In the rat striatum, the neurotoxin, 1-methyl-4-phenylpyridinium ion (MPP⁺), elicits dopamine (DA) release with a concomitant increase in hydroxyl radical ([•]OH) formation. It is not clear if DA release is required for [•]OH production or whether [•]OH is formed directly by redox cycling of MPP⁺. We have studied [•]OH formation by administering MPP⁺ either at the level of the anterodorsal striatum or the lateral occipital cortex, the latter as a control for low dopaminergic activity. Microdialysis probes were implanted bilaterally in the striatum and were perfused with salicylate (5 mM; 1 µl/min; 110 min), then with MPP⁺ unilaterally (5 mM; 20 min), followed by an 80 min recovery period. The probes were then implanted in the cortex. After a 60 min equilibration period with salicylate, MPP⁺ was perfused (20 min) unilaterally, followed by a 60 min recovery period. DA, dihydroxyphenylacetate (DOPAC) and homovanillate (HVA) were assayed by HPLC-EC, while 2,3- and 2,5-dihydroxybenzoate (DHBZ) (formed by salicylate hydroxylation) were measured either by HPLC-EC or by GC-MS. Basal release (pmol/20 min uncorrected for probe recovery) of DA, DOPAC and HVA was 0.04-0.3, 10-14 and 3-10, respectively. MPP⁺ produced an increase of DHBZ (2-3 pmol/20 min) and DA (5-10 pmol/20 min), with a concomitant decrease in DOPAC and HVA. MPP⁺ also induced DHBZ production (1-3 pmol/20 min) in the cortex where DA release was not detectable. While these results are consistent with the hypothesis that [•]OH formation may be induced by MPP⁺ through the release of DA, the observation that [•]OH is produced in an area displaying no significant DA release suggests that a second mechanism is also involved. The protective potential of MAO-B inhibitors, selegiline and MDL72,774A ([E]-4-fluoro-6-(fluoromethylene)benzene-butanamine), in our model is currently under investigation. INDUCTION OF C-FOS FOLLOWING MPTP TREATMENT IN THE YOUNG ADULT AND AGING MICE. M. Gupta*, C. Hitchener and X.L. Chen. Department of Anatomical Sciences and Neurobiology, University of Louisville, Louisville, KY 40292.

Previous studies from this laboratory have shown a loss of dopaminergic neurons in the substantia nigra (SN) and decreased levels of dopamine in the striatum following MPTP treatment in the young adult mice. By six months after MPTP, there is a significant recovery in the SN of young adult mice compared to the aging mice, treated in a similar manner. Immediate early genes that are induced by extracellular signals and alter transcription of other genes, are activated in the rat striatum by cocaine and amphetamine treatment. The present studies examined the effects of MPTP treatment on the induction of c-fos in the striatum of young adult and aging mice. Young adult (2-3 month old) and aging (19 month old) male C57BL/6 mice were given a single i.p. injection of MPTP (30 mg/kg body weight) and sacrificed 30 min, 1 hr, 4 hr and 24 hr later. Mice were anesthetized, perfused with fixative and brain sections were immunostained for c-fos. Results show an induction of c-fos in the young adult striatum 30 minutes after MPTP treatment, particularly in the dorso-medial striatum, and was maximal at 1 hr after MPTP. At 4 hr, after MPTP, there was a relatively reduced immunostaining for c-fos and by 24 hr, it was similar to those in the controls. In the aging mice, induction of c-fos was seen at 30 min and 1 hr after MPTP and was seen throughout the striatum with a denser distribution in the dorso-medial portion. This increased distribution of c-fos induction in the aging striatum might be due to an increased alteration of protein synthesis in the aging mice treated with MPTP. Supported in part by USPHS Grant NS24291 to MG.

MPTP INDUCES A PROGRESSIVE HIGH AMPLITUDE SWELLING OF TH-POSITIVE AXONS THAT ARE MYELINATED IN DOG. J.S. Wilson¹, B.H. Turner and J.H. Baker. Dept. Anatomy, Coll. Med., Howard Univ., Wash. D.C. 20059

A single systemic injection (3.0 mg/kg; i.v.) of MPTP, a neurotoxin that induces a Parkinsonian-like syndrome, produces a progressive high amplitude swelling of tyrosine hydroxylase (TH) positive neural processes in the proximal third of the nigrostriatal (NS) pathway of dog. This swelling is evident one day after an injection; and by 14 days, many profiles reach a diameter of 30 μ m or more. In parasagittal sections, the swellings have a club-like appearance with the head pointing rostrally towards the striatum and the handle tapering towards the nigra. The club-like swellings are acidophilic and are immunopositive for the non-phosphorylated neurofilaments. The periphery of the swellings reacts positively for antibodies against myelin basic protein. Examination of the TH-positive swollen profiles with the electron microscope reveal that they are myelinated axons. Thus, unlike rats whose NS-neurons are unmyelinated and survive exposure to MPTP, NS-neurons of the dog are myelinated and are killed by MPTP. We hypothesize that the degree of myelination is positively correlated with a DAminergic neuron's ability to recover from a MPTP insult.

A NONINVASIVE APPROACH TO TEST DOPAMINE OXIDATION BLOCKADE BY MPTP AND MPP⁺ NEUROTOXINS IN RATS. S.P. Bagchi¹, Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY 10962.

MPTP and MPP⁺ may induce Parkinson's disease syndrome and also impair oxidation of dopamine (DA) by mouse striatum. A noninvasive approach based upon urinary DA and DOPAC levels to test oxidation defect induced by MPTP, MPP⁺ or other causes may be clinically useful. Neurotoxin was administered i.p. to rats put in metabolic cages for collecting urine over 1 N HCl for subsequent 0-12, 12-24 or 0-24 hr. time periods. Urinary DA and DOPAC were quantitated by published methods employing gas chromatography. A single 5.0 mg/kg dose of MPTP or MPP⁺ acutely depressed urinary DOPAC level and DOPAC/DA ratio compared to saline control. Reserpine (RES) (2.5 mg/kg) acutely raised DOPAC level and DOPAC/DA ratio and these effects were reversed by either MPTP, MPP⁺, or pargyline (30.0 mg/kg), but not by the MPP⁺ congener paraquat (5.0 mg/kg), given 1 hr. before RES. At 13 days after a single MPP⁺ dosage, DOPAC level and DOPAC/DA ratio did not differ from the control. RES effects, however, were still blunted at 13 days. Five daily 5.0 mg/kg MPP⁺ dosages had powerful effects at 0-24 hrs. following the last dosage but the values reverted to normal by 6 or 13 days; at 27 days, reserpine revealed impairment of DA oxidation. In conclusion, MPP⁺ may cause an acute as well as a long-lasting impairment of peripheral DA oxidation and the latter may become apparent only in reserpinized animals. Also, the RES induced sensitivity is due to an enlargement of the limiting free DA level at MAO site rather than because of the release of stored neurotoxin. STRUCTURAL STUDIES OF CONDENSATION PRODUCTS OF BIOGENIC AMINES AS INHIBITORS OF TRYPTOPHAN HYDROXYLASE. M. Ota, K. Matsubara¹, W. Maruyama, T. Takahashi, Y. Saito², K. Kimura¹ and M. Naoi. Dept. of Biosci., Nagoya Institute of Technology, Nagoya 466 and Depts. of ¹Legal Med. and ²Anesthesiol., Shimane Med. Univ., Izumo 693 and Japan.

The effects of condensation products of dopamine and indoleamines on the activity of tryptophan hydroxylase (TPH) were evaluated to determine the structures associated with modulation of this enzyme activity. The compounds having a catechol structure, such as 6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline (6,7-dihydroxy-TIQ), potentially inhibited the activity of the enzyme prepared from the rat brain. The inhibition was non-competitive in terms of both the bipterin cofactor and the substrate L-tryptophan. The substitution on 1 or 2 positions of 6,7-dihydroxy-TIQ did not affect their inhibitory capacities to TPH activities. Among these compounds, a charged substance, 1-methyl-2(N)-methyl-6,7-dihydroxy-isoquinolinium ion, was an extremely potent inhibitor; the K_i values were 0.88 ± 0.17 and $0.64 \pm 0.08 \mu$ M (mean \pm SD) in terms of the substrate and cofactor, respectively. On the contrary, the condensation products of indoleamines scarcely affected TPH activities. 1-Methyl-TIQ, MPTP, and MPP⁺ were almost inactive. These results indicated that the catechol structure recognized and combined with TPH at the binding site different from that of the substrate and cofactor, and the positive charged moiety of the dopamine-derived substance enhanced the affinities to TPH. The inhibitory capacities of these compounds would be enhanced by the cyclizing reaction of dopamine. (Supported by a Grant-in-Aid for Scientific Research on a Priority Area #313 of Japan).

SPECIFIC MIDBRAIN DOPAMINERGIC NEURONS DEGENERATE FOLLOWING MPTP TREATMENT IN THE FVB MOUSE: RELATIONSHIP TO CALCIUM-BINDING PROTEINS. C.-L. Liang¹, E. Nelson, S.G. Speciale, P.K. Sonsalla and D.C. German. Dept. of Psychiat., UT Southwestern Med. Cntr., Dallas, TX 75235, and Dept. of Neurol., Robert Wood Johnson Sch. of Med., Piscataway, NJ 08854.

The present study sought to map and quantify the number and location of midbrain dopaminergic (DA) neurons that are susceptible to degeneration following MPTP treatment, and determine whether the vulnerable cells contain the calcium-binding proteins calbindin-D_{28k} (CALB) or calretinin (CALR). Brain sections from adult male FVB mice were processed for simultaneous two-color fluorescence immunocytochemistry for tyrosine hydroxylase (TH) and CALB, and TH and CALR. Three groups of 3 FVB mice received 4X25 mg/kg MPTP (at 2h intervals) either on Day 1 alone, Days 1 and 3, or Days 1,3, and 5, for cumulative doses of 100, 200, and 300 mg/kg, respectively. Mice were sacrificed 7 days after the last injection. There was over an 80% reduction in striatal dopamine concentrations in all three treatment groups, however, DA cell loss was only observed after the 300 mg/kg dose. There was an average of >40% cell loss that was confined to a mid-rostrorocaudal portion of the substantia nigra pars compacta, in a region largely devoid of CALB or CALR in the DA neurons.

EVALUATION OF THE EFFECTS OF HEAT STRESS ON THE NEUROTOXICITY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP) IN C57/B6N MICE. T.E. Freyaldenhoven¹, W. Slikker, Jr. and S.F. Ali. Division of Neurotoxicology, NCTR/FDA, Jefferson, AR 72079 and Dept. of Biochem. & Mol. Biol., UAMS, Little Rock, AR 72205.

MPTP is known to cause neurotoxicity in rodents and nonhuman primates. The present study was designed to determine whether heat stress, with the subsequent induction of stress proteins, 24 hr prior to dosing with MPTP might have an effect on striatal dopamine depletion. Adult male C57/B6N mice were dosed with 4 x 10 mg/kg, ip MPTP at two hr intervals with or without previous heat stress. Animals were sacrificed at 24 hr after the last dose. Striatal dopamine and its metabolites were measured by HPLC/EC and stress proteins by SDS/PAGE. MPTP produced 70% depletion of dopamine in the striatum of non-heat stressed animals, whereas in heat stressed animals striatal dopamine depletion was 83%. Animals subjected to heat stress alone or injected with saline showed no depletion of striatal dopamine. Stress protein induction could not be detected by SDS/PAGE or immunoblotting in either the striatum or the substantia nigra. These results suggest that heat stress has lasting effects which enhance the neurotoxicity of MPTP.

674.12

POTENTIAL BIOACTIVATED NEUROTOXICANTS, N-METHYLATED β -CARBOLINIUM IONS, IN THE LUMBAR CEREBROSPINAL FLUID OF PARKINSON'S PATIENTS. K. Matsubara¹, S. Kobayashi¹, A. Akane², T. Hattai³, S. Takahashi, T. Izu and K. Kimura. Depts. of Legal Med., ¹Internal Med. III and ³Anatomy I, Shimane Med. Univ., Izumo 693 and ²Dept. of Legal Medicine, Kansai Univ., Moriguchi, Osaka 570, Japan.

Recent studies show that β -carbolinium ions (BC⁺s) resemble the synthetic parkinsonian toxicant, MPP⁺, with respect to structure and neurotoxic activity (Brain Res. 570, 154, 1992) and are identified in human brain by the GC/MS analysis (Brain Res. 610, 90, 1993). These potential bioactivated neurotoxicants, 2-N-methyl- β -carbolinium (2-MeBC⁺s) and 2,9-N,N'-dimethyl- β -carbolinium ions (2,9-Me₂BC⁺s), were analyzed in the lumbar cerebrospinal fluid (CSF) of 16 parkinsonian and 16 non-parkinsonian patients using HPLC/fluorescence detection. The levels of BC⁺s in the lumbar CSF of parkinsonian patients were significantly higher than those in non-parkinsonian individuals. On the other hand, there was no significant difference in the CSF levels of simple β -carboline, which are precursors of BC⁺s, between parkinsonians and non-parkinsonians. These results strongly support the hypothesis that "bioactivated" carbolinium ions, which are 2-MeBC⁺s and 2,9-Me₂BC⁺s, could be endogenous causative factors in Parkinson's disease. (Supported by a Grant-in-Aid for Scientific Research on a Priority Area #313 of Japan).

BEHAVIORAL RECOVERY IN STRIATAL VERSUS SUBSTANTIA NIGRAL 6-HYDROXYDOPAMINE-LESIONED RATS. M.L. Leavitt*, C. Devenyi, K. Klein and J.C. Maroon. Allegheny-Singer Research Inst., Medical College of PA, Pittsburgh, PA 15212.

We are comparing the effects of a single unilateral injection of the neurotoxin 6-hydroxydopamine (6-OHDA) into the striatum versus the substantia nigra on ipsilateral rotational responses to D-amphetamine injection. Seventeen out of nineteen rats rotated ipsilaterally to D-amphetamine (3.0 mg/kg) when tested at 13-18 days following injection of 25 μ g (1.5 μ l) of 6-OHDA into the right striatum. Repetition of the 1 hr. rotational test at between 25 and 53 days post-lesion revealed a decreased response in twelve of the fourteen originally positive responders. Ipsilateral rotations were significantly ($P < .005$) reduced to a mean value (\pm SEM, 189 ± 50) which was only 43% of the original response (474 ± 49). Substantia nigral-lesioned rats ($N=6$) that tested positive at 10-21 days post-lesion showed a mean response upon retesting at 61-79 days post-lesion (606 ± 63) which was 160% of their original value (472 ± 110). These findings demonstrate a limited behavioral recovery in striatal but not substantia nigral 6-OHDA-lesioned rats.

Supported by a BRSR grant to M.L.L.

RAPID ATP LOSS CAUSED BY METHAMPHETAMINE IN THE MOUSE STRIATUM: RELATIONSHIP BETWEEN ENERGY IMPAIRMENT AND DOPAMINERGIC NEUROTOXICITY. P. Chan*, D.A. Di Monte, J.J. Luo, L.E. DeLanney, J. Irwin and J.W. Langston. The Parkinson's Institute, Sunnyvale, CA 94089.

