bistable, but now the disengaged state is more stable than the engaged state. Thus, the probability of being disengaged increases with time after the warning event. The go-signal changes the system to be monostable. During the relaxation to its equilibrium, $a(t)$ crosses the threshold after a time which depends on the state at go signal onset.

Simulations show the basic phenomenology of gap paradigms, including skewed SRT distributions and the dichotomy of E- and R-saccades as well as the reduction of regular SRTs with increasing gap interval.

INFLUENCE OF FAST SACCADIC GAIN ADAPTION AND FATIGUE ON SACCADDE METRICS IN THE MONKEY. A. Straube, S. Usher, F. R. Robinson, and A. F. Fuchs*. Neurologische Klinik, Ludwig-Maximilians University, 81377 Munich, Germany and Dept. of Physiology and Biophysics and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195, USA.

To provide accurate saccades, the oculomotor system must be able to compensate for changes in its neural elements. Such changes can be simulated by altering saccade accuracy optically. We increased or decreased the gain of visually-guided saccades by electronically detecting a targeting saccade and then causing the target to step either forward or backward by 30 or 50%. After about 1500 trials, this paradigm caused either a decrease or increase of saccadic gain to the initial target step by an average of 0.28 and 0.24 to 30% step, respectively in 3 monkeys. There was no difference in the adaptation in vertical or horizontal direction. The time constant for the readaptation towards the normal gain was always smaller than the time constant of the primary adaptation. For 30% backadaptation, the gain decrease was still 18% after 20 hours in the dark.

Associated with the gain change, however, there also was a change in saccade metrics. For both forward and backward adaptation, saccades were slower with longer durations. The percentage decrease in peak velocity was larger for larger saccades. It also varied from monkey to monkey and became less if saccades were adapted with a background. Saccade slowing could not be explained solely by fatigue because the same number of visually-guided saccades without a artificial target step caused smaller changes in duration and peak velocity.

573.6

DO SACCADDES SHOW TORSIONAL ADAPTATION?

B.J.M. MELIS AND J.A.M. VAN GISBERGEN*

Department of Medical Physics and Biophysics, University of Nijmegen, P.O.Box 9101, 6500 HB NIJMEGEN, The Netherlands.

The torsional components of saccades and fixations are relatively small (Listing's law). From an oculomotor point of view this reduces position signals to 2D. On the other hand, Listing's law could serve the visual purpose of providing orientational invariance of the retinal images. In contrast to torsional eye position, the horizontal (H) and vertical (V) components of fixation are under accurate and voluntary control. In addition, H-V saccadic components can be adapted, which obviously serves the visual function of foveation. If the torsional component could also be changed in a short-term adaptation paradigm, this would provide a possible visual basis for Listing's law.

Binocular human eye movements were recorded using the 3D magnetic search coil technique. Subjects made leftward saccades between two points on a large, grey-scaled checkerboard pattern. During these saccades the whole stimulus was rotated about the left target. To check classical H-V adaptability, in some experiments this rotation was combined with a horizontal translation.

Translation of the stimulus induced rapid adaptation of horizontal saccade amplitude. By contrast, rotation of the visual field did not elicit a significant adaptation in torsion. Thus, our results do not support the hypothesis that Listing's law serves a visual purpose.

EYE SACCADDES GUIDED BY VISUAL, TACTILE AND PROPRIOCEPTIVE STIMULI IN MAN. O. Blanke, O.-J. Grüsser and W.O. Guldin*. Department of Physiology, Freie Universität, 14195 Berlin, Germany.

Horizontal visual saccades (binocular stimulation with light-emitting diodes, distance up to ± 40 degrees horizontal eccentricity) were used to calibrate eye position recordings (DC-electrooculography or infrared reflection method). In addition to "visual" saccades the subjects performed saccades in the dark directed to the left and right index fingers positioned along a perimeter circle at eye level but different horizontal eccentricities. A short (<10 ms) mechanical stimulus was applied to the fingertips. The subjects were asked to look at the stimulated fingertip (alternation rate 0.7-7 per sec). The subjects were also asked without tactile stimulation to look at the index fingers (same position as in the preceding paradigm), whereby a short auditory click determined the alternation frequency.

At an alternation rate of 0.7-4 per sec the "tactile" and "proprioceptive" saccades were significantly larger than the visually guided saccades in all but one subject, i.e. there was a considerable overshoot, indicating that the efference copy signals controlling eye position in the dark were operating at a gain below 1. This "error" in saccade amplitude increased with crossed hands. When visual saccades were suddenly changed into tactile or proprioceptive saccades, the increase in saccade amplitude occurred gradually with a time constant between 3 and 5 sec. The same was true when saccades were guided 20 times by two alternately lit diodes and thereafter by spatial memory. (Supported in part by a grant from the Bundesministerium für Wissenschaft und Technologie, Germany).

DYNAMICAL PROPERTIES OF AUDITORY EVOKED SACCADDES M.A. Frens and A.J. Van Opstal * Department of Medical Physics and Biophysics, University of Nijmegen, P.O. Box 9101, 6500 HB Nijmegen, The Netherlands.

We measured saccadic eye movements of human subjects towards visual and auditory targets throughout the oculomotor range. It was noted that auditory-evoked saccades had trajectories and velocity profiles that were less stereotyped than visually-elicited saccades. This often resulted in curved trajectories for saccades driven to auditory targets in oblique directions. Close inspection of the velocity profiles showed that the main sequence properties of the horizontal and vertical components of auditory-evoked saccades seem to be independent of saccade direction. This phenomenon may reflect the fact that the auditory system derives azimuth and elevation of a sound through different neural pathways. Therefore, convergence of these pathways in a late stage of the audio-oculomotor pathway may give rise to these effects.

This is in strong contrast to visually-driven saccades, the dynamics of which seem to be vectorially encoded, resulting in approximately straight saccades.

In order to further study these apparent differences, we are currently recording the activity of saccade related burst neurons in the deep layers of the monkey Superior Colliculus during saccades towards auditory and visual targets.

TRANSCRANIAL MAGNETIC STIMULATION OF THE CEREBELLUM ELICITED DYSMETRIC SACCADDES IN MAN.

M. Hashimoto, K. Ohsuka and M. Sawa*. Dept. of Ophthalmology, Sapporo Medical Univ. Sch. of Med., Sapporo, Hokkaido 060, Japan.

Previous neurophysiological studies in the monkey have shown that lobules VIc and VII of the vermis (oculomotor vermis) are involved in the control of saccades. Microstimulation of the oculomotor vermis evokes ipsilaterally directed saccades. When the oculomotor vermis is stimulated before the onset of visually guided saccades, ipsilateral saccades overshoot the target, and contralateral saccades undershoot the target. The oculomotor vermis, especially the lobule VII is located just under the skull bone in man. Therefore, it will be possible to stimulate the lobule VII with a transcranial magnetic stimulation (TMS) device in man.

In this study, single TMS pulses were applied systematically at various locations over the occipital area during visually guided saccades using TMS device (NIHON KODEN, SMN-1100, 1.5 Tesla). The experiment was conducted on four normal volunteers. The effective area was marked on the head by a marker which produces high signal intensity on T1 image of MRI. The stimulation site was identified by parasagittal sections of MRI in each subject. Dysmetric saccades were elicited by TMS pulses near the external occipital protuberance before the onset of visually guided saccades. By TMS of right side of the cerebellum, rightward saccades overshoot the target, and leftward saccades undershoot the target. These findings suggest that the posterior vermis in man has the same role in the control of saccades as shown in the monkey.

FUNCTIONAL MRI OF COOPERATIVE CORTICAL ACTIVATION PATTERNS DURING EYE MOVEMENTS. A. Kleinschmidt*, K.-D. Merboldt, M. Requardt, W. Hänicke, J. Frahm, Biomedizinische NMR, Pf. 2841, 37018 Göttingen, Germany.

Gradient-echo MRI is sensitive to regional changes in cerebral blood oxygenation occurring during brain activation. Using this property for functional neuroimaging we analysed MRI signal changes during various oculomotor tasks comprising mainly smooth pursuit and saccades along the horizontal meridian.

Five healthy subjects (23-32 years, written informed consent) were studied on a conventional MRI system (2 T, Siemens Magnetom, standard headcoil). Dynamic MR recording (rf-spoiled FLASH, TR/TE/α=62.5ms/30ms/10°, measured in-plane resolution 0.8x1.6 mm² interpolated to 0.82 mm², section thickness 4 mm, 6 s/image) serially monitored task-associated signal changes in several sections mostly parallel to the bicommissural plane. Data evaluation was based on correlation maps calculated with reference to the stimulation protocol and individually corrected for noise.

Eye movements were associated with signal changes in the precentral and posterior median frontal gyrus ("frontal eye field"), the medial part of the superior frontal gyrus ("supplementary eye field") and the anterior cingulate. Responses were stronger in the saccadic condition but did not depend on visual cueing. Further foci were detected in dorsal parietal and dorsal visual associative cortex and depended to differing degrees on visual cues. Activation in primary visual cortex was studied in cued conditions and reflected retinotopic positioning of the stimuli (prior to eye movement). Additional sections covering the flocculus showed its activation during smooth pursuit while basal ganglia and thalamus were not included in the volume studied and activation in the superior colliculus could not be detected.

Overall, these results are in line with what has been inferred from electrophysiology in monkey and positron emission tomography in man. Additionally, the data suggest that MRI may even resolve activation in small subcortical structures that participate in the distributed network for gaze control.

EFFECTS OF AUDITORY STIMULI ON HUMAN GAZE SHIFTS TO VISUAL TARGETS. B.D. Cornell and D.P. Munoz* MRC Group in Sensory-Motor Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

We investigated the effects of presentation of auditory stimuli on gaze shifts (eye-head movements) to visual targets in human subjects. Subjects were instructed to look as fast as possible from a central LED to an eccentric LED, either 40° to the right or left of center. An auditory stimulus was presented at either the same location as the eccentric LED (enhancer), on the opposite side (distracter), or not at all (control). The auditory stimuli had predictable effects on gaze shifts to the visual targets. Reaction times to acquire the eccentric LED were reduced significantly in all subjects during enhancer trials and increased significantly in about half of the subjects during distracter trials. These experiments were also performed in a gap condition in which the central LED was turned off 200ms before onset of the eccentric LED. In this gap condition, subjects frequently produced direction errors in the distracter condition, incorrectly looking to the auditory stimulus. The proportion of direction errors made by each subject was tightly correlated to their reaction time during control trials. Subjects with the fastest reaction times produced the most direction errors, while those with the slowest reaction times produced no direction errors. Thus, subjects able to disengage fixation during the gap and produce the shortest latency (express) movements, reacted to the first perceived stimulus. In multimodal trials, the auditory cue is perceived first due to its shorter afferent pathway. We varied the temporal disparities between presentation of the auditory and visual cues ±200ms. Presentation of the auditory cue more than 50ms after onset of the visual target eliminated all direction errors and did not modify reaction times. Auditory cues presented prior to onset of the visual target strongly influenced reaction time and the number of direction errors. Supported by MRC Canada and the Sloan Foundation.

573.12

REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION OVER THE PREFRONTAL LOBE DISTURBS MEMORY-GUIDED SACCADDES. S.A. Brandt, B.-U. Meyer, C. Ploner, A. Villringer and P. Stoerig*. Laboratory of Neurophysiology, Department of Neurology, Charité, 10098 Berlin, Germany.

Repetitive, rapid-rate transcranial magnetic stimulation (rTMS) was used to study the role of the dorsolateral prefrontal cortex (DLPFC) for memory guided saccades. Precision of horizontal memory guided saccades, made to remembered targets after a 3 and 10 seconds delay were measured in 5 volunteers. We compared precision of saccades after stimulation (10 pulses at 10 Hz) of the prefrontal cortex (PFC), after stimulation of the posterior parietal cortex (PPC) and without stimulation. In all conditions the subjects made saccades towards the correct side of the remembered target. Without stimulation the average error was 9% of saccade amplitude. Presaccade stimulation over the PPC increased error to 14%, over the PFC to 18% of saccade amplitude. Saccades were predominantly hypometric but were unchanged in velocity and latency. Results show that stimulation over the PPC and the PFC does not extinct but significantly alters the ability to execute memory-guided saccades. Since elementary saccade parameters remain unchanged it can be speculated that rTMS unspecifically affects the premotor planing of memory guided saccades by disturbing parietal and prefrontal visuospatial representations of extrapersonal space.

573.14

SACCADDE ADAPTATION WITH A NON-VISUAL CUE. M. FUJITA* and T. OGAWA. Communications Res. Lab., Koganei-shi, Tokyo 184, Japan.

Repetitive intrasaccadic target step induces saccade adaptation (Deubel, 1987). After several hundred trials, subjects make first saccades to a second target position. The cerebellum seems to be responsible for the adaptation (Goldberg et al., 1993). In amplitude lengthening adaptation, changes in saccade velocity profile suggests a modification of the saccadic motor command (FitzGibbon et al., 1986). To elucidate the adaptation inducing factors, we made adaptation experiments with an auditory cue which taught subjects, 500 msec posterior to a saccade onset, whether the primary saccade was hypometric, normometric, or hypermetric to an expected saccade, in place of target step. Subjects, instructed to make a saccade to a briefly flashed target, made corrective saccades to the expected position, and after several hundred trials became to make, for example, an 8 deg saccade to an instantaneously illuminated 10 deg target. This excludes a case that the adaptation may take place with coupling of the estimate of the saccade performance and the motor command of a preceding primary saccade, because of the sufficiently long latency between them. In another experiment, subjects, instructed to make a saccade not to a flashed target but to an expected position by the sound, did not show any sign of adaptation. Simple association of a flashed target position to a saccade of preset size could not be acquired reflexively. Inevitability of making corrective saccades, not excluded by the second experiment, remained unresolved.

A new model is proposed that the adaptive modification of voluntary motor command can be realized either by strengthening or by weakening the feature of the command signal automatically by the cerebellum, if the accumulation of repetitive error estimation is responsible.

574.1

A SYSTEM FOR NAKED-EYE NEAR-FIELD DEPTH PERCEPTION AND LOCAL VIRTUAL SPACE SCANNING OF TYPE II FORMATTED STEREO PAIRS USING OCULOMOTOR LEARNING R.E. Winter¹*, T.C. Chisnell¹, and S.W. McLeskey², ¹The Winter Co., Falls Church VA 22044, and ²Lombardi Cancer Research Center, Georgetown University Medical Center, Washington, DC 20007.

The invention of the stereoscope in 1830 (Wheatstone) and the synthetic stereoscope in 1969 (Chisnell and Winter), made possible depth perception using type I formatted stereo-paired images. These images supply each eye with a picture appropriate to its field of vision. Type II formatted stereo-paired images are viewed at a normal distance and must be integrated by the brain for the perception of field depth. Unlike the task of real fixation, this task requires a pre-fixation on two displaced fixation points, translation of the two fixation points, merging them, and fusing them into one integrated perception in the fixation plane. Each eye must view the member of the stereo pair which is diagonally opposite it so that the target image impinges on the fovea in a way that it can be integrated with the image from the other member of the pair on the opposite fovea upon merging of the target images. Because of this translation requirement, motor re-learning is necessary to achieve naked-eye depth-of-field perception using type II formatted stereo pairs. We submitted *Begonia Rosalora* - Winter, 93, an 8"X10" type II formatted stereo pair to the *Green Springs Gardens* photo contest in August, 1993. Of about 400 persons who viewed it, none spontaneously acquired an integrated image with depth-of-field perception. Approximately 50 people volunteered for one-on-one training in visualization of the integrated image. Twenty percent (10 people) were able to achieve integration of the image with depth-of-field perception. Training time was limited to 30 minutes. *Begonia Rosalora* in type I format in a stereoscope was perceived by all viewers without formal training. Thus, although it is not a spontaneously acquired skill, motor learning necessary for viewing of type II formatted stereo pairs can easily be taught. Persons with such training could view type II formatted stereo pairs supplied from virtual reality or television monitors in real or delayed time, or photographed or printed pairs. This technology could be used for 3-dimensional viewing of arthroscopic or endoscopic surgery, low power microscopy, macro-imaging, televised scenes or printed stereo pairs.

574.3

SHORT-LATENCY DISPARITY VERGENCE RESPONSES IN HUMANS. C. Busetini*, F. A. Miles, and R. J. Krauzlis. Lab. Sensorimotor Research, National Eye Institute, Bethesda, MD 20892 and Dipartimento di Elettrotecnica, Elettronica ed Informatica, University of Trieste, 34100 Trieste, Italy.

The latency of disparity vergence has generally been estimated to be ≈ 160 ms. Using large stimuli, we now report latencies approximately one-half this value.

Subjects faced a tangent screen onto which two identical, densely textured images subtending $40^\circ \times 40^\circ$ were back-projected. Orthogonal polarizing filters in the two projection paths ensured that each of the two eyes saw only one of the two patterns, and their horizontal binocular disparity was controlled by mirror galvanometers. Positions of both eyes were recorded using the search coil technique. Stimuli were disparity steps [0.5, 1 and 2 meter angles (MA), 300ms duration] applied in the wake of 10° leftward saccades into the center of the pattern.

Vergence responses were highly repeatable with very short latencies. For example, the mean latency (\pm SD) for 5 subjects using 0.5 MA steps applied 50 ms after the centering saccade was 79 (± 5) ms. The largest initial vergence accelerations were generated by the smallest disparity steps (0.5MA) and were always in the correct direction: convergent with crossed steps and divergent with uncrossed. However, with the largest uncrossed steps (2MA), responses started in the wrong (convergent) direction in 2 of the 3 subjects tested and only later reverted to the correct direction.

In all 5 subjects, small disparity steps (0.5MA) applied 50 ms after the centering saccade resulted in higher initial vergence accelerations than when applied 500 ms after the saccade. This transient enhancement of disparity vergence after a saccade is reminiscent of the post-saccadic enhancement of initial ocular following responses to sudden (conjugate) drifts of the visual scene (Gellman et al. *Vis. Neurosci.* 5:107,1990). We suggest that this enhancement will help to speed the realignment of the two eyes when gaze is redirected to (large?) objects in a different depth plane.

574.5

EFFECTS OF PRISMATIC VERGENCE ON LISTING'S PLANE. S. Mikhail, T. Villa*, D. Nicolle, Department of Ophthalmology and Physiology, University of Western Ontario, London, Ont., N6A-5C1

During convergence on near targets Listing's plane (LP) is preserved but rotated temporally in the two eyes (Mok et al, *Vis Res*, 1992). Here we examined the changes in LP resulting from prismatically induced vergence. The three dimensional rotations of the two eyes were compared in five normal subjects wearing search coils and gazing at targets 1.9 m away with and without prisms. For horizontal base out prisms, the results were similar to gaze at near targets without prisms. Each degree of convergence yielded $+0.83^\circ$ (r^2 0.70) in LP. The results from vertical prisms were not what might be expected from the horizontal results. A base up prism on the right eye induced a downward, rather than the expected upward, rotation of LP. For each degree of vertical vergence LP rotated $+1.27^\circ$ (r^2 0.63). In addition the eyes rotated temporally $+0.72^\circ$ (r^2 0.43). A base down prism on the right eye induced an upward and nasal rotation of LP. The effects of oblique prisms were qualitatively those expected from combining the effects of horizontal and vertical prisms. For each degree of vertical vergence, LP rotated by $+0.67^\circ$ (r^2 0.73) in the same direction. The temporal rotation was greater with the base up and out than with the base down and out. In summary, horizontal, vertical and oblique prisms appear to rotate LP, but in opposite directions in the two eyes. Thus in addition to producing a horizontal or vertical misalignment of the gaze line, prisms induce an unexpected position dependent torsional disparity.

VERGENCE FOLLOWING VERTICAL SACCADDES IS UNDER ADAPTIVE CONTROL. Z. Kapoula*, T. Eggert and F. Fioravanti¹. Lab. Physiol. de la Perception et de l'Action, CNRS-Collège de France, Paris, France. ¹DEEI, Univ. Trieste, Italy.

Prior studies (Collewijn et al. *J. Physiol.* 1988; Enright *J. Physiol.* 1989; Kapoula et al. *J. Neurophysiol.* 1993) described horizontal vergence movements during and after vertical saccades. Such movements could be due to mechanical and/or innervational coupling of the vertical and horizontal muscles. The present study tests whether vergence movements following vertical saccades are under adaptive control.

Identical patterns were projected, one to each eye (dichoptic viewing). At first the patterns were superimposed; subjects fused them. At the end of each vertical saccade the patterns drifted exponentially, one left the other right, by the same amplitude, 10% of the antecedent saccade. The resulting disparate retinal slip was divergent after up saccades, convergent after down saccades. Four subjects were trained for 1 to 3 hrs. Binocular recordings were done with search coils. Prior to training, up saccades showed a rapid intrasaccadic divergence time locked to the onset of the saccade (group mean: 1.48°); this was followed by postsaccadic convergence (0.34°). Down saccades showed a slower convergence that started around the peak velocity of the saccade (0.73°); postsaccadic vergence was also convergent (0.2°). Adaptation was assessed from saccades in an open loop condition precluding visual following systems. Changes occurred in the intrasaccadic vergence but they were idiosyncratic: the group mean was still divergent for up saccades (1.18°) and convergent for down saccades (0.6°). In contrast, the change in postsaccadic vergence was always in the direction of the former pattern drift: up saccades decreased their baseline convergence (0.19°); down saccades increased their convergence (0.46°).

We conclude that the vergence coupled with vertical saccades is under adaptive control. Separate adaptive controllers exist for the intrasaccadic and postsaccadic components. The postsaccadic vergence controller stimulated in this study may be responsible as well for the disconjugate drifts we induced after horizontal saccades (Kapoula et al. *Neurosci. Abstr.* 1993). Supported by SCI*-CT91-0747 and CRAMIF.

574.4

BINOCULAR COORDINATION, STEREO VISION AND LISTING'S LAW. D. Tweed*. Departments of Physiology and Ophthalmology, University of Western Ontario, London, N6A 5C1, Canada.

Recently Mok et al. and van Gisbergen et al. have shown that when the eyes converge on near targets, the Listing's plane of each eye rotates temporally through about half the vergence angle. The aim of the present study was to use computer simulations to identify the functional purpose of this behaviour. The first hypothesis, suggested by a paper by Howard, was that the brain strives to avoid binocular disparity of images of horizontal lines; but simulations of binocular coordination strategies that eliminated this disparity did not match the observed pattern of Listing's plane rotations. The hypothesis that the system minimizes pointwise disparity over the horopter fared no better. Van Rijn and van den Berg have shown that the pattern reported by Mok et al. is consistent with the brain trying to eliminate binocular disparity of images of lines orthogonal to the plane of regard. However, there are many different strategies that eliminate this disparity, so some additional performance criterion must be introduced to uniquely determine the observed behaviour. Adding the criterion that the rotational displacements of the eyes from their centre positions be minimized yielded a model that matched the observed behaviour. The motivation behind this second condition was that it would reduce extraocular muscle work, and it would keep the eyes near the centres of their motor ranges, for fast responses to new events. This combined strategy reduces to Listing's law for targets at optical infinity, and yields the correct temporal rotations of Listing's planes for near targets. On this view, the neural circuits transforming 3-D target locations into eye positions embody a mixed strategy with a sensory constraint and a motor cost function.

A LONG-TERM STUDY OF EYE BLINK RESPONSES AFTER HYPOGLOSSAL-FACIAL ANASTOMOSIS. A. Gruart*, A. Gunkel, W.F. Neiss, E. Stennert and J.M. Delgado-García. Lab. of Neuroscience, Faculty of Biology, Univ. of Seville, E-41012. Sevilla, SPAIN and E.N.T. Department and Institute I of Anatomy, University of Cologne, D-50931, Cologne, GERMANY.

Hypoglossal-facial anastomosis is used in man to restore the activity of facial muscles following irrecoverable facial nerve lesions and other pathological conditions. As the kinematic of reflexively-induced eye blinks is very well known, the nictitating membrane/eyelid response can be used as a good experimental model to study the adaptability of hypoglossal motoneurons to a new motor role and to follow the (possible) recovery of lost motor functions, as the corneal reflex. Four cats were prepared for the recording of eyelid and tongue movements with the magnetic search-coil technique. The electromyography (EMG) of both orbicularis oculi (OO) muscles was also recorded. After control recordings, a left hypoglossal-facial anastomosis was carried out in the four animals. Two of them were also prepared for the chronic recording of anastomosed hypoglossal motoneurons. Recorded units were identified by their antidromic activation from the reinnervated upper lid. The first signs of OO muscle reinnervation were observed 6 weeks after surgery. The innervated lid moved in complete synchronicity with tongue displacements. Reflex blinks in response to corneal air puff or flashes of light were not recovered up to three months after reinnervation, as noticed in EMG recordings of the OO muscle. The discharge rate of anastomosed hypoglossal motoneurons was always related to tongue movements. However, a significant increase in the gain of the eye retraction system, mediated through accessory abducens motoneurons, was noticed even before reinnervation. The present results indicate that hypoglossal motoneurons are unable to adapt their discharge properties to a new motor task, but some plastic changes seem to be induced in the retractor bulbi system, which is non-directly affected by the anastomosis.

ACTIVITY OF PONTINE OMNIPAUSE NEURONS DURING EYE BLINKS. L. E. Mays* and D. W. Morrisse. Dept. of Physiological Optics and Vision Science Research Center, University of Alabama at Birmingham, Birmingham, AL 35294.

Pontine Omnipause Neurons (OPNs) are known to play a crucial role in the generation of saccades and quick phase eye movements. These neurons are located in the *nucleus raphe interpositus* of the monkey, near the midline and just ventral and rostral to the abducens nucleus. OPNs are tonically active in the awake monkey and cat and cease firing just before and during saccades and quick phases of nystagmus. OPNs have been shown to inhibit saccadic excitatory and inhibitory burst cells, and electrical microstimulation of the OPN region suppresses saccades and quick phases but not slow eye movements.

Several investigators have briefly noted that OPNs pause for blinks as well as saccades. Since blinks are often associated with saccades, it can be difficult to determine whether a cessation of OPN activity is associated with a blink or the eye movements which accompany a blink. In experiments using rhesus monkeys trained to maintain fixation on a visual target, we have also observed that OPNs pause during blinks. Since the animals are actively fixating the targets, the eye movements which accompany the blinks are often quite small (<2°) and brief. We have observed that during blinks the duration of the pause is often greater than 100 ms, a value which is much larger than that seen for small saccades. This suggests that cessation of OPN activity may be related to blinks *per se* and not simply to the eye movements which accompany the blinks. Furthermore, the duration of the pause is positively correlated with the duration of the blink. Analysis of data obtained using lid coils shows that OPNs pause ~ 10 ms before the blink onset and that the pause lasts considerably longer than the downward phase of the movement. EFFECTS OF SUPERIOR COLLICULUS STIMULATION ON THE BLINK REFLEX IN MONKEYS. S-M Lu*, B Breznien, MA Basso, C Evinger and JW Gnadt. Departments of Neurobiology & Behavior and Psychology, SUNY Stony Brook, NY 11794.

In alert Rhesus monkeys, the effects of SC stimulation on reflex blinks were studied by delivering 100-300 ms trains of electrical pulses beginning 30-50 ms before a 30-50 ms air puff to one eye. Eye and lid position were monitored using the search coil technique. Location within the SC motor map was determined with 10-25 μ A biphasic pulses at 250-300 Hz. The threshold current for blink suppression was always higher than for saccades. The most effective sites for blink suppression was located in the deep layers of SC near the rostral pole, where the ratio of thresholds was roughly 1.5. This ratio increased to 3 or greater at superficial and caudal sites.

The gradient of relative threshold within the SC correlates well with the gradient of excitatory projections of the SC to brainstem omnipause neurons (OPN). Moreover, stimulation of OPN suppresses blinks. Nevertheless, the difference in the threshold for producing blink suppression and saccades suggests that the underlying neuronal circuitry may differ for the two processes.

GRAVITY-DEPENDENCE OF TORSIONAL OPTOKINETIC GAIN IN RHESUS MONKEYS. D Straumann*, M Dieterich, V Henn, BJM Hess. Neurology Department, University Hospital, CH-8091 Zürich, Switzerland.

In three rhesus monkeys we have measured torsional optokinetic nystagmus using the three-dimensional search coil technique. The animals were exposed to 30 seconds of stimulation by an optokinetic sphere, which rotated about the naso-occipital axis at different velocities. Gain (eye-stimulus-velocity coefficient) during the last 5 seconds of stimulation was determined for upright and supine body position. Compared to stimulations in the supine position, we found that torsional gain of optokinetic nystagmus was strongly attenuated in the upright position with angular eye velocity saturating at 5-10 deg/s (see also Schiff et al. (1986) Soc Neurosci Abstr 12: 774). Gain values in supine position varied considerably among the three monkeys, and we found a correlation with the time constant of the corresponding torsional vestibulo-ocular reflex. The data can be interpreted that the velocity-storage mechanism actually enhances torsional optokinetic nystagmus in supine position. In upright position, however, the rotation axis of torsional nystagmus does not coincide with the gravity vector. Hence, velocity storage is inhibited and torsional optokinetic gain decreases.

THE ULTRASTRUCTURE OF EYELID MOTONEURONS IN THE MACAQUE. P.J. May* Departments of Anatomy, Neurology and Ophthalmology, Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

Eyelid movements are primarily controlled by two muscles: the orbicularis oculi, which produces blink down-phases, and the levator palpebrae, which produces blink up-phases and moves the lid in conjunction with vertical gaze changes. The motoneurons which control these two muscles have been identified using retrogradely transported WGA-HRP/HRP. The ultrastructure of these identified lid motoneurons and the axon terminals synaptically contacting them have been characterized to provide a basis for determining the pattern of inputs that produce blink and gaze-related lid movements. Levator motoneurons have a relatively low density of synaptic contacts upon the plasma membrane of their somata and proximal dendrites. In addition they occasionally display short somatic and dendritic spines. A variety of different terminal classes contact the surface of levator motoneurons. Type 1 profiles have large numbers of clear, spherical synaptic vesicles (40-50 nm) and make asymmetric synaptic contacts. Some examples of these extend along the postsynaptic membrane and make multiple synaptic contacts. Type 2 profiles contain clear pleomorphic vesicles and a very small number of dense-cored vesicles. They make symmetric synaptic contacts. Type 3 profiles are similar to Type 1, but also contain larger (90 nm) scattered, dense-cored vesicles. Their synaptic densities are variable in extent. Orbicularis motoneurons have a higher density of synaptic contacts on their somatic and dendritic plasma membranes, with terminals often forming a continuous lining along some membrane segments. An unusual feature of these motoneurons is the occasional presence of a subsurface cistern immediately beneath a synaptic contact. The same three classes of profile were observed in contact with orbicularis oculi motoneurons, but there appeared to be two subclasses of Type 1 ending. One [Type 1A] was densely packed with vesicles, while the other [Type 1B] had fewer, scattered vesicles. The greater synaptic density present along the membranes of orbicularis oculi motoneurons may correlate with the very high firing rates these cells must attain during the phasic action of blinking. BRAINSTEM LINKAGE BETWEEN THE SUPERIOR COLLICULUS AND BLINKING. M.A. Basso*, and C. Evinger. Depts. of Psychology, Neurobiology & Behavior and Ophthalmology. SUNY Stony Brook, NY 11794.

Both clinical and experimental data show that the basal ganglia can dramatically modulate the brainstem blink reflex circuit. Previously, we have demonstrated that the superior colliculus (SC) is an important mediator of these effects, such that substantia nigra inhibition of the SC increases blink magnitude. The goal of the current study was to identify the brainstem neurons that mediate the SC modulation of blinking. The inhibitory omnipause neurons (OPN) are one candidate because electrical stimulation of the OPN region suppresses blinks (Mays, 1994) and stimulation of the rostral SC, a region which provides a large input to the OPN, is the most effective for suppressing blinks with electrical stimulation. However, since blink suppression with SC stimulation has a higher threshold than that for evoking saccades or producing fixation (Lu et al., 1994), it is also possible that a nonsaccadic group of brainstem neurons mediate SC blink suppression.

By presenting a single, electrical pulse to the SC in urethane anesthetized rats, we determined the latency of SC suppression of orbicularis oculi EMG (OOemg) activity to be 7 ms. Single unit recordings in the brainstem revealed a group of tonically active neurons caudal to the OPN that paused with reflex blinks. Stimulation at the site of these neurons produced a decrease in OOemg activity within 5 ms. Stimulation at other brainstem sites, however, produced blink suppression at much longer latencies.

Consistent with SC stimulation in monkeys and behavioral studies in humans, the SC appears to modulate reflex blinking through brainstem neurons other than those involved in saccadic eye movements.

LEAKY NEURAL INTEGRATION OF TORSIONAL VESTIBULAR SIGNALS IN HUMANS. S.H. Seidman*, R.J. Leigh, R.L. Tomsak, M.P. Grant, and L.F. Dell'Ossa. University of Rochester Med Ctr, Dept of Neurol., Rochester, NY, Case Western Res. Univ, and the Veterans Admin. Med. Ctr., Cleveland, OH.

We investigated the dynamic properties of the human torsional vestibulo-ocular reflex (VOR) during roll head rotations, and compared them with those of the horizontal VOR. Differences were related to the contributions of the extraocular plant and the neural integrator.

Three subjects underwent position-step stimuli in the roll plane, and the resulting torsional eye movements were recorded using the magnetic search-coil technique. Using optimal parameter estimation techniques, the data were fit to a pulse-step model of the torsional VOR, which incorporated plant parameters obtained through previous forced-duction experiments. Following the position step, the eye drifted back to its resting position in the torsional plane, demonstrating a time constant of neural integration typically <2.5 sec. Despite previous evidence of an asymmetry in the ocular-motor plant between intorsion and extorsion, torsional eye movements appear to be well yoked during roll stimulation.

When subjects underwent similar VOR stimulation in the yaw plane, the eyes held their new horizontal position for a much longer period of time, always yielding a time constant of neural integration of much greater than 20 sec.

We hypothesize that the incomplete integration of vestibular signals for torsional eye movements reflects different visual demands placed on this reflex. In addition, the yoking of binocular torsional eye movements despite possible asymmetries on the plant may demonstrate a larger separation of control of individual muscles than previously thought to hold true.

THREE-DIMENSIONAL CONSTRAINTS ON COORDINATED EYE-HEAD GAZE SHIFTS IN THE MONKEY. D. Guitton* and J.D. Crawford, Montreal Neurological Institute and Department of Neurology and Neurosurgery, McGill University, Montreal, Canada, H3A 2B4.

We have studied the normal orienting behaviour of one head-free *Macaca Fascicularis*. Dual search coils were implanted in one eye, and temporarily screwed onto the skull cap. Eye and head position quaternions were recorded while the animal looked at visual targets presented randomly throughout its gaze range. With the head fixed, the eye was constrained to a Listing's plane with a torsional standard deviation of $\sim 1^\circ$. Listing's plane was no longer maintained with the head free, because VOR slow phases produced torsional changes in eye position. However, opposite torsional components in the rapid eye movement components of the gaze shift prevented accumulated torsion. Both the head and eye-in-space loosely followed a strategy resembling a set of Fick gimballs (Glenn & Vilis, *J. Neurophysiol.*, 1992): horizontal rotations occurred about a relatively fixed vertical axis, but vertical rotations occurred about a horizontal axis that tended to rotate with the head. These axis tilts were not as stereotyped as those observed with the head fixed, and thus the ranges of head and eye position-in-space were not so tightly constrained (torsional standard deviations were $\sim 4^\circ$ and $\sim 4.5^\circ$ respectively). However, these ranges showed the curvature characteristic of the Fick gimballs strategy: Up-left & down-right gaze directions were accompanied by a clockwise torsional tilt of the eyes & head, and down-left & up-right gaze had counterclockwise tilts (in earth-fixed coordinates). These results agree with human studies (Glenn & Vilis, 1992), suggesting that the monkey provides an appropriate experimental model for invasive studies of this behaviour.

CONTROL OF POSTURE AND MOVEMENT VIII

575.1

A NEURAL MODEL OF VOLUNTARY MOVEMENT AND PROPRIOCEPTION. D. Bullock*, P. Cisek, S. Grossberg, Boston University, Dept. of Cognitive and Neural Systems, Boston, MA 02215.

A neural model of voluntary movement and motor proprioception is developed within constraints from neurophysiology and motor psychophysics. The model generates trajectories to a desired endpoint in spatial coordinates, while using motor command corollary discharges and muscle spindle error feedback to construct an accurate perception of position. Responses of model elements resemble observed cortical and subcortical physiological data while functional characteristics suggest explanations of proprioceptive illusions and load effects. Simulations show the system's ability to execute voluntary movements while reducing oscillations caused by limb dynamics and compensating for external forces such as those caused by loads or obstacles. Further simulations demonstrate how the network can self-organize its sensorimotor transformations through spontaneous co-contractions of synergistic muscles.

575.2

DYNAMIC NEURAL FIELD THEORY OF MOTOR PROGRAMMING. W. Erlhagen, G. Schöner*, Inst. Neuroinformatik, Ruhr-Universität Bochum, 44780 Bochum, Germany

Recent evidence suggests that motor programs are specified gradually (Hening W., Favilla M., Ghez C.: *Exp. Brain Res.* 71, 116-128 (1988)), can be continuously updated, and are part of a closed feedback loop. The implied theoretical challenge is to address the dynamic properties of motor programs. We present a dynamic field theory of motor programs that is based on a neural representation of movement parameters such as movement direction and amplitude. The topology of such parameters is expressed by structuring the neural representations as fields. Motor programs are stable localized solutions in such neural fields. They evolve under two types of external influences: (1) localized input representing the perceptual specification of movement parameters and (2) input representing the pre-structuring of motor plans and thus reflecting the nature of the task space defined by the experimental paradigm. The distance of this pre-shape from the specified motor program in a dynamic sense determines the time need to generate the correct motor program and therefor affects reaction time in the theory. We compare our model to experimental results of Ghez and colleagues on the gradual build-up of motor programs. We account for the Hick-Hyman law, the dependence of reaction time on the metrics of tasks, on pre-cued information, and discuss effects such as range or bias effects and deprogramming. The longer term goal of integrating such a dynamic description with a dynamic account of coordination (Schöner G., Kelso J.A.S.: *Science* 239, 1513-1520 (1988)) is sketched.

575.3

A DYNAMIC THEORY OF THE WALK-RUN TRANSITION: THE EFFECTS OF GRADE. F. J. Diedrich* and W. H. Warren, Jr., Department of Cognitive and Linguistic Sciences, Brown University, Providence, RI 02912.

Why do humans shift from walking to running when speed increases? We have proposed a dynamic theory of human locomotion in which preferred gaits are attractors that exhibit stable phase relationships, and gait transitions are bifurcations characterized by a loss of stability (Diedrich & Warren, in press). According to this theory, manipulation of the location of the attractors should have an effect on the speed of the transition. As suggested by energy expenditure data, one way to manipulate the attractors is to vary the inclination of the treadmill. Six participants walked and ran on a treadmill at grades of 0% and 10% while speed was varied. As expected, the speed at which fluctuations of the ankle-hip phase relationship were at a minimum shifted downward from 1.63 m/s on a 0% grade to 1.54 m/s on a 10% grade, consistent with movement of the attractor to a lower speed. Similarly, the mean transition speed, averaged over ascending and descending trials, shifted downward from 2.19 m/s at 0% to 2.00 m/s at 10%. In sum, changing treadmill inclination led to movement of the attractors and corresponding changes at the walk-run transition. These directional shifts were generally consistent with those expected on the basis of previous energy expenditure data.

A NEURAL NETWORK MODEL OF BASAL GANGLIA THALAMOCORTICAL RELATIONS IN NORMAL AND PARKINSONIAN MOVEMENT. J.L. Contreras-Vidal* and G.E. Stelmach, Arizona State University, Laboratory of Motor Control, Tempe, AZ 85287.

Anatomical, neurophysiological, and neurochemical evidence support the notion of segregated parallel basal ganglia-thalamocortical motor channels. We developed a neural network model for the function of this system in simple and complex (sequential and simultaneous) movements in normal and Parkinsonian (PD) behavior. Non-linear differential equations are used to model the membrane potential for each cell type (short-term activation), its physiological action (inhibitory or excitatory), as well as neurotransmitter/neuromodulators (medium-term dynamics: e.g. GABA, enkephalin, substantia P). The model reproduces motor impairments in PD due to dopamine depletion such as akinesia, bradykinesia, and pauses between movement components (the figure shows a normal and PD simulation of a two-stroke sequential movement). Specific observations of the effect of subthalamicotomy and pallidotomy on PD improvement are made. The model also suggests how the motor load is distributed across several brain structures during multijoint movements.

ACUTE EFFECTS OF LEVODOPA ON WRIST MOVEMENT IN PARKINSON'S DISEASE: KINEMATICS, VOLITIONAL EMG MODULATION, AND REFLEX AMPLITUDE MODULATION MTV Johnson*, A Mendez, AN Kipnis, P Silverstein, F Zwiebel, & TJ Ebner Departments of Neurology, Neurosurgery, and Physiology, University of Minnesota, and Minneapolis Clinic of Neurology, Minneapolis, Minnesota, USA

Acute changes in motor performance due to levodopa were evaluated by a series of four motor tests unified by their focus on wrist flexion-extension movements. Subjects with idiopathic Parkinson's disease were evaluated with a test battery consisting of a repetitive self-paced movement in which velocity was to be maximized, visually guided tracking of a sinusoid and a square wave, and an assay of stretch reflex modulation during volitional sinusoidal tracking. The maximal wrist joint velocity of self-paced reciprocating flexion and extension movements increased after levodopa (ON), without significant changes in the movement period or amplitude. In the two tracking tasks, the RMS error, peak velocity, or peak movement amplitude did not change after levodopa. Significant and consistent changes did occur in an assay of reflex modulation during error-constrained tracking after levodopa. The amplitude of volitional EMG increased after levodopa, concurrently with a reduction in reflex EMG. These changes are consistent with the noted increase in movement velocity. These results show that the effects of levodopa on movement velocity were not translated into increased accuracy. Also, the changes in the long latency reflex gain argue for a central control of this reflex, mediated by structures sensitive to levodopa. Supported by NIH grants R44 NS28633 and T32 NS07361

VISUAL PERCEPTIONS OF EARTH- AND BODY- FIXED AXES. W.G. Darling*, T. Gebhardt, S. Liu. Department of Exercise Science, University of Iowa, Iowa City, IA 52242.

Target location encoded by the visual system must be transformed into kinesthetic and motor coordinate frames for the upper limb to perform reaching movements. Recent studies in this laboratory have shown that the perceptually preferred anterior/posterior (a/p) axis of kinesthetic coordinate system is trunk-fixed (Butler et al. 1993 - Soc. Neurosci. Abstr. 19, 550) and for the visual system is also likely trunk-fixed (Darling and Williams 1993 - ASB Proceedings of 17th Ann. Mtg., pp. 115). The earth-fixed gravitational axis is preferred by the kinesthetic system at the perceptual level (Darling, manuscript in preparation). The purpose of this investigation was to determine if the visual system prefers the earth-fixed gravitational axis to body-fixed axes at the perceptual level.

Ten normal healthy individuals positioned a hand-held lighted wand under four different experimental conditions that were each run under light and dark conditions: (1) earth-fixed - subjects stood in anatomical position and moved the wand parallel to the gravitational axis, (2) earth - same as (1) except that subjects head and trunk orientations were varied, (3) head - same as (2) except that subjects positioned the wand parallel to their head-fixed longitudinal axis and (4) same as (2) except that subjects positioned the wand parallel to the trunk-fixed longitudinal axis. Orientations of the head, trunk and wand were recorded optoelectronically. The results clearly showed that subjects were most accurate at positioning the wand parallel to the gravitational axis even when head and trunk orientations were varied ($p < .001$). Control experiments showed that kinesthesia was not used for precise positioning of the hand-held wand. Thus, the visual system prefers the earth-fixed gravitational axis to body-fixed longitudinal axes at the perceptual level and coordinate transformations at this level are simplified because of the parallel axes for the visual and kinesthetic coordinate systems.

FOCAL INTRASPINAL NMDA IONTOPHORESIS PRODUCES DISTINCT ACTIVATION PATTERNS IN THE FROG. P. Saltiel and E. Bizzi. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

In the spinalized frog, microstimulation of the lumbar grey produces only a few possible orientations for the convergent force fields recorded in the horizontal plane from the isometrically contracting hindlimb: flexor towards body, rostral flexor, outward extensor and medial extensor. To determine if this represents activation of fibres of passage or of neurones, and as a preliminary step to anatomical studies aimed at identifying such neurones, NMDA (4mM, 100nA x 30 sec.) was iontophoresed at cord sites where microstimulation through the same pipette had been effective. Forces and 11 EMG's were recorded.

38% of sites (32 sites in 7 frogs) did not respond to NMDA. Of the NMDA-responsive sites (average latency 16 sec., range 4-29 sec.), the forces evoked by chemical stimulation had the same four types of orientation than seen with microstimulation, actually matching them at 68% of sites. For the EMG's, a close match was seen in only 38% of cases.

However the NMDA-evoked EMG's fell in a few distinct patterns which could be related to the forces produced. One pattern (8/17 sites) consisted of a nearly simultaneous onset of a tonic or rhythmic coactivation of all muscles except for RA (rectus anterior), VI (vastus internus) and GA (gastrocnemius) which were only weakly activated. With one exception, this pattern produced flexion towards body forces. In a second pattern (6/17 sites), muscle recruitment occurred progressively over a succession of cycles, with the production at first of rostral flexion and then flexion to body forces. RA, VI and GA were among the most active muscles. Cord sites eliciting the first and second patterns were generally located caudally and rostrally to the 8th root respectively. A third pattern (2/17 sites) produced outward extensor forces.

In conclusion, focal intraspinal NMDA iontophoresis may be helpful to localize groups of neurones responsible for the generation of distinct EMG patterns which produce the same set of force orientations previously identified with electrical microstimulation. (Supported by ONR:N00014/K/0372).

575.6

THE EFFECTS OF GRAVITATIONAL CUES ON THE TRANSFORMATION BETWEEN KINESTHETIC AND VISUAL INFORMATION TO REACHES TO REMEMBERED TARGET LOCATIONS A.J. Butler*, W.G. Darling, M.A. Pizzimenti. Department of Exercise Science, University of Iowa, Iowa City, IA 52242.

The abilities of human subjects to point to kinesthetically presented targets which are no longer present during a reaching movement was studied under 2 gravitational and 3 reaching conditions: (1) VR/NG, VR/G - visual reach, no gravity, gravity; (2) BR/NG, BR/G - reach with vision occluded, no gravity, gravity; (3) VRPT/NG VRPT/G - visually reach with pointer, no gravity, gravity. The ability to specify target locations on the basis of kinesthetic information alone has been found to be accurate (Darling and Miller, *Exp Brain Res*, 1993, Vol. 93 pp 534). Reaching with a pointer requires transformation of kinesthetically derived limb coordinates into a visual coordinate system. Availability of gravitational information about target locations was not manipulated in previous studies and is thought to be used in the kinesthetic representation of upper limb orientation. Thus, the main purpose of this experiment was to study the abilities of subject to reach to a remembered kinesthetic target location with or without gravitational information on target location. We presented 10 targets in two planes using a programmable robot arm. Positions of the arm, hand, fingertip and target object in three-dimensional space were recorded using optoelectronic techniques (WATSMART system, Northern Digital). Manipulating gravitational information on target location had little influence on directional and distance errors during visually guided reaching with the hand. When using the pointer, there was a substantial increase in distance errors, but not in direction errors. Availability of gravitational information had little influence on performance when reaching with the pointer. Consistent with the findings of previous work, subjects' tended to overshoot close targets and undershoot far targets during visually guided reaching to kinesthetic targets. These results suggest that removing gravitational information about kinesthetic target location does not interfere with reproducing a kinesthetically remembered hand location or with transformation of kinesthetic information into a visual coordinate system.

575.8

ATTRACTION OF VOLUNTARY MOVEMENT TO INTRINSIC OSCILLATORS: A SYSTEM INHERENT PHENOMENON ? G. Staudel*, W. Wolf¹ and J. Ekle². ¹Universität der Bundeswehr München, D-85577 Neubiberg. ²Medizinische Hochschule Hannover, D-30625 Hannover, Germany

Attraction of motor coordination to oscillatory components is one of the fundamental features of biological systems. Recently, we reported a systematic phase relationship between tremor and the onset of fast voluntary motor responses in patients with Parkinson's disease (PD) (Staudel, G et al. Soc.Neurosci.Abst. 1992;18:862). Experiments with control subjects mimicking tremor showed similar results. The aim of this study was to establish a functional model for the attractive effect of the tremor oscillator in the framework of the equilibrium point (EP) hypothesis. According to the EP hypothesis, there is only one central variable that controls the behavior of a muscle, the threshold λ of its tonic stretch reflex (Feldman, AG Biophysics. 1966;11:565-578). Single joint movements are induced by a shift (virtual trajectory) in control variables λ_A, λ_N of at least one pair of antagonist muscles from an initial value (that depends on the actual phase of the tremor cycle) to a final state. With the virtual trajectory known, both the movement trajectories and the electromyographic patterns of the antagonist muscles can be predicted. Movement patterns of PD tremor patients and control subjects mimicking tremor were recorded under both isometric and kinetic reaction time paradigms and compared to computer simulations. The EP hypothesis proved to reliably predict the observed movement patterns under various conditions. We conclude that attraction of voluntary motor response to intrinsic oscillations is a system inherent phenomenon of motor control and does not depend on the origin of the oscillatory component.

MOTOR TEMPLATES IN TYPING. ^{\$}S.P. Viviani* and ^{\$}G. Laissard. ^{\$}Faculty of Psychology and Educational Sciences, Univ. of Geneva, Geneva, Switzerland and ^{\$}Dept. of Cognitive Science, Istituto S. Raffaele, Milan, Italy.

We investigated the performance of professional typists transcribing texts presented visually. The timing of the keystrokes was analyzed as a function of the following factors: 1) the combination of fingers used for typing digrams; 2) the relative frequency of the digrams in the language; 3) the word-context in which trigrams are embedded; 4) the total duration of the typing sequence for the word. Biomechanical and linguistic factors were found to influence the interstroke intervals. However, over and above these factors, we demonstrated that words (i.e. well-formed lexical items) are typed with sequences of keystrokes whose temporal structure depends idiosyncratically on the word and on the typist. Within the range of variability of the rhythm that is normally observed in transcription, this structure - defined as the set of all ratios between interstroke intervals - remained unchanged (homothetic invariance). The results suggest that these highly complex motor sequences are controlled by global motor plans that include an abstract representation of the timing of the keystrokes. A simple counting mechanism was postulated to explain the findings. We contrasted four variations of the mechanism on the basis of the pattern of temporal variability.

HINDLIMB MUSCLES OF THE RAT: FORCE FIELDS AND REDUNDANT SUMMATION. M.C. Tresch*, E. Loeb, and E. Bizzi. Dept. Brain & Cog. Sci., M.I.T., Cambridge, MA 02139.

Previous work from this laboratory has described a set of movement primitives encoded in the frog spinal cord. In order to examine the generality of these findings, we are currently exploring the movements encoded in the spinal cord of the rat. As a first step in this project, we describe here the pattern of position dependent forces, i.e. the force fields, produced by rat hindlimb muscles and the result of combined stimulation of two muscles. In the frog, simultaneous stimulation of two muscles produces a force field which is the vector summation of the force fields of the two muscles stimulated separately. This property of summation holds for the non-redundant case, with the force transducer attached to the ankle, as well as for the redundant case, with the force transducer attached to the foot. We found a similar pattern of results in the rat: the force field predicted by summation of the two separate muscle fields was highly correlated with the field produced by the costimulation of the muscles for both the redundant and non-redundant case. This result implies that, at least for the degrees of redundancy in these experiments, the combination of muscles can be approximated as a linear vector sum, potentially simplifying the control of the hindlimb. Supported by NIH NS09343 and AR26710 and ONR N00014/90/J/1946.

A PHA-L STUDY ON DESCENDING PATHWAY FOR VOCALIZATION FROM THE PERIAQUEDUCTAL GRAY TO THE LOWER BRAINSTEM IN CATS. Y. Kobayashi, A. Katada, H. Myoga and T. Sakamoto*, Dept. of Physiol., Asahikawa Med. Col., Asahikawa 078 JAPAN.

Tonic electrical stimulation to the midbrain periaqueductal gray (PAG) induced naturally sounded vocalization. The stimulation to the pontine call site (PCS) within the ventrolateral pons also induced vocalization. To know whether the PCS is the descending pathway for vocalization from the PAG to the lower brainstem, an anterograde tracer, Phaseolus vulgaris leucoagglutinin, was applied at sites located in the lateral PAG where the electrical stimulation induced vocalization.

At the level of the caudal superior colliculus, labelled fibers sparsely distributed and passed laterally through the dorsal part of the midbrain tegmentum where the stimulus threshold for vocalization was higher than the PAG. At the level of the inferior colliculus, they could be traced ipsilaterally to the ventral area along the medial lemniscus and consisted of a narrower bundle around the PCS where the stimulus threshold was the lowest.

At the level of the upper pons, they occupied a broad but thin region in the dorsal portion of the trapezoid body ventral to the medial lemniscus. Further caudally, they appeared to be concentrated in a discrete area ventral to the inferior olive and dorsal to the pyramidal tract, and could be continuously traced to the upper cervical spinal cord.

It was known that the PAG stimulation induced vocalization associated with rage, while the PCS stimulation induced vocalization without rage. The present results suggested that the PCS is the descending pathway specific for vocalization from the PAG to the lower brainstem.

MOTION SICKNESS HELPS PRESERVE SENSORIMOTOR COORDINATION IN THE PRESENT AND FUTURE. D.W. Jensen*. Department of Biology, Tomball College, Tomball, TX 77375.

A new hypothesis is proposed for the function of the mechanisms of motion sickness. The hypothesis accounts for data from plasticity of postural control, development of sensorimotor coordination, motion sickness, vomiting, pharmacology, and neurotoxicology.

The mechanisms giving rise to the early symptoms of motion sickness impel an individual to remove the sensory conflicts of an offending motion. The early symptoms are a variety of ill feelings and actions that do not interfere greatly with motor control. The sufferer can still remove sensory conflicts, so the brain is not stimulated to undergo long-term adaptive changes that alter sensorimotor coordination. Thus, the early symptoms and their mechanisms serve to resist redefining normal motion while concordantly preserving the existing sensorimotor coordination. Later developing symptoms of vomiting and severe nausea, however, impede motor control profoundly: in such a state one cannot control much of anything. This extremely ill feeling is the same as what is produced by certain neurotoxins. The state of being poisoned by provocative motion is strongly associated with the motion. When the same kind of sensorimotor-coordination-altering motion occurs again that association is recalled. Acting on this recall and avoiding that motion preserves the existing sensorimotor coordination in the future.

THE ROLE OF DOPAMINE TERMINALS IN THE NUCLEUS ACCUMBENS IN LOCOMOTION INDUCED BY ACTIVATING THE HIPPOCAMPAL → ACCUMBENS GLUTAMATE PROJECTION.

M. Wu and S. M. Brudzynski*. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Earlier electrophysiological evidence has shown that the stimulation of the hippocampal input to the nucleus accumbens evokes short-latency, short-duration, glutamate-mediated excitatory responses in the nucleus accumbens neurons (Yang & Mogenson, 1984). It has also been shown in our recent behavioral studies that injecting glutamate receptor agonists, NMDA or AMPA, into the nucleus accumbens activates the glutamate receptors located on mesolimbic dopamine terminals (Wu et al., 1993). This evidence suggests that glutamate in the nucleus accumbens may act on glutamate receptors, both on mesolimbic dopamine terminals and accumbens output neurons. The objective of this study was to investigate the role of the mesolimbic dopamine terminals in the nucleus accumbens in the initiation of locomotion by activating the hippocampal excitatory input to the nucleus accumbens.

Locomotion (measured in an Opto-Varimex-3 activity cage) was significantly increased by unilateral injections of NMDA into the ventral subiculum of the hippocampus. This NMDA-induced locomotion from the hippocampus was abolished after the destruction of the mesolimbic dopamine terminals in the accumbens, by injecting 6-OHDA into the ventral tegmental area (VTA). The results suggest that the mesolimbic dopamine terminals are essential in transmitting hippocampal signals to the output neurons within the nucleus accumbens.

ACTIVITY IN VENTROLATERAL THALAMIC AREAS DURING CONDITIONED VOCALIZATIONS IN CAT. G.R. Farley*, Research Division, Boys Town National Research Hospital, Omaha, NE 68131.

Although ventrolateral thalamus has been implicated in other motor control tasks, its role during vocal behavior might be questioned. Jürgens and colleagues, based on electrical stimulation and lesion data, indicated that it was not part of a core system of brain structures capable of producing vocalizations in the absence of concomitant reinforcing potential. In the current study, we recorded single- and multi-unit activity from sites in the ventrolateral thalamic area in awake, behaving cats. A substantial proportion of recording sites showed strong temporal correlations in neural activity with various aspects of the instrumentally conditioned vocalization paradigm, including both vocal production and feeding behavior. Activity related to feeding was generally strongest and most prevalent, typically involving bursts of firing during ingestion of the food reward. However, there were also numerous examples of increased and decreased firing during vocalizations, as well as changes in firing rate immediately following vocalization. There were no obvious changes in firing related to background respiratory activity. However, a number of loci showed bursts of activity apparently related to laryngeal EMG activity not associated with vocalizations. Finally, we also noted apparent long-term fluctuations in background firing rate associated with periods of intense behavioral activity versus periods of behavioral quiescence. These data are consistent with a possible role of this structure in motor control during vocal production. (Supported by NIH grant 5-RO1-DC01535-01.)

ESTIMATION OF IDENTIFIED INTERNEURONS FORMING A FUNCTIONAL GROUP CONTROLLING ABDOMINAL POSITIONING IN THE CRAYFISH. L.D. Brewer and J.L. Larimer*. Dept of Zoology, Univ. of Texas at Austin, Austin, TX 78712.

Several studies have indicated that the command elements controlling abdominal positioning (flexion and extension) in the crayfish *Procambarus clarkii* are organized into groups through extensive synaptic connections (Larimer 1988, Trends in Neurosci.: 11). We have designed a method to estimate the size of these functional groups. Fictive abdominal positioning was observed in isolated nerve cords by recording from motor roots while stimulating single command elements intracellularly. Extracellular recordings of interneurons were made from rostral and caudal connectives or hemiconnectives* (1-2 and 5-6). When one of these command elements is stimulated it activates a number of previously silent command elements and increases or inhibits the spontaneous activity of still other interneurons. We then compared spontaneous with evoked activity. The largest number of recruited interneurons was 64, the smallest was 4, and the average was 23 (n=15). Some of these command elements are identified cells based on morphology and physiology. Data was gathered from one identified cell on three separate occasions. A comparison of these data revealed that although the number of recruited cells and their firing frequencies were not identical they were surprisingly similar. These data support the functional group hypothesis, and suggest that on average about 23 interneurons controls each abdominal positioning behavior. Furthermore, these data and previous studies indicate that the interneurons within a group may or may not be tightly coupled to each other, and their recruitment may be based upon such factors as stimulus intensity and synaptic efficacy. *Counts from only hemiconnectives were doubled since motor output and nerve cord activity are usually symmetrical. (Supported by NIH Grant NS 05423, to J.L.L.)

SEPARATE PERIPHERAL NERVES INNERVATE THE HEADS OF THE HUMAN LATERAL PTERYGOID MUSCLE. M. A. Aziz and R. J. Cowie * Anat. Dept, Col. of Med., Howard Univ., Washington, D.C., 20059.

Anatomical, developmental and biomechanical studies of the human lateral pterygoid (LPt) muscle indicate that it is divisible, at least partially, into two heads. Electromyographic (EMG) studies supporting the independent action of the superior (SLPt) and inferior (ILPt) heads during the masticatory cycle have been questioned. The precise peripheral nerve path(s) to the two heads and the full structural complexity of the masticatory space remain uninvestigated. Therefore, we have grossly dissected the LPt muscle and nerves, and measured the muscle fiber orientations of 7 dissection room specimens. Photographs, drawings, and whole sections through the masticatory space were analyzed. Our results show that: i) the two heads are independently innervated, such that the SLPt receives a single branch from the root of the masseteric nerve, while the ILPt receives two or more branches from the root of the long buccal n., as well as loops bridging the anterior and posterior mandibular (V3) divisions; ii) the origins of the heads are easily recognizable, but in two cases each head shows further horizontal segmentation; iii) the mean insertion orientations of SLPt and ILPt fibers are 27° ($\pm 6^\circ$) and 338° ($\pm 4^\circ$) from the Frankfort plane, respectively.

These findings support: 1) a claim that the two LPt heads are enclosed in separate fascial compartments; 2) EMG studies indicating their independent functions; 3) the likely segregation of their central control mechanisms. These data are prerequisite to a planned histochemical demonstration of the latter in primates.

MODULATIONS OF THE NORMAL LOCOMOTOR PATTERN DURING VISUALLY EVOKED YAW TURNS IN THE LAMPREY. P. Wallén*, F. Ullén, T.G. Deliagina, G.N. Orlovsky, and S. Grillner Dpt. of Neuroscience, Karolinska Institutet, S-171 77 Stockholm, SWEDEN

Negative phototaxis in the river lamprey (*Lampetra fluviatilis*) was characterized behaviourally, and the strategies for performing yaw turns away from light were investigated with video recordings, combined with EMG-recordings from the myotomal musculature, in freely behaving animals. In swimming lampreys, illumination from one side evoked a yaw turn away from the light. An increase in light intensity resulted in a significant increase in mean turning angle. Strong lateral illumination frequently evoked an escape response, characterized by a decrease of swimming speed, an approximately 180° yaw turn either away from or towards the light, and subsequent locomotion in a direction opposite to the initial one. During yaw turns the locomotor rhythm became slower and asymmetrical, so that the lateral displacement of the undulatory wave was larger in the direction of the turn, and smaller on the other side. In the EMG-records, the intensity and duration of individual locomotor bursts were highly variable also during straight swimming, which presumably reflects variations in the activity of individual motor units between cycles. Stronger turns ($> 60^\circ$) were correlated with an asymmetrical increase in burst intensity and duration on the ipsilateral side, and a slowing down of the rhythm. During weak turns no consistent changes in the EMG-pattern were seen. Eye illumination of quiescent lampreys, attached with their suckers to the bottom, evoked a strong yaw turn away from light, and locomotion. The initial turn was reflected in the EMG-recording, as a unilateral burst of high intensity and long duration. Burst intensity was positively correlated with the turning angle.

MASTICATORY FUNCTION IN PATIENTS WITH CORTICAL BRAIN INFARCTION AND HEMIPLEGIA. P. Kemppainen*, A. Waltimo, M. Kaste, H. Palomäki and O. Salonen ¹Dept. of Prosthetic Dentistry, Univ. of Helsinki, ²Dept. of Neurology and ³Dept. of Radiology, Helsinki Univ. Central Hosp., Finland.

The masticatory function of sixteen patients (11 men and 5 women) with severe hemiparesis caused by brain infarction (A. cerebri media) was studied by means of interview, clinical examination and bite force measurements. The location of the infarction was assured with computer tomography and magnetic resonance imaging to be localized in the facial primary motor cortex. The Rankin Disability Score and the Scandinavian Stroke Study Group Index showed that patients had an infarction causing marked invalidity, eg. facial paralysis and a marked loss of hand grip force on the contralateral side of the cortical lesion. However, the patients reported no change in their chewing ability, although four of them reported hoarding of food in the buccal sulcus area of the paralysed side. The clinical examination revealed no major signs of craniomandibular disorders, and masticatory muscles contracted symmetrically when examined by palpation. Bite force measurements also indicated symmetrical contraction, since we could not detect any difference in the maximal bite force between the healthy and paralysed side. These results are in agreement with recent laboratory findings in monkeys supporting the importance of bilateral representation and cortical projections in the production and coordination of orofacial functions.

NOREPINEPHRINE MODIFIES THE BACKGROUND FIRING RATE OF RED NUCLEUS NEURONS OF THE RAT. G. LI VOLSI*, F. LICATA, G. MAUGERI, F. SANTANGELO. Istituto di Fisiologia umana Viale Andrea Doria, 6 - 95125 CATANIA - Italia

A significant concentration of norepinephrine (NE) has been detected in mesencephalic red nucleus (RN). Although the role of this amine on the RN function remains unknown, it has been observed that NE amount in the RN appears strongly modified in various syndromes.

The aim of this work was to establish whether this amine influences the rubral neuronal activity. In anaesthetized rats, we analyzed the firing rate of single rubral neurons during microiontophoretic injections of NE and its agonists or antagonists.

More than 90% of the tested RN neurons modified their background firing rate in response to microiontophoretic NE. Decreases of the firing rate were recorded in 50%, enhancements in 30% and biphasic effects (decreases followed by enhancements) in 20% of the cases. Phentolamine and yohimbine antagonized the inhibitory and unaffected, or eventually enhanced, the excitatory responses, that were reduced by timolol. Clonidine mimicked the NE-evoked decreases of the firing rate.

It is concluded that norepinephrine can influence the RN neuronal activity using both α - (mostly α_2) and β -receptors. A modulatory action of noradrenergic pathways on the rubral function, and therefore on the motor systems, is proposed.

AN ASYMMETRICAL VISUAL INPUT CAN ABOLISH POSTURAL DISTURBANCES EVOKED BY UNILATERAL LABYRINTHECTOMY IN THE LAMPREY. T.G. Deliagina*. Nobel Institute for Neurophysiology, Department of Neuroscience, Karolinska Institutet, 171 77 Stockholm, Sweden.

In all classes of vertebrates, removal of the vestibular organ (unilateral labyrinthectomy, UL) results in severe motor disorders. In the lamprey (a lower vertebrate) one of the most pronounced symptoms induced by UL is continuous rotation (rolling) around the longitudinal axis during swimming. The aim of the present study was to abolish this symptom by means of an artificially organized, asymmetrical visual input. This idea emerged from our finding that an asymmetrical visual input exerts a strong influence upon the vestibular-driven roll control system (Deliagina et al., Exp. Brain Res. 95, 421-428, 1993). Swimming of the lampreys subjected to UL (control), and the effects produced by different types of asymmetrical visual inputs combined with UL were investigated. The animals of the first control group (UL only, n=11) rotated continuously during swimming, and this symptom lasted up to 15 weeks after surgery. In the animals of the second group (UL plus bilateral blinding, n=14) rotation during swimming was observed even longer, for 6-10 weeks. However, if a removal of the labyrinth was accompanied by a removal of the eye on the same side, the animals (n=17) swam normally, without rotation, immediately after surgery. In animals subjected to UL and bilateral blinding, which were rotating continuously, the rotation terminated immediately with onset of electrical stimulation (10 Hz) of the stump of the optic nerve ipsilateral to the intact labyrinth (n=5). In the lamprey deprived of the labyrinth and the eye on the same side, input from the remaining eye was able not only to functionally substitute the lost vestibular input, but also to induce adaptive changes in the roll control system: a removal of the remaining eye in 10-30 days after the first surgery did not destabilize the postural control, and the animal driven by only one labyrinth swam normally, without rotation.

MULTI-JOINT COORDINATION DURING THE WIPING REFLEX IN FROGS. M.G. Sirota, R. Dubuc and A.G. Feldman* CRSN, Université de Montréal H3C 3J7 and Dép. de kinanthropologie, Université du Québec à Montréal, Québec, Canada H3C 3P8.

Intact and spinal frogs produce non-rhythmical target-directed hindlimb movements in response to stimulation of the skin (the wiping reflex or WR). Analysis of the WR allows us to study the problems of redundancy in terms of degrees of freedom. We studied the redundancy problem by analyzing interjoint coordinations with kinematic techniques for the WR in response to rostral body surface stimulation in grass frogs ($n = 9$). These frogs were spinalized between the 1st and 2nd vertebrae under tricaine anesthesia. WRs were elicited by a series of 3-5 light pricks with a needle. Hindlimb movements were recorded in two dimensions using a video system (60 Hz) and light-reflecting markers (8 points on the hindlimb joints and body). Movement duration was effectively increased by cooling the preparation. Trajectories of the limb's endpoint and angle-angle diagrams were analyzed. Results show that there are phases of the WR in which a significant excursion in a single ("leading") joint is associated with relatively small excursions in the other joints. The leading joint can be different for different phases of the WR. However, there are phases in which joint angles change simultaneously. In the latter case, the coordination between joints was not fixed and might be changed in repeated movements. It is concluded that target-directed reaching can be accomplished by relatively independent movements in the joints despite motor task constraints. Funded by a Group Grant from MRC Canada and FRSQ Québec.

EXAMINATIONS OF POSSIBLE EXPLANATIONS FOR TRAJECTORY CURVATURE IN MULTI-JOINT ARM MOVEMENTS. Osu, R.^{1,2}, Uno, Y.², Koike, Y.², & Kawato, M.² ¹Dept. of Psychol., Fac. of Letters, Kyoto Univ. ²ATR Human Inf. Processing Res. Labs., Kyoto, Japan.

We discuss the coordinate frame in which visually guided human multi-joint arm movements are planned. In point-to-point planar reaching movements, hand paths tend to be gently curved. Models that rely on intrinsic-dynamic coordinates such as the minimum-torque-change model predict curved paths whereas models that rely on extrinsic-kinematic coordinates such as the minimum-jerk model predict straight paths. To decide between these two coordinate frames, we tested following three possible explanations for observed curvature in extrinsic-kinematic models (Wolpert, et al., 1993): (1) The planned trajectories are straight but imperfection of control causes the curvature. (2) Visual misperception causes the curvature. (3) Arm trajectories are controlled using straight virtual trajectories and the biomechanics of the arm causes the curvature. In Exp. 1 we examined the movements from the side of the body to the front of the body. We found that if subjects were explicitly instructed to generate straight paths for such movements, these movements were straighter than those generated spontaneously. This result argues against (1). In Exp. 2, subjects generated spontaneously curved trajectories even in the fronto-parallel plane where visual misperception was not expected to be a factor. This result argues against (2). In Exp. 3, EMG signals of 6 related muscles of the same movements as Exp. 1 suggest that subjects can make straighter paths without raising stiffness. This poses a problem for the portion of (3), namely, the virtual trajectory hypothesis that accounts for the performance of straighter trajectories using straight virtual trajectories by raising stiffness. Thus our results support the hypothesis that the CNS plans trajectories using intrinsic-dynamic coordinates. Supported by JSPS Fellowships for Japanese Jun. Scientists.

The Three-dimensional Curvature of Unrestrained Straight-ahead Movements. F. E. Pollick*, G. Ishimura. ATR Human Inf. Processing Res. Labs, Kyoto, Japan.

We examined the three-dimensional curvature of unrestrained point-to-point hand movements in the forward direction. Subjects moved their hand from a position above the start point to a forward position above targets of different size and distance. Paths showed curvature resulting from an initial lateral and primarily downward movement that was compensated for in the second half of the movement. The downward component of motion was temporally coupled to the forward motion, with the maximum drop occurring at the time of peak forward velocity. The curvature was greatest for movements to the near target and decreased as target distance increased. Analysis of the relationship between velocity and radius of curvature showed that velocity was related to radius of curvature by a power law with an exponent of 0.59, different from the value of 1/3 typically obtained in curvilinear drawing motions. Aspects of the downward motion suggest that it was purposeful in speeding up the movement and offer explanation to the deviation from the typically reported exponent.

576.2

ORGANIZATION OF CENTRAL CONTROL SIGNALS ASSOCIATED WITH MULTIPLE DEGREE OF FREEDOM ARM MOVEMENTS. L.E. Sergio* and D.J. Ostry. McGill University, Montreal, PQ, Canada H3A 1B1

To gain insight into the organization of central control signals associated with motion in one or more degrees of freedom, we examined the behaviour of bi-articular muscles during movements in which they acted as agonist in one degree of freedom and antagonist in another. As an example, the activity of biceps brachii, which acts to flex and supinate the forearm, was studied during a series of flexing pronations, where it acted as an agonist to the flexion movement and an antagonist to the pronation movement. We addressed the following question: Will bi-articular muscles display purely agonist or antagonist activity depending on factors such as movement amplitude or required torque, or will the muscle display both agonist and antagonist activity. Subjects performed flexions or extensions of a fixed amplitude while simultaneously performing supinations or pronations of increasingly larger amplitude. The activity of eight muscles about the elbow was recorded using surface electrodes while arm position was monitored using OPTOTRAK*. Results show that bi-articular muscles display an activity pattern which has both agonist and antagonist components. For example, during a small flexion combined with a large supination, pronator teres, which acts to flex and pronate the forearm, displays phasic activity concurrent with brachialis, a pure agonist. It also displays a burst of activity concurrent with pronator quadratus, a pure antagonist. This suggests that central commands for motion in individual degrees of freedom may be specified independently and superimposed.

576.4

LEARNING AND TRAJECTORY PLANNING IN KINEMATIC ALTERATION OF JOINT ANGLES. H. Imamizu*, Y. Uno and M. Kawato ATR Human Information Processing Research Labs, Kyoto, Japan

We investigated whether trajectories of the human arm are planned solely in an extrinsic (kinematic) space or in both an intrinsic (dynamic) space and an extrinsic space. We virtually minified (1/2) the elbow angle and magnified (5/4) the shoulder angle of normal human subjects while they were aiming at targets. A position marker was attached to the subject's hand and its current altered position was displayed as a cursor on a CRT screen. This linear transformation in joint angles corresponds to nonlinear transformation between the hand plane and the screen, and makes a straight trajectory in the hand plane a curved one on the screen. If trajectories are planned in an intrinsic space then they are invariant in the intrinsic space (the hand plane) and distorted in the extrinsic space (the screen) under the kinematic alteration. On the other hand, if they are planned in the extrinsic space, they are invariant in the extrinsic space and distorted in the intrinsic space. The task for the subjects was to move the cursor to a target within a short time period (900 ms). The aiming error decreased with practice. We compared the trajectories after 320 trials of training to those under no alteration on the screen. There was significant difference between them. This suggests that the trajectories were distorted in the extrinsic space. The result supports the hypothesis that trajectories are planned in the intrinsic space. We also investigated intermanual transfer of the learning effect to obtain evidence of internal representation of intrinsic coordinates (joint angles) in the central nervous system.

LEARNING AND GENERALIZATION OF LIMB DYNAMICS.

R.L. SAINBURG* & C. GHEZ Ctr. for Neurobiol. & Behav., Columbia Univ. and NYS Psych. Inst., New York, NY 10032.

We have recently shown that impaired control over interaction torques in proprioceptive deafferentation can be dramatically reduced when, prior to movements performed without vision, patients are allowed to view their limb in motion. We therefore proposed that vision updated an internal model of limb dynamics used to program movement. We now ask whether intact subjects also use feedforward mechanisms to control interjoint dynamics and examine the learning and use of internal limb models.

Subjects were to trace linear hand-path templates presented on a computer screen with rapid, overlapping out-and-back movements. Their arms were supported in the horizontal plane by a low-inertia friction-free system. An outrigger to which weights could be attached enabled the distribution of mass of the forearm-hand segment to be varied. Subjects were trained in a given direction, and with a given inertial configuration, by providing them with visual feedback of the screen cursor. Accuracy was then tested during movements in other directions and with different inertial configurations.

After training, subjects made errors in initial direction, movement linearity and interjoint coordination. Simulations showed that these errors resulted from the production of torques appropriate to the inertial conditions during training. Such after-effects also occurred for movement directions that differed from the training direction, however, their magnitude was greatest in the trained direction. We conclude that the normal control of interjoint dynamics is dependent on feedforward mechanisms that employ internal models of limb mechanics that can be rapidly recalibrated. However, recalibration through training in a single direction allows only incomplete generalization to untrained directions. (NS22715).

SPATIAL ORGANIZATION OF KINEMATIC AND DYNAMIC CHANGES DURING PREHENSION IN THE CAT. J.H. Martin*, S. Cooper, A. Hacking, C. Ghez. Ctr. Neurobiol. & Behav., Columbia Univ. and NYS Psychiatric Institute, New York, NY 10032

The present study examines the spatial control of distal joint angles when interaction torques produced by the motion of proximal joints vary. Cats reached to grasp a piece of beef from the end of a narrow food-well at different inclinations and heights. The coordinates of markers at the shoulder, elbow, wrist, MCP and 4th digit were acquired at 100Hz for kinematic and dynamic analysis. Joint torques were partitioned into components reflecting inertia of segments distal to the joint, interjoint interactions, gravity and a residual term that includes active muscle contraction and passive visco-elastic resistance.

Paw paths comprised two linear segments in which the paw was aimed first to a via point in front of the food-well (lift), and then, within the well, to the food (thrust). During lift, kinematic changes, including wrist speed and angular motions of wrist and elbow, were scaled with reach height. During thrust, distal kinematics were independent of target height but varied with target inclination.

Initially during lift, passive interaction torques flexed the wrist and digits; later, as the via point was approached, they extended them. Although the late extensor torque scaled with height, and thereby could have extended the wrist and digits more at higher targets, the animals compensated by varying residual (muscle) torque and muscle activation so distal angles stayed independent of reach height.

Our findings indicate that torques and muscle patterns at distal joints are adapted to both the interactions produced by motions of proximal joints and to the spatial demands of the task. Cats apparently do not adjust proximal kinematics to vary interaction torques acting on distal joints, for example, to reduce the contraction required of distal muscles. (NS31391)

576.9

DIRECTIONAL BIASES IN ARM MOVEMENTS REFLECT BIASED ESTIMATES OF INITIAL HAND POSITION. M.F. GHILARDI*, J.E. GORDON, C.P. GHEZ INB, CNR, H.S. Raffaele, Milano; Ctr. Neurobiol. & Behav., Columbia Univ. and NYS Psych. Inst., New York, NY 10032.

We have previously reported that when subjects reach to visual targets without seeing their limb, movements show directional biases that vary with the initial position of the hand. The spatial organization of these biases suggest that in planning movement direction the nervous system underestimates the distance of the hand from a bias-free position between midline and shoulder. Since this is the habitual workspace of the hand, we hypothesized that these errors reflect this prior experience. We now asked: (1) Can directional bias in a specific location be eliminated by training with visual feedback? (2) Does such training alter the biases in other untrained areas of the workspace?

Subjects moved their hand on a digitizing tablet from different central points to 12 radial targets displayed on a computer screen. Subjects were trained to perform accurate movements from initial positions normally associated with clockwise or counterclockwise biases by providing visual feedback of cursor and hand during movement. They were then tested without feedback for movements initiated from the same and other points. Training significantly reduced or abolished directional biases for movements initiated in the region of training. Movements initiated from other locations, including the previous error-free region, showed new biases that again represented underestimates of the distance of the initial hand position, but from the new trained location. The present findings are compatible with the hypothesis that training in a particular region of workspace resets subjects' default estimate of their initial hand position. Kinematic planning is highly dependent on learned representations of the hand in the workspace. (NS 22715)

576.11

THE RELATIVE CONTRIBUTIONS OF GEOMETRIC VERSUS BEHAVIORAL CONSTRAINTS IN RESOLVING JOINT-LEVEL MOTOR EQUIVALENCE. Rebecca A. States* & Charles E. Wright. Psychology Dept., Columbia Univ., 406 Schermerhorn Hall, New York, NY 10027.

Motor equivalence exists when a task may be performed using various movement patterns. For example, in a pointing task, all arm configurations that suffice to position the hand at a desired location constitute a "motor equivalence set." Motor equivalence provides flexibility, but also complicates motor planning. Whenever a movement is performed, subjects must select a single arm configuration from those available in the motor equivalence set.

Previous work has shown that, at the end-point of aimed, arm movements, much of the indeterminacy associated with joint-level motor equivalence can be accounted for (Soechting and Flanders, 1989; States & Wright, 1993). Two factors may contribute to the predictability of final arm configurations: geometric constraints imposed by a fixed linkage system, and behavioral strategies. We evaluate their relative contributions, by investigating aimed, arm movements performed with two excess degrees of freedom.

Arm configurations are measured while five subjects make repeated pointing movements from 30 starting points to 1 target. Five targets are tested on separate days. Motion is permitted in a horizontal plane, using four degrees of rotational freedom: one each at the right wrist, elbow and shoulder, and one at the torso.

We compare the variability in arm configurations sampled at the end-point of movements to a single target with the variability that would exist if all configurations within the motor equivalence set were sampled. Results show that behavioral strategies make a substantial contribution for all subjects, even though individuals' strategies differ dramatically. Effects of particular strategies are explored through simulation modelling.

Results suggest new techniques for evaluating models of joint-level motor equivalence (Rosenbaum et al., in press; Bullock & Grossberg, 1992; Bruwer & Cruse, 1990) by testing the extent to which they replicate the partitioning of variance between geometric and behavioral strategies observed here.

576.8

ADAPTATION TO DISPLAY ROTATIONS AND ALTERED GAINS IN PLANAR REACHING MOVEMENTS. Z.M. Pine*, J. Gordon, and C. Ghez. Dept. Rehab. Med., Prog. Phys. Ther., Ctr. Neurobiol. & Behav., Columbia Univ. and NYS Psych. Inst., New York, NY 10032.

We have previously shown that direction and extent of hand movement represent independently planned features of reaching movements. The purpose of this study was to compare the time courses of adaptation to experimentally imposed rotations and gain alterations in the virtual workspace. Human subjects made aimed movements on a horizontal digitizing tablet. However, vision of the hand and arm was blocked, and virtual targets and hand positions were displayed on a computer screen. We separately applied either a rotation or a change in gain to the screen display of hand path while leaving the virtual targets unchanged. The hand display was blanked during movement, but the path taken by the virtual hand was displayed following each movement as knowledge of results.

Adaptation to both types of distortion showed evidence of two distinct processes: a relatively rapid reduction in mean error over trials, and a more gradual reduction in variability of movement error. Adaptation to rotational distortions, and re-adaptation to control conditions after rotations, was generally slower than for gain changes. Increased variability was also more pronounced and prolonged during adaptation to rotational distortions.

Differences between directional and extent adaptation support previous findings of independent specification of direction and extent. The learned visuomotor transformation between target and hand direction is generally resistant to short-term adaptation, perhaps because this involves altered specification of which muscles to contract. The target-extent relation is more rapidly recalibrated, perhaps because it involves shifting a scaling factor. (Supported by HD 01018, NS 22715)

576.10

PRACTICE AND MOTOR LEARNING. R. Barth-Neander, J. Hynes & A.M. Gentile*. Teachers College, Columbia Univ, NY 10027.

Learning a novel movement pattern requires developing a new dynamic model of limbs and objects ("getting into the ball park" Greene, *Prog Theoret Biol*, 1972). It is proposed that initial learning is enhanced under consistent practice conditions which permit stabilization of the dynamic model. Practice under variable conditions of high similarity (requiring scaling) precludes stabilizing the dynamic model and disrupts learning. These hypotheses were tested with similar tasks (SIM): using chopsticks to pick up and transport small, medium or large buttons to a container; or dissimilar tasks (DIS): chopsticks/medium button, card sorting, mirror tracing. Adult subjects (N=36), naive in chopstick use, were assigned to one of 4 practice conditions: Blocked/SIM (15 successive trials on one task before switching to another), Random/SIM (15 trials on each of 3 tasks randomly ordered), Blocked/DIS, Random/DIS. Movement time was assessed on 15 acquisition trials (medium button), immediate and delayed retention tests and 2 transfer tests (new button sizes). Findings confirmed predictions: Blocked/SIM yielded better learning than Random/SIM practice. DIS conditions did not differ in retention but tended to be better than Random/SIM. These results contradict reports (Magill & Hall, *QJEP*, 1990) favoring random practice over blocked ("contextual interference effect").

576.12

EFFECTS OF SOME CONSTRAINTS FOR SINGLE-JOINT MOVEMENTS.

Di-An Hong*, G. L. Almeida*, D. M. Corcos**, G. L. Gottlieb*. *Rush Medical Center, Chicago, IL 60612, **Universidade Estadual de Campinas, São Paulo, Brazil, and University of Illinois at Chicago, Chicago, IL, 60608.

Four healthy subjects performed mechanically constrained single-joint elbow-flexion movements, in a transverse plane, and unconstrained single-joint elbow and shoulder flexion movements, in a sagittal plane.

In the unconstrained paradigm, the movements of the elbow were accompanied by varying degrees of movement at the shoulder and movements of the shoulder were accompanied by varying degrees of movement at the elbow. The pattern of muscle activity was the same for mechanically unconstrained single-joint elbow movements. The duration of the agonist EMG bursts scaled with distance while their rate of rise remained constant. The antagonist muscles were activated earlier for shorter distances. This uniform initial rising phase was also observed for torque.

At the shoulder-task, the biceps long head and the anterior deltoid displayed strong coupling in terms of the muscle activity burst. At the elbow-task, for the unconstrained movement, the anterior deltoid also scaled with distance but it was less coupled with the biceps long head than in the shoulder-task. These findings are interpreted in terms of rules that control the activation of different muscles to suggest the forces sufficient and necessary to perform the movement tasks.

UNCONSTRAINED SINGLE-JOINT MOVEMENTS IN INDIVIDUALS WITH DOWN SYNDROME. G. L. Almeida⁺, Di-An Hong⁺, D. M. Corcos^{*}, G. L. Gottlieb^{*}. ⁺Rush Medical Center, Chicago, IL 60612, ^{*}University of Illinois at Chicago, Chicago, IL, 60608 and ⁺⁺Universidade Estadual de Campinas, SP, Brazil.

Three individuals with Down syndrome performed unconstrained single-joint elbow and shoulder flexion movements, in a sagittal plane. First, the subjects were instructed to move one joint (the "focal joint") "as fast as possible", while keeping the "non-focal" joint stationary. These movements were performed over three different distances. Second, the subjects were instructed to move a "focal joint" at three different speeds, over one distance.

The movements of the focal joint were accompanied by varying degrees of movements at the non-focal joint. On average, the movements at the non-focal joint were twice as large as those observed in neurologically normal individuals, and they displayed slower movement speed at the focal joint. For the movements performed over three distance, the pattern of muscle activity was typical for "speed insensitive strategy". The duration of the agonist EMG bursts scaled with distance while their rate of rise remained constant. Nevertheless, there was more variability related to the antagonist latency. One subject presented a pattern of co-contraction, whereas for the others, the antagonist latency did not scale with distance.

For the movements performed at three different speeds, the pattern of muscle activity was typical of "speed sensitive strategy". The rate of rise of the agonist EMG burst scaled with distance with the antagonist latency being activated early for fast movements.

These findings suggest that, in comparison with neurologically normal individuals, individuals with Down syndrome use similar rules to control the muscle activation. Nevertheless, they seem to have a coordination problem which is reflected in their poor coupling of the muscle activity burst and in the large range of the movements in the "non-focal joint".

ANALYSIS OF KINEMATIC AND DYNAMIC PARAMETERS OF HUMAN MOTOR LEARNING. S.J. Shambhag^{*} and T.J. Ebner. Departments of Neurosurgery and Physiology, and Graduate Program in Neuroscience, University of Minnesota, Minneapolis, MN 55455.

In order to more fully understand the characteristics of human motor learning, human subjects were evaluated using a step-movement task. Subjects were seated in front of a video display and controlled the movement of a cursor on the display with the right hand using a planar 2-joint manipulandum. A sling supporting the elbow constrained movement to the horizontal plane to permit explicit determination of shoulder and elbow joint angles and torques. The task consisted of maintaining the cursor in a central "start box" until one of eight equidistant "target" boxes appeared; the cursor then had to be moved to and held in the target box within a movement time window. After practicing on a normal hand-cursor movement relationship, the gain was changed, forcing the subjects to learn a new relationship between hand and cursor movement. Once the subjects' performance had returned to an acceptable level, the gain was restored to the initial conditions. Initially, subjects' hand paths were nominally straight with characteristic bell-shaped hand velocity profiles and biphasic accelerations. Biphasic ("accelerating" and "decelerating") torque profiles varied predictably with direction during the normal gain condition. Upon initial presentation with the new gain, movement errors increased, with larger errors in directions involving larger shoulder torques, and smaller errors in directions involving larger elbow torques. Compared to other targets, learning in these directions appeared to be more difficult. The "accelerating" phases of the joint torques followed a stereotyped profile, while the "braking" phases of the joint torques were prolonged in the early stages of learning, regaining their characteristic form as net performance improved. The correlation of the shoulder/elbow torques with the spatial dependence of the errors suggests that the control scheme for reorganization of two-joint movements is more complex than that for single-joint movements.

ADAPTIVE BEHAVIOR OF THE MONKEY MOTOR SYSTEM TO VIRTUAL ENVIRONMENTS. F. Gandolfo, B. Shadmehr, B. Benda and E. Bizzi^{*}. Dept. Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

It has been shown (Shadmehr and Mussa-Ivaldi, J. Neurosci., in press) that humans can adapt to virtual dynamic environments. We are interested in finding the neural mechanisms underlying this phenomenon. As a first step, before beginning the recording of single cells from cortical areas, it is necessary to assess how well the data observed in human subjects apply to macaque monkeys. Psychophysical tests were performed in an awake behaving monkey using the following paradigm: The monkey was trained to move a manipulandum to a set of targets sequentially appearing on a computer screen and hold the cursor in the target for at least one second in order to get a reward. In the baseline condition, the manipulandum behaves like a damper in order to help the monkey move smoothly. In the perturbation condition, non-homogeneous viscous field is superimposed on the baseline field. In the latter condition, a dramatic alteration of the trajectory was observed initially, followed by a gradual return to the baseline trajectory. This is consistent with the hypothesis of an underlying kinematic planner cascaded with an execution module cancelling out the dynamics of the environment by learning a model of the disturbing field. We ruled out the possibility of co-contraction, which would be an alternative explanation of the data, by looking at the after effects obtained by restoring the baseline condition. The after-effect appeared as a distortion in the path opposite to that induced by the field. Such after-effects decay rapidly when the monkey is no longer exposed to the field. CIRCUITRY AND PATTERN GENERATION III

577.1

FUNCTION OF STOMATOGASTRIC NETWORKS IN INTACT CRAYFISH. H.-G. Heinzel^{*}, H. Böhm, P. Eitner, D. Hallbusch and E. Messai^{*}. Inst. of Zool., Uni. Bonn, Poppelsdorfer Schloß, D-53115 Bonn, Germany.

Rhythmic-motor patterns of the dorsal ventricular nerve of the stomatogastric ganglion were monitored with chronically implanted electrodes in intact crayfish, *Orconectes limosus*, while the activity of the gastric mill and the cardio-pyloric valve was monitored by endoscopic imaging. Feeding experiments of free-moving crayfish demonstrate a decrease in the pyloric activity during presentation and grabbing of food which is followed by a strong increase in the pyloric frequency. After food intake the gastric activity starts vigorously and stays on a high frequency level for long duration (see Figure). The activity level increases further depending on the amount of food.

Application of juice from mussels or fish into the stomach induces an amplification of movements of the gastric mill as well as a modification in the opening and closing of the cardio-pyloric valve. Gastric movements often show pyloric modulations which reflect complex gastro-pyloric patterns probably due to changes in the consistency of food. The investigations on the function of the stomatogastric system and neuroanatomical studies of the networks indicate the importance of sensorimotor mechanisms of integration which are involved in initiation and feedback-control of the stomach's rhythmic motor-patterns. Supported by HFSP.

577.2

INITIATION AND MODULATION OF GASTRIC MILL ACTIVITY BY MECHANOSENSORY ORGANS IN THE LOBSTER.

M. E. T. Boyle^{*}, A. M. Schweins, and A. I. Selverston. Dept. of Biology, University of California at San Diego, La Jolla, CA 92093-0357.

The lobster gastric mill (GM) consists of three teeth in the stomach, two lateral and one medial, which masticate food and are under the control of the stomatogastric ganglion (STG). The posterior stomach receptor organs (PSRs) are mechanoreceptors which monitor medial tooth activity. There are two clusters of 15–20 PSRs located in the ventral branch of the posterior stomach nerve (v-psn). By injecting neurobiotin intracellularly into the PSRs we show that the PSRs are dye-coupled to a subset of neurons in the STG. We have been able to trace PSR processes leading into the main STG output nerve, the lateral ventricular nerve (lvn). Our aim is to find out how sensory input from the PSRs affects the gastric motor output pattern produced by the STG. In both the intact and semi-intact animal, we record from STG neurons and the v-psn while initiating gastric mill activity in response to pumping sea water into the stomach. We use an endoscope to observe, quantify, and compare GM movement patterns produced by sensory stimulation in the intact and deafferented animal. In five preparations the d-psns were bilaterally cut while monitoring the sensory induced GM activity. Minutes after the d-psns were cut, GM activity was substantially lower. These preliminary results suggest that the PSRs may mediate the sensory induced chewing.

NOVEL DEPOLARIZING GLUTAMATERGIC CONDUCTANCE EXPRESSED IN CRUSTACEAN STOMATOGASTRIC NEURONS IN PRIMARY CULTURE. T.A. Cleland* and A.I. Selverston. Dept. of Biology 0357, Univ. Calif. San Diego, La Jolla, CA 92093-0357.

The stomatogastric ganglion (STG) of the Pacific spiny lobster, *Panulirus interruptus*, is one of the most well-defined central pattern generators studied at the intercellular and circuit level. In this study, STG neurons were individually isolated in primary culture in order to investigate cellular membrane properties under improved space-clamp conditions and without the complicating effects of other networked cells. Glutamate-induced currents were studied using two-electrode voltage clamp in these cultured neurons. The dominant glutamatergic response in most cells examined was a moderately calcium-dependent depolarizing current mediated by a conductance increase and reversing at -30 ± 15 mV. This stands in sharp contrast to all previously described glutamate responses within the intact ganglion, which are all chloride or potassium-mediated ipsp's. Biophysical and pharmacological characterizations of this glutamatergic conductance are presented.

PHYSIOLOGICAL AND MOLECULAR HETEROGENEITY OF PY MOTONEURONS OF THE PYLORIC NETWORK. R.M. Levini, D.I. Baro, S.A. Hughes and R.M. Harris-Warrick*. Dept. of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The 8 PY motoneurons in the stomatogastric ganglion of the spiny lobster *Panulirus interruptus* are integral members of the pyloric central pattern generator and innervate 13 intrinsic constrictor muscles on the pylorus. Electrophysiological differences between cells of this class have been acknowledged for many years (Hartline, et al., 1987). Consistent with previous studies we found two distinct physiological phenotypes which can be quickly identified. PY1 cells do not respond to stimulation of the hepatopancreatic duct nerve (*hdn*) at 20 Hz, respond strongly to puffer (10^{-3} M) or bath (10^{-4} M) applied dopamine (DA), are strongly electrically coupled to LP cells (-5 nA into PY cell), are strongly active during pyloric cycling, and can overlap the LP firing phase in a combined preparation. PY2 cells do respond to *hdn* stimulation, respond weakly or not at all to DA application, are not detectably electrically coupled to LP (-5 nA into PY), are often silent during the ongoing pyloric rhythm and never overlap LP activity in a combined preparation. Four superficial muscles (p2,8,10,12) were used to test for differences in innervation patterns between the PY subtypes. The results showed no segregation of innervation on the muscles by either subtype: each muscle is innervated by at least one neuron of each type. We are currently looking at PY heterogeneity at the level of expression of mRNA for the *shaker K+* channel family using *in situ* hybridization. Supported by NIH NS17323 and 5PO1 NS25915.

DISTRIBUTED AMINE MODULATION OF GRADED CHEMICAL SYNAPTIC INTERACTIONS BETWEEN NEURONS OF THE PYLORIC MOTOR NETWORK. B.R. JOHNSON*, J.H. PECK AND R.M. HARRIS-WARRICK. Section of Neurobiology and Behavior, Cornell University and Dept. of Psychology, Ithaca College, Ithaca, NY.

Dopamine (DA), serotonin (5HT) and octopamine (Oct) are endogenous neuromodulators in Crustacea, and each evokes a distinct motor pattern from the quiescent pyloric network in the stomatogastric ganglion of the spiny lobster. We examined amine effects on graded chemical interactions between synaptically isolated pairs of neurons in the pyloric network to determine if these could contribute to the amine-generated motor patterns. Each amine had a unique and distributed spectrum of effects on graded chemical synaptic strength across the pyloric synapses. DA (10^{-4} M) enhanced some pairs of synaptic interactions and weakened others. 5HT (10^{-5} M) also enhanced and weakened different pairs of synaptic interactions but to a lesser degree than DA. Oct (10^{-5} M) strengthened some synaptic interactions and had no effect on others. At some previously described pyloric chemical synapses (AB-IC and PY-IC, for example), graded chemical transmission could not be detected in the absence of modulatory inputs in the control TTX-saline (20° C). In these cases, amine application (especially DA) created functional synaptic interactions. This suggests that neuromodulators are required for the functional expression of some chemical synapses within the pyloric network. This completes our survey of amine effects on all 18 of the graded chemical and electrical synaptic interactions within the pyloric network. Supported by NIH grant NS 17323 and the Human Frontier Science Program.

MODES OF OSCILLATION AND SETTING RELATIVE PHASE IN SMALL MOTOR PATTERN GENERATING NETWORKS. P.F. Rowat* and A.I. Selverston Biology Department, U.C. San Diego, La Jolla, CA 92093-0357

We have constructed a simplifying, biologically constrained, network model of the gastric mill CPG which shows that only a few basic mechanisms are sufficient to produce the relatively complex patterns characteristic of the cycling gastric mill. These mechanisms include a cell model having a fast current with an N-shaped I-V curve and slow inward and outward currents with linear steady-state I-V curves; graded synaptic transmission; and "slow" synapses. The cell model captures important characteristic behaviors of gastric mill cells such as plateau potentials, post-inhibitory rebound, and endogenous oscillations. The reciprocal inhibitory pair is an essential sub-network of the gastric mill network, which enables the model network to produce a pattern whether or not the individual cells are endogenous oscillators.

An isolated cell has six distinct behaviors: endogenous oscillations; silence; almost an oscillator; plateau potentials; tonically firing; hyperpolarized. Using pairs of two-dimensional phase-portraits, we have studied in detail the modes of oscillation of two cells connected with reciprocal inhibitory synapses, in which the center of the synaptic transfer function, or "threshold", was allowed to be different for the two synapses. Every combination of behaviors in the individual cells can give rise to oscillations, provided the thresholds and weights are correctly adjusted. In the symmetric cases, the cells are exactly out of phase, but when asymmetries are allowed many other phase relationships are obtained. In addition, one can get 1:N (N=1,2,3) or even M:N phase locking, and chaos from the reciprocal inhibitory pair.

EFFECT OF DOPAMINE ON THE TRANSIENT POTASSIUM CURRENT AND THE HYPERPOLARIZATION-ACTIVATED CURRENT IN PY AND LP NEURONS OF THE LOBSTER STOMATOGASTRIC GANGLION. L.M. Coniglio* and R.M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853

The stomatogastric ganglion of the lobster, contains a network of neurons, called the pyloric network, which controls rhythmic movements of the pylorus, part of the lobster foregut. The pyloric motor pattern is altered by the endogenous neuromodulator dopamine. The effect of dopamine on the motor pattern is due to both effects on synaptic connections between neurons of the pyloric network and direct effects on the neurons themselves. We show that in two pyloric cell types, PY cells and LP cells, dopamine specifically affects the transient potassium current, *I_a*. In the PY cell type, dopamine decreases *I_a* by reducing its maximum conductance, shifting its voltage of half-activation in the depolarized direction, and increasing its rate of inactivation. In the LP cell, dopamine also decreases *I_a* by reducing its maximum conductance and shifting its voltage of half-activation in the depolarized direction. In the LP cell, however, dopamine has no effect in the rate of inactivation of *I_a*. In addition, in the LP cell dopamine affects a second current, the hyperpolarization activated current *I_h*. Dopamine effectively increases *I_h* by shifting its voltage-dependence of activation in the depolarizing direction and increasing its rate of activation. Understanding the specific effects of dopamine on these neurons is important in understanding how alterations in particular neuronal properties can underlie the alteration of a motor pattern. Supported by NIH grant NS17323.

577.8

FUNCTIONAL ROLE OF ELECTRICAL COUPLING IN CONTROLLING THE LOCAL ACTIVITY OF A MODULATORY PROJECTION NEURON. M.J. Coleman*, P. Meyrand* and M.P. Nusbaum*. *Neurobiology Research Center, Dept. Physiol. & Biophys., Univ. Alabama at Birmingham, B'ham, AL 35294/Dept. of Neuroscience, Univ. Pennsylvania Medical School, Philadelphia, PA 19104; *Lab. de Neurobiologie et Physiologie Comparées, CNRS, 33120 Arcachon, France.

Intra-axonal recordings at the entrance to the stomatogastric ganglion (STG) of the crab *Cancer borealis* show that the STG terminals of modulatory commissural neuron 1 (MCN1) excites the pyloric and gastric mill rhythms in the STG, receives IPSPs from the lateral gastric (LG) neuron and is electrically-coupled to LG (Nusbaum et al., J Neurosci 12:2706). The LG inhibition of MCN1 controls the gastric mill rhythm-timed activity of MCN1 in the STG (Coleman & Nusbaum, J Neurosci, in press).

Despite the synaptic inhibition from LG to MCN1, LG can also influence MCN1 via the electrical coupling between these two neurons. For example, depolarizing LG to levels subthreshold for transmitter release activates MCN1. Slightly stronger LG depolarization first activates and then inhibits MCN1. When the LG-mediated inhibition is eliminated by bath-applying picrotoxin (10^{-6} M), LG stimulation activates MCN1 enough to enable MCN1 to excite its STG targets.

During MCN1-elicited gastric mill rhythms, the MCN1 hyperpolarization is largest at the start of each LG burst. This response in MCN1 then exhibits a depolarizing sag, despite little decrease in the LG firing frequency or its underlying membrane potential. This enables MCN1 to escape from inhibition before the end of the LG burst. We are studying whether the electrical coupling between LG and MCN1 contributes to this escape from inhibition by MCN1.

MUSCARINIC MODULATION OF EXCITABILITY AND SYNAPTIC OUTPUT IN A GASTRIC PATTERN-GENERATING NEURON OF THE LOBSTER STOMATOGASTRIC GANGLION. R.C. Elson* and A.L. Selverston
Department of Biology, UCSD, La Jolla CA 92093.

In the isolated stomatogastric ganglion of spiny lobsters, the muscarinic agonist, pilocarpine, activates rhythm generation in the gastric mill CPG. The lateral gastric neuron, LG, an important pattern-generating cell, goes from quiescence to spontaneous spiking and then to firing strong bursts underlain by plateau potentials.

Even before the onset of spontaneous activity, however, one can detect a large increase in the strength of LG's inhibitory outputs to other gastric neurons. IPSPs evoked by ortho- and antidromic spikes grow larger, the input-output function for graded synaptic transmission gets steeper, and the threshold for transmitter release is seemingly reduced. We used electrotonic coupling potentials to monitor neuromuscular input resistance during synaptic potentiation, and found a large increase in synaptic conductance. The resting input resistance of LG could also increase, but it is not clear whether this can account for all the observed potentiation.

Concurrently, pilocarpine decreases LG's spike threshold and increases the slope of the spike frequency - voltage plot. Together with potentiated synaptic output, these changes enhance the role of spike-mediated transmission at low presynaptic depolarizations. Also induced is a slow, seemingly active, depolarization, which may be the plateau current, and which is a good driver of graded transmission.

A possible interpretation of these results is that muscarinic modulation leads to enhanced activation of calcium currents in LG's distal neurites, allowing greater transmitter release. Present experiments seek to identify which conductances are modulated in LG and to clarify how these changes relate to modifications of excitability and synaptic efficacy.

RECIPROCALLY INHIBITORY NEURAL NETWORKS: EFFECTS OF VARIATIONS IN SYNAPTIC PARAMETERS. F.K. Skinner*, A.A. Sharp, and E. Marder. Ctr. for Complex Systems and Dept. of Biology, Brandeis University, Waltham MA 02254-9110.

Reciprocally inhibitory circuits are ubiquitous components of oscillatory neural systems. We characterize how modulation of synaptic properties alter the responses of such a two cell system (half-center oscillator) using a combined theoretical/experimental approach. We employ two computational models: (i) a simple model consisting of I_{leak} , leak, and synaptic currents and (ii) a compartmental model which includes HH-like spikes. Experimentally, we take advantage of the dynamic clamp technique (Sharp et al., J. Neurophys., 69:992, 1993) to couple pairs of gastric mill neurons in the stomatogastric ganglion, and to introduce artificial I_{leak} . As the synaptic threshold is increased, the frequency first decreases and then increases. This frequency transition occurs as the system switches from a synaptic escape mechanism to a synaptic release mechanism (Skinner et al., J. Computational Neurosci., in press). As the synaptic time constant is increased, the network frequency and oscillator amplitude both decrease. Increasing the maximal synaptic conductance causes a decrease in frequency and an increase in oscillator amplitude. For large synaptic conductances, oscillations can not be initiated for values of the synaptic threshold which fall in the transition between synaptic escape and release mechanisms. This interactive approach allows for a detailed understanding of how interactions between synaptic and intrinsic parameters generate network behaviour. Supported by NIMH MH46742 and NSF BNS9009251.

577.13

GROSS MORPHOLOGY OF LOBSTER PYLORIC NEURON TYPES. J.B. Thuma* and S.L. Hooper. Dept. Bio. Sci., Ohio U., Athens, OH 45701

The pyloric network neuron types are distinctly different on the basis of muscle innervation, electrophysiological activity, and synaptic connectivity in the network. We examined whether the individual neuron types also have different morphologies by injecting neurons with the fluorescent dyes Lucifer yellow or rhodamine dextran and reconstructing the neurons with a Eutectic three dimensional neuron tracing system.

In agreement with the results of King (1976) and Selverston and Mulloney (1973), the main neurite of the Ventricular Dilator (VD) (n=4) neuron splits in the neuropil into two processes, each of which continues to form one of the neuron's axons. In addition, we have observed that the VD neuron consistently also has a process that leaves the main neurite at or well before the axon bifurcation and that branches extensively within the neuropil. Detailed analysis of the neuropilar arrays of the two axonal processes reveals they occupy non-overlapping regions of the neuropil.

The pyloric network has two Pyloric Dilator (PD) neurons that seem to be identical electrophysiologically. However, these neurons appear to have two distinct morphologies. In one class (n=4), the main process loops over itself as it courses through the neuropil. The first process of these looped PD neurons is always relatively close to the soma (av. distance \pm s.d., $36 \pm 26 \mu\text{m}$). The other class of PD neurons (n=7) do not loop and have more distant initial branches (av. distance from soma, $133 \pm 41 \mu\text{m}$). In four double PD neuron fills, one of each class was present in the ganglion. In a fifth very poor double fill, it appeared that two unlooped PD neurons were present.

These results suggest that at least some the pyloric neuron types have distinct morphologies. Perhaps more interestingly, the distinct volumes occupied by the VD neuron neuropilar arrays could provide a basis for anatomical segregation of the stomatogastric neuropil.

RECIPROCALLY INHIBITORY NEURAL NETWORKS: EFFECTS OF VARIATIONS IN INTRINSIC PARAMETERS. A.A. Sharp*, F.K. Skinner, and E. Marder. Ctr. for Complex Systems and Dept. of Biology, Brandeis University, Waltham MA 02254-9110.

We characterize how modulation of an intrinsic conductance (I_{leak}) alters the responses of a half-center oscillator formed by reciprocally inhibitory connections. We use a combined theoretical/experimental approach employing conventional model neurons and experiments using the dynamic clamp (Sharp et al., J. Neurophys., 69:992, 1993). A plot of network period vs. synaptic threshold produces an inverted U-shaped relationship (see accompanying abstract). As the maximal I_{leak} conductance is increased or the I_{leak} activation curve is moved in a depolarizing direction, the period vs. synaptic threshold relationship is shifted in the depolarizing direction. This indicates that these changes cause a frequency increase if a synaptic escape mechanism is being used, and a frequency decrease if a synaptic release mechanism is in operation. For a small range of synaptic threshold values, it is also possible for the system to switch between synaptic escape and release modes for these changes. If the maximal conductance is made too small or the activation curve is shifted too far in the hyperpolarizing direction, oscillations cease. This indicates that there is a critical relationship between synaptic and intrinsic properties in order to generate a robust half-center oscillator. This interactive approach allows for a detailed understanding of these relationships. Supported by NIMH MH46742 and NSF BNS9009251.

577.12

EFFECTS OF INFERIOR VENTRICULAR NERVE STIMULATION ON GASTRIC MILL AND PYLORIC CENTRAL PATTERN GENERATORS IN SPINY LOBSTER. M.S. Beauchamp* and A.L. Selverston. UCSD, La Jolla, CA 92093-0357.

The inferior ventricular nerve (IVN) links the brain to the stomatogastric ganglion (STG) in the spiny lobster, *Panulirus interruptus*. The STG is a network of neurons comprising two central pattern generators (CPGs) which control the lobster's digestive behaviors, and a role for the IVN in coordinating swallowing movements has been proposed (Sigvardt & Mulloney J. Exp. Biol. 97:153-168). The effects of IVN stimulation were studied under a muscarinic agonist, pilocarpine, which generates stable, reproducible rhythms in the gastric mill and pyloric CPGs. Spontaneous IVN bursts have a long period and consist of three sequential phases: low frequency spike discharge, high frequency, intermediate frequency. Identified STG neurons were recorded intracellularly during stimulation with artificially generated bursts, whose temporal pattern closely matched that of spontaneous bursts. To better understand the mechanisms of IVN action, post-synaptic potentials (PSPs) and rhythm-altering effects of simple spike trains of various lengths and frequencies were also examined.

IVN stimulation has a powerful influence on the CPGs, interrupting ongoing gastric and pyloric activity. In the gastric mill network, LPG neurons are active during the first phase of the burst, then become inhibited by high frequency IVN firing, then fire a rebound burst. This corresponds to the observed excitatory response in LPG to a long low frequency spike train and the observed inhibitory response to a short high frequency spike train. Other identified gastric and pyloric neurons also have complex responses to IVN bursts that are well predicted by their responses to simple spike trains. Consistent with these results, low frequency IVN stimulation gives small EPSPs in LPG, small IPSPs in GM and large EPSPs in VD, PD and CD2. Both short and long-lasting alterations in rhythmic activity occur following stimulation. Gastric rhythm phase shifting, in which GM and AM fire synchronously, occurs in the first few cycles following stimulation. Pronounced pyloric rhythm alterations, consisting of several-fold increases in period and burst length, take tens of seconds to return to pre-stimulation values, suggesting that the IVN may also release a neuromodulator. Supported by HHMI fellowship to MSB and NIH 09322 to AIS.

DORSAL DILATOR MUSCLES IN *PANULIRUS* MAY EXPRESS BOTH PYLORIC AND GASTRIC MILL MOTOR PATTERNS. L.G. Morris* and S.L. Hooper. Dept. of Biological Sci., Ohio Univ., Athens, OH 45701

The two pairs of dorsal dilator muscles (cpv1a and b) are innervated by the Pyloric Dilator (PD) neurons and have been assumed to express a pyloric motor pattern. We examined the isotonic contractions of these muscles in *in vitro* preparations maintained in oxygenated saline with glucose. In 3 of 5 preparations, we observed no or only very small (<0.1mm) pyloric timed contractions. In the other preparations, the muscles produced large (~1mm), long duration (~4s) contractions every 6 to 8 sec., very different from the PD neuron burst length (~250ms) and cycle period (~1s) present in these preparations. In 10^{-6} M dopamine (DA), all preparations showed large (up to 2mm) contractions, with long durations and periods. Large (>0.1mm) pyloric timed activity was never observed in either saline or DA.

In two experiments, we observed that the large contractions were phase locked with Gastric Mill (GM) neuron activity, and that contraction duration covaried with GM neuron burst length. In one experiment we stimulated the anterior lateral (aln) nerve, which contains GM neuron axons; this elicited, at constant short latency, contractions whose duration covaried with the stimulation parameters. Strikingly, the relaxation time of the large contractions was much longer than the pyloric period, suggesting that even if pyloric activity could induce large contractions, the muscles would not fully relax within a pyloric period. This idea was tested by applying DA to augment contraction amplitude and stimulating the lateral ventricular (lvn) nerve or aln using parameters (40Hz for 250ms every 1s) mimicking pyloric neuron bursts. Under these conditions the contractions summated, resulting in a sustained contraction.

These results suggest that the dorsal dilator muscles, at least under some conditions, 1) may respond to pyloric input with sustained contraction and 2) can express gastric mill timed and duration motor output.

577.15

CONTROL OF FOLLOWER NEURON PHASE IN THE PYLORIC NETWORK. S.L. Hooper*. Dept. of Bio. Sci., Ohio U., Athens, OH 45701

The rhythmic pattern produced by the lobster pyloric network maintains relatively constant phasing as cycle frequency is altered by current injection into the pyloric pacemaker. Perfect phase maintenance requires appropriate changes in both pacemaker burst duration and firing delay of follower neurons after inhibition. Previously I showed that when trains of hyperpolarizing current pulses are injected into isolated pyloric neurons, firing delay of Inferior Cardiac (IC) and Lateral Pyloric (LP) neurons primarily depends on pulse amplitude, whereas Pyloric (PY) neuron firing delay primarily depends on the temporal characteristics of the input.

Intracellular recordings from LP and IC neurons in the intact network show that inhibition amplitude in these neurons changes as pyloric frequency is altered. However, this change is small and opposite to the change expected if the cellular properties of these neurons play a role in phase control. Re-analysis of prior experiments with respect to delay after the pacemaker burst, rather than phase, shows these neurons fire with a constant lag after pacemaker activity.

In the intact network, PY neurons do show appropriate changes in firing delay, and thus the firing delay properties described previously likely are relevant to their phasing. This work did not directly address whether PY neuron firing delay depends on pulse length or interpulse interval. Experiments in which these lengths were varied independently show that interpulse interval, not pulse length, mainly determines PY neuron firing delay.

Maintenance of LP and IC neuron phase as pyloric frequency changes thus is largely due to the associated changes in pacemaker burst length. PY neuron phase maintenance, alternatively, is likely associated with PY neuron cellular properties that alter neuron firing delay as pyloric frequency is altered. However, this delay may be primarily determined by the length of the PY neuron burst in the preceding pyloric cycle, not the changing duration of pacemaker inhibition received by the PY neuron.

MORPHOLOGY OF STOMATOGASTRIC NEURONS OF *CANCER BOREALIS*. K. Graubard*, A. E. Wilensky. Department of Zoology NJ-15, University of Washington, Seattle, WA 98195.

The stomatogastric ganglion (STG) is a small pattern generator, comprised of 30 neurons. For most neurons, including DG, LP, and PD, the primary neurite exits the ganglion to become a single large axon that does not divide until it nears its target muscles. However, some neurons, including IC, GM and VD, have axon divisions that occur close to or within the ganglion. The primary neurite of the IC neuron first branches to produce smaller neurites that terminate within the neuropil and then bifurcates near the edge of the neuropil into two equal-diameter axons which exit the neuropil without further branching. GM neurons have a similar pattern; the primary neurite branches repeatedly to produce 3-5 axons of unequal diameters, with no further neuropil branching. In contrast, the VD neuron's primary neurite splits early in its course into two equal-diameter neurites; they then branch extensively to produce smaller neuropil-contained neurites, after which the two large-diameter axons exit the neuropil. The regions of neuropil innervated by the VD's fine neurites are distinct, with little overlap. Since the VD has two sites of spike generation, it is interesting to speculate that this unique neuropil organization subserves some function. Supported by NIH grant NS15697.

TWO DISTINCT PATHWAYS FOR ACTIVATING cGMP IN THE CRAB STOMATOGASTRIC NERVOUS SYSTEM. N. L. Scholtz, M. E. Goy*, J. W. Trumant, and K. Graubard. *Univ. of Washington, Dept. of Zoology, Seattle, WA 98195 and †Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

We are investigating pathways of cGMP activation in the crab stomatogastric nervous system (STNS), a collection of motor circuits known to be extensively modulated by both synaptically-delivered transmitters and circulating neurohormones. Using antisera selective for cGMP, we have conducted parallel radioimmunoassay (RIA) and immunocytochemical (ICC) studies to screen for stimuli that activate cGMP synthesis in the STNS. We have found two classes of activators that are effective: nitric oxide (NO) donors and peptide-containing extracts of crab sinus gland.

In RIA studies, three NO donors (SNP, SNAP, and SIN-1) were all found to produce large increases in cGMP levels when applied with the phosphodiesterase inhibitor IBMX. A similar result was obtained with ICC studies: treatments with NO donors and IBMX consistently caused the appearance of cGMP immunoreactivity in a subset of neurons. We used an arginine-to-citrulline conversion assay to screen tissues in the vicinity of the STNS for a nitric oxide synthase (NOS), and found a candidate in crab heart. This tissue contains an arginine-metabolizing enzyme with properties that resemble a constitutive NOS, including calcium-dependence, NADPH-dependence and sensitivity to arginine analogs. No such activity was observed in the STNS, the supraoesophageal ganglion, or muscle (GM1).

The sinus gland is a crustacean neurohemal organ that is known to contain peptides (members of the CHH/MIH family) that stimulate cGMP synthesis in a variety of target tissues. In RIA studies, extracts of crab sinus gland strongly elevated the cGMP content of the STNS when applied with IBMX. We are currently using cGMP ICC to identify which cells are targeted by the active component of the extract; preliminary results indicate that the peptide extract has a different target specificity than do the NO donors. Based on these results, we suggest that NO and a sinus gland peptide represent two non-overlapping pathways for activating cGMP in the STNS. MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL PROPERTIES OF LAYER I NEURONS IN RAT NEOCORTEX. F.M. Zhou* and J.J. Hablitz. Neurobiology Research Center, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

The basic morphological properties of layer I neurons were described by Ramon y Cajal about 100 years ago. Yet, the electrophysiological properties of these neurons has remained an enigma and their neuronal nature has been questioned. Using an in vitro slice preparation, we have examined the morphological and electrophysiological properties of visually identified layer I neurons. Whole cell patch clamp techniques were used in slices from 2-3 week-old rats. Biocytin labeled cells were multipolar with somas 10-20 μ m in diameter. Most cells processes were smooth and spread horizontally for up to 1.5 mm within layer I. Some presumed axonal processes going to layers II-IV were observed. All the layer I cells (N=30) tested had electrophysiological properties typical of interneurons. Action potentials evoked by depolarizing current pulses showed minimal or no frequency adaptation. Action potential durations, measured at the base, were short compared to pyramidal neurons recorded under similar conditions (2.5 vs 5 ms at 22°C). In the presence of 20 μ M APV and 10 μ M CNQX, bicuculline-sensitive spontaneous IPSCs were recorded in the majority of cells. The amplitude of sIPSCs ranges from less than 10 pA to more than 200 pA, at a holding potential -60 mV in symmetrical Cl⁻, and reversed at 0 mV. Adding 0.5 μ M TTX reduced sIPSC frequency and blocked large amplitude sIPSCs. These results suggest that layer I neurons have firing properties characteristic of interneurons and receive inhibitory inputs. They appear to have extensive processes which may serve in controlling cortical excitability. (Supported by NS18145 and NS22373)

PROJECTIONS FROM THE PARATENIAL NUCLEUS OF THE THALAMUS. T. van Groen* and J.M. Wyss. Dept. of Cell Biology, University of Alabama, Birmingham, AL 35294-0019

Previous studies indicate that the paratenial (PT) nucleus of the thalamus projects primarily to anterior cingulate cortex (area infraradiata; IR), and ventral striatum. However, our anterograde tracing studies suggest that many PT axons extend beyond these areas to synapse in more caudal limbic cortical areas. The present study used anterogradely and retrogradely transported tracers to characterize the projections of PT. Injections into PT reliably label a terminal field in the anterior olfactory nucleus, in the medial orbital and rostroventral IR (IRbx) cortices, in the lateral and basolateral nuclei of the amygdala, in the ventral subiculum, and in the caudal entorhinal and perirhinal cortices. In addition to the cortical projections, PT injections label a dense terminal field in the ventral striatum and a less dense terminal field in the olfactory tubercle and in the ventrolateral part of the lateral septal nucleus. PT projections display a general topographic organization, i.e., rostral parts of PT project to more rostral parts of IRbx, whereas caudal parts of PT project to more caudal parts of IRbx. Further, caudal parts of PT project predominantly to rostral areas of limbic cortex (i.e., IRbx and orbital cortices), but rostral parts of PT project to both rostral and caudal areas of limbic cortex (i.e., subicular, entorhinal, and perirhinal cortices). Axons of PT terminate primarily in layers I and III/IV in most cortical areas, but the PT projections to the subiculum end in layer I, and the PT projections to the caudal entorhinal cortex terminate in the deep layers (i.e., layers V-VI). These results demonstrate that PT projects to functionally distinct limbic areas, e.g., regions implicated in learning and memory versus regions involved in cardiovascular regulation and control of emotions.

578.3

EFFERENT PROJECTIONS FROM THE ROSTRAL THALAMIC RETICULAR NUCLEUS TO THE IPSILATERAL AND CONTRALATERAL THALAMUS: AN ANTEROGRADE TRACING STUDY IN THE RAT. G. Battaglia¹ and C. Lizio². Dept. of Neurophysiology, Neurological Institute "C. Besta", 20133 Milano, Italy.

The conventional view that the interthalamic connections are sparse or absent has been recently challenged by anatomical studies from different groups (Bentivoglio et al., '93; Paré and Steriade, '93; Battaglia et al., '94). These studies, mainly based on retrograde tracing techniques, pointed out that in different mammalian species the thalamic reticular nucleus (R), and particularly its rostral part, projects to contralateral as well as to ipsilateral dorsal thalamic nuclei. The anterograde transport of biotin-dextran amine (BDA) was employed in the present study to reinvestigate the pathways connecting different regions of the rostral pole of R to the ipsilateral and contralateral dorsal thalamic nuclei. Small iontophoretic injections of BDA were delivered into the medial, ventral, and lateral regions of the rostral pole of R. After a survival time of 7 to 10 days, the rats were perfused with 1% paraformaldehyde followed by 4% paraformaldehyde, the brains coronally cut with a vibratome, and the sections processed with an antibiotin antibody to reveal the anterogradely transported BDA.

After BDA injections in the medial region of the rostral R anterogradely labeled fibers were almost symmetrically found in the anterior thalamic nuclei of the two sides, and in the corresponding medial region of the contralateral R. The midline nuclei of both sides were also symmetrically labeled, particularly after the most rostrally placed injections. After ventral injections, anterograde labeling was particularly evident in the rostral intralaminar and mediodorsal nuclei of the two sides, but the ipsilateral labeling was predominant. After lateral injections, anterograde labeling was evident in the medial part of the ventrolateral nucleus, in the ventromedial nucleus, and in the caudal regions of the intralaminar nuclei. The labeling was bilateral, though clearly more evident on the ipsilateral side. No labeling in the contralateral thalamus was ever observed after injections not involving the rostral pole of R.

The present data demonstrate that the interthalamic connections in the rat thalamus are more dense than previously thought. The data confirm moreover a functional heterogeneity between different sectors of the reticular nucleus, and that its rostral part plays a pivotal role in the crosstalk between the two thalamic sides.

A PHA-L STUDY OF THE PERIRHINAL PROJECTION TO THE THALAMUS IN THE RAT R.D. Burwell¹, M. Caballero², M.P. Witter² and D.G. Amaral¹. ¹The Center for Behavioral Neuroscience, SUNY at Stony Brook, Stony Brook, NY 11794-2575. ²Anatomy and Embryology, Vrije University, Amsterdam, The Netherlands.

The precise relationship of certain thalamic nuclei with distinct regions of the neocortex has provided one mechanism for defining the cytoarchitectonic boundaries of the cortical mantle. This study was designed to examine whether projections from various locations of the perirhinal cortex might differentiate subdivisions of this region. Using adult male Sprague-Dawley rats as subjects, the anterograde tracer, *Phaseolus-vulgaris* leucoagglutinin (PHA-L), was iontophoretically injected at twenty-one sites along the rostrocaudal extent of perirhinal cortex, in areas 35 and 36 according to borders adapted from Swanson (1992). The thalamic projections arise from deep layers of perirhinal cortex, and those from area 36 are more robust than those from area 35. All portions of perirhinal cortex project lightly to midline thalamic nuclei, terminating in the reuniens nucleus and the rhomboid nucleus. Importantly, subregions of areas 35 and 36 can be distinguished by the patterns of their efferent connectivity with other thalamic regions. For example, rostral area 36 projects primarily to the posterior nuclear group, while mid-rostrocaudal levels project primarily to the central medial nucleus; and caudal levels project to the anterior nuclear group and the lateral nuclear complex. Rostral area 35 is distinguished by a moderately dense projection to the central division of the mediodorsal thalamus. These data about the definition of thalamic nuclei in receipt of perirhinal regions will be used to define the functional roles for perirhinal subdivisions.

EVOLUTION OF THE FRONTAL LOBES: AN MRI STUDY ON APES AND HUMANS. K. Semendeferi¹, H. Damasio^{2*} and G.W. Van Hoesen^{2,3}. Depts of Anthropology¹, Neurology², and Anatomy³, Univ. of Iowa, Iowa City, IA 52242.

How much did the frontal lobes (FL) enlarge during hominoid evolution and which of the subdivisions (dorsal, mesial, orbital) changed the most? We studied all 5 living hominoids (human, chimpanzee, gorilla, orangutan, gibbon) and one monkey (macaque). Thin cut MRs were obtained from each non-human brain specimen and from a living human subject. All were reconstructed in 3-D. Major landmarks were identified and used to separate the frontal lobe from the rest of the hemisphere. We subdivided the cortex and the immediate subjacent white matter in 3 sectors (orbital, dorsal and mesial). The remaining tissue was considered another sector and contained white matter and subcortical grey structures.

Relative to the rest of the hemisphere, the size of the FL is largest in the chimpanzee and human, where it is nearly identical (36.3% and 36.9% respectively). The macaque and gibbon have the smallest (31.4% and 31.5%). The FL show a trend towards increased relative size in hominoid evolution, but the 3 sectors are more conservative. Across the species the dorsal, mesial and orbital sectors are close in relative size and, as expected, the dorsal is largest followed by the mesial and orbital. A noteworthy difference was found in the fourth sector, which was largest in the human followed by the chimpanzee and gorilla. The most marked difference was seen in the anterior third, which contains the white matter, underlying prefrontal cortices.

Supported by NSF G13, Wenner-Gren 5553 and P01 NS 19632-11. We thank Yerkes Regional Primate Research Center, Bush Gardens Zoo, Houston Zoo, Toledo Zoo, Gladys Porter Zoo and Metro Washington Park Zoo for providing the ape specimens.

SYNAPTIC PHYSIOLOGY OF THE AMYGDALA-PERIRHINAL PATHWAY STUDIED *IN VITRO* J.M. Beggs¹ and E.W. Kairiss. Department of Psychology and Center for Theoretical and Applied Neuroscience, Yale University, New Haven, CT 06511.

Although cortical and limbic areas have been suggested to play complementary roles in mammalian memory, little work has been done to study synaptic interactions between these two regions. To address this issue, we have been engaged in the development of an *in vitro* slice preparation which maintains connectivity between perirhinal cortex (PRh) and the lateral nucleus of the amygdala (LA). Here we describe our procedures for reliable preparation of these slices and present the results of studies of plasticity in this system.

Coronal slices 400 μ m thick were taken from rat brain in the range of -2.2 to -3.8 from bregma. Stimulation in LA using 100 μ A produced field potentials in PRh in 33% of these slices. Current-source density analysis reveals a current sink restricted to layers II-III of PRh. Injection of the lipophilic tracer Di-I also confirms that a fiber pathway from LA to the superficial layers of PRh is contained in the slice.

To identify a monosynaptic component in PRh which responds to stimulation of LA, high-frequency following tests and intensity-latency measurements were performed. Recordings from PRh indicate that there is a component that can follow at 100 Hz with a constant latency of 5 ms over a range of stimulation intensities (40-220 μ A).

To examine use-dependent synaptic plasticity, field potentials were recorded in superficial layers of PRh while applying high-frequency stimulation in LA. Preliminary results indicate that this amygdalar pathway can be potentiated. Stimulation applied to superficial layers of adjacent cortical areas can either potentiate or depress responses recorded in superficial PRh. We are investigating whether there exists cooperativity or associativity between the LA and intracortical inputs to PRh. Future studies will examine whether this plasticity is NMDA-dependent, and if the input from LA can serve as a "reinforcement signal" to consolidate intracortical plasticity in PRh. (Supported by NIH and Yale University)

INTRINSIC CIRCUITS OF FUNCTIONALLY SPECIALIZED SUBDIVISIONS OF HUMAN CEREBRAL CORTEX. M.F. Kritzer¹. Dept. Neurobiology and Behavior, SUNY @ Stony Brook, Stony Brook, N.Y. 11794-5230.

Analyses of intrinsic cortical circuits in non-human primates have shown that the organization of these connections is region-specific (e.g., Lund et al., Cerebral Cortex 3:93; Harel and Malach, J. Comp. Neurol. 334:93). This study indicates that local circuitry, and particularly that of upper layers, likewise provides anatomical signatures to functionally specialized cortices in man.

Intrinsic circuits were labeled with dil in post-mortem human primary motor, somatosensory and visual cortex, and orbitofrontal, inferotemporal and posterior parietal cortices of 7 adult males. Comparison of circuits among corresponding layers of these areas revealed i) region-specific differences in the local circuits of supragranular layers and ii) cortical-wide similarity in the wiring of infragranular laminae. In area 17, for example, supragranular sites yielded the expected pattern of strong bilaminar lateral labeling of comparable density and breadth (3-5 mm) in layers I/II and V (Burkhalter et al., J. Neurosci. 13, '93). Similar injections in somatosensory cortex, however, were distinguished by lateral labeling in layers I/II which was not only more dense but extended almost twice as far (-6 mm) as labeling in layer V. Layer I/II sites in areas 40 and IT also produced dense lateral labeling (3-4 mm) in layers I/II; however, a sparse complement of fibers in layer V which consistently spread further laterally (5-7 mm) than supragranular axons was characteristic of these injections. Finally, layer I/II sites in motor cortex were unique in yielding laterally restricted labeling (1-3 mm) in all layers. These areally-specific supragranular patterns contrasted with labeling produced by crystals placed in layers V or VI which was laterally extensive (3-7 mm) in layers III and V, or layer VI (5-7 mm), respectively, in every region. The local circuits of supragranular layers may thus be of particular importance to the generation and/or elaboration of the computations/physiology which distinguish functionally specialized domains of the human cerebral cortex.

Ultrastructural analysis of the A-subtype of the α_2 -adrenergic receptor in the monkey prefrontal cortex reveals enrichment of post-synaptic and axonal labelling in lamina 5. C. Venkatesan¹, H. Kurose² and C. Aoki¹. ¹Center for Neural Science, New York University, NY, NY 10003 & ²Univ. of Tokyo, Dept. of Toxicology and Pharmacology, Hongo 7-3-1, Bunkyo-ku, Tokyo 113.

Activation of α_2 -adrenergic receptors (α_2 AR) in monkey prefrontal cortex has been shown to enhance memory and learning. Recently, antibodies were produced against the A, B and C subtypes of the α_2 AR. Using an antibody against the A subtype, we show that the distribution of perikarya labelled for the α_2 AR resembles the pattern obtained by Nissl staining. Puncta, ca. 1 - 2 μ m, can be visualized over cells bodies. Electron microscopy reveals these puncta to reflect labelled endoplasmic reticulum and Golgi apparatus within perikarya and intensely labelled axons which course along the perikaryal plasma membrane. The immunoperoxidase product is also present within glial, presynaptic, postsynaptic and nonsynaptic profiles. Immunoreactive presynaptic and postsynaptic profiles form both symmetric and asymmetric junctions. Semi-quantitative analysis reveals that the relative proportions of labelled profiles are distinct within and across cortical laminae. The majority of labelled profiles in layers II, IV, V and VI are axonal. Layer V, which contains the highest noradrenergic fiber density, also contains the highest areal density of profiles labelled for the α_2 AR. Moreover, this layer exhibits a relatively higher proportion of ir-axons and ir-postsynaptic densities than the other laminae. These results demonstrate that the functionally and anatomically distinct laminae also contain unique subcellular distribution patterns of the receptor. CA is supported by NIH EY08055 (FIRST), NS30944, NSF RCD9253750 (Presidential Faculty Fellowship) & HFSP RG-16/93.

COMPARISON OF INTRA- AND INTER-AREAL PATTERNS OF CONNECTIVITY IN MONKEY PREFRONTAL CORTEX. M.L. Pucak^{*1}, J.B. Levitt³, J.D. Classey³, J.S. Lund³, and D.A. Lewis^{1,2}. Depts. of Psychiatry¹ and Neurosci.², U. of Pittsburgh, Pittsburgh, PA 15260, and Dept. of Visual Science³, U. of London, England.

The excitatory axon terminals that furnish intra- and inter-areal connections in monkey prefrontal cortex (PFC) are both arranged in discrete clusters. However, little is known about the relations between these two types of terminal fields, or about the distribution of their neurons of origin. Single injections (350 µm diam.) of biotinylated dextran amine in superficial layers of areas 9 or 46 of macaque monkey PFC produced two distinct types (intra- and inter-areal) of clusters of anterogradely-labeled axon terminals. Within areas 9 or 46, labeled terminals formed multiple stripes (.45 × 1.4 mm) in layers 1-3 that were similar to the intrinsic lattice structure formed by the intra-areal axon collaterals of layer 2/3 pyramids as revealed by the tracer biocytin (Levitt et al., 1993). Terminals from the same injection also formed bands (.49 × 1.2 mm) at substantially greater distances from the injection site. These axon terminals, which were distributed across all cortical layers, arose from labeled axons in the underlying white matter. Similar injections of cholera toxin B (CtB) revealed two analogous types of clusters of retrogradely-labeled pyramidal neurons. Within areas 9 and 46, labeled neurons formed stripes (.42 × 1.2 mm) primarily in layers 2/3, whereas in other PFC regions, clusters of labeled neurons were present in both superficial and deep layers. Anterogradely-labeled CtB axon terminals overlapped both the intra- and inter-areal cell clusters, revealing the reciprocity of these connections. These findings confirm the discontinuous distribution of both intra- and inter-areal connections in monkey PFC. They also demonstrate that each point in the intrinsic lattice furnishes divergent output to multiple zones within the lattice as well as to other PFC regions, and receives convergent input from these same zones. These patterns of reciprocal intra- and inter-areal connections provide an anatomical substrate for the simultaneous and recurrent activation of specific distributed networks of neurons in monkey PFC.

578.11

DENDRITIC MORPHOLOGY OF NEURONS WITH DIFFERENT AXONAL PROJECTIONS IN MONKEY PREFRONTAL CORTEX. A.S. Soloway^{*1}, M.L. Pucak², and D.A. Lewis^{1,2}. Depts. of Neuroscience¹ and Psychiatry², Univ. of Pittsburgh, Pittsburgh, PA 15260.

The dendritic morphology of pyramidal neurons, the major source of excitatory intra- and inter-areal cortical connections, has been reported to differ depending upon the target of their efferent axons. In addition, separate populations of neurons have been shown to furnish associational and callosal projections from a given region of monkey prefrontal cortex (PFC). In this study, injections of the fluorescent tracer Fast Blue (FB) into areas 9 or 46 of cynomolgus monkey PFC were used to identify associational and callosal neurons in these areas. Retrogradely-labeled neurons were then intracellularly injected with Lucifer Yellow in fixed slices (300 µm), converted to an immunoperoxidase label, and reconstructed using the Eutectic Neuron Tracing System. Neurons providing associational projections were pyramidal or modified pyramidal cells located predominantly in layers 2-3, with a smaller number in layers 5-6. Associational neurons in the superficial layers shared the following characteristics: an apical dendrite which extended into layer 1, a basilar dendritic tree which was confined to layers 2-3, and a dendritic arbor with a horizontal extent of 200-400 µm. The laminar location, vertical and horizontal spread of the dendritic tree, and the pattern of dendritic arborization of associational neurons is quite similar to that of neurons whose axon collaterals form the lattice-like structure of intra-areal connections. These similarities are consistent with other evidence indicating that a subpopulation of PFC neurons furnishes both inter-areal and intra-areal connections (Melchitzky et al '94). Callosal neurons were also similar to associational neurons in their laminar distribution and somal morphology; quantitative assessments of dendritic arborization and complexity, as well as measures of excitatory input, will be used to directly compare these two non-overlapping cell populations.

REGIONAL NONHOMOGENEITIES IN CORTICAL ASTROGLIA IN ADULT MONKEYS. PERSISTENCE OF TRANSITIONAL FORMS. J.A. Colombo^{*} and V. Puissant. Programa Unidad de Neurobiología Aplicada (PRUNA)(CEMIC-CONICET), Av. Galván 4102, 1431 Buenos Aires, Argentina.

Cerebral cortex organization during development depends on radial glia. Both, radial- and transforming (intermediate) glia reportedly do not persist into late postnatal life. We report findings in three adult, *Cebus apella* monkey brains processed for vimentin and GFAP, utilizing the peroxidase-antiperoxidase procedure. Regional non-homogeneities in the distribution of cortical, vimentin + and GFAP + astrocytes were characterized by dense patches of astroglial processes with no obvious relationship to vascular elements, followed by others with scattered immunoreactive material. Additionally, relatively abundant, long astrocytic processes were observed stemming from layer I through III/IV in several areas of the temporal lobe, medial- and dorsolateral frontal cortices, as well as cingulate cortex. Persistent presence of "transforming" astrocytes in adult life of the New World monkey *Cebus apella* are of unknown physiological role. These observations reinforce the notion that astroglia plays ubiquitous roles in cortical function during postnatal life. Acknowledgments: CONICET, Fundación Conectar, Petrolera Argentina S. Jorge, Universidad de Belgrano.

MORPHOLOGY AND EXTRINSIC TARGETS OF PYRAMIDAL NEURONS FURNISHING INTRA-AREAL CONNECTIONS IN MONKEY PREFRONTAL CORTEX. D.S. Melchitzky^{*1,2}, M.L. Pucak¹, R.S. Dammerman², and D.A. Lewis^{1,2}. Depts. of Psychiatry¹ and Neurosci.², University of Pittsburgh, Pittsburgh, PA 15260.

Pyramidal neurons in the superficial layers of monkey prefrontal cortex (PFC) furnish horizontally-spreading axon collaterals which form a lattice-like structure comprised of multiple stripes (Levitt et al., 1993). Because the function of this intra-areal circuitry depends on the input and output of the cells which furnish it, we investigated the dendritic morphology and extrinsic projections of those neurons. Small iontophoretic injections of biotinylated dextran amine (BDA) were made into areas 9 or 46 of cynomolgus monkeys. We analyzed those retrogradely-labeled neurons 1) which were labelled via their axon collateral projections and 2) for which BDA provided complete filling of dendrites. Typical features of these pyramidal neurons included: location in layers 2/3, an axon which emitted collaterals on its course toward the white matter, apical dendrites extending into layer 1, and basilar dendritic trees which were confined to layers 2/3. The horizontal extent of the dendritic arbor (250-450 µm) was similar to the width of intrinsic lattice stripes (Levitt et al., 1993), suggesting that these neurons sample input from a single stripe. In order to determine the destination of the extrinsic projection of these neurons, dual injections were made: 1) cholera toxin B (CtB) in areas 9 or 46, to label neurons with intrinsic axon collaterals within these areas, and 2) Fast Blue (FB) in another area of PFC, to label associationally-projecting neurons. In locations where the tracers overlapped, 46.5% (144/310) of FB-labelled neurons were also labelled with CtB. Thus, neurons which furnish axon collaterals of the intrinsic lattice also provide associational projections. The laminar location of the dendritic arbor of these neurons indicates that they may receive intra- and/or inter-areal input. These features suggest that the intrinsic lattice plays an important role in cortical information processing by permitting the simultaneous activation of discrete, spatially segregated groups of neurons, resulting in a specific pattern of output from the PFC to other cortical areas.

578.12

CALRETININ-IMMUNOREACTIVE NEURONS IN MONKEY PREFRONTAL CORTEX: ULTRASTRUCTURE AND ASSOCIATIONS WITH DOPAMINE AFFERENTS. D.A. Lewis^{*}, C.L. Snyder, and S.R. Sesack. Depts. Psychiatry and Neuroscience, Univ. Pittsburgh, Pittsburgh, PA, 15213.

The calcium-binding protein, calretinin (CR), is present in a morphologically distinct population of local circuit neurons in superficial layers of monkey prefrontal cortex (PFC). This morphological cell class has previously been shown to target both pyramidal and non-pyramidal neurons. Furthermore, the morphological features and laminar position of CR-containing cells suggest that they may be synaptic targets of dopamine (DA) afferents. We examined the ultrastructural features of these neurons in area 9 of macaque monkey using a pre-embedding immunogold marker and investigated their association with DA terminals by combining immunogold staining with peroxidase immunoreactivity for tyrosine hydroxylase (TH). CR-positive axon terminals made synaptic contacts with cell soma, as well as large and small diameter dendrites. These contacts were primarily of the symmetric type. Many of the small dendritic targets had the morphological characteristics of non-pyramidal neurons, but were not immunoreactive for CR. CR immunoreactivity was also observed in small non-pyramidal neurons whose dendrites were distinctly varicose and received abundant synaptic input. In double labeled sections, immunomarkers for CR and TH were frequently observed in adjacent areas of the neuropil. However, appositions between labeled processes were rare, and specific instances of synaptic input were not observed. Although our previous findings demonstrated that DA terminals directly innervate some GABAergic interneurons in the PFC, the present findings suggest that CR-containing interneurons are not included in this target population. However, a more indirect modulatory interaction between CR and TH-containing processes is suggested by their common distribution.

AGE-DEPENDENT GABA_A RECEPTOR REGULATION IN RAT SENSORY AND ASSOCIATION CORTEX. J.C. McEachern, J. Church^{*}, C.A. Shaw. Depts. of Physiology, Anatomy & Ophthalmology, Vancouver, BC V6T 1Z3.

Sensory cortex exhibits age-dependent differences in magnitude and direction of ionotropic receptor regulation in response to agonist and depolarizing stimulation (Shaw & Scarth, *Mol. Brain Res.*, 14 (1992) 207). These developmental changes in receptor regulation correspond temporally with the critical period for long-term potentiation (LTP) (Perkins & Teyler, *Brain Res.*, 439 (1988) 222) and are postulated to be an important mechanism underlying this form of neuroplasticity. Neuroplasticity in association cortex, however, may not be limited to a critical period. If this is the case, its developmental profile of receptor regulation may differ from that characteristic of sensory cortex. A profile of GABA_A receptor regulation at various ages was prepared for frontal association areas Fr 1, 2 and 3 (Kolb & Tees, *The Cerebral Cortex of the Rat*, 1990) versus sensory cortex areas. Cortical slices from these areas in rats aged 10d, 16d or >70d were treated with veratridine or muscimol, labeled using [³H]-SR 95531 and compared to controls. In both sensory and association cortex veratridine treatment resulted in a decrease in receptor number at 10d, but an increase at 16d and older. At all ages muscimol treatment resulted in a decrease in receptor number in both cortical areas. These comparable profiles suggest either: 1) similar age-dependent characteristics of receptor regulation in the two areas, and hence a) association cortex critical period for neuroplasticity may be identical to that of sensory cortex, or b) age-dependent receptor regulation is not a key determinant of critical periods; or 2) these frontal areas in the rat are not true association cortex.

CORTICOCORTICAL CONNECTIONS MEDIATE DIRECTED ATTENTION IN RATS: BEHAVIORAL AND ANATOMICAL EVIDENCE. R.L. Reep*, I. Vandeveld, E. Duckworth, M. Stoll and J.V. Corwin, Department of Physiological Sciences, University of Florida, Gainesville, FL 32610; and Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

We investigated the role of corticocortical connections in directed attention by selectively disconnecting areas AGm and PPC, then testing animals for signs of hemispatial neglect. In rats, these two cortical areas are involved in spatial orientation and are highly interconnected via rostrocaudally directed axons traveling both directions in the deep gray matter. Therefore, coronally oriented knife cuts which extend into layer VI but do not encroach upon the white matter should selectively transect these axons without interrupting those directed subcortically.

Knife cuts extending into layer VI (N=6) produced neglect, whereas control cuts extending only as deep as layer V (N=4) did not ($p < .02$). The deeper knife cuts resulted in appreciably less axonal labeling than normal and a very sparsely labeled region rostral to the cut, whereas control subjects with shallower cuts exhibited labeling which was comparable to normals.

These results suggest that the corticocortical axons linking AGm and PPC play a pivotal role in directed attention.

FUNCTIONAL NEURAL IMAGING OF NAUSEA IN HUMANS. T. Roberts, A. Miller, H. Rowley and J. Kucharczyk*, Neuroradiology Section, UCSF, San Francisco, CA 94143 and + Lab. Neurophysiol., Rockefeller Univ., New York, NY 10021

Considerable progress has been made in recent years in determining the CNS mechanisms which mediate vomiting. However, the neuronal substrates that subserve nausea are completely unknown. The present study used functional neuroimaging techniques to determine if a localized cortical area is activated during nausea. Functional data were obtained using a 37-channel SQUID-based magnetic source imaging (MSI) device (Magnes, Biomagnetic Technologies Inc., San Diego, CA) and were overlaid on neuroanatomical information from high-resolution 3D SPGR MRI. Data were analyzed for the occurrence of transient bursts of magnetic activity (exceeding 400fT when data were filtered in the range 8-100Hz). These were used to derive the location of the responsible neural source using the single equivalent dipole model. Data have been obtained from one volunteer in which nausea was produced on two separate days by either oral ingestion of syrup of ipecac or by vestibular stimulation (induced by head movements during yaw-axis rotation, while wearing vision-reversing goggles). Current dipoles indicative of neuronal activation were localized to a 2-3cm diameter region of cortex in the inferior frontal gyrus, when nausea was produced by either stimulus. Such activity was not observed during baseline controls or during sequences involving swallowing or exaggerated respiratory movements. While preliminary, the data suggest that MSI may provide a quantitative means of measuring the effects of various pharmaceutical interventions on nausea and suggest a new CNS target for such intervention.

Supported by grants from NIH (NS20585 to AM).

APOMORPHINE ADMINISTRATION PRODUCES ACUTE DOSE-DEPENDENT RECOVERY FROM NEGLECT FOLLOWING UNILATERAL POSTERIOR PARIENTAL CORTEX LESIONS IN RATS. J.V. Corwin*, G.J. Hix, K.J. Burcham, and C. Gordy, Psychology Dept., Northern Illinois Univ., DeKalb, IL 60115.

Previous research from our laboratory (Corwin et al., 1986; King and Corwin, 1990) has indicated that apomorphine (apo) has an acute dose-dependent therapeutic effect on neglect induced by unilateral destruction of the medial agranular prefrontal cortex (AGm), suggesting that neglect may result from a disruption of dopaminergic mechanisms. To extend the potential applicability of these findings to humans, in which the vast majority of cases of neglect are produced by unilateral destruction of the posterior parietal cortex (PPC), the present study examined the effects of apo administration on neglect induced by unilateral destruction of the PPC.

Subjects were 20 Long-Evans hooded male rats. After extensive handling, the subjects received an ablation of either the left or right PPC via aspiration. At 48-96 hrs post-surgery, the subjects were tested for the presence of multimodal neglect, determined by the degree of head orientation in response to presentation of visual, tactile, or auditory stimuli. Subjects which met the criterion for severe neglect (defined by a ratio of responsiveness of the neglect side:non-neglect side of $\leq 1:3$) were randomly assigned to one of four apo dosage groups: vehicle, 0.1, 0.3, or 0.5 mg/kg. Apo or the vehicle was administered i.p. 45-60 min after behavioral testing. Eighteen minutes post-injection, the subjects were retested. All behavioral testing was done with the experimenter "blind" with respect to the dosage administered.

There was a significant reduction in the severity of overall neglect in the 0.3 and 0.5 mg/kg groups ($p < .05$), but not in the vehicle or 0.1 mg/kg groups. The results indicated that apo produces an acute dose-dependent therapeutic effect on multimodal neglect produced by PPC lesions. As found for the AGm, neglect produced by unilateral PPC removal may be a result of disruption of dopaminergic mechanisms.

COMPARATIVE NEUROANATOMY: SENSORY SYSTEMS

579.1

SOME MORPHOLOGICAL FEATURES OF A VISUAL THALAMIC NUCLEUS IN A REPTILE. M.B. Pritz*, Sect. of Neurol. Surg., Indiana U. Sch. of Med., Indianapolis, IN 46202-5124.

Nucleus rotundus is a prominent nucleus in the dorsal thalamus of all non-mammalian vertebrates. In one group of reptiles, Caiman crocodilus, this neuronal aggregate contains relay cells only and lacks local circuit neurons. The present study investigated some aspects of rotundal cytoarchitecture based on examination of Nissl morphology. Neurons were not uniformly distributed throughout the nucleus but were grouped in clusters commonly ranging from 2 to 5 cells. Somas were round, oval or triangular in shape. The following neuronal morphological features were investigated: area, perimeter, and roundness or eccentricity expressed as the ratio of greatest width to greatest length. Preliminary observations, mean \pm standard deviation, examined neurons in each of 3 planes: horizontal (N=50), sagittal (N=50), and transverse (N=50). Measurements were as follows: (1.) area (μm^2) = 196.88 ± 46.13 - horizontal; 205.58 ± 50.69 - sagittal; and 202.93 ± 39.12 - transverse; (2.) perimeter (μm) = 55.32 ± 7.64 - horizontal; 56.46 ± 7.35 - sagittal; and 54.96 ± 5.70 - transverse; (3.) roundness: 0.67 ± 0.13 - horizontal; 0.62 ± 0.10 - sagittal; and 0.71 ± 0.11 - transverse. Additional observations will be made to determine whether these morphological features identify subpopulations of relay cells in nucleus rotundus.

579.2

A COMPARISON OF THE EIMER'S ORGANS OF THE STAR-NOSED MOLE (CONDYLURA CRISTATA), THE HAIRY TAILED MOLE, (PARASCALOPS BREWERI), AND THE EASTERN MOLE (SCALOPUS AQUATICUS). K. C. Catania*, Neurobiology Unit, Scripps Institution of Oceanography and Dept. of Neurosciences, School of Medicine, Univ. of Calif., San Diego, La Jolla, CA 92093-0201.

Eimer's organ is a tactile sensory structure found on the snouts of moles and some shrews. It consists of a raised dome of epidermis containing a column of cells associated with sensory receptors. Scanning electron microscopy and light microscopy were used to compare the structure and distribution of these organs in three North American moles.

Eimer's organs are visible on the skin surface of the hairy tailed mole and the star-nosed mole, but not the eastern mole. The external appearance, distribution, and internal structure of the Eimer's organs of the hairy tailed mole are similar to those most commonly found in other species. The structure of the Eimer's organs of the star-nosed mole and the eastern mole diverge from this basic form in seemingly opposite directions. The Eimer's organs of the star-nosed mole are more numerous, smaller, highly organized units with little variability and a consistent pattern of terminal swellings within a cell column, just below a thin keratinized epidermis. By contrast, the Eimer's organs of the eastern mole lie below a thick keratinized epidermis, are larger and more variable in structure, and have no central cell column. These differences may be influenced by the soil type through which each species burrows; saturated mud allowing a more elaborate and delicate sensory apparatus in the case of the star-nosed mole, and dry abrasive soil requiring a thick keratinized epidermis over the receptor complex in the case of the eastern mole. Supported in part by NIH grants NS24869 to R. Glenn Northcutt, and 5132-GM 08107 (Biology Training Grant).

579.3

THE ANURAN DORSAL COLUMN NUCLEI: ORGANIZATION, IMMUNOHISTOCHEMICAL CHARACTERIZATION AND FIBER CONNECTIONS. A. Muñoz, M. Muñoz, A. González and H.J. ten Donkelaar* Dept. of Cell Biology, Fac. Biol. Complutense University of Madrid, 28040 Madrid, Spain, and *Dept. of Anatomy and Embryology, Fac. Medical Sciences, University of Nijmegen, P.O. Box 9101 6500 HB Nijmegen, The Netherlands.

The organization and fiber connections of the dorsal column nuclei (DCN) of the anurans *Rana ridibunda* and *Xenopus laevis* are studied with immunohistochemistry and tract tracing. Primary afferents from cervical, thoracic and lumbar spinal dorsal roots reach the DCN somatotopically arranged. Primary afferents from the cranial nerves V, VII, IX and X innervate the DCN via the descending trigeminal tract. Nonprimary afferents arise bilaterally in cells of the rhombencephalic reticular formation, area octavolateralis, cerebellar nucleus, raphe and throughout the spinal cord. The main efferent projection of the DCN, i.e. the medial lemniscus is formed by DCN fibers that cross the midline at the level of the nuclei and innervate contralaterally the rhombencephalic reticular formation, the octavolateral area, cerebellum, the principal, magnocellular and mainly the laminar nucleus of the torus semicircularis, the anterodorsal and anteroventral (including the red nucleus) mesencephalic reticular areas and in *X. laevis* the intermediate and deep layers of the tectum. At diencephalic levels the medial lemniscal fibers innervate the posterior tubercle, the ventral thalamus (ventromedial and ventrolateral nuclei), and sparsely the posterior and central nuclei of the dorsal thalamus. Ipsilateral, extralemniscal, DCN efferents reach the granular layer of the cerebellum and descending efferent fibers innervate the spinal cord. Histochemical and immunohistochemical observations of the DCN area revealed the presence of GABAergic, glycinergic, as well as parvalbumin (in *X. laevis* also calbindin), and NADPH diaphorase positive neurons in the DCN. Terminal structures positive for 5-HT, CGRP, SP, NPY and NADPH diaphorase are present in the DCN.

579.5

PROJECTIONS OF THE NERVUS TERMINALIS IN THE THORNBARK RAY, (*PLATYRHINOIDIS TRISERIATA*)

M.H. Hofmann, R.G. Northcutt and T.H. Bullock*. Dept. Neurosciences, U.C. San Diego, La Jolla, CA 92093-0201.

The nervus terminalis (NT) was discovered more than a century ago in elasmobranchs. Presumed homologs of this cranial nerve have been investigated in many vertebrate classes. However, only a few data are available on the connectivity of the NT in elasmobranchs.

We investigated the projections of the NT by means of biotinylated dextran amine (BDA) injections into the olfactory bulb (OB) and rostral telencephalon at the entrance of the NT in the thornback guitarfish, *Platyrhinoidis triseriata*.

Injections of BDA into the OB revealed labeled fibers entering the forebrain in the NT, proceeding caudally in a medial position adjacent to the recessus neuroporici and penetrating septal and preoptic areas. Labeled cell bodies were observed only in the medial part of nucleus preopticus, above the optic chiasm. Injections into the area where the NT enters the forebrain revealed labeled cells in all of the ganglia along the course of the NT towards the lateral part of the OB. Previous work has shown that the NT carries tonic efferent activity [Bullock and Northcutt Neurosci Lett 44(1984)155-160]. The labeled cells we found in the nucleus preopticus are possibly the source of these efferents.

-Supported by a DFG grant to MHH and NIH grants to RGN and THB.

579.7

AFFERENT AND EFFERENT CONNECTIONS OF THE VESTIBULOLATERAL CEREBELLUM IN THE CHANNEL CATFISH R.C. Raybourn and J.G. New*. Dept of Biology and Parmlly Hearing Institute, Loyola University Chicago, Chicago, IL 60626.

The vestibulolateral cerebellum of the catfish is comprised of two discrete granule cell nuclei: a lateral (ELG) and medial (EGm) eminentia granularis. Previous studies have demonstrated that these two areas receive afferent nerve fiber input from lateral line (mechanosensory and electrosensory) and octaval nerves respectively. Axons of granule cells in the eminentiae form a portion of the cerebellar crest that projects back over the medullary octavolateralis nuclei and modulates the activity of ascending medullary sensory neurons. The purpose of this study is to determine other sources of afferent input to the eminentia granularis.

Channel catfish were anesthetized with MS-222 and the divisions of the eminentia granularis were labelled with either horseradish peroxidase or Dil. After suitable transport times the brains were sectioned and viewed via light or fluorescence microscopy.

The bilateral eminentiae granularis are heavily interconnected by commissural fibers that decussate through a deep cerebellar commissure dorsal to the cerebral aqueduct. Additional afference arises bilaterally from the inferior olivary nuclei and two basal medullary nuclei. One of these nuclei is located in the posterior brainstem dorsal to the inferior olive, the other is positioned more rostrally and laterally. In the metencephalon both the nucleus praeminialis and the nucleus of the medial longitudinal fasciculus provide bilateral afference to the EC.

The eminentia granularis is part of a descending central control system that provides gain control and adaptive filtering to the octavolateralis sensory systems. Our results indicate several new sources of afference that presumably play a role in modulating the flow of ascending information. These sources may provide proprioceptive and somatosensory reafferent input to the brain which is then filtered to increase the signal to noise ratio in the sensory lemniscal system.

Supported in part by NIH NS30194 to JGN.

579.4

A NOVEL CUTANEOUS SENSORY SYSTEM IN HAGFISH. C.B. Braun* Neurobiology Unit, Scripps Institution of Oceanography and Dept. of Neurosciences, School of Medicine, University of Calif., San Diego, La Jolla, CA 92093-0201.

Ultrastructural and neuroanatomical investigations of the skin of the Pacific Hagfish, *Eptatretus stouti*, have revealed sensory buds, similar to those previously described on the barbels (Georgieva et al. 1979, Zoo. Scr. 8:61-67), in large numbers in the skin of the prenasal duct and on the head, trunk, and tail. Densities are highest near the snout and mouth (mean density 24 buds per mm²) and decrease caudally to about 11 buds per mm² on the trunk and tail. Interestingly, sensory buds are uncommon or absent from most of the oral epithelium and pharynx. These organs resemble taste buds, and are likely chemosensory, but differ from taste buds in their distribution and innervation. Unlike vertebrate taste buds, hagfish sensory buds are innervated by both cranial and spinal nerves. All internal sensory buds, and those on the snout and rostral head are innervated by branches of the trigeminal complex. All other sensory buds are innervated by spinal nerves. Such a pattern of innervation is unique among vertebrate special sensory organs and may explain some aberrant features of the myxinoide hindbrain. A large portion of the sensory trigeminal nucleus is argued to actually represent the rostral segment of the special visceral sensory (gustatory) column. Supported in part by NIH grant DC01081 to R.G. Northcutt

579.6

MIDBRAIN ROOF-DORSAL THALAMIC CONNECTIONS IN RANID FROGS. T.J. Neary* and W. Wilczynski. Anatomy Div., Creighton Univ., Omaha, NE 68178 and Psychology Dept., Univ. of Texas, Austin, TX 78712.

Iontophoretic injections of WGA-HRP were made in the anterior nucleus and middle thalamic zone (MTZ) of the dorsal thalamus in bullfrogs (*R. catesbeiana*) and midbrain roof populations examined for labelled cells. Injections involving the anterior nucleus consistently labelled cells bilaterally in the pretectal grey and ipsilaterally in the principal toral nucleus (TSp), particularly in its lateral, somatosensory part. Medial applications in the MTZ labelled cells in the ipsilateral pretectal grey and in the TSp, where most labelled cells were present medially and centrally. Injections in the intermediate MTZ resulted in greater labelling in the lateral part of the TSp and less in its medial part. They also labelled cells in the pretectal grey and a few cells in laminae 6 and 8 of the optic tectum. Lateral injections of the MTZ labelled more cells in laminae 6 and 8 of the optic tectum and also labelled cells in the pretectal grey and the lateral part of the TSp. In general, dorsal thalamic injections of WGA-HRP only rarely labelled cells in the laminar or magnocellular toral nuclei. Our findings suggest that the anterior nucleus may be more concerned with somatosensory than auditory information and that there is a crude topographic map between the tectum/torus and the middle thalamic zone.

MULTIPOLAR INTRAZONAL NEURONS IN THE MORMYRID ELECTROSENSORY LATERAL LINE LOBE: MYELINATED DENDRITES AND RECIPROCAL SYNAPTIC CONNECTIONS INVOLVED IN CENTER SURROUND INHIBITION. J. Meek¹, K. Grant^{2*} and T.H.M. Hafmans¹. ¹Department of Anatomy and Embryology, University of Nijmegen, P.O. Box 9101, 6500 HB Nijmegen, The Netherlands, ²Institut Alfred Fessard, CNRS, 91190 Gif sur Yvette, France

The mormyrid electrosensory lateral line lobe (ELL) compares primary sensory electroreceptive input with electromotor command feedback to localize objects in the environment of the fish. To investigate the neuronal and synaptic basis of the underlying sensorimotor integrative mechanisms, we injected neuroanatomical tracers into the ELL (phaseolus-leucoagglutinin and Biotinylated Dextran Amine), analyzed the labeled neurons and terminals light- and electronmicroscopically, and extended the results with GABA immunohistochemistry. Tracer injections in the deep layers of the ELL resulted in the labeling of large and smaller neurons in the ipsi- and contralateral ELL, corresponding to the intrazonal neurons described previously (Bell CC, Finger TE and Russell CJ, 1981, Exp Brain Res 42:9-22). The large neurons exclusively have myelinated processes: a single one with clear axonal features and a number of others probably representing myelinated dendrites. They are GABAergic, have only a few synaptic terminals on their cell bodies, and make contacts with gap-junction-like specializations on granule- and intermediate layer cells. These contacts might well allow for reciprocal signal transport, i.e. excitation of the intrazonal neurons by primary afferents via the granule- and intermediate layer cells, and inhibition of the latter neurons by intrazonal neuron activity. Thus, they probably subserve the center-surround inhibition described by Bell on the basis of intracellular unit recordings (1990, J Neurophysiol 63:304-318).

579.9

THE DEVELOPMENT OF THE ELECTROSENSORY LATERAL LINE LOBE IN THE CATFISH *AMEIURUS NEBULOSUS* (SILURIFORMES: SILUROIDEA). M.J. Lannoo* and S.J. Lannoo. Muncie Center for Med. Educ., Indiana Univ. Sch. of Med., Muncie, IN 47306

Within electrosensory siluriform teleosts, generalized, passively electroreceptive species (silurids) form an electrosensory lateral line lobe (ELL) consisting of one somatotopic map. Derived species (gymnotids) are actively electroreceptive with an ELL composed of four somatotopic maps. This system is an experimentally accessible model for the study of multiple map formation. The development of the gymnotoid four map nucleus has been described previously. Here, we begin to describe the development of the one map silurid nucleus for comparison with the gymnotoid four map system. *Ameiurus* embryos and larvae were staged according to Armstrong and Child, in which hatching occurs at stage 43. Using nissl-stained histological sections of *Ameiurus* larvae, juveniles, and adults cut at 6 μ m in transverse and sagittal planes we report that: 1) the ELL can be distinguished as a subpial, laterally positioned cellular region located dorsal to the central projection of the unfused anterior ganglion by stage 35, the youngest stage in our sample; 2) the ELL cellular layers develop from the extreme dorsolateral periventricular region; 3) the ELL molecular layer begins to form by stage 45; 4) the ELL can be distinguished from the (mechanosensory recipient) nucleus medialis by stage 50; and 5) lamination of ELL cellular layers is visible by stage 53. Supported by NIH grant NS 30702, to M.J.L.

COMPARATIVE NEUROANATOMY: CHEMICAL ANATOMY

580.1

COMPARATIVE LOCALIZATION OF NITRIC OXIDE SYNTHASE IN THE VERTEBRATE SPINAL CORD. G. Brünig* Department of Anatomy, Free University of Berlin, D-14195 Berlin, Germany.

The localization of nitric oxide synthase was investigated in the spinal cord of mouse, chicken, turtle, frog and goldfish by NADPH diaphorase histochemistry. Specificity of the histochemical detection method was verified by colocalization with an antiserum against nitric oxide synthase purified from porcine cerebellum. In all vertebrate species, the motoneurons were, as a rule, unstained. Strongly stained neurons were concentrated in the dorsal horn. Widespread areas of the dorsal horn were filled by a dense terminal plexus which appeared to be formed chiefly by intrinsic neurons as dorsal root fibers were mostly negative. Intensely stained neurons were also scattered in the intermediate grey and the ventral horn. In the mouse, intensely positive neurons were clustered in the preganglionic sympathetic and parasympathetic nuclei. In the corresponding cell columns of nonmammalian species, stained neurons were detected only occasionally. In summary, these results indicate that, despite certain species differences, there is a considerable conservation in the expression of nitric oxide synthase in the spinal cord, suggesting that nitric oxide may influence sensory information processing throughout vertebrate species.

580.3

NITRIC OXIDE SYNTHASE IN THE LOCUS COERULEUS OF THE CHICK: DEVELOPMENT, DISTRIBUTION AND LACK OF CORRELATION WITH TRANSMITTER PHENOTYPES. A. Schober^{1,2}, M. Bothwell¹, and C.S. von Bartheld^{1*}. ¹Department of Physiology & Biophysics (SJ-40), University of Washington, Seattle, WA 98195; ²Department of Anatomy & Cell Biology, University of Heidelberg, D-69120 Heidelberg, FRG.

The distribution and morphology of nitric oxide synthase (NOS)-containing neurons was investigated in the locus coeruleus complex (LC) of chick embryos. The NADPH-diaphorase technique was used to detect the presence of NOS at the incubation days E8, E12, E18 and 14 days posthatch (P14). The first NOS expression in LC was found at age E12. The number of NOS-positive cells in the locus coeruleus proper (LoC) increased from E12 to E18 (450 to 850) and decreased slightly after hatching (P14). In the locus subcoeruleus (SC), NOS-containing neurons could be identified first at age E18. The number of NOS-expressing neurons increased from E18 to P14 (70 to 270). To determine which classical transmitter phenotype may be coexpressed with NOS, adjacent sections were immunolabeled for choline acetyltransferase (ChAT), for somatostatin (SOM) and for the low-affinity neurotrophin receptor (P75) as a marker for noradrenergic LC neurons (von Bartheld and Bothwell, 1992, J.Comp.Neural. 320:479-500). In addition, NADPH-diaphorase histochemistry was combined with immunocytochemistry of P75, ChAT and SOM in the same sections. NOS is not colocalized with the P75 receptor (noradrenergic cells) or SOM, and only few cholinergic cells (<10%) were double-labeled with NOS. In birds, NOS is an excellent marker for a major subpopulation of LC neurons. None of the classical neurotransmitters examined is colocalized in NOS-positive LC neurons. These results indicate that major differences exist between species, as the rat LC contains only few NOS-positive cells (Xu et al., 1994, Exp. Brain Res. 98:75-83). The expression of NOS may indicate a role of nitric oxide in developmental and physiological aspects of the LC in the chick brain.

580.2

DISTRIBUTION OF THE SUPEROXIDE DISMUTASE 1 (SOD1) IN THE MAMMALIAN NERVOUS SYSTEM. CA Pardo^{1*}, Z-S Xu², DW Cleveland³, and DL Price^{1,3,4}. Departments of ¹Pathology, ²Biological Chemistry, ³Neurology, and ⁴Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

SOD1, an enzyme participating in the free radical scavenger system, protects against oxidative stress. Recent evidence indicates that some cases of familial amyotrophic lateral sclerosis are linked to mutations in SOD1, but it is not clear how these mutations cause degeneration of motor neurons. A first step in understanding these processes is to define the cellular distributions of SOD1 in the nervous system. To this end, we have produced new specific antibodies to be used in Western blot and immunocytochemical studies. In human, monkey, baboon, rat, and mouse, SOD1 immunoreactivity (SOD1-IR) was identified primarily in neurons in the CNS and PNS. In spinal cord, SOD1-IR was present in motor neurons, interneurons, and diffusely in the substantia gelatinosa. Immunoelectron microscopic analysis disclosed that SOD1 was localized predominantly in the perikaryon, axonal and dendritic compartments, and euchromatic areas of the nucleus, and there was evidence of different levels of SOD1-IR among cell groups. In the hippocampal formation, neurons of the CA3-CA4 sectors were intensively SOD1 immunoreactive, whereas CA1 neurons showed less immunoreactivity. SOD1-IR was also demonstrated in large- and medium-sized pyramidal neurons of neocortex, subsets of neurons in pyriform cortex, amygdala, striatum, and thalamus. These findings indicate that SOD1 is present in many neuronal populations throughout the nervous system and that certain subsets of nerve cells, including motor neurons in spinal cord and brainstem, are enriched in this enzyme.

580.4

DISTRIBUTION OF CATECHOLAMINE IMMUNOREACTIVITY IN THE CENTRAL NERVOUS SYSTEM OF THE LIZARD *ANOLIS SAGREI*.

A. Rehn, P. Ekström and T. Östholm*, Dep. of Zoology, Univ. of Lund, Sweden. Adults of the "brown anole", *Anolis sagrei* (fam. Iguanidae, order Squamata) caught in Miami, Florida, USA and juveniles obtained from our own breeding colony were used in this study. Immunohistochemical methods with antibodies against the transmitter dopamine (DA) and the synthetic enzymes, tyrosine hydroxylase (TH), dopamine β -hydroxylase (DBH) and phenylethanolamine-N-methyltransferase (PNMT) were used to locate the distribution of catecholamine neurons in the anole CNS. Catecholaminergic neurons were observed in all parts of the brain. In the olfactory bulb, TH and DA immunoreactive (ir) neurons were observed in the glomerular layer and the external plexiform layer. In the telencephalon, THir neurons were seen in the nucleus septalis medialis. In the diencephalon, THir and DAir neurons were present in the periventricular preoptic area, the periventricular hypothalamic nucleus and the lateral hypothalamic area. CSF-contacting neurons in the periventricular hypothalamic organ were only DAir. THir neurons were present in the posterodorsal nucleus. Large groups of catecholaminergic neurons were found in the mesencephalon. THir and DAir neurons were located in the ventral tegmental area, the substantia nigra and the presumed reptilian equivalent of the mammalian A8 group. THir neurons were seen on the both sides of the cerebral aqueduct. In the rhombencephalon, THir, DAir and DBHir neurons were found to exist in the isthmus region, the nucleus of the solitary tract and in the area postrema. THir, DAir and PNMTir neurons were observed in the lateral part of the reticular formation. In the spinal cord, THir and DAir CSF-contacting neurons were present in the ventral wall of the central canal. The distribution of catecholaminergic neurons in *A. sagrei* is generally similar to that in previously studied reptiles (*Anolis carolinensis*, *Gekko gekko*, *Varanus exanthematicus*, *Chameleon ssp.*, *Pseudemys scripta elegans* and *Python regius*). However, a number of interspecific differences were observed. Supported by grants from the Swedish Natural Science Research Council.

580.5

DISTRIBUTION OF TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN THE BRAIN OF A GYMNOPHIONAN AMPHIBIAN. A. Gonzalez*, M. Munoz, A. Munoz, O. Marin and W.J.A.J. Smeets. Dept. Cell Biology, Fac. Biology, Univ. Complutense de Madrid, Spain and Research Inst. Neurosci. Vrije Univ. Amsterdam, The Netherlands.

The aim of the present study was to extend our knowledge of catecholamine systems (CA) in amphibians to the limbless amphibians, i.e. the gymnophionans. For that purpose, the distribution of CA neuronal structures in the permanent aquatic gymnophionan *Typhlonectes compressicauda* was studied by means of tyrosine hydroxylase (TH)-immunohistochemistry. A total of 14 TH-immunoreactive (THi) cell groups were found. They are located in the olfactory bulb, preoptic area, hypothalamus, pretectum, mesencephalic-isthmus and rhombencephalic tegmental areas, the nucleus of the solitary tract, the spinal cord and the retina. In addition, elaborated plexuses of THi fibers occur throughout the brain. Compared to the distribution patterns observed in anuran and urodele species, major differences were observed in the innervation of the pallial regions, the septum and the mesencephalic tegmentum. Nevertheless, when the distributional patterns of TH immunoreactivity of representatives of the three amphibian orders (Anura, Urodela and Gymnophiona) are compared with each other, it is obvious that there exists a basic pattern. Moreover, the organization of the CA in *Typhlonectes compressicauda* shares many features not only with other anamniotes, but also with amniotes.

(Supported by DGICYT PB90-0628 and NATO CRG 910970)

580.7

LHRH AND FMRF-AMIDE IMMUNOREACTIVITY IN THE GREEN TREEFROG. W. Wilczynski* and R. G. Northcutt. Dept. of Psychol., Univ. of Texas, Austin, TX 78712 and Dept. of Neurosci., UCSD, La Jolla, CA 92093.

Telencephalic gonadotropin releasing hormone cells are thought to be the principal regulators of gonadotropin, and hence sex steroid, secretion in vertebrates (Muske, BBE, 42:215-230, 1993). In some vertebrates, these cells are immunoreactive for both mammalian LHRH and FMRF-amide. We used standard immunocytochemistry methods to visualize these peptides in male *Hyla cinerea*. LHRH-ir cells were seen only in the medial septum and in a cluster rostral and dorsal to the anterior preoptic area (POA). LHRH-ir fibers appeared outside these areas in the medial and dorsal pallia, lateral septal nucleus, and nucleus accumbens. A few fibers extended to the olfactory bulbs and dorsal lateral pallium. Caudally, LHRH-ir fibers traveled periventricularly through the POA and in the medial forebrain bundle (MFB). Some fibers left the MFB to travel dorsally to the habenula. Most MFB fibers continued caudally to pretectal levels, where LHRH-ir fibers were also seen in the posterior tuberculum and dorsal hypothalamus. This system eventually formed a dense subpial plexus beneath the ventral hypothalamus. Some fibers continued caudally in the lateral and ventral midbrain fiber tracts. The periventricular system diminished caudal to the POA, but remained medial to the posterior tuberculum and dorsal hypothalamus and continued through the midbrain around the cerebral aqueduct and in the laminar toral nucleus. Caudal to the isthmus, only a few fibers remained beneath the 4th ventricle above the raphe nuclei. FMRF-amide immunoreactivity was much more extensive. Cells were present in the medial septum and POA where LHRH-ir cells were seen, as well as in the medial pallium, suprachiasmatic nucleus, posterior tuberculum, and dorsal hypothalamus. FMRF-amide-fibers were seen in all areas expressing LHRH-ir fibers, plus in a dense periventricular bundle adjacent to the ventral hypothalamus, in the deep layers of the optic tectum, and scattered in the diencephalon, midbrain, and reticular areas of the medulla as far caudal as the nucleus solitarius. (Supported by NIMH MH45350 and NIH NF24869.)