There has been considerable interest in the possibility that perturbations of energy metabolism play a role in the nigrostriatal degeneration. *d*-Methamphetamine (METH) has been shown to cause a long-lasting dopaminergic neurotoxicity in the striatum. Although it has been suggested that endogenous dopamine (DA), excitatory amino acids, and oxidative stress are involved in METH toxicity, the relationship between energy impairment and the toxic effects of METH on dopaminergic neurons remains to be explored. In the present study, experiments were conducted to investigate the effects of METH on mouse brain ATP levels and the relationship between METH-induced changes in striatal dopamine and ATP concentrations. C57BL/6 mice were treated with either a single or 4 doses of METH (10 mg/kg, i.p., given at 2 hr intervals) and killed by microwave irradiation of the brain at either 1.5 hr or 1 week after the last injection. ATP levels were measured in the striatum, hippocampus and cerebellar cortex, and striatal DA levels were also determined. Neither striatal ATP nor DA concentrations changed after a single injection of METH, but both were decreased after 4 doses of METH. No changes in ATP were observed in the hippocampus and cerebellar cortex. In a second set of experiments, an intraperitoneal injection of 2-deoxyglucose (2-DG, 1 g/kg), an inhibitor of glucose uptake and utilization, was given 30 min prior to the last 2 injections of the 4 doses of METH. 2-DG significantly potentiated METH-induced striatal ATP loss at 1.5 hr and DA depletions at 1.5 hr and 7 days. These results indicate that a toxic regimen of METH results in a selective energy impairment in striatum, and raise the possibility that energy impairment plays an important role in METH-induced dopaminergic neurotoxicity.

NEUROTOXICITY: OXIDATION

Excitotoxic mechanisms in cultured neuronal and glial cells overexpressing Cu/Zn-superoxide dismutase (Cu/ZnSOD). Q. Bar-Peled* and Y. Groner. Molecular Genetic and Virology Dept., The Weizmann Institute of Science, Rehovot, Israel 76100.

To study the involvement of Cu/ZnSOD overexpression in excitotoxic cell death, susceptibility of cortical and spinal-cord neurons of transgenic-Cu/ZnSOD (TgHS) mice to Kainic acid (KA) was investigated. Glial-free neuronal cultures grown in medium without serum, were exposed to KA for 16-20h and surviving cells monitored by counting the number of Neuron Specific Enolase positive cells. As previously recorded in mixed neuronal and glial cultures, 50 and 100 μ M KA led to 1.5-2 fold increase in cell death when glial-free cultures from TgHS were compared to control mice. The role of glial cells in this differential vulnerability was studied. Astroglial cultures were prepared and uptake of 3 H-glutamate was measured. 50% increase in glutamate uptake per cell was found in control cultures as compared to cultures from TgHS mice. Glutamate uptake is an energy dependent process driven through a sodium gradient maintained by Na^+/K^+ ATPase. To examine whether lower activity of the Na^+ pump in TgHS astrocytes was involved in the reduction of glutamate uptake, ouabain, an inhibitor of Na^+ pump was added. At 10^4 M it caused a reduction of glutamate uptake in both TgHS and control astrocytes, however, the inhibition in TgHS cells was 40% larger. When subjected to KA, TgHS spinal-cord neurons were more susceptible than control neurons. Upon incubation with Ouabain (10^{-6} M) for 20h, 60% more spinal neurons died in the TgHS cultures. Electron microscopy analysis of KA-treated neurons revealed condensed chromatin and abundant vacuolization in the cytoplasm, indicating that KA-induced cell death is mediated by apoptosis.

AUTORECEPTOR PRESYNAPTIC CONTROL OF DOPAMINE RELEASE FROM STRIATUM IS LOST AT EARLY STAGES OF MANGANESE POISONING. H. Suarez-Roca*, M.C. Cuesta, G. Gomez, Bonilla E. Sec. of Neurochemistry, Instituto de Investigaciones Clínicas, Univ. of Zulia, Apartado 1151, Maracaibo 4001-A, Venezuela.

Manganese (Mn) poisoning in man produces an early psychotic disorder that is later followed by a Parkinson-like syndrome. Alterations in the CNS DA system are thought to be involved. In the present study, we assessed the presynaptic autoreceptor regulation of DA release in the striatum during early and late stages of Mn poisoning. Albino mice were treated i.p. with 5 mgMn/Kg weight/day for 2 and 8 weeks. Controls received equivalent doses of NaCl. Slices preloaded with 3 H-DA were superfused, depolarized with K^+ 25 mM and the radioactive efflux was counted. Apomorphine (APO), a D2 DA receptor agonist, was used to evaluate the presynaptic autoreceptor modulation of DA release from mouse striatum. Mn poisoning, at either 2 or 8 weeks, did not change basal and evoked DA release. In controls, 1 μ M APO, produced an inhibition of evoked DA release that was blocked by 1 μ M S(-)-Sulpiride, a DA receptor antagonist. APO lost its capacity to inhibit the evoked DA release after 2 weeks of Mn poisoning, although, APO was then able to reduce again evoked DA release after 8 weeks of Mn poisoning. MK-801 (0.3 μ M), an NMDA-glutamate receptor antagonist, could restore APO inhibitory control on DA release that had been lost at week 2 of Mn poisoning. These findings suggest a NMDA-glutamate-receptor-mediated loss of autoreceptor presynaptic control of striatal DA release at early Mn poisoning.

COMBINATIONS OF OXYGEN DEFICIENCY AND DEXAMETHASONE TREATMENTS: EFFECT ON BEHAVIOR AND BRAIN DEVELOPMENT. E.-M. E. Montgomery* and C. R. Almli. Lab of Developmental Neuropsychobiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Oxygen deficiency and chronic dexamethasone treatment are known to cause damage to the central nervous system. Cortical regions, such as the hippocampus, are vulnerable to these insults. Several groups were formed based on treatment and timing. Rats received oxygen deficiency treatment on the day of birth (P0), at P7, or at both P0 and P7. Dexamethasone treatment was received by rats with and without oxygen deficiency treatment(s). There were 7 treatment groups including the controls. Oxygen deficiency consisted of 3 treatments each separated by 30 minutes for both the P0 and P7 ages. At P0, oxygen deficiency criterion was reached when the rat demonstrated either 2-15sec or 1-45sec intergasp intervals while in the chamber. At P7, the criteria was 2-10sec or 1-30sec intergasp interval. Dexamethasone treatment was given for 7 consecutive days at .5mg/kg body weight. Openfield activity measures and performance on the holeboard memory task were assessed. Preliminary results indicate that P7 oxygen deprivation caused the greatest behavioral disruption. Rats of groups that received a P7 oxygen deficiency treatment showed a decrease in activity, and were less efficient in completing the memory task. Histological analysis are being conducted. (Conducted under NIH Guide for care and Use of Laboratory Animals).

RADIO-RESTORATIVE EFFECTS OF RILUZOLE IN THE YOUNG RAT.

J. Prati¹, F. Alaoui², S. Trocherie², A. Uzan¹, L. Court² and J.-M. Stutzmann¹.

1) Biology, Rhône-Poulenc Rorer S.A., Vitry sur Seine, FRANCE

2) Laboratoire de Neurobiologie de la Division de Radiologie du Service de Santé des Armées, Fontenay aux Roses, FRANCE.

Exposure of the mammalian brain to ionizing radiation, whether as part of a cancer therapy or due to industrial nuclear accidents, causes severe cerebral damage. This study examines the effect of the antilutamate neuroprotector, riluzole, on the acute structural and behavioural damage inflicted by a dose of 2.5 Gray to the brains of 15 day old rats. Rats were irradiated from a Cobalt 60 source. They received riluzole at up to 8 mg/kg i.p., 20 minutes after the start of the irradiation. Six hours later animals were perfused and brains removed for histological examination. The hippocampus was cut in 1 µm sections and stained with toluidine blue. The proportion of pycnotic cells per 1000 cells in the granular and subgranular layers of the dentate gyrus was counted in three non-serial slides. In other animals behaviour was examined in an open field.

Irradiation at 2.5 Gray caused pycnosis in neurones in the dentate gyrus. Riluzole reduced the number of pycnotic cells in irradiated rats, with a dose-dependent and statistically significant protection seen between 1 and 4 mg/kg i.p. (at 1 mg/kg 18.0±0.7% of neurones pycnotic compared to vehicle-treated controls with 24.6±0.8% cell death; n=12/group, p<0.05). In the open field irradiated animals showed signs of lethargy, unco-ordinated movements and the number of squares crossed in the field fell. Riluzole significantly increased motility to levels of non-irradiated siblings from doses of 2 mg/kg i.p. (squares crossed per 3 minutes: 4.6±0.8, 13.3±2 and 19.7±3.1 for irradiated, irradiated plus riluzole at 2 mg/kg and sham-treated rats). Riluzole may have potential as a neuroprotective agent for use after accidental or deliberate exposure to ionizing irradiation.

NEUROTOXICITY ASSOCIATED WITH OXYGEN RADICAL GENERATION IS EXACERBATED BY GLUCOCORTICOID. L.J. McIntosh* and R.M. Sapolsky. Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305

Glucocorticoids (GCs) are secreted by the adrenals in response to stress, and are also used clinically to control inflammation and autoimmune disorders in millions of people annually. Thus elevated GC levels are not uncommon in populations at risk for neurological injury and it is known that GCs exacerbate various forms of neuronal injury. GCs act on cellular pathways relevant to oxygen radical formation, but it is unclear whether GCs have an effect on oxygen radical toxicity. To test the hypothesis that glucocorticoids may decrease the ability of neurons to protect themselves against reactive oxygen species, we examined the effect of the oxygen radical generator adriamycin in rat primary neuronal cultures. Susceptibility to adriamycin was determined by cell counting after MAP-2 staining, and correlated with biochemical measurements. After establishing a dose-response curve for adriamycin, we determined that the lipophilic antioxidants Trolox and butylated hydroxytoluene were effective in decreasing the adriamycin toxicity, indicating that adriamycin was in fact producing toxicity through reactive oxygen pathways. Increasing GC concentration in the culture media (up to 10⁻⁶ M) exacerbated the toxicity in the center of the adriamycin dose-response curve. Hippocampal and cortical cultures (brain regions with high or moderate concentrations of corticosteroid receptors, respectively) were compared. Our results indicate that GCs may be directly involved in the pathways that mediate oxygen radical formation, and further study of the connections between oxidative stress and glucocorticoids could indicate useful points at which antioxidant intervention will decrease neuronal death after a neurological insult.

675.7

PEROXYNITRITE TOXICITY IN CEREBELLAR GRANULE CELLS: REVERSAL BY TIRILAZAD MESYLATE (U-74006F). G.J. Fici, J.S. Althaus, J.R. Zhang, E.D. Hall and P.F. VonVoigtlander*. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

During ischemia, peroxynitrite may be a toxic intermediate which forms *in vivo* when nitric oxide condenses with superoxide. Alone, peroxynitrite appears to directly react with aromatic and thiol nucleophiles. At physiological pH, peroxynitrite rapidly (within seconds) decomposes to species with "OH and NO₂" character. These reactive species are shown to initiate lipid peroxidation, hydroxylate aromatic residues, and nitrate aromatic residues. This reactivity may contribute to differential toxicity *in vivo* and *in vitro*. Tirilazad mesylate (TM) is a lipid-soluble antioxidant shown to inhibit iron-dependent lipid peroxidation. It is an effective therapy in a variety of neurotraumatic models of CNS injury, and is currently undergoing human clinical evaluation in stroke and head and spinal injury. This study was designed to investigate the cytoprotective properties of TM in a cerebellar granule cell model of toxicity involving treatment with peroxynitrite. Cytoprotective performance of TM was based on viability measurements ([³H]-aminoisobutyrate uptake), blockade of lipid hydroperoxide generation, and blockade of nitrotyrosine formation. Results show that viability measurements associated with peroxynitrite toxicity increased with TM treatment. Interestingly, TM was found to be an effective cytoprotectant (EC₅₀ = 100 µM) even as a post-treatment following exposure of cells to peroxynitrite. Similar post-treatment with superoxide dismutase (50 units/ml) or allopurinol (100 µM) failed to produce any cytoprotection. These and other parameters of peroxynitrite-dependent cytotoxicity will be described with respect to TM cytoprotection.

EFFECTS OF IONIZING RADIATION ON OH RADICAL GENERATION IN RAT STRIATUM. H.T. Chen, W.R. Prichard, S.B. Kandasamy* and A.H. Harris. Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20889.

Using microdialysis techniques, we applied salicylate hydroxylation as an *in vivo* trapping procedure to monitor the time course of 2,3- and 2,5-dihydroxybenzoic acid (DHBA) generation in the striatum following whole-body irradiation. Male Sprague-Dawley rats were exposed bilaterally to 10 Gy of ⁶⁰Co radiation at a dose rate of 10 Gy/min. Microdialysis was performed in anesthetized rats either immediately or on day 1, 2, or 3 after irradiation. The probe was inserted into the right striatum and perfused with artificial cerebrospinal fluid (aCSF) at a flow rate of 1 µl/min. Sample collection every 15 min was started 1 h after probe insertion. After the initial 2 samples were collected, *in vivo* trapping of OH radicals in the striatum was initiated by perfusing 1 mM Na salicylate in aCSF through the microdialysis probe. Formation of 2,3- and 2,5-DHBA was detected by HPLC-EC. The mean concentrations of DHBA in the initial 2 samples were taken as baseline, and their concentrations after salicylate perfusion were expressed as percentage of baseline. The respective baselines for 2,3- and 2,5-DHBA in sham controls were 123.4 ± 17.6 and 250.5 ± 31.7 fmoles/20 µl (n=16). There was no significant difference between the baselines in irradiated rats and sham-irradiated controls. The concentrations of DHBA increased significantly (p<0.05) following salicylate perfusion, and reached plateau by 45 min. A significant difference in the striatal 2,5-DHBA levels was observed between irradiated rats and sham controls on day 3 after irradiation. This study demonstrates that there are increased levels of OH radicals found in the rat striatum 3 days after exposure to ionizing radiation.

675.6

ASSESSMENT OF OXIDATIVE STRESS IN NEURONS AND GLIA. O. Ben-Yoseph*, P.A. Boxer¹, N. Dujovny² and B.D. Ross. Dept. Radiology and Biological Chemistry, University of Michigan Ann Arbor, MI 48109, and ¹Dept. Neuroscience, Parke-Davis Research, Division of Warner-Lambert Co, Ann Arbor, MI 48105.