DISTRIBUTION OF LAMPREY GONADOTROPIN-RELEASING HORMONE-III IN LAMPREY BRAINS. S.A. Sower*¹, M. Nozaki, A. Gorbman, J.H. Youson and S.A. Tobet². ¹Dept. of Biochem. & Molec. Biol., Univ. of N.H., Durham, NH, 03824 and ²Prog. Neuroscience, Shriver Center, Waltham, MA 02254 and Harvard Medical School, Boston MA 02115.

Two immunoreactive forms of gonadotropin-releasing hormone (GnRH), lamprey GnRH-I and lamprey GnRH-III, were found in the neurons in larval and adult sea lamprey, *Petromyzon marinus*. Using antisera preferentially directed against either lamprey GnRH-I or -III, dense reaction product was seen in cell bodies in the rostral hypothalamus and preoptic area. Reaction product was also dense in fibers to and within the neurohypophysis, in addition to numerous fibers which projected caudally, beyond the neurohypophysis through the mesencephalon. The majority of immunoreactive GnRH in larvae was lamprey GnRH-III, and when lamprey GnRH-I was seen, it was in cells that appeared to contain both forms of GnRH. A small number of cells were found in the caudal hypothalamus of larvae but not adults. These cells contained only immunoreactive lamprey GnRH-III and may constitute a functional subgroup within the population of GnRH neurons. In animals undergoing metamorphosis there was a large increase in reaction product in all GnRH containing cells and fibers. The results are consistent with the hypothesis that lamprey GnRH-III is an important form of GnRH during the maturation of GnRH cells and fibers, and further indicates that these cells have attained their normal positions in the preoptic area and hypothalamus before metamorphosis. (Supported by Great Lakes Fishery Commission, and NSF DCB-9004332 and -8904919).

580.6

THE DISTRIBUTION OF GABA-LIKE IMMUNOREACTIVITY IN THE MIDBRAIN OF THE ATLANTIC STINGRAY. R.B. Leonard*, R.L. Puzdrowski and G.A. Kevetter. Depts. of Anat. & Neurosci., Physiology & Biophysics, Otolaryngology and Marine Biomedical Institute, Univ. TX Med Branch, Galveston, TX. 77555

As part of a study of projections to and from the midbrain in elasmobranch fishes, we have begun to examine the distribution of neurotransmitters within the brainstem of the Atlantic stingray (*Dasyatis sabina*). Because there are some theories about the distribution of inhibitory neurotransmitters within the brain, we have begun our study by examining the distribution of GABA. Our most consistent results to date have been obtained using a polyclonal antiserum against GABA conjugated to BSA (Sigma) combined with the ABC (Vector) method. Although we have not undertaken specificity controls in this species, specificity is suggested by the staining observed in other areas (e.g., cerebellum, and cerebellar crest). A large number of stained cells are observed in the optic tectum. The density of stained cells is greatest superficially, dropping to essentially zero in the deepest layers. Stained cells extend forward into portions of the pretectal area. There is a high density of stained cells in the medial mesencephalic complex, particularly in the ventral portion. In contrast, few stained cells are observed in the lateral mesencephalic nucleus. The exception is a population that extends laterally from the medial mesencephalic complex that appears to overlap the ventral portion of the lateral mesencephalic complex. Labeled cells are scarce in other areas of the midbrain. Labeled axons and terminals are numerous in the optic tectum, particularly in the superficial layers. Labeled terminals are observed around motoneurons in both the dorsal and ventral subdivisions of the oculomotor nucleus. Terminal label is also present in the Edinger-Westphal nucleus, is sparse in the periaqueductal grey and may be present in the red nucleus. Supported by grants from the NIH, DRF and Sealy Foundation.

580.8

DISTRIBUTION OF IMMUNOREACTIVE GLUCOCORTICOID TYPE II RECEPTOR STAINING IN THE BRAIN OF *Anolis carolinensis*.

Cliff H. Summers*, Amy-Lacy Adams, Jennifer Anderson, and Gary Ten Eyck. Department of Biology, University of South Dakota, 414 E. Clark, Vermillion, SD 57069-2390.

Brains of the lizard *Anolis carolinensis* were either frozen in tissue freezing medium or dehydrated, cleared, and embedded in wax. Following sectioning, 5 - 12 μ , brains were incubated at 4°C for 48 h with a polyclonal rabbit-anti-human glucocorticoid type II receptor antibody (Affinity Bioreagents). This antibody was raised against amino acids 346 - 367 from the amino terminus of the human glucocorticoid receptor. Receptor staining was accomplished by diaminobenzidine reaction to a biotinylated secondary antibody (goat-anti-rabbit). Most immunoreactive staining was localized in cell nuclei.

The area with the greatest concentration of glucocorticoid immunoreactive staining was the anterior dorsal ventricular ridge. This area has also been referred to as the hypopallium and hyperstriatum anterius in lizards. Staining is heavy at and adjacent to the ventral margins of the lateral ventricles at the level of the optic chiasm and epiphysis. More anteriorly, dense staining was seen in the margin of the anterior dorsal ventricular ridge between the lateral and olfactory ventricles. Staining was also prevalent in cells of the medial cortex, also referred to as the hippocampal cortex or hippocampus pars dorsomedialis.

580.10

MUSCARINIC ACETYLCHOLINE RECEPTOR SUBTYPES IN THE PIGEON TELENCEPHALON: DISTRIBUTION OF PIRENZEPINE-SENSITIVE AND AF-DX 116-SENSITIVE SITES. E.C. Kohler*, #W.S. Messer, Jr. and V.P. Bingman. Dept. of Psychology, Bowling Green State University, Bowling Green, OH 43403 and #Dept. of Medicinal & Biological Chemistry, College of Pharmacy, University of Toledo, Toledo, OH 43606.

There is evidence suggesting the existence of at least five subtypes of muscarinic acetylcholine receptors (mAChRs). Furthermore, autoradiographic studies have demonstrated a heterogeneous distribution of mAChR subtypes in the mammalian brain. Data from studies on birds (Kohler et al., Nsci Abstr. 19:1131, '93; Tietje et al., J. Biol. Chem. 266:17382, '91 & 265:2828, '90) suggest that there may also be more than one type of mAChR in the avian brain. Here we examine the possibility of multiple mAChRs by investigating the binding of [³H]-(-)-quinuclidinyl benzilate ([³H]-(-)-QNB) and the ability of the M₁ receptor antagonist pirenzepine (PZ) or the M₂ receptor antagonist AF-DX 116 (AF) to reduce the binding of [³H]-(-)-QNB in the pigeon telencephalon. Autoradiograms indicate high densities of mAChRs in dorsal archistriatum, combined hyperstriatum dorsale and ventrale, parolfactory lobe, and paleostriatum augmentatum (490-620 fmoles/mg protein) and low densities of mAChRs in nucleus basalis (Bas), ectostriatum (Ecto), and paleostriatum primitivum (275-380 fmoles/mg protein). An ANOVA indicated that sites with significantly higher affinity for PZ (vs. AF; suggesting relatively higher M₁ density) were found in most telencephalic regions. These analyses also indicated that sites in Ecto and septum showed no significant difference in affinity for PZ or AF while sites with significantly higher affinity for AF (vs. PZ; suggesting relatively higher M₂ density) were found in Bas. These data will be useful in determining some of the specific roles of the cholinergic system in studies of avian behavior. Current investigations include the role(s) of putative mAChR subtypes in avian learning and memory. This work was supported in part by NS 01493.

DISTRIBUTION OF NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN THE FOREBRAIN OF THE TURTLE *CHRYSEMYS PICTA*. A.S. Powers* and M. Rodriguez. Dept. of Psychology, St. John's Univ., Jamaica, NY 11439.

Neuropeptide Y (NPY), a 36-amino-acid peptide, has been shown to be localized in neurons of the cerebral cortex, striatum, and amygdala of mammals. The present study examined its distribution in the forebrain of the painted turtle (*Chrysemys picta*). We used fluorescence immunohistochemistry to visualize the NPY cells and fibers. Sections were incubated in a polyclonal primary antibody against synthetic NPY made in rabbit (Accurate) and then in a biotinylated anti-rabbit secondary, followed by avidin conjugated to the fluorophore FITC. In the telencephalon, NPY-positive cells were found in the tuberculum olfactorium, in the medial, dorsomedial, dorsal, and lateral cortices, and in the dorsal ventricular ridge. NPY-positive cells were also found in the paleostriatum augmentatum (equivalent to the striatum), in area d (the reptilian equivalent of nucleus accumbens), and in the amygdala. Few cells were seen in globus pallidus or in the septal area. NPY-positive fibers were widely distributed throughout the telencephalon, but were especially prominent in the molecular layer of the medial and dorsomedial cortices. In the diencephalon, NPY-positive cells were seen only in the dorsal nucleus of the supraoptic decussation, which is equivalent to the thalamic reticular nucleus of mammals. Fibers were present in the hypothalamus, including a dense plexus in the nucleus ventromedialis hypothalami. These results are similar to those seen in mammals, especially in the telencephalon, and together with results of studies of other nonmammals, show continuity in forebrain systems during the course of evolution. Supported by NS31785 to ASP.

BRAIN METABOLISM AND BLOOD FLOW: BASIC MECHANISMS II

581.1

CEREBRAL BLOOD FLOW MEASUREMENT USING RADIOACTIVE Xe^{133} UNDER PENTOTHAL AND FENTANYL ANESTHESIA. A. Elrifai*, J. Bailes, S. Govindan, E. Teeple, M. Taylor, S. Shih, M. Adatepe and J. Maroon. Allegheny General Hospital, Allegheny-Singer Research Institute and The Medical College of Pennsylvania, Pittsburgh, PA 15212.

rCBF was measured twice in six dogs within one week. The first measurement was done while animals were sedated using Pentothal, a short acting barbiturate, 20 mg/kg and in the second Fentanyl was titrated as 50 μ g/dose for a maximum of 10 doses. The rCBF was measured using a modified NOVO 10a Cerebrograph using two detectors on each side; the remaining detectors were shielded. Animals were sedated, endotracheally intubated & connected to the cerebrograph. ECG, heart rate, respiration and tidal volume were monitored. The end tidal PCO_2 was kept at 35-40 mmHg. Radioactive Xe^{133} (Dupont Pharmaceuticals) was mixed with low dissolved oxygen saline (LDO). Following registration of background activity for 0.5 min, a bolus of Xe^{133} in saline was injected in a cephalic vein. Xe^{133} clearance was recorded throughout 11 minutes and expired air was monitored to supply the air curve. CBF results were expressed in ml/100gm/min as the initial slope index between 30 and 90 sec, as CBF15 and as the fast compartment flow F1. Corrections for hemoglobin and CO_2 were not instituted. Hemispheric CBF was treated as the average value of the 2 detectors on each side & an average for each animal was calculated. ANOVA showed a difference in rCBF between the 2 measurements as described in ISI, CBF15, and F1. There were no differences in PCO_2 , hemoglobin levels or the injected Xe^{133} .

581.3

SODIUM CYANIDE MICROINJECTED INTO THE ROSTRAL VENTROLATERAL MEDULLA (RVL) ELEVATES CEREBRAL BLOOD FLOW (rCBF) AND EXCITES CEREBRAL CORTICAL "VASODILATOR" NEURONS. E.V. Golanov* and D.J. Reis. Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell Univ. Med. College, New York, NY 10021.

Sympathoexcitatory reticulospinal neurons of RVL are central oxygen detectors rapidly and reversibly excited by ischemia, hypoxia, or NaCN (Sun and Reis, *J. Physiol.* 476:101, 1994). As a consequence, they increase sympathetic nerve activity and arterial pressure (AP) (Sun and Reis, *Am. J. Physiol.* 266:R245, 1994). The facts that systemic hypoxia increases rCBF without metabolism, stimulation of RVL (Underwood et al., *J. Cereb. Blood Flow Metab.* 12:844, 1992) replicates this response, and bilateral lesions of RVL reduce, by over 50%, hypoxic vasodilation (Underwood et al., *Brain Res.* 635:217, 1994) suggests that hypoxic stimulation of RVL neurons may increase rCBF. To test the hypothesis, NaCN was microinjected (150 μ M, 5 nl) into RVL of anesthetized rats. CN rapidly (<2 sec), site-specifically, dose-dependently and reversibly increased rCBF (measured by laser-Doppler flowmetry) to $21 \pm 6\%$ ($p < 0.01$, $n=8$) and AP to 138 ± 13 mmHg ($p < 0.05$). After spinalization, NaCN only increased rCBF. CN also increased the numbers of cortical burst-rCBF wave complexes (Golanov and Reis, *Am. J. Physiol.* 266:R204, 1994) and excited neurons in lamina V which discharge during the negative potential of spontaneous or RVL-evoked burst-wave complexes ("vasodilator neurons") (Golanov and Reis, *Am. J. Physiol.*, in press). The cerebrovascular and neuronal responses were blocked by intracortical tetrodotoxin. We conclude that hypoxic excitation of O_2 -sensitive RVL neurons in RVL increases cortical rCBF and activates "vasodilator" neurons of cerebral cortex. The results add support to the hypothesis that hypoxic cortical vasodilation is, in part, neurogenic resulting from reflexogenic activation of a pool of cortical neurons by oxygen-sensitive neurons in RVL.

RELATION BETWEEN CYCLIC GMP GENERATION AND CEREBROVASCULAR REACTIVITY: MODULATION BY NPY AND α -TRINOSITOL. J. P. You, W. H. Zhang, I. Jansen, D. Erlinge* and L. Edvinsson. Dept. of Exp. Res, Malmö General Hospital, S-214 01 Malmö, Sweden

The present study examines the possible correlation between cerebrovascular vasodilator agents and generation of cGMP in guinea pig cerebral vessels. Acetylcholine (ACh), substance P (SP), nitroglycerine (NTG) and sodium nitroprusside (SNP) not only elicited concentration-dependent relaxation of basilar artery segments; but also significantly increased the generation of cGMP of cerebral vessels. Neuropeptide Y (NPY) increased the generation of cGMP by 2%-46% of control levels (at 10^{-7} - 10^{-6} M of NPY; * $p < 0.05$). In addition, NPY (10^{-6} M) induced a transient relaxation of the precontracted guinea pig basilar arteries with endothelium. This transient relaxation was blocked by nitro-L-arginine (NOLAG 10^{-4} M). α -trinositol did not alter the formation of cGMP. In the presence of α -trinositol NPY (10^{-7} - 10^{-6} M) did not significantly elevate the production of cGMP. The rise in cGMP induced by ACh, SP and NTG was slightly increased by the addition of NPY (3×10^{-7} M). ACh and SP induced an endothelium-dependent relaxation of the precontracted guinea pig basilar arteries, while SNP and NTG induced an endothelium-independent relaxation. ACh, SP and NTG induced concentration-dependent relaxations of basilar artery, respectively. This relaxation elicited by ACh or SP, but not NTG, was markedly attenuated by NPY (3×10^{-7} M). This inhibitory effect of NPY on vasomotor responses was completely reversed by α -trinositol (10^{-4} M). In conclusion, there is a close correlation between relaxation and cGMP formation induced by ACh, SP, NPY, SNP and NTG. The relaxant response to ACh, SP and NPY are mediated via the release of endothelium-derived relaxing factor/nitric oxide (EDRF/NO), while SNP and NTG act directly on the guanylyl cyclase. The inhibitory effect of NPY on endothelium mediated relaxation by ACh and SP are not mediated via cGMP, but inhibited by α -trinositol.

581.4

RESPONSES OF CEREBRAL COLLATERAL VESSELS TO INHIBITION OF ATP-SENSITIVE POTASSIUM CHANNELS. C.A. Mazzocchi, J.S. Gerdes, M.G. Muhonen, S.C. Robertson* and C.M. Loftus. Div. of Neurosurgery, Univ. of Iowa College of Medicine, Iowa City, IA 52242 and Veterans Affairs Medical Center, Iowa City, IA 52246.

The mechanism of collateral vasodilatation following cerebral arterial occlusion is not completely understood. The canine cerebral vasculature was investigated for the presence of ATP-sensitive potassium channels, and effects of an inhibitor to these channels as they relate to collateral blood flow.

In eight mongrel dogs a left sided craniotomy was performed with temperature controlled artificial cerebrospinal fluid (aCSF) superfused over the brain. Normal cerebral artery pressure was measured with a glass micropipette. A branch of the middle cerebral artery (MCA) was cannulated and back pressure measured. Collateral-dependent tissue was identified using the "shadow flow" technique. Glibenclamide (10^{-5} M) was added to the aCSF. Regional cerebral blood flow (rCBF) to subcortical cerebrum was measured with radioactive microspheres.

Baseline blood flow to ipsilateral normal cerebrum was 98 ± 16 ml/100g·min⁻¹ and did not change during glibenclamide. Flow to collateral-dependent tissue was 93 ± 13 ml/100g·min⁻¹, and 68 ± 7 ml/100g·min⁻¹ following glibenclamide ($p < 0.05$). The attenuation of collateral blood flow was associated with a profound decrease in cannulated MCA branch back pressure. Pressure in the normal MCA branch was unchanged.

When ATP-sensitive potassium channels, which probably participate in compensatory vasodilatation were inhibited, a reduction in rCBF occurred in collateral-dependent tissue, but not in normal cerebrum. This would imply that ATP-sensitive potassium channels are involved in collateral vasodilatation following MCA occlusion, but may not be involved in maintenance of resting basal tone of cerebral arteries.

581.5

STIMULUS PARAMETERS INFLUENCE MAGNITUDE AND TIME COURSE OF OPTICAL INTRINSIC RESPONSES IN RODENT BARREL CORTEX A.J. Blood*, S.M. Narayan, A.W. Toga, Laboratory of Neuro Imaging, UCLA School of Medicine, Los Angeles, CA 90024.

Optical imaging of intrinsic signals was performed in primary somatosensory cortex of the rat during single whisker deflections of varying frequencies and durations, as well as during competitive stimulation of forelimb and whisker. A dose-response relationship was shown between whisker stimulus parameters and the intensity and spatial/temporal characteristics of the optically recorded intrinsic signal. When frequency was constant, longer durations of stimulation resulted in larger magnitude responses, as determined by pixel intensity in a statistically defined region of interest. Similarly, when duration was constant, higher frequencies of stimulation resulted in larger magnitude responses. In addition, greater numbers of deflections per trial resulted in higher magnitude responses than relatively smaller numbers of stimuli. Conversely, there were no differences in response magnitude between different combinations of frequency and duration which had in common the same number of stimuli. Temporally, there is evidence that the time between stimulus onset and peak response is influenced by frequency, with higher frequency stimulation resulting in a faster time-to-peak. Registration with certain aspects of vascular anatomy and stereotaxic coordinates demonstrated that intrinsic responses were well spatially localized with both types of fiducial points. Electrophysiological recordings demonstrated that optical response regions were coincident with areas of neuronal activity, although the time course of optical responses was slower than that of neuronal firing. Finally, competitive forelimb stimulation caused decreases in whisker response magnitude, and the intensity of forelimb stimulation determined the degree to which the whisker response decreased. Thus, both whisker stimulus parameters and introduction of competitive stimuli are critical variables in determining the magnitude and/or timing of optical intrinsic responses in rat barrel cortex.

581.7

BLOOD FLOW RESPONSES IN THE RAT BARREL CORTEX DURING WHISKER STIMULATION D. Liu, J. Dowling, M.E. Spence, C. Royainen, and T. Woolsey*, Dept. of Neurol. and Neurol. Surg., and of Cell Biol. and Physiol., Washington Univ. School of Medicine, St. Louis, MO 63110.

Arteriovenous transit times (AVTTs) of 0.001% FITC-dextran were measured by videomicroscopy through a closed cranial window to examine blood flow responses during whisker row and single whisker stimulation. Areas of cortical activity during stimulation were targeted with optical imaging of "intrinsic" responses. Whiskers were stimulated at 4-5 Hz for 1 min. Whisker row stimulation produced a mean AVTT decrease of 24.0% (n=24, SD±11.61, p<0.0001), whereas single whisker stimulation resulted in a mean decrease of 16.5% (n=68, SD±9.0, p<0.0001). Single whisker stimulation produced a significantly smaller decrease AVTT (p<0.001) in vessel pairs studied. Decreases in AVTTs could be detected within 5 seconds of the onset of whisker stimulation. Recovery to baseline values occurred within 5-10 seconds after stimulation ceased. These studies show that targeted measurement of AVTTs can be used for measurements of quantitative localized changes in blood flow in response to natural stimuli.

COMPARISON OF NEURAL AND VASCULAR UNITS IN MOUSE BARREL CORTEX I. Sui, C.M. Royainen, T.A. Woolsey and A.I. Cohen*, Depts. Neurol. & Neurosurg., Cell Biol. & Physiol., and Ophthalm. & Vis. Sci., Washington Univ. Sch. Med., St. Louis, MO 63110.

Blood flow increases locally during stimulation of single whiskers in rodent barrel cortex. The control and precision of the vascular response depends in part on the structure of cerebral vascular units: a terminal arteriole, the capillaries it feeds and venules draining those capillaries. Vascular units were demonstrated in barrel cortex by dye injection into single arterioles. Adult mice were anesthetized and perfused with 4% paraformaldehyde in HEPES-saline from the abdominal aorta. The aim of fixation was to prevent further constriction, dilation or changes of relative resistance in the cerebrovascular network. A craniotomy was opened over the left somatosensory cortex. Pial vessels were visualized by steady perfusion at 60cm H₂O with 1% Procion Red in 150 mM NaCl. Single penetrating 7-23 µm arterioles were impaled with glass micropipettes and injected with 0.4% Patent Blue or 2% FITC-albumin. Injected markers emerged in 1-7 venules <0.5 mm from the arteriole. An arteriolar domain was defined as the polygon of the injected arteriole and its emerging venules at the pial surface. Arteriolar domains were approximately the same size as projected layer IV barrels stained for cytochrome oxidase but formed independent maps. Portions of arteriolar domains overlapped, indicating shifts in perfusion of internal capillaries. Injections of internal arteriolar branches may clarify the structure of finer capillary modules in somatosensory cortex.

Supported by NIH Grants NS 28781 and HL 41075, the McDonnell Center for Studies of Higher Brain Function and an award from the Spastic Paralysis Foundation of the Illinois-Eastern Iowa District of the Kiwanis International.

581.6

FUNCTIONAL NEURAL-VASCULAR CONGRUENCE OVER SOMATOSENSORY CORTEX

S. M. Narayan*, A. J. Blood and A. W. Toga

Laboratory of Neuro Imaging, Dept of Neurology, UCLA, Los Angeles CA.

We examined the relationship between cerebral blood volume (CBV) and activation of primary somatosensory cortex (S-I) in the rat, using plasma-fluorescence, optical intrinsic signals and single unit recordings. Cortices of urethane-anesthetized male Sprague-Dawley rats were exposed, and fluorescent Texas Red Dextran dye (MW 70,000) given i.v. Vibrissa deflection or foredigit electroshock were associated with dye-related fluorescence increases over contralateral posteromedial barrel subfield or forelimb S-I. Fluorescence change foci overlay areas of increased cortical layer III cell firing on single unit recordings. Surface boundaries of even the smallest foci overspilled the electrophysiologic center receptive field. Larger stimuli caused fluorescence foci to enlarge considerably while the receptive field did so only slightly, increasing this spatial discrepancy. Fluorescence change was delayed and prolonged, suggesting that CBV increases at 1-1.5 s, and peaks 2-2.5 s after the onset of 1-2 s stimulation in both regions. Interleaved optical intrinsic studies revealed reflectance decreases between 550-850 nm, with similar timing and location to fluorescence increases after identical stimuli.

Thus, we observed delayed increases in vascular dye-fluorescence (related to CBV) over activated cortex. The striking similarity between optical reflectance and fluorescence suggest that changes in intrinsic cortical reflectance are strongly related to changes in CBV.

581.8

WHISKER STIMULATION INCREASES BLOOD FLOW AND GLUCOSE UTILIZATION IN THE TRIGEMINAL PATHWAY OF AWAKE RAT C. Royainen*, L. Wei, J. Fenstermacher, T. Woolsey, Dept. of Neurol. Surg., & Dept. Cell Biol. Physiol., Washington Univ., Sch. Med., St. Louis, MO 63110, and Dept. Anesthesiology, Henry Ford Hospital, Detroit, MI 48202

Local cerebral blood flow (LCBF) and local cerebral glucose utilization (LCGU) in response to natural stimulation of the trigeminal (whisker) pathway were investigated in conscious rats. LCBF and LCGU in the trigeminal (V) pathway were measured autoradiographically by ¹⁴C-iodoantipyrine and by 2-deoxyglucose respectively. Structures measured in the trigeminal pathway were: V nerve and tract; V motor root and nucleus; V spinal nuclei and principal nucleus; ventrobasal thalamus and barrel cortex. LCBF and LCGU were compared bilaterally after mechanical stimulation of the right whiskers. Whisker stimulation increased LCBF 1.29-1.95 X and LCGU 1.27-1.76X in all sites of gray matter along the trigeminal pathway. The greatest increases of LCBF and LCGU occurred in left barrel cortex. LCGU values of various structures during whisker stimulation were highly correlated (r=0.95) with their corresponding LCBF values. The unstimulated and stimulated sides had identical slopes indicating close coupling between LCBF and LCGU during whisker stimulation.

581.10

INTRINSIC CORTICAL RESPONSES IN THE RAT BARREL CORTEX WITH PROLONGED WHISKER STIMULATION

M. Henegar, J. Dowling, D. Liu, C. Royainen, T. Woolsey and R. Grubb*, Dept. of Neurosurgery and Dept. of Cell Biology and Physiology, Washington Univ. Sch. of Med., St. Louis, MO 63110

Intrinsic cortical responses were examined over the rat barrel cortex during continuous whisker stimulation. Videomicroscopy through a closed cranial window was recorded before and during stimulation of C-row and single whiskers at 4-5 Hz for 10-30 min. Computer analysis of these recordings and of "live" images revealed "intrinsic" responses localized to the appropriate areas of barrel cortex by later histology. Responses remained localized to these areas for up to 10 min., but subsequently appeared to spread. The quality of images constructed from video recordings was comparable, though slightly inferior, to live images. These studies demonstrate that "intrinsic" optical signals persist and remain localized for at least several minutes of continuous whisker stimulation. Video tape recording facilitates subsequent analysis of "intrinsic" optical responses.

This work supported by NIH Grants NS 17763, NS 28781, and HL 41074, the McDonnell Center for Studies of Higher Brain Function and an award from the Spastic Paralysis Foundation of the Illinois-Eastern Iowa District of the Kiwanis International.

581.11

RED CELL FLUXES CHANGE WITH STIMULATION OF RAT WHISKER BARREL CORTEX. G.E. Liang, B. Gilmore, M.E. Spence, D. Liu, C.M. Rovainen, T.A. Woolsey and R.E. Schmidt*. Depts. of Neurosurgery, of Cell Biology and Physiology and of Pathology, Washington University School of Medicine, St. Louis MO 63110.

Fluorescent erythrocytes (fRBCs) were used to measure blood flow changes in cerebral cortex with whisker stimulation. fRBCs (PKH2-GL, fluorescein isothiocyanate, and fluorescent beads) are long lived intravascular markers ($t_{1/2} \approx 2$ hours) permitting changes to be evaluated prior to, during and after controlled whisker stimulation. fRBCs were recorded continuously by video microscopy through a cranial window over rat whisker-barrel cortex and were counted as they emerged from cortical venules. "Optical intrinsic" signals were used to target activated barrel cortex; after the experiments vessels and barrels were mapped by histology. Stimulation of a row of whiskers promptly and significantly increased flux draining optically active cortex; flux recovered quickly to baseline after stimulus termination. Venules draining non-optically active barrel cortex have reduced or unchanged fluxes. Venule diameter did not change. Localized changes in RBC flux were consistent with previous measurements by other methods. In contrast to plasma markers, fRBCs permitted continuous evaluations over long periods and allowed selection and detailed sampling of multiple venules from images $\approx 1\text{mm}^2$.

Supported by a Howard Hughes Fellowship (G.E.L.), NIH Grants NS 28781 and HL 41075, the McDonnell Center for Studies of Higher Brain Function and an award from the Spastic Paralysis Foundation of the Illinois-Eastern Iowa District of the Kiwanis International.

COGNITION IV

582.1

CORPUS CALLOSUM DEVELOPMENT IN CHILDREN. L.A. Rowe^a, J. Kranzler^a, L.J. Lombardino^b, L. Mercado^b, S.R. Brownd^c, G.W. Hynd^d, O.F. Agee^e, W.G. Luttig^c & C.M. Leonard^c. Depts. of Education^a, Communication Processes^b, Neuroscience^c, Radiology^d, Univ. of FL, Gainesville, FL, 32610 & School of Professional Studies^e, Univ. of GA, Athens, GA 30602.

The corpus callosum (CC) can be easily visualized and measured on midsagittal magnetic resonance imaging (MRI) sections. Variations in the size of anatomically defined subregions, such as the genu, body, isthmus and splenium, have been associated with verbal fluency, language lateralization, handedness, sex, and age. In this study these subregions of the CC were measured using Witelson's method. Intra-rater and inter-rater reliability estimates ranged from 0.87 to 0.94. We investigated the development of these regions in a group of 32 control children between the ages of 5.7 and 12.5 (18 boys and 14 girls) who had received the Test of Nonverbal Intelligence (TONI, mean score = 106). The area of each region was divided by the area of the total intracranial volume to correct for overall differences in brain size. After this correction, the body of the corpus callosum was the only region that was significantly smaller in girls ($F_{1,30} = 6.42$, $p < 0.02$). The body and the isthmus were the only regions to show a significant increase in size with age (isthmus: $r = 0.42$, $p < 0.02$; body: $r = 0.39$, $p < 0.03$). In girls, the size of the genu showed a trend toward correlation with the TONI score ($r = 0.48$, $p < 0.10$). In boys, none of the subregion correlations with the TONI were greater than 0.15. We are currently studying the relation between subregion size and asymmetries in association cortex. SYLVIAN FISSURE ANOMALIES IN CHILDREN WITH LEARNING DISABILITIES. L.R. Mercado^a, S.R. Brownd^b, C.M. Leonard^{a,b}, L.J. Lombardino^a, K.K.S. Voeller^c, J.J. Ross^d, K. Noffsinger^d, O.F. Agee^e. Depts. of Communication Processes^a, Neuroscience^b, Psychiatry^c, Pediatrics^d and Radiology^e, University of Florida, Gainesville, FL 32610.

Previous research has indicated that individuals with dyslexia have an increased incidence of multiple Heschl's gyri (MH) and anomalies in the region of the planum temporale (P) and the supramarginal gyrus (S). We analyzed these regions in 32 control children [mean age: 9.0 yrs; 19 males (M), 13 females (F)] and 31 children with language and learning disabilities [LD, mean age: 10.4 yrs; 19 M, 12 F] using thin sagittal magnetic resonance images. Three raters trained to reliability in classification schemes developed by Steinmetz (extra or missing supramarginal gyri) and Witelson [missing horizontal (H) or vertical (V) banks of the planum] identified sylvian fissure morphology. Additionally, Heschl's gyrus was categorized as being single or multiple. The distributions of anomaly types in the two groups were significantly different ($\chi^2 = 8.69$, $p = 0.013$). In the controls, anomalies in P or S occurred more often than MH (15 P/S, 5 MH), while in LD, MH anomalies occurred more often (8 P/S, 15 MH). In both groups, P/S anomalies occurred on both left and right (left: 35%, right: 28%) while MH occurred more frequently on the right (left: 8%, right: 24%). Multiple Heschl's gyri may arise as a result of errors in cell migration or axonal pathfinding during fetal development. Such errors may lead to scrambled auditory connections that put children at risk for auditory processing problems such as those reported by Tallal and Elliott.

INCREASED ASYMMETRY OF THE PLANUM TEMPORALE PARALLELS IMPROVED PHONOLOGICAL CONCEPTUALIZATION IN CHILDHOOD. C.M. Leonard^a, L.J. Lombardino^b, L. Mercado^b, J.I. Breier^a, A.L. Foundas^c, S.R. Brownd^c, O.F. Agee^e, K.M. Hellman^{a,c}. Depts. of Neuroscience^a, Communication Processes^b, Radiology^d, Neurology^e, Univ FL, Gainesville, FL, and Dept. Psychiatry & Neurology^f, Tulane Univ, New Orleans, LA.

Asymmetry of the planum temporale may be the most robust anatomical correlate of functional localization for language. The fetal planum demonstrates asymmetry but developmental changes have not been investigated. We used a 3d volumetric MRI sequence to study 32 normal children aged 5.7 to 12.5 (19 male, 13 female, 17 strongly righthanded, 15 nonrighthanded). The area of the planum temporale (defined as the lower bank of the sylvian fissure between Heschl's gyrus and the posterior ascending ramus) was measured between 46 and 54 Talairach units. The children received the Lindamood test of auditory conceptualization (LAC). Between ages 5 and 10, planar asymmetry increased [$r(n = 25) = 0.51$, $p < 0.01$]. Over the entire age range, a multiple regression analysis indicated that LAC scores increased with age ($F_{3,26} = 5.8$, $p < 0.0001$) as well as with planar asymmetry, independent of age ($F_{3,26} = 2.2$, $p < 0.05$). Consistent with Galaburda's work, increased asymmetry was accompanied by decreased size of the right planum. Studies of brain damaged children suggest a developmental reduction in the right hemisphere's ability to mediate language. This reduction may be due to the loss of right planar tissue. It is not known whether planar asymmetry changes in individual children. The possibility of structural changes in perisylvian regions during childhood should be verified in a developmental study. (Supported by Social and Behavioral Sciences Research Grant No 12 FY93-0551 from the March of Dimes Birth Defects Foundation.)

ABNORMAL CORTICAL ACTIVATION GENERATED BY SIMPLE AUDITORY STIMULATION AND MUSIC IN CHILDHOOD AUTISM. M. Zilbovicius^a, B. Garreau, C. Barthélemy, Ph. Remy, A. Syrota, G. Lelord and Y. Samson. SHFJ, CEA, Orsay and INSERM U 316, CHU Bretonneau, Tours, France.

Abnormal behavioral and electrophysiological responses to auditory stimuli are typical of childhood autism, and may reflect an abnormal cortical processing of auditory inputs. We investigated a putative abnormal pattern of cortical activation in autistic children using an auditory stimulation rCBF paradigm. Eleven autistic children (mean age \pm sd : 7 ± 2.4 years) were compared to five non-autistic children (mean age \pm sd : 8.5 ± 3.5 years). rCBF was measured under premedication using SPECT and $^{133}\text{Xenon}$ at 1) rest, 2) during simple binaural auditory stimulus (750 Hz tones, duration of 200 msec, intensity of 80 dB, frequency of one tone per second), and 3) while listening to music (Schubert piano sonata # 9). No rCBF abnormality was observed at rest. The simple auditory stimulus induced a rCBF increase in the left temporo-occipital region in controls ($+5\% \pm 3\%$; $p < 0.005$). Autistics showed a rCBF increase in the right temporo-occipital cortex ($+3\% \pm 4\%$; $p < 0.005$). Comparison between both groups revealed a significant difference in the left temporo-occipital region ($p < 0.05$). Listening to music induced in autistic children a rCBF increase in the right anterior temporal ($+5\% \pm 4\%$; $p < 0.001$) and in the temporo-occipital regions (left: $+6\% \pm 8\%$; $p < 0.02$; right: $+6\% \pm 12\%$; $p < 0.05$). Controls showed a trend toward activation in the left temporal anterior region ($+3\% \pm 5\%$; $p = 0.09$). Comparison between both groups revealed a difference in the right anterior temporal region ($p < 0.05$). Thus, autistic children seem to have an abnormal lateralization pattern of cortical activation induced by auditory stimulations, with deficient left cortical processing of short simple auditory stimuli, and increased right cortical processing of music. VISUAL RECOGNITION MEMORY IN HUMAN INFANTS. O. Pascalis* and S. de Schonen. Developmental Unit, Lab. of Cognitive Neuroscience, C.N.R.S., Marseille, France.

Visual recognition memory was assessed in 3-day-, 2-month-, and 3-month-old infants with a paired-comparison task. Infants were first habituated to a picture of a face using an infant-controlled procedure, and, after a 2-min retention interval, they were presented with the familiar face and a novel face for two retention periods of 16 sec for the youngest group and 20 sec for the oldest groups. Time spent looking at either stimuli during the two retention periods was measured and percent fixation to the novel face was calculated. At the age of 3 days and 3 months, infants looked significantly longer at the novel face ($p < .001$), whereas at the age of 2 months, infants looked longer at the familiar face ($p < .01$). These data demonstrate the presence of visual recognition memory for delays of 2 min as early as 3 days of age in human infants. In addition, the change in preferential viewing in 2-month-old infants (preference for familiar instead of novel face) suggests a discontinuity in the development of this memory system. Together with the lack of novelty preference found in amnesic patients (McKee & Squire, 1992, *J. Exp. Psychol.*) and in infant monkeys with early medial temporal lobe lesions (Bachevalier et al., 1993, *Neuroreport*), the findings indicate that, in human neonates, the medial temporal lobe makes a critical contribution to recognition memory. These results are discussed in relation with neuroanatomical data on the maturation of the visual system and medial temporal lobe structures in human and non-human primates.

AUDITORY EVOKED POTENTIALS AND VERBAL AND SPATIAL ABILITIES IN PREADOLESCENT CHILDREN. J.L. Shucard*, D.W. Shucard, G.L. Ciupak, C.P. Schaeffer, R.L. Clopper, T. Quattrin, M.L. Voorhes. Departments of Neurology and Pediatrics, SUNY @ Buffalo School of Medicine, 100 High Street (D6), Buffalo, NY 14203.

Evidence from both behavioral and electrophysiological studies has supported the notion that there are differences between the sexes in both anatomical/functional brain organization as well as in cognitive abilities, such as visual spatial information processing. Our laboratory has been exploring these purported cognitive sex differences using both neuropsychological and electrophysiological techniques. In the present study, we examined the pattern of cerebral activation across a well characterized sample of pre-adolescent males and females in order to further explore possible relationships between cognitive abilities and electrophysiological indices of cortical organization.

Boys and girls (20 each) between 8 and 11 years of age were studied. Children were determined to be prepubertal by the Tanner Scale of Pubertal Development. Subjects participated in (a) neuropsychological assessment and (b) electrophysiological testing to obtain auditory evoked potentials (AEPs) to probe stimuli from Frontal, Temporal, Central and Parietal scalp sites during the performance of spatial and verbal tasks.

Subjects were categorized into high, medium, and low spatial abilities groups based on a linear combination of three behavioral measures of visual-spatial skills. Differences in AEP amplitude occurred between the high and medium versus low spatial abilities groups obtained during the performance of spatial tasks. High and medium spatial subjects showed greater amplitude AEPs as compared to the low spatial subjects. These differences were most prevalent in the parietal leads and were not seen during the verbal task. High spatial subjects, regardless of sex, showed this AEP pattern.

582.9

THE RELATIONSHIP BETWEEN DERMATOGLYPHIC ASYMMETRY, SEX, AND COGNITIVE STYLE: DISSOCIATION IN THE PERFORMANCE OF SPECIFIC SPATIAL TASKS. C.M. Fernandez-Carol*, B.D. Fantie, D. Rabois, and C.A. Patterson. Human Neuropsychology Laboratory, Psychology Department, The American University, Washington, DC 20016-8062.

Previously, Kimura and Carson (1993) reported a correlation between cognitive pattern and finger ridge asymmetry on tasks traditionally associated with sex differences in performance. Specifically, both male and female subjects who had a greater number of loops in the right thumbprint compared to the left thumbprint performed better on cognitive tests usually associated with enhanced performance by males (e.g., spatial processing, math). In contrast, subjects with higher left-hand counts did better on tests frequently associated with superior performance by female (e.g., fluency, perceptual speed). In this preliminary attempt to replicate Kimura and Carson's findings, young adult male and female subjects performed a variety of paper-and-pencil cognitive tasks and their thumbprints were examined. As expected, based on this earlier work, the males, overall, had significantly more thumbprint loops than did the females. We also found that all subjects performed equivalently on a putative gender-neutral task (i.e., vocabulary). On three tests of spatial ability, however, there was a dissociation between dermal ridge asymmetry and sex. The Hidden Patterns test showed a greater relationship between dermatoglyphic asymmetry than it did a sex difference. Surface Development and Card Rotation test performances, on the other hand, were more greatly related to sex differences. Spatial ability is not a unitary function. Dermatoglyphic asymmetry may be related directly to the amount of material in the sex chromosomes. We speculate, however, that there may be different events or mechanisms, other than those associated with gender (e.g., the presence of hormones in the developing brain), that contribute to the development of spatial performance.

582.6

RELATIONSHIP OF PLASMA MHPG TO COGNITIVE FUNCTIONING IN CHILDREN WITH ATTENTION-DEFICIT HYPERACTIVITY DISORDER. L.H. Pick, J.M. Halperin*, J.H. Newcorn and S.T. Schwartz. Dept. of Psychology, Queens College, Flushing, NY 11367 and Dept. of Psychiatry, Mt. Sinai Sch. of Med., New York, NY 10029.

Data suggest that central noradrenergic (NA) mechanisms are involved in the mediation of attention and information-processing. Psychopharmacologic evidence also indicate a role for NA mechanisms in the pathophysiology of children with attention-deficit hyperactivity disorder (ADHD). Studies comparing ADHD children to controls on urinary measures of the NA metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), have yielded inconsistent results. The inconsistent findings may be due in part to the heterogeneity of ADHD children with regard to both MHPG levels and a variety of cognitive functions. This study examined measures of cognitive and academic function in 44 boys with ADHD who were divided into three groups based upon plasma MHPG level (low, medium and high). Plasma, rather than urinary, levels of the metabolite was assessed because it has been found to be more highly correlated with central MHPG in both animals and humans. Academic achievement test scores in reading, spelling and arithmetic were all linearly related to MHPG level. The low MHPG group scored significantly higher than the high MHPG group, and those with medium MHPG levels scored between the other two. The groups did not differ in IQ, as assessed by the WISC-R, however the high MHPG group scored significantly lower on the academically-related Information and Arithmetic subtests. On a computerized continuous performance test, the high MHPG group made significantly more inattention errors, but not more impulsivity errors. Finally, the three MHPG groups did not differ on parent or teacher ratings of hyperactivity or aggression. These data suggest that central NA function may be related to a dimension of inattention/learning problems in children with ADHD.

COGNITIVE DECISION-MAKING STRATEGIES AS A FUNCTION OF GENDER AND HANDEDNESS. S. R. Ginn* and D. A. Whetstone. Dept of Psychology, East Carolina Univ, Greenville, NC 27858-4353.

This abstract reports the results of a cognitive bias task (CBT) using both right- and left-handed subjects of both sexes. During the CBT, the subject is presented with a circle or square target stimulus followed by two choice circle or square stimuli. Target and choice stimuli are constructed along 3 dimensions: size (large or small), color (red or blue), and contour (filled or outlined). Subjects are instructed to indicate a preference for either of the choice stimuli after target presentation. In this study, subjects' response biases were tested by varying target-choice similarity; reaction time before choice was also recorded. However, in contrast to Goldberg, et al., we found no significant differences for either gender or handedness on response choice. Results indicate that both men and women, right- and left-handed, make choices in this task in a context-dependent manner.

582.10

SEX DIFFERENCES, SPATIAL WORKING MEMORY AND EVENT-RELATED POTENTIALS. J. M. Hoessing*, J. D. Lewine, R. Yeo, & C. Edgar. Depts. of Psychol., Univ. of New Mexico, Albuquerque, NM 87131 and Radiology, V.A. Medical Center, Albuquerque, NM.

Research on individual differences in cognitive functioning is beginning to reveal important sex differences in problem-solving strategies. It has been found that males outperform females on certain tasks that require imaginary manipulation of objects, navigating through a route, guiding or intercepting projectiles, and mathematical reasoning tasks. Females do better on tasks in which perceptual speed is important (eg., identifying matching items). They have greater verbal fluency, are superior in arithmetic calculation, recalling landmarks along a route, and manual tasks that require fine-motor coordination.

Here we report a novel sex difference. The task, based upon a procedure described by Sternberg (1969), is presented in two phases. Phase 1 requires the subject to memorize a) an array of letters, or b) the locations occupied by letters in an array. In phase 2 the subject is shown single letters and is asked to identify whether the letter a) was a member of the memorized array (letter identification), or b) was in a location occupied by any letter in the memorized array (location identification). Females take the same amount of time for letter identification as for location identification. Males respond significantly faster in the location versus letter identification conditions. This suggests that males use different processing mechanisms to solve location versus item-recognition memory tasks. Females appear to use a common processing mechanism for the two tasks.

582.11

GENDER DIFFERENCES IN SENSORY INTERHEMISPHERIC TRANSMISSION TIMES. S. Caillé and M. Lassonde*. Groupe de Recherche en Neuropsychologie Expérimentale, Univ. de Montréal, Qué., Canada.

The fibers of the corpus callosum (CC) connect the hemispheres following a rostro-caudal distribution: visual fibers course through the splenium, auditory fibers through the posterior body (isthmus) and somesthetic fibers through the anterior body. The aim of this study was to estimate the interhemispheric transmission time (ITT) in the visual, auditory and somesthetic modalities in men and women, given that previous data suggest a gender dimorphism favoring women in the posterior part of the CC (splenium and isthmus). Sensory ITTs consisting of lateralized flashes of light, puffs of air and pure tones were presented to 50 normal dextral subjects (25 males and 25 females) to evaluate visual, somesthetic and auditory ITT respectively. Results indicated that while somesthetic (13.61 ms) and visual (3.75 ms) ITTs did not differ according to gender, auditory ITTs of men (2.52 ms) and women (0.09 ms) differed significantly. This finding is cautiously interpreted as the consequence of women having a larger isthmus than men. Moreover, it offers an anatomical substrate for the reported weaker lateralization of function in women.

582.13

SEXUAL ORIENTATION AND ANATOMY OF THE CORPUS CALLOSUM. A. Scamvongeras¹, S. F. Witelson¹, M. Bronskill², P. Stanchev², S. Black³, G. Cheung⁴, M. Steiner⁵ and B. Buck^{1,2}. ¹Dept. of Psychiatry, McMaster Univ., Hamilton, ON, L8N 3Z5; ²Depts. of ³Medical Imaging, ⁴Medicine (Neurol.) and ⁵Radiol., Sunnybrook Health Science Centre, Univ. of Toronto.

An increased prevalence of left handedness (defined as not exclusive right-hand preference) was found in gay men compared to the general population (McCormick & Witelson, *Psychoneuroendoc.*, 1991). Left handedness and, by inference, hemispheric functional asymmetry, was found also to be correlated with increased cross-sectional area of the isthmus of the corpus callosum in men (Witelson & Goldsmith, *Brain Res.*, 1991). Based on these and other findings it was hypothesized that the isthmus is larger in gay than heterosexual men even when hand preference is controlled. Eleven gay men and 10 heterosexual men matched for age and educational level, all selected to be in good health and consistently right-handed, underwent a research MR scanning procedure specifically designed for this study. Callosal measurements were obtained from 4 mm midsagittal slices. Area measures of the total corpus callosum, the isthmus and other subregions were obtained. The isthmus was larger in gay men by 13% ($p = .05$, one-tailed t -test). Similar results were reported for the anterior commissure (Allen & Gorski, *PNAS*, 1992). The isthmus interconnects right and left parietotemporal regions involved in linguistic and spatial cognitive functions, tasks on which gay and heterosexual men differ (e.g., McCormick & Witelson, 1991). Our findings add to the evidence of a neurobiological factor in the origin of male sexual orientation. Moreover, our results indicate that sexual orientation is linked to functional lateralization of higher cognitive functions and may be part of a larger constellation of cortical and cognitive characteristics.

Supported in part by grant NS18954 to SFW.

582.15

THE RELATIVE VALUE OF SPEECH ARREST, READING AND REPETITION ERRORS TO DETERMINE CEREBRAL DOMINANCE FOR LANGUAGE DURING THE INTRACAROTID SODIUM AMYTAL TEST. J. Robidoux* & J. Rouleau. Université du Québec à Montréal & Hôpital Notre-Dame, Montréal, Québec, Canada.

The intracarotid Sodium Amytal (ISA) test is commonly used to establish cerebral dominance for language (CDL) prior to surgery for intractable epilepsy. CDL determined clinically is based on a general analysis of deviant productions during the ISA test but the respective lateralizing value of speech arrest, reading and repetition errors has not been fully examined. To address this issue, the ISA sessions of 30 (clinical CDL: 25 left (L), 2 right (R) and 3 mixed) right-handed epileptic patients, with a unilateral temporal focus, were examined retrospectively. For each patient, presence of speech arrest and dysphasic errors during reading and repetition of words and phrases were compared for L and R injections. Speech arrest was observed in 28 patients (L only: 21; R only: 3; L & R: 4). The presence of suppression corresponded for all patients but 2 (with mixed dominance) with the established clinical CDL. The analysis of 114 reading errors produced by the patients with a L CDL revealed the expected dissociation between neglect error (R inj.) and phonemic paralexia (L inj.). However, morphological errors were found after both injections. In contrast, repetition errors were observed only following the dominant injection and were mostly phonemic transformations. Taken together, these results suggest that speech arrest and repetition errors are specific to the injection of the dominant hemisphere while reading errors are not. Whether these findings would apply to all epileptics (e.g., left-handers, frontal focus etc.) will also be discussed.

582.12

SEX DIFFERENCES IN NUMERICAL DENSITY OF NEURONS IN HUMAN AUDITORY ASSOCIATION CORTEX. S. F. Witelson¹, I. I. Glezer² and D. L. Kigar¹. ¹Dept. of Psychiatry, McMaster Univ., Hamilton, ON, L8N 3Z5; ²Dept. Cell Biol. Anat. Sci., CUNY Med. School, New York, N.Y.

Brain size is approximately 10% larger in men than women. This sex difference could be reflected in some microscopic difference: e.g., in the total number, size or numerical density of neurons. Sex differences have been documented in the gross anatomy of and in the cognitive functions mediated by parietotemporal regions (Witelson & Kigar, *JCN*, 1992). The aim of the present study was to assess microscopic features of cytoarchitectonic area T4₁ (von Economo), auditory association cortex in the planum temporale within the Sylvian fossa. The brains of 5 women and 4 men were studied (mean age = 54 and 49 yr, respectively), all selected to be of documented normal neurologic and cognitive status and consistently right-handed. Cortical depth (D), the number of neurons in a column under 1 mm² surface area through the depth of the cortex (N_c), and the number of neurons per unit volume (N_v) were obtained using direct counting under the light microscope. Counts were made from 25µm Nissl-stained sections from right and left hemispheres. These three measures were also obtained for each of the 6 cortical layers. Results indicated that regardless of hemisphere, D did not differ between sexes, but N_v did by 11% ($df = 7$, $p < .008$, two-tailed t -test). There was no overlap between the sexes. This sex difference was observed for layers II and IV only. These findings suggest that sex differences in architectonics and, as a consequence, possibly in synaptology, are expressed mostly in non-pyramidal, granular layers associated with reception and distribution of information to the cortex. Such a sex difference could have consequences for neural function and cognition.

We thank Dr. M. Colonnier for his contribution in the early stages of this work. Funded in part by grants NS18954 and MRC (CA) MA-10610.

SEMANTIC INTERHEMISPHERIC INTEGRATION IN THE SPLIT-BRAIN: MORE ILLUSORY THAN REAL

Alan Kingstone & Michael S. Gazzaniga*

Center for Neuroscience, University of California, Davis, 95616

Subcortical semantic transfer is strongly suggested when a callosotomy patient draws pictures that *integrates* the meaning of words lateralized to the separated hemispheres. In our study patient J.W. drew pictures with the left hand (right hemisphere) or the right hand (left hemisphere), with or without visual feedback of the drawing. Sometimes the presented words were conceptually ambiguous (e.g., words "toad" and "stool" may be drawn as a toad sitting on a stool, or as a single emergent object -- a mushroom). Results indicated that word integration (e.g., a toad sitting on a stool) occurred mainly when visual feedback was provided; hemispheric control of the *ipsilateral* as well as the contralateral response hand was observed; and emergent objects were never drawn when words were lateralized. We conclude that what might first appear as evidence of subcortical semantic integration is in fact each hemisphere drawing its own separate picture with the same response hand on the same piece of paper. Our results support the view that the evidence for interhemispheric semantic integration in the split-brain patient is not compelling. (Supported by NIH/NINDS P01 NS17778).

NEUROSOMATIC ASYMMETRY AND HANDEDNESS. T.J. Andrews, L.E. White*, M.F. Groelle, D. Purves. Dept. of Neurobiology, Duke University Medical Center, Durham NC 27710.

We examined hand size in 50 adult volunteers who described themselves as right-handers, and 50 who considered themselves left-handers. Volumetric measurements of the two hands, assessed for each subject by a simple water displacement technique, showed that right-handed individuals have larger right hands than left (mean difference = $3.5 \pm 0.4\%$; $p < 0.0000001$). In contrast, the hands of left-handers are much more nearly symmetrical (mean difference = $0.3 \pm 0.5\%$; $p < 0.5$). Based on what is known about trophic interactions between neurons and their targets, these findings predict a corresponding asymmetry of the relevant parts of the sensorimotor system in right handers. This implication accords with preliminary studies of the human sensorimotor cortex, which show a leftward hemispheric asymmetry in the region where hand and upper limb are represented (White et al. *Nature* 368: 197-198, 1994). Corresponding studies of the spinal cord show a rightward asymmetry at the level of the cervical enlargement (mean difference of the cross-sectional area of the hemicord = $6.3 \pm 2.7\%$, $n = 5$; see also Nathan et al. *Brain* 113: 303-324, 1990). Measurements of hand size and related neural structures in infants could address whether these asymmetries arise from differential use or intrinsic factors.

582.17

FUNCTIONAL HEMISPHERIC ASYMMETRY IN HUMANS: METABOLIC EVIDENCES OF DIFFERENT CONNECTIVITY IN FOCAL HIPPOCAMPAL LESION. F. Parker and M.F. Lévesque*.

Epilepsy and Brain Mapping Program. Los Angeles, CA 90048

To investigate different patterns of neuronal connectivity in human brain, interhemispheric differences in metabolic activity were analyzed in subjects with unilateral hippocampal lesion causing focal hippocampal epilepsy. 16 right-handed patients with proven unilateral Right (R: n=8) or Left (L: n=8) focal hippocampal onset by stereoelectroencephalographic (SEEG) criteria were selected. Interictal metabolic changes with fluoro-deoxyglucose positron emission tomography (18F-FDG PET) were quantified using an accurate stereotactic methodology and correlated with the side of seizure onset by SEEG. For each patient, 46 individual anatomical regions (ROI) were defined on stereotactic MRI and superimposed to stereotactic PET. For each ROI the number of count per pixel was computed. An asymmetry index (onset side - opposite side / onset side + opposite side) was defined and analyzed with T-tests and Wilcoxon tests. The Left subgroup showed lateralized dysfunction for the hippocampus* (p=.001), the lateral temporal neocortex* (p=.002), thalamus* (p=.003), and medio-lateral frontal cortex (p=.001)* while the Right subgroup showed preferential desactivation of the pallidum* (p.0001), cingulum* (.003) and supplementary motor area (p=.03). These results suggest intrinsic differences in connectivity between right and left hemisphere in response to an identical functional lesion. *

* significant at .05 level after Bonferroni correction

IMMUNOCYTOCHEMISTRY OF CALCIUM-BINDING PROTEINS REVEALS FUNCTIONAL LATERALIZATION

IN HUMAN BRAIN. I.I. Glezer*, S.F. Witelson², D.L. Kigar¹. ¹Cell Biol. Anat. Sci. CUNY Med. School, New York, NY 10031, USA, ²Dept. Psychiatry, McMaster University, Hamilton, Ont., CA.

Light microscopic immunocytochemical analysis of three calcium-binding proteins: calretinin (CR), calbindin (CB) and parvalbumin (PV) was applied to 24 adult, 14 male, 10 female human brains (left and right hemispheres) obtained postmortem from cognitively normal individuals with tested psychological characteristics including hand preference. The 50 µm vibratome sections from the posterior part of the superior temporal gyrus (area T4₁, von Economo) were incubated with primary polyclonal antibodies against CR, CB and PV. It was found that in human neocortex all three calcium-binding proteins were well expressed and represented in three different populations of non-pyramidal neurons. The degree of the immunostaining, especially for the PV-positive neuronal population was associated with hand preference. In the group of consistent right-handers (CRH), all 13 cases showed high degree of immunostaining (grades 3 to 4 on a scale from 0 to 4). In contrast 7 of the 11 nonCRH people showed a very low degree of immunostaining (grades 0-2) in either both or in one of the hemispheres. The difference between the CRH and nonCRH groups was significant ($\chi^2 = 11.7$, df=1, $p < 0.001$). These results are the first demonstration of an association between biochemical characteristics of cortical non-pyramidal neurons and hemispheric lateralization of human cognition. Supported by grants: NS18954, MRC(CA) MA-10610, EJLB Fdn(CA), CUNY, RF-776615.

Regional Variation of Parvalbumin-Immunoreactive Neurons in Human Auditory and Language Cortices Jeffrey J. Hutsler* and Michael S. Gazzaniga, Center for Neuroscience, University of California, Davis, CA 95616

Regional variation in the architecture (Brodman '09) and distribution of chemically identified cell groups within the cerebral cortex likely contributes to functional specialization. Homologous regions of the right and left parietal-temporal junction vary in their contribution to language, but little attention has been focused upon the presence or absence of asymmetric neuronal microcircuitry within these areas.

Parvalbumin-immunoreactivity (PV-IR) has been shown to label a subgroup of GABAergic interneurons in the cerebral cortex (Van Bredenoord et al '90). This cell group possesses distinct physiological properties (Kawaguchi & Kubota '93) and thus contributes uniquely to cortical processing. An examination of the distribution of PV-IR neurons within auditory, auditory association, and putative language regions of two whole postmortem human brains revealed regional differences at various auditory processing levels, as well as differences between hemispheres. Specifically, the density of PV-IR neurons is lowest within anterior portions of the superior temporal gyrus (STG) and is greatest within cortical regions of the planum temporale, posterior STG, and supramarginal gyrus. An analysis of this density variation within individual laminae reveals a three-fold increase in the number of PV-IR cells within infragranular layers of posterior regions. An examination of homologous regions from each hemisphere shows density differences within individual lamina of the posterior locations. These results suggest that inhibitory interneurons make a unique contribution to cortical processing at different locations within the auditory cortex as well as within homologous regions of the hemispheres that are functionally unique. GENETIC AND ENVIRONMENTAL CONTRIBUTIONS TO CRANIAL SIZE IN BLACK AND WHITE

ADOLESCENTS. J. P. Rushton* and R.T.

Osborne. Department of Psychology, University of Western Ontario, London, Ontario, N6A 5C2, Canada.

Data from 236 pairs of twins (472 individuals) aged 12-18 years were used to examine genetic and environmental factors influencing cranial size, an indirect estimate of brain volume. Measures were taken of zygosity, head length, head breadth, age, sex, race, height, and weight for 187 males and 285 females, 222 whites and 250 blacks. Cranial size was calculated from head length and head breadth using standard equations. Group differences were found. Cranial size increased from ages 13 to 17 from 1,223 to 1,279 cm³. After adjusting for the effects of age and body size, boys averaged 1,290 and girls 1,229 cm³, whites averaged 1,269 and blacks 1,251 cm³. Intraclass correlations were calculated and models fitted of proportionate environmental and genetic contributions to variance. The heritability for the sample as a whole was 51 percent with 6 percent due to common environment and 43 percent due to unique environmental factors including error variance.

NEURAL PLASTICITY I

583.1

RECOVERY OF A VIBRISSE-DEPENDENT BEHAVIORAL RESPONSE FOLLOWING PHOTOTHROMBOTIC INFARCTION OF SOMATO-SENSORY CORTEX IN RATS A.J. Pazos*, M.D. Mayberry, A. Font, P.M. McCabe, W.D. Dietrich, E.J. Green. Dept. of Psychology, University of Miami, Coral Gables, FL 33124

Previous work indicates that rats trained to perform an appetitively motivated vibrissa sensory discrimination task exhibit substantial behavioral deficits following an infarction of the primary somatosensory cortex (Sml). These deficits recover gradually over the course of post-infarct testing. The present study sought to determine whether this behavioral recovery requires the involvement of either ipsilateral secondary somatosensory cortical tissue (SmlI) or the homologous Sml area in the contralateral hemisphere.

Sixteen adult male Wistar rats were trained to turn ipsilaterally in a T-maze following unilateral vibrissa stimulation, and contralaterally in response to control stimulation. Rats received 50 randomly alternating daily trials until they achieved criterion (>80% correct). Rats then received either a unilateral infarction of Sml, a unilateral infarction involving both Sml and SmlI, bilateral Sml infarcts, or sham surgical procedures. The cortical infarcts were produced through the interaction of a photosensitive dye (rose bengal) injected into the rat's tail vein, and the direct irradiation of the cranium with a light beam (Watson et. al., 1985). Shams underwent the same procedure, except saline was injected in place of rose bengal.

Post-infarction behavioral testing revealed that animals in each of the infarct groups required a significantly greater number of days to reattain criterion than did sham rats. Nevertheless, each animal eventually recovered to pre-infarct levels of responding. These results indicate that none of the somatosensory areas evaluated are essential for behavioral recovery from Sml infarcts in this task. The data thus suggest that either a) recovery from these deficits results from the dissolution of remote effects of the infarcts on some undetermined neural region, or b) behavioral recovery requires neural plasticity in that region. MK-801 FAILS TO INDUCE RECOVERY FROM CHRONIC TACTILE PLACING DEFICITS AFTER UNILATERAL LESIONS INCLUDING THE ROSTRAL AND CAUDAL FORELIMB AREAS OF THE RAT SOMATIC SENSORIMOTOR CORTEX. S. Barbay* and T.M. Barth. Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

Previous studies have shown that unilateral lesions of the caudal forelimb area (CFL) of the rat somatic sensorimotor cortex (SMC) produce a transient ipsilateral somatosensory asymmetry on a bilateral-tactile stimulation test and transient contralateral impairments in tactile-forelimb placing (lasting 14-28 days). Recovery from these deficits is facilitated by a regimen of the noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 beginning 16 hrs after the lesion. The present study investigated whether a similar regimen of MK-801 would attenuate chronic deficits produced by a unilateral lesion including the CFL and the rostral forelimb area (RFL) of the rat SMC. Rats received large unilateral lesions of the SMC followed by a regimen of MK-801 (1 mg/kg) beginning at 16 hrs after the brain injury. In untreated control rats (i.e. SMC lesions + saline) severe contralateral tactile-forelimb placing deficits were observed for the duration of the postoperative test period (i.e. 6 months) and no recovery was apparent. Control rats also showed an ipsilateral asymmetry on the bilateral-tactile stimulation test that partially recovered in the 6 month postoperative observation period. Treatment with MK-801 failed to induce recovery of the tactile-placing deficits but facilitated the rate of recovery on the bilateral-tactile stimulation test. These data suggest that while MK-801 may be effective in facilitating the rate of recovery from transient deficits, there is no evidence to suggest this agent has the potential to induce recovery when no restoration of function is expected. Moreover, the present results indicate that an intact rostral forelimb area may be involved in the process of recovery from unilateral CFL lesions because removing this structure (along with the CFL) prevents the occurrence of recovery.

UNILATERAL DAMAGE TO THE FORELIMB SENSORIMOTOR CORTEX: LONG-TERM EFFECTS OF TWO-WEEK LIMB IMMOBILIZATION ON DENDRITIC GROWTH AND FORELIMB FUNCTION. **D.A. Kozlowski*** & **T. Schallert**, Institute for Neuroscience & Department of Psychology, University of Texas at Austin, Austin, TX 78712.

Unilateral damage to the forelimb-representation area of the sensorimotor cortex in adult rats results in time-dependent enhancement of dendritic processes in layer V pyramidal neurons of the homotopic contralateral cortex and compensatory over-reliance on the ipsilateral/unimpaired forelimb (Jones & Schallert, 1992). Immobilization of the ipsilateral forelimb, by a one-sleeved cast, prevents this anatomical event (Jones & Schallert, 1994). In addition, behavioral function, when examined two days following cast removal, is more impaired by immobilization of the ipsilateral limb than of the contralateral limb. Thus, dendritic enhancement and functional recovery may be driven by compensatory forelimb use.

At this time, however, the long term effects of limb immobilization are unknown. In the present study, the unimpaired forelimb in groups of unilaterally lesioned rats was immobilized with a one-sleeved cast during the arborization period (Days 1-15 post-lesion). Analysis of dendritic arborization using Golgi-Cox procedures and tests of limb function were performed at various times following cast removal, for up to 60 days post lesion. Ipsilateral immobilization of the forelimb caused a chronic disruption of function, and substantially reduced the rate, and maximal extent, of dendritic arborization enhancement. AFFERENT INPUT INTEGRATION AND SEGREGATION IN LEARNING ARE INPUT TIMING DEPENDENT. **X. Wang***, **M. Merzenich**, **K. Sameshima**, **W. Jenkins**, Keck Center, Coleman Laboratory, UCSF, San Francisco CA 94143-0732.

Earlier studies suggest that a) changes in coincident input-based, Hebb-like synaptic effectiveness underlie the afferent input co-selection that marks the emergence of behaviorally-important stimulus-specific neuronal responses in the cerebral cortex, and b) representational segregation results from consistently non-correlated inputs. Here, we tested both hypotheses by documenting the cortical representations of the hands in area 3b of adult owl monkeys trained to discriminate multiple-site tactile stimuli. Unrestrained monkeys received sequences of tactile stimuli delivered to their fingers via two narrow bars. One bar simultaneously struck limited surfaces of the distal segments of fingers 2, 3 & 4; the second struck surfaces of the proximal segments of the same digits. Background stimuli were step indentations (50µ, 50ms) delivered alternatively by the two bars (ISI=200ms). The monkey's task was to detect two consecutive step indentations delivered to the same skin site by either the distal or proximal bar. After weeks of training with monkeys performing >300 daily trials, cortical neuronal responses to these and other general tactile stimuli were defined with 30-50 samples/mm² derived all across the area 3b zone engaged by these behaviorally important stimuli. Many sampled neurons had cutaneous receptive fields that were comprised of the discontinuous skin patches on two or three digits that were co-stimulated by either the proximal or distal bar stimuli. At the same time, non-simultaneously excited distal and proximal skin surfaces were largely or completely segregated from one another representationally, and in some cases were further separated by a band of cortex representing inputs from the hand dorsum. No comparable multiple-digit receptive fields were recorded in the hand zone of ventroposterolateral nucleus of the thalamus that was also mapped in detail. These findings support the conclusion that coincident input co-selection operates to create neuronal response specificity in learning. They provide a further demonstration that discontinuities in cortical maps are functional and not anatomical entities, and that temporally non-simultaneous inputs are sorted by cortical networks into largely-segregated zones. FUNCTIONAL MAPPING OF THE REORGANIZATION OF HUMAN HAND SENSORIMOTOR CORTEX AFTER PERINATAL INJURY USING MRI TECHNIQUES.

Y. Cao, **P.R. Huttenlocher***, **E.M. Vikingstad**, **V.L. Towle** and **D.N. Levin**, Departments of Radiology, Neurology and Pediatrics, The University of Chicago Hospitals, Chicago, IL 60637

Functional magnetic resonance imaging was used to map the hand sensorimotor cortex of hemiparetic patients who had suffered unilateral brain damage in the perinatal period. Six patients (mean age: 15 years) who had porencephaly or diffuse cortical atrophy performed a finger opposition task during functional MRI scanning. The control group consisted of eight right-handed normal subjects. T₂*-weighted images were obtained with a modified gradient-echo pulse sequence during a baseline scan period followed by 4-8 alternating task and rest periods. The results indicated that the intact hemispheres of the patients had approximately equal cortical volumes activated during contralateral (normal hand) and ipsilateral (paretic hand) finger movements. In contrast, the left or right hemispheres of right-handed normal subjects were primarily activated by contralateral finger movements, and had little ipsilateral sensorimotor activation. Our study of patients with unilateral perinatal brain damage indicates that their intact hemispheres are much more strongly linked to the ipsilateral hand than is the case in the normal subjects. In two patients, cortical regions distant from the central sulcus were activated by paretic hand movements. Our findings are consistent with previous clinical observations and animal experiments which suggest that the immature brain is able to reorganize in response to focal injury.

583.4

EFFECTS OF SCOPOLAMINE AND MK-801 ON RECOVERY OF FUNCTION FOLLOWING SENSORIMOTOR CORTEX LESIONS IN THE RAT. **R.M. Saponic***, **M.R. Hoane**, **S. Barbay**, and **T.M. Barth**, Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

Following brain injury there is an excessive release of glutamate and acetylcholine which may lead to secondary cell death proximal and distal to the site of the trauma. Previous research has suggested that agents which antagonize glutamatergic and cholinergic receptors may serve as neuroprotective agents and facilitate behavioral recovery. Although research has demonstrated the efficacy of treatment with MK-801 (a noncompetitive antagonist at the N-methyl-D-aspartate [NMDA] receptor) and scopolamine (an antagonist at the muscarinic acetylcholine receptor) following brain injury, very few studies have systematically examined the "window of opportunity" for these drugs. Moreover, the effects of treatments with a combination of neuroprotective drugs are largely undetermined. The present study examined the "window of opportunity" for MK-801 and scopolamine by themselves and in combination. Rats received unilateral lesions of the forelimb representation in the somatic sensorimotor cortex (SMC) and a single injection of either scopolamine (1 mg/kg), MK-801 (1mg/kg), scopolamine + MK-801, or saline. In addition to the type of treatment, the timing of the drug injections was varied among groups with some animals receiving their treatments at 15 minutes, 2 hrs, or 48 hrs after the brain lesion. Behavioral tests included measures of forelimb tactile placing and locomotor placing. The results were that although scopolamine and MK-801 by themselves facilitated the recovery of function on some of these tests when given at 15 minutes or 2 hrs, the combination treatment provided the most consistent beneficial effects regardless of the time of injection or the behavioral test. These data support the idea that activation of both muscarinic and NMDA receptors are involved in the production of secondary brain damage and that combination treatments with antagonists may provide the most consistent facilitative effects on behavioral recovery.

EVIDENCE FOR EXTENSIVE REORGANIZATION OF THE SOMATOSENSORY CORTEX IN ADULT HUMANS AFTER NERVOUS SYSTEM INJURY. **T. Elbert***, **H. Flor**, **N. Birbaumer**, **S. Knecht**, **S. Hampson**, **E. Taub**, Institute of Experimental Audiology, University of Münster, 48149 Münster, Germany.

In five patients with unilateral upper extremity amputation, we demonstrated alteration of the topographic representation of the cortical face area and the cortical upper arm (stump) areas which lie adjacent to the former receptive field of the amputated limb. Magnetic source imaging revealed that the focus of cortical activation elicited by facial stimulation was shifted 1-2 cm toward the receptive field which would normally receive input from the now amputated hand and fingers. A similar tendency was observed for the receptive field for the upper arm (stump). Additional responsiveness of these reorganized cortical areas was evidenced by an enhanced evoked electroencephalographic potential and magnetic field, compared to stimulations on the intact side. Observed alterations provide evidence for extensive plastic reorganization in the adult sensory cortex of humans following nervous system injury. This may constitute the neurophysiological basis of such phantom limb phenomena like the persistent sensory mislocation; however, they are not a sufficient cause of the phantom phenomenon termed "facial remapping" (i.e. of the phantom hand on the skin of the face; Ramachandran, *Science*, 1992).

583.8

PERIPHERAL NERVE CROSS INDUCES PLASTICITY IN THE SOMATOSENSORY CORTEX OF ADULT MACAQUES. **L. Hahn***, **R.W. Luehke**, **J. Danielsson** & **T.P. Pons**, Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892, and Johns Hopkins University, Baltimore, MD 21205.

The contributions of peripheral versus central factors to reorganization of cortical representational maps after peripheral nerve injury are not well understood. To explore contributions mediated by peripheral regeneration, we surgically altered the pattern of sensory innervation in the hand, then mapped the cortex. In two adult macaques, the sensory components of the distal median and ulnar nerves were transposed at the level of the palm. This procedure induces regeneration of the median nerve into skin normally subserved by the ulnar nerve, and ulnar nerve regeneration into median nerve territory. The radial nerve was severed and sutured into muscle in the forearm. Motor portions of the nerves were not altered. After a 6 or 9 month recovery period the hand representation in cortical areas 3b and 1 was mapped using multiunit electrode recording techniques. Our data indicate that cortex became reorganized according to the altered input. Instead of the normal mediolateral topographic progression from D5 to D1, we found a disordered progression from D1 to D5 across this dimension; the D4 and D5 representations were located where D2 and D3 representations are normally found, and the reverse. Two D1 representations were found, one located next to the forearm representation, and one next to face representation, presumably due to a remaining intact branch of the median nerve. 10% of the recording sites had discontinuous receptive fields of a type not seen in normal monkeys. The representation of the palmar pads were disproportionately large relative to the representation of distal digits. Since regeneration of the nerves in the proximal portion of the hand occurs prior to regeneration in the distal finger segments, the palmar pads may have already "claimed" cortical territory before the distal finger segments could compete for cortical space. These results suggest that the pattern of central reorganization that occurs after nerve damage is mediated by both the spatial and temporal regeneration pattern of peripheral nerves.

COORDINATED SYNAPTIC AND ASTROCYTIC STRUCTURAL CHANGES IN RATS REARED IN COMPLEX ENVIRONMENTS. T.A. Jones*, N. Hawrylak, and W.T. Greenough. Dept. Psychology and Neuroscience Program, Beckman Institute, Univ. of Illinois, Urbana, IL, 61801.

Rats in a complex environment (EC) have larger neuronal dendritic fields and an increased number of synapses per neuron in the visual cortex in comparison to animals housed individually (IC) or socially (SC) in standard laboratory cages. These neuronal effects are accompanied by hypertrophy and proliferation of astrocytes expressing glial fibrillary acidic protein (Sirevaag & Greenough, 1991). To more closely assess the relationship between synaptic and astrocytic changes, astrocytes were examined at the electron microscopic level in layers I, II-III and IV of the visual cortex in rats following 30 days of EC, IC, or SC housing. Stereological measures of the volume fraction and surface density of glial processes showed little change in these size variables following exposure to EC. However, there was a specific increase in the region of contact between glial processes and pre- and post-synaptic elements in EC rats, measured as the surface density of glial membrane in direct apposition to these synaptic elements. That is, glial processes become more ensheathing of synapses, an effect which may be indicative of greater involvement in synaptic activity and/or a response to elevated synaptic activity. The increased glia-synapse apposition bears a resemblance to the glial response previously reported in relation to increases in synapse efficacy (Wenzel et al., 1991). Ongoing work is assessing the possibility that structural and positional changes in perisynaptic astrocytic processes occur in close temporal coordination with synaptic events. TIME-DEPENDENT EFFECTS OF OPTIC NERVE CRUSH ON SUPERIOR COLLICULUS LOCAL CEREBRAL GLUCOSE USE. U. Schmitt*, B.A. Sabel*, R. Cross*, F.E. Samson* and T.L. Pazdernik*. *Inst. Med. Psychol., Univ. Magdeburg, Germany. †R.L. Smith Res. Cent., Univ. Kansas Med. Cent., Kansas City, KS 66160.

Rats given an optic nerve crush regain visual function despite a 90% loss of retinal ganglion cells. Thus, there is either restoration of information transfer from retina to brain or there is an adaptation in that visual function occurs with less information transfer. The 2-[¹⁴C]-deoxyglucose technique was used to determine local cerebral glucose use (LCGU) as an assessment of information transfer from retina to brain visual centers. Male adult Long Evans rats (6/group) were given a mild crush to the right optic nerve and LCGU was assessed 2, 9, or 22 days later. LCGU procedure was determined during stimulation with a flashing strobe-light and rotating bar pattern with or without physostigmine (300 µg/kg; i.m.), a cholinesterase inhibitor known to activate retinocollicular pathways. Qualitative inspection of LCGU autoradiograms from rats 2 days after crush revealed a marked reduction in LCGU in the left superior colliculus, especially the superficial layer. There was only minimal restoration of LCGU at 9 or 22 days after crush, restoration was greatest in the portion of the superior colliculus adjacent to the brain midline. Quantitation of LCGU according to the Sokoloff equation is in progress. These results provide evidence that visual function is restored after optic nerve crush in spite of a marked dysfunction in retinocollicular information transfer. Supported by BMFT 07 NBI 04/3.

INHIBITION OF NITRIC OXIDE SYNTHASE BLOCKS TOUCH AND VISUAL LEARNING AND INHIBITION OF HEME OXYGENASE-2 INHIBITS TOUCH LEARNING IN *OCTOPUS VULGARIS*. J. David Robertson*, J. Bonaventura, Adam Kohm, Amy Lane, Nicolas Limthong and Kenneth Harbaugh. Duke University Marine Laboratory, Pivers Island, Beaufort, NC. 28516.

We have recently demonstrated that inhibition of nitric oxide synthase by intramuscular injections of 75 mg/kg of N-w-nitro-L-arginine methyl ester (L-NAME) one hour before each training session blocks touch learning in *Octopus vulgaris* (*Proc. Roy. Soc., London, B* -in press). We used discrimination between -2 cm. black plastic balls, one smooth and one rough as the learning paradigm. The balls could not be discriminated by vision alone but were readily distinguished by touch. We have now extended these studies to visual learning using discrimination between vertical and horizontal white rectangles as the learning paradigm. We have now begun a study of the effects on touch learning of intramuscular injections of Zn-protoporphyrin-9 at 10 mg/kg. After a few days this resulted in significant inhibition of touch learning. Since this inhibits heme oxygenase-2, the source of CO in brain tissue, it seems that CO, as well as NO, is necessary for touch learning. Wayne, Bonaventura and Sheetz have recently shown that NO, at low concentrations, causes active extension of filopodia in neuronal cultures (*Proc. Soc. Neurosci.*, 1993). We have shown that cytochalasin D, which also blocks filopodial extension, blocks touch learning in *Octopus*, so our findings suggest that filopodial extension may be essential to touch learning in *Octopus*. There is always some doubt when using drugs to inhibit learning as to whether the primary effect is on sensory or motor output rather than on the learning process itself. To address this question, we have shown that animals treated with L-NAME can recall a previously learned touch paradigm but cannot learn a reversal of the paradigm. This suggests that the drug acts directly on the learning process.

GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) IMMUNOREACTIVITY IS ALTERED IN THE RAT VISUAL CORTEX FOLLOWING MONOCULAR DEPRIVATION DURING DEVELOPMENT. N. Hawrylak*, W.T. Greenough. Neurosci. Prog., Dept. of Psych. and Cell & Struct. Bio., Beckman Inst. Univ. of Illinois, Urbana 61801

Astrocytes demonstrate dynamic experience-dependent growth and possibly proliferative responses in the visual cortex of rats reared in a complex environment compared to those raised in individual cages (Sirevaag and Greenough, 1991 Brain Res. 540:273-278). To further delineate the effect of experience on the growth and differentiation of astrocytes in the visual cortex, monocularly deprived rats were examined with GFAP.

Eye lids were sutured at P12. Sutured rats were assigned to one of two groups; those with sutures that remained in place until P80 (MD, n=6); those that had the sutures removed at P75 and were allowed 5 days of light exposure (MD+L, n=6). A nonsutured control group P80 (CL, n=6) was used for comparison. Optical disectors and random systematic sampling were used to estimate the numerical densities (Nv) of astrocytes, neurons and total glia. A stereological cycloid intersection method was used to estimate the surface density (Sv) of GFAP immunoreactive processes. The numerical densities and (Sv) were estimated in layers 2/3, 4, 5, 6.

The Nv of astrocytes was not significantly different between the three groups. Group MD had a significant (35%) decrease in the Sv in layer 4 compared to control. The ratio of Sv to Nv of neurons (Sv/Nv), an estimate of the amount of GFAP-immunoreactive astrocyte surface area per neuron, was significantly decreased in layer 4 in both monocularly deprived groups compared to control. These results suggest that early experience has a profound effect on the morphological characteristics of astrocytes in the mature brain. Supported by MH35321.

583.12

A NITRIC OXIDE SYNTHASE (NOS) INHIBITOR REDUCES THE OCULAR DOMINANCE SHIFT AFTER MONOCULAR DEPRIVATION. N.W. Daw*, S.N.M. Reid, D. Czepita and H. Flavin. Dept. of Ophthalmology, Yale Univ. Sch. of Med., New Haven, CT 06520.

Nitric oxide (NO) is an intercellular messenger. This intercellular messenger has been shown to modify activity-dependent synaptic efficacy in hippocampal slices (Schuman & Madison, *Science* 245:1503-1506, 1991; O'Dell et al., *Proc. Natl. Acad. Sci. USA* 88:11285-11289, 1991). We are interested if NO is also involved in activity-dependent modification of eye-specific connections occurred in the visual cortex during the critical period for monocular deprivation. Eight kittens were monocularly deprived for 10 days starting at 44-46 days of age. Four of the kittens also received infusion of N^o-nitro-L-arginine methyl ester (NAME) into one visual cortex by an osmotic minipump while deprivation. At the end of the monocular deprivation, the ocular dominance of visual cortical cells was evaluated electrophysiologically. Our data showed that the ocular dominance histogram in NAME treated cortex shifted less than untreated cortex. However, NAME did not completely abolish the effect of monocular deprivation. Preliminary results also showed that the effect of this NOS inhibitor on the ocular dominance shift was found in layers I-V but not in layer VI. Our results suggest that nitric oxide may play a role in modification of eye-specific connections in the visual cortex. However, the activity of nitric oxide synthase is probably not essential for the modification of the connections. Supported by EY 06474 and NS 29343.

ARC, AN ACTIVITY-REGULATED CYTOSKELETAL PROTEIN, IS A BRAIN SPECIFIC IMMEDIATE EARLY GENE THAT ASSOCIATES WITH THE CYTOSKELETON. G.L. Lyford, K. Yamagata, W. Kaufmann, A. Lanahan, and C.A. Barnes* and P.F. Worley*. Department of Neuroscience, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205 and *ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

To define the molecular mechanisms of neuronal plasticity, we have identified novel proteins that are rapidly regulated by neuronal activity. In particular we have isolated a novel gene, *Arc*, which demonstrates co-localization and interaction with the neuronal cytoskeleton. *Arc* was isolated by differential cloning techniques from electrically stimulated hippocampus. The message encodes for a 55kD protein that is homologous to loops 21 and 22 of the structural protein, α -spectrin. *Arc* mRNA and protein are rapidly and transiently induced by seizure and LTP stimuli and mRNA induction is not blocked by pretreatment with cyclohexamide. Basal *arc* mRNA expression shows developmental regulation with levels rising in post-natal brain and peaking at P16. Immunohistochemistry demonstrates *Arc* expression is restricted to neurons with protein detected in both cell soma and dendrites. Confocal images show that *Arc* co-localizes with the actin cytoskeleton in the sub-membranous cell cortex. *In situ* hybridization after seizure shows signal in both the cellular and molecular layers of the dentate gyrus, suggesting that *arc* mRNA is induced not only in the cell somas but also in the dendritic tree of the granule cells. Biochemical data corroborate the evidence from sequence homology and protein localization that *arc* codes for a cytoskeletal-related protein. We have demonstrated in a cellular fractionation from brain that greater than 90% of *Arc* immunoreactivity resides in the cytoskeletal pellet which is resistant to 2M KCl and 1% triton washes. We have further demonstrated that *Arc* copurifies with actin up to the last steps of an actin preparation. Finally we have demonstrated that an *in vitro* *Arc* translation product cosediments with F-actin. Taken together these evidence suggest that *arc* is a cytoskeletal-associated protein which may play a role in dendritic structural changes underlying neuronal plasticity. HEBBIAN PAIRING OF TACTILE STIMULATION. I. CORTICAL PHYSIOLOGY: RAPID TOPOGRAPHIC REORGANIZATION OF SOMATOSENSORY CORTEX OF ADULT RATS. B. Godde, F. Spengler, H.R. Dinse* Institut für Neuroinformatik, Theoretische Biologie, Ruhr-Universität Bochum RUB, D-44780 Bochum, Germany

We address the problem of fast reorganizational plasticity using a protocol of simultaneous, paired peripheral tactile stimulation (PPTS), motivated by the postulate of Hebb that temporal coincidence of external events are required to evoke plastic changes. In studies of cortical reorganization in the hindpaw representation of somatosensory cortex of adult rats, a few hours of PPTS induced a dramatic reorganization that included: 1) enlargement of receptive fields (RFs) that always comprised the RFs of the stimulated sites. Quantitative analysis of response planes confirmed these findings. 2) RF overlap increased significantly between RFs representing stimulated skin fields. 3) Cortical representational areas of the stimulated skin fields were severalfold enlarged and were paralleled by a shift of the hindpaw representational borders. 4) Response durations were elongated due to enhancement of late response components. 5) Computer-based reconstruction of somatosensory maps revealed distortions that were selectively related to the stimulated skin sites, but the overall topography was mostly preserved. 6) All effects were fully reversible after 6 to 8 hours after termination of PPTS. 7) Response amplitudes and latencies were not affected. The implications of residual plasticity for short term plasticity in representational maps of adults are now investigated in computer simulations based on self-organizing maps, which include modifications of synaptic coupling without involving anatomical changes.

583.16

HEBBIAN PAIRING OF TACTILE STIMULATION. II: HUMAN PSYCHOPHYSICS: CHANGES OF TACTILE SPATIAL AND FREQUENCY DISCRIMINATION PERFORMANCE. H.R. Dinse, B. Godde, F. Spengler, B. Stauffenberg, R. Kraft (sponsor ENA) Institut für Neuroinformatik, Theoretische Biologie, Ruhr-Universität Bochum RUB, D-44780 Bochum, Germany

We address the problem of fast reorganizational plasticity using a protocol of simultaneous, paired peripheral tactile stimulation (PPTS). We demonstrated that a few hours of PPTS induced dramatic reorganization in the hindpaw representation of somatosensory cortex of adult rats (Godde et al. 1994, this meeting).

In order to study the functional implications of this short-term representational plasticity at a behavioral level, we initiated human psychophysical experiments using spatial (two-point discrimination) and frequency discrimination performance (in the flutter range). The index finger tip of the right hand was stimulated with a protocol analogous to the electrophysiological experiments (Godde et al. 1994, this meeting). We found a significant increase of the spatial discrimination performance after 6 or 2 hrs of passive stimulation (PPTS), but not after 30 min. Also, we found full reversibility of this improvement 8 hrs after termination of PPTS. The modifications of the frequency discrimination task were more complex including a transient deterioration of the performance.

The results are discussed in relation to the observed changes of RF size and overlap. We suggest that an increased number of neural elements involved in this task may be causally related to the improvement of the global processing.

NEURAL PLASTICITY II

GENERATION OF A SUBTRACTED cDNA LIBRARY FROM THE CEREBRAL CORTICES OF AN ENVIRONMENTALLY ENRICHED RAT AND A STANDARD ENVIRONMENT RAT. S.A. Brooks*, D.T. Riverat*, M.C. Diamond, and J.L. Martinez Jr. Department of Integrative Biology and Department of Psychology†, University of California, Berkeley, CA 94720

Environmental enrichment in rats, when compared to rats housed in a standard environment, induces a number of anatomical and structural changes in the cerebral cortex including: an increase in dendritic branching (Holloway 1966, *Brain Res.*, 2:393-396), an increase in dendritic spine counts (Globus et al. 1973, *J. of Comp. Physiol. Psych.*, 82:175-181), an increase in glial cell counts (Altman et al., 1964, *Nature*, 204:1161-1163), and an increase in the hybridization of rat cerebral cortical RNA to unique rat DNA sequences (Uphouse et al., 1975, *Dev. Psychobiology* 8(2): 171-178). Together these results suggest that changes in gene expression underlie the enrichment-induced changes in the cerebral cortex. In an effort to identify some of the up-regulated genes, we performed a cDNA library subtraction, using a ten-fold excess of standard cortex cDNA as the negative, and generated an environmentally enriched subtracted cDNA library. We have begun characterization of the subtracted cDNA library and to date have isolated two genes. Preliminary analysis indicates that these genes are differentially expressed. Further analysis will include sequencing the genes and *In Situ* hybridization with the genes in the brains of both enriched and standard environment animals. Supported by Rennie Fund to Joe L. Martinez, Jr.

SYNERGISTIC SENSORY INNERVATION OF THE DORSAL AND VENTRAL HAND SURFACES IN PRIMATES. S. Seto*, J.P. Noonan, M. Steinschneider, J.C. Arezzo, P.E. Garraghty and C.E. Schroeder. Depts. Neurosci. and Neurol., Albert Einstein Coll. Med., Bronx, NY 10461 and Dept. Psych., Indiana Univ., Bloomington, IN 47405.

Previous studies have established the presence of nondominant radial nerve inputs within the median nerve representation of monkey Area 3b. Such co-representation of inputs may underlie the preferential patterns of hand map reorganization seen after peripheral nerve section. The present study assessed the degree of similar co-representation in Areas 4, 5, 7 (IP) and S2. Macaques were surgically prepared for chronic awake electrophysiologic recording. Linear array, multicontact electrodes were used to record laminar current source density and concomitant multiunit activity (MUA) profiles generated from electrical stimulation of the median, radial and ulnar nerves in the forearm. Within glabrous surface representations in S1, median or ulnar nerve stimulation produced a "dominant" laminar response profile characterized by robust short latency activation in Lamina 4, and later activation of supra- and infragranular laminae. Radial nerve stimulation produced a "nondominant" profile- small initial PSPs centered on Lamina 4, without clear MUA correlates, followed by a longer excitatory phase consisting of large PSPs and increased MUA. A qualitatively similar dominant/nondominant co-representation was found in all areas studied. Co-localization of inputs in these areas may, as in S1, influence the pattern of reorganization following peripheral injury. However, its role in normal function may be a counterpart to that of synergistic muscle innervation. That is, integration of temporally correlated inputs from the dorsal and volar hand surfaces may be important to somatosensory perception and routine hand use. (Supported by MH06723, MH47939, & by a J.S. McDonnell Foundation Grant).

PREOPERATIVE AND POSTOPERATIVE PRACTICE AFFECT THE RECOVERY OF LOCOMOTOR PLACING FOLLOWING UNILATERAL CORTICAL DAMAGE IN THE RAT. T.M. Barth*, S.L. Irish, and S. Barbay. Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

Behavioral compensation is one mechanism of recovery of function after brain injury. In this case, the brain-damaged organism makes learned adjustments in behavior to compensate for the lost function. Although this mechanism of recovery is well noted, it has not been systematically studied. Experimental methods used to determine if behavioral compensation is the mechanism of recovery involve manipulating preoperative and postoperative experience with the task. If recovery is related to learning new behaviors then it is reasonable to predict that task-specific experience should facilitate this process. The present experiments were designed to investigate whether pre- or postoperative practice can affect the recovery of locomotor placing following unilateral lesions of the rat somatic sensorimotor cortex (SMC). Locomotor placing was measured with the foot-fault test. Animals were placed on an elevated grid floor and allowed to freely locomote for 2 minutes. Rats without lesions use the rungs for footholds but occasionally a limb slips through one of the openings in the grid (i.e. a foot-fault). Rats with unilateral SMC lesions make a significant number of foot-faults with the forelimb contralateral to the lesion. Previous studies have suggested that recovery on the task is related to learning to inhibit the continuation of inaccurate forelimb placing movements based on somatosensory and proprioceptive feedback. In Experiment 1, rats received unilateral SMC lesions and either 7 days of preoperative practice or no practice. In Experiment 2, postoperative experience was manipulated by beginning to test the animals either 2 (practice group) or 14 (no practice group) days after the SMC lesion. The results of these experiments were that both pre- and postoperative task-specific practice facilitated the rate of recovery when compared to the no practice groups. These data support the idea that recovery of locomotor placing is related to behavioral compensation.

PREFRONTAL CORTEX INJURY TIME-DEPENDENTLY ALTERS STRIATAL ZIF268 AND JUN B EXPRESSION. J.F. Marshall* and J.M. Vargo. Dept. of Psychobiology, University of California, Irvine, CA 92717-4550.

The nigrostriatal dopaminergic system has been implicated in the behavioral neglect and recovery seen following unilateral ablation of the medial agranular region of prefrontal cortex (AGm). In this study, immunohistochemistry for immediate early gene (IEG) protein products was used to examine alterations in striatal neuronal response at 5 days (neglect group) or 21+ days (recovered group) after unilateral AGm ablation. Basal and dopamine agonist-induced (5 mg/kg d-amphetamine [AMPH]) levels of IEG expression were examined. Adjacent brain sections were reacted with antisera to Zif268 or Jun B, and the amount of immunoreactivity in the CPU was determined through image analysis. At 5 days postlesion, basal and AMPH-induced Zif-immunoreactive (IR) nuclei in the ipsilateral CPU were fewer in number (25-30%, $p < .003$) and smaller in size (6%, $p < .003$) compared to those in contralateral CPU. For Jun-IR nuclei at 5 days postlesion, no hemispheric asymmetries in basal levels were evident, while AMPH-induced levels were reduced by 25% in the ipsilateral CPU ($p < .03$). This reduction was due to decreases in both number (20%) and size (10%) of Jun-IR nuclei. For both Zif and Jun, hemispheric asymmetries were primarily restricted to dorsolateral CPU, the region receiving dense afferents from AGm. In contrast to the 5-day findings, all hemispheric asymmetries were significantly diminished or not evident in recovered rats (21+ days).

PREFRONTAL CORTEX INJURY TIME-DEPENDENTLY ALTERS STRIATAL [3 H]GLUTAMATE BINDING. J.M. Vargo*, S.J. O'Dell, J.D. Blakey, and J.F. Marshall. Dept. of Psychobiology, University of California, Irvine, CA 92717-4550.

Unilateral removal of the medial agranular region of prefrontal cortex (AGm) results in behavioral neglect of contralateral stimuli followed by recovery in about 3 weeks. The present study used autoradiography to examine regional alterations in striatal NMDA receptors at 5 days (neglect group) and 21+ days (recovered group) after unilateral AGm ablation. Time-dependent asymmetries in [3 H]glutamate (GLU) binding were seen. [3 H]GLU binding in the ipsilateral caudate-putamen (CPu) was decreased by 13% at 5 days postsurgery and increased by 9% at 21+ days postsurgery ($p < .05$). These effects were restricted to the dorsolateral CPu, the region receiving dense afferents from AGm. Controls demonstrated symmetrical binding. These results are unlikely to be due to changes in CPu neuronal density following partial deafferentation since no lesion effects on [3 H]SCH-23390 (D_1 receptor) binding were evident in adjacent brain sections. These findings indicate that a partial loss of corticostriatal afferents leads to an initial reduction followed by an upregulation of striatal NMDA receptor binding, perhaps as a compensatory response to the loss of GLU input. These NMDA receptor changes may be partly responsible for the behavioral neglect and recovery, and for the time-dependent alterations of striatal immediate early gene expression seen following unilateral AGm ablation (see Marshall and Vargo, this volume).

WHAT ARE THE NECESSARY AND SUFFICIENT CONDITIONS FOR DENDRITIC REORGANIZATION AFTER CORTICAL INJURY? M.L. Forgie*, R. Gibb, S. Rowntree, and B. Kolb. Department of Psychology, The University of Lethbridge, Lethbridge, Canada, T1K 3M4.

There are several reports of dendritic reorganization after neocortical injury in adult rats. We have found that prefrontal, cingulate, and motor cortex lesions all lead to a chronic increase in dendritic arbor in parietal cortex ipsilateral to the lesion. Jones & Schallert (1992) also found increased dendritic growth in the normal hemisphere of rats with unilateral motor cortex lesions, and they correlated this with behavioral asymmetry. In contrast, we found that large unilateral strokes result in chronic dendritic atrophy ipsilateral to the lesion and no change in the normal hemisphere, in spite of a large behavioral asymmetry. The presence or absence of dendritic growth following these lesions may be due to differential astrocyte reactivity, lesion size, or be secondary to behavioral change. We therefore made unilateral motor cortex lesions of varying sizes and at different ages throughout the lifespan and measured behavioral asymmetry. Animals were sacrificed at different postoperative intervals for GFAP, bFGF, vimentin, synaptophysin, and OX-42 immunohistochemistry, or Golgi-Cox analysis. Dendritic change was related to age, the magnitude of the astrocytic reaction, and lesion size, but we found no relationship between behavioral change and dendritic growth in the normal hemisphere.

584.9

NEUROCHEMICAL AND BEHAVIORAL RECOVERY AFTER COLCHICINE LESIONS OF THE NUCLEUS BASALIS MAGNOCELLULARIS IN RATS. L. W. Shaughnessy¹, S. Barone Jr.², W. R. Mundy³ & H. A. Tilson¹. ¹Curriculum in Neurobiology, UNC, Chapel Hill ² METI & ³ Neurotoxicology Division, U.S. EPA, RTP, NC 27711.

It has been proposed that the cholinergic system plays a critical role in learning and memory (Deutsch, 1971, *Science* 174:788-794; Bartus *et al.*, 1985, *Ann NY Acad Sci* 444:332-358). In support of this hypothesis are data demonstrating that cortical cholinergic hypofunction correlates with cognitive deficits in humans (Perry *et al.*, 1978 *Br Med J* 2:1457-1459; Wilcock *et al.*, 1982 *J Neurol Sci* 57:407-417). In the present study, infusions of colchicine into the basal forebrain have been used to further explore the relationship between cholinergic and behavioral function. Bilateral infusions of either colchicine (3.0 μ g/0.5 μ l/site) or vehicle (0.5 μ l/site) were made in the nucleus basalis magnocellularis (NBM) of male Long-Evans rats ($n=12$ /group). Four weeks post-lesion, behavioral assessments were made for one-half of the rats in each group. Five weeks post-lesion, these rats were sacrificed and ChAT activity was measured in several brain regions. The second half of the rats were tested behaviorally 11 weeks post-lesion and sacrificed twelve weeks post-lesion. Five weeks after colchicine infusion, there was a significant decrease in cortical ChAT activity and passive avoidance cross-over latency and a deficit in the acquisition rate of a water maze task. Twelve weeks after colchicine infusion, ChAT activity in the parietal cortex and acquisition of the water maze task were not significantly different than vehicle-infused rats, although a significant decrease was seen in the passive avoidance cross-over latency. These data suggest an association between time-dependent recovery of a cholinergic deficit and recovery of a spatial learning task. In contrast, the passive avoidance task had an equivalent deficit at both timepoints. In summary, these data show task-specific behavioral recovery associated with time-dependent recovery in a specific regional cholinergic marker.

NONCOMPETITIVE NMDA ANTAGONIST AND ANTIOXIDANT DRUGS FACILITATE BEHAVIORAL RECOVERY FOLLOWING ELECTROLYTIC LESIONS OF THE RAT CORTEX. M.R. Hoane* and T.M. Barth. Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

Following brain injury due to ischemia, hypoxia or fluid percussion trauma there is an excessive release of glutamate that appears to trigger a sequence of events leading to secondary cell death proximal and distal to the initial site of damage (i.e. excitotoxicity). Models of traumatic brain injury suggest that excitotoxicity may be attenuated by neuroprotective drugs that either prevent or limit the activation of the N-methyl-D-aspartate (NMDA) receptor by glutamate or prevent the breakdown of the cell membrane by free radicals (i.e. free radical scavengers). These neuroprotective drugs may facilitate behavioral recovery by limiting the extent of secondary brain damage. The present experiment investigated the possibility that neuroprotective drugs facilitate behavioral recovery following electrolytic lesions of the cortex. Three drugs were studied: MK-801 (a noncompetitive NMDA antagonist working at the PCP binding site); magnesium chloride ($MgCl_2$); a voltage dependent noncompetitive NMDA antagonist; and N-tert-butyl- α -phenylnitron (PBN; an antioxidant and free radical scavenger). Rats received unilateral electrolytic lesions of the somatic sensorimotor cortex (SMC) and a regimen of MK-801 (1 mg/kg), $MgCl_2$ (1 mmol/kg), PBN (100 mg/kg) or saline beginning 15 min after the lesion. The rats were tested on a locomotor placing task. Saline treated animals showed the expected severe impairment in placing the contralateral forelimb during locomotion on the grid floor. In contrast, rats receiving MK-801, $MgCl_2$ or PBN showed a reduction in the magnitude of the initial deficit as well as an acceleration of recovery. These results suggest that neuroprotective drugs identified in models of ischemia and traumatic brain injury have the expected behavioral effects in an electrolytic lesion model. Moreover, they suggest a process similar to that of excitotoxicity may occur following electrolytic brain lesions causing transneuronal degeneration in areas distant from the lesion site.

584.8

TACTILE STIMULATION ENHANCES RECOVERY AND DENDRITIC GROWTH IN RATS WITH NEONATAL FRONTAL LESIONS. Bryan Kolb*, Grazyna Gorny and Robbin Gibb. Dept of Psychology, University of Lethbridge Lethbridge, Canada, T1K 3M4.

Rats were given medial frontal lesions or sham operations on postnatal day 4. Beginning on day 5 half of the animals were given 15 min of tactile stimulation with a small paint brush three times per day until weaning at day 21. At 60 days the animals were trained in the Morris water task and the Whishaw reaching task. The behavioral results showed large behavioral deficits in lesion animals relative to normal control rats. These deficits were significantly attenuated by the stroking. At the end of testing the brains were processed for a modified Golgi-Cox stain or immunohistochemistry. Frontal lesions reduced brain weight and decreased dendritic branching. The tactile stimulation significantly reversed these effects, with the effects being larger in female than male rats. Spine density was decreased by tactile stroking in both normal and operated rats. GFAP, OX-42, and synaptophysin immunohistochemistry is in progress. Overall, the results suggest that tactile stimulation during infancy may modulate the effects of perinatal cortical injury and may affect synaptic development in the normal brain.

584.10

BEHAVIORAL EFFECTS OF BILATERAL CORTICAL LESION ON REACTION-TIME PERFORMANCE IN THE RAT. C. Baunez, P. Salin, A. Nicoullon and M. Amalric*. Cellular and Functional Neurobiology Laboratory, CNRS, 13402 Marseille cx 9 (France).

There is substantial evidence that suppression of cortical projections enhance striatal dopaminergic activity. Cortical ablation however does not result in obvious motor deficits on spontaneous behaviors. The effect of a bilateral cortical lesion were thus studied in a conditioned motor task known to be sensitive to striatal dopamine activity. Rats were trained to depress and hold a lever until the presentation of a visual conditioned stimulus (CS) and then to release it with a reaction time (RT) of less than 500 ms for food reinforcement. Cortical lesions were performed by thermocoagulation of fronto-parietal areas. Such lesions are known to induce a progressive degeneration of cortical layers. The animals were tested daily from day seven to thirty-five post-lesion. A dramatic short-lasting increase in the number of delayed responses (over 500 ms), recovering after 20 days, could be observed in the reaction-time task. This effect was classically considered as a motor impairment. In contrast, a slight and long-lasting increase in the number of anticipated responses (premature release of the lever before the CS) was observed throughout the 35 days of testing. These results show that an extensive lesion of the fronto-parietal cortical areas induced a mixed effect with different time recovery. The long-lasting effect on anticipated responses could be related to the effects produced by a dopaminergic hyperactivity in the striatum. The short-lasting effect on delayed responses is suggested to result from damage of the direct motor pathways following extensive cortical lesions that are rapidly compensated by other mechanisms.

584.11

THE CONTRIBUTION OF TASK-SPECIFIC EXPERIENCE TO THE AMPHETAMINE-INDUCED FACILITATION OF RECOVERY IN RATS WITH CORTICAL DAMAGE. T.D. Schmanke* and T.M. Barth, Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

In an early study it was shown that amphetamine facilitates the recovery of beam-walking ability in rats with unilateral sensorimotor cortical damage (SMC) only if the animals receive task-specific practice while under the influence of the drug. More recently it has been suggested that amphetamine and practice have independent effects on the recovery of beam-walking. The present study evaluated the effects of amphetamine and practice on the recovery of tactile forelimb placing following unilateral SMC lesions. This behavior was chosen because amphetamine facilitates recovery from placing deficits even though the animals do not show placing reactions during the time of drug intoxication. If task-specific experience has a role in the facilitation of recovery it does not require the execution of the motor response while under the influence of the drug. Experiment 1 tested whether amphetamine (2 mg/kg) and practice interact to affect recovery. Four groups were used: drug + practice (dp); drug + no practice (dnp); saline + practice (sp); saline + no practice (snp). The dp group showed the fastest rate of recovery. Statistical analyses showed that there were main effects for drug and practice but no significant drug x practice interaction. These data suggest amphetamine and practice have independent effects on recovery of tactile placing. Experiment 2 attempted to isolate the type of experience necessary to facilitate recovery of forelimb placing. Unilateral SMC damaged rats were given amphetamine and assigned to one of four different groups: practice on the contralateral side only; practice on the ipsilateral side only; handling only; no practice. The results were that rats receiving either ipsilateral or contralateral experience during the period of drug action recovered significantly faster than animals receiving no practice. These data suggest that either task-specific somatosensory stimulation contralateral to the lesion or ipsilateral sensory and motor experience on the task facilitate recovery of tactile placing.

QUANTITATIVE DENDRITIC AND SPINE ANALYSES OF HUMAN PREFRONTAL AND OCCIPITAL CORTICES. L. Larsen, R.L. Swanson, M.L. Wainwright and B. Jacobs* Laboratory of Quantitative Neuromorphology, Dept. of Psychology, The Colorado College, Colorado Springs, CO 80903.

A fundamental issue in quantitative neuromorphology is the extent to which processing demands affect the complexity of dendritic systems. To this end, the basilar dendritic systems of supragranular pyramidal cells in human supramodal association cortex (prefrontal, area 10) were compared with those in unimodal association cortex (occipital, area 18). Tissue obtained from the left hemisphere of 5 neurologically normal subjects was processed with a modified rapid Golgi technique. Quantification of 100 neurons (10 neurons per tissue block) was performed on a NeuroLucida system (MicroBrightfield, Inc.) according to accepted criteria (Jacobs & Scheibel, 1993, *J. Comp. Neurol.*, 327, 83-96). Dependent measures were total dendritic length (TDL), mean dendritic length (MDL), dendritic segment count (DSC), and dendritic spine number (DSN). A distinction was also made between proximal (1st, 2nd, and 3rd order) and the ontogenetically later developing distal (4th order and above) dendritic branches.

Despite interindividual variation, neurons in area 10 consistently exhibited higher TDL (19.8%), DSC (19.9%), and DSN (31.6%) values than those in area 18. Proximal-distal distribution was similar between both cortical areas for TDL, DSC, and DSN, but distal segment MDL was an average of 79.6% greater than proximal segment MDL (which is consistent with Jacobs et al., 1993, *J. Comp. Neurol.*, 327, 97-111). An order by order analysis of the dendritic envelope revealed that differences between the two cortical areas were most pronounced in 4th order dendritic segments. Significant age-related decreases in TDL, MDL, and DSN were also noted. This finding of greater dendritic neuropil in area 10 over area 18 provides tentative support in humans for the notion that dendritic system complexity roughly reflects the computational demands placed on those systems. FAST AND REVERSIBLE REORGANIZATION OF THE THALAMO-CORTICAL PATHWAY OF ADULT RATS INDUCED BY INTRACORTICAL AND INTRATHALAMIC MICROSTIMULATION. R.F. Zepka, F. Spengler and H.R. Dinse, (sponsor EBBS) Inst. Neuroinformatik, Theoret. Biol. Ruhr-Univ. Bochum RUB, D-44780 Bochum, Germany

Recent experiments revealed rapid reorganization of the cortical representations of the primary somatosensory cortex (SI) of adult rats following intracortical microstimulation (ICMS) (Recanzone et al. (1992) *Cerebr. Cor.* 2: 181; Dinse et al. (1993) *Neuroreport* 5: 173; Spengler & Dinse (1994) *Neuroreport* 5: 1). While there is a substantial body of information about the reorganization at a cortical level, little is known about the nature of subcortical plasticity.

The present study investigated the contribution of the thalamic ventral posterior lateral nucleus (VPL) to the cortical reorganization induced by ICMS and the degree and nature of reorganization of the somatosensory representation in this thalamic nucleus induced by direct intrathalamic microstimulation (ITMS). The experiments were performed in adult rats anaesthetized with Urethane. Neurons within the hindpaw representation in SI and in VPL were recorded with glass microelectrodes, microstimulation was applied at a selected cortical (ICMS) or thalamic (ITMS) site for 2 to 4 hours. We studied the effect of 1) ICMS on VPL; 2) ITMS on VPL; and 3) ITMS on SI. In contrast to the extensive cortical reorganization following ICMS, small effects in the reorganization of the somatosensory map at the VPL were found. ITMS elicited significant changes of the RFs in VPL. However, unlike the cortical ICMS effects, no spatial expansions of the skin representations surrounding the RF of the stimulated site were observed neither in VPL nor in SI after ITMS.

The present results indicate that a few hours of ITMS leads to plastic reorganization at the VPL. However, the changes are small compared to those describe for SI, suggesting that this type of fast plasticity is a predominantly cortical phenomenon.

LEARNING INDUCED PLASTICITY OF CORTICAL MAPS - LACK OF CHANGES IN REPRESENTATIONS OF ADJACENT, UNTRAINED SENSORY RECEPTORS. M. Kossut* and E. Siucińska, Dept. of Neurophysiology, Nencki Institute, 3 Pasteur st. 02-093 Warsaw, POLAND.

Sensory training is known to produce an enlargement of cortical representations of receptors activated during the training (Jenkins et al. 1990, Recanzone et al., 1992, Weinberger et al., 1993). Increase of cortical representations of trained receptors was accompanied by a decrease in extent of adjacent representations of receptors not involved in training. We have previously demonstrated that short lasting classical conditioning involving stimulation of vibrissae results in enlargement of vibrissal cortical representation. In the present experiment we examined if the enlargement of the trained row B of whiskers representation takes place at the expense of neighboring, untrained rows.

During training stimulation of row B was paired with electrical irritation of the tail. Four pairings per minute were repeated for 10 min. a day for 3 days (altogether 120 pairings). A day after completion of training 2-deoxyglucose mapping was performed, in which cortical representation of the trained row B and control row B on the other side of the snout were visualized. As we have shown previously, representation of the trained row B was broader by 45 %, expanding into territories of row C and A. In another group of animals we examined if cortical representation of rows A and C bordering the trained row B, are narrower than usually. Analysis of 2DG autoradiograms revealed that labeling induced by stimulation of rows A and C is not decreased either in area or in intensity compared to control. The cortex corresponding to the trained row B (unstimulated during 2DG mapping) showed higher labeling than on the control side. The results indicate that training-induced expansion of row B representation is a dynamic phenomenon, where regions of cortex are activated by a new input without losing normal reactivity to the old one.

DIFFERENTIAL EXPRESSION OF THE TRANSCRIPTION FACTOR ZENK IN RESPONSE TO ENVIRONMENTAL COMPLEXITY AND HANDLING. C.S. Wallace*, D.F. Clayton & W.T. Greenough Neuronal Pattern Analysis, Beckman Inst., Univ. Illinois, Urbana, IL 61801.

Exposure to environmental complexity (EC) rapidly induces morphological plasticity in the visual cortex of weanling rats (Wallace et al., 1992). Previously we reported (Withers et al., SN Abstr. 1991) that a transcription factor, ZENK, associated with LTP (Cole et al., 1989, Wisden et al., 1990) is elevated in the visual cortex of EC animals following short term exposure as well. ZENK is also known as Zif/268, Egr-1, NGFI-A and Krox 24. To assess the behavioral regulation of ZENK, we used quantitative *in situ* hybridization to measure the expression of ZENK mRNA after 2-4 days of either: 1) group housing in a complex environment (EC); 2) individual housing with once-a-day handling (HIC) and 3) housing in complete isolation (IC). Active exploration (EC) resulted in significant increases of ZENK in visual cortex (OC2) of HIC and IC, suggesting behavioral regulation of ZENK in a region that supports robust plasticity. HIC alone significantly elevated ZENK above IC values. No significant differences were observed in frontal region FR2. ZENK levels were significantly increased in hippocampal subfield CA1 following EC. Significant elevations of ZENK in the striatum were only observed in the EC animals, suggesting plasticity in this region may be induced by EC. Regardless of condition, ZENK was distributed in a modular pattern in many cortical regions. The sensitivity of ZENK to behavioral context indicates that experience can dynamically regulate neuronal gene expression. Supported by MH35321 & Kiwanis Foundation to WTG and NS25742 to DFC.

LONG-TERM POTENTIATION AND KINDLING-INDUCED POTENTIATION OF FIELD POTENTIALS IN ENTORHINAL CORTEX EVOKED BY PYRIFORM CORTEX STIMULATION. C.A. Chapman* and R.J. Racine, Department of Psychology, McMaster University, Hamilton, Ontario, Canada L8S-4K1.

Long-lasting potentiation phenomena in the rat entorhinal cortex have not been completely described in the chronic preparation. Monopolar field potentials (EPs) were recorded in the entorhinal cortex in response to pyriform cortex test-pulses (1ms, 16-1259µA). The major component was a negative-going potential, ≈ 0.75 mV in amplitude with a ≈ 16 ms latency to peak. Responses were tested 4 times over a 7 day baseline period. Five animals then served as controls, 5 received high-frequency trains to the pyriform cortex (40-60 400Hz trains of 16.1ms 1259µA pulses), and 5 were begun on a 6 day pyriform cortex kindling procedure (1sec 60Hz trains of 1ms 600µA pulses 3 times/day). EP amplitudes remained stable in the control group. Kindling-induced potentiation of EP amplitudes (mean=201% of baseline) was observed during the kindling protocol, and declined over the next two weeks to 137% of baseline. Peak LTP at test-pulse intensities of 501 or 794µA was 156% of baseline levels on average. However, the amount of potentiation observed roughly tripled to 240% when each high-frequency train was subsequently embedded in a frequency potentiating pyriform cortex train (11 pulses, 15Hz). The responses showed little decay over a 7 wk testing period except at the highest test-pulse intensities. These results indicate large, reliable, and long-lasting potentiation effects in entorhinal cortex EPs in the chronic preparation.

SPATIAL MEMORY FOLLOWING PERIPHERAL NERVE GRAFTS AND FORNIX-FIMBRIA TRANSECTION. A.D. Davis^{1,*}, L.F. Kromer², and L.A. Rothblatt¹ Dept. of Psychology, George Washington Univ., Washington, DC 20052 and ²Dept. of Anatomy and Cell Biology, Georgetown Univ., Washington, DC 20007.

The purpose of this study was to determine whether peripheral nerve grafts in the CNS can promote axonal regeneration resulting in behavioral recovery. Fourteen rats received bilateral knife-cut lesions of the fimbria-fornix. Eight of the animals also received a sciatic nerve transplant placed between the septum and hippocampus. Four animals served as normal controls. Beginning 2 weeks after the transplant procedure, all animals were tested on a discrete-trial rewarded alternation task and the Morris water maze. Testing continued for 2 months. Both experimental groups were significantly impaired on the spatial tests compared to normal controls throughout testing. Moreover, preliminary analysis of the results indicate that the sciatic nerve transplants had no facilitating effects on spatial performance. Correlations between cholinergic innervation and behavior are currently being conducted.

RHEB, A RAS HOMOLOG ENRICHED IN BRAIN, INTERACTS WITH RAF1 SERINE/THREONINE KINASE IN AN ACTIVITY-REGULATED MANNER. W. M. Yee^{*}, A. Lanahan, and P. F. Worley. Department of Neuroscience, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205

It has been postulated that production of specific gene products in response to neuronal stimulation is required for the establishment and maintenance of neuronal plasticity. In our efforts to characterize activity-regulated gene products associated with neuronal plasticity and long-term potentiation (LTP), we have isolated and characterized Rheb, a novel Ras homolog enriched in brain that is induced by LTP and seizure stimuli and is regulated as an immediate early gene. Rheb is also induced by NGF, EGF, and FGF in neuronal cell lines and is enriched in the granule cell layer of the hippocampus following stimulation. Rheb has significant homology with human H-Ras and yeast RAS1 in conserved domains required for GTP-binding and hydrolysis, and appears to be a functionally close relative of human H-Ras as determined by Rheb's ability to transform mammalian cells. In order to characterize Rheb's physiological role in neurons following neuronal stimulation, we have utilized the yeast two-hybrid system of identifying protein-protein interactions to isolate upstream and downstream interactors of Rheb. We report here that Rheb interacts with Raf1, a serine/threonine kinase required for the oncogenic activity of human H-Ras. Using an *in vitro* co-precipitation assay, we have confirmed that Rheb interacts with Raf1 kinase isolated from the hippocampus and cortex of postnatal day 21 rats. In addition, we have experimental evidence suggesting that the interaction between Rheb and Raf1 may be regulated by neuronal activity. This line of evidence suggests that Rheb may be acting as an activity-regulated "molecular switch" that activates Raf1 serine/threonine kinase following depolarizing stimuli or neurotransmitter binding.

VARIABILITY OF POPULATION SPIKE AMPLITUDE IN LONG-TERM POTENTIATION IN BEHAVING RATS. S.J. Jones, D. Moore, and M.E. Corcoran^{*}. Dept. of Psychology, University of Victoria, POB 3050, Victoria, B.C., Canada, V8W 3P5.

Although long-term potentiation (LTP) has been postulated to be a mechanism of learning and memory, relatively few investigations of LTP have been performed in awake rats carrying chronic electrodes, and, of those, large variation in the amount of LTP has been observed across laboratories. To study factors influencing LTP, we measured the amplitude of the population spike (PS) evoked in the dentate hilus by stimulation of the perforant path in awake rats. In Experiment 1, LTP was induced in 1 group with hilar chemitrodes receiving infusions of aCSF, in another group with chemitrodes but no infusions, and in a third group with electrodes. The electrode group exhibited greater LTP than either chemitrode group. Experiment 2 tested the effects of behavioural state on LTP. Data from 1 group were collected only when rats were immobile; data from group 2 were collected irrespective of ongoing behaviour. All rats in Experiment 2 received i.p. injections of saline 30 min before tetanization, to mimic conditions of drug administration. No LTP was observed in either group at 60 min post-tetaniation, whereas significant LTP was observed 24 hr later. Experiment 3 tested the hypothesis that the saline injection may have suppressed LTP at 60 min. Group 1 received an i.p. injection of saline prior to tetanization, and group 2 received no injection. At 60 min, only group 2 exhibited significant LTP, whereas both groups showed LTP at 24 hr. In Experiment 4, one series of tetanic stimulations was applied each day for 9 days. Significant LTP was observed only after session 2 and asymptotated after session 6.

We conclude that the magnitude of LTP is affected by the presence of a chemitrode and by prior injections and that induction of LTP is more reliable with multiple sessions of tetanization. (Supported by NSERC)

Null mutation of *c-fos* Impairs Functional and Structural Plasticities in the Mammalian Nervous System. Yoshinori Watanabe^{1,4}, Randall S. Johnson², Linda S. Butler¹, Bruce M. Spiegelman², Virginia E. Papaioannou³, and James O. McNamara^{1*} ¹Duke Univ. Med. Center, ²Harvard Med. School, ³Columbia University, ⁴Fukushima Medical College.

Fleeting changes of neuronal activity produce a lasting reorganization of synaptic connections in development of the mammalian nervous system. Activity-dependent interactions also contribute to a formation of abnormal synaptic connections in the mature nervous system. Expression of the immediate early gene, *c-fos*, has been postulated to link fleeting changes of neuronal activity to lasting modifications of neuronal function and structure in the mammalian nervous system. To test this idea, we examined behavioral and electrophysiologic indices of kindling development and kindling-induced sprouting of hippocampal granule cell axons in wild type (+/+), heterozygous (+/-), and homozygous (-/-) mice carrying a null mutation of *c-fos*. Defects of both electrophysiologic and behavioral features of kindling development were evident in null mutants. Kindling-induction of granule cell axon sprouting measured by Timm staining was significantly attenuated in null mutants compared to +/+ mice with intermediate values evident in +/- mice. We conclude that *c-fos* is necessary for both normal development of kindling and complete expression of kindling-induced synaptic reorganization of granule cell axons. We suggest that the null mutation of *c-fos* produces this phenotype by altering seizure-induced transcriptional activation of target genes.

A NOVEL PROTEIN REGULATED BY SYNAPTIC ACTIVITY IN VISUAL CORTEX AND HIPPOCAMPUS. P. B. Brakeman^{*}, A. Lanahan and P. F. Worley. Depts. of Neuroscience and Neurology, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

A novel activity-regulated developmental immediate-early gene (Ard62) was cloned by differential screening of a rat hippocampal cDNA library. Ard62 encodes a brain-specific 6.5 kD mRNA with a 186 amino acid open reading frame that is not homologous to known proteins. Sequence analysis predicts that Ard62 has multiple phosphorylation sites, but no glycosylation sites. Antisera raised against a bacterial fusion protein containing the 186 amino acid open reading frame recognizes a single 28 kD band in HEK 293 cells transiently transfected with an expression construct containing the open reading frame and a 28 kD doublet in rat hippocampus. This 28 kD doublet is rapidly induced in hippocampus following seizure with a maximal induction at 4 hours. Fractionation of hippocampal tissue shows that Ard62 is primarily cytosolic, but not nuclear, and also is associated with the membrane fraction.

Northern blot analysis shows that Ard62 is induced in hippocampus within 30 minutes following seizure and is super-induced by pre-treating with cycloheximide. In situ hybridization studies show that Ard62 is strikingly inducible in visual cortex. Exposing dark-reared rat pups to light dramatically increases Ard62 mRNA in visual cortex, and unilateral intraocular injection of TTX reduces basal expression of Ard62 in the contralateral visual cortex. A role for Ard62 in synaptogenesis is suggested by the redistribution of Ard62 message in cortex during a critical period of excitatory synaptogenesis in the second post-natal week in rats. The distribution of Ard62 changes from a diffuse cortical distribution in day 10 rats to a specific localization in cortical layers II and V/VI in day 14 rats. In addition, Ard62 is strongly induced in dentate gyrus in an NMDA-dependent manner following a high frequency LTP stimulus. Ard62 is a novel protein regulated by synaptic activity in cortex and may be involved in cortical synaptogenesis. Supported by EY08347.

DEHYDROEPIANDROSTERONE SULFATE INCREASES PS IN DENTATE GYRUS LTP IN INTACT RATS. A. Yoo, J. Harris^{*} and B. Dubrovsky. Dept. of Physiology, McGill University Montreal, Quebec, CANADA H3A1A1

Dehydroepiandrosterone Sulfate (DHEAS), a neurosteroid secreted by both the adrenal cortex and the glia, has been shown to behave as a non-competitive antagonist of the GABA_A receptor which exerts inhibitory effects on LTP development when activated. Thus, it could be hypothesized that DHEAS would enhance LTP formation. Experiments were performed in intact anaesthetized rats (urethane, 1.5mg/Kg). Electrodes were stereotactically positioned in the perforant path (bifocal for stimulation) and in the dentate gyrus (monofocal for recording). DHEAS (20 mg/Kg) was injected in the femoral vein, dissolved in Nutrilipid 10% which served as control injection. Our data showed that after hormonal treatment, 10 minutes before priming tetanic stimulation (8 trains of impulses, total duration of 1 sec, train rate of 0.03 Hz, frequency of 350 Hz and pulse duration of 500 μ sec each half wave), the amplitudes of the population spike (PS) increased approximately 2 fold over the ones from control experiments. In contrast, slopes of EPSPs did not change. Both latencies of EPSPs and PSs were shifted towards shorter durations with the hormone. The results, consistent with the work of Meyer et al. (1993) in CA1 area of rat hippocampal slices, further suggest that hormonal compounds could differentially affect selected neuronal loci.

REWARD-SCHEDULE EFFECTS AND GRANULE CELL NEUROGENESIS IN THE DENTATE GYRUS OF THE RAT G.Y. Espinoza & A. Amsel*. Dept. of Psychology & Inst. for Neuroscience, University of Texas, Austin, TX 78712

Granule cell neurogenesis in the rat dentate gyrus has been shown to continue well into adulthood, although peak neurogenesis occurs at the end of the first postnatal week. We recently examined the effect of a number of kinds of learning on granule cell neurogenesis in 11-12-day-old pups (Espinoza & Amsel, *Soc. Neurosci. Abs.*, 1993). No significant training effect was found, but there was a significant effect due to handling. The experiment has now been replicated with 17-18-day-old pups. They were trained in 6 sessions over 2 days (3 sessions per day), 30 trials per session. There were 3 groups defined by reinforcement schedule: continuous reinforcement, partial reinforcement, or reinforced in a pattern of single alternation (PSA). A fourth group, a handled control, got no runway training, but was put through all other specific aspects of handling in the training situation. A fifth group was an unhandled control: no handling and no training. At the end of each of the 2 training days, pups from all groups were injected intraperitoneally with Methyl-³H-Thymidine (activity 5Ci/mmol, 5mCi/gm wt) in order to label newly forming cells. Coronal brain sections were coated with Kodak NTB-2 emulsion, exposed, developed and then counterstained with cresyl violet. Computer-aided counts revealed no significant differences among all five groups including no handling effect. At 17 days of age, rat pups can learn PSA with intertrial intervals (ITIs) up to 60 seconds, whereas 11-day-olds can learn PSA only at an 8-second ITI. To test the possibility that neurogenesis of granule cells in the dentate gyrus is influenced only at longer ITIs, the first four 17-day-old experimental groups are being replicated with longer ITIs. Data are also being collected on the effects of postnatal alcohol administered by artificial rearing from days 4 - 9. Supported by NIAAA grant AA07052.

SYSTEMIC ADMINISTRATION OF NALOXONE AFFECTS EPSP-SPIKE COUPLING IN LONG-TERM POTENTIATION OF THE LATERAL PERFORANT PATH. R.D. Kirkby*, C.R. Bramham, and J.M. Sarvey, Department of Pharmacology, Uniformed Services University, Bethesda, MD 20814.

Previous research suggests that activation of opioid receptors is necessary for the induction of long-term potentiation of field responses evoked in the dentate gyrus by electrical stimulation of the lateral perforant path, the terminals of which may release both glutamate and opioid peptides. To further assess the role of opioid receptors in long-term potentiation in this pathway, we systemically administered naloxone (10 mg/kg; i.p.) 60 min prior to tetanic stimulation of the lateral perforant path in urethane-anesthetized adult rats. Tetanic stimulation consisted of 10 trains (60-s intertrain interval) of 8 pulses (200- μ s duration; 400 Hz).

Contrary to expectation, naloxone- and saline-treated rats demonstrated similar increases in the initial slope of the excitatory postsynaptic potential (EPSP) recorded in the hilus. On the other hand, the magnitude of the population spike as a function of the slope of the EPSP after tetanus was somewhat smaller in rats treated with naloxone. The findings may shed light on the participation of opioid receptors in synaptic plasticity in the lateral perforant path. Supported by NIH NS23865.

ROLES OF RETROGRADE SIGNALS IN LTP AND LTD: A COMPUTATIONAL MODEL. M. Migliore*, F. Alicata, G.F. Ayala, I.A.I.F. - Natl. Res. Council, Palermo, Italy, and Oasi Institute for Research and Treatment of Mental Retardation and Brain Aging, Troina (EN), Italy.

We propose a kinetic model that suggests an interpretation of experiments in terms of the molecular processes that control the induction and maintenance of Long-Term Potentiation (LTP) and Long-Term Depression (LTD). The model suggests that LTP and LTD could be maintained by two similar but distinct autocatalytic processes activated by the same class of retrograde messengers. In particular, we propose that these two processes could interfere with the normal synaptic transmission mechanisms, increasing (LTP) or decreasing (LTD) the amount of neurotransmitter released at each stimulus. We present simulations of the effects of application of inhibitors of retrograde signal production such as L-NAME and ZnPP, and application of Nitric Oxide scavengers, such as Hemoglobin. Simulations' results suggest an explanation of the experimental findings that retrograde messengers are influential to maintain LTP or LTD, whereas an appropriate level of retrograde signal is needed to induce or maintain LTP and/or LTD during tetanic stimulation.

LESION-INDUCED COLLATERAL SPROUTING AND THE BRAIN'S RESPONSE TO INJURY. J. Knapp*, J.J. Norden, Dept. of Cell Biology, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232

Growth-associated protein-43 (GAP-43) is a nervous system-specific phosphoprotein whose expression is correlated with axon growth during regeneration and development. We are interested in the involvement of GAP-43 in axon elongation and employ lesion-induced collateral sprouting to study the correlation between axon growth and GAP-43 in the adult rat CNS. One of the most widely used paradigms to study collateral sprouting is unilateral removal of the entorhinal cortex (EC). This results in a partial denervation of the dentate gyrus (DG) of the hippocampus, and subsequent growth and reinnervation of the denervated areas by other afferents projecting to the DG. Preliminary data suggest that the sprouting response induced by electrolytic and aspiration methods may be qualitatively and quantitatively different. While under nembutal anesthesia (50 mg/kg), the right EC is lesioned (aspiration or electrolytic) in male Sprague Dawley rats. The animals survive for 2, 6, 15, or 30 days before sacrificing. The brain is removed, embedded, sectioned, and then immunoreacted with GAP-43 or GFAP antibodies. Following electrolytic lesions of the EC, the inner molecular layer of the DG expands to a greater width than following aspiration lesions as evidenced by GAP-43 immunoreactivity of brain sections. In addition, astrocytes are more immunoreactive with GFAP antibodies indicating a more robust gliosis following electrolytic lesions than after aspiration lesions. We are currently investigating other differences between the two types of lesions in generating a sprouting response in the DG. We hypothesize that seizures generated by electrolytic lesions influence the sprouting and astrocyte response following electrolytic lesions.

A MODEL FOR ASSOCIATIVE LTP: ROLES OF RETROGRADE MESSENGERS. F. Alicata, G.F. Ayala*, M. Migliore, Oasi Institute for Research and Treatment of Mental Retardation and Brain Aging, Troina (EN), Italy, and I.A.I.F. - Natl. Res. Council, Palermo, Italy.

We present a kinetic model of associative Long-Term Potentiation (LTP) in the hippocampus. We used an extension of a previous work on simulation of LTP (M. Migliore and G.F. Ayala, *Neur. Comp.* 5, 103 (1993)) to implement the two population of synapses activated by a weak (*W*) and/or a strong (*S*) afferent pathways to the same hippocampal dendritic region. The model is in good agreement with experimental data on the associative properties of LTP and its modifications when using different protocols of stimulation. The model suggests a possible interpretation of the experiments in terms of molecular processes and a possible key role of retrograde messengers in the induction of associative LTP. In particular, the model suggests that the associative properties of LTP could be explained in terms of the modulating effects by the retrograde messengers on the coupling mechanisms between the *S* and *W* pathways. Two possible modes of coupling the two pathways have been tested with this model, one pre- and one post-synaptic, and both are in good qualitative agreement with experimental data.

HIPPOCAMPALLY-DEPENDENT TRACE EYEBLINK CONDITIONING INDUCES CHANGES IN THE IMMUNOREACTIVITY FOR MUSCARINIC ACETYLCHOLINE RECEPTORS AND PKC γ IN THE RABBIT HIPPOCAMPUS. E.A. Van der Zee*, M.A. Kronforst, and J.F. Distenfeld, CMS Biology, Northwestern University Med. Sch., Chicago, IL 60611.

Cholinergic neurotransmission, mediated through muscarinic acetylcholine receptors (mAChRs) and the subsequently activated Protein Kinase C (PKC) modulates neuronal activity in the hippocampus in relation to learning and memory. Previously, we demonstrated changes in the hippocampal immunoreactivity (ir) for mAChRs and PKC γ after spatial learning (Van der Zee et al., *J. Neurosci.* 12:4808-4815; 1992). In the present study we determined whether 500 msec. trace eyeblink conditioning induces changes in mAChR- and PKC-ir in the hippocampus. Young adult (3 months) female NZW rabbits were trace conditioned (n=8). Pseudoconditioned (n=8) and behaviorally naive animals (n=8) served as controls. 24 Hrs after a rabbit reached the 80% criterion or after the 15th day of training, the animals were transcardially perfused with 2.5% paraformaldehyde + 0.05% glutaraldehyde. Free-floating sections were immunolabeled for mAChRs (M35) or PKC-isoenzymes (PKC α , β I, β II, and γ [both for the regulatory domain (36G9) and the catalytic domain]). Naive animals showed low levels of mAChR-ir throughout the hippocampus, and only moderate levels for all PKC-isoenzymes. Conditioned rabbits showed increased ir for mAChRs and PKC γ (both the catalytic and regulatory domain) in granule cells and pyramidal cell soma and their associated apical dendrites. In contrast, no changes were observed for PKC α , β I, or β II. The level of mAChR- and PKC γ -ir in pseudoconditioned animals was intermediate between naive and traceconditioned animals. One animal which only reached 40% CR's showed similar changes for mAChRs and PKC γ as the pseudoconditioned rabbits. These results demonstrate protein-selective changes in the hippocampal principal cells in trace eyeblink conditioned rabbits which may underlie the accompanying behavioral and electrophysiological changes. HIPPOCAMPALLY-DEPENDENT TRACE EYEBLINK CONDITIONING INDUCES CHANGES IN THE IMMUNOREACTIVITY FOR THE LOW SUBUNIT OF NEUROFILAMENTS IN THE RABBIT HIPPOCAMPUS. M.A. Kronforst*, E.A. Van der Zee, and J.F. Disterhoft. CMS Biology, Northwestern University Med. Sch., Chicago, IL 60611.

Neurofilaments (NFs) are cytoskeletal proteins which play a fundamental role in neuronal morphology and axonal transport. Enhanced neuronal connections are formed during learning. However, changes in NFs have not been previously reported in relation to learning and memory in the brain. In the present study we determined whether the immunoreactivity (ir) for the low subunit NF changes in the hippocampus during acquisition of trace eyeblink conditioning, a hippocampally-dependent task. Young adult (3 months) female NZW rabbits were trace conditioned (n=8). Pseudoconditioned (n=8) and behaviorally naive animals (n=8) served as controls. 24 Hrs after the rabbits reached the 80% criterion, or was trained for 15 days, the animals were transcardially perfused with 2.5% paraformaldehyde + 0.05% glutaraldehyde. Free-floating cryostat sections were immunolabeled with a phosphorylation-independent (68kD, Sigma, NR4) or a phosphorylation-dependent (70kD, Chemicon, MAB1615) anti-NF-L antibody. No gross changes in staining-intensity were found for either antibody in the principal cells or interneurons between the different groups. However, trace conditioned rabbits showed a twofold increase in fiber-density for NR4 in the stratum oriens, and approximately a 50% decrease in the number of fiber crossings for MAB1615 was found in the stratum radiatum as compared to pseudoconditioned and naive animals. The increase for NR4-ir most likely results from an increase in NF-content in CA1 output fibers. The decrease in the MAB1615-positive fibers most likely indicates an increase in dephosphorylation allowing the assembly of NFs formed from the low subunit, and enabling the neurons to reshape their axons. These results indicate region-selective changes in the hippocampus of trace eyeblink conditioned rabbits which may underlie learning and memory processes. BRIEF TETANIC STIMULATION CAUSES SELECTIVE TRANSIENT INHIBITORY SUPPRESSION IN THE DENTATE GYRUS N.W. Milgram* and J. Ferbinteanu. University of Toronto, Scarborough Campus, 1265 Military Trail, Ontario, Canada, M1C-1A4

Several studies have reported that repeated activation of hippocampal afferents leads to a loss of recurrent inhibition. These findings suggest that inhibition is susceptible to use dependent breakdown. To further understand the conditions necessary for such breakdown, we have investigated the effect of brief stimulus trains to the perforant path on both paired pulse inhibition and facilitation in the dentate gyrus with urethane anesthetized male hooded rats. A three pulse procedure with a reference pulse, a variable intensity conditioning pulse (C-pulse) and a test pulse (T-pulse) was used. The interval between the C and T pulse was set at 25 msec and the intensity of the T pulse was held constant. Under the control condition, there was paired pulse facilitation with a low intensity C pulse, while a high intensity C pulse caused paired pulse inhibition. Trains with 5 pulses were applied at frequencies of 2 or 200 Hz, 15 seconds before delivery of the C-T pulse pair, caused a loss of both paired pulse facilitation and inhibition. Increasing the number of pulses to 17 at a 2 Hz frequency had no incremental effect on paired pulse suppression, but attenuated the loss of paired pulse facilitation. There was evidence that the inhibitory loss was transient, since it was reduced when the delay between the trains and the C-T pulse pair was set at 1 minute. Work currently in progress is examining whether this use dependent inhibitory loss is enhanced by treatments which induce epileptic seizures.

AGING DOES NOT AFFECT SYNAPSE RESTRUCTURING ASSOCIATED WITH THE INDUCTION OF LONG-TERM POTENTIATION. Y. Geinisman*, L. deToledo-Morrell and F. Morrell. Dept. of CMS Biol., Northwestern Univ. Med. Sch. and Dept. of Neurol. Sci., Rush Med. Coll., Chicago, IL 60611.

Aged rats can be potentiated to the same degree as young ones by perforant path stimulation, but they lose their potentiated response in the dentate gyrus more rapidly (Barnes, J. Comp. Physiol. Psychol., 1979, 93: 74; deToledo-Morrell et al., Neurobiol. Aging, 1988, 9: 581). We showed earlier that the induction of LTP in the dentate gyrus of young rats is followed by a selective increase in the number of axospinous synapses with multiple, completely partitioned transmission zones (Geinisman et al., Hippocampus, 1993, 3: 435). The aim of this study was to determine whether structural synaptic plasticity induced by LTP in aged animals is similar to that observed in young adults. Aged (27 mo. old) F344 rats were implanted with stimulating electrodes in the medial perforant path and recording electrodes in the hilus of the ipsilateral dentate gyrus. Potentiated rats were stimulated (with fifteen 20 ms bursts of 400 Hz delivered at 0.2 Hz) on each of 4 consecutive days and sacrificed 1 h after the fourth stimulation. Aged animals did not differ significantly from previously studied young adults in terms of the extent of potentiation. The number of synapses per neuron was differentially estimated for various synaptic subtypes in the middle (MML) and inner (IML) molecular layer of the dentate gyrus using the unbiased disector technique. Only axospinous synapses with multiple, completely partitioned transmission zones were significantly increased in numbers in the MML (but not in the IML) of potentiated aged rats relative to their stimulated (at a frequency of 0.2 Hz) or implanted controls. The magnitude of this change was practically the same in old and young rats as compared to their respective controls. This finding suggests that the observed structural synaptic modification may account for the equivalent extent of potentiation in rats of different chronological ages.

TIME-FREQUENCY ANALYSIS OF EEG FROM ENTORHINAL CORTEX AND DENTATE GYRUS. Y. Xu^{1,2}, S. Haykin¹, R.J. Racine² and C.A. Chapman². Communications Research Lab¹, Dept. of Psychology², McMaster University, Hamilton, Ontario, Canada, L8S 4K1

Neurobiological signals, such as the EEG, are usually nonstationary over time. One way to account for the temporal nonstationarity of a signal is to use time-frequency analysis to reveal its time-frequency relations. In this report, the short-time Fourier Transform (STFT), an extension of the Fourier Transform, has been used to analyze the EEG recorded from entorhinal cortex (EC) and dentate gyrus (DG). The resulting 2-dimensional time-frequency spectrum image is obtained via a 2s sliding window with a 1.9s overlap. Thirty second samples of EEG (sampled at 256 Hz) were recorded simultaneously from the EC and the DG of behaving rats. During the middle 10s of each 30s epoch, a low intensity train of electrical pulses at one of 5 frequencies (2,6,10,14,18Hz) was applied to the pyriform cortex (PC), which projects to the EC. The EC projects, in turn, to the DG. Although there was no or little visibly apparent change in the EEG produced by the stimulation, the time-frequency spectrum image showed clear peaks at the stimulation frequency and its harmonics. The time-frequency form of the coherence function was calculated based on the STFT (15 EEG epochs) to study the connectivity between the EC and the DG. Coherence was high for the theta frequency, which fluctuated around 7-9 Hz during the 30s sampling period, and was also enhanced during stimulation at the stimulation frequency and its harmonics. The STFT was also used in signal synthesis (or extraction). The portion of the time-frequency image at the stimulation frequency and its harmonics (± 1 -2Hz) were extracted and an inverse Fourier transform was then performed on the extracted signal. The effect of the stimulation train, originally embedded in the raw EEG, showed up clearly in the reconstructed signal. Our results indicated that the STFT is an effective technique for signal processing of the nonstationary EEG.

A NOVEL NEURAL ACTIVITY-REGULATED PENTRAXIN EXPRESSED IN THE BRAIN. C.C. Tsui* and P.F. Worley. Department of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent studies indicate that activity is tightly correlated with the expression of immediate early genes which may regulate long-term neuroplastic changes. To examine cellular mechanisms involved in activity-dependent plasticity, we have used a differential screening strategy to identify genes that are rapidly induced in neurons by depolarizing stimuli. Here we describe a novel immediate-early gene that we term *narp* (neural activity-regulated pentraxin) because of its sequence homology with known pentraxins, which include serum amyloid protein (SAP) and C-reactive protein (CRP). A full length *narp* cDNA has been identified and sequenced. The open reading frame predicts a 443 a.a. protein that contains a pentraxin family Ca²⁺-binding domain and an eight amino acid pentraxin family signature sequence. The overall level of aa sequence identity between *Narp* and CRP is only 20%, however within the 15 a.a putative calcium and the 17 a.a. phospholipid binding domains these proteins are 87% and 53% identical, respectively. Pentraxin family proteins are known to be secreted and possess N-terminal hydrophobic signal sequences. *Narp* is also predicted to include an N-terminal signal sequence. Using *in vitro* transcription and translation assays in the presence of canine microsomes, we have determined that *Narp* protein is expressed in the intravesicular compartment consistent with it being a secreted protein.

narp mRNA is expressed at high levels in normal cortex, hippocampus, habenula, trigeminal ganglia, and ventral medial hypothalamus. Basal expression is rapidly responsive to natural synaptic activity as the level of *narp* mRNA in the visual cortex decreases after intraocular injection with TTX. *narp* mRNA is also rapidly induced in the dentate gyrus of the hippocampus by high frequency synaptic stimulation using the LTP paradigm and is dependent on NMDA receptor activation.

Pentraxins share the property of binding to specific glycoproteins and may function as natural lectins. We propose that *Narp* may function as an activity-regulated lectin to modify neuronal interactions with extracellular glycomolecules. Research supported by EY09374.

SELECTIVE SYNAPTIC PLASTICITY IN THE CEREBELLAR CORTEX OF THE RAT FOLLOWING COMPLEX MOTOR LEARNING. J.A. Kleim, R.M.A. Napper, R.A. Swain*, K.E. Armstrong, T.A. Jones and W.T. Greenough. Depts of Psych. and Cell & Struct. Bio., Neurosci. Prog., and Beckman Inst. Univ. Illinois, Urbana, IL 61801.

Following complex motor learning, rats exhibit an increase in the number of synapses/Purkinje cell in the cerebellar cortex. This experiment examined which synapse types are altered. Female rats, approximately 8 months of age, were randomly assigned to an Acrobatic motor learning Condition (AC), a Voluntary Exercise Condition (VX) or an Inactive Condition (IC). AC animals were trained for 30 consecutive days on a motor learning task which consisted of a series of obstacle laden pathways requiring a significant amount of motor coordination to complete. The VX animals were housed with running wheels attached to their home cages to which they had unlimited access and the IC animals were subjected only to a daily handling equivalent to that experienced by the other groups. The density of synapses was obtained using the physical disector on serial electron micrograph montages taken within the molecular layer of the cerebellar cortex and synapses were classified as to their pre and postsynaptic origins. Purkinje cell density was obtained using the physical disector on serial 1 μ m sections of the cerebellar cortex and data were expressed as synapses/Purkinje cell. Results indicate that the AC animals have a greater number of parallel fiber to Purkinje cell synapses in comparison to controls. Detailed assessment of other synaptic subtypes is in progress. Supported by AG 10154, NSF BNS 88 21219 and NSERC.

FOS EXPRESSION IN THE MOTOR CORTEX OF THE RAT DURING THE ACQUISITION OF A COMPLEX MOTOR LEARNING TASK.

E.R. Schwarz, J.A. Kleim*, E. Lussnig, T.A. Comery and W.T. Greenough. Depts. Psych. Cell Struct. Bio. Neurosci. Prog. and Beckman Inst., Univ. Illinois, Urbana, IL 61801.

Following training on a complex motor learning task, structural changes have been observed in the rat motor cortex (see adjacent poster). Previous research has also shown FOS to be expressed during learning. In this study, the expression of FOS was examined during the acquisition and maintenance phases of training on a complex motor learning task. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Condition (FW) or an Inactive Condition (IC). AC animals were trained to complete an elevated, obstacle laden course which required a substantial amount of motor skill to traverse. Each AC animal was pair matched with a FW animal which was forced to travel down a flat elevated runway equal in length to the acrobatic course. The IC animals received no motor training or activity but were handled daily. Five animals from each condition were sacrificed after 1, 2, 5, 10 and 20 days of the experimental manipulation. Four 60 μ m coronal sections containing motor cortex (1.6 mm to -1.4 mm from Bregma) were taken from one hemisphere of each animal and immunohistochemically stained for FOS. Sections were Nissl counterstained and the percentage of FOS positive cells was counted through a volume of tissue within Layer II/III of the motor cortex. Results show the AC animals to have a greater percentage of FOS positive cells during the acquisition phase (days 1, 2 and 5) versus the maintenance phase (days 10 and 20) of training. FOS expression was not significantly changed as a function of time in the FW and IC animals. Supported by AG 10154, MH 40631, NSF BNS 88 21219 and NSERC.

VISUALLY-GUIDED PLASTICITY IN THE AUDITORY SPACE MAP OF ADULT BARN OWLS. M. S. Brainard* and E. I. Knudsen. Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305-5401.

The optic tectum (superior colliculus) contains mutually aligned neural maps of visual and auditory space. Prior experiments have demonstrated that during development the topography of the auditory map is calibrated by visual experience: in owls reared with prismatic spectacles that optically shift the visual field along the horizon, the map of auditory space in the tectum gradually shifts to become aligned with the optically displaced visual map. In this study, we examined the capacity of the auditory space map in adult prism-reared owls to recover normal topography following restoration of normal visual experience.

Owls were reared from shortly after eyelid opening (16-19 days) with prismatic spectacles that displaced the visual field by 23° to the left or the right. After owls reached adulthood, the tectal auditory space map was assessed by measuring extracellular responses to dichotically presented stimuli of varying interaural time difference. For owls in which visual experience had significantly shifted the tectal auditory space map, prisms were removed at ages ranging from 120-1208 days, and subsequent changes in the auditory map were assessed.

In all prism-reared owls, regardless of the age at which normal vision was restored, the tectal map of auditory space recovered essentially normal topography. This recovery occurred rapidly, over periods ranging from 10-30 days. The results indicate that substantial visually-guided plasticity in the tectal representation of auditory space is maintained in adult owls. This finding contrasts with prior behavioral and neurophysiological results that have suggested a loss of plasticity in the tectal map of auditory space and in sound localization behavior beyond a critical period in development.

FORMATION OF DOUBLE SYNAPSES IN THE CEREBELLAR CORTEX OF THE RAT FOLLOWING MOTOR LEARNING. K. Federmeier, J.A. Kleim, B.J. Anderson* and W.T. Greenough. Depts of Psych. and Cell Struct. Bio., Neurosci. Prog., and Beckman Inst., Univ Illinois, Urbana, IL 61801.

Following complex motor learning, rats exhibit increased numbers of synapses/neuron in the cerebellar cortex. Here we present two experiments examining the structural plasticity of the parallel fiber following motor skill acquisition. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Voluntary Exercise Condition (VX) or an Inactive Condition (IC). AC animals were trained for 30 consecutive days on a complex motor learning task which consisted of a series of obstacle laden pathways requiring a substantial amount of motor coordination to complete. The VX animals were housed with running wheels attached to their home cages to which they had unlimited access and the IC animals received no motor skill training or access to running wheels. The mean intervaricosity distance along Golgi impregnated parallel fibers did not significantly differ among the three groups suggesting that few new presynaptic varicosities had developed. The second experiment utilized the same behavioral paradigm and examined the number of single varicosities forming multiple synaptic contacts (double synapses) using unbiased stereological measures from serial electron micrographs. AC rats had significantly more double synapses/Purkinje cell than VX or IC rats. The increase in synapses in the cerebellar cortex following motor skill acquisition appears to involve the formation of new synapses on existing parallel fiber varicosities. Supported by AG 10154, NSF BNS 88 21219 and NSERC.

586.4

SYNAPTOGENESIS WITHIN THE MOTOR CORTEX OF THE RAT FOLLOWING COMPLEX MOTOR LEARNING. E. Lussnig, J.A. Kleim, E.R. Schwarz, T.A. Comery and W.T. Greenough*. Depts. Psych. Cell and Struct. Bio. Neurosci. Prog. and Beckman Inst., Univ. Illinois, Urbana, IL 61801.

Following training on a complex motor learning task, changes have been observed in synaptic number in the rat cerebellar cortex. In this study, the number of synapses per neuron was examined in Layer II/III of the motor cortex following training on a complex motor learning task. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Condition (FW) or an Inactive Condition (IC). The AC animals were trained to complete an obstacle laden course which required a substantial amount of motor skill to traverse. Each AC animal was pair matched with a FW animal which was forced to travel down a flat elevated runway equal in length to the acrobatic course. The IC animals received no motor training or activity but were handled daily. Five animals from each condition were sacrificed after 1, 2, 5, 10 and 20 days of the experimental manipulation. Ten, 200 μ m, coronal sections were taken through one hemisphere (1.6 mm to -1.4 mm from Bregma) from each animal. Blocks of tissue containing the motor cortex were removed and embedded for electron microscopy. The physical disector was used to obtain neuronal density from 80 serial 1 μ m sections through Layer II/III of the motor cortex. Synaptic density was measured using the physical disector on 16 serial electron micrographs taken within Layer II/III. The number of synapses/neuron in each animal was estimated from these two measures. The AC animals had a significantly greater number of synapses/neuron than the FW and IC animals. SOILED-BEDDING INDUCES STRUCTURAL CHANGES OF SYNAPSES IN RAT ACCESSORY OLFACTORY BULB.

M. Ichikawa*, M. Matsuoka^{1,2}, and Y. Mori² ¹Dept. of Anat. & Embryol., Tokyo Metropolitan Inst. for Neurosci., Tokyo 183, and ²Lab. of Veterinary Ethology, The University of Tokyo, Tokyo 113, Japan.

The effects of soiled bedding on synaptic morphology in the accessory olfactory bulb (AOB) were examined in adult male rats. Forty-day-old male rats were isolated. One group was exposed to bedding soiled by male and female rats (EC). Another group was only to male soiled bedding (SC). The last was exposed to clean bedding (IC). After 2 months, the animals were sacrificed for electron microscopy. The size and the numerical density of synapses were measured in the glomerulus and the granule cell layer. In the glomerulus, the length of the synaptic contact zone was significantly greater in the EC than in the SC and the IC, while there was no statistically significant difference in the density of synapses among the three groups. Two types of synapses were classified in the granule cell layer: (1) perforated synapses, which are characterized by discontinuities in their postsynaptic thickenings and (2) nonperforated synapses. For perforated synapses, the length of the synaptic contact zone was significantly greater in the EC than in the SC and the IC. For nonperforated synapses, there was no statistically significant difference in the length of the synaptic contact zone among the three groups. In the density of both perforated and nonperforated synapses, there was no statistically significant difference among the three groups. These results demonstrated that exposure to bedding soiled by female rats, which contains female odour substances (pheromones) can induce structural changes of the synapses in the AOB of male adult rats.

THE AT-14 mRNA IS ENRICHED IN SEVERAL AVIAN SONG CONTROL NUCLEI AND ENCODES AN RC3/NEUROGRANIN-RELATED PROTEIN S.M. Siepka*, J.M. George, H. Jin and D.F. Clayton. Dept. of Cell & Structural Biology, University of Illinois, Urbana 61801

Differential cDNA hybridization experiments led to the identification of a brain-specific, forebrain-enriched RNA (HAT-14) that is especially abundant in song control nuclei HVC and IMAN of canaries and zebra finches. The sequence of the HAT-14 cDNA predicts a 73 amino acid protein that contains a domain found in the GAP-43 and RC3/neurogranin proteins, where it is believed to mediate protein kinase C-regulated calmodulin binding. Further analysis of the sequence reveals the first 50 amino acids are 84% identical between rat RC3 and HAT14. The identity drops to 25% in the remaining C-terminal portion, with lack of conservation of the residues identified as "collagen-like" in the rat sequence. Antibodies raised against predicted HAT-14 peptide sequences react with neurons in the songbird telencephalon. In sharp contrast to RC3/neurogranin (which is not expressed outside the telencephalon), high levels of HAT14 expression are also observed in cerebellar Purkinje cells in the songbird.

ESTROGEN EFFECTS ON SPATIAL PERFORMANCE AND HIPPOCAMPAL PHYSIOLOGY IN FEMALE RATS. D.L. Korol*, K. Unick, K. Goossens, C. Crane, P.E. Gold, and T.C. Foster. University of Virginia, Charlottesville, VA 22903

Gonadal steroids influence performance on a variety of spatial tasks in both humans and rodents. In addition, estrogen modifies the structure and response properties of neurons in the hippocampus, an area believed to be involved in processing spatial information. The present study examined the effects of estrogen on spatial performance and various measures of hippocampal physiology. Ovariectomized rats with and without hormone replacement (estrogen-progesterone regimen structured to mimic the natural cycle) and control rats at various stages of the estrous cycle were tested in the Morris swim task. Synaptic function and plasticity in the CA1 region of the hippocampus was then assessed *in vitro* at the same stage of the estrous cycle as at behavioral testing. A gradient of effect of hormones was observed for swim task performance and potentiation following primed burst stimulation: High levels of circulating estrogen related to poorer swim task performance and to higher levels of primed burst potentiation. Thus, a significant negative correlation between spatial memory and magnitude of synaptic plasticity emerged. We are presently examining the effects of fluctuations in estrogen on sleep and other behavioral measures in female rats. Possible actions of circulating estrogen on hippocampal function include: 1) neuromodulatory effects, via hippocampal afferents 2) direct, activational effects on hippocampal function and 3) regulation of number and/or function of synapses. Supported by AG05540 (DLK), AG07648 (PEG) and NS31830 (TCF).

NIGROSTRIATAL PROJECTION AFTER UNILATERAL 6-HYDROXYDOPAMINE INJECTION INTO THE STRIATUM IN NEONATAL RATS. Y. Ichitani*, M. Takasuna and T. Iwasaki. Inst. of Psychology, Univ. of Tsukuba, Tsukuba, Ibaraki 305, Japan.

In order to investigate the reorganization of nigrostriatal dopamine neuron system after a lesion of this system, we examined the effects of neonatal 6-hydroxydopamine (6-OHDA) injection unilaterally into the striatum on the subsequent development of contralateral projections from the intact side of substantia nigra (SN). After a treatment of desmethylimipramine (20mg/kg, s.c.), Wistar rats received unilateral injection of 6-OHDA (10µg/5µl) into the striatum on postnatal day 2 and 4. At the age of 4 weeks to 5 months, cholera toxin B subunit (CTB, 1%) was injected (0.4µl) into the striatum ipsilateral to 6-OHDA injection. After a survival time of 48h, rats were perfused and their brain sections were treated for immunocytochemistry of CTB. We could detect almost no CTB-immunoreactive cell bodies in the SN contralateral to the injection regardless of the age of animals. Results suggest that unilateral lesion of the neonatal nigrostriatal system did not have marked effects on the formation of interhemispheric connections of this system.

DEVELOPMENTAL REGULATION OF GAP43 MRNA IN AVIAN SONG CONTROL NUCLEI. H. Jin, H.B. Simpson, S. Siepka, C. Mello, M. Huecas, K.L. Nastiuk, J.M. George and D.F. Clayton*. Dept. of Cell and Structural Biol., Univ. of Illinois, Urbana, IL, 61801

GAP-43 is an axonal protein whose expression increases during neuritic outgrowth, and which undergoes phosphorylation by Protein Kinase C during long-term potentiation. Thus a central role has been proposed for GAP-43 in both neural development and adult plasticity. The avian song control system stands as one of the best models of regulated neural plasticity. To determine whether GAP-43 may regulate plasticity in the song system, we cloned the canary homolog of the GAP-43 cDNA. We used this cDNA to measure (by *in situ* hybridization) the expression of GAP-43 RNA in the adult canary brain, and in the zebra finch brain during the critical period for song circuit development. Two observations have emerged. First, GAP-43 is notably *less* abundant (compared to surrounding telencephalon) in the principal song nuclei HVC and RA in adult songbirds, but is relatively enriched in nucleus IMAN. Second, GAP-43 RNA levels remain relatively stable throughout zebra finch development (15-110 days of age) in most song nuclei, with one exception: RNA levels are increased in nucleus RA when the bird is first learning to sing (before day 60) then fall to the low levels observed in adults. These results suggest GAP43 gene regulation does not play a significant role in the initial establishment of connections within the song control circuit, although the gene is expressed constitutively and thus the protein itself may serve a function. In RA, downregulation of the gene may be correlated with stabilization of the motor control pathways for song production.

CELL TYPE SPECIFIC EXPRESSION FROM THE TYROSINE HYDROXYLASE PROMOTER MAY ACCOUNT FOR THE ROTATIONAL BEHAVIOR INDUCED BY ACTIVATION OF THE PROTEIN KINASE C PATHWAY IN SUBSTANTIA NIGRA PARS COMPACTA NEURONS WITH A HSV-1 VECTOR. J.S. Song*, Y. Wang, D. Hartley, D. Ulrey, J.S. Bak, D. Ashe, J. Bryan, J. Haycock, M. Daring, R. Neve, K. O'Malley, A. Geller. Children's Hosp., Boston MA; *Louisiana St. Med. Ctr., New Orleans LA; Yale Univ. Sch. Med., New Haven CT; *McLean Hosp., Belmont MA; *Wash. Univ. Sch. Med., St. Louis MO.

Regulation of rat motor behavior by the PKC pathway in substantia nigra pars compacta (SNc) neurons is being analyzed by a genetic intervention strategy with a HSV-1 vector system. Expression in cultured neurons of the rat PKC β II catalytic domain (pkc Δ), which is unregulated and constitutively active, causes activation of the PKC pathway and an activity dependent increase in neurotransmitter release (Soc. Neurosci. Abstr. 1991, 17, 603). We hypothesized that using the tyrosine hydroxylase (TH) promoter to restrict expression of pkc Δ to SNc neurons would potentiate striatal dopamine release, resulting in rotational behavior. This hypothesis is being tested with vectors that use a 6.8 kb TH promoter to control expression of LacZ (pTHlac) or pkc Δ (pTHpkc Δ).

The cell type specificity of expression directed by the TH promoter was investigated in cultured cells and in the rat midbrain. The efficiency of infection of several TH expressing (TH⁺) and TH lacking (TH⁻) cell lines was corrected for by counting the number of cells expressing β -galactosidase following infection with pHSVlac, which contains the constitutive HSV-1 immediate early (IE) 4/5 promoter. pTHlac directed a 10 to 20-fold increase in the number of cells expressing β -galactosidase comparing infection of TH⁺ peripheral (PC12) or CNS (MN9D) cells to infection of TH⁻ peripheral (N18TG2) or CNS (E27) neuronal cells. pTHlac was tested *in vivo* by stereotaxic injection into midbrain followed by either double staining (X-gal and anti-TH or anti- β -galactosidase and anti-TH) or cell counts based on cell morphology and location, and the results showed that over 80 % of the X-gal positive cells were neurons and 40 % of the X-gal positive cells were TH⁺ SNc neurons. In contrast, after injection of pHSVlac, 37 % of the cells expressing β -galactosidase were neurons and 5 % were SNc neurons. Thus, the TH promoter directed a marked increase of cell type specific expression in TH⁺ neurons; however, expression in inappropriate cell types, particularly TH⁻ CNS neurons following injection of pTHlac into the midbrain, may reflect either limitations of the current HSV-1 vector system or regulatory elements missing from the 6.8 kb TH promoter used in this study. The cell type specific expression directed by the TH promoter may explain the rotational behavior caused by pTHpkc Δ (Soc. Neurosci. Abstr. 1993, 19, 806).

MORPHOLOGICAL CHANGES IN RAT RED NUCLEUS FOLLOWING COMPENSATION FOR LIMB LESIONS. P.R. Kennedy*, N. Ishihara, L. Rutherford and J. Wilson. Neuroscience Lab., Georgia Tech, Atl., GA 30332.

Morphological changes are found in finches whose song-related nuclei regress and regrow each season. This degree of plasticity has not been described in animals where changes in cortical sensory maps have been found to be use-dependent. Such plasticity has not been shown to produce changes in the number or morphological appearances of neurons in specific nuclei. We here describe use-dependent changes in rat red nucleus.

Long-Evans rats, 3 to 8 weeks of age, were subjected to transection of their Achilles tendons and walked without a limp within 3 days. Ten to 30 days later, rats were sacrificed and brain sections stained with thionin. Prior experiments in several rats showed the caudal pole contained predominantly lumbo-sacral projecting neurons. Therefore, the caudalmost 300 microns were examined under brightfield microscopy, and neuron number and type determined. Initial results suggest that neurons in caudal RN contralateral to the lesion are reduced in number and size.

These data indicate that morphological changes occurred following compensation for the Achilles tendon lesions.

DEVELOPMENTAL CHANGES IN THE VESTIBULO-OCULAR PATHWAYS DURING METAMORPHOSIS IN FLATFISH. J.K.S. Jansen* and P.S. Enger. Dept. of Physiology and Institute of Biology, University of Oslo, 0317 Oslo Norway.

During the first two months after hatching flounders go through a very unusual metamorphosis. They tilt their bodies progressively to one side while the one eye migrates in the opposite direction across the dorsal midline to settle next to the other eye, on the opposite side of the head. During this process the vestibulo-ocular pathways are presumably reorganized to compensate for the 90 degrees misalignment of visual and vestibular frames of reference. In the present study we have examined the vestibular nuclear complex with anterograd and retrograd neuronal tract tracing techniques (HRP and dextranamines) before and after the period of eye migration in larvae and juvenile turbot.

We find: 1. that the vestibular complex consists of spatially segregated groups of neurons selecting distinct pathways to reach their targets in rostral eye motor nuclei and in the spinal cord. 2. All groups can be recognized in premetamorphic larvae as well as in juveniles. 3. The number of projection neurons increase comparably in the vestibulo-ocular and the vestibulo-spinal components of the vestibular complex. 4. Some of the projection neurons change their terminal fields in the rostral eye motor nuclei from predominately unilateral terminals in the larvae to bilateral termination after the period of eye migration in juveniles.

We conclude that the vestibular complex is basically similar in flatfish and other teleosts. The reorganization of terminal fields in vestibulo-ocular pathway during metamorphosis may be part of the plasticity required to compensate for the eye migration.

MAP KINASE KINASE (MEK-1) IS ENRICHED IN RADIAL CELL PROCESSES IN ZEBRA FINCH BRAIN. J.M. George*, H. Jin, W.S. Woods, and D.F. Clayton. Dept. of Cell and Structural Biol., Univ. of Illinois, Urbana, IL, 61801.

A differential screening strategy previously led to the identification of cDNA clones representing RNAs enriched in parts of the songbird telencephalon (Mol. Br. Res. 12:323, 1992). The sequence of one of these clones (HAT-5) predicts a protein 95% identical to the recently cloned mammalian MEK-1 protein (Crews et al., Science 258:478, 1992), which functions as an activator of MAP Kinase/ERK-1 and is part of the signal transduction pathway for various growth factors. By Northern analysis, the HAT-5 RNA is in most and perhaps all songbird tissues (zebra finch, canary), but is noticeably enriched in the brain. Expression in brain is minimal in newly hatched finches, moderate at 7 days of age, and more abundant still in adults. An antibody raised against residues 38-50 of the MEK-1 peptide reacts with a band of ~48 kD on immunoblots of brain extracts. By immunocytochemistry, the antibody stains cellular processes that appear to arise from the ventricular lining, especially at the tips of the ventricles. In Nissl counterstained sections, the processes are occasionally associated with small elongated cells. Processes with these features have previously been identified as elements of radial cells, which serve both as neuronal precursors and as substrates for migration of young neuroblasts in the adult avian brain. The enrichment of MEK-1 in radial cell processes suggests the radial cells may respond to signals generated deep within brain tissue, far from their soma in the ventricular lining. NETWORK'S AFFERENT CONNECTIVITY IS GOVERNED BY NEURAL MECHANICS. O.V. Favorov* and D.G. Kelly. Departments of Biomedical Engineering and Mathematics, The Univ. of North Carolina at Chapel Hill, N.C. 27599.

Lateral interactions among neurons in a Hebbian network can modify the afferent connections to those neurons. Excitatory lateral connections cause the connected cells to acquire similar afferent connections, whereas inhibitory lateral connections cause them to acquire different sets of afferent connections. That is, excitatory lateral connections induce attracting forces, and inhibitory lateral connections induce repelling forces on the afferent connections. Thus neurons can change the positions of - i.e., move - the groups of afferent cells that project to them, via their lateral interconnections. Forces, positions, and motions are the subject of mechanics, and therefore the development of afferent connectivity to a network can be approached as a problem in *neural mechanics*. To formulate neural mechanics, with Newtonian mechanics as a paradigm, we first measured the forces in the simplest system, consisting of two neurons with a single lateral connection, each with Hebbian connections from the same afferent field; then we studied whether systems of more than two laterally-connected neurons can be analyzed vectorially in terms of their two-neuron subsystems. The force between two neurons is found to depend linearly on the strength of the lateral connection, and also nonlinearly on the distance between the afferent groups of the two neurons. Hebbian plasticity of lateral connections offers the means to alter the shape of this dependency. Forces induced by excitatory and inhibitory connections act in opposite directions. Multiple forces acting on the afferent connections of the same neuron (induced by its multiple lateral connections) add vectorially and linearly. The space in which these forces act is not identical with the physical space of the afferent network; its metric is defined by correlations in the behaviors of afferent cells, and is very different from the familiar space of Newtonian mechanics. This formulation provides a theoretical and mathematical framework in which to analyze and predict the experience-driven development of afferent connectivity of networks throughout CNS. Supported, in part, by NIMH MH48654 and NINDS NS30686.

FUNCTIONAL DESENSITIZATION OF NMDA RECEPTORS IN AN ANIMAL MODEL OF CHRONIC UP-REGULATION OF GLUTAMATE RELEASE. P. Marini, M. Di Luca, A. Caputi, L. Pastorino, M. Cimino, G. Bonanno, M. Raiteri, I. Perez* and E. Cattabeni. Institute of Pharmacological Sciences, University of Milano, 20133 Milano and Institute of Pharmacology and Pharmacognosy, University of Genova, 16148 Genova, Italy.

Rats exposed *in utero* to methylazoxymethanol (MAM) at embryonic day 15 show a profound disorganization in the CA region of the hippocampus. These animals show cognitive deficits and impairments in LTP induction (Ramakers et al., 1993). At a molecular level, in the presynaptic compartment increased phosphorylation of B-50/GAP-43 is present with a parallel and persistent increase in the membrane-associated PKC. As a consequence, increased basal glutamate release (332 ± 23 pmol/mg of protein control; 575 ± 50 pmol/mg of protein MAM-treated) has been observed in hippocampal synaptosomes of MAM-treated rats, whereas basal release of GABA is unaltered.

The functional state of NMDA receptors was evaluated in hippocampal plasma membranes by ^3H -MK801 binding under nonequilibrium conditions, with a mathematical model allowing for the study of simultaneous modulation of the receptor by two agonists, Glycine and Glutamate, according to Marvizon and Baudry, 1993. The data show that in MAM-treated rats the allosteric interaction between Glycine and Glutamate sites shows a 10 fold difference with respect to controls, without changes in the number of binding sites as measured by ^3H -CGP39653 binding.

It is known that phosphorylation processes can influence the function of NMDA receptor. In these animals *in vivo* PKC dependent phosphorylation of the post-synaptic substrate neurogranin is markedly altered, suggesting that alterations of plasticity mechanisms involve pre- and post-synaptic parameters. Marvizon J.-C. and Baudry M. *Analyt. Biochem.* 213:3-11, 1993. Ramakers G.M.J. et al., *Neurosci.* 54:49-60, 1993.

ANTIBODIES TO HAT-3, A NOVEL SONGBIRD PROTEIN, RECOGNIZE SYNAPTIC ELEMENTS IN CULTURED RAT HIPPOCAMPAL NEURONS. G.S. Withers*, J.M. George, G.A. Banker and D.F. Clayton.

¹Neuroscience Dept., Univ. Virginia, Charlottesville, VA 22908; ²Cell & Structural Biology, Univ. Illinois, Urbana, IL 61801.

Previous studies of differential gene expression in songbird brain led to the identification of a brain-specific mRNA (HAT-3) which is developmentally regulated in the song control system (George et al., SN Abstr., 1993). The sequence predicts a 143 amino acid protein which contains a repeating amphipathic motif of 11 amino acids. Antibodies raised against the predicted C-terminus detected a single band (~17 kD) on immunoblots of both songbird and rat brain synaptosomal extracts, and stained zebra finch brain sections in a pattern consistent with synaptic localization.

With the ultimate goal of analyzing the function of the novel protein, we have used these antibodies to stain cultured hippocampal neurons from rat brain. Before synaptic contacts are present (e.g. 1-3 days *in vitro* [DIV]), HAT-3 is present in the cell body but appears diffuse and in low levels in processes. The antibodies yield a punctate staining pattern in more mature neurons (e.g. 7 DIV or older) that have established synaptic contacts. In double staining experiments, the protein is colocalized at the light microscopic level with the well-characterized synaptic vesicle protein synapsin I. Double staining with MAP2 revealed that HAT-3 puncta were concentrated around the soma and along dendrites. These results suggest that, while initially diffuse, in later stages of development HAT-3 protein becomes concentrated at regions of synaptic contact, and is localized presynaptically. Supported by NS17112 (GB), NS07199 (GW), HD07333 (JG), NS25742 (DC).

ELECTRICAL ACTIVITY IN HEMI-SECTED SUPRACHIASMATIC NUCLEI (SCNs). P. Zlomanczuk, G.R. Lynch*, EPO Biology, University of Colorado, Boulder, CO 80309-0334

The phenomenon of "splitting" - separation of an overt circadian rhythm in two components - indicates the possible presence of two component oscillators in the circadian pacemaker. In mammals, a potential site for a single oscillator is each of the SCNs. A previous study (Zlomanczuk et al., *Brain Research* 559:94-99, 1991) demonstrated that the SCNs of hamsters with a split locomotor activity rhythm exhibit matching bimodal profiles of firing rate *in vitro*. In this study, we examine the effect of severing neuronal connections between the SCNs on firing pattern. Brain slices containing the SCNs were prepared from Djungarian hamsters which expressed a split in locomotor activity under constant light (LL, 70-80 lux, n=8) or entrainment to long day (LD, 16:8, n=7). The slice was halved into left and right hemisections, and each isolated in a recording chamber. Single units were recorded. Sampling proceeded for 18-24h.

In six LD animals the firing pattern in both nuclei was similar to that observed in an intact slice: a low firing rate (4.23 ± 0.67) during the projected time of locomotor activity and a high firing rate (8.21 ± 0.25) during the absence. Both SCNs had a similar firing profile. In one slice no circadian pattern was present. In six of the LL animals two peaks of electrical activity were observed in each hemisection. Peak amplitude was ipsilaterally asymmetrical (6.79 ± 0.48 and 9.44 ± 0.75 , $p < 0.01$) with the lower amplitude in one SCN coinciding with the higher amplitude in the contralateral SCN. Firing rate during both peaks was higher than during troughs (4.11 ± 0.24). SCNs from two LL animals did not express circadian pattern. Each hemisection exhibited a bimodal firing pattern independently, although the amplitude of one peak was greater than the other. Further, the timing of maximal firing in the left hemisection is 180° out of phase with the right hemisection. (NIH MH52546)

587.3

NICOTINE INDUCES *c-fos* IN THE FETAL BUT NOT ADULT SUPRACHIASMATIC NUCLEUS. D.A. Clegg, B.F. O'Hara*, E.S. Macdonald, V.H. Cao, H.C. Heller, J.D. Miller, T.S. Kilduff, Center for Sleep and Circadian Neurobiology, Depts. of Psychiatry and Biological Sciences, Stanford University, Stanford, CA 94305.

The suprachiasmatic nucleus (SCN) is the location of the circadian pacemaker in mammals. Circadian rhythmicity is evident in the fetal rat SCN as early as embryonic day 18 (E18), and is entrained by maternal cues. Various stimuli, the most notable being light, but also some drugs such as carbachol, can phase shift the circadian system. We examined whether nicotine was capable of causing phase shifts and inducing *c-fos* mRNA production in the SCN in a manner similar to light. Although nicotine causes phase shifts in the adult SCN *in vitro*, nicotine injection (1 mg/kg s.c.) did not induce detectable *c-fos* in the SCN *in vivo* at any circadian time (CT3, 9, 15 or 21) although *c-fos* was induced in the habenula. In contrast, nicotine administered to pregnant dams on E20 induced *c-fos* in the fetal SCN as well as in the fetal habenula. These responses were blocked by pre-administration of mecamylamine. Subsequent investigations suggested that nicotine failed to induce *c-fos* expression at E16, caused minimal expression at E18, robust expression at E20 and postnatal day 1 (P1), and no expression at P3 or thereafter.