In view of the importance of oxidative stress in a range of neuropathological conditions, we have characterized the anti-oxidant capacity of primary cerebrocortical cultures. Since the anti-oxidant glutathione pathway is coupled to the pentose phosphate pathway (PPP), monitoring the activation of the PPP could provide an index for cellular oxidative stress. We developed a novel technique to monitor the percentage of glucose metabolized through the PPP relative to glycolysis (Ben-Yoseph *et al.*, J. Neurochem, 61, 230). Exposure of primary neuronal cultures to H₂O₂ for 30 min stimulated PPP activity in a concentration-dependent fashion from basal levels of 1.3±0.3% to a maximum of 20±1.9% with 100 µM H₂O₂. In primary astrocytic culture, PPP activity increased from basal levels of 5.9±1.2% to 66.7±0.8% with 300 µM H₂O₂. This striking difference in the capacity of these cell types to stimulate the PPP suggests selective neuronal vulnerability to oxidative stress. Indeed, estimated by LDH release, glial cultures exhibited a higher resistance to H₂O₂ (EC₅₀=597 µM) compared to neurons (EC₅₀=102 µM). In the presence of 2 mM deferoxamine (DFX), an iron chelator, maximal PPP activity was increased to 33.4±1.9% while H₂O₂ toxicity decreased (EC₅₀=458 µM). DFX therefore probably reduces H₂O₂ toxicity because it inhibits OH formation by the Fenton reaction, thereby maintaining H₂O₂ as a substrate for glutathione peroxidase (GPx). Under these conditions, only when the PPP became saturated did toxicity occur, indicating that OH formation from H₂O₂ is more rapid than the ability of GPx to remove H₂O₂. Aminotriazole (AT, 30 mM), a catalase inhibitor, stimulated PPP above 100 µM H₂O₂ to an extent higher than that observed in the absence of AT, suggesting that GPx is the main anti-oxidant enzyme at low [H₂O₂]. We therefore conclude that monitoring PPP activity can provide a useful means to assess the cellular capacity to alleviate oxidative stress.

Effect of regulation of Cu,Zn-Superoxide dismutase (SOD-1) on *in vivo* toxicity of kainic acid. Paul J. Schwartz* and Joseph T. Coyle. Neuroscience Dept., The Johns Hopkins Medical School, Baltimore MD; Psychiatry Dept., Harvard Medical School, Boston MA.

Over the past 10 years, the importance of copper, zinc superoxide dismutase (SOD-1) in disease states has become recognized. For many years, SOD-1 has been implicated in the etiology of Down's Syndrome (human trisomy 21). In addition, a defect in the SOD-1 gene which both decreases activity and possibly increases the nitrosylation of tyrosine residues is responsible for a familial form of amyotrophic lateral sclerosis (ALS). There is evidence that failure of antioxidant defense mechanisms is in part responsible for neuronal vulnerability to excitatory amino acids (EAAs). Since SOD-1 is one of the most important of the antioxidant enzymes, we have investigated its role in EAA neurotoxicity. We have used molecular and pharmacologic techniques to modify the *in vivo* expression of SOD-1 activity. Mice transgenic for and overexpressing SOD-1 exhibit less damage to a 0.3 µg unilateral intrastriatal injection of kainic acid than their control counterparts (64% vs 53% of contralateral choline acetyl transferase activity, p<0.05; and 2.27 vs 4.72 mm³ lesion volume, p<0.05). The toxicity decrease resembles the protection elicited by administration of the antioxidant idebenone (a ubiquinone-10 analog). We have also used intrastriatal injection of both antisense oligonucleotides directed against SOD-1 mRNA and SOD-1 inhibitor diethylthiocarbamate to decrease SOD-1 activity previous to EAA injection. The inverse relationship between SOD-1 activity and neuronal degeneration, coupled with data suggesting that apoptosis is retarded by antioxidant enzymes, implicates failure of antioxidant defense systems as a generalized mechanism for neuropathologic phenomena.

INHIBITION OF NEURONAL NITRIC OXIDE SYNTHASE (NOS) PROTECTS AGAINST NEUROTOXICITY PRODUCED BY 3-NITROPROPIONIC ACID, MALONATE, AND MPTP. J.B. Schulz*, R.T. Matthews, D.R. Henshaw, M.F. Beal. Neurology Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114

Nitric oxide (NO) is synthesized from the guanidino nitrogen of L-arginine and molecular oxygen by nitric oxide synthase (NOS). At least three isoforms of NOS have been identified: constitutive (i) neuronal and (ii) endothelial isoforms, and (iii) an inducible isoform originally isolated from macrophages. 7-Nitroindazole (7-NI) was recently found to be a potent and selective inhibitor of rat cerebellar NOS activity after intraperitoneal administration (Br. J. Pharmacol., 110: 225-228). We examined whether treatment with 7-NI is protective against neuronal injury produced by mitochondrial toxins, which are known to cause secondary excitotoxic cell death. Lesions produced by striatal injections of malonate, a reversible inhibitor of succinate dehydrogenase, were dose-dependently attenuated by 7-NI treatment in rats. 3-Nitropropionic acid is an irreversible inhibitor of succinate dehydrogenase which causes selective striatal lesions closely resembling Huntington's disease. 7-NI treatment significantly delayed the occurrence of 3-nitropropionic acid lesions in rats. MPTP induced depletion of dopamine and its metabolites was significantly blocked by 7-NI treatment in mice. Our data indicate that NO plays a role in toxicity of neurotoxins which impair oxidative phosphorylation. Inhibitors of neuronal NOS may be therapeutically useful in neurological diseases hypothesized to be related to an impairment of energy metabolism, such as Parkinson's disease and Huntington's disease.

NEUROTOXICITY: MISCELLANEOUS

EFFECTS OF COMBINED GESTATIONAL AND LACTATIONAL EXPOSURE TO COPLANAR PCBs OR TCDD ON SPATIAL LEARNING AND MEMORY IN RATS. B.W. Seo, J. Moshtaghian, R.W. Moore, R.E. Peterson, & S.L. Schantz*, Institute for Environmental Studies and Neuroscience Program, Univ. of Illinois, Urbana, IL 61801 and School of Pharmacy, Univ. of Wisconsin, Madison, WI 53706

In a previous study, monkeys showed facilitated spatial learning following combined gestational and lactational exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Here, we tested spatial learning and memory of rats following gestational and lactational exposure to coplanar polychlorinated biphenyls (PCBs) or TCDD. Time-mated Sprague-Dawley rat dams were gavaged with 2 or 8 mg/kg PCB 77 (3,3',4,4'-tetrachlorobiphenyl), 0.25 or 1.00 µg/kg PCB 126 (3,3',4,4',5-hexachlorobiphenyl), 0.025 or 0.1 µg/kg TCDD, or corn oil vehicle on days 10-16 of gestation. Litters were culled to eight on day two and weaned on day 21. Beginning on day 80, one male and one female from each litter were tested on an eight-arm radial maze with all arms baited. The animals were tested for 20 sessions, and the data were averaged into blocks of five sessions. All groups had similar numbers of errors (reentries into arms already visited) in the first block of sessions, but the TCDD-exposed males subsequently displayed a pronounced dose dependent decrease in errors relative to controls. The decrease in number of errors was statistically significant at both TCDD doses in the second block and at the higher dose in the third and fourth blocks. The pattern of effects was similar, but less pronounced in the PCB 77- and PCB 126-exposed males. The PCB- and TCDD-exposed females did not show a similar facilitation of spatial learning. Microtubule-Associated Protein 2 (MAP-2) and Glial Fibrillary Acidic Protein (GFAP) Colocalize in Reactive Astrocytes. M.G. Filbert, H.F. Shafer, B.E. Hackley* and G.P.H. Ballough. U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010-5425.

For more than a decade, MAP-2 immunostaining has been the quintessential marker for neuron identification. Found almost exclusively in the somatodendritic compartment of adult neurons, MAP-2 plays a key role in neuronal growth, differentiation and plasticity. Recent studies by our laboratory demonstrated loss of MAP-2 immunoreactivity that closely paralleled dendritic collapse and neuronal loss resulting from seizure-induced brain damage. However, at the same time, we observed increased MAP-2 immunoreactivity in the penumbral regions bordering necrotic lesions, i.e., regions exhibiting pronounced reactive astrogliosis. The present study was undertaken to examine the possibility that reactive astrocytes express MAP-2. Brain sections, from rats exposed to seizure-inducing doses of soman were double-immunostained with antibodies directed against GFAP and MAP-2; these antigens were visualized by immunofluorescence using FITC and TRITC secondary antisera. Our results demonstrate that MAP-2 and GFAP are colocalized in reactive astrocytes bordering seizure-induced brain damage. Therefore, we conclude that penumbral elevations in MAP-2 immunoreactivity result from expression by reactive astrocytes. Furthermore, these results suggest that caution should be exercised when interpreting MAP-2 immunopositive staining.

676.2

COMPLEMENT-MEDIATED NEUROTOXICITY IS REGULATED BY HOMOLOGOUS RESTRICTION. Y. Shen, J. Halperin*, M. Brandy, D. Casato, T. Sullivan, M. Russell and C.-M. Lee*. Neuroscience Research, Pharmaceutical Discovery Division, Abbott Laboratories, Abbott Park, IL 60064, +Department of Cellular and Molecular Physiology, Harvard Medical School, Boston, MA 02115

The ability of β-amyloid peptides to activate the classical complement cascade and the presence of various complement proteins including the membrane attack complex (C5b-9) on dystrophic neurites in Alzheimer's disease brains raises the possibility that this neurodegeneration may be complement-mediated. To address this issue, we have studied the effect of complement activation on nerve growth factor (NGF)-differentiated rat pheochromocytoma PC12 cells and retinoic acid (RA)-differentiated human neuroblastoma SH-SY5Y cells. Incubation with complement sufficient human serum (5%) resulted in an activation of complement pathway as monitored by iC3b formation in both differentiated PC12 and SH-SY5Y cells. This treatment can also cause the death of PC12 but not SH-SY5Y cells as shown by a significant increase in the release of lactate dehydrogenase. The killing of PC12 cells by human serum is dose-dependent (3-20%) and time-dependent (1-3 days). Heat-inactivated complement, however, was not neurotoxic. The presence of CD59 (a glycosylphosphatidylinositol-anchored homologous complement cascade inhibitor) was shown in SH-SY5Y cells by both PCR amplification and immunocytochemistry. CD59 could potentially inhibit the action of the membrane attack complex and account for the inability of human complement to lyse the human cells. Indeed, removing glycosylphosphatidylinositol (GPI)-anchored complement inhibitor with a phosphatidylinositol (PI)-specific phospholipase C (PI-PLC) rendered SH-SY5Y cells vulnerable to complement attack and eventually led to cell lysis. Reconstituted C5b-9 was also toxic to PC12 cells and PI-PLC-pretreated SH-SY5Y cells. These observations suggest that complement activation can cause neuronal cell death and this process is regulated by homologous restriction.

676.4

EFFECTS OF REVERSIBLE AND IRREVERSIBLE ANTICHOLINESTERASES ON THE MOLECULAR FORMS OF ACETYLCHOLINESTERASE. M.C. Lintern¹, M.E. Smith¹ and C.B. Ferry², Spon. by Brain Research Association, ¹Dept. Physiology, The Medical School, University of Birmingham, Birmingham, B15 2TT, UK. ²School of Pharmaceutical Sciences, University of Aston, Birmingham, UK.

Acetylcholinesterase (AChE) occurs as different molecular forms. The asymmetric (A12) form localised at the neuromuscular junction is probably involved in the hydrolysis of acetylcholine during neuromuscular transmission. In this study the effect of a single dose of a reversible AChE inhibitor, pyridostigmine (Pyr) or an irreversible inhibitor echothiophate (ECO) on the activity of the molecular forms in mouse diaphragm was investigated. Adult male BKW mice were given Pyr (100µg/kg) or ECO (500nmole/kg) subcutaneously. Pyr treated mice were killed by cervical dislocation 3, 6 and 24h post treatment and ECO treated mice were killed 6, 24, 48 and 120h post treatment. The diaphragm was removed and homogenised in high salt solubilising buffer. The molecular forms of AChE were separated on a sucrose gradient. AChE activity was determined by a radio assay. Three peaks which corresponded to the globular monomer (G1), the globular tetramer (G4) and the functional A12 form could be distinguished. At 3h after Pyr treatment there was a slight reduction in the A12 form and a slight increase in the G1 form. The effects were more pronounced at 6h with the increase in the G1 form especially prominent. At 24h the profile resembled that of the controls with a return of A12 activity towards normal and a decrease in the G1 form. The total AChE activity did not change significantly throughout the period studied. Therefore any decrease in A12 activity was masked by an increase in G1 activity. After 6h, ECO treatment had reduced the activity of all forms and by 24h the effect was maximum. By 48h the activity of each form had returned to normal with the G1 form returning first. At 120h the activity profile resembled that of the control. The results are consistent with the operation of a feedback mechanism where inhibition of the functional A12 form leads to an increase in the precursor G1 form. This could be via upregulation of the AChE gene in the muscle.

SCIATIC MOTOR NEURON NEUROFILAMENTOUS INCLUSION FORMATION FOLLOWING INTRACISTERNAL ALUMINUM CHLORIDE EXPOSURE IN AXOTOMIZED RABBITS. MJ Strong*, S Gaytan-Garcia. The Department of Clinical Neurological Sciences, The University of Western Ontario, London, Ontario, Canada

We have previously shown that intracisternal inoculums of $AlCl_3$ to New Zealand white rabbits induces a dose-dependent selective suppression of NFL and NFM mRNA levels while NFH mRNA levels remain unchanged at 48 hours postinoculation. To determine whether alterations in NF mRNA steady state levels are integral to the induction of neurofilamentous inclusions, we examined the response of spinal motor neurons to aluminum exposure *in vivo* 48 hours following a unilateral sciatic axotomy, in which a uniform suppression of all NF mRNA levels occurs. Forty eight hours following either a proximal or distal (mid thigh) axotomy, rabbits received an intracisternal inoculation of either 1000 μg $AlCl_3$ in 100 μl 0.9% NaCl, or 0.9% NaCl alone. At either 48 or 96 hours later, rabbits were killed and the extent of neurofilamentous inclusions quantified. Following proximal axotomy, rabbits developed a complete hindlimb paralysis, while distal axotomy yielded foot drop only. No difference was observed in the number of lumbar spinal motor neurons with inclusions following a distal axotomy at either time interval. Following a proximal axotomy, chromatolytic changes were observed. At 48 hours post $AlCl_3$ inoculation, 29% of contralateral neurons demonstrated inclusions whereas 43% of ipsilateral neurons demonstrated inclusions (Fisher's test, two tailed, $p = 0.0196$). At 96 hours post axotomy, 75% and 83% (resp.) of neurons were involved ($p = 0.0212$). Neurofilamentous inclusions did not form in NaCl-inoculated rabbits. These observations indicate that alterations in steady state NF mRNA levels are not critical to the pathogenesis of Al-induced neurofilamentous inclusions.