There are several possible explanations which could account for the developmentally restricted *c-fos* induction in the SCN. 1) The composition of the nicotinic receptor (nAChR) subunits may change during these critical periods. Evidence from our laboratory and others suggests that the primary nAChRs in the adult SCN may produce inhibitory rather than excitatory responses. The fetus and neonate may express the more typical, excitatory nAChRs that would lead to *c-fos* expression. 2) Ongoing synaptogenesis may alter responses to nicotine. 3) The fetus may not yet express secondary components present in the adult SCN which generate a net inhibition. We are currently investigating these possibilities in the fetal vs. adult SCN. (Supported by NIH grants HD29732 and AG05556)

INDIVIDUAL DIFFERENCES IN REENTRAINMENT CORRELATE WITH SPECIFIC 2- 125 I-iodomelatonin (2-IMEL) BINDING IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF C3H/HeN MICE. S. Benloucif* and M.L. Dubocovich, Dept. Molec. Pharmacol. and Biol. Chem., Northwestern Univ., Chicago, IL 60611.

Melatonin entrains free running activity and facilitates adjustment to a change in the light/dark cycle. These effects appear to be mediated through activation of melatonin receptors in the "biological clock", the hypothalamic SCN. This study examined whether individual differences in rates of reentrainment and 2-IMEL binding densities in SCN of C3H/HeN mice are related. Upon establishment of stable entrained running wheel activity, the LD cycle was advanced by 6 hours. Mice were treated with either melatonin (90 μ g s.c.) or vehicle (10% ethanol/saline) for 3 days at the new dark onset. Melatonin facilitated the rate of reentrainment [$F(1,29) = 6.13$, $p < 0.05$], measured by daily advances in activity onset from pre-shift baseline. Melatonin treated mice reached an average shift in activity onset of 6.07 ± 0.28 h ($n = 16$) in 5 days, in contrast to 7 days for vehicle treated mice (6.06 ± 0.23 h, $n = 14$). Mice selected for varying rates of reentrainment were sacrificed, and brain sections containing the SCN and paraventricular thalamic nucleus (PVNT) were processed for quantitative receptor autoradiography. Specific 2-IMEL binding (181 pM) defined with 1 μ M melatonin was observed in both the SCN and PVNT. There was a significant correlation between 2-IMEL specific binding in the SCN and the reentrainment rate in the melatonin treated group ($r = 0.77$, $p < 0.01$, $n = 8$), but not in controls ($n = 4$). No correlation was observed with PVNT binding. These data suggest that individual differences in reentrainment in response to exogenous melatonin may be due to variations in the density and/or affinity of melatonin receptors in the SCN, and further support the SCN as the locus of melatonin's effects on circadian activity. Supported by a Glaxo grant (MLD) and NIH F32-AG05608 (SB).

587.2

DIFFUSE CLOSED HEAD INJURY INDUCES PHASE SHIFTS IN CIRCADIAN RHYTHMS AND EXPRESSION OF FOS PROTEIN IN THE SCN AND IGL IN THE RAT. K. Edelstein*, B. Robinson, and S. Amir, Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada.

Diffuse closed head injury has been associated with cognitive and behavioral deficits in humans and animals. Little is known about the effects of such injury on the circadian system. Wistar rats were implanted with biotelemetry transmitters, and circadian temperature and activity rhythms were recorded under constant dark (DD) conditions for 10 days. Pentobarbital-anesthetized rats were then mounted in a stereotaxic apparatus and injured using a 250 gm weight drop device. Behavioral results indicated that such injury induced phase delays that were greater than those induced by anesthesia alone. Differences in amplitude and period were observed in injured animals as well. The effects of such injury on the circadian system was further examined using the expression of Fos protein, previously shown to be a marker of light-induced activation of cells in the suprachiasmatic nucleus (SCN) and intergeniculate leaflet (IGL). Rats sacrificed up to 3 hours after head injury exhibited Fos-like immunoreactivity in the SCN and IGL, while pentobarbital-anesthetized controls did not. Therefore, the induction of Fos protein in these regions is not a specific response to photic stimulation. Taken together, these results suggest that diffuse closed head injury alters circadian rhythmicity. Some of the behavioral deficits observed in head injured animals may be secondary to the effects of such damage on the circadian system.

587.4

LIGHT-INDUCED EXPRESSION OF IMMEDIATE EARLY GENES IN THE SUPRACHIASMATIC NUCLEUS (SCN) AND RETINA OF C3H/HeN MICE AND THE EFFECT OF MELATONIN ADMINISTRATION. M.J. Masana*, S. Benloucif and M.L. Dubocovich, Dept. Mol. Pharmacol. and Biol. Chem., Northwestern University Medical School, Chicago, IL, 60611.

Induction of immediate early genes and behavioral responses to light ensue only with light pulses delivered during the subjective night. To investigate the possible effects of circadian fluctuations of melatonin levels on photic responses, we studied the effect of melatonin administration on light-induced phase shifts and *c-fos* mRNA expression in the SCN and retina of C3H/HeN mice. Wheel running activity was recorded from male mice (7-8 weeks old) housed in constant dark. Mice injected with melatonin (90 μ g s.c.) or vehicle (10% ethanol/saline) were exposed to light (300 lux 15 min) at various CTs, with CT12 (CT = circadian time) as the onset of activity. Melatonin administration 5 minutes before the light pulse produced a phase advance at times where light produced little or no response (CT2 to CT10). At the end of behavioral measures, treatments were repeated and the brains and eyes processed for 2- 125 I-iodomelatonin binding or *in situ* hybridization. Initial analysis indicated an increase in light-induced *c-fos* mRNA expression by melatonin with a dramatic gradient throughout the SCN. In the retina, light-induced *c-fos* expression was observed in a small number of ganglion cells and specific 2- 125 I-iodomelatonin binding was observed in the inner plexiform and the ganglion cell layers. These results suggest a role for melatonin receptor activation in retina and/or SCN of the C3H/HeN mice in the modulation of light responses. The Glial Intermediate Filament Vimentin Defines the SCN in the Syrian Hamster but not the Rat. A.S. Elliott* and A.A. Nunez, Dept. of Psychology / Neuroscience Program, Michigan State University, East Lansing, MI 48824

The suprachiasmatic nucleus (SCN), the site of the biological pacemaker, has been shown to undergo circadian variations in the expression of glial fibrillary acid protein in the Syrian hamster (*NeuroReport* 4: 1243). Vimentin, an intermediate filament that demarcates radial glia, is the dominant intermediate filament of immature astrocytes. Vimentin has also been shown to be expressed in glial cells of adult rats in the supraoptic nucleus (*J. Neuroendocrin.*, 5:1), a nucleus in which astrocytes also have been shown to change morphology under osmotic challenges (*Progress in Neurobiology*, 34: 437). We tested the hypothesis that vimentin may be a marker of areas that retain plasticity, and may play a role in regulation of the circadian timing by glial cells. Animals were housed in a 12:12 light:dark cycle (dim red illumination), with lights out at 12:00 noon. Animals were hooded and perfused at selected times (Hamsters 8 am, 10 am, 2 pm, 4 pm; Rats 8 am, 12 noon, 4 pm), and brains were sectioned at 40 μ m. Immunocytochemistry for vimentin was performed and sections were evaluated for the presence of immunoreactivity. Vimentin was present in the SCN of the hamster, and ranged in defining only the ventrolateral portion of the SCN to being ubiquitous throughout the nucleus. Cell bodies were frequently noted along the SCN/chiasm border, with processes from these cells invading the ventral SCN. However, no circadian variation in the distribution of immunoreactivity was noted. No immunoreactivity for vimentin was seen in the SCN of the rat, but some immunoreactive fibers were seen in the retrochiasmatic area. Supported by grant IBN 9209437 from NSF.

LOCAL SYNAPTIC CIRCUITS IN THE RAT SUPRACHIASMATIC NUCLEUS. G.J. Strecker* and F.E. Dudek. Dept. Anatomy and Neurobiology, Colorado State Univ., Fort Collins, CO 80523.

Previous anatomical studies have indicated that a large fraction of neurons and presynaptic terminals in the suprachiasmatic nucleus (SCN) contain GABA. Furthermore, electrical stimulation of regions outside the SCN has been found to produce GABAergic synaptic potentials in SCN neurons, but it is unclear whether such evoked potentials arise from the stimulation of GABAergic neurons within the SCN, or of fibers originating in other areas. To test whether SCN neurons form local inhibitory synapses among themselves, we applied brief pulses of glutamate (10 mM, 0.2 s) to the SCN during whole-cell voltage-clamp recording in thin (150 μ m) hypothalamic slices. Such glutamate pulses would be expected to stimulate predominantly cell bodies in the SCN rather than fibers of passage.

Whole-cell voltage-clamp recordings in SCN from 12 to 18 day-old Lewis rats revealed spontaneous outward currents in all neurons ($n = 33$), with amplitudes ranging from 5 to 60 pA at holding potentials near 0 mV, and a frequency of occurrence ranging from 0.05 to 10 Hz. Bicuculline (10 μ M) blocked these events in 9 of 9 neurons, indicating that they were GABA-mediated inhibitory postsynaptic currents (IPSCs). Pressure ejection of glutamate-containing bath solution onto the SCN resulted in clear increases in the rate of IPSCs in 6 of 18 neurons. Spontaneous inward currents, which were presumably excitatory postsynaptic currents (EPSCs), were seen in fewer neurons ($n = 11$ of 15), possibly due to their lower rate of occurrence (about 0.1 Hz, on average). Glutamate microstimulation did not evoke EPSCs reliably in any of 12 cells. These results suggest that local synaptic circuits within the SCN exist, and are predominantly inhibitory.

LOCALIZATION OF PRETECTAL NEURONS IN THE RAT WITH EXTENSIVE PROJECTIONS TO THE SUPRACHIASMATIC NUCLEUS (SCN) AND THE INTERGENICULATE LEAFLET (IGL).

Jens D. Mikkelsen* and Niels Vrang. Inst Med Anat, Univ Copenhagen, Blegdamsvej 3, 2200 N, Denmark

A characteristic anatomical feature of the two most important components of the mammalian circadian timing system: the SCN and the IGL, is that they are bilaterally innervated from the retina. Parts of the olivary and posterior pretecal nuclei have been shown to be bilaterally innervated from the retina as well, and we therefore aimed to explore whether these two nuclei were anatomically related to the circadian system. The anterograde neuronal tract tracer, *Phaseolus vulgaris*-leucoagglutinin (PHA-L), was injected iontophoretically into different pretecal nuclei of adult male rats. Only if PHA-L was injected in the medial part of the pretecal i.e. involving the *olivary* and *posterior pretecal* nuclei, PHA-L-ir nerve fibers were observed to course laterally and rostrally into the optic tract, and within the optic tract and chiasm, under the diencephalon to penetrate dorsally into the SCN. Along this pathway, the projection gave rise to a large number of branches, varicose nerve fibers, and nerve endings in the IGL. In the SCN, varicose PHA-L-labeled nerve fibers were found exclusively in its ventrolateral part, apparently overlapping with the retino- and geniculorecipient zones. The pretecal injections gave rise to a bilateral innervation of the SCN and IGL, but mostly ipsilaterally to the side of injection. To determine the precise location of the projecting neurons in the pretecal, the retrograde tracer *Cholera toxin*, subunit B, was iontophoretically injected either into the SCN or the IGL. The presence of labeled neurons scattered in both the posterior and olivary pretecal nuclei was observed in both experiments. Most neurons were found in the medial part of the posterior pretecal nucleus and in the dorsomedial part of the olivary pretecal nucleus ipsilateral to the injection, confirming the anterograde tracing studies. These neuroanatomical tract tracing results reveal the presence of a novel pathway linking the pretecal, the SCN and the IGL, indicating that the projecting pretecal neurons and their efferent projections are potentially involved in phase-shifting mechanisms.

ONTOGENY OF THE MOTOR CIRCADIAN SYSTEM IN CRAYFISH. J. Hernández-Falcón*, A. de la O-Martínez and B. Fuentes-Pardo. Depto. Fisiología, Facultad de Medicina, UNAM. AP 70-250, México, 04510, D. F. MEXICO.

The ontogeny of motor circadian rhythm of the crayfish (*Procambarus clarkii*) was studied using specimens kept under controlled conditions of light and temperature (17°C). The motor activity of animals aged between 10 to 180 days after hatching was recorded. During 10 days the movements of unrestrained crayfish were monitored by means of a video camera coupled to a digital converter. Recordings were obtained under free-running in darkness (DD), free-running in light (LL) and LD 12:12 photoperiods. From each recording circadian parameters (amplitude, : ratio and night/day ratio) were measured; was calculated by means of periodogram technique. The mean for the youngest crayfish was 23.9 hrs in either LL or LD. In the oldest animals the mean was 22 hrs in LL, 22.9 hrs in DD, and 20 hrs in LD. The younger the crayfish the more irregular the locomotor patterns. However, the ability to be synchronized by LD photoperiods is better in the younger than in the older crayfish. The results indicate that the circadian organization appears very early in the development. They suggest also a progressive increment in the number, kind and amount of dispersion of the oscillators during the ontogenic development.

DIFFERENTIAL INNERVATION OF THE HAMSTER SUPRACHIASMATIC NUCLEUS (SCN) AND INTERGENICULATE LEAFLET (IGL) BY RAPHE NUCLEI. E.L. Meyer* and L.P. Morin, Dept. Psychiatry and Neurobiology, Stony Brook University, NY 11794.

The SCN and IGL, components of the circadian system, receive serotonergic (5-HT) innervation from the dorsal (DR) or median (MR) midbrain raphe. In the rat, the data are inconsistent as to which nucleus projects to SCN or IGL. Studies of DR and MR efferent pathways to the hamster circadian system have not been performed.

Retrograde (Fluoro-Gold, cholera toxin, Fast Blue) and anterograde (*Phaseolus vulgaris* leucoagglutinin; PHA-L) tracing techniques were used to show raphe neurons and their projections. Retrograde tracers were injected into the SCN or IGL of male golden hamsters and locations of labeled cells in DR and MR were noted. PHA-L was injected into the DR or MR and the projections to the SCN and IGL were mapped.

The anterograde data show MR, but not DR, projections to the SCN. Retrograde label placed in the SCN labels cells in the MR, but not DR. In contrast, placement of PHA-L in either the DR or MR labels fibers in the IGL. Retrograde analysis is in progress. The results are consistent with data (unpublished) showing that MR, but not DR, lesions destroy 5-HT projections to the SCN. DR, but not MR, lesions eliminate 5-HT fibers in the IGL. The anterogradely labeled MR fibers to the IGL may not contain 5-HT. This issue is being evaluated. Supported by NS22168.

THE SUPRACHIASMATIC NUCLEUS AND INTERGENICULATE LEAFLET OF *ARVICANTHUS NILOTICUS*, A DIURNAL MURID RODENT.

L. Smale*, Dept. Psychology, Michigan State University, East Lansing, MI, 48824

Little is currently known about how the neural substrates controlling circadian rhythms differ in diurnal compared to nocturnal species. One reason has been the absence of a suitable diurnal rodent model. *Arvicanthus niloticus*, a murid rodent recently imported from Kenya, exhibits a diurnal pattern of precisely timed wheel-running activity and may represent an ideal diurnal mammal for studies of the neural control of circadian rhythmicity. To provide background information for future experimental studies, we used immunohistochemical techniques to examine the distribution of peptides in the SCN and IGL of 8 adult *A. niloticus* (2 females and 6 males); in this initial study animals were not pre-treated with colchicine. In *A. niloticus*, as in other mammals, distinctly different subdivisions of the SCN contained VIP and VP immunoreactive (IR) cell bodies. Within the SCN, we did not observe cell bodies containing NPY, met-enkephalin or substance-P immunoreactivity. NPY-IR, M-enk-IR and SP-IR fibers were present within the SCN. The IGL contained a substantial number of NYP-IR cells, as well as SP-IR and M-enk-IR terminals. Overall, the IGL and SCN of *A. niloticus* resembled, in many respects, those previously described in rats.

EFFECT OF SKELETON PHOTOPERIODS UPON THE CIRCADIAN MOTOR ACTIVITY RHYTHM DURING ONTOGENY IN CRAYFISH. M.L. Fanjul-Moles*, O. Castañón-Cervantes and M. Miranda-Anaya. Lab. de Neurofisiología Comparada, Fac. de Ciencias UNAM. México D.F., 70371, México.

During ontogeny of crayfish *Procambarus clarkii* the synchronization of the circadian activity rhythm (CAR) to complete photoperiods (CP) is not clear (1) probably due to a masking effect of light. We tried to rule out this effect, studying the influence of symmetrical skeleton photoperiods (SSP) upon the CAR at different stages of development. *Procambarus clarkii* juvenile instars between 10 up to 150 days after hatching were individually housed in activity recording cages under constant darkness and temperature conditions. Each crayfish was free running recorded during 15 days. Afterwards it was changed to 3 different SSP equivalent to the following CP: 12:12, 8:16 and 20:4. After 15 days of SSP stimulation they were left free running again. The results suggest that only animals older up to 60 days are able to synchronize to SSP adjusting its maximal phase to the longest scotophase.

THE ROLE OF CENTRAL NEURAL DIRECT CONNECTIONS ON THE CONTROL OF RAT PINEAL METABOLISM. J. Cipolla-Neto, I. Bartol, S.M. Mondoni, P.M. Seraphim, S.C. Afeche, L.G. Brito, J. Scialfa and A.M.C. Peracoli. Dept of Physiology and Biophysics, Inst. of Biomed. Sci., Univ. of São Paulo, São Paulo, Brazil, 05508-900.

The aim of the present work was to study the effects of lesions on the intergeniculate leaflet (IGL) or the deep pineal / lamina intercalaris region (DP) on the diurnal profile of N-acetylserotonin (NAS) and on the nocturnal pineal inhibition process induced by acute light exposure. Male adult albino rats (n=214, 12h:12h light-dark cycle, lights on at 0600h), intact or previously lesioned, were killed along the 24 hours or during the night immediately after 1 or 15 minutes of exposure to 500 lux white lights. The pineal glands were collected and frozen (-70°C) until NAS was assayed by HPLC-ED. The 24-hour experiment shows that there is no phase shifting on the diurnal NAS curve of groups of rats with large bilateral IGL lesion compared to the controls. On the other hand there is a significant reduction on the amplitude of pineal NAS content observed in every nocturnal point of the curve (p<0.05). The pineal glands of IGL-lesioned rats do not respond to brief (1 min.) retinal photostimulation keeping its NAS content equal to the lesioned dark killed rats (p=0.93). On the other hand, 15 min. of photostimulation bring the pineal NAS content of the IGL group to nearly zero equally to the control animals. In experiments done at 2400 h, DP lesion does not modify the content of NAS in the pineal gland of rats killed in the dark. However, the pineal photo-inhibition process induced by 1 min of light exposure is impaired since the lesioned group has its NAS content reduced much less than the intact animals. These results suggest that: 1-the nocturnal photo-inhibition process of the pineal gland is partially dependent on central direct neural projections, probably from the IGL region; 2- The IGL exerts a tonic excitatory control on the nocturnal pineal NAS production, probably via its indirect projections controlling the hypothalamus-spinal cord-sympathetic pineal system. LOCALIZATION AND CHARACTERIZATION OF 2-[¹²⁵I]-IODOMELATONIN BINDING SITES IN GUINEA-PIG BRAIN. L.J.M. Beresford, M.L. Dubocovich¹, J. Andrews, R. Nicholls, J.C. Coughlan, S. Jacob², A. G. Hayes² and R.M. Hagan. Dept. Pharmacol., Glaxo Res. & Devel., Ware, Herts. UK, SG12 0DP, ¹Dept. Pharmacol., Northwestern Univ. Medical School, Chicago, IL 60611.

ML-1 receptor binding sites have been localized within a number of circadian and visual areas of the mammalian and avian CNS. We have localized and characterized 2-[¹²⁵I]-iodomelatonin ([¹²⁵I]-MEL) binding sites in guinea-pig brain.

Specific [¹²⁵I]-MEL (90pM) binding, defined using melatonin (1µM), was identified in coronal sections of guinea-pig brain by receptor autoradiography at the level of the arcuate, suprachiasmatic and lateral geniculate nuclei, superior colliculus (SC) and nucleus accumbens. In SC and hypothalamic membranes, high-affinity, specific, saturable and reversible binding was observed. In the SC, [¹²⁵I]-MEL bound to a single population of high-affinity binding sites (K_D 14.1±0.4pM, B_{max} 66±6fmol/g tissue), while in hypothalamus both high and low affinity sites were identified (K_{D1} 33.3±6.5pM, B_{max1} 19.1±0.7fmol/g tissue; K_{D2} 6.6±2.8nM, B_{max2} 153±47fmol/g tissue), which appear to represent two affinity states of the ML-1 receptor. In hypothalamus, melatonin agonists inhibited binding with a rank order of potency (IC₅₀ values) 2-iodomelatonin (0.16±0.02nM) ≥ N[2-(7-methoxy-1-naphthalenyl)ethyl]-acetamide (MNEA; 0.37±0.07nM) > melatonin (1.8±0.2nM) ≥ 6-chloromelatonin (3.1±1.0nM) >> N-acetylserotonin (1.4±0.3µM) >> 5-HT (>100µM). 5-methoxycarbonylamino-N-acetyltryptamine (GR135531), which has higher affinity for N-acetylserotonin-preferring (ML-2) receptors (Dubocovich et al., IUPHAR, 1994), was only weakly active (<1µM). The rank order of potencies in SC membranes was identical (correlation coefficient 0.998).

In conclusion, [¹²⁵I]-MEL binding sites, with the characteristics of ML-1 receptors, were localized in guinea-pig SC and hypothalamus, areas in which this receptor may regulate visual and circadian information, respectively.

EVENING ADMINISTRATION OF MELATONIN PROMOTES SLEEP IN HUMANS. I.V. Zhdanova, R.J. Wurtman, H.J. Lynch, J. Ives, J. Matheson, C. Morabito, A.B. Dollins, D.L. Schomer and C.J. Watkins.* Clin. Res. Ctr., MIT, Cambridge, MA 02139 and Neurology, Beth Israel Hosp., HMS, Boston, MA 02215.

Sleep-inducing effects of low doses of melatonin were examined in young healthy volunteers. The hormone (0.3 or 1.0 mg, p.o.) or placebo was administered at 1800 or 2000 h; the lower dose elevated serum melatonin to concentrations comparable to those normally occurring nocturnally in adults (80-120 pg/ml). Effects of the treatment on performance and mood were monitored all day prior to evening treatment and until 0900 the next morning. The volunteers' subjective evaluation of the hypnotic effect showed that they could distinguish between melatonin and placebo, especially after treatment at 2000 h. Beginning 2 hours after treatment, sleep latency was measured by a switch release or by a polysomnographic system. Either dose given at either time point decreased both sleep onset latency and the most sensitive index of melatonin's effect, stage 2 sleep latency.

These observations indicate that raising blood melatonin levels to those normally occurring nocturnally promotes sleep onset in humans.

INTRACELLULAR CA²⁺ DYNAMICS IN DISSOCIATED CELLS OF THE CHICK PINEAL GLAND. T. D'Souza & S. E. Dryer*, Program in Neuroscience, Florida State University, Tallahassee, FL 32306.

The regulation of intracellular free Ca²⁺ concentration was examined in dissociated chick pineal cells using the fura-2 technique. Approximately 10% of cells examined exhibited spontaneous Ca²⁺ oscillations. Membrane depolarization evoked large increases in intracellular free Ca²⁺ that were dependent upon external Ca²⁺ ions. Application of thapsigargin (2 µM) evoked increases in intracellular free Ca²⁺ in the absence of external Ca²⁺ indicating the presence of internal stores. Application of 100 nM vasoactive intestinal peptide (VIP) induced a sustained increase in intracellular free Ca²⁺ and, in a small number of cells, evoked Ca²⁺ oscillations. Application of 200 µM norepinephrine had no effect on intracellular free Ca²⁺ in quiescent or oscillating pineal cells. Application of 8-Br-cyclic AMP (5 mM), papaverine (50 µM), IBMX (100 µM), or forskolin (200 nM) evoked sustained increases in intracellular Ca²⁺. The responses to forskolin could be observed in Ca²⁺ free external salines suggesting mobilization of internal stores. These results suggest new mechanisms for the regulation of melatonin synthesis and secretion, and possible sites of action for the intrinsic circadian oscillator. Supported by AFOSR F-49620.

NON G-PROTEIN COUPLED HIGH AFFINITY MELATONIN RECEPTORS ARE PRESENT IN THE SHEEP BRAIN. Barrett P.*, Lawson W., Maclean A., Hazlerigg D., Williams I.M. and Morgan P.J. Rowett Research Institute, Bucksburn, Aberdeen AB2 9SB Scotland. Melatonin receptors have been localised to both neuronal and non-neuronal sites by *in vitro* autoradiography using the radioligand 2-[¹²⁵I]-iodomelatonin. In general these receptors are characteristically of the G-protein class, as they are membrane-bound, of picomolar affinity which is modulated by guanine nucleotides. In non-neuronal ovine pars tuberalis cells, melatonin acts to inhibit forskolin-stimulated adenylate cyclase through a coupling to two independent inhibitory G-proteins. Recent evidence suggests that unique Gs-like G-protein, which is both cholera toxin-sensitive and recognised by α₅ subunit C-terminally directed antibodies mediates this response. In contrast sheep neuronal tissue has markedly different characteristics. Homogenate binding assays reveal that the hippocampal binding site has high affinity (K_d = 56 pM), yet binding is not affected by GTPγS, cholera or pertussis toxins, each of which modulate the affinity of the PT melatonin receptor. Native polyacrylamide gel electrophoresis resolves the PT receptor as a complex which migrates with a molecular mass of ~515kDa. Under the same conditions the hippocampal receptor migrates with a molecular mass of ~365kDa. This assay also provides a visual demonstration of the lack of GTPγS sensitivity of the hippocampal receptor. With this technique we also show that the melatonin receptor present in the cerebral cortex and pre-optic area have a similar mass to the hippocampal receptor and are not affected by GTPγS. This suggests that these receptors are not G-protein coupled and therefore belong to different class of receptor.

S-20098, A MELATONIN-AGONIST, PHASE SHIFTS THE CIRCADIAN CLOCK OF MICE AND SYRIAN HAMSTERS ACCORDING TO A PHASE-RESPONSE-CURVE. YAN REETH O., OLIVARES Y., ZHANG F.W., TUREK F.W., DEFRANCE R., MOCAER E.* CERB, Université Libre de Bruxelles, Brussels; Dept of Neurobiology and Physiology, Northwestern University, Evanston, USA; Institut de Recherches Internationales Servier, Paris, France.

S-20098, a naphthalenic analogue of melatonin, has potent and specific agonist properties on melatonin receptors both *in vitro* (YOUS et al., 1992) and *in vivo*. Like exogenous melatonin, daily injections of S-20098 in late subjective day can entrain the activity rhythm of rats free-running in constant darkness (DD) (BONNEFOND et al., 1993). S-20098 can also accelerate the rate of re-entrainment of the activity rhythm in rats subjected to an 8-h advance shift in the light-dark cycle (REDMAN et al., 1993). The aim of this study was to see whether single administration of this new compound has any effect on the circadian system of hamsters and mice. In two separate studies, we have determined the effects of single injections of S-20098 on phase and period of the circadian rhythm of wheel running in C3H/He mice (10 mg/kg) or (5 mg/kg). Single intraperitoneal injections (vehicle versus S-20098) were administered at one of ten different circadian times (CTs 3, 6, 9, 10, 11, 12, 15, 18, 21 and 24; CT 12 = onset of locomotor activity) in mice or hamsters free-running in DD (N = 7-10 animals per CT).

Phase advances in the activity rhythm were observed between CT9 and CT12 in both species. Maximal phase advances were of a larger magnitude in mice (CT11; mean = 37±8 min) than in hamsters (CT 9; mean = 17±7 min). No significant phase-delays in the activity rhythm were observed. Treatment with S-20098 had no significant effect on the period length and any of the CTs tested.

Results of these studies indicate that single injections of S-20098 can induce phase shifts in the circadian clock of rodents, and suggest a potential role of S-20098 as a chronobiotic in the treatment of disorders where biological rhythms are disrupted.

MELATONIN RHYTHMS IN THE JUVENILE DJUNGARIAN HAMSTER: MAGNETIC FIELD EXPOSURES AND THEIR REPRODUCTIVE CONSEQUENCES. SM Yellon*, JC Smith and H Trong Div. Perinatal Biology, Depts. Physiol. & Peds., Loma Linda Univ. Sch. of Med., Loma Linda, CA 92350

The pineal melatonin rhythm in a variety of rodents is suppressed by exposure to 60 Hz magnetic fields (MF) and may alter the clock mechanism involved in the photoperiodic control of reproduction (*J Cell Biochem* 51: 394, 1993). To determine if MF disrupts photoperiodic regulation of sexual maturation, males in long (16L) or short days (10L) were exposed each day to a 1 Gauss MF (15 min. beginning 2 h before lights out) from 18 to 25 days of age. A single exposure of juveniles or adults to this MF reduces duration and phase delays the nighttime rise in melatonin. Sham-controls were in an adjacent system but current was not applied. Hamsters were decapitated every 1 to 4 h to define the melatonin rhythm ($n=6/\text{time}/\text{group}$); serum and pineal gland levels were determined by RIA. In long days, testes growth in both sham-exposed and MF-treated hamsters was typical for the normal onset of puberty (group means >216 mg). In short days the testes were small, regardless of exposure (<118 mg). Therefore, daily MFs did not interfere with the photoperiodic mechanism controlling reproductive development. For the melatonin rhythm, MF exposure reduced the duration of the nighttime melatonin rise in hamsters in long days by several hours relative to that in controls. MF treatment was without effect in short days; melatonin increased in the pineal and circulation within 3 h of dark onset and remained elevated for nearly 10 h. These data support the conclusion that daily MF exposure neither alters the normal onset of puberty nor disrupts the photoperiodic mechanism that arrests sexual maturation. The findings raise the hypothesis that adaptation to prevailing MF conditions may underlie the lack of responsiveness by juvenile hamsters to repeated MF exposures, a proposal that may also apply to the adult Djungarian hamster. MELATONIN INDUCES OUTWARD CURRENTS IN A SUBPOPULATION OF RAT SUPRACHIASMATIC NUCLEUS (SCN) NEURONS. Z.G. JIANG* AND C.N. ALLEN Center for Research on Occupational and Environmental Toxicology and Dept. of Physiology, Oregon Health Sciences University, Portland, OR 97201.

Several lines of evidence support a role for melatonin in entrainment of circadian rhythms via direct actions on SCN neurons. However, the cellular mechanisms of melatonin's actions remain largely unknown. We used whole-cell recording techniques and brain slices to examine the membrane currents activated by melatonin. Young adult male rats were housed on a 12:12 h light-dark cycle and their locomotor activity and body temperature monitored for 2-4 weeks before the experiments. Full entrainment with the light-dark schedule was always achieved in less than a week. Animals were killed 3-5 h (CT3-5) after lights on and recordings were made during the next 1-10 h (CT5-15). Melatonin (0.1-30 μM) induced an outward current (3-40 pA, at -60 mV), in 4 of 20, 8 of 27 and 5 of 18 cells tested between CT6-CT9, CT9-CT12 and CT12-CT15, respectively. The current was associated with an increase in membrane conductance. The response was concentration-dependent with a threshold of about 100 nM and a maximum effect at 10-30 μM . The melatonin-activated currents were blocked by 1 mM Ba, partially blocked by 3 mM Cs, but not affected by TTX and/or a combination of CNQX and APV. The current amplitude was reduced and, in a few cases, reversed by a hyperpolarization over -100 mV. These data suggest that melatonin activates a potassium current thus causes inhibition in a subpopulation of SCN neurons. Study supported by grant AG10794.

AGE RELATED DIFFERENCES IN THE STRUCTURE OF HUMAN PINEAL CALCIUM DEPOSITS: RESULTS OF TEM, SEM AND MINERALOGRAPHIC MICROANALYSIS. ¹A.W. Klein, ²H.A. Schmid, ¹E.G. Stopa, ¹J.T. Parmelee* and ¹P. McMillan, ¹Dept. of Pathology, Brown Univ.

Sch. of Med./Rhode Island Island and ²Veterans Admin. Med. Ctr., Providence, RI.

Pineal calcifications increase with advancing age in man and in many other mammals. Melatonin biosynthesis decreases with advancing age, and has several calcium dependent steps, suggests the possibility that pineal cell dystrophy related to the aging process may accelerate biomineralization in the pineal gland. Pineals from a range of aged men (14, 47, 62 and 82 years) were metallographically embedded, polished, and studied by scanning EM and transmission EM for age related differences. The data show that: 1) concentrically arranged crescent shaped lamellae increase in number and decrease in width, with advancing age. This suggests remodeling. 2) There is an increase in the calcium: phosphorus ratio (1.27-1.41 in 14 to 62 year ages), with advancing age (1.49-1.62 at 82 years) in all lamella. C/P lamellar increases may parallel cell dystrophy and dysfunction. 3) The architecture of the deposits show an age progression from a) round-smooth-stage, through a round beaded stage and into acervuli (i.e. antlered) stage. This suggests mineralization and growth by methods other than simple apposition. These results suggest a biomineralization followed by a remodeling that changes throughout the organism's life span and may relate to the decline of melatonin biosynthesis.

MELATONIN DURATION AND REPRODUCTIVE RESPONSES IN MALE SYRIAN HAMSTERS. J.B. Powers*, A.E. Jetton and R. A. Mangels, Departments of Psychology and Biology, Univ. of Massachusetts, Amherst, MA 01003-7710.

Syrian hamsters are long day breeders; exposure to short days causes inhibition of the reproductive system. This response requires the nightly secretion of melatonin which serves as a hormonal indicant of night length. Traditional views suggested that day lengths shorter than 12.5 hrs were equally effective in generating reproductive inhibition, independent of the actual day length used and its associated melatonin duration. In the experiments presented here we determined if variations in melatonin duration or photoperiod history would affect the rate of reproductive inhibition following melatonin treatment. Forty-five male Syrian hamsters were exposed to long days (16L:8D) for two months and then assigned to one of four groups; three remained in 16L and were pinealectomized (PINX); the fourth was shifted to a short day (7L:17D) and was sham pinealectomized (SH-PINX). The three PINX groups received nightly sc infusions for nine weeks containing either vehicle (VEH) or melatonin (MEL - 50 ng/hr) for 8.5 hrs or 12.0 hrs. The SH-PINX group was not infused. At three week intervals, testis widths were measured and blood withdrawn for assay of follicle stimulating hormone (FSH) and prolactin (PRL). Both MEL durations caused significant testicular regression but this occurred more rapidly with the longer MEL duration ($p<.05$). In a second experiment, MEL duration was held constant but groups were exposed to differing long day conditions prior to MEL treatments. Forty-eight males were divided into two groups - one exposed to 18L:6D, the other to 14L:10D for six weeks. All hamsters were then PINX and switched to 16L:8D. Within each condition, one-half the males were infused for 9.5 hrs each night for nine weeks with either MEL or VEH; their reproductive condition was assessed as in the first experiment. MEL infusions caused significant reproductive inhibition ($p<.05$) but this was only moderately influenced by photoperiod conditions prior to MEL treatment. Results derived from serum assays of FSH and PRL will be reported. Supported by HD30372, HD07673 and MH44132.

Melatonin Regulates CREB Phosphorylation in Ovine ParsTuberalis A.W. Ross, S. McNulty*, P. Barrett, M.H. Hastings* & P.J. Morgan, Rowett Research Institute, Bucksburn, Aberdeen, AB2 9SB.

*Department of Anatomy, University of Cambridge, Cambridge, CB2 3DY.

Ovine pars tuberalis (oPT) cells containing melatonin receptors, and pars distalis (oPD) cells lacking such binding sites, were studied for the involvement of the transcription factor CREB, in the transduction of the melatonin signal. Experiments included gel shift and immunocytochemical studies to determine the presence of CRE-binding nuclear factors and to investigate the effects of forskolin and melatonin, on the level of CREB activation, measured as P-CREB immunoreactivity (P-CREBIR). Gel shifts identified two specific CRE oligonucleotide-protein complexes in oPT nuclear extracts. These were displaced by excess unlabelled CRE but not by excess TRE oligonucleotides and both bands were supershifted using anti-CREB and anti-P-CREB antisera. Immunocytochemistry results were quantitated using digitized image-analysis to measure observed cell treatment differences in nuclear optical density. Increased PCREBIR in response to forskolin stimulation was time and dose dependent. This change in staining was not detectable using the anti-CREB antibody, hence increased PCREBIR is due to rapid phosphorylation rather than de novo CREB synthesis. The time course for forskolin stimulated P-CREBIR was consistent with nuclear translocation of protein kinase A. In oPT but not oPD cells, CREB phosphorylation was inhibited by melatonin in a time and dose dependent manner, with the dose also being dependent on the forskolin concentration used. The IC50 for melatonin was around 10nM. Melatonin is therefore thought to regulate expression of cAMP-responsive gene expression through exerting an inhibitory effect, via the cAMP/PKA pathway, on the level of activation of the transcription factor CREB. Funded by SOAFD and Wellcome trust.

STRESS TRIGGERS DIFFERENT PATHOPHYSIOLOGICAL MECHANISMS IN YOUNG AND OLDER CARDIOMYOPATHIC HAMSTERS (CMHs). Q. Chang, R. Conway, J. E. Ottenweller, B. H. Natelson*, UMDNJ-GSBS, -NJMS, and -RWJMS, Newark & New Brunswick, and Neurobehavioral Unit (127A), VAMC, East Orange, NJ 07018.

Because BIO 14.6 CMHs in the lesion forming period of their disease are more susceptible to the lethal effects of stress than older CMHs¹, we hypothesized stress triggered coronary vasospasm in younger CMHs and congestive heart failure (CHF) in older CMHs. To test these hypotheses, we stressed 2.5 and 6.5 mo male CMHs (2 hr of supine cold immobilization for 5 consecutive days). Three, 5 and 7 days after stress, anesthetized CMHs were sacrificed and their hearts were mounted by the aorta for retrograde perfusion of the coronary arteries using a modified Langendorff system. Baseline developed pressure (DP), maximum dp/dt and coronary vascular resistance (CVR) were recorded at 80 mmHg perfusion pressure and following coronary infusion of arginine vasopressin (AVP) at 0.2 unit/min. In younger CMHs, stress produced a decrease in DP and maximum dp/dt on day 3, but not on days 5 or 7. Stressed older CMHs had significantly lower DP and maximum dp/dt than nonstressed on all 3 days ($p < .05$). Baseline CVR in younger CMHs was significantly higher than in older CMHs ($p < .05$). AVP infusion produced a bigger increase in CVR in younger stressed CMHs than in either younger nonstressed or older stressed CMHs ($p < .05$). The data support our hypotheses. The coronary vasculature shows increased AVP-induced vasoconstriction in stressed younger but not older CMHs. In contrast, older but not younger CMHs develop a consistent decrease in cardiac mechanics indicative of CHF. The lethal effects of stress in younger and older CMHs appear to occur because of the activation of different pathophysiological processes. (Supported by VA Medical Research Funds) Ref: 1. B. H. Natelson, W. N. Tapp, S. Drastal, R. Suarez, J. E. Ottenweller. Hamsters with coronary vasospasm are at increased risk from stress. *Psychosom Med* 1991; 53: 322-331

EFFECTS OF MILD INTERMITTENT TAIL SHOCK ON COLONIC MOTOR ACTIVITY. N.S. Morrow¹ and T. Garrick^{1,2}. Center for Ulcer Research and Education, Dept. of Veteran Affairs Medical Center, Los Angeles CA 90073, Dept. of Psychiatry, UCLA, Los Angeles, CA 90024.

Changes in colonic motor activity during exposure to tail shock were examined in rats chronically implanted with 2 force transducers on the proximal colon. Baseline colonic contractility was monitored in home cages for 3 days. Meal-stimulated changes in colonic activity were then examined in 2 testing periods. Following the second feeding trial, rats were randomly divided into 3 groups (n=6 each) for testing. All rats were loosely restrained in a plexiglass tube and 2 electrodes taped to the tail. One group of rats was administered unpredictable, intermittent shocks (1 ma, 5 sec, VI= 1 min) for 1 h. A second group was exposed to the tail shock chamber but was not shocked. The third group of rats received tail shocks for 1 h and then 24 h later were re-exposed to the tail shock chamber but were not shocked. Fecal output was recorded throughout the experiment and rated for consistency on a 4-point scale. Results indicated that following a meal, the duration of long duration contractions increased significantly from baseline measures. During exposure to tail shock, the amplitude of both short and long duration contractions were significantly suppressed ($p < .05$) when compared to basal values. Tail shock increased the number of feces evacuated ($p < .05$) and affected fecal consistency in a variable manner. Exposure to the shock chamber, alone, did not significantly alter the colonic contractility pattern or fecal output from basal values. These results indicate that alterations in colonic motor activity can be induced by exposure to environmental stressors and may be a contributing factor in stress-induced bowel dysfunction.

NEITHER PRENATAL STRESS NOR NEONATAL HANDLING ALTER RAT'S PERFORMANCE ON THE MORRIS WATER MAZE. A.C. Segarra*¹, J.L. González², R. Keller², K. Salim² and B.S. McEwen². ¹Dept. of Physiology, Sch. of Med, Univ. of Puerto Rico, San Juan, P.R. 00936 and ²Lab. of Neuroendocrinol., Rockefeller Univ., 1230 York Ave., NY, NY 10021.

Prenatal stress and neonatal handling are known to have long-lasting effects on rat emotionality. The hippocampus mediates, at least partially, some of these effects. In this study we investigated the effect of prenatal stress and of neonatal handling on spatial ability and learning, behaviors regulated by the hippocampus. From GD 14 to 21 pregnant Sprague-Dawley rats were restrained for 45 min 3 times/day. From PN 1-10, half of the pups were handled daily by placing them in a cage at 37°C for 3 min. At approximately 23 and 63 days rats were tested in a Morris Water Maze (MWM).

Prenatal stress had no effect on rat performance in a MWM, nor did handling. A sex difference in latency to find the platform, was observed in adult animals, males performing better than females. This sex difference was not observed in prepubertal animals. An age difference was also observed, with older animals learning to reach the platform twice as fast as prepubertal animals. Our previous results show that the prenatal stress treatment was effective since an increase in emotionality and in basal corticosterone plasma levels was observed in the same animals. These findings indicate that spatial cognitive abilities in rats are unaffected by prenatal stress and by neonatal handling.

589.2

EFFECTS OF AEROBIC EXERCISE TRAINING ON THE RESPONSES TO CHRONIC STRESS. S.P. Bailey, A.M. York, K.W. Grasing*, S.D. Schlusman, J.P. Advis, and D.H. Overstreet. Dept. Exercise Science & Sport Studies and Dept. Animal Studies, Rutgers Univ., New Brunswick, NJ 08903. Clinical Research Center, Robert Wood Johnson Medical School, New Brunswick, NJ 08903. Skipper Bowles Center for Alcohol Studies, Univ. of North Carolina School of Medicine, Chapel Hill, NC 27599.

Aerobic exercise training (ET) modifies the behavioral responses to acute stress. The effects of ET on the responses to chronic stress are less clear. The purpose of this study was to examine the effectiveness of ET in attenuating the behavioral and endocrine responses to chronic unpredictable stress (CUS). 16 Flinders Sensitive Line (FSL) and 16 Flinders Resistant Line (FRL) rats were used in this investigation due to their respective sensitivity and resistance to CUS. Animals were subjected to 10 weeks of ET (25 m·min⁻¹ & 7% grade, 30 min per day) or remained sedentary (SED). Animals were then subjected to 1 wk of CUS. Open field mobility (OFM) and sucrose consumption (SC) were evaluated prior to and after CUS. After CUS, blood was collected for measurement of plasma corticosterone (CORT). Following CUS the number of squares entered during OFM was reduced ($p < .05$) in sedentary animals (both FSL and FRL); however, the number of squares entered during OFM was unchanged in FSL-ET and FRL-ET. The number of rears during OFM was reduced ($p < .05$) in all animals following CUS. Following CUS, SC consumption was reduced ($p < .05$) in all groups except FRL-ET. Plasma CORT was greater ($p < .05$) in FRL-SED than FRL-ET following CUS. In comparison, plasma CORT values in FSL-SED and FSL-ET were similar to normal resting values. These results indicate that ET is effective in attenuating some, but not all, of the behavioral responses to CUS. Furthermore, FSL animals did not benefit as much from ET as FRL animals. Resistance to the behavioral effects of stress by ET was associated with lower CORT levels in FRL animals.

A NEW COMPUTER-BASED METHOD FOR ANALYZING RAT ULTRASONIC VOCALIZATIONS. J. Martinez, K. Krogh and L.D. Lyle*. Department of Psychology, University of California, Santa Barbara, CA 93106.

Rat ultrasonic vocalizations have proven useful for assessing maturational changes in maternal-infant interactions and other aspects of behavior, as well as for monitoring the effects of various psychoactive drugs. In most instances, changes in the number of vocalizations are the dependent variable. Expensive equipment and time-consuming sonagram-based procedures limit more complete analyses of the vocalization response (e.g., possible changes in amplitude, duration, frequency). We now report the development of a new computer-based method that allows for a rapid, inexpensive, and relatively simple analysis of changes in the number, amplitude, and frequency of rat ultrasonic vocalizations. This new system employs a 386 SX or more advanced personal computer outfitted with an A/D converter, a timer and a counter. The computer receives its input from a zero-crossing and an envelope detector circuit which in turn receive a high frequency signal from an S-25 ultrasound detector (Ultrasound Devices, Ltd., London). A Quick Basic software routine developed at UCSB was used to analyze call frequency, amplitude, and duration in 1 msec time frames.

We used this new method to monitor maturational changes in albino rat's ultrasonic vocalizations following separation from their dams and littermates for a 30 min period (at 23±1 °C) beginning at birth, and extending at 5 day intervals until the time of weaning. The number, duration, and frequency of calls emitted changed with age in a fashion essentially replicating previously published results [Okon, E.E. *J. Zool., Lond.* (1970) 162: 71-83] using more expensive and time consuming methodology. The number and amplitude of pup calls emitted peaked at age 10 days and declined thereafter; the average call frequency was highest between ages 5-15 days.

SOCIAL AND ENVIRONMENTAL CHALLENGES PRODUCE CHANGES IN CIRCADIAN AND ULTRADIAN RHYTHMS. D.G. Harper, W. Tor-natzky* and K.A. Miczek. Dept. of Psychology, Tufts University, Medford, MA 02155

If circadian and ultradian rhythms of temperature and heart rate reflect optimal homeostasis then the speed of recovery of these rhythms may reflect the time required to recover homeostasis following a challenge. In our present study, we examine the adaptation of rats to several experimental manipulations designed to disrupt or disorganize the circadian and/or ultradian rhythms of these animals. Telemetry readings of heart rate, temperature and activity were collected in 5 minute epochs in 8 adult male Long Evans rats throughout the experiment. Following implantation of a telemetry sender, animals were allowed to recover from the surgery and adapt to a 12:12 light cycle (lights off 14:00, lights on 02:00) for a period of 21 days. (1) The light cycle was then advanced 6 hours (lights off 08:00, lights on 20:00) and the animals allowed to entrain to the new rhythm. (2) The animals were given 30 ml. of a 10% sucrose solution at 10:30 (access limited to 1/2 hour) over a period of 3 weeks to test for food entrainment effects. (3) Animals were then subjected to a social defeat experience for 5 days with submissive behavior and ultrasound vocalizations monitored. Changes in the amplitudes of circadian and ultradian rhythms following social stress and light shift and entrainment effects following drinking were observed.

THE IMMEDIATE EFFECTS OF PHYSICAL EXERCISE ON PASSIVE-AVOIDANCE MEMORY AND ANXIETY IN RATS. J.E. BRYANT*, Tracey Smith, Leslie H. Hicks and Michael J. Lewis. Neurobehav Lab, Dept of Psych, Howard University, Washington, D.C. 20059

Participation in physical exercise is currently fashionable. Although many people report psychological benefits following exercise, experimental data on this issue remain sparse. The present study examined whether a brief voluntary wheel-running exercise (20 min a day for 10 days) could facilitate passive-avoidance memory while concurrently examining anxiety in young male rats. Previous exercise, when compared to a nonexercise condition, was not found to significantly facilitate passive-avoidance memory in rats. However, voluntary wheel-running did significantly increase anxiety [$t(40) = 2.43$, $p < .05$], as measured by defecation rates, in acquisition of one-trial step-through passive-avoidance. The finding that engagement in physical exercise increased anxiety is discordant with the reports of many exercisers who suggest an anxiolytic effect following exercise.

EXAGGERATED ACOUSTIC STARTLE IN GULF WAR VETERANS WITH PTSD. C. A. Morgan III, C. Grillon*, S. M. Southwick, and D. S. Charney. Department of Psychiatry, Yale University School of Medicine, West Haven VAMC, West Haven CT 06516.

Exaggerated startle is reputed to be one of the cardinal symptoms of Post Traumatic Stress Disorder (PTSD). Objective studies have given conflicting results as to whether or not startle is increased in PTSD. However these studies were conducted on subjects with chronic PTSD (Vietnam and Israeli combat veterans). The present study investigated the acoustic startle response of eight Gulf War veterans with acute PTSD and 15 healthy age matched controls. The eyeblink component of the startle reflex was measured in response to six blocks of pseudorandomized 40 ms white noise bursts of varying intensities (90, 96, 102, 108, 114 dB). No war related or stressful cues were presented to subjects prior to or during testing. Startle amplitude was significantly greater and habituation significantly reduced in the PTSD subjects compared to controls. Because other studies in the literature, as well as our own laboratory, which have investigated the startle response in combat related PTSD, have failed to find exaggerated startle or reduced habituation of startle at baseline (i.e. absence of stress), it is likely that the present results reflect an acute elevation of startle in this group. The higher amplitude and decreased habituation of startle in the PTSD subjects may reflect a sensitization of the fear/alarm response created by the recent stress of combat trauma consistent with preclinical studies of shock sensitization and startle.

589.11

DIFFERENTIAL EFFECTS OF ACUTE STRESS EXPOSURE ON RADIAL ARM MAZE PERFORMANCE. M.J. Stillman*, B. Shukitt-Hale, A. Levy, H.E. Modrow, and H.R. Lieberman. Military Performance and Neuroscience Division, United States Army Research Institute of Environmental Medicine, Natick, MA 01760-5007, ¹GEO-CENTERS, INC., Newton Centre, MA 02159, and ²IIBR, Ness Ziona, ISRAEL.

This study examined radial arm maze (RAM) performance following exposure to two stress conditions and a normothermic-freely-moving control condition. Male Fischer 344 rats were trained on the win-shift RAM procedure for 7 days by which time they achieved asymptotic performance. The next day, rats were exposed to 15 min of restraint in either 37 °C water (normothermic-restraint) or in 20 °C water (cold-restraint). Rats were removed from restraint and were allowed 40 min in a dry cage prior to being tested in the RAM. Performance was measured using the following dependent variables: time per choice, the total number of choices, the percent error, and the number of correct out of the first eight choices (number correct). ANOVA indicated significant effect of stress on number correct ($p < .001$) as well as the other variables. Performance decrements were observed in both stress conditions relative to the normothermic-freely-moving condition, with the normothermic-restrained rats displaying less impairment than the cold-restrained rats (e.g., mean \pm SEM values for number correct were 7.4 (\pm 0.22), 4.0 (\pm 0.52), and 1.83 (\pm 0.51), respectively). These findings suggest that restraint and cold stress impair performance on a memory task, with the extent of the impairment being related to stress severity.

589.8

EFFECTS OF INDUCED POSITIVE AND NEGATIVE STRESSORS ON IMMUNE FUNCTIONING IN CHRONIC DEPRESSION AND CONTROLS. A.V. Ravindran*, J. Griffiths, S. Zalcman & H. Anisman. Royal Ottawa Hospital, Ottawa, Ontario, Canada K1Z 7K4.

Stressful events encountered by humans have been reported to influence immune functioning. Depending on severity, stressors may influence natural killer (NK) cytotoxicity, circulating lymphocyte subsets (e.g., NK cells), as well as cell proliferation in response to mitogens. In the present investigation a brief mild, laboratory stressor (cognitive challenge) increased NK cell numbers in controls and in dysthymic (chronic, low grade depressive) patients. The extent of the increase was directly related to plasma norepinephrine levels, and may reflect effects on cell trafficking. Likewise, a more meaningful stressor (having subjects complete the day-to-day hassles scale with subsequent discussion of the stressors) resulted in an increase of NK cell numbers in both dysthymic and control subjects. Cell proliferation in response to a mitogen was reduced in dysthymic patients who discussed hassles. These effects were less marked when patients discussed uplifts, or in control subjects who discussed their hassles. Finally, control subjects who had undergone a stressor perceived as being more severe (final academic examination) exhibited NK cell alterations, as well as variations of several other lymphocyte subsets (e.g., CD-3, CD-4 and CD-19). The data are discussed in terms of the relationship between stress and depression and the impact of stressors on immune functioning.

589.10

CONTROL OVER CHRONIC STRESS REDUCES THE TERMINAL ACCURACY, BUT NOT THE ACQUISITION OF SIMPLE ALTERNATION. R.A. Bauman* & G. J. Kant. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307.

The purpose of the present study was to characterize the disruptive effects of chronic stress on the acquisition and terminal accuracy of a simple alternation task in rats. All rats lived in individual cages that were exposed to a 12:12 light/dark cycle. During the preshock period, two levers were available and any leverpress resulted in the delivery of a food pellet. Subsequently, rats in group A/E were trained to (A)void/(E)scape signaled footshocks. After learning to escape, food was only available for alternating leverpresses. Alternation was also required in groups Y and C. In group Y, signals and shocks were yoked to those delivered to rats in group A/E; rats in group C were not shocked.

Although no differences were evident among groups during acquisition, terminal accuracy (percent correct alternation) was significantly higher in group C than in the A/E or Y groups. This resulted from a significantly higher mean number of correct presses (food pellets) for Group C than for either shock group. Since mean number of incorrect presses was significantly higher for group A/E than for group C or Y, the requirement to A/E footshock may have interfered with the accuracy of alternation.

589.12

DIFFERENTIAL PAIN TOLERANCE RESPONSE TO HIGH DOSE NALOXONE FOLLOWING EXPOSURE TO CONTROLLABLE AND UNCONTROLLABLE STRESS. J. Fertig*, R. Peters, J. Leu, G. Mueller. Walter Reed Army Institute of Research, Washington, D.C. 20307

In an attempt to characterize the pain tolerance response to naloxone administration following exposure to stress, forty healthy male subjects were exposed to bursts of 95 dB noise while attempting to solve a visual-spatial task under either controllable stress (CS) or uncontrollable stress (UCS) conditions. Stress induction was followed by a double blind infusion of the opiate antagonist naloxone (1.5 mg/kg) or placebo. A muscle ischemia pain tolerance test was given following drug administration. Physiologic reactivity and biochemical response were monitored throughout stress induction, drug administration and pain tolerance testing. Although naloxone administration dramatically elevated heart rate ($p < .0001$), plasma cortisol ($p < .0001$), and immunoreactive beta-endorphin ($p < .0001$), it had a differential effect on pain tolerance depending upon subject's prior exposure to CS or UCS. Pain intensity ratings were highest for CS exposed subjects and lowest for UCS subjects. Results suggest that prior exposure to UCS or CS can mediate pain tolerance following naloxone exposure.

589.13

PERSISTENT HIGH CORTISOL RESPONSES TO REPEATED PSYCHOLOGICAL STRESS IN A SUBGROUP OF HEALTHY MALES. C. Kirschbaum, J. Prüßner, A.A. Stone, I. Federenko, J. Gaab, D. Lintz, N. Schommer and D.H. Hellhammer*. Center for Psychobiology and Psychosomatics, University of Trier, 54286 Trier, Germany.

The present study tested the hypothesis that some subjects may not readily show habituation of adrenocortical stress responses to repeated psychological stress. 20 healthy males were each exposed five times to the same, brief psychosocial stressor (public speaking and mental arithmetic in front of an audience) with one stress session per day. Salivary cortisol levels were assessed as an index of adrenocortical stress responses. For the total group, cortisol levels were significantly elevated on each of the five days. The mean response decreased from day 1 to day 2, however, no further attenuation could be observed on the remaining days. Cluster analysis revealed two groups of subjects who showed completely different response kinetics. In the first group ($n=13$), termed "low responders", cortisol levels were elevated on day 1 only. Days 2-5 cortisol levels were unaltered. In contrast, subject in the second group ("high responders") displayed large increases to each of the five experimental treatments. This group had no significant response decrement from day 1 to days 2-4 and only a marginal response difference between day 1 and day 5. Discriminant analysis revealed that a combination of five personality scales plus the scores on a symptoms checklist significantly discriminated between high and low responders. Using this discriminant function, all 20 subjects were correctly classified to the two groups. These results are discussed with a focus on the possible impact of adrenocortical response types on health and disease.

STRESS: NEUROTRANSMITTER STUDIES

590.1

HABITUATION OF GLUTAMATE AND LACTATE RELEASE INDUCED BY STRESSFUL STIMULI IN RAT FRONTAL CORTEX. M. Takita¹ and M. OGURI²*, ¹Neuroinformatics Lab., Biosignalling Dep., Natl. Ins. of Bioscience and Human-Technology, Ibaraki 305, Japan. ²Dept. Biometrics and Faculty of Sci., Toho Univ., Chiba 274, Japan.

To clarify information processing for novel stress in rat medial frontal cortex (mpFC), we developed newly system to monitor glutamate (GLU) and lactate with a high time-resolution (less than 1 min) by using *in vivo* brain microdialysis. The dialysate was mixed directly with an enzyme solution (containing GLU- or lactate-dehydrogenase and NAD⁺) in a T-tube. The fluorescent of produced NADH in the mixture was measured continually by a fluorometer equipped with a flow cell. The basal level of mpFC GLU release (GR) was about 2 μ M and was a one-200th lower than that of LR. The mpFC GR was clearly demonstrated to increase immediately and transiently from its steady state levels after 1min tail pinch (TP) so that the mpFC LR was increased by various stimuli (TP, 5min 100dB white noise (100dB), and 5min immobilization (IMB)). These stimuli-induced increments were suppressed partially by the 2nd trial 1 hour later in a manner of habituation (GR; TP: 32.9 \pm 8.3%, LR; TP: 34.5 \pm 7.1%, 100dB: 35.3 \pm 9.2%, IMB: 45.5 \pm 6.2% vs. the initial responses, all was at least $p < 0.05$ by paired t-test ($n=4-5$), consistent with dishabituation to a novel stimulus or "below-zero" habituation by several repetitions. GR and LR both showed the decreasing response by TP in septum. The mpFC GR response was appeared under reserpinization (0.5 mg/kg, sc.) while these of LR were completely not. These results suggested that there are two different systems for stress processing specialized in rat mpFC.

590.3

LEARNED HELPLESSNESS AND IN VIVO BIOGENIC AMINE RELEASE IN HYPOTHALAMUS AND CAUDATE. F. Petty*, G.L. Kramer, P. Zukas, and S. Jordan. VAMC and Dept. Psychiat., Univ. Texas Southwestern Med. Cent., Dallas TX 75216

We have developed a theoretical neuronal map of learned helplessness (LH) in the rat involving serotonin (5-HT), dopamine (DA) and GABA in medial prefrontal cortex, GABA and norepinephrine (NE) in hippocampus, and 5-HT in septum. In hypothalamus, other investigators have reported decreased 5-HT uptake into synaptosomes, and decreased basal and K⁺-stimulated release from tissue slices of LH rats, as well as decreased pargoline and unchanged β -adrenergic receptor binding. We have now applied *in vivo* microdialysis to measuring DA, NE and 5-HT simultaneously in hypothalamus and caudate of conscious, freely moving rats in a LH paradigm. Rats received 100 trials of inescapable tailshock stress, and after testing for LH, microdialysis probes were implanted into either caudate or lateral hypothalamus. One day later, perfusion was maintained with Ringer's solution until a stable baseline was obtained, then switched to Ringer's with high K⁺. No differences were found in caudate in DA or 5-HT among any of the three experimental groups (LH, NH - stressed, nonhelpless, or TC - unstressed tested control). In hypothalamus, no differences were seen for DA or 5-HT. For NE in hypothalamus, significantly higher levels of basal NE were observed for LH rats, compared to NH and TC, while the NH rats had significantly higher K⁺-stimulated NE release than LH or TC. For all the stressed rats, there was a significant positive correlation between shuttlebox escape latencies and basal NE release. These data suggests that the caudate may not be involved in the *in vivo* biogenic amine neurochemistry of LH, and that in the lateral hypothalamus, NE mechanisms predominate in this animal model of depression.

590.2

EFFECT OF REPEATED FOOTSHOCK STRESS, APOMORPHINE AND THEIR COMBINATION ON THE INCIDENCE OF APOMORPHINE (APO)-ELICITED SELF-INJURIOUS BEHAVIOR (SIB) IN JUVENILE NEONATAL 6-HYDROXYDOPAMINE (6HD)-TREATED RATS. C.J. Stodgell*, S.R. Schroeder, J.M. Hyland & R.E. Tessel. Dept. of Pharmacol. & Toxicol. and The Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS. 66045-2505

Male rats received bilateral intraventricular injections of 6HD (50 μ g/inj.) or vehicle (0.1% ascorbic acid in saline; SAL) on postnatal day 3. At 30 days of age, half the 6HD and SAL animals were primed with 6 IP H₂O injections, or 6 APO injections (10 mg/kg; IP; every 3-4 days) unless SIB was elicited during earlier injections. If SIB was elicited, APO was replaced with H₂O injections. Half of the APO- and H₂O-primed animals were further primed with 7 1-hr footshock sessions (6 1-mA 300-V shocks/2 sec every 10 sec; every 3-4 days); the other half remained in their home cages. One week later acute APO dose-effect curves (DEC; 0-10 mg/kg IP; 30 min interinjection interval) were constructed in each rat and the behaviors manifested recorded on video tape. The following week, the animals were sacrificed for striatal catecholamine determinations. SIB was not elicited by footshock *per se* in any animal. During the DEC, 3/10 6HD animals primed only with APO displayed SIB, and 2/10 rats primed only with footshock displayed SIB. However, 7/10 6HD rats primed with the APO-footshock combination displayed SIB, (χ^2 ; $p < 0.05$ compared to both prior groups). No DEC-associated SIB occurred in any SAL rats except for one animal that had been combination-primed. 6HD decreased striatal catecholamine and metabolite concentrations by 96% in H₂O-primed, unshocked animals. However, these depletions were modestly but significantly reversed ($p < 0.01$) in combination-primed 6HD-treated animals. These and other findings from our laboratory suggest that stress can potentiate APO-induced SIB in 6HD rats by increasing dopamine release and postsynaptic dopamine receptor stimulation, and if dopamine availability is sufficiently increased, may have the capacity to elicit SIB in such animals. (Supported by grant 1 P01 HD26927).

590.4

BETA-1 ADRENOCEPTOR BLOCKADE MIMICS THE BEHAVIORAL EFFECTS OF ACUTE STRESS IN MICE. E.A. Stone*, D. Quartermain, J. S. Manavalan, and Y. Zhang, Depts. Psychiatry and Neurology, New York University School of Medicine, New York, NY 10016

Reduced brain adrenergic neurotransmission has long been implicated as a factor in inducing behavioral changes after stress. The nature of the receptor at which transmission is deficient, however, has not been elucidated. The present studies were undertaken to clarify this problem by comparing the effects of acute stress with those of beta adrenoceptor blockade on behavioral function. Male Swiss Webster mice were either subjected to one of three types of stress, immobilization (IMO), tube restraint or subordination, or were given an injection of one of several types of blocking agents and then examined for swimming behavior, locomotion and grooming. Each of the stressors was found to reduce swimming and locomotion and to increase grooming. Administration of the nonselective beta blocker, propranolol, and the beta-1 selective blocker, betaxolol, reproduced all three effects of stress. The beta-2 blocker, ICI 118,551 was only partially effective and the peripherally active beta-1 antagonist, atenolol was inactive. The 5HT_{1A} receptor blocker, WAY 100478, and the dopaminergic blocker, fluphenazine, reduced locomotion but failed to increase grooming. The findings indicate that the effects of stress can be reproduced selectively by central beta-1 receptor blockers and suggest that neurotransmission at these brain receptors is reduced after acute stress. Supported in part by grants AFOSR F49620-92-J-0084, MH45265 and MH08618.

EFFECT OF BETA-1 ADRENOCEPTOR BLOCKADE ON c-FOS RESPONSE TO STRESS IN MOUSE BRAIN. Y. Zhang* and E.A. Stone, Dept. Psychiatry, New York University School of Medicine, New York, NY 10016

We have previously shown that beta-blocker-reversible c-fos expression can be used as a marker for postsynaptic noradrenergic activity at beta receptors in the brain. The present study utilized this method to determine in which regions of the brain beta-1 receptors are activated during stress. Male Swiss Webster mice were injected with the selective beta-1 blocker, betaxolol, 20 mg/kg or not injected and 0.5 hr later were subjected to immobilization (IMO) stress or to control conditions for 1 hr. Two hrs after the end of the stress the animals were anesthetized and perfused. Brains were processed for c-fos immunohistochemistry using a fos-specific antibody by standard procedures. Noninjected-nontreated and betaxolol injected-nontreated mice showed little c-fos immunoreactivity in the brain. IMO stress caused widespread c-fos expression in the forebrain and brainstem. Betaxolol treatment prior to stress significantly reduced c-fos ir in most forebrain structures but not in the brainstem. These results suggest that stress activates beta-1 receptors primarily throughout the forebrain. Supported in part by grants AFOSR F49620-92-J-0084, MH45265 and MH08618.

ACUTE STRESS DISRUPTS DEFENSIVE BEHAVIOR IN MICE. D. Quartermain*, E.A. Stone and G. Charbeneau, Depts. Neurology and Psychiatry, New York University Sch. Medicine, New York, NY 10016

Recent experiments with rats in semi-naturalistic environments have indicated that chronic subordination stress impairs risk assessment, i.e., reduces the likelihood that the animal will engage in species typical behaviors to evaluate the location and source of possible danger. The present study was undertaken to determine if acute stress disrupts risk assessment in mice measured in terms of latency to emerge from a dark safe place into a novel, potentially dangerous environment. Groups of male Swiss Webster mice (N=12) were subjected to either immobilization, tube-restraint, unavoidable footshock or exposure to a dominant aggressive mouse. All stressors were administered to individual mice for a duration of 1 hr. Risk assessment behavior was examined 30 min following stress termination. Mice were placed in a small dark enclosed entry chamber which was attached to a large brightly lit open field which could be entered through a small door at the end of the chamber. Latency to emerge (max. 5 min) was determined. Immediately after, animals were observed in the open field for a 5 min period during which time locomotor activity was measured and rearing, grooming and defecation frequencies were recorded. Results showed: 1. Mean entry latency for all stress groups was significantly faster than that of a non-stressed control group. 2. All stressed groups showed significantly less locomotor activity and rearing and significantly more episodes of grooming than non-stressed mice during a 5 min period in the open field. These data indicate that acute stress can disrupt defensive behavior by impairing the animal's ability to respond to potentially threatening stimuli. Supported in part by grants AFOSR F49620-92-J-0084, MH45265 and MH08618.

590.9

THE ROLE OF NORADRENALINE IN THE MEDIAL PREFRONTAL CORTEX IN THE ELEVATION OF HEART RATE INDUCED BY TAIL PINCH IN THE RAT.

D. Funk* and J. Stewart, Center for Studies in Behavioral Neurobiology, Dept. Psychology, Concordia University, Montreal, Canada, H3G 1M8.

The noradrenaline (NA)-containing projections to the medial prefrontal cortex (MFC) are activated in response to stress. The functional role of MFC NA release in the stress-induced activation of the autonomic nervous system (ANS), however, remains undefined. This study examined the effects of microinjections of NAergic drugs into the MFC on a response mediated by ANS activation, the increase in heart rate (HR) induced by tail pinch. Male rats anesthetized with urethane (1.5 g/kg) received 2-10 s tail pinches separated by 5 minutes prior to and after infusions of 10 nmol of the beta adrenergic agonist isoproterenol (ISO) unilaterally into the right MFC. Tail pinch elevated HR, which returned to basal levels in the succeeding 5 minutes. Injection of ISO into the MFC increased baseline HR, and potentiated the increases in heart rate induced by tail pinch. The alpha adrenergic agonist phenylephrine (20 nmol) was without effect on either baseline HR or tail pinch-induced increases in HR. These results suggest that NA released in the MFC, via stimulation of beta adrenergic receptors, plays a facilitatory role in the stress-induced activation of the ANS. Studies are in progress to examine the function of the dopaminergic projection to the MFC in stress responses mediated by the ANS.

590.6

EFFECT OF PROPRANOLOL ON STRESS-INDUCED CHANGES IN PASSIVE AVOIDANCE AND OPEN FIELD EMERGENCE TESTS. J.S. Manavalan*, M. Najimi, E.A. Stone and D. Quartermain, Depts. Psychiatry & Neurology, New York University School of Medicine, New York, NY 10016

The present study examined the effect of propranolol on the ability of stress to elicit behavioral inhibition in Harlan Hsd:N4 mice. Mice were given propranolol prior to immobilization or tube-restraint stress and then were tested for either passive avoidance performance or time to emerge into an open field. In contrast to previous findings by others, propranolol was found to markedly potentiate stress-induced increases in latency in these tests. These unexpected results were not due to peculiarities of the behavior measured, the stressors used or the dosage of the drug administered. As propranolol has blocking actions at beta adrenergic and serotonergic receptors, the results raise the possibility that, under some conditions, the response of the noradrenergic and/or serotonergic systems to stress may have anxiolytic or anti-stress effects. Supported in part by grants AFOSR F49620-92-J-0084, MH45265 and MH08618.

THREAT OF ATTACK INCREASES IN VIVO DOPAMINE RELEASE IN PREFRONTAL CORTEX AND NUCLEUS ACCUMBENS. J.W. Tidey* and K.A. Miczek, Department of Psychology, Tufts University, Medford MA 02155.

Exposure to various aversive environmental events appears to activate central and peripheral catecholamine systems. In the present study, we used microdialysis in freely-moving rats to examine whether a "social stressor", namely exposure to an aggressive male rat would specifically increase central dopamine (DA) release in mesocorticolimbic structures. Microdialysis samples from prefrontal cortex, nucleus accumbens and striatum were collected from each rat (1) while in its home cage, (2) while in the empty, soiled cage of a rat which had previously attacked and defeated it, and (3) while in the presence of an aggressive stimulus rat. Samples were compared with those from rats placed into a clean, novel cage. Each test was videotaped and the frequencies and durations of all elements of social and motor behavior were later analyzed. Increased DA release was observed in CSF samples obtained from prefrontal cortex and n. accumbens of rats placed into either a novel cage or the soiled cage of an aggressive rat; further increases were observed in samples obtained while rats were in the presence of the aggressive stimulus rat. These neurochemical responses occurred at the time when the rats displayed increased defensive postural displays, but not at times of heightened motor activity, suggesting that mesocorticolimbic DA may be involved in the initiation of biologically significant behavioral responses to social stress.

EFFECTS OF CHLORDIAZEPOXIDE ON FOOTSHOCK-INDUCED OVERFLOW OF CEREBRAL NOREPINEPHRINE.

Artur H. Swiergiel*, Zhongyou Wei, Yaohui Li and Adrian J. Dunn, Department of Pharmacology, Louisiana State Univ. Med. Ctr., Shreveport, LA 71130-3932.

Synaptic release of cerebral catecholamines is increased during stress. The effects of benzodiazepines on the stress-related release of catecholamines has been varied. We have used *in vivo* microdialysis to examine the effect of chlordiazepoxide (CDP) pretreatment on the footshock-induced release of norepinephrine (NE). Freely moving rats were implanted with microdialysis probes in the medial hypothalamus and the medial prefrontal cortex (PFM). Footshock (60 x 0.1-0.2 mA shocks over 20 min) significantly increased microdialysate concentrations of NE in the first sample collected. The subsequent two samples showed small elevations that were not statistically significant. In both the hypothalamus and the PFM dialysates, NE was significantly augmented over the prefootshock baseline. CDP administration (5 mg/kg ip) had no statistically significant effects on the basal dialysate concentrations of NE, although there was a tendency towards a reduction. CDP administered before the footshock significantly attenuated the dialysate concentrations of NE.

These results suggest that footshock increases the synaptic release of NE in the cortex and hypothalamus, and that this response is attenuated by CDP. The experimental design used cannot determine whether systemic CDP alters the input to LC noradrenergic neurons, or whether benzodiazepines exert a direct effect on the noradrenergic neurons.

FLUOXETINE TREATMENT ATTENUATES STRESS-INDUCED NOREPINEPHRINE (NE) EFFLUX IN THE HIPPOCAMPUS M.E. Page* and E.D. Abercrombie. Center for Molecular & Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

The noradrenergic locus coeruleus (LC) has long been implicated in various aspects of the regulation of behavioral state. This system is responsive to a wide variety of stimuli, especially novel or threatening cues. Norepinephrine (NE) turnover increases in LC target regions in response to stress. It has previously been shown that presentation of acute stressors increases the synthesis and release of NE in the hippocampus (Abercrombie et al., 1988). Dysfunction of the LC/NE system is thought to contribute to a number of mental health problems including depression, anxiety and panic disorder. Chronic treatment with antidepressants alleviates many of the symptoms of depression and has been shown to alter LC function. However the mechanism of the therapeutic action of these drugs is unclear. It has been demonstrated that serotonin selectively attenuates LC responses evoked by local application of glutamate or noxious sensory stimuli. The effect of acute treatment (2 days; 10 mg/kg/day) with the antidepressant fluoxetine, a selective 5-HT reuptake inhibitor, on hippocampal NE and DOPAC efflux was examined using *in vivo* microdialysis. Because there is no significant DA innervation of the hippocampus, DOPAC levels in this region are thought to reflect NE synthesis. Basal levels of NE and DOPAC did not differ between vehicle controls and 2-day fluoxetine-treated animals. Application of a clamp to the rat's tail for 30 min. evoked an 80% increase in extracellular NE in vehicle control animals (n=3) and a 33% increase in animals which received FLU for 2 days (n=5). Tailpinch evoked an 89% increase in extracellular DOPAC levels in vehicle animals compared to a 34% increase in FLU-treated animals. Experiments are presently underway to determine the effects of chronic (14 day) administration of FLU on stress-induced NE efflux. One function of fluoxetine may be to modulate stress-induced responses of the LC-NE system. This work supported by PHS DA08086.

CHRONIC COLD STRESS ENHANCES THE RESPONSE OF LOCUS COERULEUS NEURONS TO STIMULATION OF NUCLEUS PARAGIGANTOCELLULARIS M.J. Mana* and A.A. Grace. Depts of Neuroscience & Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260

We have previously demonstrated that chronic cold stress increases the footshock-evoked response of locus coeruleus (LC) neurons in the anesthetized rat. Using *in vivo* extracellular single-unit recordings, we now demonstrate that this stress-related enhancement of evoked activity also occurs in response to direct electrical stimulation of the nucleus paragigantocellularis (nPGi), the major glutamatergic afferent to the LC. Twenty-four hours after termination of chronic cold stress (5°C for 17-22 days), LC neurons from cold-stressed rats displayed a significant elevation in basal firing rate (mean = 2.7 Hz for Cold Stress v. 1.8 Hz for Controls); these basal rates were significantly higher than we have previously reported and may be related to the implantation of the stimulating electrode into nPGi. There were no differences in the threshold for activation of LC cells by nPGi stimulation (Cold Stress = 190 μ A v. Control = 155 μ A; 0.3 ms duration, constant current) or in their response latencies (Cold Stress = 0.013 ms v. Control = 0.014 ms). However, the incidence of spike activation by nPGi stimulation was greater in LC cells from the cold stressed rats (Cold Stress = 40 responses v. Control = 34 responses; 50 stimulations at 150% of threshold), as was the incidence of burst firing (Cold Stress = 8 bursts/50 stimulations v. Control = 4 bursts/50 stimulations). In addition, the duration of postactivation spike suppression was shorter for LC cells from cold stressed rats (Cold Stress = 600 ms v. Control = 780 ms). We are currently investigating whether these stress-induced changes in the LC response to glutamatergic excitation from nPGi are due to changes in their sensitivity to glutamate or to a change in some other system which modulates this response. ALTERED EXPRESSION OF mRNAs ENCODING GABA_A RECEPTOR SUBUNITS α 1 AND α 2 FOLLOWING RESTRAINT OF JUVENILE AND ADULT RATS. Roberts, Alice A.*, Plegier, Gloria L., Jones, Amy W. and Kellogg, Carol K. Dept. of Psychology, Univ. of Rochester, New York, 14627.

The GABA_A receptor, a multimeric protein complex located on neuronal cell membranes, mediates inhibition in cortical circuits by altering GABA-gated chloride permeability. Cortical GABA_A receptors of male rats functionally respond to acute stressors in young adulthood (P70-90) but not at juvenile (P28) or adolescent (P35-42) ages. Likewise, young adult males exhibit altered behavioral and GABA_A responsiveness to acute stressors based on prior experience, whereas juveniles do not. We have found modest increases (30-40%) in cortical mRNAs encoding α 1 and α 2 GABA_A subunits immediately after two-hour restraint in young adult, but not juvenile, brains. The present study tracks expression of GABA_A subunit mRNAs in young adult and juvenile brains taken at 0, 2, 4, and 6 hours following two-hour restraint; levels of α 1 and α 2 mRNAs in cortex, hippocampus, and cerebellum, are determined by RNase Protection Assay. Our initial results (t = 0) suggest that the impact of experience on cortical GABA_A subunit expression may develop across adolescence in parallel with functional responsiveness of cortical GABA_A receptors to acute stressors. Since juveniles lack experience-dependent behavioral responses to stressors, it may be that altered GABA_A subunit expression underlies inhibitory synaptic plasticity critical for specific behavioral adaptation to challenging environmental stimuli. Supported by Grant No. DA 07080.

DIFFERENTIAL EFFECTS OF INESCAPABLE STRESSORS ON LIMBIC ACETYLCHOLINE RELEASE. G.P. Mark*, T.J. Shors, P.V. Rada & B.G. Hoebel. Dept. of Psychology, Princeton Univ., Princeton, NJ 08544

Results from a variety of experimental paradigms have pointed to a cholinergic involvement in the stress response. Recently, analytical techniques have become available to measure ACh release *in vivo* during exposure to various stressors. In these experiments, microdialysis was used to monitor ACh output every 15 min in the dorsal hippocampus (HIPP), amygdala (AMY), nucleus accumbens (NAcc) and prefrontal cortex (PFC) before, during and after 1 hr of restraint, including a 15 min session of intermittent tail shock (1/min, 1 mA, 1 sec duration) in rats. In response to the stressor, ACh release was significantly increased in the PFC (180%; $p < .01$), HIPP (170%; $p < .01$) and AMY (144%; $p < .05$) but not in the NAcc. In each site tested however, maximal release occurred in the 15 min sample following release from restraint at which point ACh levels reached significance in the NAcc (130%; $p < .05$). These data demonstrate an enhancement of cholinergic activity during application of the stressor in three ACh projection systems (HIPP, AMY, PFC).

AGE-DEPENDENT CHANGES IN 5-HT_{1A} RECEPTORS FOLLOWING FORCED SWIM STRESS AND RESTRAINT STRESS. R. K. Raghupathi* and P. McGonigle. Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

This study examined the effect of age on the 5-HT_{1A} receptor response to two stressors, namely, forced swim stress (15 min) and restraint stress (2 hr). Rats were studied 14, 21 and 60 days after birth (n = 6-8 per group). Coronal sections of rat brain were labeled with [³H]-8-OH-DPAT (DPAT) to quantitate 5-HT_{1A} receptors. At 14 days of age, restraint stress did not affect DPAT binding in the hippocampus or cortex. At 21 days of age, neither forced swim stress nor restraint stress affected DPAT binding in the hippocampus or cortex. However, in 60 day old rats, forced swim stress produced a 20-40 % decrease in DPAT binding in the CA1, CA2, CA3 and dentate gyrus subfields of the hippocampus and in the cortex. Restraint stress also produced a significant decrease in DPAT binding, albeit less profound, in the CA2, CA3 and dentate gyrus subfields of the hippocampus, but not in the CA1 region or the cortex. In conclusion: (1) Forced swim stress and restraint stress produce a decrease in 5-HT_{1A} receptor binding in discrete regions of the adult rat brain. These data, in conjunction with the previously described increase in 5-HT_{1A} receptors following adrenalectomy, suggest that the 5-HT_{1A} receptor response to stress is mediated by adrenal steroid hormones. (2) The 5-HT_{1A} response to stress is age-dependent. Unlike 60 day old rats, 14 and 21 day old rats showed no 5-HT_{1A} receptor response to either stressor. There appears to be a period during development when the 5-HT_{1A} receptor system is non-responsive to stress. (3) The 5-HT_{1A} receptor response to stress is stressor-dependent. Forced swim stress produces a more profound and widespread decrease in 5-HT_{1A} receptors, compared to restraint stress. (Supported by USPHS MH 43821 and MH 48125)

REGIONAL CHANGES IN DOPAMINE AND SEROTONIN ACTIVATION WITH VARIOUS INTENSITY OF PHYSICAL AND PSYCHOLOGICAL STRESS IN THE RAT BRAIN. T.Inoue*, K.Tsuchiya and T.Koyama. Dept. of Psychiatry, Hokkaido Univ. Sch. of Med., Sapporo 060, Japan.

The present study examined whether regional patterns of brain dopamine (DA) and serotonin (5-HT) activation after physical and psychological stress depend on the intensity of that stress. Monoamine concentrations (DA, 5-HT and their metabolites) were measured using high performance liquid chromatography with electrochemical detection in eight brain regions of rats exposed to two different intensities of footshock stress for 30 min (1.5 mA or 2.5 mA) or conditioned fear stress regarded as psychological stress (CFS, after single or repeated footshock). A low level of footshock selectively increased the DA metabolism in the medial prefrontal cortex (mPFC), whereas a high level of footshock increased it in most of the brain regions examined in the present study. A low level of footshock did not increase the 5-HT metabolism in any regions, but a high-intensity shock increased the 5-HT metabolism in the mPFC, nucleus accumbens, and lateral hypothalamus. The increased DA and 5-HT metabolism were especially marked in the mPFC after CFS (24 hours after receiving footshock, the animals were placed in a shock chamber without being given shock) following a single footshock session (2.5 mA). CFS following repeated footshock for 10 days, like footshock *per se*, increased the DA metabolism in most of the brain regions except for the striatum and increased the 5-HT metabolism in the mPFC, nucleus accumbens and amygdala. These results suggest that regional patterns of brain DA and 5-HT activation after physical and psychological stress depend on the intensity of that stress, although there are some differences between these stress.

INVOLVEMENT OF 5-HT_{1A} DORSAL RAPHE AUTORECEPTORS IN THE ENHANCEMENT OF FEAR CONDITIONING AND ESCAPE DEFICITS PRODUCED BY INESCAPABLE SHOCK. S. F. Maier*, R. E. Grahm, S. A. Horwood, and K. L. Nichols. Behavioral Neuroscience Program, Department of Psychology, University of Colorado, Boulder, CO, 80309.

Exposure to uncontrollable aversive stressors such as inescapable tailshock (IS) lead to a variety of behavioral alterations not produced by controllable stressors. We have recently suggested that some of these effects might occur because IS leads to an intense activation of the dorsal raphe nucleus (DRN), a consequent downregulation of inhibitory somatodendritic 5-HT_{1A} autoreceptors, and a resulting hyper-responsive DRN at the time of later testing. The present experiments tested these possibilities by inhibiting DRN activity either before IS exposure or before behavioral testing 24 hr later. By the above argument both should block the behavioral effects of IS. Male Sprague-Dawley rats were either exposed to 100 unsignalled 1.0 mA tailshocks or were loosely restrained for an equal time period. Testing occurred 24 hr after shock or restraint and involved fear conditioning and shuttlebox escape testing. The 5-HT_{1A} agonist 8-OH-DPAT was infused into the region of the DRN (1 µg in 1 µl) either before the IS treatment or the later testing. 8-OH-DPAT completely blocked the enhancement of fear conditioning and interference with escape behavior produced by IS when administered before IS, and attenuated these effects when given before testing. These results differ from those reported for systemic administrations of 8-OH-DPAT. However, high doses of systemic 8-OH-DPAT may facilitate rather than inhibit 5-HT activity through action at post-synaptic receptors. Therefore, different doses of 8-OH-DPAT were systemically administered before testing. A dose of 0.01 mg/kg blocked the enhanced escape deficit produced by IS, 0.10 mg/kg attenuated this effect of IS, and 1.0 mg/kg had no effect on escape performance. Conditioned fear, however, was blocked by all doses of 8-OH-DPAT. Support provided by NIH MH-50479.

THE EFFECTS OF SOCIAL STRESS ON SEROTONERGIC INDICES IN PREFRONTAL CORTEX OF ADULT MALE CYNOMOLGUS MONKEYS. MB Botchin*, JR Kaplan, SB Manuck, JJ Mann. Dept. of Comparative Med., Bowman Gray Sch. of Med., Wake Forest Univ., Winston-Salem, NC 27157 and Depts. of Psychology and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15213.

The effects of social stress and social status on monoamine concentrations in the prefrontal cortex were examined in adult male cynomolgus monkeys (*Macaca fascicularis*). Seventy-five animals were housed in five-member social groups for 28 months. Social groups either remained stable in group membership (no-stress condition) or had their group membership reorganized at monthly intervals during months 1-14 (past-stress condition) or during months 15-28 (recent-stress condition). At necropsy, cerebrospinal fluid (CSF) and brain samples were collected and stored at -70° C until analyzed. Frontal pole cortical and CSF monoamines (serotonin [5-HT], dopamine, norepinephrine) and metabolites (5-hydroxyindoleacetic acid [5-HIAA], homovanillic acid, 3-methoxy-4-hydroxyphenylethylglycol) were assayed using high-performance liquid chromatography with electrochemical detection. Animals exposed to past social stress had significantly lower 5-HIAA ($p < 0.02$) and 5-HT ($p < 0.01$) concentrations in the prefrontal cortex compared to animals in the no-stress condition. Prefrontal cortical 5-HIAA and 5-HT concentrations in the recent stress condition were intermediate between the concentrations in the no- and past-stress conditions. These data suggest that past exposure to chronic social stress may be associated with an enduring and perhaps progressive reduction in serotonergic function in the prefrontal cortex. Such an effect may underlie the behavioral sequelae of stress such as post-traumatic stress disorder.