PERIODIC HIGH-DOSE METHAMPHETAMINE CAUSES DRL 36-S ACQUISITION DEFICITS IN RATS. K.E. Sabol*, J.B. Richards, L.S. Seiden. Dept. Pharm./Phys. Sci., University of Chicago, Chicago, IL 60637

Large dose regimens of methamphetamine (METH) cause long term depletions of dopamine (DA) and serotonin (5HT), as well as acquisition deficits in reaction time in rats (Richards et al., Brain Res., 627, 254-260, 1993). In the present experiment, rats were administered large doses of METH and evaluated in the acquisition of the DRL 36-s task, subsequent to the METH treatment. Rats were administered 2 METH regimens, at 6 wk intervals. Each regimen consisted of 4 injections of 15 mg/kg METH, at 2 hr intervals, or 4 injections of saline. In one group (cooling group) rats which showed signs of overheating during the drug regimen, were placed on ice for 15-30 min. In a 2nd group, the temporary cooling procedure was not used (no-cooling group). Two wks after treatment, DRL 36-s acquisition began. Four wks later, the 2nd METH regimen was administered and DRL 36-s training began again two wks after the 2nd METH regimen. The cooling group showed acquisition deficits after the 1st METH regimen, but not after the 2nd regimen. However, in this group 4 rats died after the 1st regimen and 6 more died after the 2nd regimen (starting with a total of 16 rats). In contrast, the no-cooling group showed acquisition deficits after the 1st and 2nd regimens; lethality in the cooling group was reduced to 3 rats/regimen. Post-mortem tissue assays (13 wks survival time after the 1st regimen) showed that all METH treated rats had significant reductions in DA and 5HT. The rats with the temporary cooling treatment were more depleted in forebrain structures (frontal, somatosensory, and posterior cortex, and hippocampus) than the rats which were not cooled; however, in basal structures such as hypothalamus and ventral midbrain, the cooled rats were less depleted than the rats which were not cooled. The depletion results in the hypothalamus and ventral midbrain may represent a hyper-reinnervation in rats which were more depleted in forebrain regions.

In summary, rats which were temporarily cooled during the METH regimens, showed a better survival rate, greater acquisition deficits on the DRL 36-s schedule, and larger DA and 5HT depletions in comparison to rats which were not temporarily cooled. (Supported by NIDA DA-00085 & RSA 10562, L.S. Seiden).

EUK-8, A SYNTHETIC CATALYTIC SCAVENGER OF REACTIVE OXYGEN SPECIES, PREVENTS β -AMYLOID PEPTIDE-INDUCED NEURONAL DEATH IN ORGANOTYPIC HIPPOCAMPAL CULTURES. A.J. Bruce*, B. Malfroyt, and M. Baudry. USC Program in Neurosciences, Los Angeles CA 90089-2520, and *Eukarion, Inc., Bedford MA 01730.

The β -amyloid peptide (β AP), the core constituent of senile plaques in Alzheimer's Disease (AD), has been shown (both *in vivo* and *in vitro*) to be neurotoxic under certain conditions. To test the hypothesis that oxygen free radicals are involved in β AP-induced neurotoxicity, we evaluated the effects of EUK-8, a synthetic catalytic superoxide and hydrogen peroxide scavenger, on neuronal injury produced by β AP in organotypic hippocampal slice cultures. Mature hippocampal cultures were exposed to various doses of β AP (1-42 or 1-40) in the absence or presence of EUK-8. Neuronal injury was assessed by LDH release into the media, semi-quantitative analysis of neuronal propidium iodide (PI) uptake, and loss of Nissl stain. Treatment with β AP (50-250 $\mu g/ml$) resulted in a reproducible pattern of damage, causing a 200-800 % increase in neuronal PI uptake. β AP-induced PI uptake was observed in both CA1 and CA3 pyramidal neurons, and to a lesser extent, in dentate granule cells. The same treatment also caused a 60-300 % increase in LDH release. In Nissl stained sections, β AP treatment resulted in widespread neuronal swelling, and in many cases, a complete loss of identifiable neurons.

Slices exposed to β AP in the presence of EUK-8 were significantly protected from β AP toxicity. EUK-8 at a concentration as low as 5 μM provided significant protection, and slices co-incubated with 25 μM EUK-8 and β AP (50-100 $\mu g/ml$) were fully protected from β AP toxicity. These results support a role for oxygen free radicals in β AP toxicity, and highlight the therapeutic potential of synthetic catalytic scavengers in AD.

676.6

EFFECT OF ANTICHOLINESTERASE TREATMENT ON THE EXPRESSION OF PRO-OPiomelanocortin IN MOTONEURONES. M.L. Amos¹, M.E. Smith¹ and C.B. Ferry², Spon. Brain Research Association*. ¹Dept. of Physiology, Medical School, University of Birmingham, Birmingham, UK. ²Dept of Pharmaceutical Sciences, Aston University, Birmingham, UK.

The pro-opiomelanocortin (POMC) gene is upregulated in motoneurons in conditions where motor neuropathy is present including inherited muscular dystrophy in C57BL/6J mice and following nerve transection. Increased expression of the POMC-derived peptides beta endorphin and alpha melanotropin have been demonstrated in adult motoneurons in diabetes mellitus, where peripheral neuropathy can be a late complication, and after treatment with a neurotoxin which targets motoneurons. In the present study we investigated the effect of administration of a reversible and an irreversible acetylcholinesterase (AChE) inhibitor on the expression of the POMC gene in motoneurons as a marker for early neuronal damage.

A single submyopathic dose (100 $\mu g/kg$) of the reversible AChE inhibitor pyridostigmine bromide or a single dose (500nm/kg) of echothiophate (an irreversible AChE inhibitor) which caused myopathic damage, were administered subcutaneously to adult mice of the B/W strain. The animals were killed at different times after the injection, by cervical dislocation. The spinal cords were removed and POMC mRNA expression was detected using *in situ* hybridization histochemistry. cDNA oligonucleotide probes encoding for the adrenocorticotropin (ACTH) 4-11 and beta endorphin 1-8 regions of POMC conjugated to alkaline phosphatase were used. POMC expression was not affected by the sign free dose of pyridostigmine. However treatment with a myopathic dose of echothiophate induced a significant but transient increase in POMC mRNA in motoneurons at 3h and 24h post treatment. The level had returned to normal 5 days following the treatment. It is possible therefore that upregulation of the POMC gene can accompany abnormal changes at the neuromuscular junction.

COMPLEMENT MEDIATED CYTOTOXICITY OF AMYLOID β PEPTIDE. I.J. Schultz*, J. Schaller, M. McKinley, and J. Rogers. Sun Health Research Institute, Sun City, AZ 85372.

Cytotoxic effects of amyloid β peptide ($A\beta$) have previously been observed on cultures of embryonic rodent brain. We investigated the potential of $A\beta$ to exert its neurotoxic effects via a complement mediated mechanism. The first component of the classical pathway of complement activation, C1q, binds $A\beta$ and thereby activates the classical cascade *in vitro*. The terminal component of the classical pathway, C5b-9, decorates neurites in the vicinity of $A\beta$ deposits *in situ*. This final component is termed the membrane attack complex due to its lytic action on bound cells. We utilized lactic dehydrogenase release and morphologic evaluation to determine the effect of complement availability on $A\beta$ induced lysis of rodent embryonic hippocampal cultures. We demonstrated that $A\beta$ required an active source of complement in order to exert its neurotoxic effects in the nM and low μM range. We accomplished this by incubating embryonic brain cultures with increasing amounts of $A\beta$ together with either 3% normal human serum or 3% C3 depleted serum. C3 depletion halts complement activation before the lytic components are generated, but otherwise provides normal serum components. We observed a large complement mediated enhancement of cytotoxicity to embryonic cultures over a 800 nM to 50 μM range of $A\beta$. The physiological condition of complement availability rendered even nM concentrations of $A\beta$ cytotoxic whereas high μM concentrations are required to induce cytotoxicity when $A\beta$ alone is present. These results suggest that the neurodegeneration associated with AD could result from complement mediated cellular destruction induced by $A\beta$.

676.10

NEUROTOXICITY OF BETA AMYLOID PEPTIDE ($A\beta$) AND ITS POTENTIATION BY BLOCKAGE OF CD59 COMPLEMENT PROTEIN IN SH-SY5Y HUMAN NEUROBLASTOMA CELLS. T. Sullivan, C.-M. Lee and Y. Shen*. Neuroscience Research Department, Abbott Laboratories, Abbott Park, IL 60064

Accumulation of β -amyloid peptide ($A\beta$) in the brain is one of the major features in Alzheimer's disease (AD) and is considered to contribute to the neuronal degenerative processes. This neurodegeneration may be mediated by the activation of complement cascade which is found in AD brain. The levels of CD59, a glycoprotein linked to the cell membrane via glycosylphosphatidylinositol anchor that inhibits lysis of the cell by the final complex of the complement cascade (C5b-9), are reported to be increased in AD brain. Using retinoic acid-differentiated human neuroblastoma SH-SY5Y cells as a neuronal *in vitro* model as opposed to mixed primary rat cultures, the toxic effects of freshly prepared and aged different fragments of $A\beta$ peptides (1-40) and (1-42) were compared. The $A\beta$ peptides were aged in serum-free media at 37C for 1, 3 and 7 days. Treatment with aged $A\beta$ (1-42) led to SH-SY5Y cell degeneration characterized by a swollen, chromatic or centric cell body with swollen or shrunken neurites. In addition to morphological changes, cell injury by the peptide was further characterized by LDH release measurements. Aged $A\beta$ (1-42) caused dose- (1-30 μM) and time-dependent (1-3 days) increases in LDH release from SH-SY5Y cells. Increased toxic potency was found as the aging period of $A\beta$ (1-42) was extended with 7 days being the most toxic. Little or less cell death was induced by $A\beta$ (1-40) or freshly prepared $A\beta$ (1-42) peptides. To determine if a CD59 deficiency can cause cell vulnerability, we examined the effects of aged $A\beta$ (1-40) and freshly prepared $A\beta$ (1-42) on SH-SY5Y cells following pretreatment with a CD59 antibody. Significant cell death was observed compared to treatment with either of these peptides alone.

676.11

INCREASING INTRACELLULAR MAGNESIUM LEVELS CAUSES A RISE IN FREE INTRACELLULAR CALCIUM LEVELS IN *XENOPUS* OOCYTES. J.M. Nave * and J.D. Connor. Department of Pharmacology, The Pennsylvania State University College of Medicine, Hershey, PA 17033

It has been shown that zinc (Zn^{2+}) can pass through open AMPA receptors and enter neuronal cells (Weiss, J.H. et al, 1993). Although it is known that Zn^{2+} and magnesium (Mg^{2+}) can interfere with molecules important in signal transduction, the net effects of altering intracellular concentrations of these divalent cations on corresponding intracellular calcium (Ca^{2+}) levels have not yet been studied. Ionic interactions of this type would be of interest because there are many reports indicating a direct correlation between high intracellular Ca^{2+} levels and neuronal toxicity caused by excitatory amino acid receptor agonists. The *Xenopus* oocyte expression system and the fluorescent Ca^{2+} indicator fura-2 were used to address two questions: 1) What effect does increasing the intracellular Mg^{2+} concentration have on free intracellular Ca^{2+} levels in *Xenopus* oocytes? and 2) If increasing the concentration of Mg^{2+} intracellularly changes resting levels of intracellular Ca^{2+} , is this effect correlated with cell death? *Xenopus* oocytes previously injected with water or rat brain poly(A⁺) mRNA were injected a second time with either fura-2 free acid (200 nM) or a fura-2 and $MgCl_2$ mixture. The final intracellular concentrations of Mg^{2+} (i.e. once diluted inside the cell) ranged from 1.5 times (1.33×10^{-7} mM $MgCl_2$ injected) to 6 times (1.33×10^{-6} mM $MgCl_2$ injected) physiological levels in oocytes. Increases in intracellular Mg^{2+} caused a steep rise in free intracellular Ca^{2+} levels which could not be increased further by the addition of glutamate and glycine. The high intracellular Ca^{2+} levels were not directly correlated with cytotoxicity. The Mg^{2+} -induced increases in intracellular Ca^{2+} levels may be part of a mechanism and/or pathway whereby divalent cations participate in the phenomenon of excitotoxicity.

676.13

IDENTIFICATION OF UBIQUITINATED CALCIUM BINDING PROTEINS IN ADULT RAT FOREBRAIN. S.J. Smith, A.J. Hunter*, A.P. Chapman, R. Mummery, C.C. Rider, P.W. Beesley. Royal Holloway, Dept. Biochemistry, University of London, Egham, TW20 OEX, UK and SmithKline Beecham, Neurology Research, Coldharbour Road, Harlow, Essex, CM19 5AD UK

We have prepared a calcium binding protein fraction from adult rat forebrain using phenyl Sepharose hydrophobic chromatography. Ubiquitin conjugates were identified in EGTA eluted fractions by SDS PAGE (8%) and Western blotting with a specific anti-ubiquitin monoclonal. Bands of 68, 58, 51, 41, 36 and 28 kDa were present in this fraction. Comparison with Coomassie blue stained gels shows that a subset of these proteins was ubiquitinated. Staining with ruthenium red confirmed that this fraction contained calcium binding proteins (Charuk et al. (1990) Analytical Biochem 188 123-131).

This is the first evidence for ubiquitinated calcium binding proteins in normal brain. Calmodulin from plant sources, and vertebrate tissues, (reticulocytes, RBC, skeletal muscle and testis), has previously been shown to be ubiquitinated.

676.12

CALBINDIN GENE TARGETING AND NEURON-SPECIFIC OVEREXPRESSION OF CALBINDIN AND PARVALBUMIN. M. S. Airaksinen*, M. Meyer and H. Thoenen. Max-Planck-Institute for Psychiatry, Department of Neurochemistry, D-82152 Martinsried, Germany.

The calcium-binding proteins calbindin and parvalbumin are differentially expressed in many neurons of the central nervous system, but their function is unclear. For example, it has been suggested that they may protect against ischemia and excitotoxic damage. In order to study their physiological roles, loss- and gain-of-function transgenic mice are being generated.

First, the calbindin gene has been disrupted by homologous recombination. Several targeted clones of embryonic stem cells have been injected into blastocysts; this should produce highly chimeric mice and good germline transmission. Preliminary analysis of the phenotype of the mutant animals will be presented in the meeting.

Second, several founder mice were obtained after pronucleus injection of a transgene in which neuron specific enolase promoter drives parvalbumin or calbindin cDNA. These should overexpress the proteins in most neurons; the pattern and levels are being determined by immunostaining. They will be used to test whether these proteins can protect neurons against, e.g., ischemia, kainic acid injection or facial nerve lesion.

FRIDAY AM

SYMPOSIUM

677

SYMPOSIUM. NEURAL CODING OF VISUAL SPACE: VISUAL MECHANISMS AND MULTIMODAL INTEGRATION. G. Rizzolatti, Univ. of Parma, Italy (Chairperson); J.W. Gnadt, SUNY, Stony Brook; C.L. Colby, NEI, NIH; M.T. Wallace, Bowman Gray Sch. of Med., Wake Forest Univ.

The aim of this symposium is to review recent progress in understanding how cortical areas and subcortical centers code space. Jim Gnadt will discuss visuo-motor integration in area LIP of the parietal lobe and describe how LIP neurons express a premotor signal for directing gaze that is encoded in three dimensional space. Carol Colby will compare how space is represented in LIP and in area VIP. She will present evidence that whilst LIP neurons encode spatial location in oculocentric coordinates, some VIP neurons encode stimulus trajectories in head-centered coordinates. Giacomo Rizzolatti will provide an overview on how space is coded in the premotor cortex (area F4). In this area, which controls arm movements plus head movements, most neurons are bimodal (somatosensory and visual) and code space in head-centered coordinates. Mark Wallace will discuss how multisensory integration takes place in the Superior Colliculus and polysensory cortex of the cat. He will show that the maturation of multisensory integration requires a protracted postnatal period during which time a functional relationship between cortex and midbrain is being established. An important point which results from the different presentations is that the space is represented differently in different areas and that the representation in a given area reflects the motor output by which a stimulus can be acquired.

678.1

COGNITIVE ESTIMATION AND THE FRONTAL LOBES.

R.E. O'Carroll* and R. Taylor of MRC Brain Metabolism Unit, Royal Edinburgh Hospital, Edinburgh, EH10 5HF, Scotland, U.K.

The Cognitive Estimation Test (CET) was devised by Shallice & Evans (Cortex, 1978, 14, 294-303) in an attempt to quantify the tendency observed in some patients with frontal lobe lesions to produce bizarre estimates in response to questions to which people do not usually know exact answers (e.g. "what is the length of an average man's spine?"). Despite performing normally on standard intelligence tests. In the present study, the CET performance of 370 patients suffering from head injury, brain tumour, ruptured aneurysm (anterior communicating artery and other), multiple sclerosis, dementia, encephalitis, Korsakoff's syndrome and anxiety/depression were compared with CET scores from 150 healthy controls. Only the patients with Korsakoff syndrome demonstrated significantly impaired CET performance. This impairment of CET performance in Korsakoff's syndrome is interpreted as possible resulting from: (a) a dysfunctional semantic memory system, and (b) lack of cognitive "error checking", perhaps related to the confabulatory behaviour which is characteristic of the disorder. A sub-group of patients with discrete frontal lesions (N = 15) was compared with a group with localised posterior lesions (N = 17). No significant difference in CET performance was observed between anterior and posterior lesioned patients (frontal CET score (mean, s.d.) = 5.9 (4.3), posterior = 6.3 (3.8), $t = 0.34$, N.S.). The sensitivity of the CET to anterior brain dysfunction is called into question by the present findings.

NEURAL BASIS FOR RETROGRADE KNOWLEDGE RETRIEVAL.

D. Tranel*, R.D. Jones, J.P. Brandt, H. Damasio, & A.R. Damasio. Dept. of Neurology, University of Iowa, Iowa City, IA 52242.

As a part of a project to elucidate the neural basis of retrograde memory, we studied 30 patients with focal, stable lesions caused by cerebrovascular disease (n=12), herpes simplex encephalitis (n=5), temporal lobectomy (n=9), and anoxia/ischemia (n=4). Hypothesis-driven cognitive experiments were developed to investigate retrograde memory at different levels (e.g., unique/nonunique), in different domains (e.g., public/personal), along different dimensions (e.g., recent/remote), and for different types of material (e.g., verbal/nonverbal). The procedures were standardized in 60 normal controls. The results indicated that: (1) Severe defects for retrieval of unique personal and public knowledge were associated with bilateral anterolateral temporal damage involving the temporal polar region (area 38) and the anterior sector of the inferotemporal (IT) region (areas 20/21); (2) Mild, albeit significant, defects in retrieval of unique personal and public knowledge were associated with unilateral right-sided damage to these same structures; (3) Damage to more posterior temporal regions, including posterior IT, produced circumscribed, modality- and material-specific defects in conceptual (e.g., in prosopagnosia) or lexical (e.g., in anomia) knowledge retrieval, but not the defects described in #1 and #2; and (4) damage confined to mesial temporal structures (amygdala, entorhinal cortex, hippocampus) produced expected material-specific defects in anterograde memory, but did not affect retrieval of knowledge from the retrograde compartment. The findings implicate nonmesial, anterolateral temporal cortices, especially those on the right, in the retrieval of retrograde knowledge.

PRAXIC AND NONVERBAL COGNITIVE DEFICITS IN A LARGE FAMILY WITH A GENETICALLY TRANSMITTED SPEECH AND LANGUAGE DISORDER

F. Vargha-Khadem¹, K.E. Watkins¹, K. Alcock², P. Fletcher³, R.E. Passingham². ¹Inst. Child Health and Great Ormond Street Hospital for Children, London, ²Dept. Exp. Psychol., Uni. Oxford, and ³Dept. Ling. Sci., Uni. Reading, U.K. (SPON: European Brain and Behaviour Society).

A severe developmental dysphasia has been described in half of the members of a large family of 4 generations. This suggests that the disorder is transmitted by a dominant gene. Gopnik (Nature, 344, 1990) and Pinker (The Language Instinct, 1994) have suggested that the affected members suffer from a selective grammatical defect. Our investigations of the same family indicate that the affected members' disorder transcends the expression of grammar to include grossly impaired articulation of speech sounds, the processing and expression of areas of the grammar unrelated to features, and, further, a severe extralinguistic orofacial apraxia. In addition, the affected family members have Verbal and Performance IQ scores that are on average 18-19 points below those of the unaffected members. This psychological profile indicates that the disorder does not affect syntactical-semantic features exclusively, or even primarily; rather it affects cognitive, linguistic and orofacial praxic functions generally. It is therefore erroneous to conclude, as Gopnik and now others, such as Pinker, have done, that the affected members suffer from a genetic disorder that affects only grammar, and indeed only certain aspects of grammar, and that this family provides evidence for the existence of "grammar genes".

678.2

HOW DEEP IS THE "DENIAL" OF PARALYSIS (ANOSAGNOSIA) IN PARIETAL LOBE SYNDROME?

Y.S. Ramachandran*, UCSD, Brain and Perception Lab, Psychology, 0109, La Jolla, CA 92093-0109

Patients with right parietal lobe disease often deny their paralysis. Is the denial only at a verbal/semantic level so that the patient is subconsciously aware that the arm is paralyzed? We devised three novel tasks: a) A vertical mirror was placed on the table so that he could see the reflection of his right hand superimposed on his paralyzed hand. When moving his right hand, his paralyzed left hand appeared to move. Would this startle the patient as measured by raised eyebrows or a GSR? b) Given a choice between performing an easy bimanual task (e.g., making a "bow knot"; cutting circular shape) vs. a difficult unimanual task (e.g., threading a nut on a bolt), would the patient spontaneously prefer the latter? If so, would the preference be reversed by caloric stimulation? c) If the patient watched his failure to perform in a large mirror, would he admit paralysis?

Two patients (LR & BM) with right parietal lesions were studied. Interestingly, on most tests they showed no evidence of "subconscious knowledge" of paralysis, suggesting that the denial was deep. BM, however, showed a consistent preference for the unimanual task but "didn't know why." Intriguingly, with caloric stimulation she acknowledged having been paralyzed for several days; the denial apparently had not prevented memory consolidation! Yet 8 hours later, she denied having admitted the paralysis during stimulation. Far from being merely a bizarre manifestation of cerebral disease, these syndromes may be an "encapsulated" form of the kinds of denials, repressions and rationalizations, that characterize our normal mental life. Our tests may therefore provide a novel and sensitive probe for studying these enigmatic effects.

678.4

IMPLICIT BUT NOT EXPLICIT CONJUNCTION INFORMATION IN A BALINT'S PATIENT.

E. Wojciulik*, L. Robertson, and N. Kanwisher University of California, Los Angeles (EW & NK), University of California, Davis (LR)

This experiment examined a patient (RM) with bilateral parietal damage, testing for the presence of implicit information about feature conjunctions under conditions where the subject was at chance in an explicit conjunction task. In a Stroop display with two color-name words, one word was presented in one of four colors (the target), and the other was presented in white (the distractor). The patient's task was to name the color in which the target word was displayed. The display duration was adjusted for each block to a level at which RM showed chance performance on an interleaved explicit conjunction task. The Stroop results showed that RM's response time was significantly slower when the target only was incompatible with the color (1419 ms) than when the distractor only was incompatible (1148 ms), suggesting that correct conjunction information must have been available at some level in the visual system. These findings show that despite the absence of explicit conjunction information and despite his presumed attentional deficit, RM nonetheless has implicit knowledge of color and shape conjunctions.

CATEGORY-SPECIFIC ANOMIA: IMPLICATIONS FOR THE NEURAL BASES OF OBJECT KNOWLEDGE.

J. Hart & B. Gordon*. Depts. of Neurology and Cognitive Science, and the Zanvyl Krieger Mind/Brain Institute, The Johns Hopkins University, Balto., MD 21287

Considerable evidence supports a hierarchy of processing modules in human cognition, including featural, object, and supraordinate category levels. The assumed hierarchical organization of these levels has implied that category level knowledge does not modulate processing of subordinate levels. We present evidence from three patients with category-specific anomias suggesting that supraordinate information is a strong influence on object naming and featural processing. Patient 1 had a category-specific anomia for animals, fruits and vegetables, and plants; Patient 2, for small household objects and tools; and Patient 3, for animals only. Patient 1 had a co-existing deficit for identifying features of objects within her impaired category. In each case, processing of object names (and feature identification in Patient 1) that were in the affected category was strongly impaired, while processing of names in different categories was relatively unaffected. These data imply that categorical information strongly influences access to other levels of information within human language and its subsystems. The existence of this highly nonlinear interaction is a strong constraint for theories of processing dynamics within cognitive systems. Moreover, bilateral temporal pathology in each of the three cases strongly implicates this region of the brain as the repository of such types of information and their interactions.

678.7

MODEL ANALYSIS OF STROOP INTERFERENCE.

Kiyohiko Nakamura*. Grad. Sch. of Information Systems.
Univ. of Electro-Communications, 1-5-1 Chofugaoka, Chofu
Tokyo 182, Japan.

A model of cortical circuitry for processing the Stroop word-color tasks is presented. MODEL: The circuitry consists of the Wernicke area, the color-processing pathway, the Broca area, and the premotor area. The former two project to both the latter two. Each area is assumed to be an array of cortical columns, which are composed of populations of pyramidal cells and inhibitory interneurons. Membrane characteristics are given by the Hodgkin-Huxley circuit. Instruction to subjects controls excitability of the areas by norepinephrine release from the brain stem, which reduce potassium conductance. RESULTS: The model demonstrates: (1) The circuitry of each area performs temporal competition of the millisecond range: lateral inhibition between the columns restricts firing to the first activated columns by suppressing the others before firing. This enables the whole nervous system to select relevant response in a few hundred milliseconds. (2) The competition delays the columns' response if incongruent stimuli (e.g., word "red" printed in blue ink) activate mutually inhibiting columns of the Broca area to name the ink color. (3) Assume the projection of the Wernicke area to the premotor area is not so strong as the fasciculus arcuatus. Then, in cases where other response is instructed than verbal one, the same stimuli do not delay the response. These results suggest the temporal competition should be the neural mechanism of cortical processing of the millisecond range.

678.8

DIVISION OF INPUTS BETWEEN THE HEMISPHERES REDUCES INTER-WORD INTERFERENCE. Liederman, J.*, Thome, M., Sohn, Y.S., and Palomo, D., Psychology Dept., Boston University, Boston, MA 02215

We examined whether division of inputs between the hemispheres, as compared to single hemisphere presentation of all inputs, reduces the amount of inter-item interference. On the first display, a centrally-placed target word was presented. In the second display, 4 three-letter words were presented: 2 words to each hemisphere, or all four to a single hemisphere. In 50% of the trials, the target matched one of the 4 words; in 25% of the trials, the target did not match any of the words, and in 25% of the trials, the target word was a re-combination of two separate words in the second display. Half of these conjunction matches blended letters of words which were presented to a single hemisphere, and half were a blend of words presented to opposite hemispheres. Results indicated that performance was most accurate when inputs were divided between the hemispheres, and that this was especially the case when subjects needed to resist mistaking the conjunction for a match. This was not confounded by inter-item distance. We conclude that division of inputs between the hemispheres improves performance at least in part by reducing the number of inter-word intrusions as compared to intrusions among words presented to a single hemisphere.

678.9

NON-PHYSICAL MIND WOULD VIOLATE PHYSICAL LAWS. David L. Wilson* Dept. of Biology, Univ. of Miami, Coral Gables, FL 33124

Beck and Eccles (PNAS, 1992) propose a mechanism by which voluntary movements occur through non-physical mental activity. Their model proposes that, as a consequence of volition, increased EPSPs occur because of quantum mechanical actions that increase the probability of exocytosis at hundreds of thousands of boutons on pyramidal cells. They claim that such events can occur "...without violating physical conservation laws" even though they view the causative mental events as not being part of the physical universe. I have earlier argued that a non-physical mind cannot produce changes in the physical universe without violating physical laws (Wilson, 1976, 1993). Have Beck and Eccles found a way to avoid such violation? Quantum mechanical effects such as those proposed by Beck and Eccles are random events, such as occur with radioactive decay. In the case of the Beck and Eccles model of mental events interacting with quantum probability amplitudes, the result would be distinctly non-random. Therefore, a set of neurons that fired at times linked directly to volition, but whose firings were not caused by physical events, would violate physical laws.

VISUAL PSYCHOPHYSICS AND BEHAVIOR III

679.1

Perceptual contour completion: a model based on local, anisotropic, fast-adapting interactions between oriented filters

Jochen Braun*, Ernst Niebur, Heinz G. Schusterl, and Christof Koch
Computation and Neural Systems Program, Caltech, Pasadena, CA 91125, †
Univ Kiel, Inst Theor Physik, 24098 Kiel, Germany.

Long contours are perceptually salient despite missing segments and distracting contours in the background, evidently because the visual system is able to integrate information along the length of the contour. In principle, such integration of information can be accomplished by an iterative comparison of neighboring locations (Ullman and Shashua, MIT AI Memo 1061, 1988). However, it is unclear how this iterative scheme can be realized by a neuronal network in primary and secondary visual cortex. As a first step towards a neuronal realization, we simulated a network of oriented filters, with anisotropic interactions of a range matching psychophysical evidence (Polat and Sagi, Vision Res, 34: 73-78, 1994). In addition, we allowed interaction strengths to adapt in response to a given stimulus, implementing the iterative scheme of Shashua and Ullman.

The model was tested on gray level images composed of discrete 2-D Gabor elements (spatial period λ). Oriented filters were spaced by $\lambda/2$ in visual space and by $\pi/16$ in orientation. The initial strength of the interaction between filters (before adaptation took place) peaked at a center-to-center separation of 3λ and for roughly collinear configurations. Performance of the model was compared to that of simpler, non-adapting networks. The model exhibited contour integration in good qualitative agreement with human observer performance.

Effects of Non-Local Interactions on the Perceived Direction of Motion of Fourier and Non-Fourier Line Segments
H.S.Orbach* and H.R.Wilson Univ. of Chicago, Chicago, IL.

A tilted (3.4° wide) bar moving (1, or 2, °/sec) in the vertical direction appears to move in the direction perpendicular to its orientation (63° to the horizontal) when seen through a small (0.375°) circular aperture. Vertical motion is perceived when two flanking apertures are added which show the ends of the bar. For increased aperture separation, the perceived direction of motion shifted back to the direction perpendicular to the orientation of the bar. An analogous experiment, with the center bar a non-Fourier contrast modulation, found similar interactions produced by non-Fourier and Fourier terminators. Changing aperture positions, we found a 2-dimensional interaction region with space constants of 1° and 0.4° (parallel and perpendicular to the bars' orientation). For a large separation of the flanking apertures, increasing the size of the center aperture biased the perceived motion back towards the vertical, indicating a strong effect of interaperture distance. This suggests a non-local interaction, after motion signals are combined by pattern units, that damps out when one unit is inactive but increases when both units are active. Models, based on simple, physiologically plausible, modifications of local models will be discussed.