HORMONAL CONTROL OF REPRODUCTIVE BEHAVIOR: PARENTAL/AGGRESSIVE

591.1

PREOPTIC AREA (POA) INFUSIONS OF MORPHINE (MOR) DISRUPT -- AND NALOXONE (NAL) RESTORES -- PARENTAL-LIKE BEHAVIOR (PB) IN JUVENILE RATS (JR). J. Wellman, D. Carr, A. Graham, H. Jones, J.L. Humm, M. Ruscio, B. Billack & C.H. Kinsley* Dept. Psych., U. Richmond, VA 23173.

As in the adult lactating female, opioids disrupt (and NAL restores), PB in JR (~25 days of age). Because the POA regulates the display of PB in lactating females, we examined its PB-role in the JR. At 21 days of age, JR were implanted with bilateral cannulae aimed at the POA using a modified Kopf stereotaxic and extrapolating from adult rat atlases (Paxinos & Watson, 1986; Sherwood & Timiras, 1970), and divided into two groups: Initiation [INIT] and maintenance [MAINT]. On day 25, group INIT received bilateral infusions of either MOR (0.50 µg), saline (0.25 µl), or MOR plus NAL (0.25 µg). 30-minutes later, they were exposed to three 1-6 day-old pups; group MAINT was exposed to pups until they displayed two consecutive days of PB, then infused. MOR disrupted PB in both INIT and MAINT, and NAL restored the behavior to control/saline levels, particularly in males. Maturation within the POA, therefore, may serve to inhibit PB after a certain age. (NSF-9250537 & Keck Foundation)

591.2

PREOPTIC AREA INVOLVEMENT IN PROLACTIN-INDUCED PARENTAL BEHAVIOR IN DOVES. J.D. Buntin* and B.A. Kelleher. Dept. of Biol. Sciences, Univ. of Wisconsin-Milwaukee, Milwaukee, WI 53201.

The role of the preoptic area (POA) in mediating PRL-induced parental responsiveness toward young was investigated in non-breeding doves with previous breeding experience. Birds received microinjections of the axon-sparing excitotoxin ibotenic acid to destroy neuronal cell bodies in the POA (n=13). Sham-lesioned controls (n=8) received POA injections of vehicle. Upon recovery, birds received subcutaneous injections of ovine PRL for seven days, followed by a 2.5 hour test with foster squabs to assess parental responsiveness. Lesioned doves displayed significantly fewer parental feeding invitations, parental regurgitation feeding bouts, and total regurgitation movements than did sham-lesioned animals. As a result, squabs given to sham-lesioned birds gained significantly more weight than squabs given to lesioned birds. A significant negative correlation was obtained between the extent of POA damage induced by ibotenic acid infusion and the amount of parental behavior displayed by lesioned animals. These deficits in parental behavior were apparently a selective effect of POA damage because another PRL-mediated behavior, hyperphagia, was unaffected. These results suggest that the POA is an important component of the neural circuitry underlying the expression of PRL-induced parental feeding behavior in non-breeding ring doves. Because elevated PRL levels are temporally associated with parental activity during the breeding cycle, these results also implicate the POA in the spontaneous display of parental feeding activity that occurs naturally at the time of hatching (supported by NIMH grant MH41447).

591.3

RAT PLACENTAL LACTOGENS: ACCESS TO THE BRAIN DURING PREGNANCY AND CENTRAL STIMULATION OF MATERNAL BEHAVIOR IN RATS. R.S. Bridges*, M.C. Robertson*, R.P.C. Shiu*, H.G. Friesen*, A.M. Stuer and P.E. Mann. Dept. Comparative Med., Tufts Univ. Sch. Veterinary Med., North Grafton, MA 01536, USA and *Dept. Physiol., Univ. Manitoba Sch. Med., Winnipeg, Manitoba, R3E 0W3, Canada.

Recent research has established a central site of action for the lactogen, prolactin, in the induction of maternal behavior in the rat (PNAS 87:8003, 1990). Since plasma levels of other lactogens, i.e. rat placental lactogens (rPLs), are also elevated during gestation, we conducted a series of studies to determine (1) whether rPL-I and rPL-II are present in the cerebrospinal fluid (CSF) during pregnancy, and (2) the effects of central infusions of rPL-I and rPL-II on the induction of maternal behavior. In the first study, CSF samples were collected from days 7 to 21 of gestation using a pull-pull perfusion apparatus (20 µl CSF/min). Significant mitogenic activity measured in a Nb₂ lymphoma cell bioassay was detected from days 12 to 21 of pregnancy (481-595 pg/ml; ovine prolactin standard). Activity in day 12 samples was neutralized equally with antibodies to rPL-I and rPL-II, while activity on day 21 was only reduced by antibodies to rPL-II. The possible behavioral actions of rPL-I and rPL-II were then assessed by infusing rPL-I and rPL-II directly into the medial preoptic area (MPOA) of steroid-primed, bromocriptine-treated, nulliparous rats (see PNAS 87:8003, 1990). Latencies of females to respond maternally to foster young were significantly reduced in rPL-I and rPL-II treated rats, e.g. rPL-I animals had response latencies of 2 days compared with 6 days for controls. Thus, rPLs gain access to the CSF during pregnancy and are able to stimulate maternal behavior when infused directly into the MPOA. Supported by PHS Grant HD19789 [RSB].

591.4

THE ROLE OF THE PARAVENTRICULAR NUCLEUS IN THE CONTROL OF MATERNAL BEHAVIOUR IN SHEEP. A. Da Costa*, R. Guevara-Guzman*, S. Ohkura, J. Goode and K.M. Kendrick. Dept. Neurobiology, The Babraham Institute, Cambridge CB2 4AT, UK; *Dept. Physiology, UNAM, Mexico 04510

Maternal behaviour (MB) in sheep has been shown to be induced by intracerebroventricular (ICV) administration of oxytocin (OT) in non-pregnant steroid primed ewes. In these studies, *in vivo* microdialysis and retrodialysis on free moving animals were used to investigate whether OT release in the paraventricular nucleus of the hypothalamus (PVN) might be responsible for the induction of MB. *In vivo* sampling showed that OT concentration in the region of PVN at birth ($P < 0.05$). Retrodialysis administration of OT in the PVN for 1h induced OT release in the blood. OT 1µM induced MB in 6/8 ewes and OT 10µM 5/8 ewes. The ring structure of OT, tocinoic acid (TOC) induced MB in 5/6 ewes while OT intracerebrally (ICV) and artificial stimulation of the vagina and cervix (VCS) induced MB in 6/8 and 8/9 ewes, respectively. Vasopressin (AVP) 1µM did not induce MB whereas AVP 10µM induced MB in 2/8 ewes. The release of NA increased after the administration of OT 1µM and 10µM ($P < 0.05$), TOC 10µM, VCS and OT ICV. AVP 1µM produced a short term increase in the concentration of NA. The release of dopamine (DA) significantly increased after the administration of OT 10µM ($P < 0.01$), TOC ($P < 0.05$) and AVP 1µM. OT and VCS produced increases in DA but only VCS achieved significance ($P < 0.05$). The release of aspartate (ASP) decreased after OT 1µM and 10µM ($P < 0.05$), whilst the behavioural tests increased it. The release of glutamate (GLU) decreased after the administration of OT 1µM ($P < 0.01$), followed by an increase during the behavioural test. TOC, OT ICV and VCS did not produce significant changes in GLU in these experiments. GLU also decreased after AVP 1µM and 10µM. The release of GABA was unaltered after the administration of 1µM of OT, but significantly increased during the first behavioural test ($P < 0.05$). The release of GABA increased immediately following the administration of AVP and OT ICV. Conversely, neither the administration of TOC nor the VCS produces any effect in the release of GABA in the PVN. These studies provide evidence for a positive action of OT in on its own release, peripherally and centrally, with the consequent induction of MB. This potentiation might be mediated through the neurochemical changes in the monoamines and/or aminoacids.

EXCITOTOXIC LESIONS OF THE VENTRAL BED NUCLEUS OF THE STRIA TERMINALIS DISRUPT MATERNAL BEHAVIOR IN RATS. M. Numan* and M.J. Numan. Dept. Psychology, Boston College, Chestnut Hill, MA 02167.

Lesions of the medial preoptic area (MPOA) severely disrupt maternal behavior in rats, but these lesions also usually damage the ventral part of the bed nucleus of the stria terminalis (VBNST). Other work has shown that Fos expression increases in both the MPOA and VBNST of maternal female rats. Finally, anatomical work has suggested that it may be VBNST efferents to the brainstem, rather than MPOA efferents, which are important for maternal behavior.

The present work directly tests the importance of the VBNST. Fully maternal postpartum rats received one of the following: bilateral injections (3 µg/.1 µl) of the excitotoxin, N-methyl-D-aspartic acid (NMDA) into either the VBNST or the dorsal BNST, or bilateral injections of the inactive stereoisomer, N-methyl-L-aspartic acid, into the VBNST. Only animals that received NMDA injections into the VBNST showed severe deficits in maternal behavior.

These results suggest that VBNST efferents are important for maternal behavior. Additional work is iontophoretically applying PHA-L to the VBNST in order to examine its major projection routes and termination sites.

THE DISTRIBUTION OF PROLACTIN BINDING SITES IN THE BRAIN OF BROODING SALAMANDERS. L.P. Mangurian*, K.J. MacArthur, R.L. Smetana and D.C. Forester. Department of Biological Sciences, Towson State University, Towson, MD 21204.

Prolactin (PRL) influences reproductive behaviors and has been shown to stimulate maternal behavior in rats and doves. The reproductive behavior of amphibians, such as the water drive prior to oviposition, is also influenced by PRL. *Desmognathus fuscus* females exhibit egg brooding behavior. This study was designed to investigate the possibility that prolactin may influence brooding behavior by examining their brain for potential prolactin sensitive areas. The localization of PRL target areas was carried out using in vitro autoradiography. Frozen brain sections were incubated with ¹²⁵I ovine PRL alone (total binding) or with a 500 fold excess unlabeled oPRL (non-specific binding). Specificity was assessed using excess unlabeled ovine luteinizing hormone (oLH). A strong autoradiographic reaction was observed in the choroid plexus, the anterior hypothalamus and other areas of the brain. Excess PRL caused a significant reduction ($p < .001$) in the binding of ¹²⁵I-PRL while oLH had no effect. These results support a possible role for PRL in regulating some aspect of behavior in brooding *D. fuscus* females.

QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF D1 AND D2 DOPAMINE RECEPTORS IN RAT BRAIN ACROSS PREGNANCY.

J.C. Bakowska¹, Ian Creese², J.I. Morrell²*. ¹Institute of Animal Behavior, ²Cnt Mol. & Behav. Neuroscience, Rutgers University, Newark NJ 07102.

Previous work has suggested that dopamine may be a neurotransmitter involved in some aspects of maternal behavior in rats (Phys & Behav. 48:211). In addition, treatment of females with pharmacological doses of estrogen, a hormone important in late pregnancy, increased the level of D2 dopamine binding in the striatum (Brain Res. 442:349, 1988). We hypothesized that the naturally occurring physiological and endocrine events of pregnancy may alter the level of the D1 and D2 dopamine receptors in a regional specific manner. Using quantitative autoradiography (D1 receptors: 1.0 nM 3H-SCH-23390; D2 receptors: 1.0 nM 3H-spiperone), brains from pregnant females (day 2 and 21), non-pregnant females, and males were examined. As predicted from previous work, even in pregnant females, in most brain regions D1 receptors were present in greater density than D2 receptors. The highest levels of D1 and D2 binding were in striatum, nucleus accumbens, and olfactory tubercle. Moderate to low levels of D1 binding were found in zona incerta, thalamus and hypothalamus, and low levels of D2 binding were found in olfactory bulb and hypothalamus. In some brain regions, pregnancy did not alter the D1 or D2 receptor levels; in other brain regions receptor binding was significantly different in females on day 2 compared to day 21 of pregnancy. For example, d21 females had substantially lower levels of D1 receptors in lateral and medial striatum than 2 day pregnant females. Preliminary results also show that late pregnant females had modestly lower levels of D2 receptors in anterior striatum, nucleus accumbens and olfactory tubercle. These results may provide clues to the brain regions that are most important for dopamine mediation of maternal behavior in rats. Supported by HD 22983 to JIM.

CHOLECYSTOKININ (CCK) AND THE REGULATION OF MATERNAL BEHAVIOR. P.E. Mann*, L.L. Felicio, J.D. Sturgis, A.M. Stuer and R.S. Bridges. Comp. Med., Tufts Univ. Sch. Vet. Med., N. Grafton, MA 01536.

Recent work in our laboratory has established that concurrent intracerebroventricular (icv) infusions of CCK-8 with β -endorphin prevents the disruptive effects of β -endorphin on the maintenance of maternal behavior in lactating rats (Felicio et al., 1991). CCK has also been reported to stimulate the onset of maternal behavior in virgin rats; Linden et al. (1989) found that chronic pretreatment with CCK-8S (i.p.) for 12 h stimulated maternal behavior within 2 hours of exposure to pups. The goal of the present series of experiments was to further examine the role of CCK in the induction of maternal behavior and characterize CCK's involvement in ongoing maternal behavior. In a set of studies evaluating the role of CCK in the onset of maternal behavior, we were unable to stimulate maternal behavior in virgin Sprague-Dawley rats treated chronically with CCK-8 (i.p. infusions) or in steroid-primed, ovariectomized, virgin rats given icv infusions of CCK-8. Moreover, chronic infusions of CCK-8 into the lateral ventricle of primigravid rats late in pregnancy also failed to stimulate maternal behavior. In contrast to the apparent lack of involvement of CCK in the onset of maternal behavior, ongoing maternal behavior appears to be regulated in part by CCK. When lactating rats were infused icv on day 5 postpartum with either 25 or 125 µg of proglumide, a nonspecific CCK antagonist, lactating rats displayed longer latencies to first crouch over their young, an effect similar to the inhibitory response found after central infusions of β -endorphin (Mann et al., 1991, 1992). Together, these data suggest to us that CCK-8 is more strongly involved in the regulation of ongoing maternal behavior than in the induction of maternal behavior in the rat. Further studies are needed to determine sites and modes of CCK action. Supported by PHS Grants DA04291 and HD19789 [RSB].

591.8

FOS IMMUNOREACTIVITY IN THE HYPOTHALAMUS ASSOCIATED WITH PATERNAL BEHAVIOR IN THE PRAIRIE VOLE, *M. OCHROGASTER*. B. Kirkpatrick*, D. Litman, J.W. Kim. Maryland Psychiatric Research Center, Department of Psychiatry, University of Maryland School of Medicine, Baltimore, MD, 21228.

A number of studies have implicated the paraventricular nucleus of the hypothalamus (PVN) in the onset of maternal behavior in rats. However, we found no increase in Fos immunoreactivity associated with male or female parental behavior in the PVN in the prairie vole, a species in which both males and females spontaneously exhibit parental behavior prior to sexual maturity.

To clarify the role of the hypothalamus in paternal behavior, we examined cellular activation in areas of the hypothalamus other than the PVN, following exposure to a pup in male prairie voles. Fos immunoreactivity was quantified in suprachiasmatic, ventromedial, dorsomedial, and premammillary nuclei, and the anterior and posterior hypothalamic areas. Compared to controls exposed to a novel olfactory stimulus, males exposed to pups showed an increase in several discrete areas. These results suggest hypothalamic areas other than the PVN may be involved in the control of paternal behavior in this species.

EFFECTS OF FOOD RESTRICTION ON MONOAMINE CONCENTRATIONS IN HYPOTHALAMIC NUCLEI OF THE CHICKEN BRAIN. L. Moons, Y. Qu and F. Vandesande*. Lab. of Neuroendocrinology, Zoological Institute, Naamsestraat 59, 3000 Leuven, Belgium, Europe.

Intensive selection for increased muscle growth in meat-type chickens has led to a decrease in the reproductive performances. Early quantitative food restriction has become the standard industrial procedure to improve the reproductive efficiency of the meat-type parent stocks. The neural control of both the feeding and the reproductive behavior seems to happen through identical neurotransmitters, catecholamines and serotonin. In order to determine whether food restriction alters in some way the concentration of monoamines in hypothalamic nuclei -assumed to be involved in the control of reproduction-, *ad libitum* fed and food restricted female meat-type chickens were killed at the ages of 4, 10, 16 and 22 weeks. A quantitative determination of the concentration of biogenic amines was performed in ten different micropunched hypothalamic brain areas. The amines L-DOPA, dopamine, norepinephrine (NE), epinephrine and serotonin and their major metabolites were separated on a C-18 HPLC column and determined by electrochemical detection. In most hypothalamic areas studied and for most neurotransmitters determined, no concentration difference, resulting from food restriction, was found. However, food restriction did affect the amount of certain biogenic amines in a few hypothalamic nuclei. The most striking difference occurs in the median eminence, where the concentration of NE is largely increased in food restricted animals. These quantitative data provide an excellent basis for further research on the possible role of catecholamines and indolamines in the altered feeding and reproductive behavior in the meat-type chicken.

NPY, SS, AND GAD MOLECULAR LAYER SPROUTING IN HUMAN EPILEPTIC HIPPOCAMPI. G.W. Mathern, T.L. Babb, J.L. Leite, J.K. Pretorius, and J. Engel, Jr.*. UCLA School of Medicine, Los Angeles, CA 90024-1769.

Patients with Hippocampal Sclerosis (HS; n=18), Mass Lesions (Mass; n=9), or autopsies were compared for differences in: 1) percentage of hilar neurons immunoreactive (IR) for NPY, somatostatin (SS), and GAD, 2) patterns of fascia dentata (FD) IR-sprouting, and 3) densities of FD IR-sprouting. Results were: 1) NPY-IR hilar neurons decreased in an equal proportion to all hilar neurons (p=0.47), SS-IR neurons were significantly decreased in HS in excess of all hilar neurons (p=0.03), and GAD-IR neurons were not significantly different (p=0.26). 2) Outer molecular NPY-IR decreased in HS compared to Mass (p=0.0002), was unchanged in SS-IR (p=0.37), and was increased in the inner molecular layer with GAD-IR (p=0.007). 3) The patterns of IR-sprouting between HS and Mass were significantly different (p=0.001). This supports the notion that peptide hilar counts and molecular layer synaptic reorganization differ among peptides and between patients with HS and Mass pathogenic mechanisms. Supported by NS 02808 and KO8-NS 01603.

RELATIONSHIP BETWEEN INTERICTAL EEG SPIKE AND NEURONAL SYNCHRONY AND FUNCTIONAL LIMBIC PATHWAYS. A.L. Velasco, C.L. Wilson*, B.W. Colder, M.H. Shomer, E.J. Behnke, S.U. Khan, and J. Engel, Jr. Depts. of Neurology, Anatomy, Neurosurgery, and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

In order to investigate the prevalence of neuronal synchronization in specific pathways of the human hippocampal formation and amygdala, EEG spikes, single and multiple cell action potentials were recorded in patients with surgically implanted intracranial depth electrodes required for diagnostic studies. MRI guidance was used to place electrodes bilaterally in amygdala, anterior and middle hippocampus, entorhinal cortex, and parahippocampal gyrus. Bundles of 9 microwires were used for extracellular unit recording. In one group of patients interictal EEG spikes were monitored continuously for 6 to 30 hr and bipolar spike detection records were obtained at each recording site using EEG spike detection software. Spike frequency distributions (spikes/min) were plotted over the entire period and cross-correlations between recording sites were computed. Although correlations varied widely, a direct relationship was found between spike rate and the probability of a significant positive correlation between specific anatomical pathways, including the perforant, longitudinal associational, and retrohippocampal pathways. In a second group of patients, microelectrode recordings 5 to 30 min in duration were obtained from a total of 295 cells and subjected to cross-correlation analysis between 2 to 8 simultaneously recorded cells. Of 93 possible within-bundle unit correlations, 49% were significant, and of 516 possible between-bundle correlations dependent upon anatomical connections, 25% were significant. Both showed a greater proportion of significant correlations in the temporal lobe where seizures originated. Supported by NS 02808.

NETWORK PROPERTIES OF CARDIAC-RELATED SINGLE CELL DISCHARGE IN EPILEPTOGENIC HUMAN TEMPORAL LOBE. R.C. Frysinger*, B. Colder, C. Wilson, J. Engel and R.M. Harper. Depts. of Anatomy and Cell Biology, Neurology, and the Brain Research Institute, UCLA Sch. of Med., Los Angeles, CA 90024.

Modulation of neuronal discharge by the cardiac cycle is relatively common in temporal lobe structures. The proportion of cardiac-related cells in amygdala is markedly higher ipsilaterally to seizure onset, suggesting an interaction of these cells with epileptogenesis. We examined 314 spike trains from 19 patients with epilepsy undergoing depth recordings of mesial temporal EEG. Bilateral recordings were performed in amygdala, hippocampus, anterior and posterior perirhippocampal cortex, and transitional cortex. From 3 to 20 spike trains were recorded simultaneously from each patient, permitting direct evaluation of the nature and number of cell interactions. Spike trains were characterized on the basis of cross- and auto-correlograms, with inhibitory and excitatory phenomena recorded as the proportion of possible interactions. Cardiac-modulated cells were more likely to participate in networks, and were strongly associated with inhibitory interactions. In amygdala, this relationship was strikingly dependent on the side of seizure onset. Cardiac-related amygdala cells on the contralateral side participated in inhibitory interactions, and were likely to "drive" cells in other structures. On the ipsilateral side, cardiac dependency was associated only with a bursting pattern of discharge. This difference may result from a loss of regional inhibitory connections to cardiac-dependent cells. Supported by NS 02808.

592.2

THREE HUMAN CASES OF STATUS-EPILEPTICUS-INDUCED BRAIN DAMAGE. D.G. Fujikawa* and H.H. Itabashi. Neurology Service, VA Med. Ctr., Sepulveda, CA and Depts. of Neurology and Pathology, UCLA Sch. of Med., Los Angeles, CA U.S.A.

Although status epilepticus (SE)-induced brain damage is well-documented in animal models, human cases of neuronal damage caused strictly by SE have been difficult to document because of confounding systemic factors or a history of pre-existing epilepsy. It has been hypothesized that excessive release of the neurotransmitter glutamate is responsible for the SE-induced neuronal necrosis. We report 3 patients who died 11-27 d after the onset of focal motor SE, in whom hypotension, hypoxemia and hypoglycemia do not complicate the interpretation of results. Two of the 3 patients had no prior seizures and no known cause of their SE. The third patient, who had leptomeningeal carcinomatosis, had 1 seizure 2 months before the onset of SE. The duration of SE was 2.5 h-3 d. EEGs showed unilateral temporal lobe sharp-wave discharges in 1 and independent temporal lobe sharp-wave discharges bilaterally in the other 2. There was widespread neuronal loss in the hippocampus (CA1-3 and hilus), amygdala, piriform cortex, dorsomedial thalamic nucleus and cerebellum (Purkinje cells), with scattered neuronal loss in the cerebral cortex. In 2 of the 3 cases the damage was unilateral and occurred on the side in which seizure discharges were most prominent. The regional distribution of the damage in these 3 cases was similar to that found in animal models of limbic SE: it occurred primarily in limbic structures with high densities of glutamate receptors. (Supported by the Dept. of Veterans Affairs.)

592.4

BURST DISCHARGE CONTRIBUTION TO NEURONAL SYNCHRONY IN EPILEPTIC HUMAN TEMPORAL LOBES. B.W. COLDER*, C.L. WILSON, R.C. FRYSSINGER, L. CHAO, R.M. HARPER AND J. ENGEL. Dept. of Anatomy and Cell Biology, Dept. of Neurology, and Brain Res. Inst., UCLA School of Med., Los Angeles CA 90024.

Synchronized neuronal burst discharge is hypothesized to initiate ictal events. If so, inter-ictal neuronal synchrony in epileptogenic structures may include a higher percentage of burst action potentials (burst AP's). We therefore wished to examine the relative contributions of isolated and burst AP's to synchronous interactions both ipsilaterally and contralateral to seizure onset in patients with complex partial seizures. Spontaneous inter-ictal single cell activity was recorded from the hippocampus, amygdala, and other temporal lobe structures of patients undergoing chronic depth electrode implantation to localize seizure onset. When cross-correlation histograms between pairs of simultaneously recorded cells contained a significant central peak, implying a synchronous interaction between those cells (n=70 ipsilateral, n=93 contralateral), the proportion of burst AP's contributing to that peak was calculated for each cell. Bursts AP's showed a strong trend towards a proportionally greater contribution to synchronous interactions contralateral to the side of seizure onset. The correlation between the likelihood of a neuron to discharge bursts and the contribution of burst AP's to synchronous interactions involving that cell was stronger in the contralateral hemisphere (r =.72) than the ipsilateral (r =.27). Our results suggest that in the inter-ictal state, regions that commonly initiate seizures are less likely to contain synchronously bursting neurons. Supported by NS 02808.

IN-VIVO PAIRED-PULSE STUDY OF INHIBITION IN THE HUMAN HIPPOCAMPUS. K.P. Vives, D.D. Spencer, and G. McCarthy*. Section of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510 and Neuropsychology Lab., VA Medical Center, West Haven, CT 06516.

Paired-pulse stimulation of the perforant pathway has been used in animal models of epilepsy to examine the status of inhibitory processes in the dentate granule cells; relative facilitation of the granule cell population spike has been observed following experimental treatments which destroy inhibitory interneurons in the dentate hilus. We report the intraoperative use of the paired-pulse paradigm in eighteen patients undergoing anteromedial temporal resection for medically intractable seizures. During the resective surgery, after removal of the lateral neocortex, multicontact depth electrodes with 1 mm contact spacing were placed freehand through the dentate gyrus and into the perforant path. Four contact strip electrodes were also placed on the hippocampal alvear surface and on the entorhinal cortex. Stimulation to the perforant path was performed utilizing single pulses and paired pulses with interpulse intervals (IPI's) of 20, 40, 60 100 and 200 msec. In the initial 10 patients, PSPs were recorded without population spikes. Technical improvements have allowed us to record clear population spikes in six of the last 8 patients. Inhibition was quantified in each patient by taking the ratio of the PSP or spike amplitude elicited at each IPI to that measured after a single pulse. In an on-going study, these measures are compared to pathological studies of the excised hippocampus, other *in-vivo* and *in-vitro* electrophysiological studies, and patient outcome. (Supported in part by an American Heart Assoc. Fellowship and NIH Grant NS30619)

592.7

DISTRIBUTION OF CALCIUM-BINDING PROTEINS PARVALBUMIN, CALBINDIN D-28K, CALRETININ, AND PERINEURONAL NETS IN THE HUMAN EPILEPTIC HIPPOCAMPUS. C. Fickhoff¹, I. Blümcke¹, M.R. Celio², O.D. Wiestler^{1*}. ¹ Dept. of Neuropathology, University of Bonn Medical Center, 53105 Bonn, Germany. ² Dept. of Histology and General Embryology, University of Fribourg, 1705 Fribourg, Switzerland.

Neuronal vulnerability during epileptic seizures has been associated with an increase in intracellular free calcium concentration. Hippocampal neurons which contain the calcium-binding proteins (CaBPs) parvalbumin (PV), calbindin D-28k (CB) and calretinin (CR) are, therefore, interesting candidates for studies on the morphological and neurochemical alterations in human temporal lobe epilepsy (TLE). PV-immunoreactive (PV-ir) neurons are also covered with different extracellular matrix molecules forming the perineuronal nets (PN's) and are surrounded by astroglial processes. PN's may protect these neurons from an excess release of excitatory neurotransmitters during seizure activity. We studied the distribution of PV-ir, CB-ir, and CR-ir neurons in hippocampus (HC) specimens obtained from patients with TLE. Autopsy brains were used as controls. The immunohistochemical staining patterns were correlated with the following histopathological changes: (1) HC without histological alterations; (2) HC with focal lesions or tumors; (3) HC with Ammonshorn sclerosis (AS); (4) HC with both, focal lesions/tumors and AS. In general, the neuronal loss observed in TLE-patients was associated with a decrease in CaBP-ir neurons. However, among the surviving neurons, many PV-ir and CB-ir cells were covered with PN's. In some patients, CR-ir showed an increase in neuropil staining in the dentate gyrus and CA 3 region, as well as "de-novo" granule cell staining. None of the CR-ir cells were covered with PN's. We conclude that neurons expressing PV and CB, which were surrounded by PN's, were less vulnerable to degeneration in TLE. In addition, CR may serve as an interesting marker for activated and reorganizing neuronal systems in human TLE. Supported by the German BMFT Helmholtz-fellowship for I.B.

592.9

MORPHOLOGY OF GRANULAR NEURONS IN THE HUMAN HIPPOCAMPUS. G. von Campe, P. Rai, D.D. Spencer, N.C. de Lanerolle. Yale University School of Medicine, Section of Neurosurgery, New Haven, CT 06510.

Examination of hippocampi removed from patients with medically intractable temporal lobe epilepsy (TLE) has shown considerable neuronal reorganization within the seizure focus. Granule cells and their mossy fiber axons contain the opioid peptide dynorphin, which in normal hippocampi is not expressed in the molecular layer. In patients with mesial temporal sclerosis, a dense band of staining is observed in the inner molecular layer, suggesting collateral sprouts from granule cells into the molecular layer. To directly examine the presence of such collaterals from granule cells we studied the morphology of individual cells by using an intracellular injection technique. Paraformaldehyde (4%) fixed hippocampi were sliced into 80-100 μ m thick sections on a Vibratome. Individual neurons were iontophoretically injected (at 2 nA for 5-15 minutes) with Lucifer Yellow (3-5% aqueous solution) under UV epillumination. Selected filled cells were then photoconverted by UV irradiation in the presence of diaminobenzidine (DAB) to produce a permanent Golgi-like appearance. In patients with mesial temporal sclerosis at least two morphological types of granule cells were found. One type was spindle shaped with a single branched apical dendrite and a single axon-like process extending from the opposite end toward the hilus. The other type of granule cell has a more rounded cell body with two to several apical dendrites and a single basal axon. In several neurons, fiber-like processes were observed to arise from the basal to lateral region of the cell body, and after a short course toward the hilus, they curved back up toward the molecular layer. Such processes may be the morphological basis of the dynorphin immunoreactivity observed in the inner molecular layer of hippocampi from patients with temporal lobe epilepsy. Supported by NS06208.

Distribution of AMPA Receptor Subunits in the Hippocampal Formation of Temporal Lobe Epilepsy Patients. E. Lynd-Balta*, W.H. Pilcher, and S.A. Joseph. Division of Neurosurgery, University of Rochester Medical Center, Rochester, N.Y., 14642.

Glutamate is the principal neurotransmitter identified within the intrinsic circuitry of the hippocampal formation. It is hypothesized that glutamate plays a central role in excitotoxic injury associated with temporal lobe epilepsy. In this report we have addressed the organization of glutamate receptor subunits within this hippocampal circuitry by immunocytochemical localization of the AMPA selective subunits GluR1 and GluR2/3 in relation to patterns of cell loss in patients with temporal lobe epilepsy.

Hippocampal tissue was resected during surgery from patients with medically intractable temporal lobe epilepsy. Blocks of tissue were placed in 4% paraformaldehyde with 0.2% picric acid. Serial sections were cut either on the vibratome or freezing microtome and stored in a cryoprotectant solution. Tissue was processed immunocytochemically using antibodies generated against the GluR1 subunit and the GluR2/3 subunits.

The localization of these subunits is distinct in the hippocampus. The GluR1 subunit is restricted to fibers of the molecular layer of the dentate gyrus. In contrast, the GluR2/3 subunits' distribution is widespread. Surviving pyramidal cells in all CA subfields stain positively for GluR2/3. In addition, immunoreactive neurons are also present throughout the granule cell layer of the dentate gyrus. Knowledge of the distribution of selective glutamate receptor subunits can elucidate the anatomical substrates by which excitotoxic injury may proceed in temporal lobe epilepsy. Supported by NIH grant NS21323.

GABA-A ALPHA AND BETA RECEPTORS AND GAD-IR AXON SPROUTING IN HUMAN HIPPOCAMPAL EPILEPSY. T.L. Babb*, G.W. Mathern, J.P. Leite, and J.K. Pretorius. UCLA School of Medicine, Los Angeles, CA 90024-1769.

Resected human hippocampi (HC) with Hippocampal Sclerosis (HS; n=6) or little HC cell loss (e.g. lateral mass lesions; n=2) were compared for GABAergic (GAD-ICC) fascia dentata (FD) molecular layer (ML) axon sprouting and "matching" changes in postsynaptic GABA-A receptor subtypes alpha and beta. GABA axon densities in the FD-ML were weakly correlated with cell losses in the HC (p=0.07) and FD (p=0.07; i.e. reactive synaptogenesis). The densities of FD-ML receptors for GABA-A alpha (p=0.28) and beta (p=0.85) did not correlate with neuron loss (i.e. HS). There was a trend for the GABA receptors subtypes to have similar densities in the FD-ML (p=0.08) suggesting that both the alpha and beta types were similarly affected in epileptic FD. Finally, the GABA axon patterns in the FD-ML scored semi-quantitatively, showed varying densities and distributions across the inner through outer molecular layers, and these did not predict GABA-A alpha (p=0.15) or beta (p=0.70) densities, suggesting that in epilepsy there may be heterogeneous remodeling of receptor subtypes that do not "match" to aberrant presynaptic terminals. Supported by NS 02808, NIH-FIC, CNPq (Brazil) and K08-NS 01603.

ANALYSIS OF HUMAN EPILEPSY-ASSOCIATED GENE EXPRESSION BY MESSENGER RNA DIFFERENTIAL DISPLAY. H. Xie, M.L. Brines, J.H. Kim*, N.C. de Lanerolle. Sections of Neurosurgery, Neuropathology, and Neuroendocrine Program, Yale University School of Medicine, New Haven, CT 06510

Human diseases (including temporal lobe epilepsy; TLE) are usually associated with alterations in patterns of cellular gene expression. These changes in gene regulation may be the consequence or the cause of the underlying diseases. Detailed study of the alterations in patterns of gene expression could provide insight into the etiology of the disease. The objective of this study is to identify genes which are differentially expressed in one subgroup of epilepsy characterized by typical mesial temporal sclerosis and associated hippocampal reorganization (MTLE), compared to another subgroup characterized by an extrahippocampal temporal or neocortical mass lesions (MaTLE group). We used mRNA differential display methodology, which involves the reverse transcription of mRNA into cDNA and the use of PCR with random primers to amplify the cDNA signals. We applied the differential display methodology to two pairs of hippocampal specimens obtained from patients operated to control TLE. More than eighty different primer pairs were used for the PCR differential display, which statistically should cover almost all mRNA species. Fifty two uniquely displayed bands were identified and the corresponding DNA fragment extracted from the dried sequencing gels. Five of the 52 bands have been cloned and sequenced to date. Four of them have no matches in the database Genbank, which indicates that those sequences may represent novel mRNA species yet to be characterized. The fifth cDNA fragment is 320 bases long, with a 70% homology (in a 150 bp overlap region) to the invertebrate transposase gene mariner. Our preliminary PCR, Northern, and Southern blot data indicate that this 320-base sequence is represented in the normal human genome. However, the level of expression in normal humans is reduced compared to epilepsy patients. Further characterization of this gene is in progress. We conclude that mRNA differential display is highly efficient in identification of disease specific genes and in the analysis of gene expression alterations in human epilepsy brain tissue. Supported by NS 27081.

HIPPOCAMPAL NMDA RECEPTOR NR1 SUBUNIT EXPRESSION IN EPILEPTIC HUMAN HIPPOCAMPUS.

I. Najm*, G. Tocco, Y. Comair, R. Kaakaji, H. Lüders, and M. Baudry. Section of Epilepsy Surgery, The Cleveland Clinic, Cleveland, OH, and Neurosciences Program, USC, Los Angeles, CA.

NMDA receptors, subtype of glutamate receptors, have been shown to play an important role in the genesis of seizures. Their expression is associated with increased neuronal excitability in temporal lobe epilepsy (TLE). We examined the changes in the prevalence of the NR1 subunit mRNA of the NMDA receptor in frozen-thawed sections obtained from temporal lobe resections in patients with intractable TLE (n=12). In situ hybridizations using a labeled oligonucleotide recognizing the NR1 subunit mRNA of the NMDA receptor were used to generate autoradiograms. Optical density measurements were performed in different hippocampal subfields. Our results show significant increase in NR1 subunit expression in dentate gyrus (DG), CA1, and CA3 areas of the hippocampal formations from patients suffering from intractable TLE as compared to control hippocampal tissue obtained at autopsy. The increased expression of NMDA receptor subunit mRNA in epileptic hippocampi is in apparent contrast with a previous report showing a decrease in total NMDA receptor/channel binding. This may represent a preferential expression of certain subtypes of NMDA receptors that may explain the hyperexcitability and participate in the genesis of seizures in patients with TLE. IMMUNOHISTOCHEMICAL DISTRIBUTION OF NMDA- RECEPTOR (R1), AMPA- RECEPTOR (R2), AND KAINATE (R5/6/7)-RECEPTOR SUBUNITS IN HUMAN EPILEPTIC HIPPOCAMPUS. L. Blümcke¹, C. Eickhoff, H.K. Wolf, Q.D. Wiestler. Dept. of Neuropathology, University of Bonn Medical Center, Sigmund-Freud Str. 25, 53105 Bonn, Germany.

Glutamate - receptors and receptor - mediated excitotoxicity have recently been associated with the pathogenesis of human temporal lobe epilepsy (TLE). Using monoclonal antibodies, which selectively recognize the *N*-methyl-D-aspartate (NMDA) R1-receptor, the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) R2-receptor and the kainate R5/6/7-receptor subunits (kindly provided by J.H. Morrison), we have examined the immunohistochemical distribution of these glutamate receptor isoforms in the hippocampal formation (HC) of patients with intractable TLE. Normal human HC-specimens obtained at autopsy were used as controls. Histopathologically, the specimens were classified into 4 categories: (1) HC without histological alterations (7%); (2) HC with focal lesions, e.g. ganglioglioma, low-grade glioma, dysembryoplastic neuroepithelial tumors, hamartoma or vascular malformations (21%); (3) HC with Ammonshorn sclerosis (AS; 54%); (4) HC with both, focal lesions and AS (18%). The analysis of the regional and cellular distribution of NMDA R1, AMPA GluR2, and kainate GluR5/6/7 immunoreactivity showed that the vast majority of neuronal cellbodies and dendrites of the granule and pyramidal cell layers exhibited immunoreactivity for all three proteins. We found no evidence for compensatory upregulation or selective loss of receptor expression in the HC of patients with chronic TLE. A decrease in or loss of immunoreactivity was closely correlated with the overall neuronal loss. So far, there was only one patient with a subtle increase in NMDA R1 staining in the polymorph layer of the dentate gyrus and in the stratum lucidum of CA3. However, this data may indicate that the glutamate receptor subunits are not directly involved in the pathogenesis of human TLE.

GENE TRANSFER INTO HUMAN HIPPOCAMPAL SLICES WITH AN ADENO-ASSOCIATED VIRUS VECTOR. A. Freese^{*}, M.J. Kaplitt, M.J. O'Connor, W.M. O'Connor, and M.J. During. Div. Neurosurgery, U. Penn., Philadelphia, PA; Div. Neurosurgery, Graduate Hosp., Philadelphia, PA; Lab. Neurobiology, Rockefeller U., New York, NY; Div. Neurosurgery, Yale Univ., New Haven, CT.

The transfer of genetic information into hippocampal cells in primary culture, slice preparations and test animals is yielding significant, new information about the physiology and pathology associated with the hippocampus. In addition, gene transfer into the hippocampus provides hope for gene therapy in diseases affecting the hippocampus, including some forms of epilepsy.

We have recently developed an adeno-associated virus (AAV) vector containing the Lac Z gene, encoding a bacterial β -galactosidase, under control of a cytomegalovirus Immediate Early promoter. This vector and appropriate controls were injected into hippocampal tissue derived from human patients undergoing temporal lobectomies for medically intractable seizures. Five hundred micron thick slices were maintained in artificial CSF @ 37°C for 5 hours, fixed, and then 30 μ m thick slices were generated from the larger slices and X-gal staining was performed to ascertain the presence of the bacterial β -galactosidase. In those slices exposed to the AAV vector with the Lac Z gene, significant β -galactosidase activity was observed in cells surrounding the injection tract. No staining was seen in controls. The implications for gene transfer into the human hippocampus and other CNS locations are addressed.

NEURONAL GLUTAMATE RECEPTORS AS AUTOANTIGENS: II. PARANEOPlastic DISEASE. J. Greenlee^{1,2}, L.C. Gahring^{1,2}, R.E. Twyman², J.H. Petajan², and S.W. Rogers^{1,2}. ¹SLC VA and GRECC, Salt Lake City, UT, 84148 and ²Univ. Utah School of Medicine, Salt Lake City, UT 84112.

Paraneoplastic (PN) cerebellar degeneration is a remote complication of systemic cancer. This disease is characterized by loss of Purkinje neurons, variable loss of granule cells, and occasional perivascular lymphocytic infiltrates. High titer anticerebellar antibodies are common. We have examined the sera of 16 patients with Type 1 or Type 2 PN disease for autoimmune reactivity to glutamate receptor (GluR) subunits using both Western blot and immunohistochemical analyses. We identified one patient with Type 1 paraneoplastic disease whose serum exhibited immunoreactivity to GluR5. Unexpectedly, immunohistochemical analyses of mouse brain sections with serum from the same patient exhibited highly specific regional staining of the lateral septum, bed nucleus of the stria terminalis, central nucleus of the amygdala, entire hippocampus, and Purkinje cells of the cerebellum. Staining of this pattern persisted to dilutions of 1:20,000. This pattern of expression is strongly suggestive of the immunohistochemical pattern for GluR1 (e.g., Rogers, et al. JNS 11:2713, 1991). These results suggest that this patient may harbor autoantibodies to more than one GluR subunit. This is the first report that autoimmune reactivity towards GluR subunits can occur in PN disease, and that this differs from the anti-GluR3 immunoreactivity observed in Rasmussen's encephalitis (see abstract by Rogers et al.) suggesting that various GluR subunits may serve as autoantigens in neurodegenerative disease.

A HSV-1 VECTOR EXPRESSING GLUR6 RESULTS IN EPILEPTIFORM DISCHARGES BY EITHER NMDA-DEPENDENT OR NMDA-INDEPENDENT MECHANISMS. P.J. Bergold^{*}, P. Casaccia-Bonneli, H. Shen, Z.-X. Liu, A. Stelzer, and H.J. Federoff^{*}. Department of Pharmacology, SUNY- Health Sciences Center at Brooklyn, NY, NY 11203; ^{*}Department of Medicine, Albert Einstein Sch. of Medicine, NY, NY, 10461

Epileptiform discharges *in vitro* or limbic seizures *in vivo* are readily induced by transduction of hippocampal neurons using HSVGluR6, an HSV vector expressing a fully edited kainate receptor subunit. Discharges appear within 2.5 hours after localized gene transduction to the CA3 region of cultured hippocampal slices. We have previously demonstrated experimental control of the number of transduced cells using HSVlac, an HSV-1 vector that expresses the reporter gene β -galactosidase. We presently investigated how may transduced cells were needed for discharge initiation. Discharge initiation was effectively blocked with the non-NMDA receptor antagonist, CNQX (50 μ M), regardless of the number of HSVGluR6-transduced cells. The NMDA receptor antagonist, DL-APV, (100 μ M), blocked discharge initiation in cultures containing fewer than 10 transduced cells. In cultures containing greater than 400 transduced cells, discharges appeared despite the presence of APV. These data suggest that discharges were induced by a small number of HSVGluR6-transduced neurons in addition to non-transduced CA3 neurons recruited by an NMDA-dependent mechanism. If sufficient CA3 neurons are transduced, NMDA receptors are not needed.

Rasmussen's encephalitis is a childhood disease of intractable focal seizures and characteristic inflammatory histopathology in the affected brain hemisphere. Two rabbits injected with a bacterial fusion protein expressing a portion of the glutamate receptor subunit, GluR3, were observed to develop seizures and early histopathological changes similar to those observed in Rasmussen's encephalitis. To test the hypothesis that an autoimmune response to GluR3 may be associated with Rasmussen's encephalitis, the sera from affected patients and age and sex matched controls were examined for immunoreactivity towards GluR subunits using Western blot analysis and transfected cells. Rasmussen patients with active disease were found to have circulating IgG antibodies to GluR3. In a therapeutic trial of one patient, removal of circulating GluR3 antibodies by plasmaphoresis correlated with a reduced rate of seizure and improved cognitive function. Our results suggest that Rasmussen's encephalitis consists of an autoimmune component which includes autoreactive antibodies towards glutamate receptors of the CNS. NEURONAL GLUTAMATE RECEPTOR ANTIBODIES -- POTENTIAL EXCITOTOXINS? L.C. Gahring, R.E. Twyman, J.M. Eichen, S.N. Sudweeks, L. Jackson, J.R. Baringer^{*}, and S.W. Rogers. Programs in Neuroscience and Human Molecular Biology & Genetics, Univ. of Utah School of Medicine and VA-GRECC, Salt Lake City, UT 84112

Two rabbits injected with bacterially prepared protein of neuronal glutamate receptor (GluR) subunit, GluR3, developed seizures and pathology similar to those observed in Rasmussen's encephalitis (see abstract Rogers et al). Our initial studies have focused on rabbit immune serum and the mechanisms of antibody action. Results indicate that at least two epitopes exist in the region of aminoacids 245-457 of GluR3 near the presumed extracellular glutamate binding site. Immunohistochemical examination on mouse brain reveal patterns of GluR3 expression consistent with *in situ* hybridization studies. These antibodies also identify a small subset of morphologically similar cells in live mouse (E14) cortical neurons in culture. Whole cell electrophysiological studies of these neurons indicate that GluR3 antibody rapidly and reversibly activates non-NMDA sodium currents and that these neurons also have kainic acid inducible currents. Antibody evoked currents were blocked by CNQX and currents were not elicited by other sera. Single cell RT-PCR analysis of these neurons identifies the presence of GluR3 and additional GluR subunits. These results indicate that antibodies to GluR3 have agonist properties on unique cultured neurons containing putative GluRs. This suggests the possibility that autoimmunity targeted against specific epitopes on GluR containing neurons may contribute to neurotoxicity in conditions such as epilepsy, neurodegenerative diseases and paraneoplastic syndromes.

CHANGES IN HIPPOCAMPAL GLUTAMATE/AMPA RECEPTORS IN EPILEPTIC HUMAN HIPPOCAMPUS

Y. Comair*, G. Tocco, I. Najm, R. Kaakaji, H. Luders and M. Baudry
 Section of Epilepsy Surgery, Cleveland Clinic, Cleveland, OH 44195, and
 Neuroscience Program, USC, Los Angeles, CA 90089

Changes in glutamate receptor properties in the limbic system have been proposed to participate in the increased neuronal excitability observed in human temporal lobe epilepsy (TLE). We examined the changes in binding properties of hippocampal glutamate/AMPA receptors using quantitative ligand binding autoradiography in frozen-thawed sections obtained from temporal lobe resection in patients with intractable TLE. As observed in rat hippocampal sections, preincubation of human hippocampal sections (n=12) at 35°C resulted in a large decrease in ³H-AMPA binding as compared to sections preincubated at 0°C. Preincubation at 35°C in the presence of calcium (2 mM) resulted in a large increase in binding as compared to the absence of calcium. Sections from epileptic patients exhibited an increase in binding following preincubation at 35°C in the absence of calcium and no change after preincubation in the presence of calcium as compared to control tissue obtained at autopsy. Our results indicate that TLE is associated with a decrease in synaptic receptors and an increase in non-synaptic (possibly cytoplasmic) AMPA receptors.

Thus, the changes in AMPA receptor binding are more complex than previously reported, and the increase in functional AMPA receptors with calcium at physiological temperature, may contribute to the hyperexcitability in epileptic human hippocampus.

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS II

593.1

POTENTIATION OF AUDIOGENIC SEIZURES BY TMPP AND PTZ IN NAIVE ADULT FISCHER-344 AND SPRAGUE-DAWLEY RATS G.D. Ritchie*, J. Rossi III, M.S. Buring, C. Ademujohn, J. Smith, T. Morton and M. Langley. Naval Medical Research Institute Detachment (Toxicology) and Geo-Centers, Inc., Wright-Patterson AFB, OH 45433-7903.

Trimethylolpropane phosphate (TMPP) and pentylenetetrazol (PTZ), two potent convulsants thought to antagonize the GABA_A inhibitory system, potentiated audiogenic seizures in naive adult Fischer-344 and Sprague-Dawley rats. Doses of TMPP (0.0125-0.05 mg/kg i.p.) insufficient to produce observable behavioral convulsions or EEG response nevertheless potentiated wild running fits or wild running fits followed by tonic seizures 30 min. after the initial administration. TMPP doses (0.10-0.20 mg/kg i.p.) sufficient to effect observable behavioral response and EEG paroxysms reliably potentiated wild running fits followed by severe tonic-clonic seizures in 80%+ of animals tested. Time to initial seizure response following onset of the audiogenic stimulus was linearly dose dependent. In some animals a single TMPP administration potentiated an audiogenic seizure response when animals were acoustically stimulated up to three months later. PTZ (5.0-25.0 mg/kg i.p.) potentiated audiogenic seizures in naive adult Sprague-Dawley rats 30 min. following the initial dose. This result was unexpected, and may reflect the use of a mixed frequency (8,000 Hz predominant frequency, 110 dB for 60 sec.) audiogenic stimulus as opposed to the traditionally used bell or pure tone. The results are discussed in terms of possible neurological mechanisms of action.

593.2

DIFFERENTIAL SUSCEPTIBILITY OF BALB/c, SWISS-WEBSTER AND DBA/2 MICE TO INTRAHIPPOCAMPAL γ -ACETYLENIC GABA. E. Urbanska*, G. Ceresoli and R. Schwarcz. Maryland Psych. Res. Center, Baltimore, MD 21228.

Intrahippocampal application of the "indirect" excitotoxin γ -acetylenic GABA (GAG) (240 nmol) causes a unilateral loss of hippocampal CA1 and CA3 neurons but no behavioral seizures in rats (Exp. Neurol. 124:184, 1993). Unilateral GAG injections were now made into the hippocampus of 10-week old Balb/c, Swiss-Webster and DBA/2 mice. Animals were killed 3 days later, and their brains were analyzed by light microscopy. Mortality, behavioral convulsions and hippocampal neurotoxicity differed substantially among strains (DBA/2 >> Swiss > Balb/c). 360 nmol GAG had virtually no effect in Balb/c mice and led to seizure-related death in 30% of Swiss mice. In contrast, 90 nmol GAG caused 50% mortality in DBA/2 mice. Convulsions developed by 3-5 hrs post injection and often progressed to status epilepticus and tonus/death. Hippocampal necrosis was seen in all (and only in) animals which had status epilepticus. Neuronal damage occurred bilaterally in area CA1 and often also in area CA3. Granule and hilar cells degenerated mostly ipsilaterally to the GAG infusion. In DBA/2 mice treated with 90 nmol GAG, the anticonvulsant valproic acid (2 x 350 mg/kg) and the NMDA antagonist CGP 40116 (20 mg/kg) totally abolished seizures and nerve cell death. In mice, therefore, GAG-induced hippocampal neurodegeneration seems to be seizure-related and mediated via NMDA receptors.

593.3

ENHANCED KAINATE SENSITIVITY IN THE HAN-WISTAR RAT. R.W. Cohen*, C. Cepeda, C.A. Crawford, J.E. Margulies, J.B. Watson and M.S. Levine. Mental Retardation Res. Center, UCLA School of Medicine, Los Angeles, CA 90024.

We are studying a mutant Han-Wistar (HW) rat strain which displays a pattern of hippocampal degeneration (CA3 pyramidal cells) and mossy fiber sprouting similar to rat models of epilepsy (i.e., kainate-injected, kindling). We first studied the sensitivity of 40 day old mutants and littermate controls (n=20 pairs) to kainate injections (7-9mg/kg). Bipolar electrodes were implanted in the dorsal hippocampus and EEG recordings were made 3-5 days later. Prior to kainate injections, both mutants and controls did not show any abnormal paroxysmal discharges. After injection, behavioral and electrographic seizures occurred earlier (15-30 mins) and were more intense in the mutant. The mutants' seizures resembled the tonic-clonic type, while the controls exhibited short duration, high amplitude, paroxysmal discharges. Kainate injection was lethal to 50% (10/20) of the mutants but only 5% (1/20) of the controls. Another set of kainate-injected pairs (n=3) was analyzed by immunohistochemistry for the presence of c-Fos, a gene regulating protein which becomes elevated in epileptic cells. Mutant hippocampus, which showed no differences in c-Fos expression prior to kainate treatment, exhibited a 30-40% increase in c-Fos compared with controls. To determine a molecular basis of sensitivity, we examined the expression of non-NMDA glutamate receptor mRNA in the HW hippocampus by ³⁵S-labeled *in situ* hybridization. We observed a two-fold increase in GluR2 mRNA in all regions of the mutant hippocampus, suggesting an enhanced kainate sensitivity in the mutant. We propose that the HW model, because of its kainate sensitivity, can be used to understand the complex relationship between cell degeneration and hippocampal reorganization in epilepsy.

593.4

PROCONVULSIVE ACTION OF PERIPHERAL-TYPE (OR MITOCHONDRIAL) BENZODIAZEPINE RECEPTORS IN EL AND 'NERVOUS' MUTANT MICE. Y. Nakamoto*, M. Yoshii¹, S. Watabe² and T. Shiotani². ¹Dept. of Neurophysiology, Tokyo Institute of Psychiatry, Tokyo 156 and ²Tokyo R & D Center, Daiichi Pharmaceutical Co. Ltd., Tokyo 134, Japan.

We have recently reported that Ro 5-4864, a specific agonist for the peripheral-type (or mitochondrial) benzodiazepine receptor (PBR), can efficiently induce seizures in El mice, an animal model of epilepsy (Nakamoto et al., Soc. Neurosci. Abstr. 18, 380, 1992). To further characterize the proconvulsive action of PBR, we have examined the 'nervous' mutant mouse, which develops a selective degeneration of cerebellar Purkinje cells with abnormal mitochondria. Ro 5-4864 at a dosage of 20 mg/kg or higher (i.p.) induced seizures consistently in nervous mice, whereas in their controls (heterozygous littermates) seizures could be induced at a lower dosage of 10 mg/kg. In binding assay for [³H]Ro 5-4864 in brain homogenates, the binding of [³H]Ro 5-4864 was reduced more than 50% in cerebella of nervous mice when compared with controls. In contrast, no significant changes in [³H]Ro 5-4864 binding were observed in forebrains between nervous and control mice. There was no apparent alteration in receptor affinity for [³H]Ro 5-4864. The results suggest that PBRs in the cerebellum could contribute to seizures as those in the forebrain.

593.5

KAINIC ACID-INDUCED SEIZURES IN RATS: DOES ROUTE OF ADMINISTRATION MAKE A DIFFERENCE? G.T. Golden*, N.K. Krishna, G.G. Smith, P.F. Reyes, T.N. Ferraro. Department of Veterans Affairs Medical Center, Coatesville, PA 19320 and Jefferson Medical College of Thomas Jefferson University, Philadelphia, PA 19107

Parenteral administration of drugs can result in differential rates of absorption. The glutamate agonist kainic acid (KA) is usually administered systemically by either the intraperitoneal (ip) or subcutaneous route (sc) to produce acute limbic seizures in rats and is used as a model for temporal lobe epilepsy. In the present study, KA was systemically administered by ip, sc or intramuscular (im) routes to seizure sensitive Fisher 344 rats (F344) and seizure resistant Long Evans rats (LEH) to determine if route of administration differentially effected seizure parameters. A total of 54 F344 and 54 LEH adult rats received one of three KA doses (adjusted to a neutral pH) by the ip, sc or im route. Behavior was monitored for 30 minutes before and for 240 minutes after injection of KA. The number of animals demonstrating behavioral seizures, number of animals exhibiting status epilepticus, behavioral seizure scores, latency to first seizure and latency to status epilepticus were compared for the three parenteral injection routes. Results showed trends for rats with sc injections to have shorter latencies to first seizure and to status epilepticus, for im injected rats to have the longest and ip injected rats intermediate latencies. There was also a trend for ip and im injected rats to have higher seizure scores than sc injected rats. However, there were no statistically significant differences between the three routes of parenteral administration on any of the seizure parameters measured. Seizure response variability due to route of administration and strain differences will be discussed. Supported by the Department of Veterans Affairs.

593.7

CHANGES OF DOPAMINERGIC NEUROTRANSMISSION AFTER KAINIC ACID-INDUCED BEHAVIOURAL ALTERATIONS. H. Baran* Dep. of Pediat., University of Vienna, 1090 Vienna, Austria. Injection of kainic acid (KA, 10 mg/kg, s.c.) in the rat results in the development of characteristic epileptic syndromes. We analysed dopamine (DA), noradrenaline (NA) and serotonin (5-HT) in amygdala/hippocampus, hippocampus, septum, and frontal and parietal cortex 10, 20, 30, 60, and 120 min after KA. At 10 and 20 min the marked increase of DA was found in amygdala/hippocampus cortex (+61% and +57%), in hippocampus the DA content was reduced (-25% and -50%) and 30 min after KA in both regions the DA content was normalized. At 1 and 2 h the increase of DA was measured in hippocampus (+63% and +86%). In septum DA was decreased (-30%) 10 min after KA, increased (+50%) 20 min after, and was however decreased at 1 and 2 h (-53% and -64.2%). NA content was reduced (-20 %) in parietal cortex 10 and 20 min after KA, in hippocampus and parietal cortex 30 min after, and in all regions examined (ca. -50%) 2 h after. 5-HT was mildly but significantly lowered 2 h after KA. In summary, the induced changes of DA content in the brain after KA indicate notable regional circuits of DA-ergic neurotransmission, which may play pivotal function in the induction of epileptic activity. This study has been performed at the Inst. of Biochem. Pharmacol. Univ. Vienna. Supported by Austria Research Fund 5647 and Charlotte-Buehler Fund H00043-MED to H.B..

CHANGES IN CEREBRAL BLOOD FLOW PRECEDE ELECTROGRAPHIC SEIZURE DISCHARGES. J.M. Germano*, L. Guarino, J.B. Bederson. Department of Neurosurgery, Mount Sinai School of Medicine, New York, (NY) 10029.

Treatment of epilepsy depends on the identification of the epileptogenic focus. Minimally invasive methods for this identification are sought. The aim of this study is to compare the use of intracranial and depth electrode EEG recording versus laser doppler flowmetry (LDF) in detecting the onset of seizure activity. Adult Sprague Dawley rats were anesthetized with chloral hydrate, intubated, ventilated and kept anesthetized with halothane. Intracranial electrodes and LDF probe were placed epidurally; depth electrodes were stereotactically implanted in the hippocampus. Seizures were induced with kainic acid (20 mg/kg i.p.). A blood flow increase greater than 200% of baseline was seen in 4 of 5 rats prior to electrographic discharges recorded from depth and intracranial electrodes. These findings suggest that LDF should be further investigated as a diagnostic modality in the evaluation and study of epilepsy.

593.6

THALAMIC-TRIGGERED SEIZURES. G.A. Cottrell*, H. Gnanasekaram and W.M. Burnham. Bloorview Epilepsy Laboratory, Dept. Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Past research has shown that the midbrain and hindbrain can produce convulsive seizures when subjected to high levels of stimulation. The present experiment was designed to investigate convulsive behavior patterns elicited from the thalamus. Male Long-Evans rats were implanted with single bipolar electrodes using standard stereotaxic techniques. High-intensity electrical stimulation was administered to 14 thalamic nuclei, at 3 anterior-posterior planes. The posterior nuclei of the thalamus produced a generalized convulsion which was tonic or tonic-clonic, depending on the intensity of the stimulation. These convulsions resembled maximal electroshock seizures. Stimulation of the anterior and middle nuclei of the thalamus produced bilateral forelimb clonus, sometimes preceded by contralateral forelimb clonus. These seizures were never tonic, even at high stimulation levels. The data suggest that the thalamus is capable of producing two separate convulsive patterns, one purely clonic and the other tonic-clonic.

This research was supported by the Bloorview Epilepsy Program Grant and the Medical Research Council of Canada.

CITRULLINE INCREASE DURING TEMPORAL LOBE SEIZURES SUPPORTS THE ROLE OF NITRIC OXIDE FORMATION IN EPILEPSY: AN *IN-VIVO* MICRODIALYSIS STUDY. M.H. Shomer, C.L. Wilson, N.T. Maidment, E.J. Behnke, A.L. Velasco, J. Engel Jr., and L. Fried*. Depts. of Neurology, Anatomy, Psychiatry, Neurosurgery, and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Seizure initiation and spread involving glutamate (GLU) activation of the NMDA receptor may be mediated by Ca^{2+} /calmodulin-dependent conversion of nitric oxide (NO) and citrulline (CIT) from arginine by nitric oxide synthase (NOS). Using *in vivo* microdialysis, Sorkin (Neuroreport, 1993, 4: 479-482) has shown an NMDA-evoked increase in the levels of CIT and GLU which is blocked by the NOS inhibitor L-NAME. Our hypothesis is that NO is involved in the cascade of events underlying seizure genesis in human epilepsy. Due to its gaseous nature, NO can diffuse to surrounding presynaptic terminals, increasing levels of cGMP and release of transmitter resulting in seizure genesis and propagation. In patients with intractable complex partial epilepsy who require diagnostic studies prior to temporal lobectomy, intracranial probes containing microelectrodes and microdialysis membranes were used to record EEG, single unit activity, and amino acid levels in the hippocampal formation, amygdala and entorhinal cortex. We have observed up to 5-fold increases in glutamate and citrulline during 3 out of 4 complex partial seizures in two patients, and a significant correlation in levels of glutamate with citrulline ($r = .71$, $p < .001$) both ictally and interictally. These increases provide evidence from the human temporal lobe in support of a role for NO in seizure genesis. Supported by NS 02808.

Possible Mechanism of the Seizure Attenuating Effects of Vagus Nerve Stimulation. S.E. Krali*, R.A. Browning, K.B. Clark, & D.C. Smith. Departments of Psychology and Physiology, Southern Illinois University, Carbondale, Illinois 62901.

Vagus nerve stimulation (VS) is a new strategy for the treatment of intractable epileptic seizures. The mechanism(s) by which VS attenuates seizures, however, have not been elucidated. The present study examined the role of the locus coeruleus (LC) in this phenomenon.

Experiment 1 investigated the effects of VS on LC single-unit activity in urethane-anesthetized female rats. Using extracellular electrodes, the activity of single LC neurons was monitored before and after VS. VS was found to significantly increase the firing rate of neurons located in the dorsal LC, while having no significant effect on subcoerulear cells. These results indicate that VS can affect LC activity, and that this effect may be regionally specific.

Experiments 2 and 3 were designed to answer two main questions: 1) were the parameters used in Experiment 1 relevant to those used for the prevention of seizures and, 2) would inactivation of the LC reduce the anticonvulsant effects of VS? In Experiment 2, female rats were either depleted of norepinephrine via a bilateral infusion of 6-OHDA into the LC (6-OHDA/VS), received a sham infusion (Sham/VS), or did not receive surgery (NonOp/VS). Two weeks later, these rats were implanted with vagus nerve electrodes. The next day they were given VS, during which they were subjected to a corneal maximal electroshock seizure (MES) test. The seizure severities of the Sham/VS and NonOp/VS groups following VS were significantly reduced as compared to pretest severities, demonstrating the effectiveness of VS as an anticonvulsant treatment. Seizure severities of the 6-OHDA/VS group following VS, however, did not differ significantly from pretest values, indicating that the LC may modulate the anticonvulsant effects of VS.

In Experiment 3, female rats had cannulae implanted in the LC, through which either lidocaine or saline was infused. Shortly thereafter, the rats were given VS and an MES test. In agreement with the results of Experiment 2, VS caused a significant reduction in seizure severity in those rats with an intact LC (saline infusion), but had little effect on those whose LC was reversibly inactivated (lidocaine infusion). These results further suggest that the LC may modulate the anticonvulsant effects of VS.

PREDICTORS FOR POST-ISCHEMIC SEIZURES IN LONG-EVANS RATS. K. H. Reid¹, V. Iyer, A. Schurr, M. T. Tseng, J. J. Miller. Depts. of Anatomical Sciences & Neurobiology, Neurology, Anesthesiology, and Pathology, University of Louisville, Louisville KY 40292.

After global ischemia, rats tend to develop sound-triggered seizures which resemble those seen in genetically epilepsy-prone rats (Reid et al., FASEB J. 8:A660, 1994). We sought to maximize the fraction of post-ischemic rats which developed audiogenic seizures through an evaluation of 5 possible predictors of post-ischemic seizures in 60 rats. All rats received 7 minutes of chest compression under ketamine anesthesia at a skull temperature of 35°C. Resuscitated rats were tested for sound-induced seizures 24 hours later. The predictors evaluated were **blood glucose, skull temperature, time to first spontaneous respiration, time to first EEG activity, and peak blood pressure during reperfusion.** Receiver operating characteristic curves indicated that the best single predictor was the duration of isoelectric EEG; this had an accuracy value of 0.79. Combinations of predictors did not significantly improve this value, in part because we tried to hold all parameters constant so that the range of measured values was narrow. Supported in part by Alliant Community Trust Fund 9210.

594.3

SEQUENTIAL CHANGES IN HIPPOCAMPAL CA1 REGION OF THE POST-ISCHEMIC SEIZURE PRONE RATS. M. T. Tseng, K. H. Reid, V. Iyer, A. Schurr, and J. J. Miller. Depts. of Anatomical Sciences & Neurobiology, Neurology, Anesthesiology, and Pathology, University of Louisville, Louisville KY 40292.

Hippocampal CA1 region is known to be susceptible to global ischemia. The time-dependent change in this region of the post-ischemic seizure prone rats following chest compression was studied in 8 seizure prone rats and 2 controls. Rats were anesthetized and perfusion fixed 4 h, 48 h, 7 day, and 6 weeks following a 7 min global ischemia. Brains were removed, fixed for 3 more days, before being vibratome sectioned at 40 µm for light microscopy or microdissected for electron microscopy processing. Decreased width of the stratum pyramidale and a concomitant increase in glial cell was observed in 7 day and 6 week samples. The early perivascular edema showed resolution through glial cuffing from day 7. Gradual neuronal death and glial migration as well as the presence of neurofilament-rich glia around the micro-vessels were verified by electron microscopy. These results confirmed selective vulnerability of the CA1 pyramidal cells and suggest that gliosis is an important sequela of this global ischemia model. Supported in part by Alliant Community Trust Fund 9210.

GABA AND SEIZURE INITIATION. K. Emori^{1,2*}, Y. Minabe¹, C.R. Ashby, Jr.³ and H. Katsumori¹. ¹Dept. of Cortical Function Disorder, National Institute of Neuroscience, NCNP, Kodaira, Tokyo 187, Japan; ²Dept. of Neuropsychiatry, Toyama Med. & Pharmaceut. Univ., Toyama 930-01, Japan; ³Brookhaven National Lab., Upton, NY 11973.

In this study we examined dynamic changes of monosynaptically evoked field potential in dentate gyrus (DG) by paired perforant path stimuli (25ms apart) for analysis of local GABA function during low-frequency (2Hz) DG kindling stimulus train using unanesthetized freely moving rats. We also observed extracellular field recording associating with afterdischarge (AD) triggering. During the kindling stimulus train, in all cases AD was triggered prior to occurrence of disinhibition of paired-pulse depression. Furthermore the triggered AD shapes changed with a population spike like component when the disinhibition occurred. By the kindling development, the paired-pulse depression was rather enhanced in the early period of stimulus train and latency until the disinhibition was prolonged. We consider that these findings suggest a possibility that collapse of local GABA mediated inhibition might contribute to seizure propagation rather than its initiation.

CHANGES IN SEIZURE PATTERN WITH VALPROATE THERAPY IN POST-ISCHEMIC AUDIOGENIC EPILEPSY IN LONG-EVANS RATS. V. Iyer, K. H. Reid, A. Schurr, L. A. Carr, M. T. Tseng and J. J. Miller. Depts. of Neurology, Anatomical Sciences & Neurobiology, Anesthesiology, Pharmacology & Toxicology, and Pathology, University of Louisville, Louisville, KY 40292.

Long-Evans rats subjected to cardiac arrest from chest compression tend to develop audiogenic seizures. (Reid et al., FASEB J. 8: A660, 1994). This may be a useful model for human generalized epilepsy. To validate this model, we compared the effect of 200 mg/kg valproate i.p. in 20 post-ischemic rats with 10 saline-injected controls. Each rat was tested 30 times; during 10 successive tests valproate/saline was injected one hour prior to the seizure test. Valproate consistently reduced the number of seizures induced by sound. In addition, the seizures which did occur were briefer and less complex than those seen pre-treatment or in saline-treated controls. Seizure suppression sometimes continued after drug treatment was stopped, suggesting a possible anti-epileptogenic effect. These effects indicate that this model may be useful in evaluating drug therapy for generalized tonic-clonic seizures. Supported in part by Alliant Community Trust Fund 9210.

SYNAPTIC FUNCTION AND ITS FACILITATION BY LOW MAGNESIUM IN HIPPOCAMPAL SLICES OF RATS SUBJECTED TO CARDIAC ARREST R.S. Payne, A. Schurr*, V. Iyer, K.H. Reid, M.T. Tseng, J.J. Miller. Departments of Anesthesiology, Neurology, Anatomical Sciences & Neurobiology, and Pathology University of Louisville, School of Medicine, Louisville KY, 40292.

Long Evans male rats were subjected to chest compression-induced cardiac arrest for 7 min. Subsequent audiogenic seizures (AGS), and histopathological changes in the CA1 region of the dorsal hippocampus were observed.

Using a dual interface recording chamber, evoked extracellular potentials in normal artificial cerebrospinal fluid (ACSF) and low Mg^{2+} -induced synaptic facilitation (LMISF) were evaluated in hippocampal slices obtained from rats not subjected to chest compression and compared with slices prepared from chest-compressed animals. CA1 extracellular responses to electrical stimulation of the Schaffer collaterals were recorded from the pyramidal cell body layer using a stimulus strength x2 threshold (~5 V). This stimulus usually evokes a PS with an amplitude of 10 mV or greater. In experiments where slices were perfused with Mg^{2+} -free ACSF, the stimulus strength was reduced just before the perfusion such that the amplitude of the PS did not exceed 3 mV.

Of 90 slices prepared from control rats, 74.4% exhibited a CA1 PS with an amplitude of ≥ 10 mV, 23.3% had an amplitude of 6-10 mV and 2.2% with an amplitude of < 6 mV. In contrast, of 172 slices prepared from rats that were exposed to cardiac arrest, only 12% exhibited a PS with an amplitude of ≥ 10 mV, 29% showed a PS of 6-10 mV while the majority of the slices (58%) exhibited a PS amplitude smaller than 6 mV. Of the latter, 32% were completely unresponsive. To test for LMISF, slices were perfused with Mg^{2+} -free ACSF. In preliminary experiments such perfusion brought about 178±48% increase in the amplitude of the PS in slices of control rats. In slices of chest-compressed, AGS rats, LMISF was attenuated (95±34%) which disagrees with results obtained from slices of AGS mice, where LMISF was enhanced (Wieraszko & Seyfried, *Epilepsia*, 34:979,1993).

We conclude that diminished PS amplitude and lack of enhancement of LMISF in slices from cardiac arrest, AGS rats is due to cerebral ischemic neuronal damage.

DETERMINISM, CONTROL AND ANTI-CONTROL IN A MODEL EPILEPTIC FOCUS. D.H. Duong, T. Chang, K. Jerger, M.L. Spano, W.L. Ditto and S.J. Schiff*. Department of Neurosurgery, Children's National Medical Center, Washington, D.C. 20010.

Following the recent theoretical prediction that chaotic physical systems might be readily controllable, there has been rapid and successful application of this technique to mechanical systems, electrical circuits, and arrhythmic cardiac tissue. One of the hallmarks of the human epileptic brain during periods of time in between seizures is the presence of aperiodic bursts of focal synchronized neuronal activity known as *interictal spikes*. The high potassium *in vitro* hippocampal brain slice preparation exhibits population burst-firing activity that is in many ways analogous to the interictal spike. We sought to determine whether such neuronal bursting activity was amenable to control.

Transverse slices 400 µm thick were prepared from the hippocampus of 125-150 gm female Sprague-Dawley rats with a tissue chopper, and placed in an interface type perfusion chamber at 32-35 °C. Experiments consisted of combinations of chaos control, periodic pacing, and the inverse of chaos control which we term *anti-control*.

Ninety-one experimental trials were performed on 22 slices from 9 rats. Good control of this neuronal circuit was achieved in 14/52 chaos control trials, 8/19 trials using periodic pulses, and in 5/21 attempts at anti-control.

This is the second attempt at achieving control of a chaotic biological system, and the first attempt in brain. Chaos control has the advantage over overdrive periodic pacing in terms of its ability to identify and track the system's activity over time. In addition, the control of chaos strategy offers the ability to break up periodic behavior with "anti-control". The anti-control method used here employs a minimum number of stimuli needed to prevent periodic behavior. Such techniques may be applicable to human epileptic foci.

LONG-TERM EVALUATION OF SPONTANEOUS RECURRENT SEIZURES AFTER INTRAHIPPOCAMPAL KAINIC-ACID INJECTION. R.L.M. Rivero, C.M. Kohmann*, D.K. Arashiro, M.S. Franca, C.D. Domingos, R.V.R. Duran and L.E.A.M. Mello, Depto. de Fisiologia, Escola Paulista de Medicina, 04023-900 São Paulo, Brazil.

After the pioneer work of Cavalheiro (EEG Clin. Neurophysiol., 53:581-589, 1982) regarding the development of spontaneous recurrent seizures (SRS) after intrahippocampal kainate (KA) administration, very little attention has been given to the behavioral aspects of this model of epilepsy. Thus, there is no reference as to how many animals submitted to this procedure develop SRS, or to the frequency of these SRS. In order to answer some of these questions we decided to study this model of temporal lobe epilepsy in more detail. Wistar rats were submitted to an stereotaxic, unilateral, intrahippocampal kainic acid injection (1.25µg/0.5 µl), under anesthesia. After surgery, the rats were visually monitored regarding occurrence of SRS, for 5 days/week, 5h/day on the subsequent days (over 300 days). 75% of the female rats and 84.5% of the male rats developed SRS after the injection. The latency period for the first SRS to be seen was similar, in males (6-188 days) and in females (11-324 days). The average seizures/week/rat was 0.21. Seizure frequency did not increase with time. After 15 weeks of observation, more than 85% of the female rats and more than 60% of the male rats were still showing SRS. Our results indicate that hippocampal injection of KA may not automatically imply in the development of SRS. Our results do not agree with the previous report of SRS remission after 60 days in this model. Seizure remission on this model was a basic tenet for some authors to suggest that mossy fiber sprouting would help to suppress SRS. Supported by: FAPESP, CNPq and FINEP; R.L.M.R., C.M.K. and R.V.R.D. are FAPESP fellows (IC 93/0665-7, 93/4965-5 and 93/0666-3). M.S.F. is a CNPq fellow.

ALTERED ELECTRICAL ACTIVITY IN THE DENTATE GYRUS OF FREELY-BEHAVING RATS AFTER KAINATE-INDUCED STATUS EPILEPTICUS. P.R. Patrylo*, G.M. Rose*, K.L. Heman*, and F.E. Dudek* 'Dept. of Anatomy and Neurobiology, Colorado State University, Fort Collins, CO 80521, and *Dept. of Pharmacology, UCHSC and VAMC, Denver, CO 80220

The kainate-treated rat, an animal model of temporal-lobe epilepsy, undergoes an initial period of status epilepticus that can ultimately result in a permanent epileptic state. The aim of the present experiments was to determine the initial effects of kainate-induced status epilepticus on evoked field potentials from dentate granule cells in freely-behaving rats. Chronic *in vivo* recordings were performed during a 2 day period prior to and 1 day after kainate treatment. Rats (n=3) were given multiple kainate injections (IP; 5 mg/kg per hr) for 5-8 hr, and class IV/V seizures were elicited for $\geq 3/4$ hr. Prior to kainate treatment, single stimuli of the perforant path (at maximal intensity) evoked a positive field-potential PSP that lasted for 18-26 ms with one or two superimposed population spikes. Paired-pulse stimulation of the perforant path (interpulse interval = 20 ms; stimulus intensity that produced a half-maximal population spike) showed attenuation or little change of the field PSP and population spike to the second stimulus. One day after kainate-induced status epilepticus, however, single stimuli evoked prolonged field PSPs (duration = 63-75 ms) with multiple population spikes. Paired-pulse stimulation led to facilitation of the field PSP and population spike to the second stimulus. The prolongation of the field PSP and the paired-pulse facilitation suggests that recurrent inhibition was depressed in the dentate gyrus of the kainate treated rats. Although further experiments are necessary, these results suggest that relatively rapid changes in dentate electrophysiology, apparently including recurrent inhibition, occur following a period of kainate-induced status epilepticus. EFFECTS OF HYPOXIA AND HYPOXIA/ISCHEMIA ON THE DEVELOPING HIPPOCAMPUS. J. Owens, Jr., C.A. Robbins, H.J. Wenzel, and P.A. Schwartzkroin*. Depts. of Physiology/Biophysics and Neurosurgery, Univ. of Washington, Seattle, WA 98195.

Exposing immature rats to hypoxia evokes epileptiform activity which is dependent upon both age and oxygen concentration (Ann. Neuro. 29:629-637). Although perinatal hypoxia leads to increased long term seizure susceptibility, morphological damage has not been demonstrated (Epilepsia 33:971-980; Life Sci. 37:1597-1604). We have attempted to identify hypoxic conditions which will produce short-term hippocampal damage in order to study the possible functional abnormalities resulting from such trauma.

Rats representing 3 age groups (P8-P12, P15-P17, and P20-P27) were exposed to either 15 minutes of hypoxia on 3 successive days or a single 60 minute treatment. Silver degeneration and Nissl staining revealed no difference between treated and control animals at 1, 4, or 7 days following treatment. Fifteen minute hypoxic exposures (on P8-P10 or P9-P11) did not significantly affect CA1 field potentials or intrinsic properties, but may have altered fast IPSP conductance in hippocampal slices prepared 1, 4, or 7 days after the third treatment.

The immature brain has been reported to be vulnerable to a combination of hypoxia and ischemia. We found that, whereas neither hypoxia nor unilateral carotid ligation alone produced neuropathology, the combination of the two reliably produced neuronal damage (see also Ann. Neuro. 9:131-141). In P8-P12 rats, unilateral carotid ligation followed by 60 minutes of hypoxia induced light terminal degeneration in the terminal field of the mossy fibers (the stratum lucidum in CA3) as well as apparent transient cell damage in the pyramidal cell region.

AFFERENT REGULATION OF THALAMIC OSCILLATIONS IN PETIT MAL EPILEPSY: A MICROPERFUSION STUDY. A. Kandel*, G. Jando, and G. Buzsáki, CMBN, Rutgers University, Newark, NJ 07102

Spike and wave high voltage spindle (HVS) pattern (7-8 Hz) in rodents is an animal model for petit mal epilepsy. These nonconvulsive generalized seizures originate in the thalamus and become bilaterally synchronous in the cerebral cortex through the neuronal interplay between thalamocortical and cortico-thalamic cells. In this study microdialysis probes were placed unilaterally to perfuse CNQX (0.01-1.0mM) and high calcium-ACSF (2.44-39.04mM) into the ventral basal (VA/VL) and reticular (RTN) thalamic nuclei to alter seizure activity in awake non-anesthetized freely-moving rats. This form of drug application greatly reduces repeated handling, which can affect seizure rate, while enabling the infusion of dialysates into discrete brain regions. EEG was recorded before, during and after drug applications with epidural screw electrodes.

High-calcium concentrations did not change overall HVS duration but seizures were limited to the time of calcium perfusion and greatly reduced during normal ACSF perfusion. Calcium infusion outside of the VA/VL, RTN did not exhibit this effect.

CNQX perfusions: 0.01mM created a 2 Hz (delta), 3mV amplitude spiking pattern ipsilaterally to the probe while not affecting the contralateral HVS pattern. 0.1mM induced a 2 Hz, 2mV ipsilateral spiking pattern, while suppressing the contralateral HVS or created ipsilateral 1 mV spiking without affecting the contralateral HVS or decreased ipsilateral HVS. 1.0mM suppressed HVS bilaterally but not completely contralateral to infusion. In most cases HVS durations and amplitudes recovered after 24 hours of ACSF infusion.

These experiments further underline the importance of calcium and the AMPA glutamergic system in the thalamic oscillations underlying petit mal epilepsy.

MEMBRANE PROPERTIES OF CA₃ HIPPOCAMPAL REGION IN THE GENETICALLY EPILEPSY PRONE RATS. Suneeta Verma-Ahuja, M. Steven Evans, and Terrence L. Pencek*, Department of Surgery, Division of Neurosurgery, and Department of Neurology, Southern Illinois University, School of Medicine, Springfield, Illinois, 62794-9230.

Genetically epilepsy-prone rats (GEPs) exhibit a generalized increase in seizure susceptibility. Several factors indicating an increased excitability in CA₁ region of the GEP-9s have previously been reported. These included an increased input resistance, reduction in spike frequency adaptation, less current required to elicit an orthodromic EPSP and marked facilitation with repetitive stimuli in GEPs. We have now recorded membrane properties from 15 neurons in the CA₃ region of Sprague Dawley (SD) rats and five neurons in the GEPs CA₃ region. The resting membrane potential and action potential amplitude were not different between the two. A significant difference was seen in the spike frequency adaptation in the GEP neurons. In SD neurons a suprathreshold stimulus of 800 ms elicits a burst of action potentials followed by a prolonged hyperpolarization lasting 600 to 750 ms. No action potentials were observed following the burst in these neurons. In GEP neurons there was a significant increase in the number of spikes in the burst. This increased firing in the burst was not followed by a hyperpolarization, and action potentials were elicited throughout the 800 ms depolarizing stimulus. This suggests an abnormality in the calcium or calcium dependent potassium conductance.

CORTICAL MICROGYRIA ARE EPILEPTOGENIC IN VITRO. K.M. Jacobs*, M.J. Gutnick, and D.A. Prince. Dept. Neurology & Neurological Sciences, Stanford Univ. Medical Center, Stanford, CA 94305.

Cortical malformations, thought to be the result of abnormal neuronal migration, are commonly found in the brains of epileptic patients. Clinical data suggest that seizures in one form of malformation, microgyria, are initiated from the sites of structural abnormality, although mechanisms underlying epileptogenesis in the maldeveloped cortex are unknown. We used a method for preparing experimental microgyria in rats described by Dvorak and Feit (1977), in which a freezing probe is applied to the skull of pups at P0 or P1, for 5 sec. The area of the microgyrus could be seen *in vitro* in coronal 400 µ slices obtained from P12-P120 rats. Intracortical electrical stimulation was used to assess intracellular and field potential responses within the microgyria and adjacent neocortex. Superficial lamina responses to deep lamina stimulation both online and horizontally-distant were recorded. At sites 4 mm or greater from the microgyrus, field potential responses were similar to those seen in control neocortex, consisting of a short latency negativity lasting 8-12 msec in control and up to 20 msec in experimental hemispheres. When stimuli were applied closer to the microgyrus, evoked activities consisted of similar early events, followed by polyphasic field potentials with a latency of 20-100 msec and duration of 100-500 msec. The short latency events were graded with stimulus intensity, but the late polyphasic activity appeared as an all-or-none response that could be abolished with higher intensity stimulation or stimulus frequencies above 0.2 Hz. Preliminary intracellular recordings showed that the polyphasic field potentials were associated with long-duration, large amplitude, complex synaptic responses. Some superficial neurons were unusual in that they generated high frequency bursts of action potentials during intracellular depolarization, atypical for neurons in layers II-III. Results suggest that hyperexcitability (epileptogenesis) occurs in this model of focal microgyria, perhaps due to circuit reorganization in the region of the malformation. Additional experiments will determine whether excitatory, inhibitory, or modulatory synaptic activities are affected in the area of the malformation. Supported by NIH grants NS06477, NS12151 and NS07280.

INTERNEURONS ARE PREFERENTIALLY INJURED AFTER SPONTANEOUS SEIZURES IN THE PILOCARPINE MODEL OF CHRONIC SEIZURES. L. Covolan and L.E.A.M. Mello*. Depto. de Fisiologia, Escola Paulista de Medicina, 04023-900 São Paulo, Brazil.

It is still a question of much debate whether single epileptic seizures can cause cell loss. Despite the clinical impression that epilepsy in general is a progressive disorder, experimental evidence is not conclusive on this point. Recently, it has been shown electrically-induced afterdischarges of less than 2 minutes may induce structural impairments in neurons (Soc. Neurosci. Abst. 1992, 18:553). Here we evaluated whether spontaneous seizures would lead to similar impairments. Chronic spontaneous recurrent seizures were induced with pilocarpine (320 mg/kg, i.p.). Animals were sacrificed from 1 to 6 h either after single or multiple seizures. A Golgi-like sensitive silver-impregnation procedure (J. Comp. Neurol. 1990, 298:654-673) was used to reveal injured neurons. Silver-impregnated dark neurons were never found in control animals or in epileptic animals that had no behavioral seizures in the 8 h prior to sacrifice. After spontaneous seizures (injured) dark neurons were mostly interneurons and were present in hippocampus (CA1 stratum radiatum), amygdala, piriform cortex and other limbic structures. Animals with multiple seizures had a higher number of dark cells than animals with single seizures. Our findings suggest that even single generalized spontaneous tonic-clonic seizures can induce long-lasting morphological changes. Our results favor the idea that epilepsy is a progressive disorder where one seizure begets the next. Supported by: FAPESP, CNPq and FINEP; L.C. is a CNPq fellow.

AXONAL ARBORIZATIONS OF BIOCYTIN FILLED CA1 PYRAMIDAL CELLS FROM HYPEREXCITABLE SLICES OF KAINATE TREATED RATS. Y. Perez, F. Morin, I. Jutras, C. Beaulieu and J.-C. Lacaille*. Center for Research in Neurological Sciences and Departments of Physiology and Pathology, University of Montréal, Montréal, Qc, Canada H3C 3J7.

Following hippocampal kainic acid (KA) lesions, CA1 pyramidal cells become hyperexcitable. To examine if sprouting of CA1 pyramidal cells contribute to this epileptiform activity, the axonal arborizations of intracellularly-marked pyramidal cells have been compared in control and hyperexcitable slices of KA treated rats. Hippocampal slices were obtained from Sprague-Dawley rats 2-4 weeks after bilateral intraventricular injections of KA (0.65 µg/µl). Hyperexcitable slices were identified using extracellular field potentials (bursts ≥ 2 population spikes). Cells were impaled in control (unoperated animals) or hyperexcitable slices with microelectrodes containing biocytin (1%) in 1M K-acetate. Synaptic responses were recorded and biocytin was injected intracellularly. Slices were subsequently fixed, cut on a vibratome and processed for visualization of biocytin with the standard ABC method. Axons from pyramidal cells that could be followed from the soma to the alveus were drawn with a camera lucida. In cells (n=10) from control slices, the axon branched on average once (mean branch points 0.9 ± 1.0) before entering the alveus and then coursing toward the fimbria or subiculum. In cells (n=7) from hyperexcitable slices, the local axonal arborizations in stratum oriens and the alveus were more elaborate, with an increased number of branches (mean branch points 2.7 ± 1.8) observed in the oriens layer. These preliminary results suggest that following KA lesions CA1 pyramidal cells develop more extensive local axon collaterals and this sprouting may contribute to the epileptiform activity.