679.3

THE EFFECTIVE LUMINANCE OF COMPLEX STIMULI IN MOTION: FIRST-ORDER SIGNALS FROM SECOND-ORDER STIMULI

R. O. Brown*, UCSD, La Jolla, CA 92093-0109.
Models of visual motion distinguish first-order, or "Fourier" stimuli (e.g. a light bar moving on a dark background) from second-order, or "non-Fourier" stimuli (e.g. a B&W striped bar moving on a grey background equal to the mean luminance of the striped bar). But the nonlinearity of luminance signals in the early visual system suggests that the effective luminance of a striped bar cannot be simply its space-averaged mean luminance.

In experiment 1, the effective luminances of moving striped bars were determined by a new technique, modified from the minimum-motion method of Anstis & Cavanagh (1983). For 5/5 subjects, the effective luminances of striped bars (at 100%, 50% and 25% contrast) were significantly less than the means of their component luminances, as predicted by nonlinear compression.

In experiment 2, the same subjects made 2-alternative forced choice discriminations of the direction of motion of striped bars on grey backgrounds. All subjects performed well when the background equalled the mean luminance of the striped bars (a second-order stimulus), but motion discrimination was specifically impaired against the [darker] background equal to the effective luminance of the striped bars (a first-order stimulus in physical luminance).

Thus, even at low contrasts, second-order stimuli may generate first-order signals that support motion perception, while first-order stimuli may not. Studies of second-order motion stimuli that were not balanced for effective luminance should be interpreted with caution. (Supported by PHS EY01711-18.)

DISCRIMINATION OF VISUAL CATEGORIES IN RHESUS MONKEYS.

R. Vogels*, Lab. Neuro- en Psychofysiologie, KUL, B-3000 Leuven, Belgium.

Several models have been formulated regarding the ability of humans to assign visual objects to categories (e.g. to identify an instance of a tree as a tree). Since behavioral methods alone were quite unsuccessful in deciding among these models, examining the representation of visual categories at the single cell level could be informative. As a prelude to this, I determined whether rhesus monkeys are able to categorize visual stimuli using a paradigm suitable for single unit recording. On each trial, a single stimulus was presented during fixation. Stimuli were color pictures of trees (the category to learn) or other objects which were similar to trees, but clearly belonging to another category for human observers. Care was taken that the tree instances, as well as non-trees, varied sufficiently in physical features. The monkey was required to make a rightward or leftward saccade if a tree or a non-tree, respectively, was presented. In order to avoid concurrent learning of the individual pictures, 20 to 40 instances of trees and of non-trees, of which some were new to the animal, were presented in a single session (400-600 trials). After the 3rd training session, the monkey responded correctly to the novel trees and non-trees, indicating categorical discrimination. Subsequent transfer tests in which the presence of simple features (e.g. color, texture, shape) was manipulated, ruled out the possibility that the monkey used a single visual feature as cue. More abstract features, such as leaves or branches, when isolated from others, kept some stimulus control, but was not sufficient to explain the discrimination. Thus, at least a combination of features, each not necessary nor sufficient, was controlling the behavior. These results show that the monkey responded to a class of physically dissimilar objects which form a natural category. (Supported by G.S.K.E.)

MAINTAINING ATTENTION ON AN EXTRAFOVEAL STIMULUS ACTIVATES THE CONTRALATERAL SUPERIOR PARIETAL LOBULE IN A FEATURE DISCRIMINATION TASK: A PET ACTIVATION EXPERIMENT.

R. Vandenberghe^{1,2}, P. Dupont¹, A. Rosier^{1,2}, B. De Bruyn², L. Mortelmans¹ and G.A. Orban², ¹PET Center, Dept. of Nuclear Medicine, UZ, GHB, ²Lab. Neuro- en Psychofysiologie, Medical School, KU Leuven, GHB, B-3000 Leuven, Belgium.

We studied the contribution of the superior parietal lobule in tonal engagement of peripheral attention and in ignoring a peripheral distractor. The 10 subjects, who gave their informed consent, performed an orientation discrimination task and a stimulus detection task in three different stimulus conditions: the stimulus was either a foveal grating, or an extrafoveal grating placed at 5 degrees to the left of the fixation point, or the foveal grating (the relevant stimulus) presented simultaneously with the extrafoveal grating (the distractor). Subtracting the extrafoveal target detection from the extrafoveal target identification condition revealed activation of the contralateral superior parietal lobule (at 62 mm posterior and 48 mm superior to the AC-PC line; $p < 0.001$). This focus was also significant in the subtraction between the extrafoveal identification minus the foveal identification condition ($p < 0.01$). In the presence of the extrafoveal distractor, the superior parietal lobule was activated ipsilaterally ($p < 0.001$). These data indicate that, at least for feature discrimination, the superior parietal lobule is activated by tonal engagement of attention.

SIZE ILLUSIONS AFFECT PERCEPTION BUT NOT PREHENSION.

M.A. Goodale*, S. Aglioti, and J.F.X. DeSouza, Department of Psychology, University of Western Ontario, London, Ontario, Canada N6A 5C2.

There are many examples of visual illusions in which perception of the relative size of objects does not correspond to their real size. One such illusion is the so-called "Titchener circles" in which two target circles of equal size each surrounded by a circular array of either smaller or larger circles are presented side by side. Subjects typically report that the target circle surrounded by the array of smaller circles appears larger than the other. By adjusting the real size of the target circles, they can be made to appear equivalent in size. Although the perception of size is clearly affected by such manipulations, one might expect that the calibration of size-dependent motor outputs, such as grip aperture during prehension, might not be. To test this idea, we used a variation of the Titchener circles illusion in which two thin "poker-chip" disks were used as the target circles. Subjects were given the following instructions: if the disks appear equal in size, pick up the disk on the left; if they appear different in size, pick up the one on the right. Subjects used their right hand and grip aperture was tracked using standard opto-electronic recording (WATSMART). The relative size of the two disks was randomly varied so that on some trials the disks appeared perceptually equivalent but were physically different in size, and on other trials they were physically equivalent but perceptually different. We found that, while subjects' perception of the relative size of the two disks was affected by these manipulations, the scaling of their grip aperture (measured before contact with the disk) was not. Instead, it was entirely determined by the true size of the target disk. These results lend further support to recent suggestions that the visual mechanisms underlying perception and visuomotor control are largely independent. (Supported by MRCC Grant to MAC)

679.6

VISUAL SURFACE PERCEPTION OF UNTEXTURED CROSS STEREOGRAM DETERMINED BY FIXATION POINT IN DEPTH IN NEAR VIEWING CONDITIONS

Wu Zhou, W.M. King*, University of Mississippi Medical Center, Jackson, MS, USA 39216

The cross stereogram shown below (Adapted from Nakayama & Shimojo, Sci., 257: 1357-1363, 1992) has no interior texture. The only source of horizontal disparity information is provided by the vertical limbs. What is the perceived depth of the interior portions of the horizontal limbs where disparity is not explicitly defined? Depth interpolation predicts a linear gradient of depth from the center of the cross to the ends of the horizontal limbs. The observer should see a vertical bar flanked by horizontal "wings" that are slanted toward or away depending on whether the vertical bar is seen behind or in front of the ends of the horizontal limbs respectively. Alternatively, the generic sampling principle (Nakayama and Shimojo, 1992) states that the visual system acts as if it were viewing surfaces from a generic rather than an accidental vantage point, and predicts that the observer should see a horizontal bar in front of or behind a vertical bar. In near viewing conditions, we found that either configuration could be seen depending on where in depth the observer fixates. If the observer fixates the same depth as the vertical bar, the seen configuration is a vertical bar flanked by horizontal "wings" that are slanted toward or away from the observer; however, if the observer fixates the same depth as the ends of the horizontal limbs of the cross, the seen configuration is a horizontal bar in front or behind a vertical bar. These observations can not be explained by either linear depth interpolation or the generic sampling principle. We suggest it is the fixation-dependent local disparity information that is important in interpreting this type of ambiguous untextured stereogram. The generic sampling principle might be important for surface perception in far viewing conditions, such as driving. (EY04045 to Dr. King)

VISUAL ATTENTION MODULATES METACONTRAST: A NEW APPROACH TO THE "BINDING PROBLEM."

S. Cobb, V. S. Ramachandran, D. Rogers-Ramachandran*, Psychology Department, UCSD, 0109, La Jolla, CA 92093-0109.

How does the visual system bind different fragments in the visual scene to create enduring object representations? When a central target square A is flashed briefly on the CRT (70 ms) and followed immediately two flanking squares for 60 ms in frame 2, the target is erased completely from consciousness ("metaccontrast" or "backward masking"). We used this basic display to develop two striking new visual effects. 1) In experiment 1 we added two new squares (B & C) in frame 1 so that B appeared right next to the target (A) and C was off to one side on the corner of the CRT. When B and C were grouped perceptually, masking continued to occur but if B was grouped with A, masking was abolished completely, i.e., "binding" A and B perceptually into a single "object," rendered A immune from masking. 2) In experiment 2, we added two new squares (B & C) to frame 1 on either side of the target (A) to form horizontal row of three. And in frame 2 we added two new squares (one above and one below) to form a vertical column of four squares. When subjects paid attention to the vertical column, the central target square in frame 1 disappeared completely but when they switched attention to the horizontal row, the target reappeared with perfect clarity. We conclude that visual attention "binds" the target with the other squares on the basis of temporal synchrony and spatial proximity and renders it immune from metaccontrast.

FILLING-IN MODEL PREDICTS AREA-SUPPRESSION FOLLOWS U-SHAPED FORWARD MASKING FUNCTION. K. F. Arrington*
Brain & Cognitive Sciences, M. I. T., Cambridge, MA, 02139

The filling-in theory¹ of surface brightness is tested under forward and backward area-suppression masking conditions. Under these conditions the brightness of a uniform area of a target disk is suppressed by a distant mask. The area-suppression of brightness follows a u-shaped function of stimulus onset asynchrony (SOA) for both forward and backward masking, unlike traditional metacontrast suppression which is usually assumed to be a contour suppression effect and which shows little forward masking². Here the Boundary Contour System / Feature Contour System (BCS/FCS) neural network model³ of brightness filling-in is evaluated under forward and backward masking stimulus conditions. The model accurately predicts that the area suppression is equal in strength for forward and backward masking and that the area suppression follows a u-shaped function of SOA for forward-masking. This u-shaped function is an emergent property of the filling-in dynamics; it occurs without incorporating delay, as has been done in sustained-transient theories that account for u-shaped functions of SOA in backward masking.

Short-Term Memory for Visual Motion. Tatiana Pasternak* and Tina M. Newman. Department of Neurobiology & Anatomy and Center for Visual Science. University of Rochester, Rochester, NY 14627

We examined short-term retention of visual motion signals with stimuli that require either local (gratings) or global (dynamic random dots) analysis of motion information. Previous studies have shown that these two types of stimuli may be processed at different levels in cortex.

Two macaque monkeys were tested in a matching-to-sample task in which they were required to match the direction of moving stimuli. On each trial, they viewed a sample stimulus moving in one of eight directions. After a temporal delay, the monkeys were presented with two choice stimuli moving in opposite directions, one of which matched the direction of the sample. The retention of local and global directional information was evaluated by varying the salience of the sample stimulus (e.g. contrast, motion coherence) and measuring motion thresholds over a range of temporal delays (0-4 sec) interposed between the sample and the choice stimuli. Performance declined gradually with increasing delays and the rate of decline was similar for both types of stimuli. This similarity suggests that short-term retention of directional information may depend on a single process even for very different types of motion information. The results also suggest that the representation of motion signals fades over a period of a few seconds.

679.10

IS HEADING BASED ON MOTION FIELDS OR MODELS OF A SCENE? J. Beusmans*. Nissan Cambridge Basic Research, 4 Cambridge Center, Cambridge, MA 02142, USA.

Neurophysiological research on egomotion is presently focused on cortical area MST, which is presumed to receive information about optic flow fields. We believe this focus is misguided on both theoretical and empirical grounds.

Our theoretical reservations derive from the fact that area MST is organized retinotopically, which implies that heading would be perceived in a retinotopic frame of reference. This seems a poor choice because observers move their eyes continually; MST's representation of a fixed direction of observer movement would thus change continually with eye movements.

Our empirical results question the assumption that heading is based directly on optic flow, the presumed MST input. First, we have found that the human perception of heading is more robust in a structured scene than in an unstructured one, even though the optic flow in both was roughly equivalent. The structured scene was a textured ground plane 60m deep; the unstructured scene was a cloud of 150 large dots whose depth varied randomly between 0 and 60m. A 3s image sequence simulated translation through these scenes at 6m/s; during the sequence, the subject fixated on a cross at eye height which required active eye movements. After about 1.5s, heading changed between 1 and 6 deg. Changes of 4 deg or more were always perceived with the ground plane, whereas such large changes generally went unnoticed with the flow generated solely by the cloud of dots. Second, subjects can perceive their heading in a scene consisting solely of spheres rotating about arbitrary axes through their centers.

These results challenge the assumption that heading is based directly on flow fields. As an alternative, we propose that the locomoting observer constructs a scene model and perceives heading based on its perceived motion within the scene. Posterior parietal cortex might be a more appropriate focus than MST for neurophysiological research on heading.

679.12

PERCEPTUAL FRAMING THROUGH NEURAL SYNCHRONIZATION A. Grunewald* and S. Grossberg. Department of Cognitive and Neural Systems, Boston University, Boston, MA 02215.

The retinal image changes rapidly during self- or world-motion. Different processing rates of features within a single image mean that parts of subsequent images may get processed together. Such wrong conjunctions are typically experienced only under extreme conditions. The process that minimizes wrong conjunctions is called perceptual framing. A neural network model is proposed that implements this process. The model rapidly synchronizes activities across a neural network, thereby reducing the variability of neural response timing. This synchronization occurs due to cooperative feedback interacting with fast and slow coupled cells (Grossberg & Somers, 1991) and does not require central entraining.

The model accounts quantitatively for data indicating a reduction of variability of response onset latencies as one ascends in the visual hierarchy. Moreover, the model accounts quantitatively for temporal order judgment data indicating that 20ms stimulus onset asynchrony suffices for 75% accurate performance (Hirsh & Sherrick, 1961) and for spatial pooling data suggesting that pooling occurs over distances beyond the size of a single classical receptive field (Essock, 1990). The model predicts that bright stimuli that are presented too briefly to be detected may become visible if their size is increased.

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS IV

680.1

LONG TERM CHANGES IN HIPPOCAMPAL EXCITABILITY FOLLOWING OVEREXPRESSION OF GLUR6. A.E. Telfeian1*, M. Durling1, H.J. Federoff2, G. Mirchandani and A. Williamson1. Section of Neurosurgery, Yale Univ. School of Med., New Haven, CT (1) and Depts. of Neurosci. and Med., Albert Einstein Univ., New York (2).

We have previously shown that overexpression of the GluR6 kainate receptor subtype can be achieved by injecting the hippocampi of rats with an HSV-1 vector which expresses the GluR6 KA receptor (HSVGLuR6; Durling et al, Soc Neurosci Abstr. 1993). These animals have limbic seizures following the injection. Seizures were not produced when HSVlac (expressing β -galactosidase) was injected. These animals have served as controls.

When studied in hippocampal slices, the initial (12-48 hour) response obtained following the injection of HSVGLuR6 was the presence of non-synaptic Na⁺-mediated spontaneous bursting. No bursting was seen in the CA1 cells of HSVlac-injected animals. The synaptic responses are normal in these animals. (Williamson et al, this meeting).

However, the physiological properties of CA1 cells in HSVGLuR6-injected hippocampi changed dramatically over time. By two weeks post-injection, non-synaptic bursts were no longer seen in any of the cells studied. Moreover, at all times longer than 1 week following HSVGLuR6 injection, synaptic inhibition was reduced and synaptically-evoked bursts in CA1 could be reliably produced. Both the fast and slow phases of the IPSP appear to have been affected. These changes persist for at least two months after the injection and were not seen in the HSVlac-injected animals at equivalent times. We have observed a similar pattern of pattern of hyperexcitability in CA1 cells epileptic patients. Therefore, overexpression of a single glutamate receptor subtype, may provide a new model for the human disease.

680.2

MULTI-COMPONENT EPSPs EVOKED FROM DENTATE GRANULE CELLS IN PILOCARPINE-TREATED RAT HIPPOCAMPUS. Masako Isokawa*. Brain Research Institute, CHS, UCLA, Los Angeles, CA 90024-1761.

Pilocarpine is a muscarinic acetylcholine receptor agonist and can produce a highly relevant model for human hippocampal epilepsy (Isokawa and Mello, 1991). We previously reported by intracellularly recording from dentate granule cells (DGCs) that, in this model, excitatory responses were increased in the perforant path neurotransmission. The present study was designed to investigate the mechanisms of this excitatory increase using the whole-cell patch clamp recording technique in slices. Male Sprague-Dawley rats (100-150g, N=23) were injected with pilocarpine (300mg/kg, i.p.). Fourteen rats showed spontaneously recurring seizures of 5-107 (average: 23.5 ± 8.4 SE) during the period of 1-3 months. In hippocampal slices prepared from these animals, single perforant path stimulation produced paired population spikes in DGCs. These spikes were often generated in an all-or-non fashion, although a weak current could occasionally separate them evoking only single spikes. When DGCs were patch clamped in a whole-cell configuration with CsMeSO₃-containing electrodes, resting membrane potentials measured right after the whole-cell formation were in average $-59.3 \text{ mV} \pm 1.39 \text{ SE}$, which was not significantly different from those in control rats (-60.7 ± 1.6 , N=5) and in rats that were injected with pilocarpine but did not show spontaneous seizures (-57 ± 2.4 , N=11). However, in DGCs of seizure-experienced rat hippocampus, single perforant path stimulation produced a complex, multi-component EPSPs with a significantly longer duration. The EPSPs were comprised of two or more peaks, and the induction of additional peaks after the primary EPSP was stimulus intensity dependent. This suggests that 1) additional peaks in the prolonged EPSPs are less likely to be spontaneously-generated miniature potentials superimposed on the evoked EPSPs, instead 2) perforant path stimulation may generate asynchronously arriving excitatory inputs that converge on DGC dendrites, summing up individually-evoked EPSPs in pilocarpine-treated rat DGCs. Supported by grants from NIH (NS31180 and NS 02808).

680.3

OVEREXPRESSION OF GLUR6 IN RAT HIPPOCAMPI PRODUCES SPONTANEOUS, NON-SYNAPTIC BURSTING IN VITRO. Anne Williamson*1, A. E. Telfeian1, P. Leone1, H.J. Federoff2 and M. Doring1. Section of Neurosurgery, Yale Univ. School of Med., New Haven, CT (1) and Depts. of Neurosci. and Med. Albert Einstein Univ., New York, NY (2)

Kainic acid injection has been extensively used as a model for temporal lobe epilepsy. We tested the hypothesis that an overexpression of kainate receptors alone would induce seizure activity. Overexpression of GluR6, a KA receptor subtype, was achieved by injecting the hippocampi of rats using HSV-1 as a vector (HSV-GluR6; Federoff et al, 1990, PNAS, 89:1636). These animals experience limbic seizures within four hours following the injection. Animals injected with HSVlac, a vector which expresses β -galactosidase did not have limbic seizures and were used as a control.

Slices were made and whole-cell patch recordings performed in hippocampi 12 to 48 hours post-injection (n=78). The majority of CA1 and CA3 pyramidal cells, but not dentate granule cells, fired spontaneous bursts at rest in HSV-GluR6-injected animals. This activity was not seen in the HSVlac-injected animals. However, the evoked synaptic responses in CA1 and CA3 in both HSV-GluR6 and HSVlac-injected animals were normal.

Physiological and pharmacological studies demonstrate that these bursts were non-synaptic events mediated by intrinsic Na⁺ conductances. The spontaneous bursting was only seen within a narrow voltage range near rest (-55 to -65 mV) and was not blocked by APV and/or CNQX. Moreover, they were not blocked by local bath application of Cd²⁺. These bursts were mediated by Na⁺ conductances as TTX blocked the potentials and they were not seen when the local anesthetic derivative QX314 was included in the recording pipette. These data suggest, therefore, that the overexpression of KA receptors has rapid effects on the electrophysiological properties of hippocampal neurons. These changes may be important in the generation of synchronized activity which underlies temporal lobe seizures.

680.5

CORTICAL SYNAPTOSOMAL ⁴⁵Ca⁺⁺ UPTAKE DIFFERENTIATES EPILEPTIC AND NON-EPILEPTIC MICE. A.F. Burroughs and M.J. Litzinger* Laboratory of Applied Neurobiology, Department of Pediatrics, University of Utah, Salt Lake City, UT 84132

Esplin et al. (Epilepsia, 1994) have suggested that N-type presynaptic voltage sensitive calcium channels (VSCC) are different in epileptic (DBA/2J) and non-epileptic (C57/Bl) mice. Whole brain synaptosomal ⁴⁵Ca⁺⁺ uptake studies were done to verify the physiological functions of presynaptic VSCCs in these mice. Additionally, cortical tissue synaptosomal ⁴⁵Ca⁺⁺ uptake was done to determine the percentage of whole brain Ca⁺⁺ flux due to cortical VSCC activity. ⁴⁵Ca⁺⁺ uptake into synaptosomes was measured in the pre-eye mouse at postnatal day (PND) 8 and in the post-eye mouse at PND 16. Synaptosomes were depolarized with a 50 nM potassium solution to induce Ca⁺⁺ flux across the membrane. Both the C57 and DBA mice showed ⁴⁵Ca⁺⁺ synaptosomal uptakes that increased significantly (by >300%) between PNDs 8 & 16. At PND 8, cortical synaptosomes accounted for 77% of the whole brain ⁴⁵Ca⁺⁺ uptake in C57 mice and 74% of that in the DBA mice. At PND 16, cortical synaptosomes accounted for 79% of the whole brain ⁴⁵Ca⁺⁺ uptake in the C57 mice and 82% of that in the DBA mice. Preliminary data shows the cortical synaptosomal ⁴⁵Ca⁺⁺ uptake in DBA mice to be significantly greater (p<0.001) than the C57 at PND 16. This data suggests that presynaptic VSCCs are functionally more susceptible to depolarization and, potentially, neurotransmitter release. A loss of calcium homeostasis may play a role in generalized audiogenic seizures in the DBA/2J mouse.

680.7

CORRELATING NEUROPHARMACOLOGICAL AND GENETIC CHANGES IN THE EL EPILEPTIC MOUSE. E.W. Johnson* and W.N. Frankel. The Jackson Laboratory, Bar Harbor, Maine 04609.

30% of all epilepsies occur without obvious pathology and may be genetic. Current therapeutic interventions have serious side effects and limitations. With genetic models for epilepsy, primary deficits can be more easily identified and examined as targets for new therapies.

EL mice exhibit spontaneous seizures at ~80 days of age but can be induced earlier by rhythmic vestibular stimulation. These tonic clonic seizures are accompanied by excessive salivation, head, limb and chewing automatisms and recur well into old age. Using EL mice, where known genetic determinates (E11, 2 and 3) can be identified unambiguously will greatly expedite the search for basic neuropharmacological mechanisms involved in endogenous epilepsy.

Modern neuropharmacological and molecular biological techniques make it possible to examine a variety of neuroactive compounds in the seizure focus. With *in vitro* quantitative autoradiography (QA), selective radioligands for specific receptor sites and second messengers are used to study changes in regional density and distribution. These approaches provide a fairly comprehensive picture of the anatomical distribution of neuromodulators in a seizure focus and may help to explain the etiology and cellular basis for epilepsy.

We are comparing brains from vestibularly stimulated EL mice and nonstimulated EL mice with two control strains, DDY and ABP as well as nonstimulated mice from all three groups at different ages.

Candidate genes that share the same relative position on the chromosome as the E1 genes and have a reasonable potential for affecting brain function are being studied using QA. Advances in the knowledge of the genetic and neuropharmacological basis of epilepsy should allow more precise and less destructive therapeutic interventions to be devised.

680.4

ENHANCED LTP IN HIPPOCAMPAL SLICES FOLLOWING *IN VIVO* PERINATAL HYPOXIA. FE Jensen*, CD Wang, and MC Stevens. Dept. of Neurology, Children's Hosp. Harvard Med School, Boston, MA 02115

We have previously shown that hypoxia is epileptogenic in immature rat pups *in vivo* (postnatal day (P) 10-12) but not in adults (*Ann. Neurol.* 29(6), 1991). Hippocampal and neocortical slices from P10 rats pups exposed to hypoxia showed evidence of hyperexcitability (*Soc. Nsci Abs.* 1992;18:159). In the present study, we evaluated the effect of prior *in vivo* hypoxia on long term potentiation (LTP) in hippocampal slices from P10 rats. Seizure activity was induced *in vivo* in P10 rats by exposure to hypoxia (4% O₂) and hippocampal slices were prepared following 10 mins recovery. Slices from hypoxic pups were coincubated with normal, nonhypoxic littermate controls. Extracellular synaptic potentials were recorded from s. radiatum of CA1 by stimulating CA3 Schaffer collaterals. LTP was induced by tetanic stimulation (100Hz for 1msec, repeated once after 20 sec) at an intensity evoking 1/2 of the maximal response. Slices from previously hypoxic rat pups showed enhanced LTP compared to controls. Over 1 hour, the mean % EPSP increase in hypoxic pup slices was significantly greater than slices from littermate controls (p<0.02). The maximum % increase in EPSP in hypoxic slices was 107 ± 18% (±SE) (n = 10 slices, n = 10 pups) versus 55 ± 6% in slices from littermate controls (n = 6 slices, n = 6 pups) (p<0.05). The latency to decay of LTP to 1/2 maximum increase was significantly longer in the slices from hypoxic pups (73 ± 21 min, ±SD) than in controls (48 ± 26 min) (p<0.04). These results show that in immature rats, prior *in vivo* hypoxia-induced seizure activity acutely increases the magnitude and duration of LTP. (Supported by NS31718, EFA, AHA, Milton Fund).

680.6

GENETICALLY EPILEPSY-PRONE RATS DISPLAY GREATER AMOUNTS OF GluR 2/3 IMMUNOREACTIVITY IN THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS THAN SPRAGUE-DAWLEY RATS. T.M. Goldenberg*, C.L. Morin, W.C. Giza and C.E. Ribak. Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717.

Genetically epilepsy-prone rats (GEPR-9s) are used as a genetic model of epilepsy and display severe audiogenic seizures when exposed to acoustic stimuli. Previous research has shown that audiogenic seizures are initiated in the inferior colliculus where an apparent imbalance of excitatory and inhibitory amino acid activity exists. Immunocytochemistry with antibodies to the glutamate receptor subunit 2/3 (GluR 2/3) in the inferior colliculus was used to compare the amount and distribution of receptors between the GEPR-9s and non-seizing Sprague Dawley (SD) rats. Light microscopy showed an increase of GluR 2/3 immunoreactivity in the ventral medial area of the central nucleus of the inferior colliculus of GEPR-9s. An analysis at the electron microscopic level revealed greater amounts of immunoreaction product in the postsynaptic structures of GEPR-9s. These data show significant differences in the amount of GluR 2/3 receptor in the inferior colliculus between the GEPR-9 and SD rats.

680.8

LOSS OF HIPPOCAMPAL INTERNEURONS IN A MODEL OF NEONATAL STATUS EPILEPTICUS. K.W. Thompson, A.M. Holm, C.G. Wasterlain* UCLA, Department of Neurology, Los Angeles, CA 90024.

The consequences of Status epilepticus (SE) in the neonate are not well understood. While childhood SE is associated with widespread neuronal necrosis, the lack of histological lesions in 15 d.o. rat brain after SE may indicate that the immature brain is selectively resistant to seizure-induced damage. We recently developed a model of perforant path stimulation in 15-16 d.o. rats which produces hippocampal lesions 24 hours post-stimulation. We now demonstrate permanent cell loss in the stimulated hilus 7 days after stimulation. The number of large pyramidal-shaped neurons within the tip of the dentate gyrus was 6.94±4.08 on the stimulated side compared with 25.69±11.59 on the unstimulated side (p<0.001). Cell loss was also evident in the CA3 pyramidal cell layer. Three of four animals showed loss of frequency-dependent paired pulse inhibition (27% inhibition before, 120% facilitation 1 week after, N.S.). These data suggest that focal status epilepticus can result in permanent neuropathological lesions in young animals, and that the limits of the immature brain's resistance or vulnerability to seizures have yet to be fully defined.

680.9

MAGNETIC RESONANCE IMAGING AND SPECTROSCOPY OF RAT BRAIN AFTER KAINIC ACID-INDUCED SEIZURES

S.C. Hong*, I. Najm, Y. Comair, Y. Wang, R. Kaakaji, T. Ng, and H. Lüders.
Section of Epilepsy Surgery and Dept of Radiology, Cleveland Clinic, Cleveland, OH 44195

MRI diffusion weighted imaging (DWI), T2 weighted imaging (TWI) and MR Spectroscopy are non-invasive methods used for *in vivo* assessment of pathology and metabolic changes in human brain. In this report, ¹H-MRS was employed to study *in vivo* temporal metabolic changes and their correlation with DWI, TWI and histopathological stages in a rat model of TLE using kainic acid (KA). The KA injection (10 mg/Kg) induces a characteristic long lasting tonic clonic seizure followed by neuronal damage. Rat brains (n=5) were scanned at the level of the body of the hippocampus, spectra were recorded and the relative ratios of N-acetylaspartate (NAA), choline, and lactate (Lac) over creatine (Cr) were calculated. Our results show significant increase in Lac/Cr and NAA/Cr and a decrease in choline/Cr ratios during the ictal and early post-ictal phases correlated with increase signals in hippocampus and piriform cortex on DWI and TWI, as compared to control brains. Late post-ictally, NAA/Cr ratio decreased in correlation with the degree of neuronal loss. The significant ictal and early post-ictal increase in lactate and late post-ictal decrease in NAA reflect increased cellular activity and neuronal loss, respectively. Moreover, the early sharp decrease in choline, a membrane precursor, together with increase MR signal in specific areas of the limbic system prone to neuronal damage might represent an early index of neuronal injury during the early stages following the excitotoxic seizures.