PARTIAL LOSS OF HIPPOCAMPAL CA1 NEURONS AND TRANSIENT IMPAIRMENT OF WATER MAZE LEARNING INDUCED BY SYSTEMIC ADMINISTRATION OF KAINIC ACID. K. Obata* and H. Asada. Lab. of Neurochemistry, Natl. Inst. for Physiol. Sci., Okazaki 444, Japan.

Long-term changes in animal behavior and hippocampal tissue were investigated on the male Wistar rats in which limbic seizures were induced at the age of five weeks by subcutaneous injection of kainic acid in order to clarify any plastic changes following neuronal loss. When status epilepticus was limited to 1-3 hours by diazepam, neuronal loss was observed in the CA1 pyramidal layer of the dorsal hippocampus. Morris water maze learning (with a hidden platform) and passive avoidance learning were impaired within two weeks after the seizure. However, the rats learned these tasks well when tested 1-2 months later. A small number of neurons survived in the lesioned pyramidal layer and extended their dendritic branches obliquely and tortuously. Synaptophysin/SVP38 immunostaining and cholinesterase histochemistry were not changed in the lesioned CA1, suggesting that some synapses and afferent fibers were well maintained. Astrocytes proliferated there and some of them immunoreacted on anti-GABA and anti-glutamate decarboxylase (GAD) antibodies. On the other hand, when the seizures continued over 5 hours without diazepam, the lesion was more extensive and permanent. Neuronal loss was observed in CA1-4 and the subiculum and the hippocampus was atrophied. The rats did not recover from the impaired water maze learning.

595.2

SELECTIVE HILAR NEURON LOSS AND PATHOPHYSIOLOGY IN THE HIPPOCAMPAL DENTATE GYRUS BY SUICIDE TRANSPORT OF VOLKENSIN. R.S. Sloviter* and J.H. Goodman. Helen Hayes Hosp., W. Haverstraw, NY 10993 and Depts. of Pharmacology and Neurology, Columbia Univ. NY, NY 10032

It has been hypothesized that inherently vulnerable dentate mossy cells excite inhibitory neurons and thereby maintain normal dentate network inhibition. Accordingly, the loss of mossy cells has been postulated to underlie the permanent granule cell disinhibition and hyperexcitability caused by experimental status epilepticus. In order to address this hypothesis, we utilized the retrogradely transported toxic lectin volkensin to destroy the commissurally-projecting mossy cells selectively by a mechanism not involving seizures. Volkensin (5ng per site) was injected into two sites in the dorsal dentate gyrus. Two months later, granule cell inhibition and excitability were evaluated on the uninjected side. Two types of responses were seen. One group (n=17) exhibited large amplitude population spikes in response to low frequency (0.1Hz) perforant path stimulation, and strong recurrent inhibition at higher stimulus frequencies (1-3Hz). Histologically, these rats exhibited destruction of the injected hippocampus, but relatively normal dentate structure on the uninjected side. The other group (n=15) exhibited similar large amplitude spikes on the uninjected side in response to low frequency stimulation, but multiple granule cell population spikes with little or no recurrent inhibition at higher frequencies. These rats consistently exhibited extensive hilar neuron loss. Immunocytochemical staining revealed that despite the loss of most hilar neurons, hilar somatostatin, neuropeptide Y, parvalbumin, calretinin, and GABA-immunoreactive populations had survived. Degeneration staining 1-2wk after volkensin revealed impregnated hilar cells and terminals in the inner molecular layer characteristic of mossy cell degeneration. These results indicate that the pathophysiology produced by prolonged perforant path stimulation is replicated by the selective loss of hilar mossy cells. The gift of volkensin by Prof. F. Stirpe, Univ. of Bologna, is gratefully acknowledged. Supported by NINDS grant NS18201.

LAMINAR ANALYSIS OF NEURONAL REORGANIZATION IN THE HIPPOCAMPUS OF PILOCARPINE CHRONIC EPILEPTIC RATS. R.V. Duran*, D.M. Finch, A.K. Tan and L.E.A.M. Mello. Depto. de Fisiologia, Escola Paulista de Medicina, 04023-900 São Paulo, Brazil, and Brain Research Institute, UCLA, Los Angeles, CA 90024, USA.

Descriptions of changes in the neuronal morphology in the brains of epileptic patients and of experimental models of epilepsy have been received with some skepticism, since some authors suggested that those findings could be based on artifacts. In this work, we took special cares such as *in vivo* perfusion and use of a chronic epileptic model in which the convulsive agent was administered systemically in order to avoid artifacts. Rats (Sprague-Dawley, males, adults) with chronic spontaneous recurrent crises were obtained by inducing status epilepticus (SE) with pilocarpine (320 mg/kg, i.p.). Between 60 and 100 days after SE, stereotaxic injection of HRP in neurons of the dorsal hippocampus was carried out under chloral hydrate anesthesia and 4 to 8 hours later, the animals were perfused and their brains histologically processed. We confirmed that loss of dendritic spines, appearance of varicose-like swellings and bizarre distortions of hippocampal pyramidal dendrites is a consistent finding in epileptic tissue. The cellular changes of the epileptic rats were never found in the controls ones. Besides the generalized gross degeneration, there were changes in the size and in the form of dendritic spines. Moreover, the spines were reduced or even absent in the dendrites of CA1 pyramids just in stratum radiatum. Our results confirm the described morphological changes as true markers of the epileptic condition and indicate that such alterations have a specific laminar distribution pattern which is relevant in understanding the epileptic brain circuitry. Supported by NIH Grants NS 23074 and NS 16721, The NIH Fogarty Center; and FAPESP, CNPq and FINEP (Brazil). R.V. Duran is a FAPESP fellow (93/0666-3).

INJECTION OF AMINOXYACETIC ACID INTO THE RAT ENTORHINAL CORTEX CAUSES POSTSYNAPTIC NEURONAL DAMAGE IN THE HIPPOCAMPUS: A POSSIBLE MODEL OF TEMPORAL LOBE EPILEPSY. F. Du*, T. Eid and R. Schwarcz. Maryland Psych. Research Center, Baltimore, MD 21228.

Injection of 75 µg aminooxyacetic acid (AOAA) into the rat entorhinal cortex (EC) produces acute behavioral seizures and selective neuronal loss in layer III of the region (Neurosci. Lett., 147:185, 1992). Since the EC provides the major excitatory input to the hippocampus, we examined the hippocampi of rats receiving an entorhinal AOAA injection using Nissl staining and heat shock protein (HSP) immunohistochemistry. HSP expression has been considered a specific marker of excitation-induced neuronal stress. Rats were sacrificed after 15 or 24 hours, or 5 days. After 5 days, neurodegeneration and gliosis were readily observed in Nissl-stained sections in the subiculum and CA1 field of the ventral hippocampus ipsilateral to the injection. Neurons expressing HSP immunoreactivity (-i) were detected ipsilaterally as early as 15 hours following the injection, mainly in the subiculum, CA1 and in the hilus. This distribution pattern of HSP-i neurons remained similar at 24 hours and 5 days after AOAA treatment. These results indicate that injection of AOAA into the EC can produce over-excitation and degeneration of postsynaptic neurons in the rat hippocampus. AOAA injection into the EC in rats may therefore provide a novel model for the study of temporal lobe epilepsy. Supported in part by USPHS grant NS 16102.

THE DENSITY OF DENTATE GRANULE CELL SPROUTING IN HEAT-INDUCED SEIZURES IN THE RAT IS RELATED TO THE NUMBERS OF SEIZURES EXPERIENCED. W. Jiang, D. D. Spencer, P. Kontur*, and N. C. de Lanerolle. Section of Neurosurgery, Yale Univ. School of Medicine, New Haven, CT. 06510

The sprouting of mossy fiber collaterals into the inner molecular layer (IML) of the dentate gyrus has been observed in patients with temporal lobe epilepsy (TLE) (Brain Res. 1989, 495:387). Patients that show such reorganization are often found to have a history of febrile seizures. The relationship of the degree of sprouting to seizure history has remained speculative in humans because of the difficulty of obtaining accurate information on the subject. Rat pups experiencing heat-induced seizures also show sprouting. These seizures are tonic-clonic seizures (lasting 30 sec to 5 min) and not status epilepticus, thus resembling seizures in TLE patients. The relationship of the number of such seizures to the degree of sprouting was examined in this experimental model. Variable numbers of seizures (1, 6, 12, 24) were induced in different experimental groups of rat pups beginning at 22 days of age. Seizure induction was by exposure of a rat for 4 minutes to water at 45°C. Consequent seizures were induced every fourth day in the multiple seizure groups. The core body temperature of the rat rose from approximately 38°C to 44°C on exposure. Sprouting was observed by the Timm stain. No sprouting was found in the IML of the dentate in the one seizure group. In the six seizure group Timm stain positive particles were limited to the tips and angle of the dentate blades in the IML. Sprouting into the IML was seen in the 12 seizure group, sprouting being stronger at the tips and angle of the blade than in the six seizure group. In the 24 seizure group there was considerably increased sprouting which extended in the IML throughout the entirety of the dentate gyrus, with most intense stain at the tips and dentate blade angle. These results support the hypothesis that sprouting is the result of the seizures, and more seizures produce more sprouting. Supported by NS 06208.

PREPRO-TRH mRNA EXPRESSION IN LIMBIC BRAIN REGIONS FOLLOWING KAINIC ACID-INDUCED SEIZURES IN THE RAT. S.A. Richardson*, A. Dutt, and A. Winokur. Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

Induction of seizure activity utilizing a variety of techniques including electroconvulsive shock (ECS) and amygdaloid kindling has consistently been reported to produce elevations in thyrotropin releasing hormone (TRH) concentration and increases in prepro-TRH mRNA expression in discrete brain regions. Studies in our laboratory have shown that induction of seizures by kainic acid administration, which activates limbic pathways preferentially, has a more pronounced and prolonged effect on limbic TRH concentrations. To further elucidate the neurochemical basis of the effects of seizure activity on TRH neuronal systems, *in situ* hybridization methods have been employed to study systemic kainic acid administration on the expression of prepro-TRH mRNA in limbic brain regions. Male Sprague Dawley rats (180-200g) received a single subcutaneous injection of either kainic acid, 12mg/kg, in 0.9% NaCl, or vehicle. Separate groups of rats (n=4) were sacrificed by decapitation at 6, 24, and 48 hours, and 4, 7, and 14 days post-seizure. Rat brains were sectioned at 10µm and processed for *in situ* hybridization using a ³⁵S-labeled riboprobe to detect TRH prohormone mRNA. Significant increases in proTRH mRNA at 6 and 24 hours were observed in the hippocampus, amygdala, piriform cortex, entorhinal cortex, and the reticular thalamic nucleus following a single stage 5 seizure. In the hippocampus, prepro-TRH mRNA grains were most dense in the dentate gyrus region. After reaching a peak within 24 hours, message levels in these areas gradually declined and reached baseline by 14 days. These findings provide further support for a role of TRH neuronal systems in seizure modulation.

DEVELOPMENTAL CHANGE IN PENTYLENETETRAZOL-INDUCED *c-fos* mRNA EXPRESSION IN THE RAT BRAIN

A. Oshima¹2), A. Kashiwa¹, M. Murata¹), T. Nishikawa¹), Y. Machiyama²). 1) Dept. of Mental Disorder Research, Natl. Inst. Neurosci., NCNP, Tokyo 187, Japan. 2) Dept. of Neuropsychiatry, Gunma University, Maebashi 371, Japan.

Employing Northern blot analysis, we examined in the rat the postnatal development of *c-fos* mRNA expression induced by systemic administration of pentyletetrazolol (PTZ). Subcutaneous injection of PTZ (50mg/kg) induced after one hour a high level of *c-fos* mRNA in the neocortex at 23 and 49 days, but not at 8 and 14 days, postpartum as compared with the saline-injected control animals. The induction increased gradually from day 8 to 23 and dramatically from day 23 to 49. In contrast, *c-fos* mRNA was nearly undetectable in the hippocampus of both groups throughout day 8 to 49. Induction of the proto-oncogene *c-fos* is considered to be a marker of increased neuronal activity. The present results thus indicate that neocortical neuronal circuits responsive to the drug may alter remarkably between day 23 and 49.

CORTICAL CONOTOXIN BINDING DIFFERENTIATES EPILEPTIC AND NON-EPILEPTIC MICE. S.K. Jensen, A.F. Burroughs, F. Matsuo*, and M.J. Litzinger. Laboratory of Applied Neurobiology, Department of Pediatrics and *Neurology, University of Utah, Salt Lake City, UT 84132

Esplin et al. (Epilepsia, 1994) have suggested that N-type presynaptic voltage sensitive calcium channels (VSCC) are different in epileptic (DBA/2J) and non-epileptic (C57/Bl) mice. Binding with the presynaptic calcium channel probe α -conotoxin, believed to mark N-type voltage sensitive calcium channels (VSCC), was used to illustrate differences in synapse formation between these two mouse types. Whole brain α -conotoxin binding showed the pre-eye opening postnatal day (PND 8) C57/Bl mouse brain to have fewer binding sites than its epileptic counterpart, the DBA/2J mouse. Post-eye opening (PND 16) C57 mouse have significantly more binding sites than the DBA mouse.

The purpose of this study was to show that the majority of binding in the whole brain studies came from cortical VSCC development. Regional dissections were performed as previously described (Litzinger et al., J. Child Neurology, 1994). Preliminary data indicates that the cortex is responsible for the developmental binding differences seen in the whole brain preparations from these two different mouse types. Cerebellar and diencephalon-brainstem binding remains relatively unchanged. This data suggests that pre-synaptic VSCC's in the cortex are potentially linked to the seizure susceptibility described by Esplin. For discussion of functional differences see Burroughs and Litzinger, this section.

LONG TERM UP-REGULATION OF OXYTOCIN MESSENGER RNA EXPRESSION IN RAT PVN FOLLOWING KAINIC ACID INDUCED SEIZURES. Q. Sun, S. Pretel*, C.D. Applegate, D. Piekut. Departments of Neurobiology and Anatomy, and Neurology, University of Rochester, Rochester, NY 14642

The paraventricular nucleus of hypothalamus (PVN) is the neuroendocrine center for stress-related responses. It is known that the CRF neurons of the PVN have an important role in regulating stress responses of the CNS. Vasopressin and oxytocin (OX) neurons of PVN are traditionally associated with the regulation of CNS responses to disturbances of osmolality. However, these neurons might also be involved in CNS responses to other stressful stimuli. Our laboratory has previously shown that the Fos protein was expressed in OX neurons of PVN in both electrical and kainic acid induced seizures, indicating that these neurons were activated by the stress stimulation induced by seizures. To further characterize the involvement of OX in response to seizures, OX mRNA in rat PVN was examined with quantitative *in situ* hybridization in kainic acid induced seizure. Fully generalized seizures were induced by injection of kainic acid (17 mg/kg in 1 ml PBS, i.p.); rats were kept for different survival times such as 1.5 hour, 1 week, 2 weeks, 3 weeks and 4 weeks. *In situ* hybridization was performed on frozen sections with a [³⁵S]-labeled oligonucleotide probe, complementary to bases 247-294 of the OX gene (Ivell and Richter 1984; generously provided by DR. S. Young, NIH). Levels of mRNA were measured by densitometry analysis of film autoradiography using the NIH IMAGE program after the *in situ* hybridization. The results show that the density of OX mRNA labeling in PVN of seizure animals was more than 20% higher than that of control animals at all time points of survival. The increase of OX mRNA occurred as early as 1.5 hour following the first stage 5 seizure and remained elevated as long as 4 weeks. These results demonstrate that OX neurons of PVN respond to seizure by up-regulating their mRNA expression. They also demonstrate that this response represents a long term effect of seizures on magnocellular PVN neurons. Supported by NIH grant NS 18626

NEUROANATOMICAL CONCORDANCE OF ABNORMAL TYROSINE HYDROXYLASE AND c-FOS mRNA EXPRESSION DURING FOCAL MYOCLONIC EPISODES IN THE MOUSE MUTANT TOTTERING (*tg/tg*). E.J. Hess* and M.E. Williams. Department of Neuroscience & Anatomy, The Pennsylvania State University College of Medicine, Hershey Medical Center, Hershey, PA 17033.

Tottering (*tg*) is an inherited autosomal recessive mutation in the mouse that results in a triad of neuropathologies including spike and wave discharges, ataxia and focal myoclonus. The spike and wave discharges and ataxia have been extensively characterized, however the myoclonus expressed by these mice has been difficult to study because these seizures have no obvious electrical correlates. We have previously identified the neuroanatomical substrate(s) of myoclonus in tottering mice using the expression of the immediate early gene (*IEG*) *c-fos* to chart the progression of abnormal nervous system activity. *In situ* hybridization revealed myoclonus-induced *c-fos* mRNA expression only in the cerebellum, pontine nuclei and faintly in motor cortex with the highest levels of expression in the cerebellum. We have refined these results and have found that *c-fos* expression in the cerebellum occurs in the more medial aspects of the cerebellum and is not induced in Crus I or Crus II. Thus, these seizures appear to delimit functionally distinct regions of the cerebellum. We have also previously observed ectopic expression of the catecholamine synthetic enzyme tyrosine hydroxylase (TH) in the Purkinje cells of these mutants (Neuron, 6:123). Interestingly, TH expression is also restricted to the medial regions of the cerebellum. In fact, *in situ* hybridization on back to back sections of the cerebellum revealed that *c-fos* induction during a myoclonic episode occurs in granule cells adjacent to Purkinje cells abnormally expressing TH. These results suggest that not only is the cerebellum important in the generation and maintenance of myoclonus, but it appears that very specific cerebellar regions are affected by the mutation. Additionally, these results suggest that the abnormal Purkinje cells may directly contribute to the phenotypic expression of the tottering mutation. Supported by a Klingenstein Fellowship.

FOS IMMUNOLABELING FOLLOWING KINDLED PARTIAL SEIZURES ELICITED FROM DIFFERENT BRAIN SITES. J. Nierenberg*, C.D. Applegate, J.L. Burchfiel & D.T. Piekut. Departments of Neurobiology & Anatomy and Neurology, University of Rochester School of Medicine, Rochester, NY 14642.

Neural circuits activated by kindled partial seizures were studied using FOS immunolabeling techniques to better understand the temporal and spatial organization of kindling epileptogenesis. Male rats received kindling stimulation through electrodes placed in either the amygdala (AM), olfactory bulb (OB) or septal nucleus (SN) until they exhibited the earliest signs of motor seizure (e.g., facial clonus; kindling stage 3). Tissue from these animals showed increased FOS-like immunoreactivity (FLI) in specific brain regions when compared with tissue sections from similarly treated rats kindled to stage 2 (or earlier). Animals kindled to stage 3 consistently expressed FLI in the basolateral/lateral amygdala and in the piriform cortex (PC). Data from our laboratory suggest that the PC is part of the core neuroanatomical circuitry underlying AM, OB and SN kindling. Onset of clonic chewing behavior also correlated with FOS labeling in a region of agranular insular cortex which is involved with the cortical control of rhythmic jaw movements in the rat. A specific laminar labeling pattern in the ipsilateral PC was consistently observed in animals showing stage 3 (or higher) seizure, irrespective of the stimulation site. These and other data indicate that FOS immunostaining is a useful tool for detecting kindling-induced reorganization in discrete neural circuits. Implications for understanding the functional neuroanatomy underlying the transition to motor seizure behavior in kindling will also be discussed.

GABAA RECEPTOR FUNCTION IN THE THALAMUS AND CORTEX IS ALTERED IN RATS WITH EXPERIMENTAL ABSENCE-LIKE SEIZURES. O. Carer Sneed III* and P. K. Banerjee. Div. Neurol. Childers Hospital Los Angeles, Dept. Neurol. Univ. Southern California, School of Medicine, Los Angeles, CA 90027

Both clinical and experimental absence seizures are exacerbated by GABAergic agonists. We investigated GABAA receptor activity during the course of absence-like seizures induced by γ -hydroxybutyric acid (GHB) in rats using receptor autoradiography. Rat brain sections obtained at different time intervals during GHB-induced seizure activity were subjected to [3 H]flunitrazepam and [3 S]TBPS binding in the presence or absence of the neuroactive steroid, alfaxalone (ALP, 3mM) or GABA (3mM). At the onset of GHB-induced seizures a transient decrease in [3 S]TBPS binding in the thalamus (approx. 25-35%) and cortex (approx. 10-15%) associated with a brief loss of ALP-induced increase in [3 S]TBPS binding was observed which returned to basal levels 10 min after the onset of seizures. [3 H]flunitrazepam binding rose in midline thalamic structures (by 30%) and cortex (by 15%) throughout GHB-induced absence seizures. There was a selective loss of ALP-induced enhancement of [3 H]flunitrazepam binding in cortex, but not thalamus during the course of seizure activity. These results suggest that GABAA receptor activity is modified in a subtle fashion during experimental absence seizures induced by GHB. Whether this is the cause or effect of the experimental absence seizures is not clear.

ACTIVATION OF CRF-EXPRESSING NEURONS IN HYPOTHALAMUS FOLLOWING EPILEPTIC SEIZURES. D.T. Piekut*, B. Phipps, S. Pretel and C. D. Applegate. Depts. of Neurobiology and Anatomy, and Neurology, University of Rochester, Rochester, NY 14642.

Activation of the pituitary-adrenal axis is clearly a response to several stress paradigms and the CRF-containing neuron of the paraventricular nucleus (PVN) of hypothalamus is the dominant component in the regulation of pituitary ACTH. Accompanying the behavioral manifestations of epileptic seizures are changes in neuroendocrine and vital autonomic functions; yet the effects of epileptic seizures on hypothalamic neurons are essentially unknown. The immunocytochemical detection of the FOS protein was used to identify neurons activated following generalized epileptic seizures elicited in the kainate injected and kindled Sprague-Dawley rats. A substantial number of activated (FOS expressing) neurons was observed in specific parvocellular components of the PVN in both seizure models; little FOS immunolabeling was seen in the control animals. Dual immunolabeling procedures and combined immunocytochemical and in situ hybridization methodology have demonstrated that a substantial percentage of activated parvocellular PVN neurons express the CRF protein and the CRF mRNA. Few CRF-containing neurons localized in other brain sites (i.e. amygdala, bed nucleus of stria terminalis) express FOS following epileptic seizures. The results indicate that a specific population of hypothalamic CRF-containing neurons are activated following seizure elicitation. This study provides new insights into the effects of epileptic seizures on the central control of the pituitary-adrenal axis in an adaptive response to this paradigm of stress. PARVALBUMIN- AND CALBINDIN-POSITIVE NEURONS ARE SURROUNDED BY SPROUTED MOSSY FIBERS IN THE GRANULE CELL LAYER. T. Kotti, R. Miettinen and P. Riekkinen Sr*. Dept. of Neurology and A.I. Virtanen Institute, Univ. of Kuopio, P.O.Box 1627, FIN-70211 Kuopio, FINLAND.

Sprouting of the mossy fibers into the supragranular region of the dentate gyrus is a wellknown regenerative process after epileptic insult. No consensus has been achieved so far about whether new circuitries formed as a result of sprouting are excitatory or inhibitory in nature. This study investigated this issue by characterizing the target cells for sprouted mossy fibers using a combination of immunofluorescent and Timm stainings. Two months after the induction of mossy fiber sprouting by kainic acid injection, rats were perfused transcardially with Na-sulfide solution followed by buffered paraformaldehyde. Hippocampal sections were first immunostained for parvalbumin (PV) or calbindin D-28k (CaBP) using FITC labelled antibodies. Then they were stained using Timm sulfide-silver histochemical method. Analysis at the conventional epifluorescent and at the confocal laser scanning microscope revealed that the Timm-positive mossy fibers were in close contacts with the PV- and CaBP-immunopositive neurons within the granule cell layer, through which the sprouted mossy fibers were spreading in the kainic acid injected rats. These results suggest that the PV- and CaBP-containing cells are the targets for the sprouted mossy fibers. Therefore if PV is present in the inhibitory nonpyramidal cells and CaBP in the granule cells sprouting results in formation of both inhibitory and excitatory circuits. However, it should be noted that we cannot rule out the possibility that the CaBP-positive neurons which were found to be surrounded by mossy fibers in the granule cell layer are not CaBP-containing nonpyramidal cells, and thus inhibitory in nature.

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS—KINDLING

596.1

GENETICALLY FAST VERSUS SLOW KINDLING RAT STRAINS: COMPARISON OF DIFFERENT KINDLING SITES. M.E. Kelly and D.C. McIntyre*. Psychology Dept., Carleton University, Ottawa, Ontario, Canada, K1S 5B6.

Previously we introduced (*Epilepsia* 1989, 30, 652) two strains of rats that were selectively bred for their amygdala excitability and disposition to kindling (called FAST and SLOW strains). The SLOW rats exhibited local afterdischarge (AD) durations that were 3 times shorter than the FAST rats throughout all stages of amygdala kindling, and they required 6 times more amygdala stimulations than the FAST rats to develop their first stage-5 convulsion. When kindled from the dorsal hippocampus, however, the SLOW strain exhibited local ADs that were similar to the FAST strain, but they required 2 times more hippocampal stimulations than the FAST strain to reach their first stage-5 convulsion. By comparison, kindling from the frontal cortex resulted in the immediate appearance of forelimb clonic convulsions in both strains, although the local ADs associated with these convulsions were shorter in the SLOW compared to the FAST strain.

These data indicate that the original selection of the two strains for high and low amygdala excitability, associated with fast and slow kindling rates, was relatively specific to the amygdala, since kindling sites in the dorsal hippocampus and frontal cortex showed strain effects that were very different from the amygdala. Further study of the kindling characteristics from each of these 3 different anatomical sites in these two strains may help clarify the functional circuitry involved in the convulsive generalization of limbic kindled seizures.

596.2

BRAINSTEM SEIZURES IN AMYGDALA-KINDLED GENETICALLY EPILEPSY-PRONE RATS (GEPR's). L.L. Coffey, M.E.A. Reith, N.-H. Chen and P.C. Jobe*. Dept. of Basic Sciences, University of Illinois College of Medicine, Peoria, IL 61656.

It is known that repeated exposure to audio-stimulated brainstem seizures in GEPR's results in EEG and convulsive patterns characteristic of forebrain seizures (FBSs). Conversely, kindling of FBSs by repeated electrical limbic stimulation increases the susceptibility to electroshock-invoked brainstem seizures, but does not induce behavioral expression of brainstem seizure activity in non-epileptic rats (NER's) under commonly used conditions. Only sporadic occurrence of brainstem seizures reportedly occurs with limbic kindling in audio-susceptible Wistar rats. In the present study, FBSs were kindled in GEPR's displaying class 9 audiogenic seizures (GEPR9's). A paradigm of daily electrical amygdala stimulation was employed. In comparison with NER's, the current required for afterdischarge was lower in GEPR9's, and kindling to severe (Stage 5) FBSs developed more rapidly. Kindling development was intermediate in seizure-naïve (SN) GEPR9's which were not subjected to audio-screening as were GEPR9's. Following the FBS, behavioral expression of brainstem seizure activity (on the average class 6-7 on the same scale used to classify GEPR's) occurred in the majority of GEPR9's and SN GEPR9's but in none of the NER's. The occurrence of these seizures within the kindling process had a random nature and was not related to kindling-dependent FBS progression. The results suggest that the spread of amygdala seizures activates brainstem seizure circuitry in epileptic animals but not in NER's. The lack of difference in brainstem seizure activity between GEPR9's and SN GEPR9's is consonant with the view that the determining factor is the genetic predisposition rather than the preexposure to audiogenic seizures delivered during the screening protocol.

596.3

ANTECEDENT TONE PRESENTATION SIGNIFICANTLY DELAYS RATE OF AMYGDALA KINDLING T.D. Hernandez*, L.A. Warner, P.J. Kahler and A.E. Kline. Department of Psychology, University of Colorado, Boulder, CO 80309

The degree to which external stimuli contribute to seizure occurrence is an important issue. Can external events elicit the aberrant neuronal activity that precipitates a seizure? Alternatively, can certain external events cue the organism to an impending seizure and result in a compensatory response that is in effect "anti-convulsant"? While several studies have addressed these issues (Yoshii & Yamaguchi, 1963; Pinel et al., 1973; Wyler & Heavner, 1979; Janowsky et al., 1980; Mostofsky & Myslobodsky, 1982; Myslobodsky et al., 1983; Freeman & Mikulka, 1986) the results have been mixed. Consequently, we conducted the present study in an attempt to clarify these issues. Twenty-seven male Long-Evans hooded rats were chronically implanted with an electrode in the right amygdala and randomly assigned to one of two groups. The *Tone* group was presented with a 2-second tone beginning immediately prior to and overlapping with the daily kindling stimulus, while the *No Tone* group was kindled without the tone. Presentation of the tone significantly delayed the rate of amygdala kindling. All animals in the *No Tone* group reached a Stage 5 kindled seizure by the 12th daily stimulation, while all animals in the *Tone* group responded with a Stage 5 seizure by the 22nd daily stimulation. These data indicate that the antecedent presentation of a mild auditory cue has a profound inhibitory effect on the rate of kindling.

HYPOTHYROIDISM DOES NOT AFFECT AMYGDALA KINDLING-INDUCED THYROTROPIN-RELEASING HORMONE (TRH) mRNA INCREASES IN LIMBIC STRUCTURES. S.Y. Kim* and J.B. Rosen. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

Our laboratory has demonstrated that TRH mRNA is dramatically increased following amygdala kindling in limbic structures including dentate gyrus, and pyriform, entorhinal and perirhinal cortices, but not in the paraventricular nucleus of the hypothalamus (PVN). The regulatory mechanisms of kindling-induced TRH mRNA elevation are not known. Since thyroid hormone regulates TRH mRNA in the PVN, we investigated whether kindling-induced TRH mRNA elevations in limbic regions are also regulated by thyroid hormone. Rats were treated with 0.05% propylthiouracil (PTU) (equivalent to ~30 mg/kg/day) or 4 µg/ml triiodothyronine (T₃) (equivalent to ~500 µg/kg/day) in drinking water for 10 days before kindling and throughout the kindling procedure. Rats were sacrificed 4 hours after a fully kindled seizure. The efficacy of oral treatment of PTU and T₃ was confirmed by Northern blotting hybridization of pituitary thyroid-stimulating hormone (TSH) β mRNA. TSH β mRNA was significantly increased by PTU and decreased by T₃, but unaffected by kindling. In addition, *in situ* hybridization showed that PTU increased and T₃ decreased TRH mRNA in the PVN while kindling had no effect on TRH mRNA in the PVN. In contrast, kindling significantly increased TRH mRNA in dentate gyrus, pyriform, entorhinal and perirhinal cortices regardless of PTU or T₃ treatment. The findings demonstrate that unlike its effects on hypothalamic TRH mRNA, thyroid hormone manipulation does not alter baseline TRH mRNA expression in extrahypothalamic areas and does not affect TRH mRNA expression following amygdala kindling. These data suggest that hypothalamic TRH mRNA and seizure-induced TRH mRNA in limbic structures are regulated by different transcriptional mechanisms.

596.7

DOES CA1 KINDLING IMPAIR SPATIAL MEMORY IN THE MORRIS WATER MAZE? T.H. Gilbert*, L.L. Armitage, D.K. Hanneson, R.K. McNamara, & M.E. Corcoran. Dept. of Psychology, University of Victoria, POB 3050, Victoria, BC, Canada, V8W 3P5.

The hippocampus has long been known to play an important role in spatial learning, in that interference with hippocampal functioning can produce deficits in tasks that involve spatial learning. Leung (1989) reported that kindling of hippocampal field CA1 disrupts performance in the radial arm maze and that this disruption was caused primarily by hippocampal afterdischarges (ADs) in the absence of behavioral seizures. We asked whether CA1 kindling would disrupt spatial learning in the Morris water maze.

We used two procedures: (1) seizures were kindled with stimulation of CA1 prior to training in the maze (acquisition); and (2) seizures were kindled following maze training, and then retesting in the maze occurred after kindling (retention). In both cases, experimental rats received one daily CA1 stimulation until 3 consecutive generalized seizures were evoked, or until a predetermined number of ADs was reached without eliciting generalized seizures (partial kindling). The rats were tested (or retested) in the maze 24 hrs after the last seizure or last AD.

We found that CA1 kindling failed to disrupt maze performance during either acquisition or retention. The results were similar for both the kindled and partially kindled groups, which demonstrated acquisition and retention performance comparable to that in nonkindled controls. These findings are inconsistent with previous results suggesting that memory deficits occur during or after hippocampal kindling and may indicate that deficits are task-specific. (Supported by NSERC)

596.4

CHEMICAL KINDLING OF EEG EPILEPTIFORM BUT NOT BEHAVIORAL SEIZURE RESPONSE IN TWO RAT STRAINS. J. Rossi III*, G.D. Ritchie, M.S. Buring, C. Ademujohn, J. Smith, T. Morton and M. Langley. Naval Medical Research Institute Detachment (Toxicology) and Geo-Centers, Inc., Wright-Patterson AFB, OH 45433-7903.

Adult Fischer-344 and Sprague-Dawley rats were given tri-weekly i.p. administrations of the convulsant trimethylolpropane phosphate (TMPP) for eleven weeks. The doses selected had been previously shown to: (a) produce EEG epileptiform activity without behavioral consequence; (b) produce both EEG paroxysms and observable sub-clinical seizure activity; or (c) produce EEG paroxysms and clinical seizures, without lethality. Dose levels were adjusted to accommodate differences in TMPP sensitivity previously observed between the two rat strains. While repeated administrations of TMPP led to significant increases in EEG epileptiform activity over that observed with the initial dose, no kindling of behavioral seizure response was observed. This increase in frequency and duration of the EEG paroxysms persisted for up to three weeks following the final drug administration, even though TMPP has been shown to clear 99.9%+ from major body tissues within 24 hours. Rats that had never exhibited more than forequarter myoclonic seizures during the kindling procedure responded with full-blown audiogenic seizures (wild running with generalized tonic-clonic seizures) when exposed to a 110 dB auditory stimulus up to three months after the final dose of TMPP. This result appears to be related to the phenomenon of sensitization currently being considered in investigation of such ailments as Multiple Chemical Sensitivity (MCS), Sick Building Syndrome (SBS), Chronic Fatigue Syndrome (CFS) and Persian Gulf Syndrome (PGS).

596.6

EXTENDED KINDLING RESULTS IN SPATIAL LEARNING DEFICITS IN THE RAT. J.Th. Rick*, S. Cammisaull, C.J. Reid, M.P. Murphy, M. Michaels, J. Ferblinteanu, and N.W. Milgram. University of Toronto, Scarborough Campus, 1265 Military Trail, Division of Life Sciences, Scarborough, ON, Canada M1C 1A4.

Kindling is a model of epilepsy in which repeated electrical stimulation of various forebrain structures leads to the progressive development of motor seizures. Impaired cognitive functioning, sometimes seen in epileptic patients, has not been observed in kindled animals except when tested shortly after a seizure. Previous kindling studies have reported no long-term deficits in spatial learning, but stimulation was terminated after fewer than 10 class five seizures (Racine Scale). However, more seizures may be required before cognitive deficits arise. In the present study, a total of 12 male Long-Evans hooded rats were stimulated 1-3 times daily through electrodes implanted either in the amygdala (N=5) or perforant path (N=7) until they became spontaneously epileptic or received 300 stimulations. Twelve additional animals with matched electrode placements served as controls. Kindled rats experienced up to 290 class four or greater seizures and 5 of these subjects experienced spontaneous motor seizures. Ten days after the termination of kindling, the rats were given 10 trials per day for 3 days in the Morris water maze. Kindled rats required more trials to reach the learning criterion (3 consecutive trials with escape latencies under 20 s) than controls (p<0.0003). The number of major seizures (class 4 and up) was a significant predictor of poor performance (p<0.003). These results suggest that extended kindling can lead to a persistent spatial memory deficit in the rat.

596.8

AMYGDALOID KINDLING BY PENICILLIN IN THE RAT. GLOBAL AND RESTRICTED CORTICAL AREA TOPOGRAPHIC MAPPING OF INTERICTAL SPIKING: EFFECTS OF NALOXONE AND ENKEPHALINS. A. Fernández Guardiola*, R. Fernández-Mas, and A. Martínez. Inst. Mex. Psiquiatría, México 14370, D.F. and Fac. Psicol. UNAM.

A single topical dose of Penicillin (Pn) induces a dose dependent "massed" amygdaloid kindling. Interictal spikes (1-3 cps) appear in 1 or 2 minutes after Pn administration and last for several hours. 20 Wistar male rats urethane anesthetized where used. A cannula-electrode was stereotactically implanted in the left temporal lobe amygdala, and a bipolar electrode was placed in the right amygdala. For cortical recording and mapping, a 16 epidural isometric electrode (stainless steel) array was implanted covering the whole dorsal cortex (frontal, rolandic, temporo parietal and visual). Mapping of restricted cortical areas was performed with a moveable 4x4 electrode matrix covering 16 mm².

After a 10 min control recording Pn doses ranging from 50 to 200 IU / 1 µl were microinjected in the baso-lateral amygdaloid nucleus. Naloxone was IP delivered (0.5-1.0 mg/Kg). D-Ala-Met and D-Ala-Leu Enkephalins were topically delivered to the same amygdala (10 µg/µl). Amygdaloid Pn biphasic spikes with a variable latency and progressive enhanced frequency and amplitude were observed during a period of 35 min. After a plateau (1-3 Hz), a frequency decrease appeared. Spiking frequency and amplitude diminished in about 45 min. (200 IU). Some animals displayed brief (5 to 10 sec) focal or generalized seizures during this period. Naloxone increased the interictal spike frequency and amplitude, and occasionally induced seizures. Both enkephalins inhibited Pn spiking when delivered after Pn. When delivered before Pn, the enkephalins depressed the interictal Pn spiking or avoided the Pn effect.

We conclude that endogenous opioids inhibit the Penicillin GABA receptor action and that this inhibition is blocked by Naloxone.

596.9

THE TIMING OF PERMANENT ALTERATIONS IN SEIZURE SUSCEPTIBILITY DURING KINDLING. J.L. Burchfiel* and C.D. Applegate. Comprehensive Epilepsy Program, Dept. of Neurology, Univ. of Rochester, Rochester, NY 14642.

When does kindled seizure development become permanent? It is well known that kindling is permanent after stage 5, but are permanent changes induced at earlier stages. Specifically, does each successive afterdischarge induce permanent alterations through the kindling process or does the process become permanent only after some threshold is reached. We designed an experiment to choose between these two possibilities.

Adult Sprague Dawley rats were kindled from the septal nucleus. Different groups of animals received 6, 9, 12, 15, 18 or 21 stimulations, respectively. Then the animals were not stimulated for 4 weeks. After the hiatus, animals were again stimulated until they reached stage 5 seizures.

If each afterdischarge induces a permanent increase of seizure susceptibility, then the hiatus should not affect subsequent kindled seizure development. One would predict that: (1) the total number of trials to reach stage 5 should be the same for each group, and (2) the number of post-hiatus trials should be inversely related to the number of pre-hiatus trials for each group.

The outcome was incompatible with these predictions, suggesting a lack of permanent alteration of seizure susceptibility during early kindling trials. We conclude that there is a threshold for permanent changes during kindled seizure development. Our data are most consistent with this threshold occurring during the transition from stage 2 to stage 3.

THE KINDLED STATE, BRAIN DAMAGE AND SEIZURE SUSCEPTIBILITY. Craig D. Applegate* and Gary M. Samoriski. Comprehensive Epilepsy Program and Dept. of Neurology, University of Rochester School of Medicine, Rochester, NY 14642.

Several studies suggest that the permanent, kindling-induced increase in seizure susceptibility is not static, but continues to evolve over time. Our studies support this interpretation, and further indicate that implantation of chronically indwelling electrodes significantly contribute to increased seizure susceptibility. Male, C57BL mice were stereotactically implanted with electrodes into the olfactory bulb and following a 4 day recovery were kindled to a criterion of 6 consecutive stage 5 seizures. Seizure susceptibility to flurothyl (HFE) was tested 2 and 30 days following the last seizure. Both implanted mice tested at the same postsurgical intervals and unimplanted mice served as controls. Kindling significantly lowered HFE thresholds to generalized seizure 2 and 30 days post-kindling in comparison with both control groups. Seizure expression differed at these timepoints, however. Only 1/9 seizures were characterized by tonic manifestations at 2 days, whereas 8/9 exhibited tonic seizures at 30 days post-kindling. Electrode implantation did not significantly alter HFE thresholds at either time point, but significantly altered seizure expression such that 7/7 exhibited tonic seizures at 30 days, but 0/7 at 2 days. Data suggest that damage caused by implantation of chronically indwelling electrodes significantly lowers the threshold for tonic seizure expression.

GP	N	HFE(2)	SZ Type	HFE(30)	SZ type
Kindled	9	301+14	Clonic	264+15	Tonic
Implanted	7	403+28	Clonic	401+42	Tonic
Control	16	442+25	Clonic	422+93	Clonic

HFE(day)=flurothyl test-latency to generalized seizure (sec+SE)
SZ type=seizure type: clonic-forelimb clonus; tonic-fore/hindlimb tonus

DIFFERENTIAL CHANGES IN THE ACTIVITIES OF MULTIPLE PROTEIN KINASE C SUBSPECIES IN THE HIPPOCAMPAL-KINDLED RAT. Kazufumi Akiyama*, Mitsuhiro Ono¹, Kimiko Tsutsui² and Shigetoshi Kuroda¹.

¹Department of Neuropsychiatry and ²Third Department of Anatomy, Okayama University Medical School, 2-5-1 Shikata-cho, Okayama 700, JAPAN.

In previous studies we demonstrated that the membrane-associated protein kinase C (PKC) activities in the right and left hippocampus (HIPP) of rats kindled from the left HIPP increased significantly 4 weeks and 4 months after the last seizure compared with those in matched control rats (Daigen et al, Brain Res 545:131-136, 1991; Kohira et al, Brain Res 593:82-88, 1992). In this study, we investigated the long-lasting effect of HIPP-kindling on the membrane-associated activities of PKC subspecies in the bilateral HIPP one and 4 weeks after the last generalized kindled seizure had occurred. The membrane-associated activities of PKC subspecies were found to be subject to differential regulation. The activity of the α -subspecies was unchanged, whereas the respective activities of the β - and γ -subspecies in the kindled group increased significantly, compared with the controls, one week (21%, $P<0.0001$ for the β -subspecies, and 23%, $P<0.001$ for the γ -subspecies) and 4 weeks (19%, $P<0.02$ for the β subspecies, and 19%, $P<0.05$ for the γ subspecies) after the last seizure. There were no significant differences in cytosolic PKC activity between the control and kindled groups for any subspecies examined at either time after the last seizure. These results suggest that activation of the PKC β - and γ -subspecies may play an important role in the enduring seizure susceptibility associated with kindling.

LATERAL OLFACTORY TRACT IS THE OPTIMAL SITE FOR KINDLING T.J. Netoff(+), W.J. Freeman(+), E. Marg(++)(spon), (+) MCB-Neuro(++), School of Optometry, University of California at Berkeley, Berkeley, CA 94720

In the late 1960s Graham Goddard discovered the phenomena of kindling, and that stimulating the amygdala produced kindling the fastest. For years this remained undisputed until recently when it was discovered that stimulation in the deep layers of the pyriform cortex (PC) caused kindling to occur even more rapidly. This lead us to look at the lateral olfactory tract (LOT) as a stimulus site. We have found that kindling here requires fewer stimulus sessions to bring an animal to stage 5 kindling than stimulating in the amygdala. The olfactory bulb (OB) provides the background excitation for the PC through the LOT. Stimulus of the LOT is more efficient than directly stimulating the PC in two ways: 1) the stimulus in the LOT projects broadly to the PC stimulating a large portion of the PC directly and not just a small area around the electrode; 2) the stimulus in the LOT stimulates the OB antidromically as well, thus altering the dynamics of the limbic system very efficiently. The other change we have made from the standard kindling model is the stimulus duration and intensity. The stimulus is much milder (0.1-0.2 ms duration, 60 Hz, 10-15 V) and impedance has been matched to the LOT so that the largest evoked potentials in the OB and PC are obtained. However, the stimulus requires a longer train (6-10 sec) to elicit a seizure.

MINIMUM REQUIREMENTS FOR GENERALIZED SEIZURE-INDUCED NEURAL REORGANIZATION INDEPENDENT OF CONTINUED SEIZURE INDUCTION. G.M.Samoriski* and C.D.Applegate. Program in Neuroscience and Comprehensive Epilepsy Program, University of Rochester School of Medicine, Rochester, NY 14642.

We have previously reported that in response to multiple flurothyl-induced generalized seizures, a permanent decrease in the latency to the motor event results. Predominantly clonic seizure behaviors are observed during the course of flurothyl sensitization. However, following a 4 week seizure-free period a significant proportion of animals expressed predominantly tonic seizure behaviors. The goal of this study was to determine the minimum number of seizures necessary to initiate the seizure-free behavioral progression and to characterize the time frame for its development. In the first experiment male C57BL/6J mice experienced 1, 2, 4, 6 or 8 flurothyl-induced generalized seizures separated by 24 hrs. Following a seizure-free period of 28 days the mice were again challenged. Whereas 6 trials were sufficient to induce a permanent decrease in the latency to the sustained generalized event, 8 trials were necessary to effect a significant shift in the behavioral progression. Tonic seizure behaviors were observed in 88% of the animals having had 8 generalized seizures compared to 0%, 17%, 33% and 33% of animals having had 1, 2, 4 or 6 events, respectively. In order to define the minimum seizure-free period sufficient to cause the behavioral progression to be manifest, mice were tested 1, 2, and 3 weeks following the last of 8 seizures. Generalized tonic seizures were prevalent following 2 (67%), 3 (50%) and 4 (88%) weeks, but not 1 (17%) week, of a seizure-free interval. These data provide a framework for which to explore the mechanisms of generalized seizure-induced neural reorganization that is independent of continued seizure induction.

ACETAZOLAMIDE, A CARBONIC ANHYDRASE INHIBITOR, ACTS AS A PROCONVULSANT IN KINDLED RATS. L.J. Burdette* and M.J. Lotharius. Dept. of Neurology, Graduate Hospital, Philadelphia, PA 19146

Seizure activity alters extracellular pH which has been shown to influence NMDA and GABA_A-mediated currents. Acetazolamide inhibits the reversible hydration of CO₂ by carbonic anhydrase, resulting in more pronounced alkaline shifts during synaptic transmission. The possibility that pH modulation of synaptic transmission may be affected by repetitive seizure activity (kindling model) was tested by comparing input/output (I/O) and paired pulse depression (20 and 200 ms interpulse intervals) functions recorded from the dentate gyrus of kindled rats before and after acetazolamide (10-20 mg/kg, ip) administration. Rats were kindled daily by perforant path stimulation (200-800 μ Amps, 0.1 ms, 5 Hz, 9 sec) until 5 consecutive generalized motor seizures were elicited. Acetazolamide had no influence on the kindling-induced potentiation of I/O functions or of GABA_A-mediated early paired pulse depression. A dose-dependent decrease was observed, however, in late paired pulse depression. The 5 Hz train duration required to elicit an afterdischarge (AD) also was significantly reduced by acetazolamide. We previously have shown that a failure of late inhibition precedes AD initiation, suggesting that the proconvulsant action of acetazolamide in kindled rats may result from the depression of late inhibition. Indirect support of a similar proconvulsant mechanism for NMDA also has been provided in earlier studies. Together with evidence that NMDA currents are increased at alkaline pH, these findings suggest that kindling may enhance the sensitivity of NMDA-mediated currents to alkaline shifts in the extracellular space, leading to a decrease in late inhibition and enhanced seizure susceptibility. Supported by NIH MH45961 to LJB.

KINDLING-INDUCED POTENTIATION OF THE EPSP BUT NOT THE POPULATION SPIKE IS BLOCKED BY MK-801. M.E. Gilbert* and C.M. Mack, ManTech Environ. Tech., RTP, NC, 27709.

Kindling produces potentiation of excitatory and inhibitory transmission in the dentate gyrus. It is well recognized that NMDA antagonism retards development of limbic kindling, but its effects on synaptic potentiation have been equivocal. In the present report a crossover design was employed in which kindling stimulation was delivered to the perforant path once daily for 10 days, 30 min following 0 or 1 mg/kg MK-801. Following a rest period, the dose groups were reversed. MK-801 blocked kindling-induced potentiation (KIP) of the EPSP and late paired pulse inhibition (IPI=250 ms). Significant KIP of the PS occurred in both groups by the 4th afterdischarge (AD). Although continued stimulation resulted in suppression of the PS in controls, MK-801 produced an additional augmentation by the 10th AD that declined to control levels during the rest period. This suggests that the potentiation of the PS was transiently augmented above control levels by MK-801. When dose conditions were reversed, MK-801 treated animals demonstrated an increase in PS amplitude above the maximum achieved under saline conditions. The data indicate a dissociation in the NMDA dependence of KIP of the EPSP and PS. Potentiation of the EPSP and late inhibition during kindling, however, is strongly suppressed by NMDA antagonism.

DOWN-REGULATION OF AMYLOID PROTEIN PRECURSOR BY ANTISENSE OLIGONUCLEOTIDES REDUCES NEURONAL ADHESION TO LAMININ. E.J. Covison^{1,2}, G.L. Barrett², P.F. Bartlett², K. Bailey¹, K. Beyreuther³ and C.L. Masters¹. 1. Dept. Pathology, University of Melbourne, Vic, 3052, Australia. 2. Walter & Eliza Hall Institute for Medical Research, Parkville, Vic, 3052, Australia. 3. Center for Molecular Biology, University of Heidelberg, D-69120, Germany.

The Amyloid Protein Precursor (APP) is known as the source of β A4 amyloid, which forms plaques in brains of Alzheimer's disease patients. APP forms a complex of alternately spliced membrane bound and secreted glycoproteins and is a member of a larger APP super-family. APP isoforms are widely expressed, and in the brain products lacking exon 7 (the KPI domain) and containing exon 15 are most prevalent. The normal function of APP and its role in neurite extension and synaptogenesis is not yet clear.

We are investigating the function of APP in neurons using phosphothiate antisense oligonucleotides. We find by cell adhesion assay that, after 24-60 hours, P2 mouse dissociated DRG neuronal cultures exposed to antisense APP oligonucleotides are less adherent to laminin ($p < 0.001$) than cultures which are exposed to nonsense oligonucleotides of matched base composition. This change in adherence is not observed on other substrates (plastic, poly-lysine, fibronectin, and matrigel). An effect on neuronal survival, neurite outgrowth, or neurite branching is not observed but this may be due to a 'lag time' of APP down-regulation by the antisense oligonucleotides. Although neuritic networks are formed 16 hours after plating, the maximal effect on reduction in adhesion is after 48 hours, coincident with the patchy expression of APP on the surface of neurons. These data are consistent with a role for APP as a mediator of medium-term adhesion of neurons to extracellular matrix, and provide support for the specificity of an interaction of APP with laminin.

AMYLOID β PROTEIN PEPTIDE (25-35) STIMULATES THE ACCUMULATION OF ALZHEIMER AMYLOID PROTEIN PRECURSOR VIA TAU PROTEIN KINASE I IN CULTURED HIPPOCAMPUS NEURON. A. Takashima¹, H. Yamaguchi², K. Ishiguro¹, K. Noguchi¹, T. Hoshino and K. Imahori¹. ¹ Mitsubishi Kasei Institute of Life Sciences, 11 Minamiooya, Machida-shi, Tokyo 194. ² College of Medical Care and Technology, Gunma University, 3-39-15 Showa-Machi, Maebashi, Gunma 371, Japan

Pathological changes of Alzheimer's disease (AD) are characterized by cerebral cortical atrophy as a result of degeneration and loss of neurons. Typical histological lesions include numerous senile plaques composed of deposits of β -amyloid (A β) and neurofibrillary tangles consisting predominantly of ubiquitin and highly phosphorylated tau proteins. The exogenous application of synthesized amyloid β protein (A β) induced the neurotoxicity in the cultured hippocampus. Recently, we found that some proteins induced by A β treatment leads to a programmed cell death in cultured hippocampus, and that tau protein kinase I (TPK I) played a role in the A β induced neuronal death. Now we tried to identify the protein which was altered by A β treatment in the cultured hippocampus neuron. The level of amyloid protein precursor (APP) in cytoplasm increased by 10 folds of control level in response to exogenous application of A β peptide (25-35). The pretreatment of TPK I antisense oligonucleotide inhibited the A β induced APP accumulation and neuronal death. These results were interpreted as that TPK I regulated the increased APP accumulation in cytoplasm due to A β treatment, and that the increased APP accumulation in cultured hippocampus neuron might contribute to a process of A β induced neuron death.

LOCALIZATION OF THE AMYLOID PRECURSOR PROTEIN (APP) AT SYNAPTIC SITES OF THE RAT BRAIN. M. Shimokawa¹, K. Yamagisawa², H. Nishiyama³, T. Suzuki⁴, J. Ikeda⁵, T. Yokota¹, M. Yamada¹, T. Kobayashi¹, S. Ishiura² and T. Miyatake⁶. ¹Dept. of Neurol., ²Dept. of Physiol. Chem. Tokyo Med. & Dent. Univ. Tokyo 113, ³Institute for Brain Res. Univ. of Tokyo, Tokyo 113, ⁴Dept. of Physiol. Juntendo Univ., Tokyo 113, ⁵Dept. of Biochem., Nagoya City Univ. Med. Sch. Nagoya 467, ⁶Institute of Molec. and Cellular Biosci. Univ. of Tokyo, Tokyo 113, Japan.

Alzheimer's disease is a progressive neurodegenerative disorder characterized by extracellular amyloid β /A4 protein (A β) deposits and the loss of neurons and synapses. A β is a 39-42 amino acid peptide derived from the larger membrane-associated glycoprotein, termed amyloid precursor protein (APP). APP is expressed in most mammalian tissues, especially in neurons, and it shows a high degree of evolutionary conservation. But the functional significance of APP has been subject to conjecture. To define the potential role of APP in the brain, we investigated the localization of APP at synaptic sites. We purified synaptic plasma membrane (SPM), synaptic vesicles (SV) and the post synaptic densities (PSD) from Sprague-Dawley rat brain, and examined them by immunoblot analysis using two specific antibodies against N-terminal or C-terminal of APP (gifts from Dr. Yasuo Ihara, the University of Tokyo). We now present that 105kDa full-length APP is localized at SPM, and that PSD contains C-terminal truncated APP. Immunoreactivity of APP was drastically decreased in SV. These data indicate that APP may have roles in physiological synaptic activity.

ECTO-PROTEIN KINASE IN BRAIN NEURONS: A TARGET FOR ALZHEIMER'S β -AMYLOID PEPTIDES. M.V. Hogan*, Z. Pawlowska, H.-A. Yang and V.H. Ehrlich. CSI/IBR Ctr. Dev. Neurosci., CUNY at Staten Island, NY 10314 and the Biol. Doc. Prog. of CUNY Grad. Sch.

Ecto-protein kinase (ectoPK) can serve as a direct target for neuroactive factors that operate extracellularly. To study the effect of amyloid peptides on this activity, we have used primary neuronal cultures prepared from the telencephalon of 7-day chick embryos. The endogenous substrates of ectoPK on these neurons were identified as proteins with MW of 116K, 105K, 67K, 17K, 13K and 12K. The surface phosphorylation of the 12K and 13K proteins is catalyzed by an ectoPK with the specificity of PKC, and is maximal during de-novo neurite outgrowth. The β -amyloid peptide 1-40, when used at neurotoxic concentrations, inhibited the phosphorylation of the 12K and 13K surface proteins (over 80% inhibition of the phosphorylation of the 13K protein by 0.1 μ M β -amyloid peptide 1-40). At the same concentration, the β -amyloid peptide 1-28, that does not have neurotoxic effects, did not inhibit this phosphorylation. On the other hand, the neurotoxic β -amyloid peptide 25-35 selectively inhibited the phosphorylation of the 12K and 13K proteins by ecto-PKC, at the same concentration range (0.1-25 μ M) in which it produces neurodegeneration in cultured neurons. At nanomolar, neurotrophic concentrations, β -amyloid 25-35 stimulated this activity. Thus, the direct regulation of extracellular PKC can mediate both the neurotrophic and neurodegenerative actions of β -amyloid peptides. Supported by HD28788

FURTHER ANALYSIS OF THE BRAIN $\text{Na}^+/\text{Ca}^{2+}$ EXCHANGER IN ALZHEIMER'S DISEASE. R.A. Colvin*, N. Davis, A. Wu, C.A. Murphy, and J. Levengood. Department of Biological Sciences, Ohio University College of Osteopathic Medicine, Athens, OH 45701

The $\text{Na}^+/\text{Ca}^{2+}$ exchanger was characterized in plasma membrane vesicles derived from frontal and temporal cortex and cerebellum of control and Alzheimer's disease (AD) frozen postmortem tissues. $\text{Na}^+/\text{Ca}^{2+}$ exchange activity was defined as the change in vesicular Ca^{2+} content seen after Na^+ loaded vesicles were diluted into choline buffer. The time course of changes in Ca^{2+} content after dilution was similar in all three regions of control brain. In AD brain, both frontal and temporal cortex vesicles showed elevated Ca^{2+} content, most evident as an increased peak Ca^{2+} content at 2 minutes. The AD cerebellar cortex time course was similar to control and did not show an elevated peak at 2 minutes. No differences were seen in the passive permeability to Ca^{2+} when comparing plasma membrane vesicles prepared from control and AD brain. Vesicles from the frontal and temporal cortex of AD brain showed increases in the V_{max} of the initial velocity of Ca^{2+} uptake when compared to control brain, whereas, the cerebellum did not. There were no significant effects of AD on the K_m for Ca^{2+} activation of the initial velocity. Ca^{2+} influx measured during the rise in vesicular Ca^{2+} content was elevated in vesicles from AD temporal cortex when compared to control. Two known inhibitors (exchange inhibitory peptide and dichlorobenzamil) of the cardiac $\text{Na}^+/\text{Ca}^{2+}$ exchanger inhibited the human brain exchanger equally well in control and AD vesicles. An antibody to the cardiac exchanger was used to determine the molecular weight of the human brain $\text{Na}^+/\text{Ca}^{2+}$ exchanger. The molecular weight determinations from western blots showed identical molecular weights of 100-110 kDa in both AD and control vesicle preparations. The data suggest that increased $\text{Na}^+/\text{Ca}^{2+}$ exchange activity in AD brain is related to the causative factors of neurodegeneration and lends support to the " Ca^{2+} hypothesis of AD".

AMYLOID BETA-PEPTIDE (A β P) POTENTIATES A CALCIUM CURRENT IN NIE-115 NEUROBLASTOMA CELLS. Lydia Shaienko*, Theodore S. Donta and Robert M. Davidson. Neuroscience Program, Department of Periodontology and the Travelers Center on Aging, University of Connecticut Health Center, Farmington, CT 06030.

One of the hallmarks of Alzheimer's disease (AD) is the presence of extracellular senile plaques composed primarily of aggregated amyloid β -peptide (A β P) surrounded typically by dystrophic neurites. It has been hypothesized that some aggregate form of A β P manifests its toxicity on neurons by forming membrane channels thereby destabilizing neuronal Ca^{2+} homeostasis. We have used patch-clamp recording techniques to study the effects of A β P (1-40) on cation currents in differentiated mouse NIE-115 neuroblastoma cells (Davidson et al., 1994). In whole-cell recordings, incubation of cells with A β P for 24 h significantly increased the median peak inward current from -201.8 pA to -352.0 pA, and shifted the voltage at peak current (V_{peak}) and that of current activation (V_{act}) towards more positive potentials. For untreated cells, median V_{peak} was 1.7 mV and V_{act} was -28.9 mV vs. 10.5 mV and -24.7 mV in A β P-treated cells. (Incubation with the reverse sequence A β P(40-1) did not produce significant changes in the amplitude or kinetic behavior of inward current). At the single channel level, A β P added to the pipette increased the open probability of cation-conducting ion channels. As determined by cell viability counts, A β P(1-40) had neurotoxic effects; within 24 h, addition of A β P reduced the number of cells by more than 50%. It is suggested that the neurotoxic effects of A β P may be mediated by its ability to form cation channels *de novo* and/or alter the activity of cation channels already present in the cell membrane. We are in the process of developing a liposomal model system with a lipid composition similar to that of the neuroblastoma cell to analyze A β P's membrane perturbation properties.

AMYLOID β -PROTEIN DISRUPTS Na-K-ATPase ACTIVITY IN CULTURED RAT EMBRYONIC CORTICAL NEURONS. R.J. Mark*, S.A. Walker, and M.P. Mattson. Sanders-Brown Center on Aging and Dept. of Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536

Amyloid β protein (A β) is a major component of the plaques that are a hallmark of Alzheimer's Disease. A large literature has shown that A β can be neurotoxic, but little has been published on the mechanism through which A β kills neurons. Here we report that treatment of embryonic rat cortical cells in culture with A β (1-40) or A β (25-35) inactivates the ouabain sensitive ATPase. Cultures were exposed to A β (10 μM -200 μM), membranes were prepared, and ATPase activity was assayed in 96-well microtiter dishes using a method adapted from Rohn et al (Biochem. Pharm. 46:525-34). We found that there is a reduction in the Na-K-ATPase activity with no reduction in the non-ouabain sensitive, non-calcium dependent ATPase activity. Co-treatment of cultures with Vitamin E (50 $\mu\text{g/ml}$) blocks the A β reduction in ATPase activity, indicating that mechanism of impairment is mediated by free radicals. By a separate assay we also find no reduction in the activity of the plasma membrane Na/Ca exchanger at concentrations of A β that are neurotoxic. We are currently examining the contribution of impairment of Na-K-ATPase activity by A β to loss of calcium homeostasis and cell death.

THE INHIBITORY EFFECT OF β -AMYLOID PEPTIDE ON RAT BRAIN NA/CA EXCHANGE. Anfan Wu, Robert A. Colvin and Venugopal Janapati*. Dept. Biological Sciences, Ohio University College of Osteopathic Medicine, Athens, OH 45701 USA.

These studies were performed to determine the effect of addition of Alzheimer's disease β -amyloid peptide (β -AP) on $\text{Na}^+/\text{Ca}^{2+}$ exchange activity. $\text{Na}^+/\text{Ca}^{2+}$ exchange activity was measured in plasma membrane vesicles (PMV) purified from rat brain. The effect of synthetic peptide β -AP₂₅₋₃₅ and scrambled (β -AP_{sc}) were examined. PMV were preincubated with each peptide for 15 minutes (37°C) in buffer containing 137 mM NaCl, 10 mM HEPES (pH 7.4), and protease inhibitors. Ca^{2+} uptake was initiated by diluting PMV 20 fold with buffer containing either 137 mM NaCl or 137 mM cholineCl and $^{45}\text{CaCl}_2$. Ca^{2+} uptake was terminated by addition of 5 mM LaCl₃ and rapid filtration. β -AP₂₅₋₃₅ inhibited Na^+ -dependent Ca^{2+} uptake with an IC_{50} of 800 μM (concentration measured in the preincubation buffer) but it had no effect on the Na^+ -dependent Ca^{2+} efflux. When β -AP₂₅₋₃₅ was added in the dilution buffer instead of during the preincubation step, the same inhibitory effect was observed. No inhibitory effect was seen when β -AP_{sc} was tested under both conditions. The inhibitory effect of β -AP₂₅₋₃₅ could not be overcome by increasing Ca^{2+} concentration. Analysis of unidirectional flux for Ca^{2+} during the initial phase of rapid uptake or after a stable plateau had been obtained showed that 800 μM β -AP₂₅₋₃₅ inhibited both Ca^{2+} influx and efflux with the same efficacy (approximately 50 % inhibition) during both time periods. These results suggest that the inhibitory effect of β -AP₂₅₋₃₅ is irreversible, and that it inhibits both $\text{Na}^+/\text{Ca}^{2+}$ exchange and $\text{Ca}^{2+}/\text{Ca}^{2+}$ exchange activity by directly interacting with the exchanger.

ELECTROPHYSIOLOGICAL STUDY OF AMYLOID β PROTEIN ACTIVITY IN RAT CORTICAL NEURONS. K. Furukawa*, M.P. Mattson, and N. Akaike. Sanders-Brown Research Center on Aging and Department of Anatomy and Neurobiology, University of Kentucky, Lexington KY 40536.

The effect of amyloid β -protein 25-35 (A β P) was examined in neurons freshly dissociated from rat cortex using the nystatin perforated patch-clamp technique. A β P at concentrations higher than 10^{-8} M induced an irreversible slow inward current associated with an increase in membrane conductance at a holding potential of -50 mV. The time lag until the appearance of the effect of A β P shortened concentration-dependently, whereas the increase in membrane conductance did not. When the extracellular Na^+ and Cl^- , and intracellular K^+ were replaced by equimolar NMG, isothionate⁻, and Cs^+ , respectively, the membrane conductance and the reversal potential were not affected. Even when Ca^{2+} was removed from the extra- and intra-cellular space by using a Ca^{2+} -free external solution and an internal solution including BAPTA (20 mM), the effect of A β P did not alter. It is suggested that A β P elicits an inward current either by forming membrane pores as suggested by Arispe et al., or by causing dysfunction of ion channels as suggested by our recent finding that A β P can damage ion-motive ATPases by a free radical-mediated mechanism (see Mark and Mattson, this meeting).

597.10

PROPERTIES OF CHLORIDE CHANNELS IN PC12 CELLS INDIRECTLY MODULATED BY ALZHEIMER'S DISEASE β -AMYLOID. R.J. Pearce*, R. Fukuyama, G. Ehrenstein, S.I. Rapoport and Z. Galdzicki. LNS, NIA and CNB, NINDS, NIH, Bethesda, MD 20892.

A pathological feature of Alzheimer's disease (AD) is the formation of plaques in the parenchyma and vasculature of the brain. β -Amyloid peptide (β -AP) is one of the defining components of these plaques.

We have previously shown from cell-attached patch recordings that β -AP (1-40) increases the activity of channels inherent to PC12 cells (Pearce et al, 1994, Biophys. J. 66:A430). We have now managed to characterize these channels further. Under conditions of symmetrical choline chloride (120 mM) and high calcium (10 mM CaCl_2), in excised patches, we could resolve two main conductance levels of 100 and 300 pS. Both had reversal potentials (RP) around 0 mV under these conditions. Exchanging the major cation on the extracellular face to Na^+ had no significant effect on the RP. However, reducing the chloride to 30 mM from 150 mM, by replacement with acetate resulted in a positive shift in the RP, irrespective of whether choline or Na^+ was the major cation. This implicated chloride as the charge carrier for this channel, but the shift was less than expected indicating poor selectivity.

The fact that both conductances were seen to be effected in the same way by these ion substitutions and that both levels were invariably seen in any one patch, means it is likely that we are observing one channel which can have differing conductance levels.

The mechanism by which β -AP or patch excision increases the activity of this channel remains unclear. A possible mechanism may be linked to the ability of β -AP to interfere with calcium homeostasis. Alternatively, disruption of cytoskeletal components linked to the channel may be involved.

597.11

NO APPARENT EFFECT OF β -AMYLOID PEPTIDES ON M1 MUSCARINIC RECEPTOR BINDING OR FUNCTION. C.M. Reeve and D.D. Flynn*, Dept. of Pharmacology, Univ. of Miami School of Medicine, Miami, FL 33101.

While accelerated β -amyloid (β A) deposition has been suggested to play an early and critical role in the pathogenesis of Alzheimer's disease (AD), the precise cellular actions of β A are unclear. The complexity of β A actions are evidenced by the opposing neurotrophic and neurotoxic actions which are dependent on peptide concentration and the presence of soluble vs. fibrillar forms. On the basis of limited sequence homology to substance P and tachykinin peptides, β A has been suggested to interact with tachykinin receptors and function as an allosteric modulator of the ionotropic NMDA receptor. Substance P-related peptides also appear to function as G protein antagonists, uncoupling receptors from G protein-mediated responses. Cortical M1 muscarinic receptor (MR) high-affinity agonist binding and receptor-stimulated, G protein-mediated phospholipase C activity are diminished in AD, resulting from an apparent receptor-G protein uncoupling. In order to test the hypothesis that β A may function as a MR-G protein "uncoupler" in AD, we have assessed the effects of amyloid peptides on MR binding and functional activity. β A peptides (1-40, 25-35; 0.01-100 μ M) had no effect on binding of the muscarinic antagonist, [3 H]-NMS, to membranes from CHO cells transfected with the m1 receptor, when incubated *in vitro* for up to 18 hr at 4° C or for 2 hr at 25° C, or in culture for 20 hr. Agonist binding as well as basal and carbachol-stimulated [35 S]GTP γ S binding also were unaffected by peptide under all conditions tested. These findings suggest that β A does not antagonize MR-G protein interaction and that MR dysfunction in AD is not a consequence of excessive β A accumulation. (Funded by NS19065 & the Alzheimer's Association)

IMPAIRED OXIDATION INDUCED BY THIAMINE DEFICIENCY CAUSES β -AMYLOID PRECURSOR PROTEIN ACCUMULATION IN RAT BRAIN. N. Calingasan*, S. Gandy, H. Baker, K.-F. R. Shew, S. G. Greenberg* and G. Gibson*, Cornell University Medical College at Burke Medical Research Institute, White Plains, NY 10605 and *Cornell University Medical College, New York, NY 10021.

β -amyloid, a fragment of the amyloid precursor protein (APP), accumulates in the brains of patients with Alzheimer's disease (AD) or Down's syndrome. As in AD, thiamine deficiency (TD) is characterized by selective cell loss, decreased thiamine-dependent enzymes and memory deficits. APP increases in the brain in animal models of central nervous system injury. The current study examined ultrastructural changes as well as β -amyloid and APP⁴²⁻⁵⁹ immunoreactivity in brains from thiamine-deficient animals. Rats received thiamine-deficient diet *ad libitum* and daily injections of the thiamine antagonist, pyriothiamine. Three, 6 and 9 days of TD did not damage any brain region nor change APP immunoreactivity. However, 13 days of TD produced pathological lesions in the thalamus, mammillary body, inferior colliculus and some periventricular areas. Electron microscopy revealed swollen, degenerating neurites with accumulations of abnormal mitochondria, tubulovesicular and filamentous structures in the thalamus. While β -amyloid immunocytochemistry, thioflavine S staining and electron microscopy failed to show fibrillar β -amyloid, APP accumulated in perikarya and aggregates of swollen, dystrophic neurites along the periphery of the lesion in the thalamus. Immunoblotting of the thalamic region around the lesion confirmed increased immunoreactivity of APP holofoms. In addition to the thalamus, APP-immunoreactive neurites were scattered in the mammillary body, medial geniculate and medial vestibular nuclei. In the inferior colliculus, increased perikaryal immunostaining occurred in neurons surrounding necrotic areas. Regions without apparent pathological lesions showed no alteration in APP immunoreactivity. Thus, the oxidative insult from TD alters APP metabolism. This model may be useful in defining the role of APP in the response to brain injury, and in clarifying the relationship between oxidative changes and altered APP metabolism, both of which occur in AD. (Supported by NIH Grant MH-48325).

SYMPOSIA

598

SYMPOSIUM. THE CELL BIOLOGY OF SECRETION VESICLES. K.J. Skinner, NIDA/NIH (Chairperson); J.E. Rothman, Memorial Sloan Kettering Cancer Ctr.; R. Kelly, Univ. of Calif., San Francisco; M. Wightman, Univ. of North Carolina, Chapel Hill; A. Fox, Univ. of Chicago.

Different types of vesicles may mediate slow and fast neuronal communication, thus contributing to significant behavioral differences. This symposium will explore the cell biology associated with these two signalling pathways. J.E. Rothman will discuss intracellular protein transport, focusing on the molecular mechanisms associated with vesicle docking, activation, and fusion. R. Kelly will present results from studies investigating secretory vesicle recycling after exocytosis. Post-fusion endocytotic steps will be reviewed, as well as endosomal differences and signal sequences which sort proteins to vesicular targets. M. Wightman will describe studies using carbon-fiber microelectrodes to resolve release of catecholamines from individual vesicles. Kinetic differences in release between synaptic and dense core vesicles will be discussed, as well as evidence related to release mechanisms from dense core vesicles. A. Fox will consider the concept that differential coupling of specific channels may contribute to different rates of transmitter or hormone release, focusing on results suggesting that different Ca^{2+} channels regulate secretion depending upon the level of electrical activity of the cell.

597.12

BETA-AMYLOID AMPLIFIES CALCIUM SIGNALLING AND INFLUENCES PHOSPHOINOSITIDE HYDROLYSIS IN CENTRAL NEURONS FROM THE ADULT MOUSE H. Hartmann, A. Eckert, D. Watson, F.T. Crews* and W.E. Mueller, Central Institute of Mental Health, Dept. Pharmacology, 68159 Mannheim, Germany, *Dept. Pharmacology, College of Medicine, University of Florida, BOX 100267, JHMC, Gainesville, Florida 32610-0267. The role of β -amyloid (β A) in Alzheimer's disease and its cellular mechanisms of action are still unclear. Based on observations that β A influences neuronal calcium homeostasis in cultured neuronal cells we investigated the effect of β A on KCl-induced enhancement of free intracellular calcium (Ca_i) and on phosphoinositide- (PI) hydrolysis in dissociated brain cells from adult female NMRI mice. For measurement of Ca_i cell aggregates were loaded with fura-2 AM (10 μ M) and fluorescence measured with a spectrofluorometer. For determination of PI-hydrolysis cell aggregates were loaded with 3 H-myo-inositol and stimulated with the agonist in the presence of LiCl (10mM). Preincubation with β A fragment 25-35 at concentrations <0.05 μ M resulted in a marked amplification of the KCl-induced calcium response. This effect was also observed with fragment 1-40, whereas fragment 1-28 or 12-28 did not affect the response. The amplification was restricted to depolarization with lower KCl concentrations whereas maximal stimulation (KCl 80mM) was not affected. Preliminary data suggest that β A fragment 25-35 (10nM) enhances KCl (20mM) and carbachol (1mM)-stimulated PI-hydrolysis. A more detailed characterization of these mechanisms will be presented. In conclusion, these findings indicate a small but consistent destabilizing effect of β A on the neuronal calcium homeostasis in adult neuronal cells, which may also result in increased activity of the Phospholipase C system. This will not only lead to an increased vulnerability of neurons to other neurotoxic stresses (e.g. ischemia, glucose deprivation, EAA), but will also influence neuronal signal transduction. The latter mechanism may contribute to memory loss and may also influence amyloid precursor metabolism. (Supported by P01 AG 10485).

SYMPOSIUM. NEUROPEPTIDE REGULATION OF BRAIN DEVELOPMENT. E. DiCicco-Bloom, UMDNJ/Robert Wood Johnson Med. Sch. (Chairperson); J.P. Schwartz, NINDS, NIH (Co-chairperson); S. Denis-Donini, CNR Ctr. Cytopharmacol. & Biology Dept., Milan; I. Gozes, Sackler Sch. of Med. Studies suggest that neuropeptides regulate the component processes of neural ontogeny, including proliferation, differentiation, and survival, as well as neurotrophin function and behavioral maturation. Peptides and receptors are expressed transiently in specific regions, and act as auto-/paracrine or trans-synaptic signals. The complexity of peptide biosynthesis, transport and metabolism provides greater opportunities for signal integration over time and space, characteristics well-suited for governing long-term processes. E. DiCicco-Bloom will define roles of PACAP in regulating neurogenesis of diverse populations: sympathetic, cerebellar granule cells, and cerebral cortex. PACAP regulates all three principal mechanisms governing stable population growth including 1) neuroblast division 2) survival of dividing precursors, and 3) promotion of long-term survival via *trk* regulation. S. Denis-Donini will describe the role of afferent neuron CGRP in regulating differentiation of dopaminergic olfactory neurons. CGRP protein and mRNA, which are developmentally regulated, appear at highest levels in afferent terminals, suggesting local peptide synthesis. J.P. Schwartz will focus on somatostatin and enkephalin ligand-receptor systems, which are expressed transiently during postnatal cerebellar ontogeny. Normal development depends on a balance of actions, since SOM stimulates differentiation whereas ENKs are inhibitory, acting via diminished astrocytic NGF expression. I. Gozes will describe hybrid and lipophilic VIP agonists/antagonists that are tissue specific and distinguish pathways mediating neurotrophism and neurotransmission. Antagonists *in vitro* inhibit neural division and produce neuronal death, whereas disruption of VIP by antagonists or transgenic methods, leads to deficits in behavior, circadian rhythms, sexual performance, and learning/memory. Thus, neuropeptides affect diverse brain regions. Interactions between peptides, as well as with classical transmitters or neurotrophins, greatly expand possible integrative signals mediating long-term developmental processes.

602.1

PARKINSONIAN AND NORMAL ACCURACY IN A POINTING TASK WHEN TASK INFORMATION IS REDUCED. W. A. Henning^{1,2}, M. Rolleri¹, and J. Gordon³. Neurology Depts., VAMC¹, Lyons, NJ & UMDNJ-RWJohnson Med Sch², New Brunswick, NJ; and Ctr for Neurobiology & Behavior³, Columbia Univ, NY, NY

We previously reported that well-trained Parkinsonian subjects can show normal accuracy in a simple planar pointing task even if they are deprived of information about their unfolding trajectories and knowledge of the results of their movements (Neurosci Abstr 18:935). It has been often suggested that Parkinsonian subjects require such information to sustain normal performance. However, such dependence might be due to task complexity or to the need to learn an unfamiliar transform. We therefore tested four groups of subjects: practiced normals (PN, N=3), practiced Parkinsonians (PP, N=1), unpracticed normals (UN, N=3), and unpracticed Parkinsonian subjects (UP, N=4). After a brief practice at making movements to match four computer screen targets requiring 8 to 32 cm excursions of the draped arm over a digitizing tablet, subjects were required to respond to randomized targets in two experimental blocks. In the first, they saw the target throughout each trial, were given instantaneous feedback, and received knowledge of results. In the second, none of this information was provided. Both NP and PP subjects sustained accuracy when deprived of information, but neither UN nor UP subjects did so: both groups undershot the larger target distances, the UP subjects much more so (for the largest target, UP, 47.5% vs. UN, 27.3%). We conclude that Parkinsonian patients have a relative inability to master a sensorimotor transform and perform under reduced information conditions rather than an absolute inability to do so. This research supported by the Dept. of Veterans Affairs Medical Research Council.

602.3

DECREASED [¹²³I] 8-CIT SPECT STRIATAL UPTAKE CORRELATES WITH DISEASE SEVERITY IN IDIOPATHIC PARKINSON'S DISEASE J. Seibyl¹, K. Marek, E. Smith, B. Sandridge, B. Fussell, S. Zoghbi, R. Baldwin, P. Hoffer, R. Innis. Departments of Diagnostic Radiology, Neurology, and Psychiatry, Yale University School of Medicine, New Haven, CT 06510 USA

Our previous studies have utilized SPECT to demonstrate decreased [¹²³I] 8-CIT striatal uptake in idiopathic Parkinson disease patients (PD). The present study extends this preliminary work by examining 1) the test-retest reproducibility of two SPECT measures (ratio specific striatal uptake:nonspecific uptake [V3'] and striatal uptake expressed as the percentage of injected dose) in healthy subjects and, 2) striatal binding using these measures in PD patients of varying disease severity. **Methods:** For the test-retest reproducibility study 7 healthy subjects (age range 19-74) had SPECT brain scans at 18, 21, and 24 hr following the intravenous injection of 10 mCi of [¹²³I] 8-CIT. Repeat SPECT scans were performed 7-14 days following the first examination. For the PD severity study, a total of 26 idiopathic PD patients (age range 41-78, Hoehn-Yahr stages I-V) had SPECT scans 18, 21, and 24 hr after i.v. injection of 10 mCi of [¹²³I] 8-CIT. The two measures were age-corrected based on our healthy control population and correlated with Hoehn-Yahr and total Unified Parkinson's Disease Rating Scale (UPDRS) scores. **Results:** The healthy subject study demonstrated excellent test-retest reproducibility of both outcome measures with a mean 6.8 and 6.7% differences in V3' and percent striatal uptake, respectively. In the PD study binding abnormality was correlated with both Hoehn-Yahr ratings and total UPDRS score for striatal V3' ($r^2 = 0.345$, $p = 0.0016$ and $r^2 = 0.408$, $p = 0.0004$, respectively) and percent striatal uptake ($r^2 = 0.33$, $p = 0.0081$ and $r^2 = 0.463$, $p = 0.001$, respectively). These data suggest both [¹²³I] 8-CIT SPECT outcome measures have a high degree of within-subject reproducibility and are strongly correlated with disease severity in idiopathic PD.

602.5

SPECT STUDIES WITH 8-CIT IDENTIFY DOPAMINE GRAFTS.

D. E. Redmond, Jr., E. O. Smith, R. H. Roth, J. D. Elsworth, J. R. Taylor, J. R. Sladek, Jr., R. B. Innis, J. P. Seibyl and P. B. Hoffer. Yale Univ. Sch. Med., New Haven CT. 06510; †Chicago Med. Sch., N. Chicago, IL. 60604

[¹²³I]-8-CIT (28-carbomethoxy-3β-[4-iodophenyl]tropane) binds dopamine (DA) transporter sites with high affinity and may assess DA-related behavioral function better than techniques using ¹⁸F-fluorodopa. SPECT studies, obtained 18 hours after [¹²³I]-8-CIT administration in African green monkeys, correlated with anatomical regional averages of postmortem DA concentrations (0.91, n=13, p<0.001) and with a detailed score of parkinsonism (-0.81, n=13, p<0.001).

We obtained SPECT scans 18 hours after [¹²³I]-8-CIT administration in African green monkeys before and twice after they received intrastriatal grafts of fetal mesencephalon. Percent of administered [¹²³I]-8-CIT dose was determined in a region of interest including the striatum and a circumferential background region.

Developing grafts were identified by [¹²³I]-8-CIT SPECT *in vivo* and confirmed by autoradiography and tyrosine hydroxylase immunohistochemistry. Over a 7 month period, mean changes in percent administered [¹²³I]-8-CIT dose in 4 untreated normals and in 6 non-transplanted MPTP-depleted monkeys were insignificant. Four grafted monkeys with robust histologically confirmed grafts showed mean increases of 70% ±22 (SD). The largest increases corresponded with histological evidence of the most robust grafts. Three monkeys (identified as transplanted for the purpose of blinding the analyses) either had no surviving grafts or were sham operated. They showed no change in striatal uptakes (-12% ±27 [SD]) from their study before transplantation.

SPECT imaging with CIT appears to provide an *in vivo* measurement of the integrity of striatal dopamine systems comparable to direct *in vitro* measurements of DA levels and DA transporters and to detect changes induced by dopamine-producing grafts. PARKINSONIAN DOMAINS AND RISK OF DEATH IN A COMMUNITY POPULATION. D.A. Bennett*, L.A. Beckett, A.M. Murray, D.A. Evans. Rush Alzheimer's Disease Center, Chicago, IL 60612

Previous work suggests a relation between parkinsonian signs and increased mortality in older persons. This study investigates the association between individual parkinsonian domains and mortality among persons in a geographically defined community population. 3622 persons (80.8%) of residents over the age of 65 had a structured interview in their homes. 467 persons (70.8% of survivors) identified by a stratified random sampling technique underwent a uniform neurologic examination including the presence or absence of 3 measures of gait disturbance, 3 of bradykinesia, 4 of rigidity, and 2 of tremor. A parkinsonian domain was defined as the presence of at least half of the signs within the domain. Proportional hazards models were used to compare the risk of death among persons with and without each domain. After adjusting for the effects of age and sex, the overall relative risks of death and 95% confidence intervals were: gait disturbance 2.36 (1.83-3.04), bradykinesia 1.72 (1.32-2.24), rigidity 1.02 (0.79-1.32) and tremor 1.12 (0.86-1.47). Of the four parkinsonian domains, gait disturbance and bradykinesia are most strongly associated with mortality.

[I-123]-8-CIT BINDING IN THE HUMAN BRAIN: SPECT STUDIES IN PARKINSONIAN PATIENTS AND NORMAL CONTROLS

T. Brücke*, S. Asenbaum, P. Angelberger, J. Kornhuber, A. Pozzera, S. Homy-kiewicz, C. Harasako-van der Meer, S. Wenger, W. Pirker, G. Koch, J. Podreka. Neurological University Clinic Vienna and Forschungszentrum Seibersdorf, Austria

The cocaine analog 2-8-carbomethoxy-3-β-[4-iodophenyl]-tropane (8-CIT) is a ligand which binds with high affinity to DA and 5HT transporters. In its [¹²³I] labeled form it can be used for SPECT. Previous studies have shown that the binding of this ligand in the striatum is specific to the DA transporter, whereas binding in the brainstem seems to be due to the 5HT transporter. The purpose of the present study is to characterize the uptake of 8-CIT in the human brain, to compare the findings in normal controls with a group of PD patients and to correlate SPECT measurements with clinical findings. SPECT was performed in 11 controls and 37 patients with PD. 111 to 185 MBq of [I-123] 8-CIT were administered i.v. and images obtained at regular intervals after injection (2, 4, 16, 20 an 24 hrs) with a three-headed scintillation camera (Siemens Multispect). Regions of interest were drawn in the striatum, the brainstem and the cerebellum and the results expressed either as target - cerebellum (specific binding) or as ratio target /cerebellum. Binding kinetics showed a maximum of specific binding in the striatum after 20 hrs, whereas maximal binding in the brainstem was reached at around 4 hrs. Results in 37 patients with PD clearly demonstrate the loss of dopaminergic nerve endings especially in the putamen with a marked reduction of the striatal/cerebellar ratio after 20 hours (controls 8.7±1.7, PD 4.4±1.1, mean±SD). In patients with hemiparkinson (n=15) a clear and highly significant side to side difference is found with a reduction of striatal 8CIT binding which is more marked contralateral to the clinically affected side, but also reduced in the ipsilateral striatum. A good correlation is found between the severity of clinical symptoms according to Hoehn and Yahr and the reduction of 8CIT binding (p=0.0001). These data suggest that PD can be clearly diagnosed with this ligand, the dopaminergic cell loss quantified and hopefully a preclinical or very early diagnosis made possible. Such studies might also open the way for a better evaluation of neuroprotective strategies in PD.

ANTIOXIDANT ENZYMES IN AN ANIMAL MODEL OF PARKINSON'S DISEASE C. Thiffault*, B. Quirion and J. Poirier. Douglas Hospital Research Centre, Dept. of Pharmacology and Therapeutics, McGill Centre for Studies in Aging, McGill University, Montreal, Que, Canada H4H 1R3

MPP⁺, a metabolite of N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), induces an irreversible Parkinson's disease (PD) like syndrome. MPP⁺ toxicity involves the inhibition of complex I activity in the mitochondrial respiratory chain. Similar respiratory deficits are reported in PD. In addition, free radicals are thought to play a role in the mechanism of MPP⁺ toxicity. They can induce lipid peroxidation leading to an alteration in calcium homeostasis and subsequent neuronal death. The major antioxidant enzymes are superoxide dismutase (SOD), glutathione peroxidase (GLU-PX) and catalase (CAT). Lipid peroxidation and SOD activity were found increased in PD brains. To date, it is not clear whether alterations in antioxidant enzymes are responsible for the increase in lipid peroxidation and/or respiratory chain inhibition reported in PD. L-deprenyl was used to up-regulate SOD activity in the striatum (ST) and substantia nigra (SN) of mice. Our results indicate that chronic administration of L-deprenyl (10mg/kg, every 2 days), MPTP (3X20mg/kg, every 2 hrs) and L-deprenyl/MPTP induce a three-fold increase in the activity of SOD in the ST of C57BL/6 mice. No concomitant increases in GLU-PX or CAT is observed while striatal lipid peroxidation was decreased. Although an increase in CAT activity and a reduction in SOD and GLU-PX activity were detected in the SN, no significant change in lipid peroxidation was observed. First, our results indicate that a mild alteration in the activity of antioxidant enzymes does not result in an increase in lipid peroxidation. Second, inhibition of the respiratory chain by MPP⁺ leads to an adaptive increase in SOD activity. We postulate that an alteration in SOD activity in PD is likely the result of respiratory chain inhibition. *Supported by FCAR studentship.

DOPAMINE-DERIVED DIHYDROXYISOQUINOLINE INDUCES PARKINSONISM TO RAT M. Naoi¹, W. Maruyama², P. Dostert³, D. Nakahara⁴, Y. Hashizume⁵, ¹Dept. Biosciences, Nagoya Inst. Technol., Nagoya, ²Dept. Neurol. Nagoya Univ. Sch. Med., Nagoya, ³Farmacia-Carlo Erba, Milan, Italy, ⁴Dept Psychol. Hamamatsu Univ. Sch. Med., Hamamatsu, and ⁵Inst. Med. Sci. Aging, Aichi Med. Univ., Nagakute, Japan

The discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine suggests that endogenous and xenogenic neurotoxins may cause cell death of dopamine neurons in the substantia nigra and thus induce in the Parkinson's disease in humans. As neurotoxin candidates, dopamine-derived 6,7-dihydroxy-1,2,3,4-tetrahydroisoquinolines (DHTIQs) have been examined on their effects on dopamine neurons. Out of DHTIQs, 1-methyl-DHTIQ (salsolinol, 1-MeDHTIQ) is methylated to 1,2-(N)-dimethyl-DHTIQ in the brain, which was found to be oxidized into 1,2-dimethyl-6,7-dihydroxyisoquinolinium ion (1,2-DiMeDHTIQ⁺). 1-MeDHTIQ and its derivatives were injected in the striatum of adult male Wistar rat, and the biochemical, behavioral, and pathological changes were examined. Both (R) and (S) enantiomer of 1-MeDHTIQ and 1-(S),2-DiMeDHTIQ did not induce any behavioral change by a single administration. 1-(R),2-DiMeDHTIQ elicited behavioral changes to the rat; akinesia, twitching, postural abnormality and rigidity were detected. The behavioral changes were transient; they disappeared several hours after the injection. Three days after the injection, the rat was sacrificed and DHTIQ derivatives and monoamines were analyzed by HPLC-electrochemical and fluorometric detection. Biochemical analysis showed that 1-(R),2-DiMeDHTIQ was detected in the striatum, and larger amount of the oxidized product, 1,2-DiMeDHTIQ⁺ was identified in the substantia nigra in addition to the striatum. Dopamine, noradrenaline, and their metabolites were found to be reduced in the striatum and the substantia nigra. The injection of 1,2-DiMeDHTIQ induced massive necrosis in the rat brain. Using a human dopaminergic neuroblastoma SH-SY5Y cells, only 1-(R),2-DiMeDHTIQ was confirmed to be taken up to the cells by dopamine-transported, among dihydroxy-isoquinoline derivatives. These results suggest that 1-(R),2-DiMeDHTIQ may be neurotoxic to dopamine neurons.

602.9

ELEVATION OF NEURONAL MAO-B ACTIVITY IN A TRANSGENIC MOUSE MODEL DOES NOT INCREASE SENSITIVITY TO THE NEUROTOXIN MPTP.

J.K. Andersen*, D.M. Frim, O. Isacson, M.F. Beal, and X.O. Breakefield, Neurology Service and Neurosurgery Service, Massachusetts Hospital, Charlestown, MA; Harvard Medical School, Boston, MA; and Neuroregeneration Laboratory, McLean Hospital, Belmont, MA.

To examine whether expressing high levels of monoamine oxidase (MAO-B) activity aberrantly in neurons results in increased sensitivity of dopaminergic neurons to the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 8 week old transgenic mice expressing high neuronal levels of MAO-B were compared with age-matched nontransgenic littermates following i.p. injections of 30 mg/kg body weight of the protoxin. Levels of striatal dopamine (DA) and its metabolite 3,4-dihydroxyphenylacetic acid (DOPAC), as well as tyrosine hydroxylase (TH)-immunopositive cell numbers in the substantia nigra (SN) were compared 1 week later between transgenics and controls. No difference was found in any of these parameters, indicating that high neuronal MAO-B levels does not cause increased sensitivity to MPTP, and therefore neither conversion of MPTP to its active form, 1-methyl-4-phenyl pyridium (MPP⁺) by MAO-B nor MPP⁺ uptake by the dopaminergic transporter are likely to be the rate-limiting step in the toxicity of this compound.

602.11

Adeno-associated virus (AAV) vectors yield safe delivery and long-term expression of potentially therapeutic genes in the adult mammalian brain M.G. Kaplitt^{1,*}, P. Leone², A. Freese³, X.Xiao⁴, D.W. Pfaff¹, K.L. O'Malley⁵, M.J. During². ¹The Rockefeller University, New York, NY. ²Yale University School of Medicine, New Haven, CT. ³University of Pennsylvania School of Medicine, Philadelphia, PA. ⁴University of North Carolina, Chapel Hill, NC. ⁵Washington University School of Medicine, St. Louis, MO.

AAV vectors are non-pathogenic, integrating DNA vectors in which all viral genes are removed and helper virus is completely eliminated. Previous gene transfer studies have used either recombinant viruses which retain viral genes or defective HSV vectors in which residual helper virus cannot be removed. To evaluate the AAV system in the post-mitotic cells of the mammalian brain, a vector containing the lacZ gene (AAVlac) was injected into rat striatum, hippocampus and substantia nigra. lacZ DNA and gene expression were detected up to 3 months post-injection. A second vector expressing human tyrosine hydroxylase (AAVth) was injected into the denervated striatum of unilateral 6-hydroxydopamine-lesioned rats. TH immunoreactivity was observed in striatal neurons and glia for up to 4 months. There was significant behavioral recovery in lesioned rats treated with AAVth versus AAVlac controls. A vector expressing both TH and aromatic acid decarboxylase (AADAC) has been created, and the efficacy of this vector in lesioned rodents in comparison with AAVth is under investigation. Safe and stable gene transfer into the denervated striatum may have potential for the genetic therapy of Parkinson's Disease.

602.8

NICOTINE PREVENTS EXPERIMENTAL PARKINSONISM IN RODENTS

F. Vaglini, F. Fascetti, F. Fornai*, R. Maggio, G.U. Corsini
Institute of Pharmacology, School of Medicine, University of Pisa, ITALY

We have demonstrated that diethyldithiocarbamate (DDC) enhances MPTP toxicity in mice. This combined treatment induces a more marked depletion of striatal dopamine (DA) and a severe loss of tyrosine hydroxylase (TH) positive perikarya in Substantia Nigra pars compacta (SNpc) (Corsini et al., Eur. J. Pharmacol.:119,127; 1985). This represents a reliable model of experimental parkinsonism in rodents on which neuroprotective molecules can be evaluated. For instance, it is now well established that non-competitive NMDA antagonists (MK-801, dextromethorphan) provide a complete protection on DDC enhancement of MPTP toxicity.

In the present study we used this model in order to evaluate the effect of nicotine, on experimental parkinsonism. (-) Nicotine (1mg/Kg, s.c.) administered three times (90 and 30 min before and 30 min after MPTP), completely prevented both the marked depletion of striatal dopamine and the severe loss of TH positive perikarya in SNpc induced by DDC+MPTP. Nicotine provided this protective effect without reducing striatal MPP⁺ levels measured at several time intervals after MPTP administration.

Despite previous contrasting findings, our data suggest that nicotine could be responsible of the reduced prevalence of Parkinson's disease among smokers.

AAV-MEDIATED TRANSFER OF TYROSINE HYDROXYLASE AND AROMATIC AMINO ACID DECARBOXYLASE GENES INTO THE PRIMATE BRAIN: A DIRECT GENE THERAPY APPROACH TO PARKINSON'S DISEASE

¹M.J. During*, ²M.G. Kaplitt Jr., ¹P. Leone, ⁴X. Xiao, ¹J.D. Elsworth, ¹R.H. Roth, ⁵J.R. Sladek, ¹D.E. Redmond Jr., ³K.L. O'Malley, ¹Yale Univ Sch Med, New Haven, CT 06520; ²Rockefeller Univ, New York, NY 10021; ³Wash Univ Sch Med, St Louis, MO 63110; ⁴UNC, Chapel Hill, NC 27599; ⁵Univ Hlth Sci/Chicago Med Sch, Chicago, IL 60604

AAV is a defective human parvovirus which has several major advantages for gene transfer in the CNS including non-pathogenicity, targeted integration and stable expression in post-mitotic cells including neurons (Kaplitt et al., Soc. Neurosci. Abstr., 1994). Moreover, AAV vectors are devoid of viral genes and a novel packaging method to generate helper-free stocks is established. This vector system may have application therefore for gene therapy of neurological disorders. The human tyrosine hydroxylase (form II) cDNA was truncated to 1.1 kb by deletion of the N-terminal regulatory region and a FLAG epitope added (FLAG-THA). FLAG-THA together with the human aromatic amino acid decarboxylase gene was packaged into AAV using the emc virus IRES sequence to form a bicistronic construct (AAVthIRESaadc). AAVthIRESaadc-transduced HEK 293t cells released dopamine into the medium at high concentrations (3.1±1 ng/10⁶ cells min⁻¹). AAVthIRESaadc was stereotactically injected into the partially denervated caudate of MPTP-treated African green monkeys. 10 days following injection, two animals were sacrificed and expression of the vector encoded TH was determined using a FLAG antibody. FLAG-IR neurons were observed around the injection sites. These data suggest that AAV can transduce neurons in the primate brain *in vivo*. If dopamine release can be increased by this strategy AAVthIRESaadc may have utility as a direct gene therapy approach to Parkinson's disease.

603.1

DEVELOPMENTALLY SPECIFIC RNA EDITING IN AMPA RECEPTOR SUBUNITS GluR-B, -C, -D. H. Lomeli¹, J. Melcher¹, J. Höger², A. Bach², G. Köhr^{1*}, M. Higuchi¹, B. Sprengel¹, H. Monyer¹ and P.H. Seeburg¹. Center for Molecular Biology¹ (ZMBH), University of Heidelberg, and BASF Inc.², Ludwigshafen, Germany

In glutamate-operated receptor channels of the non-NMDA type in central neurons several functionally critical channel residues not encoded by the genes for the channel subunits are introduced via nuclear RNA editing. This process operates on the primary gene transcripts to substitute single adenosines for guanosines. Positional selectivity and efficiency of RNA-editing appear to rest on a double-stranded RNA structure formed by the to-be-edited exonic sequence and a complementary sequence in the proximal intron [Higuchi et al., Cell 75, 1361; 1993]. Detailed cDNA analysis has now revealed that AMPA receptor subunits GluR-B, C and -D share a position either occupied by arginine (gene-encoded) or by glycine, the latter residue being introduced by site selective adenosine to guanosine RNA editing. As for the Q/R site editing of GluR-B, editing at this newly-identified site is mediated by an intronic sequence element present in the GluR-B, -C, and -D genes but is absent in the GluR-A gene. A PCR-supported analysis in brains of staged rats showed that RNA-editing at the new site progresses in extent from approximately 10% at E14 to >80% by P12. Furthermore, single-cell PCR analysis suggests that individual subunits expressed in one cell can be edited to different degrees.

603.3

REGULATION OF N-METHYL-D-ASPARTATE RECEPTOR SUBUNITS EXPRESSION IN CEREBELLAR NEURONS. B. Lambolez, E. Audinat, S. Charpak, J. Rossier* and F. Crépel. IAF CNRS, 91198 Gif/Yvette, France; Lab. Neurobio. CNRS, 91405 Orsay, France and Dpt. Physiol. CMU, 1211 Genève 4, Switzerland.

The N-methyl-D-aspartate (NMDA) subtype of glutamate receptors is an oligomer formed of different subunits named NR1 and NR2A, B, C and D the combination of which determines the channel functional properties. We have used rat cerebellar slice cultures to study the involvement of spontaneous activity and extracerebellar inputs on the changes of NR2A-C expression observed during the postnatal development of granule and Purkinje cells. The functional properties of the NMDA receptors and the expression of the NR2A-C mRNAs were correlated in single neurons by coupling patch-clamp recording and reverse transcription followed by PCR. Granule cells grown in standard culture conditions expressed mainly NR2A mRNAs when examined after 15 to 40 days in vitro. Consistent with this observation, their responses to NMDA were poorly reduced by 3 μ M ifenprodil, a non-competitive antagonist which discriminates NR2A and NR2B subunits in expression systems. The NR2C subunit, abundantly expressed in vivo by adult granule cells, was only rarely detected in slice cultures even when excitatory synapses were formed between granule cells and mossy fibers originating from co-cultured brainstem explants. In cerebellar cultures which had been chronically exposed to tetrodotoxin during 15 to 35 days in vitro to reduce spontaneous activity, granule cells expressed predominantly NR2B subunits (as it is the case only during the first two postnatal weeks in vivo) and their responses to NMDA were largely inhibited by 3 μ M ifenprodil. These results provide evidence that the expression of NR2A and B subunits is regulated through an activity-dependent mechanism leading to the formation of NMDA receptors with different pharmacological properties. Finally, in none of the experimental conditions described above, could we detect any NR2 subunit in Purkinje cells, although NR1 was consistently expressed. This was in agreement with the absence of NMDA responses.

GENERATION OF ANTIBODIES SPECIFIC FOR PHOSPHORYLATED NMDA RECEPTORS. W.G. Tingley and R.L. Huganir*. Department of Neuroscience, H.H.M.I., Johns Hopkins University School of Medicine, Baltimore, MD 21205.

A variety of neuronal processes, including synaptic plasticity, synaptogenesis, and excitotoxic neuronal damage, involve N-methyl-D-aspartate (NMDA) receptors. NMDA receptors in the brain are thought to be composed of multiple subunits, including at least one NR1 subunit and one or more NR2 subunits. A variety of studies have suggested that NMDA receptors are regulated by protein phosphorylation. We have shown previously that protein kinase C (PKC) directly phosphorylates NR1 near its C-terminus, in a region regulated by alternative splicing. For this study, we have generated multiple anti-phosphopeptide antibodies recognizing the NR1 protein only when it is phosphorylated. Immunocytochemical and immunoblot experiments with these antibodies indicate that cAMP dependent protein kinase (PKA), like PKC, phosphorylates NR1 near its C-terminus. However, PKA and PKC phosphorylate different serine residues within this region. In addition, phosphorylation in this region appears to regulate the subcellular distribution of NR1 protein expressed in HEK-293 cells. These antibodies should prove useful for monitoring the phosphorylation state of NR1 during a variety of neuronal processes, in vivo and in vitro, including the induction and maintenance of LTP in the hippocampus.

RNA EDITING AND Ca^{2+} PERMEABILITY OF THE HIGH-AFFINITY KAINATE RECEPTOR IN EMBRYONIC CHICK α -MOTONEURONS. D.Lowe* and D.O. Smith. Neuroscience Training Program, University of Wisconsin, Madison, WI 53706.

The high-affinity kainate (KA) receptor subunit GluR6 undergoes RNA editing at two sites in TM1 and at one site in TM2. To determine the extent of this editing in α -motoneurons, RT-PCR-generated cDNA encoding GluR6 from embryonic chick motoneurons and an embryonic chick cDNA spinal cord library were subcloned into M13mp18RF-DNA. In the recombinant plaques, the nucleotide sequences in the TM1 and TM2 regions were then determined. All (n=33) of the transcripts were fully edited. Since homomerically expressed GluR6 is more permeable to Ca^{2+} when fully edited, we measured motoneuron Ca^{2+} permeability during KA application in either high- Na^+ or high- Ca^{2+} extracellular solution and with intracellular Cs^+ . In whole-cell recordings, we found that 1-mM KA activated comparable currents in both solutions and that the reversal potential is more positive in the $\text{Ca}^{2+}/\text{Cs}^+$ solution than in the Na^+/Cs^+ solution. Edited GluR6 is expressed in these neurons, and AMPA (1-mM) does not activate Ca^{2+} permeability. We conclude, therefore, that the edited form of GluR6 may determine the Ca^{2+} permeability of KA receptors in chick motoneurons. Supported by NIH grant NS13600.

EFFICIENT FUNCTIONAL EXPRESSION OF NMDA RECEPTORS REQUIRES HETEROMERIC ASSEMBLY. A.M.J. VanDongen, M.W. Wood, and H.M.A. VanDongen. Dept of Pharmacology, Duke Univ Med Cntr, Durham NC27710.

NMDA receptors are ligand gated ion channels, thought to consist of five subunits surrounding a central ion conducting pore. The NR1 subunit forms functional homomeric channels following expression in *Xenopus* oocytes. The four isoforms of the NR2 subunit only form functional channels when co-expressed with NR1. In contrast, expression of NR1 subunits in mammalian cells (HEK293, CHO, PC12) does not result in functional channels. Also, NR1 mRNA is found at high levels throughout the brain, even in neurons which do not contain functional NMDA channels (i.e. cerebellar Purkinje cells). We have optimized expression levels of NMDA receptors by removing the 5' untranslated region (5'UTR) of the ϵ 1 cDNA clone, which encodes the mouse isoform of NR2A. Where expression of NR1 alone results in 50 nA of glutamate induced current (at -80 mV), co-expression of NR1 with this shortened cDNA construct (ϵ 1- Δ 5UT) resulted in 50 μ A of glutamate current, enhancing functional expression 1000-fold. The original full length ϵ 1 enhanced functional expression only 10-fold, suggesting that the 5'UTR hampers efficient translation of this NR2 subunit in oocytes. The absence of the 5'UTR also boosted the *in vitro* translation of ϵ 1 in a reticulocyte lysate system, where the shortened construct resulted in a much higher yield of a 180 kD protein. Western analysis using a NR1 specific monoclonal antibody demonstrated that the same amount of NR1 protein was present in oocytes expressing NR1 alone or NR1+ ϵ 1- Δ 5UT. This result rules out an effect of the NR2 subunit on the translation efficiency of NR1. Preliminary results using noise analysis suggested that the homomeric NR1 channels have a normal single channel conductance. Immunohistochemistry and protease protection assays are currently being used to determine the localization of NR1 subunits in homomeric and heteromeric assemblies.

Biochemical and Topological Analysis of the NMDA Receptor

Andreas K.E. Köpke, Silvia Correa, Sabine Sydow, Ines Bonk, and Joachim Spiess*. Max Planck Institute for Experimental Medicine, Molecular Neuroendocrinology, Hermann-Rein-Str. 3, 37075 Göttingen, Germany

We are interested in the structure function relationship of the NMDA receptor that is thought to be important in learning, memory and several neurological disorders. We want to analyze the properties of distinct subunit compositions by biochemical and electrophysiological methods in a defined artificial system.

Fourteen regio specific antibodies have been produced to characterize the NMDA receptor subunits NR1, NR2A and NR2C. Eight stable HEK 293 cell lines expressing single NMDA receptor subunits (NR1a, NR1b, NR2A and NR2C) or subunit combinations (NR2A/1a, NR2A/1b, NR2C/1a, NR2C/1b) were generated.

The double transfected cell lines showed distinct morphology and were sensitive to glutamic acid in the medium. We found a strong upregulation of NR1 protein expression when the NR2 protein was present, whereas the NR2 protein amount was similar in the presence or absence of NR1. In this defined artificial system, in which standard promoters are driving the receptor gene transcription, the observed upregulation should be posttranscriptionally. These findings could be explained by an increased degradation of single subunits or a translational regulation of NR1 protein expression.

The transmembrane topology of the NR2C subunit was investigated with antibodies specific for the N-terminal (NR2C-A), putative internal loop (NR2C-D) and C-terminal (NR2C-E) sequences. Anti NR2C-A and anti NR2C-E were able to detect the receptor protein on the surface of the NR2C or NR2C/1a transfected HEK293 cell lines. Anti NR2C-D stained the NR2C subunit only in punctured or Triton permeated cells. These results are direct experimental evidence that the four transmembrane domain model suggested first for the ionotropic glutamate receptor is correct. Models suggesting a cytosolic localization of the entire C-terminal domain are not in agreement with these results.

Another approach for the direct protein chemical characterization of the NR1b subunit is based on its overexpression in the baculovirus system. The recombinant protein is probably present in inclusion bodies and found at a concentration of approximately 1 mg per liter of culture medium.

TOPOLOGY OF GLUTAMATE RECEPTORS: NEW INSIGHTS FROM N-GLYCOSYLATION SITE EPI-TOPE-TAGGING. M. Hollmann, C. Maron, and S. Heinemann. Mol. Neurobiol. Lab., Salk Institute, La Jolla, CA 92037.

The transmembrane domain (TMD) topology of glutamate receptors (GluRs) is incompletely understood. Although GluRs are commonly modeled after the nicotinic acetylcholine receptor (nAChR), no direct evidence is available for the presumed four TMD model with extracellular N- and C-termini and an ion channel-forming TMD II, and even the assignment of the four hydrophobic domains has been debated (see Hollmann & Heinemann, *Annu. Rev. Neurosci.* 1994,17:31-108).

We set out to obtain experimental evidence for extracellular or intracellular localization of the various domains of the GluR1 protein expressed in *Xenopus* oocytes. We used site-directed mutagenesis to introduce N-glycosylation consensus sites (N-X-S or N-X-T) at various positions throughout the receptor protein. N-glycosylation sites were created in the N-terminal and C-terminal domains as well as in those domains located in between hypothetical TMDs. Mutant GluR1 proteins expressed by *Xenopus* oocytes were analyzed in SDS gel shift assays, for an increase in apparent molecular weight caused by the attachment of carbohydrate side chains. GluR1 was visualized on Western blots of SDS gels using polyclonal anti-GluR1 antisera (kindly provided by Bob Wenthold and Richard Huganir). Upward shifts of mutant receptors vs. wild type receptor were interpreted as evidence for the extracellular localization of the introduced N-glycosylation site.

The results of the gel shift assays demonstrate that the N-terminus of GluR1 is indeed extracellular as assumed in all models proposed to date, while the C-terminus is intracellular. Our data also indicate that the domain between TMD III and TMD IV, which generally was assumed to constitute a large intracellular loop, is actually extracellular. The topology in between TMD I and TMD III is currently under investigation.

IBOTENIC ACID ACTIVATES A Ca^{2+} MODULATED CHANNEL IN CEREBELLAR PURKINJE NEURONS. L. M. Nowak*, C. Pouloupoulou, H. Bao, and D. Paupardin-Tritsch. Dept. of Pharmacology, Cornell Univ., Ithaca, NY 14850.

Ibotenic acid acts as an ionotropic (NMDA and nonNMDA) and metabotropic excitatory amino acid agonist in vertebrate brain. In mouse cultured Purkinje neurons, cells which do not respond to NMDA, ibotenate evokes relatively small inward currents at negative membrane potentials compared to AMPA and kainate. In whole cell recordings ibotenate-activated currents were observed to increase in magnitude when the extracellular Ca^{2+} concentration ($[Ca^{2+}]_o$) was increased from 1 to 10 mM, suggesting that these channels are modulated by Ca^{2+} ions. To determine which of the nonNMDA channels might underlie this phenomenon, the effects of changing $[Ca^{2+}]_o$ on ibotenate-activated single channel currents were examined in outside-out patches from Purkinje neurons. Recording pipettes typically contained 140 mM CsCl, 4 mM ATP-Mg, 10 mM Hepes-K (pH 7.2) and 10 mM EGTA/1 mM Ca^{2+} , but occasionally 2 mM BAPTA/0.1 mM Ca^{2+} was used. In the standard extracellular solution (150 mM NaCl, 2.8 mM KCl, 1 mM $CaCl_2$, 10 mM Hepes-Na (pH 7.2)), ibotenate opened channels with slope conductances of ~20, 30 and 50 pS that reversed polarity near 0 mV. Of these, the 30 pS channel observed in more than 90% of patches from Purkinje cells, was studied in different $[Ca^{2+}]_o$ from 1 mM, to between 5 and 110 mM while substituting for Na^+ . In 5 mM $[Ca^{2+}]_o$ the open probability (P_o) of ibotenate channels increased 1.5 to 2-fold. Changing from 1 to 110 mM $[Ca^{2+}]_o$ (150 mM to 0 Na^+), P_o increased 6-fold at -60 mV with relatively little change in channel conductance, the result being between a 3.5 and 5.5-fold increase in the net flux through the channels. In time-averaged single channel records the mean current at -60 mV approximately doubled by increasing $[Ca^{2+}]_o$ from 1 to 10 mM; a similar result was obtained in whole cell recordings. These observations were made by increasing $[Ca^{2+}]_o$, however, the possibility remains that the increase in P_o is due to an increase in $[Ca^{2+}]_i$.

HETEROMERIC OLFACTORY CYCLIC NUCLEOTIDE-GATED CHANNELS: A NEW SUBUNIT THAT CONFERS INCREASED SENSITIVITY TO CAMP. J. Li, J. Bradley, N. Davidson, H. Lester*, and K. Zinn. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

One mechanism of olfactory signal transduction involves the opening of cyclic nucleotide-gated (cng) channels. Cng channels in rat olfactory neurons are activated by cAMP in the low μ M range and are outwardly rectifying. The previously cloned channel (rOCNC1), however, shows much lower cAMP sensitivity and very weak rectification when expressed in 293 cells. We have cloned another cng channel subunit (rOCNC2) from a rat olfactory epithelium cDNA library. rOCNC2 encodes a protein of 575 amino acids with 51% identity to rOCNC1. It does not form functional channels when expressed alone. When rOCNC2 is coexpressed with rOCNC1, however, the resulting conductance is characterized by an outward rectification stronger than that of rOCNC1; and by a cAMP sensitivity close to that of the native channel. Extracellular Ca^{2+} and Mg^{2+} block the inward current at rOCNC1 channels more strongly than at rOCNC1/rOCNC2. In divalent-free conditions, the openings of rOCNC1 channels are uninterrupted for tens of ms, while those of rOCNC1/rOCNC2 channels are flickery, especially at negative membrane potentials. This flickery behavior resembles the native channel. *In situ* hybridization demonstrates that the two subunits are coexpressed in olfactory receptor neurons. These results indicate that the native olfactory cng channel is likely to be heteromeric, and that the cng channels in olfactory neurons are structurally and functionally analogous to those in rod photoreceptors.

IDENTIFICATION OF A CaM-KINASE II REGULATORY PHOSPHORYLATION SITE IN NON-NMDA GLUTAMATE RECEPTORS. J.L. Yakel*, P. Vissavajhala, V.A. Derkach, D.A. Brickey & T.R. Soderling. Vollum Institute, OHSU, Portland, OR 97201.

Glutamate receptor (GluR) ion channels are colocalized in postsynaptic densities with CaM-kinase II, an enzyme which has previously been shown to phosphorylate and strongly enhance non-NMDA GluR currents in cultured rat hippocampal neurons (McGlade-McCulloh et al., 1993, *Nature* 362:640). We wanted to extend these findings by demonstrating the regulatory effect of CaM-kinase II on expressed non-NMDA (i.e. AMPA-type) GluRs, and to identify the regulatory site phosphorylated by CaM-kinase II. In this study, the intracellular application of activated CaM-kinase II into cultured mammalian 293 cells expressing GluR6 or into *Xenopus* oocytes expressing GluR1 enhanced the GluR current activated by kainate. This effect of CaM-kinase II was further investigated in the *Xenopus* oocyte/GluR1 system which gave a 1.5-fold increase in kainate current with no effect on the sensitivity of the receptor to kainate. When Ser627, which is located in the major intracellular loop of GluR1, was mutated to Ala, the expressed mutant no longer responded to the CaM-kinase II-induced enhancement of kainate current but was normal with respect to current-voltage relationship and kainate sensitivity. Since all non-NMDA GluR ion channels have a Ser in an analogous position, this regulatory phosphorylation site may be of general importance in enhancing postsynaptic responsiveness as occurs in long-term potentiation.

ODORANT INDUCED PHOSPHORYLATION OF INOSITOL 1,4,5-TRIPHOSPHATE RECEPTOR IN OLFACTORY RECEPTOR NEURONS. T. Ingi*, J.P. Steiner and G.V. Ronnett. Johns Hopkins University School of Medicine, Department of Neuroscience, Baltimore, MD 21205.

Both the cyclic adenosine 3', 5'-monophosphate and phosphoinositide second messenger systems are involved in olfactory signal transduction, which occurs in the cilia of olfactory receptor neurons. In olfactory receptor neuron, inositol 1,4,5-triphosphate (IP_3) receptor is located to the surface plasma membrane of olfactory cilia and plays roles in regulating calcium flux at the surface membranes. To explore its involvement in odorant signal transduction, the phosphorylation properties of IP_3 receptor were studied in cultured olfactory receptor neuron. Odorant remarkably enhanced IP_3 receptor phosphorylation with its peak at 2 minutes after its stimulation. Further exposure of odorants induce dephosphorylation to the previous level. This result indicates the modification of IP_3 receptor function in the late phase of odorant signal transduction. Dose-response curve revealed the maximal odorant effect at the concentration of 100 nM. These results may provide a mechanism whereby desensitization occurs in odorant perception.

ELECTROPHYSIOLOGICAL PROPERTIES OF LIGAND-GATED ATP RECEPTOR IN RAT AUTONOMIC NEURONES AND VAS DEFERENS SMOOTH MUSCLE. A. Surprenant*, B. Khakh and C. Gill. Glaxo Institute for Molecular Biology, Geneva, Switzerland, CH 1228

P2X purinoceptors exist in autonomic neurones and many vascular and visceral smooth muscle where they can mediate fast synaptic transmission by activating a cationic receptor-channel complex. We used whole-cell recording techniques to compare properties of this receptor in rat nodose and SCG neurones as well as in isolated rat vas deferens smooth muscle. Fast-flow application (0.5 - 2 s duration) of ATP, $\alpha\beta$ meATP and 2MeSATP evoked rapid inward currents in all cells; marked desensitization of the current was observed in smooth muscle but not in neurones. Calcium permeability was significant in vas deferens and nodose neurones ($PCa/PNa = 5$) but minimal in SCG neurones. Inward rectification of the current was observed in all cells but was most pronounced in vas deferens and SCG. In all neurones, agonist potency was 2MeSATP \geq ATP $>$ $\alpha\beta$ meATP. Half-maximal effective concentration (EC50) of ATP was about 1 μ M for nodose and vas but 40 μ M for SCG; $\alpha\beta$ meATP was a full agonist in nodose (EC50 = 3 μ M) but acted as a partial agonist in SCG. Properties of the ATP response in nodose and vas deferens are very similar those observed for the P2X receptor recently cloned from rat vas deferens (Valera et al., this meeting). The different pharmacological and physiological properties of the ATP response in SCG neurones suggests the presence of a distinct receptor subtype.

603.13

STIMULATION OF [³H]SEROTONIN RELEASE IN THE CEREBRAL CORTEX VIA NMDA AND NON-NMDA RECEPTORS AND INTERACTION WITH PRESYNAPTIC INHIBITORY AUTO- AND HETERORECEPTORS. M. Göthert*, K. Fink, C. Böing and V. Schmitz. Inst. Pharmacol. Toxicol., Univ. Bonn, Reuterstrasse 2b, 53113 Bonn, Germany.

The aims of the present investigation were to provide evidence that in rat and guinea-pig cerebral cortical slices, [³H]serotonin ([³H]5-HT) release can be stimulated via glutamate receptors of the NMDA and non-NMDA type and that this release is modulated via presynaptic auto- and heteroreceptors. The slices were preincubated with [³H]5-HT in the presence of maprotiline (in order to avoid false labeling of noradrenergic neurons) and superfused with Krebs' solution (Mg²⁺-free in the experiments with NMDA). NMDA (0.1-1 mM) stimulated the overflow of [³H]5-HT from slices of both species in a manner sensitive to blockade by 0.3 µM tetrodotoxin (TTX), 1.2 mM Mg²⁺, 3-100 µM CGP 37849 (DL-(E)-2-amino-4-methyl-5-phosphono-3-pentanoic acid; a competitive NMDA receptor antagonist), 100 nM dizocilpine, 10-100 µM 5,7-dichlorokynurenic acid, 100-300 µM arcaine and 0.1-1 µM ifenprodil. Kainic acid (KAI; 0.01-1 mM) also stimulated [³H]5-HT overflow. The KAI-evoked overflow in the presence of 1.2 mM Mg²⁺ was not affected by CGP 37849 and arcaine, but was inhibited by 0.3 µM TTX and 100 µM CNQX (6-cyano-7-nitroquinoxaline-2,3-dione; an antagonist of non-NMDA receptors). 5-Carboxamidotryptamine (1-100 nM; a 5-HT₁ receptor agonist) and norepinephrine (1 and 10 µM) inhibited the NMDA-evoked overflow; these responses were antagonized by the 5-HT receptor antagonist methiothepin and the α₂ receptor antagonist idazoxan, respectively, which given alone facilitated [³H]5-HT overflow. The A₁ purinoceptor antagonist DPCPX (10 nM; 8-cyclopentyl-1,3-dipropylxanthine) also increased the overflow. In conclusion, 5-HT release in the cerebral cortex is stimulated by NMDA and non-NMDA receptors. The NMDA-evoked release is modulated via presynaptic 5-HT, α₂ and A₁ receptors which under the conditions applied are activated by the endogenous agonists.

α₂-ADRENERGIC INHIBITION OF CALCIUM CURRENTS IN CHICK SYMPATHETIC NEURONS INVOLVES PHOSPHOLIPASE A₂ AND ATYPICAL PROTEIN KINASE C. S. Boehm*, S. Huck, M. Freissmuth. Depts. of Neuropharmacology and Pharmacology, University of Vienna, Wahringerstrasse 13a, A-1090 Vienna, Austria.

Autoinhibitory regulation of noradrenaline release from chick sympathetic neurons depends on α₂-adrenergic inhibition of N-type calcium channels via pertussis toxin-sensitive G_{o/i} proteins. The present study investigates the signalling cascade between G proteins and calcium channels.

A role of protein kinase C (PKC) in neurotransmitter modulation of calcium channels is generally indicated by transmitter-analogous effects of phorbol esters or diacylglycerol analogues. However, neither 4β-phorbordibutyrate (PDB, 3 µM) nor oleoylacylglycerol (OAG, 30 µM) affected whole-cell calcium currents (I_{Ca}). Nevertheless, inclusion of a pseudosubstrate peptide inhibitor of PKC (PKCI 19-36, 10 µM) in the pipette progressively reduced the inhibitory action of the α₂-adrenergic agonist bromoxidine (10 µM) upon I_{Ca}. When neurons were dialyzed with PKCI for 10 min, the bromoxidine inhibition was 6.8% (n=7) as compared to 32.7% (n=9) under control conditions. This effect of PKCI was specific for PKC as neither an inactive analogue peptide nor a peptide inhibitor of protein kinase A impaired the α₂-adrenergic reduction of I_{Ca}. The PKC inhibitors staurosporine (1 µM) or calphostin C (1 µM) reduced the α₂-adrenergic inhibition of I_{Ca}, but neither a 24h pretreatment with PDB nor acute application of PDB altered the bromoxidine effect, observations consistent with a role of atypical PKCs. At least one of these phorbol ester- and OAG-insensitive, but fatty acid-stimulated isoforms was detected by immunoblots, namely PKC δ.

Accordingly, arachidonic acid (AA) and linoleic acid (100 µM) diminished I_{Ca} in a partially reversible manner by 52.9% and 30.7% (n=6), respectively, and intracellular PKCI reduced these values of inhibition to 23.3% and 14.2% (n=6). Moreover, application of AA (30 µM) occluded a subsequent inhibition of I_{Ca} by the α₂-agonist bromoxidine. In order to identify a role of endogenous AA, cellular lipids were analyzed by thin layer chromatography after incubating neurons with [³H]AA. These experiments revealed a bromoxidine-induced AA formation, and 7,7-dimethyl-(5,8)-eicosadienoic acid (10 µM), an inhibitor of phospholipase A₂ (PLA₂), reduced the inhibition of I_{Ca} by bromoxidine.

Our results delineate the following signalling cascade in chick sympathetic neurons: α₂-adrenoceptor → G_{o/i} → PLA₂ → atypical PKC (possibly PKC δ) → N-type Ca²⁺ channels.

THE G PROTEIN, G₁₃, MEDIATES INHIBITION OF VOLTAGE DEPENDENT-CALCIUM CURRENT BY BRADYKININ. M.A. Wilk-Blaszczak*, W.D. Singer, S. Gutowski, P.C. Sternweis and F. Belardetti. Dept. of Pharmacol. Univ. of Texas Southwestern Med. Center, Dallas, TX, 75235.

In neuroblastoma x glioma hybrid cells (NG108-15) bradykinin (BK) has dual modulatory effects on ionic currents, it activates a K⁺ current, I_{K,BK}, and inhibits I_{Ca,V}. Both actions are mediated by pertussis toxin (PTX)-insensitive G proteins. Two antisera, raised against peptides representing the C-termini of the α subunits of G_{q/11} and G₁₃, recognized polypeptides of the expected size in membranes from NG108-15 cells. In whole-cell patch-clamp recording, intrapipette perfusion of the antibodies against G_{q/11} blocked only activation of the I_{K,BK}, suggesting that at least two distinct G protein pathways transduce the effects of this transmitter (Neuron 12, 109, 1994). In contrast, the anti-G₁₃ antibodies attenuated inhibition of I_{Ca,V} by BK by 76% (n=22). Perfusion of non-immune serum (n=30), and antibody preincubated with the antigenic peptide (n=9), did not affect the action of BK. The same antibody was also without any effect on inhibition of I_{Ca,V} by Leu-enkephalin (n=10) and activation of I_{K,BK} by BK (n=11). G₁₃ may play a general role in PTX-insensitive inhibition of I_{Ca,V}.

604.2

ACTIVATION OF PKC SELECTIVELY UP-REGULATES BOTH α_{1E} AND α_{1B} CALCIUM CHANNELS. A. Stea*, T.W. Soong, S.J. Dubel, W.J. Tomlinson, and T.P. Snutch. Biotechnology Laboratory, University of British Columbia, Vancouver, B.C., V6T 1Z3.

The modulation of Ca channels plays critical roles in a number of physiological processes. We have tested the effects of Protein Kinase C (PKC) activation on four classes of cloned neuronal calcium channels. Activation of endogenous PKC in *Xenopus* oocytes by application of phorbol esters (PDBu and/or PMA) caused a pronounced increase in the Ba currents from expression of the α_{1B} (N-type) and α_{1E} (Soong et al., Science 260: 1133-1136) calcium channels. In contrast, both the α_{1C} (L-type) and α_{1A} (Q-type) channels were unaffected by PKC stimulation. Application of 100 nM PMA to oocytes expressing either α_{1E} or α_{1B} caused a rapid (within 2-5 min) increase in the whole-cell Ba current to between 125 and 150% of control levels. There appeared to be no significant shift in the voltage dependent properties of the Ba currents up-regulated by PMA. The increase in the Ba current during PMA application was blocked by the addition of the PKC inhibitor staurosporine (5 - 10 µM) and was prevented by the addition of the inactive form of PMA (4-α-PMA). The increase in current due to PKC activation was dependent upon coexpression of the α₁ subunits with a β subunit. Up-regulation of the Ba current was prevented by the chelation of intracellular calcium by injection of BAPTA (2-5 mM final conc.). In addition to the increased whole-cell current, a pronounced slowing of inactivation of α_{1E} was observed with PMA application. These results provide direct evidence for the selective modulation of α_{1E} and α_{1B} calcium channels by PKC and support the notion that the differential regulation of Ca channels may play a significant role in neuronal excitability.

604.4

UP- AND DOWN REGULATION OF P-TYPE CA²⁺ CHANNELS BY TWO DIFFERENT METABOTROPIC GLUTAMATE RECEPTOR SUBTYPES. Y.M. Lu and T. Knöpfel. Department of Molecular and Cellular Biology, CNS Research, Ciba, CH-4002 Basle, Switzerland

P-type Ca²⁺ channel activity in rat cerebellar Purkinje cells was enhanced by quisqualate and (1S,3R)-1-aminocyclopentane-1,3-dicarboxylic acid ((1S,3R)-ACPD) and decreased by L-2-amino-4-phosphonobutyric acid (L-AP4). Enhancement of w-Aga-IVA-sensitive inward current by 5 µM quisqualate (6 of 9 cells) and by 50 µM (1S,3R)-ACPD (6 of 8 cells) averaged 34.3 ± 9.3 % and 22.0 ± 8.1 %, respectively. The maximal inhibition by L-AP4 amounted to ~ 42 % (18 of 18 cells) and a half maximal inhibition (EC₅₀) was obtained at 48.5 ± 14 µM.

This modulation of P-type Ca²⁺ channels required the presence of either GTP or GTPγS in the internal solution and were irreversible when using GTPγS. These results show that activation of metabotropic glutamate receptors can modulate P-type Ca²⁺ channels through a G-protein-mediated mechanism. The agonist profile together with available data on the expression pattern of mGluRs in Purkinje cells suggests that the enhancement and depression of P-type Ca²⁺ channel activity are mediated by subtype mGluR1 and subtypes mGluR4/7, respectively.

604.5

CALCIUM CHANNEL MODULATION BY LECTINS. A. Golard⁺. Howard Hughes Medical Institute, Columbia Univ. P&S, New York, NY 10032

Calcium currents were measured in dissociated chick sympathetic ganglia using the whole cell patch clamp technique. Lectins (1 μ M) were applied by local superfusion. All lectins tested reversibly inhibited Ca currents. Two types of inhibition were observed: a speeding of inactivation (SI) and a voltage-dependent inhibition (VDI) with slowing of the activation kinetics. When GTP- γ -S is substituted for GTP, VDI is irreversible, while SI is still reversible. GDP- β -S largely suppresses VDI, but has little effect on SI. These results indicate that G-proteins are involved in VDI, not SI. Thus, VDI may be due to activation of G-protein-coupled receptors, while SI may be a direct effect on the channel. Lectins with high affinities for N-acetylglucosamine or α -D-glucose preferentially induce VDI, while lectins with α -D-galactose affinity produce SI. Differential effects of concanavalin-A and succinyl-Con-A indicate that SI may be due to capping.

LEMS IgG DECREASES AND ALTERS Ca²⁺ CURRENTS IN MOUSE MOTOR NERVE TERMINALS. D.O. Smith*, M. Conklin, P. Jensen, and W.D. Atchison. Dept. of Physiology, University of Wisconsin, Madison, WI 53706 and Dept. of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Lambert-Eaton Myasthenic Syndrome (LEMS) is an autoimmune neuromuscular disorder that results in decreased release of ACh, presumably due to disrupted function of motor-nerve Ca²⁺ channels. To determine the direct effect of LEMS autoantibodies on Ca²⁺ currents (I_{Ca}) in mammalian motor nerve terminals, we measured presynaptic I_{Ca} in mouse diaphragm during phrenic nerve stimulation. Mice were injected daily for 30 days with 1.5 ml of serum derived from patients with LEMS or from disease-free individuals. As expected for LEMS, curarized end-plate currents (EPCs) elicited at 20 Hz were not depressed, while those evoked at 40 Hz were facilitated. EPCs from control mice were depressed during repetitive stimulation. At 0.5-Hz stimulation, I_{Ca} was $57 \pm 14\%$ ($n=10$) less in LEMS mice, but no differences were seen at frequencies ≥ 2 Hz. Nifedipine, which normally has no effect on I_{Ca} at mammalian motor nerve terminals, blocked I_{Ca} in the LEMS-treated animals, but ω -conotoxin GVIA reduced I_{Ca} by $41 \pm 13\%$ ($n=10$) in control animals only. We conclude that LEMS serum alters the normal characteristics of the channels, thus decreasing I_{Ca} and rendering them dihydropyridine sensitive. Supported by NIH grant ES05582.

ROLE OF TWO PUTATIVE ENDOGENOUS NEUROMODULATORS DBI 17-50-TTN AND ANANDAMIDE IN THE REGULATION OF Ca²⁺ INFLUX IN IMMUNOCOMPETENT CELLS. A. Berkovich*, A. Guidotti, E. Costa, FGIN, Georgetown Univ., Washington D.C. 20007.

Macrophages (MP) and monocytes (MC) express peripheral type receptor for both benzodiazepines (PBR) and cannabinoids (PCR). TTN (DBI 17-50), a processing product of rat Diazepam Binding Inhibitor (DBI) and 4'-chlorodiazepam (4'CD), a PBR specific ligand, have been reported to increase the level of cytokines, INT-1 β and TNF- α and their mRNAs in MP and MC cells[1]. Anandamide, an endogenous cannabinoid receptor ligand acts as an antiinflammatory and immunosuppressive agent[2]. Here we studied whether TTN, 4'CD and anandamide, acting on their specific receptors, regulate Ca²⁺ transport through the plasma membrane of rat lymphocytes and mouse macrophage cell line (ANA-1).

We have investigated whether storage regulated Ca²⁺ channel function that is stimulated by depletion of Ca²⁺ intracellular stores is controlled by PBR or PCR. This was assessed by Fura-2 fluorescence quenching with Mn²⁺ in cell with depleted Ca²⁺ stores by a 30 min preincubation in Ca²⁺ free medium. Incubation with TTN and anandamide resulted in inhibitory action on Ca²⁺ influx. However the inhibitory potency of TTN and 4'CD (full inhibition at 1 μ M) was lower than that of anandamide (full inhibition at 50nM). These results suggest that PBR and PCR agonists can inhibit Ca²⁺ influx in immunocompetent cells and thereby modify their genomic expression.

MODULATION OF CALCIUM CHANNELS AND CONTRACTION BY EXTRACELLULAR HEPARIN IN FROG SKELETAL MUSCLE FIBERS.

J.A. Sanchez*, M.C. Garcia, H. Cruzblanca, J.M. Farias and M. Martinez. Department of Pharmacology, CINVESTAV-IPN, A. P. 14-740, Mexico D.F. 07000.

Heparin binds with high affinity to the DHP receptor of skeletal muscle (Knaus et al. JBC, 265:156, 1990). Our experiments investigate the action of heparin on isometric tension, Ca signals, DHP-sensitive Ca currents (I_{Ca}) and charge movement. **Methods:** 1.- Single muscle fibers from frog (*Rana montezumae*). Cells were loaded with Rhod 2 AM (2-10 μ M) and fluorescence signals were obtained with a photodiode. Tension was simultaneously measured. 2.- Voltage-clamp experiments in cut fibers using the triple Vaseline gap technique. **Results:** Heparin (100 μ g/ml) reversibly potentiates twitch, tetanic tension and Ca signals by ca. 50%. Heparin blocks I_{Ca} movement by 30% and shifts the current-voltage relation towards more negative potentials by 15 mV. Heparin makes activation of I_{Ca} more rapid at all potentials and slows down the deactivation during tail currents. Double pulse experiments indicate that the kinetics of I_{Ca} is dependent on the frequency of stimulation as shown by others. Heparin further accelerates this process. Half-time of activation increases by 13 ms during the second pulse in control experiments and by 22 ms in the presence of heparin. Heparin blocks charge movement by 30 %. These results suggest that the potentiating effect of heparin may be related to the kinetic effects on Ca channels in skeletal muscle.

EVIDENCE FOR ALTERED REGULATION OF NEURONAL CALCIUM SIGNALLING IN DIABETES MELLITUS J.W. Wiley*, K.E. Hall, and B. Dzwoonek. Div. of Gastroenterology, Dept. of Int. Med., U. of Michigan, Ann Arbor, MI 48109.

We have previously shown that diabetes mellitus (DM) is associated with increased high-threshold, voltage-activated calcium currents in dorsal root ganglion (DRG) neurons (Soc. Neurosci. 19: 1762, 1993). In the present study we examined the possibility that calcium regulation is altered in capsaicin-sensitive DRG neurons. Two groups of Wistar Bio-Bred (BB) rats were used: i) adult male non-diabetic controls (C), and ii) matched diabetics (D), DM duration 12-32 wks treated with insulin to maintain serum glucose 350-450 mg%. Studies were performed on acutely dissociated DRGs. Cytosolic calcium ($[Ca^{2+}]_i$) was measured using the Fura-2 method in 20-35 μ m neurons. KCl (50 mM) caused a significantly ($p < 0.05$) greater increase in $[Ca^{2+}]_i$ in D (basal 42 ± 3 nM; post KCl 162 ± 12 nM; $n=12$) than C (basal 35 ± 5 nM; 84 ± 15 nM; $n=8$). Capsaicin (Cap; 1 μ M) also increased $[Ca^{2+}]_i$ to a significantly greater degree in D (133 ± 15 nM; $n=17$) than C (78 ± 13 nM; $n=17$). Approximately 80% of neurons responded to Cap. Treatment with the kappa opioid agonist dynorphin A (Dyn A; 1 μ M) reduced the KCl-mediated increase in $[Ca^{2+}]_i$ by 73% and 33% in C and D respectively ($n=8$, $p < 0.05$), an effect which was pertussis toxin-sensitive. High-threshold calcium currents were recorded in comparably-sized cells, using the whole cell variant of the patch-clamp method. Currents were evoked from a holding potential of -80 mV to a clamp potential of 10 mV. Dyn A (1 μ M) followed by 10 μ M ω -Conotoxin GVIA (ω -CgTX, N-type antagonist) were administered by pressure ejection from blunt pipettes. The percentage inhibition of peak calcium currents caused by Dyn A was significantly less in D ($8 \pm 2\%$; $n=10$) than C ($25 \pm 5\%$; $n=11$; $P < 0.05$). ω -CgTX decreased C currents by $49 \pm 3\%$, D by $26 \pm 6\%$. Following ω -CgTX, no further inhibition by Dyn A was observed (C $6 \pm 5\%$; D $5 \pm 5\%$); therefore, the decrease in the effect of Dyn A was not simply due to a decrease in the proportion of N-type current. These results suggest that inhibitory G protein modulation of calcium channels may be decreased in DM, resulting in enhanced calcium influx during depolarization.

STATE-DEPENDENT MODULATION OF NEURONAL CALCIUM CURRENTS A. Sculptoreanu, A. Figurov, W.C. de Groat*, Dept. of Pharm., Univ. Pittsburgh, Pittsburgh, PA. & Div. of Urology, Lady Davis Institute for Med. Res., SMBD-Jewish General Hospital, McGill Univ., Montreal, Quebec.

Neuronal calcium currents were studied in primary cultures of major pelvic (MPG) and dorsal root (DRG) ganglia from the adult rat using patch clamp techniques. We reported previously that synaptic transmission and neuronal integration may depend on state-dependent modulation of calcium channel function and the degree of cAMP-dependent kinase activity. The aim of this project was to further characterize the mechanism of state-dependent modulation of calcium channels. Neurons isolated from the MPG's express predominant dihydropyridine-sensitive, L-type calcium channel currents that are enhanced by 8Br-cAMP, whereas neurons isolated from DRG's express large ω -conotoxin sensitive, N-type calcium channel currents that are depressed by 8-Br-cAMP. The state-dependent modulation of L-type calcium channels by concurrent voltage dependent activation and phosphorylation of the channels predicts that they would be facilitated by high frequency, short duration stimuli. To test this hypothesis we compared the effect of a single 200 ms conditioning pulse and trains of 5 ms pulses at frequencies 10, 20, 50, 100 and 200 Hz also 200 ms in duration. A clear frequency dependence of L-type calcium channel facilitation could be demonstrated in MPG neurons. In DRG neurons, predominant N-type calcium channels were inhibited although in some neurons L-type calcium channels were unmasked. We propose that potentiation of neuronal calcium channel currents is due to state-dependent phosphorylation and may contribute to the facilitation of transmitter release after high frequency nerve discharges. This type of facilitation may be involved in the enhanced neural control of urogenital function by MPG pathways in pathological conditions such as spinal cord injury. (Support from JGF to AS and AF and skillful assistance of Ms. V. Dumitru is acknowledged.)

MODE SHIFT OF N-TYPE Ca^{2+} CHANNEL BY THE AUXILIARY SUBUNITS α_2 AND β Minoru Wakamori* and Yasuo Mori Dept. of Pharmacol. and Cell Biophys., Univ. of Cinti., Cinti, OH 45267-0575

ω -Conotoxin-GVIA-sensitive N-type channels are inhibited by various neurotransmitters. Modulation is probably mediated by G-proteins which alter equilibrium among diverse functional behaviors. To gain a clear structural insight into functional diversity of N-type channels, we have investigated the electrophysiological properties of recombinant N-type channels composed of various combinations of the pore-forming subunit α_1 (BIII) and the two additional subunits, α_2 and β , in *Xenopus* oocytes. Whole-cell measurements in 40mM Ba^{2+} showed that the BIII α_1 subunit alone elicited ω -conotoxin-sensitive HVA Ba^{2+} current, with a time-to-peak (t_p) and decay time constant (τ_b) of 16 and 215ms, respectively, at +20 mV. Modulation of the BIII channel kinetics by β subunits was strikingly different from that observed for the L-type channels, i.e., both t_p and τ_b are increased in BIII (21 and 477ms) but decreased in L-type. The β subunits shifted the current-voltage relationship in a hyperpolarizing direction by 8mV as was observed for the L-type channels. Surprisingly, the effects of the α_2 subunit contrasted with and antagonized the effects of the β subunits ($t_p=9$ and $\tau_b=144$ ms for BIII+ α_2 ; $t_p=10$ and $\tau_b=248$ ms for BIII+ $\alpha_2\beta$). Single channel analysis revealed different patterns of opening for BIII, BIII+ α_2 , BIII+ β , and BIII+ $\alpha_2\beta$, suggesting that different subunit combinations of calcium channel complexes give rise to different modes of gating dependent upon the association/dissociation of the subunits.

VISUAL SYSTEM DEVELOPMENT AND PLASTICITY

DEVELOPMENT OF DIRECTIONAL SELECTIVITY IN TURTLE RETINA: PHYSIOLOGY AND MODEL. N.M. Grzywacz* and E. Sernagor. Smith-Kettlewell Inst., 2232 Webster St., San Francisco, CA 94115.

Directional selectivity requires a spatially asymmetric mechanism to mediate the larger responses to preferred- than to null-direction motions. What developmental processes mediate the breaking of symmetry in the retina? To study this development, we recorded extracellularly from turtle retinal ganglion cells during embryogenesis (Stages 22-26), the first 40 days post-hatching, and in adults. In particular, recordings were made of the spontaneously recurring bursts of spikes in immature retinas and of the responses to edges of light moving in sixteen directions. The bursts occurred from Stage 22 until 2-4 weeks post-hatching. Light responses began at Stage 23, and early on, polar plots of the responses to motion were highly anisotropic, including orientation and directional selectivity. However, orientation selectivity reached a peak incidence at hatching, while directional selectivity disappeared only to reappear in adults (after 40 days post-hatching). Receptive-field sizes and the incidence of isotropic cells stabilized 2-4 weeks post-hatching.

We built and tested with computer simulations a biophysical model to account for the development of directional selectivity. In this model, the early anisotropy of the retina reflects immature, polarized dendritic layout, with directional selectivity being incidental to the dendrites' cable properties. As dendritic processes grow and branch, embryonic directional selectivity disappears, but orientation selectivity is maintained by a Hebbian process, which reinforces some of the early anisotropy. Later in development, the emergence of a specialized inhibitory synapse onto the dendritic inputs to some orientationally selective cells, transforms them onto weak directionally selective cells, which are then reinforced by a Hebbian process.

In conclusion, the increase in dimensions of dendritic trees, their degree of polarization, and the spontaneous bursts of spikes do not appear to account directly for the development of directional selectivity. Rather, it seems to require visual experience and/or the late establishment of a specialized inhibitory synaptic drive.

AXONAL BRANCH DYNAMICS: AN *in vivo* EXAMINATION OF THE APPLICABILITY OF HEBB'S HYPOTHESIS TO AXON MORPHOLOGY. S. Witte* and H.T. Cline. Dept. of Physiology, University of Iowa, Iowa City, IA and Cold Spring Harbor Labs, Cold Spring Harbor, NY.

We sought to examine the possibility that there is a structural correlate to Hebb's hypothesis. A high degree of dynamism, or addition and retraction of branches, occurs in retinotectal arbors in the developing frog as these arbors seek to establish and maintain contacts with topographically appropriate targets. The refinement of retinotectal topography can be blocked by interfering with NMDA receptor activation. One mechanism for the refinement of the topography may be that temporally correlated inputs from neighboring ganglion cells activate the NMDA receptor, and this activation leads to the structural stabilization of the branches on which these synapses are located. Branches having synapses with uncorrelated activity would not be stabilized and these structures would be broken down.

We examined the role of NMDA receptor activation in branch stability by 1) using APV to block NMDA receptor activation, and 2) exposing animals to strobe lighting to produce universally correlated activity. Single DiI labeled retinotectal axons were imaged in living *Xenopus laevis* tadpoles using a Noran laser scanning confocal microscope. After taking an initial image, tadpoles either swam in control solution, 100 μM APV solution, or control solution with strobe lighting. Four more images were taken at half hour intervals while the treatments continued.

Treatment with 100 μM APV caused a 33% increase in the total number of new branches normalized for initial branches ($n=10$, $p=0.057$). Branch retractions and final branch numbers tended to be greater in the APV treated group. Strobe treatment did not affect total branch additions or retractions, but there was a trend toward increased branch lifetime, i.e. branches that first appeared at the second observation did not retract as quickly in the strobe treated group. Increased branch additions in APV treated arbors may indicate that these arbors are less stable, while activation of the NMDA receptor appears to have increased arbor stability.

FUNCTIONAL COUPLING OF N-TYPE CALCIUM CHANNELS AND CALCIUM ACTIVATED POTASSIUM CHANNELS IN NEURONS. P. Sah* The Neuroscience Group, Department of Physiology, Faculty of Medicine, University of Newcastle, Newcastle, NSW 2308, AUSTRALIA

It has previously been shown that neurones of the dorsal motor nucleus of the vagus (DMV) express voltage-gated calcium and sodium channels. Calcium influx during the action potential leads to a long lasting afterhyperpolarisation (AHP) which regulates the discharge frequency of these neurones. In this study I have examined the properties of the calcium current supplying calcium to activate the AHP in these neurones. Whole cell recordings were made from DMV neurones in transverse slices of rat brainstem. Calcium currents were measured by using Cs^+ as the main internal cation, blocking sodium currents with tetrodotoxin (1 μM) and using barium (2.5 mM) as the permeant cation. Calcium current(s) were activated when the neurone was stepped to membrane potentials more positive than -50 mV from a holding potential of -60 mV. There was no evidence for a low voltage activated calcium current (T-type). The calcium current had a smooth current-voltage relation and was completely blocked by cadmium (100 μM) and nickel (1 mM) ions. Approximately 40 % of the calcium current was blocked by ω -conotoxin (200 nM), about 20 % of the current was blocked by high concentrations of nifedipine (10 μM). The remaining current was effectively blocked by cadmium. The calcium current was insensitive to agatoxin (250 nM). In current clamp, application of ω -conotoxin slowed action potential repolarisation and blocked 70% of the calcium-activated potassium current underlying the AHP. The remaining current was blocked by cadmium. Nifedipine has no effect on the action potential or the AHP. These experiments indicate that in DMV neurones N-type calcium channels are preferentially coupled to the calcium-activated potassium channels underlying the AHP. These channels are known to be SK-type calcium-activated potassium channels and are thought to be located close to the calcium channels which supply calcium ions for activating them (J. Neurophysiol. 68,2237). Thus, N-type calcium channels are co-localised with SK-type calcium-activated K channels in DMV neurones.

605.2

ROLE OF EARLY SPONTANEOUS ACTIVITY AND VISUAL EXPERIENCE IN SHAPING COMPLEX RECEPTIVE FIELD PROPERTIES OF GANGLION CELLS IN THE DEVELOPING RETINA. E. Sernagor* and N.M. Grzywacz. Smith-Kettlewell Eye Research Institute, San Francisco, CA 94115.

Receptive field properties of adult retinal ganglion cells are well documented, but little is known about their development.

To study how such properties develop, extracellular recordings of activity from turtle retinal ganglion cells were made during embryogenesis (Stages 22-26), the first 40 days post-hatching (PH), and in adults. From Stage 23, the cells fired in spontaneous recurring bursts and responded to light. Polar plots of the responses to motion were highly anisotropic in early embryonic cells (including orientation and immature directional selectivity). More than 40% of embryonic cells exhibited multi-axes anisotropy, and only 6% were statistically isotropic. The incidence of the anisotropic cells gradually decreased throughout development. The incidence of isotropic cells and the excitatory receptive field diameters of all ganglion cells gradually increased during development and their maturation coincided with the disappearance of the spontaneous bursts, at 2-4 weeks PH, when hatchlings were raised in normal light conditions.

If, on the other hand, hatching turtles were deprived of visual experience, all ganglion cells remained spontaneously active, at least during the first month PH (they were not investigated beyond that period). At the same time, their excitatory receptive field areas expanded by 82%. Responses to motion of these dark-reared ganglion cells were 30% more isotropic than in normal hatchlings.

These results show that mature spatio-temporal receptive-field properties of retinal ganglion cells emerge from initially highly anisotropic properties, which may reflect an immature, polarized dendritic layout. Embryonic spontaneous bursts and visual experience seem to play opposite roles: spontaneous activity may induce and constantly stimulate dendritic outgrowth in the developing retina, whereas exposure to light first accelerates and then terminates these processes.

INHIBITION OF NITRIC OXIDE SYNTHASE DISRUPTS ON/OFF SUBLAMINATION IN THE FERRET LATERAL GENICULATE NUCLEUS. K. S. Cramer* and M. Sur. Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Retinogeniculate axons in the ferret segregate into eye-specific layers during the first two postnatal weeks. Axons from on-center or off-center retinal ganglion cells further segregate into sublaminae by four postnatal weeks in a process dependent on postsynaptic NMDA receptors (Hahn et al., *Nature* 351: 568, 1991). During this period, the lateral geniculate nucleus (LGN) of the ferret transiently expresses NADPH-diaphorase, a nitric oxide synthase (Cramer et al., *Soc. Neurosci. Abst.* 19: 891, 1993). Nitric oxide may act downstream of the NMDA receptor as an intercellular retrograde messenger during hippocampal synaptic plasticity (e.g., Schuman and Madison, *Science* 254: 1503, 1991).

To investigate whether nitric oxide has an analogous role in the development of on/off sublaminae, we blocked nitric oxide synthase during the third and fourth postnatal weeks using an arginine analog, which competitively inhibits the enzyme at the arginine binding site. Ferrets received daily intraperitoneal injections of N-nitro-L-arginine (L-NOArg). Control animals received the inactive isomer N-nitro-D-arginine methyl ester (D-NAME) or L-NOArg together with L-arginine. L-NOArg treatment resulted in reduced NADPH-diaphorase staining compared to controls or normal ferrets. Retinogeniculate sublamination was assessed using intraocular injections of WGA-HRP at postnatal day 24. The extent of the LGN containing visible sublaminae was scored quantitatively. Animals treated with L-NOArg had significantly less sublamination than both control and normal animals. These results suggest that nitric oxide is involved in the segregation of retinal afferents into on/off sublaminae in the LGN.

RAPID ACQUISITION OF DENDRITIC SPINES BY VISUAL THALAMIC NEURONS AFTER BLOCKADE OF NMDA RECEPTORS. M. Rocha* and M. Sur, Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139; and Institute of Biophysics, Federal University of Rio de Janeiro, 21941, Brazil.

The NMDA subtype of glutamate receptor plays a critical role in the development of retinogeniculate afferents and postsynaptic target cells in the ferret lateral geniculate nucleus (LGN) (Hahm et al, 1991; Rocha et al, 1991). Here, we have examined the time course of dendritic changes of LGN cells *in vitro* after NMDA receptor blockade. Horizontal slices containing the thalamus were obtained from 28 ferret kits between postnatal day 5 (P5) and 45, and maintained alive in a slice chamber. LGN cell dendrites were labeled by Dil crystals placed into the LGN, and imaged on-line using laser confocal microscopy. Segments of dendrites (n=318) were imaged again after 2 and up to 7 hours of perfusion with control solution, d-APV (50-100 μ M), or NMDA (10-100 μ M). At P5-6, dendrites often gave rise to short side branches in control and treated slices. Acquisition of dendritic spines occurred after P7 and increased following d-APV perfusion ($p < 0.05$). From P14 to P20, blockade of NMDA receptors led to a five-fold net increase in spine acquisition ($p < 0.001$). Changes in spine acquisition declined after P21, and were unaffected by d-APV perfusion. NMDA treatment had no significant effect when compared to control conditions at all ages. Thus, NMDA receptors regulate dendritic spine acquisition in LGN cells mainly during the third postnatal week, a period when retinogeniculate axons segregate into on and off-center sublaminae. These results suggest that rapid structural changes in postsynaptic cells contribute to the formation of specific retinogeniculate connections.

POSTNATAL DEVELOPMENT OF NMDA RECEPTOR-MEDIATED, NITRIC OXIDE DEPENDENT RELEASE OF NEUROTRANSMITTERS IN THE CEREBRAL CORTEX. M.J. Friedlander*, C. Gancayco, and F. Hester, Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, AL 35294 USA.

Depolarization or activation of NMDA receptors in cortical synaptosome preparation from adult animals causes a calcium dependent release of glutamate and norepinephrine which in the case of NMDA receptor activation requires nitric oxide production (Montague, Gancayco, Winn and Friedlander, *Science*, 263, 973-977, 1994). Moreover, induction of synaptic potentiation in adult cortex requires NMDA receptor activation, although in neonates it is independent of NMDA receptor activation (Harsanyi and Friedlander, *Soc. Neurosci. Abstr.*, 370, 24, 1993). Thus, we evaluated the development of NMDA receptor mediated release of neurotransmitter in cortex. Cortical synaptosomes were prepared from guinea pigs at various postnatal ages (0, 5, 10, 15, 20, 25, 30, 35 and 70 days, n=3 animals at each age). Release of endogenous glutamate was measured with a luminometric assay and release of exogenous 3 H-norepinephrine was measured with scintillation counting. Synaptosomes were continuously washed with HEPES buffered saline (HBS) and stimulated with either a 50mM potassium depolarizing stimulus or 100 μ M NMDA either with or without a 30 minute pre-incubation with the nitric oxide synthase (NOS) blocker, L-Nitro-Arginine. Fractions of neurotransmitter release were expressed as the percentage of available transmitter and normalized to the HBS controls. Calcium-dependent depolarization-induced release of both glutamate and norepinephrine remained constant and independent of NOS activity at all ages. However, NMDA receptor-mediated release of both neurotransmitters did not occur until 10-15 days of age, with glutamate release showing a second increase in response between 30 and 70 days of age. At all ages when NMDA receptor-mediated release occurred, it was completely inhibited by NOS blockade. These results suggest that the NMDA receptor-NO system is immature in the neonate, in agreement with our neurophysiological studies.

605.9

INDUCTION OF SYNAPTIC POTENTIATION IN NEONATAL VISUAL CORTEX DOES NOT REQUIRE POSTSYNAPTIC ACTION POTENTIALS, NMDA RECEPTOR ACTIVATION OR NITRIC OXIDE PRODUCTION. K. Harsanyi* and M.J. Friedlander, Neurobiology Research Center, University of Alabama at Birmingham, AL 35294, USA.

Low frequency pairings of postsynaptic depolarizing pulses with presynaptic activation causes potentiation of postsynaptic potentials (PSPs) in mature visual cortex (Fregnac, Smith, Burke and Friedlander, *J. Neurophysiol.*, 71, 1403-1421, 1994). We previously showed that this type of synaptic plasticity is more reliably induced in the neonate (85% of cells vs. 40% of cells - Harsanyi and Friedlander - *Soc. Neurosci. Abstr.*, 370, 24, 1993). In the present study, we evaluated the mechanism underlying the reliable induction of this form of plasticity in the neonate. Intracellular recordings were made from supragranular neurons in 500 μ m thick slices of guinea pig visual cortex (from 5 to 60 postnatal days). Low frequency (0.1 Hz) low intensity (<30% threshold) stimuli were applied to cortical layer 6 with intracellular application of depolarizing pulses ($x = +2.0$ nA, 80 ms, 60 pairings). In the youngest animals (5-28 days), 85% (n=34/40) of such pairings led to synaptic potentiation (>30% for > 10 minutes after the pairing). Application of the NMDA receptor blocker, D-APV (50 μ M) did not block induction of synaptic potentiation in this age group (n=11/11). The depolarizing pulses applied to the postsynaptic neurons are effective at inducing synaptic potentiation even during action potential blockade by intracellular application of QX 314, the fast sodium current blocker. Application of the nitric oxide synthase (NOS) blocker, L-Nitro-Arginine at 100 μ M for 60-120 minutes did not block synaptic potentiation (n=11/14). Thus, subthreshold postsynaptic depolarization via activation of non-NMDA receptors, without NO production is sufficient to induce potentiation in the neonatal visual cortex.

ROLE OF THE MYELIN-ASSOCIATED NEURITE GROWTH INHIBITOR NI-35/250 IN THE TERMINATION OF CRITICAL PERIOD PLASTICITY IN KITTEN VISUAL CORTEX

C.M. Müller*, S. Gardziella and M.E. Schwab, Max-Planck-Inst. Dev. Biol., 72076 Tübingen, Germany, and Inst. Brain Res., Univ. Zürich, 8029 Zürich, Switzerland.

During a restricted period in postnatal development the thalamo-cortical circuitry of the mammalian visual system is malleable for activity-dependent changes of the interconnectivity. As neurite growth and synapse formation contribute to visual cortical plasticity the termination of the critical period may be due to a reduced growth permissiveness of the tissue. We have shown in an *in vitro* assay, where chick embryonic cortical neurons are cultured on cryostat sections of unfixed cat visual cortex sacrificed at different postnatal ages, that neurite growth is significantly impaired on tissue from kittens which have passed the critical period. This is paralleled by the appearance of the myelin-associated growth inhibitor NI 35/250 in the visual cortex. In order to test whether there is a causal relation between the reduced growth permissiveness and the appearance of NI 35/250 we treated the substrate sections with the monoclonal antibody IN-1, which has been shown to neutralize the growth inhibiting effect of NI 35/250. Controls included untreated sections and sections preincubated with the oligodendroglia-specific antibody O1.

IN-1 preincubation lead to a significant increase in the percentage of neurite-bearing cells and the neurite length of individual cells cultured on sections from more mature visual cortex. Both effects were most pronounced on the heavily myelinated infragranular cortical layers. O1 pretreatment revealed only minor effects on neurite growth. The data show that the developmental reduction of growth permissiveness of cortical tissue and possibly the termination of the critical period is due to the expression of the myelin associated neurite growth inhibitor NI 35/250. A CRITICAL PERIOD FOR INDUCTION OF LONG-TERM DEPRESSION IN VISUAL CORTICAL LAYER IV NEURONS

S. M. Dudek, F. W. Hester*, and M. J. Friedlander, Neurobiology Research Center, Univ. of Alabama at Birmingham, AL 35294.

Activity-dependent weakening of excitatory synaptic transmission has been hypothesized to play a dominant role in the mechanisms that mediate ocular dominance plasticity in the developing visual cortex. We have taken advantage of an *in vitro* model of synaptic weakening to examine whether visual cortical layer IV neurons express a developmentally dependent long term depression (LTD) corresponding to critical period plasticity. We have shown previously (Dudek & Friedlander, *Soc. Neurosci. Abstr.*, 19: 894, 1993) that LTD could be induced in a subset of immature guinea pig and kitten visual cortical neurons. However our efforts to characterize the developmental expression of this effect have been hampered by the prevalence of IPSP-like hyperpolarizing potentials that contaminate the excitatory postsynaptic potentials (EPSPs); LTD is not induced in neurons exhibiting these hyperpolarizing responses. We have extended our previous findings to include experiments where we have attempted to overcome the effects of this synaptic inhibition. Conventional intracellular recordings were made from layer IV of slices from mature (>45 days old) and immature (<8 days old) guinea-pig visual cortex and cat (day 1 through adult) striate cortex. In some cases, a mixture of the selective blocker of chloride channels, 4,4'-dinitro-stilbene-2,2'-disulfonic acid (DNDS), cesium acetate, and/or biocytin was included in the electrode. While blockade of inhibition appears to restore the ability to induce LTD in immature animals, it has no effect on the (lack of) induction of LTD in layer IV neurons from adults. These data suggest that while inhibitory synaptic potentials can influence the induction of LTD, their presence does not likely represent a subset of neurons incapable of supporting LTD.

REDUCED SYNAPTIC PLASTICITY IN VISUAL CORTEX SLICES OF α -CaM-KII KNOCKOUT TRANSGENIC MICE. A. Kirkwood*, A. Silva and M.F. Bear, Department of Neuroscience, Brown University, Providence, RI 02912 and Ctr. for Learning and Memory, Cold Spring Harbor Lab., Cold Spring Harbor, NY 11724

Recent work indicates that synaptic plasticity induced *in vitro* in the superficial layers of visual cortex and in the CA1 region of the hippocampus share remarkably similar mechanisms of induction. Several lines of evidence have implicated calcium-calmodulin-kinase II (CaM-KII) in the induction of long term potentiation (LTP) in the hippocampus. We have used a knockout transgenic mouse line that lacks the α subunit of CaM-KII to address the possible role of CaM-KII in the induction of LTP in the visual cortex.

Synaptic responses to stimulation of layer IV were recorded extracellularly in layer III. To induce LTP we used theta burst stimulation (TBS) which previous work has shown to yield robust synaptic potentiation in rat visual cortex. LTP was measured as the increase in field potential amplitude 20 min. after TBS. When TBS was applied to slices from wild type animals it resulted in significant LTP ($24.2 \pm 4\%$, 34 slices from 6 mice). In contrast, when it was applied to slices from mutants, TBS resulted in little or no potentiation ($2.2 \pm 1.0\%$, 44 slices from 7 mice). Furthermore, while potentiation of $\geq 20\%$ was observed after TBS in 50% of the control cases, 20% LTP was observed in only 5% of the mutant cases.

The dramatically reduced capability of the mutant visual cortex to sustain LTP strongly suggests that in the adult neocortex, like in the CA1 region of hippocampus, CaM-KII is crucial for the formation of LTP. Work in progress is aimed at examining (1) if there is a deficit in LTD in the mutant visual cortex, and (2) whether the deficit in LTP applies to the immature as well as the adult visual cortex.

REGULATION OF LONG-TERM POTENTIATION IN VISUAL CORTEX BY AGE AND VISUAL EXPERIENCE. M.F. Bear* and A. Kirkwood, Department of Neuroscience, Brown University, Providence, RI 02912

Binocular connections in the visual cortex are modified by sensory experience, but only during a "critical period" of early postnatal life. These modifications may employ mechanisms similar to those responsible for long-term synaptic potentiation (LTP) in slices of visual cortex. LTP of synaptic responses in layer III can be readily elicited by theta-burst stimulation (TBS) of layer IV in slices prepared from adult animals. However, we and others have found that (in the absence of GABA_A antagonists) LTP can be induced by white matter (WM) stimulation only in slices prepared from immature animals. Thus, like naturally-occurring synaptic plasticity, LTP after WM stimulation is restricted to a finite period of postnatal life, which in the rat lasts about 5 weeks. One interesting aspect of the "critical period" for modification of binocular connections is that it can be extended by rearing animals in complete darkness. The aim of the present study was to see if LTP in visual cortex also is regulated by the history of visual experience.

Slices of visual cortex were prepared from 4-5 week-old Sprague-Dawley rats that had been reared either in complete darkness or in a standard lighted environment. Synaptic responses to WM and layer IV stimulation were recorded extracellularly in layer III. In slices from control rats TBS of the WM had little effect ($5.9 \pm 3.0\%$ increase in the field potential amplitude at 20 min. after conditioning, $n = 7$ rats), while TBS of layer IV induced substantial LTP ($26.4 \pm 6.6\%$, $n = 12$ rats). In contrast, in slices from dark reared rats LTP was evoked equally well by TBS of the WM ($20.0 \pm 3.3\%$, $n = 7$ rats) or of layer IV ($24.2 \pm 4.1\%$, $n = 8$ rats).

The present results indicate that the history of visual experience can remarkably affect the probability and magnitude of LTP in visual cortex following WM stimulation. Thus LTP evoked by WM stimulation in vitro resembles experience-induced plasticity observed in vivo in two respects: both forms of plasticity can be induced only for a short "critical period", and this critical period can be prolonged by the absence of visual experience.

NEONATAL ENUCLEATION PREVENTS THE FORMATION OF A NORMAL OCCIPITAL CORTICOCOLICULAR PROJECTION IN RATS. G. Prusky*, Department of Psychology, The University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

In rats, corticocollicular axons arising from lateral-posterior visual cortex develop a restricted terminal zone in rostral superior colliculus (SC) from an initially-diffuse projection during the first two weeks of postnatal life (Jepp and Prusky, *Soc. Neurosci. Abs.*, 19, 455, 1993).

I investigated the role of the retina in this process by either enucleating rats at birth, before axons from the visual cortex normally arrive in the SC, or at postnatal day (P) 15, after order in the corticocollicular projection has been established. The distribution of Dil-labelled corticocollicular axons in the SC was then examined through development.

The corticocollicular axons of neonatally enucleated animals initially extended caudally, past their topographically-appropriate position in rostral SC, as far as its caudal border. By P15, there was a significant reduction of mistargeted axons in the caudal half of the SC, but axons in the rostral half of the SC arborized widely without forming a restricted terminal field. This pattern remained unchanged in animals that survived as late as P30. In contrast, the corticocollicular axons of animals, enucleated at P15 and viewed on P30, had clearly defined terminal zones that were indistinguishable from normal P30 controls.

These data suggest that during the first two weeks of postnatal life, a regional factor in the SC, that is independent of the presence of the retina, participates in corticocollicular map formation. However, the establishment of a precisely ordered corticocollicular projection is dependent upon normal retinal function.

NOVEL ENHANCER TRAP MUTANT REVEALS DIVERSITY OF OLFACTORY FUNCTION IN *DROSOPHILA MELANOGASTER*.

Adrienne E. Dubin*, John Molina, Haleh Razzaghi, Brett Fenson & Greg Harris, Dept. Biol., San Diego State Univ., San Diego, CA 92182.

Similarities between olfactory systems in vertebrates and insects suggest that the general rules underlying olfaction are conserved. We have taken a genetic approach to identify genes involved in olfaction in *Drosophila*. Enhancer trap line HD1 expresses the reporter gene *lacZ* encoded by a P-element inserted near position 64 in a subset of cells in the antennal third segment (the main olfactory organ). HD1 flies have no detectable olfactory defects, however after excision of the transposon, at least 2 of 62 independent lines revealed a dominant impaired sense of smell to the potent odorant ethyl acetate (EtAc) as assessed in a behavioral assay and electroantennogram recordings. The percentage of excision line 15A flies indifferent to EtAc in the behavioral assay ($12 \pm 5\%$ (mean \pm S.E.M.); $n=7$) was significantly higher than controls ($68 \pm 5\%$; $n=7$; $p<0.005$). EtAc applied at 10^{-3} dilution for 500 ms from a cotton-plugged puffer pipet caused a 4-fold decreased response in 15A (1.7 ± 0.2 mV; $n=22$) compared to HD1 (6.9 ± 0.7 mV; $n=17$; $p<0.005$) and another excision line (15B: 7.6 ± 0.5 mV; $n=18$; $p<0.005$). Responses to benzaldehyde, propionate, butanol, isobutanol, acetone, acetic acid were unaltered. The maximum response to EtAc was decreased with no change in the EC₅₀. Responses to short aliphatic chain acetates were most affected (compared to controls): 25% (EtAc), 41% (PropylAc), 54% (EtAcetoAc), and ~100% (ButylAc and tert-ButylacetoAc). A molecular analysis of the mutation is underway. Supported by AHA, California Affiliate 92-275 and NSF BNS-9022216.

HETEROLOGOUS EXPRESSION OF AMILORIDE-SENSITIVE SODIUM CHANNEL SUBUNITS AND AN ALTERNATIVELY SPLICED FORM IN TASTE TISSUES. X.-L. Li* and S.H. Snyder, Dept. of Neuroscience, Johns Hopkins Medical School, Baltimore, MD 21205

The transduction of sodium salt taste is mediated by voltage-independent, amiloride-blockable epithelial sodium channels (ASSC) in taste cells. Recent molecular cloning studies have revealed that an amiloride-sensitive epithelial sodium channel isolated from rat colon consists of three homologous subunits (α , β and γ) (Canessa et al Nature 367: 463, 1994). Utilizing polymerase chain reaction and Northern blot analysis, we have identified the presence of all three subunits and an alternatively spliced form of α subunit of ASSC in rat tongue epithelial tissues that contain taste receptor cells. The heterologous expression of α , β and γ subunits in taste tissues appear to be distinct from that in lung and kidney. In taste tissues, α and β subunits of ASSC are equally expressed and the γ subunit is undetectable by Northern analysis. In lung and kidney, however, the expression levels of β and γ subunits are about same whereas the expression of the α subunit is the greatest. The expression levels and tissue distribution of the alternatively spliced form of the α subunit of ASSC are similar to that for the native α subunit: higher in lung and kidney and lower in taste tissues. Preliminary studies on transfected cells expressing ASSC cDNAs showed that α subunits, but not β and γ subunits, were able to bind [³H]-phenamil, an amiloride analog. The heterologous co-expression of ASSC subunits may contribute to tissue specific functions of ASSC such as salty taste.

ODORANT INDUCED CURRENT BUMPS IN ISOLATED OLFACTORY RECEPTOR CELLS FROM THE SALAMANDER. S. Firestein*, C. Picco and A. Menini, Dept. of Biol., Columbia Univ., NY USA, and Istituto di Cibernetica e Biofisica, C.N.R., Genova, Italy.

We have previously shown that vertebrate olfactory receptor cells have narrow dynamic ranges and low affinities for certain odorants. Dose-response relations studied in the presence of different concentrations of cineole, isoamyl acetate or acetophenone for an exposure time of 1.2 sec were well fitted by the Hill equation with Hill coefficients greater than 1 and K_{1/2} values between 3 and 100 μ M. Although the K_{1/2} concentration for these odorants was in the micromolar range, the cellular threshold for odorant detection could be significantly lower. To investigate this possibility we exposed a single cell to low odorant concentrations for longer periods of time. In a cell with a K_{1/2} of 10 μ M as measured from dose-response curves with the odorant cineole, high gain recordings showed isolated current bumps induced by 500 nM of the same odorant. These bumps had a bell like shape with amplitudes of 1-10 pA and average durations of 300-500 ms.

Olfactory receptor neurons can therefore detect odorant concentrations lower than previously shown. They may accomplish this by sampling over longer periods and integrating information over time. Thus a cell expressing a broadly tuned low affinity odor receptor may regain sensitivity at the expense of temporal resolution, an apparently sensible trade-off for olfactory neurons. The observed small current bumps could be caused by the binding of a single odor molecule to a receptor, as in photoreceptors it is possible to observe quantum bumps caused by the absorption of a single photon.

SALAMANDER OLFACTORY RECEPTOR NEURON ODOR RESPONSES DEPEND UPON STATES ESTABLISHED BY PRIOR STIMULUS PRESENTATIONS. R.C. Gesteland*, P. Farmer and M. Overway, University of Cincinnati Medical Center, Cincinnati, OH 45267-0521.

Voltage-sensitive dyes observed with a confocal microscope allow the activity of each of hundreds of neurons to be observed as odorous stimuli are sequentially presented. The results of experiments on the salamander show that different cells can respond in different ways to a stimulus, that the responses are strongly dependent upon prior stimulus presentations, and that the difficulty in obtaining reliable and repeatable responses in microelectrode studies is not the result of experimental insult but in fact characterizes the code for odor identity and intensity. In a typical experiment, the first stimulation evokes mostly depolarizing responses from a large fraction of the cell population. Subsequent presentations of the same stimulus and other stimuli are as likely to hyperpolarize or evoke no response as to depolarize. Stimuli are presented as vapors at low concentrations for 1 sec with 5 min between presentations, responses remain vigorous throughout the experiment, and all neurons respond similarly to changes in external [K⁺]. Several different membrane ion channels have been identified in patch-clamp studies. It is likely that different cells have differing numbers of these channels and that the duration of activation can be long-lasting. The response of a cell to a stimulus will depend upon the activation states of the various channel types resulting from prior odor experience.

OLFACTORY TRANSDUCTION IS INTRINSICALLY NOISY. Graeme Lowe & Geoffrey H. Gold* Monell Chemical Senses Center, Philadelphia, PA.

The high sensitivity of olfaction suggests that olfactory receptor cells reliably detect single odorant molecules. Discrete events, presumably triggered by single odorant molecules, have been observed in insect pheromone receptor cells, but analogous events have not been reported in any vertebrate species. We sought to resolve single molecular responses in rat by recording the transduction current in dissociated olfactory receptor cells. When cells were exposed to threshold concentrations of one of the odorants: menthone, 2-isobutyl-3-methoxypyrazine, isoamyl acetate or 2-hexylpyridine, the whole-cell current displayed pronounced low frequency (< 10 Hz) fluctuations which might represent the summation of single molecular responses. However, fluctuations of similar amplitude and frequency spectrum were also observed in the absence of odorants by inhibiting basal phosphodiesterase activity with IBMX, or by photolytic release of cyclic AMP. Thus, the odorant-induced fluctuations represent the basal, or intrinsic, noise of olfactory transduction, not the activation of receptor proteins by odorants. In unstimulated cells this noise is suppressed by the threshold inherent in the cyclic-AMP activated current. Our data suggest that for many common odorants, single odorant molecules are not reliably detected by mammalian olfactory receptor cells. Supported by NIDCD Grant DC00505.