680.11

REPETITIVE ABNORMAL ELECTRICAL DISCHARGES IN BRAIN SLICES OF THE DENTATE GYRUS FROM EPILEPTIC PATIENTS. L.M. Masukawa*, K. Urano, H. Wang, W.M. O'Connor, and M.J. O'Connor. Depts. of Neurology and Surgery, University of Pennsylvania Medical School and The Graduate Hospital, Philadelphia, PA 19146.

The population response of granule cells in the *in vitro* dentate gyrus brain slice from human epileptics during perforant path stimulation varies among patients. As we reported previously (Masukawa et al., Brain Res. 493: 1989), orthodromic responses range from single to multiple population spikes. In addition to these responses, specimens from a subpopulation of patients exhibit an unusual response which was characterized by repetitive negative field potentials. Each potential was approximately 100-200 msec in duration and the first potential had a latency of about 50 msec after perforant path stimulation. Such responses also could occur without stimulation in control ACSF and were sometimes revealed by exposure to 20 μ M bicuculline. Antidromic stimulation could also drive this response. Several specimens generating this type of response also showed prominent molecular layer reorganization. Such waveforms are markedly similar to those observed in EEG records from epileptics during an epileptic discharge. Supported by NIH Grant #NS23077 to LMM.

HYPEREXCITABLE ASTROCYTES FROM HUMAN MEDIAL TEMPORAL LOBE STRUCTURES. N. Al-Rodhan*, M.G. Rioult, R. Villalba, W. T. Kim, D. Spencer and A. H. Cornell-Bell. Yale School of Medicine, New Haven, CT 06510.

To study astrocyte signaling in temporal lobe seizure pathology tissues were removed from 10 representative cases who underwent medial temporal lobectomies. Astrocyte cultures derived from areas of normal EEG and areas of seizure activity were compared using Ca²⁺ imaging (Fluo-3AM and confocal microscopy). Tissues including neocortex, hippocampus, parahippocampus and amygdala were cleaned of vessels and fascia and treated with a single step digestion of papain and Trypsin/EDTA. Cultures were grown to confluence prior to Ca²⁺ imaging. Astrocytes from regions exhibiting hyperexcitable EEG records often exhibited spontaneous rapid, Ca²⁺_i transients prior to glutamate (Glu, 100 μ M) application in the bath. Evoked responses often shut down the spontaneous Ca²⁺_i changes for minutes. In several cases Glu caused long-lasting reductions in Ca²⁺_i levels, a response never seen from cells cultured from normal EEG regions. Some astrocytes exhibited a rapid and prolonged increase in Ca²⁺_i that lasted for 75-100 sec followed by a silent period and then rapid Ca²⁺_i oscillations that persisted even in washout. In hyperexcitable cultures very few cells failed to respond to Glu. In the majority of cases the hippocampus and parahippocampus exhibited Ca²⁺ hyperexcitability in response to Glu, however there were examples where the neocortex or the amygdala was the only hyperexcitable tissue. These results imply astrocytes from any region of the medial temporal lobe may exhibit hyperexcitable Ca²⁺_i following Glu implying an active role of astrocytes in development of this hyperexcitability.

680.12

CHRONIC FOCAL IRON-INDUCED EPILEPSY IN RAT; NEUROCHEMICAL, NEUROPHYSIOLOGICAL AND MORPHOLOGICAL OBSERVATIONS. E. Ronne-Engström*, L. Hillered, R. Flink, L. Kihlström, C. Lindquist, Y. Olsson, X.J. Nie, H. Carlsson. Dpt of Neurosurg, Dpt of Neuropathology Uppsala University Hospital, Sweden.

Chronic focal iron-induced epilepsy in rats was studied with respect to extracellular levels of amino acids, electroencephalographic (EEG) changes including reaction to electrical cortical stimulation and histopathology. 93% of the animals developed spike or sharp wave activity on EEG. After 6 months the extracellular levels of amino acids aspartate (ASP), glutamate (GLU), asparagine (ASN), serine (SER), and glycine (GLY) were measured using intracerebral microdialysis both at the lesion side and in the contralateral hemisphere. The basal levels of ASP were significantly higher on both sides compared to a control group. There were unprovoked, spontaneous elevations of ASP and GLU up to 8x basal level. The levels of SER were significantly higher at the lesion side compared with the contralateral side. GABA levels were below the detection limit on the lesion side in all animals except for one, while it could be measured in five rats contralaterally. Electrical cortical stimulation was performed during the microdialysis and evoked seizure-like activity after stimulation in 5/8 animals. The amino acid levels displayed a pattern with elevations of mainly ASP and GLU in 4/8 animals. Histopathological changes were detected in all animals. Histological analysis revealed a post-necrotic cyst, containing small vessels and macrophages, some loaded with iron pigment. The cyst was surrounded by astrocytes. This glial change extended into the white matter of the ipsilateral hemisphere and changes were also seen in hippocampus, in some animals bilaterally.

DEGENERATIVE DISEASE: ALZHEIMER'S—BETA AMYLOID XII

681.1

B-AMYLOID PEPTIDES STIMULATE GELATINASE ACTIVITY IN HIGH-DENSITY HIPPOCAMPAL CULTURES. S. Deb, C. Yu, and P. E. Gottschall*, University of South Florida, Department of Pharmacology, Tampa, FL 33612-4799

Little is known about the relationship between the Alzheimer plaque core β -amyloid (A β) peptide and the production of the so-called "acute phase" inflammatory mediators, many of which are also present in plaques. Tissue remodeling and repair enzymes that are critical in peripheral inflammatory responses are the matrix metalloproteinases (MMPs), and these enzymes are present in AD brain, they may exhibit "α-secretase" activity, and they appear to be involved in neurite extension. Thus, it was of interest to determine whether A β peptides regulate the activity of MMPs in different brain tissues in culture. High density hippocampal cultures obtained from 18 day old rat embryos or enriched astrocyte cultures obtained from brains of 1 day old rat pups were incubated with A β peptides (2.5 - 40 μ M) *in vitro*. Media samples from these assays were measured for gelatinase (GLase) activity using zymography which was quantitated by densitometry. Both mixed hippocampal and astrocyte cultures showed high constitutive expression of a 58 kDa GLase. Treatment with A β (1-40) for up to 72 h stimulated the activity of a 94 kDa GLase 5-10-fold and a 52 kDa GLase 20-fold in hippocampal cultures compared to untreated cultures. A β (1-38) stimulated the activity of these two GLases to a lesser extent, whereas A β (1-16) or A β (25-35) exhibited little or no effect. Treatment of astrocytes with the four A β peptides or fragments showed little or no effect on GLase activity after 24 h, and the 52 kDa activity was never observed under any condition in astrocytes. By immunoblot, the 94 kDa GLase was identified as gelatinase B (MMP-9), the 58 kDa GLase as gelatinase A (MMP-2) and the 52 kDa GLase as rat transin (stromelysin-1; MMP-3). These results indicate that A β peptides stimulate the production of matrix degrading enzymes in hippocampal cultures and suggest they may play some role in development or growth of plaques, i.e. abnormal neurite growth. In addition, rat transin, was apparently derived from neurons and not astrocytes. (supported in part by the Alzheimer's Association/Alice M. Melady Pilot Research Grant)

681.2

THE INVOLVEMENT OF SECRETED FORM OF AMYLOID β /A4 PROTEIN PRECURSOR IN THE NEURITOTROPIC EFFECT OF NGF AND FGF. L.-W. Jin* and T. Saitoh. Dept of Neurosciences, UC San Diego, La Jolla, CA 92093.

Previously we showed that a 17-mer peptide (APP319-335) within the secreted form of amyloid β /A4 protein precursor (sAPP) binds to the surface of B103 neuroblastoma cells and mediates both neurotrophic and neuritotropic effects of sAPP. An RMSQ peptide (APP330-333) within 17-mer blocked the binding and neuritotropic effect of 17-mer (J. Neurosci., in press). We used these peptides to study the involvement of sAPP in the effect of NGF and FGF, both of which modulate the level of sAPP in PC12 cultures (Neuron, 3:689, 1989). RMSQ peptide significantly decreased the number of neurites induced by NGF or FGF. This inhibition was overcome by either increasing the concentration of NGF or FGF, or by adding the 17-mer to the culture media. The RMSQ peptide, however, did not affect the survival-promoting effect of NGF or FGF. Thus, sAPP, in particular its 17-mer domain, is probably involved in the induction or the maintenance of neurites of PC12 cells treated with NGF or FGF.

681.3

A single amino acid substitution in the amyloid β /A4 protein precursor disrupts its neuritotropic activity.

Jean-Marc Roch*, Deborah Otero, and Tsunao Saitoh, UC San Diego. We have previously shown that the secreted form (sAPP) of APP-695 is a growth-regulating molecule, a neuritotropic and neurotrophic factor, and that the domain responsible for all activities is from Ala319 to Met335 (Kang sequence), with a minimal essential sequence RERMS from Arg328 to Ser332 (Saitoh et al., *Cell* 58:615, 1989; Roch et al., *J. Biol. Chem.* 267:2214, 1992; Ninomiya et al., *J. Cell Biol* 121:879, 1993; Jin et al., *J. Neurosci.*, in press, 1994; Yamamoto et al., *J. Neurobiol.*, in press, 1994;). In the present study, we synthesized 11-mer peptides containing this active domain, introduced mutations in the RERMS site, and compared the neurite extension activity of the mutant peptides to that of a peptide of wild-type sequence or KB75, a bacterially made sAPP-695. We found 3 mutant peptides with no activity. Using PCR and recombinant DNA methods, we engineered an APP cDNA encoding an APP variant with a single amino acid substitution, Glu→Ile in the RERMS site. The affinity for heparin of the mutant sAPP was identical to that of wild-type APP. However, the neuritotropic activity of the mutant sAPP was dramatically reduced, suggesting that the heparin binding and neuritotropic properties of APP can be separated. Thus, mutations in the APP molecule can alter its physiological function.

681.5

 β -AMYLOID PRECURSOR PROTEIN EPITOPES BIND TO MICROTUBULES AND THEIR ASSOCIATED PROTEIN, TAU. E. Levy and E. Katz.* Depts. of Pharmacology and Pathology, New York Univ. Med. Cen. NY, NY, 10016 and Depts. of Neurology and Neuroscience, Cornell Univ. Med. Coll. NY, NY, 10021.

Tubulin is one of several proteins associated to amyloid β -protein (A β) deposits, as well as neurofibrillary tangle in the brains of patients with Alzheimer's disease and related disorders. Although binding to tubulin may promote A β fibril formation from the otherwise soluble peptide, A β lesions may represent the proteolytic residual of a complex between the full length β -amyloid precursor protein (BAPP) or fragments thereof and tubulin. BAPP C-terminal fragments expressed as GST fusion proteins, and immobilized on solid support, bound proteins in rat brain homogenates as well as human neuronal and glial cell lines. Both α and β tubulins bind to the 42 amino acids of A β , as revealed by SDS-PAGE, followed by amino acid microsequencing and Western blotting. This binding was localized to the 1-28 N-terminal amino acids of A β . Tubulin also binds to the predicted transmembrane sequence C-terminal to A β . However this binding seems to be mediated by the microtubule-associated protein tau. Moreover, intact microtubules are required for these interactions since colchicine treatment abolished them. The C-terminal region of BAPP has two microtubule binding sites, which may indicate that it is an integral part of the cytoskeleton and alteration of this complex may have a role in the amyloidogenic process characteristic of A β deposition disorders.

681.7

THE EFFECTS OF β -AMYLOID ON THE MOLECULAR MOTORS DYNEIN AND KINESIN K.Kopec* and J.P. Chambers. Div. of Life Sciences, Univ. of Texas at San Antonio, San Antonio, TX 78249.

Disruption of normal cellular transport is one plausible hypothesis for the pathogenesis of Alzheimer's disease (AD). β -amyloid is a 42 amino acid peptide which is thought to be processed from the amyloid precursor protein (APP) in endosomes or lysosomes, and whose abnormal accumulation in the neuropil is a hallmark of AD. Transport of APP to the cell surface has been reported to be a kinesin-dependent process, and transport of cell surface molecules from early to late endosomes has been reported to be a dynein-dependent process. The effects of β -amyloid on the motor proteins dynein and kinesin were examined using differentiated PC12 cells cultured in the presence of β -amyloid for nine days. Cells were harvested, washed in buffer, and lysed in SDS buffer for electrophoresis and immunoblot analysis. Immunoblots were visualized using antibodies against dynein intermediate chain (74 kd) and kinesin heavy chain (120 kd). Preliminary data indicates that both dynein and kinesin immunoreactivity are increased in PC12 cells cultured in the presence of 7 μ g/ml β -amyloid, and that amounts of both motor proteins leveled out between 5 and 9 days in culture. As compared to levels present at the time β -amyloid was added to the culture medium, dynein intermediate chain showed a 40-fold increase and kinesin heavy chain showed a 9-fold increase respectively after nine days in culture. Effects of increasing concentrations of β -amyloid are currently under investigation. These data suggest that exogenous β -amyloid, whose production is a motor-dependent process, can increase intracellular levels of dynein and kinesin.

681.4

AMINO-TERMINAL REGION OF THE AMYLOID PRECURSOR PROTEIN STIMULATES MAP KINASE. S.M. Greenberg*, W.O. Oju, D.J. Selkoe, A. Ben-Izhak, K.S. Kosik. Brigham and Women's Hospital & Harvard Medical School, Boston, MA 02115.

We have previously demonstrated that the secreted form of the β -amyloid precursor protein (β -APP_s) stimulates mitogen-activated protein (MAP) kinases in PC12 cells. The amino-terminal half of β -APP_s contains a region rich in cysteine residues followed by an acidic domain. In experiments to delineate the region of β -APP_s responsible for activating MAP kinase, we found that reductive alkylation of disulfide linkages by dithiothreitol followed by iodoacetamide (but not iodoacetamide alone) entirely blocked the MAP kinase stimulation caused by medium enriched in β -APP. We have confirmed the role of the cysteine-rich amino-terminal region by use of purified fragments of β -APP_s expressed in *E. coli*. Fragments extending from the KpnI to the XhoI restriction sites (spanning the cysteine-rich and acidic domains) or from XhoI to BglII (most of the remainder of β -APP_s) were cloned into the pGEX-2T vector. Purified β -APP fragments were obtained by cleavage of fusion proteins with thrombin. We found that 10 min treatment with β -APP(KpnI-XhoI) activated MAP kinase approximately 15-fold at a concentration of 50 nM, while XhoI-BglII had no effect. β -APP(KpnI-XhoI), like intact secreted protein, was inactivated by reductive alkylation. Medium from CHO cells expressing APP with deletion of XhoI-BglII stimulated MAP kinase as well. These results suggest that sites that activate MAP kinase reside in the amino terminal region of β -APP_s and that, like other extracellular trophic factors such as the EGF family, they require structural loops created by disulfide linkages for activity.

BETA AMYLOID INDUCES TAU PHOSPHORYLATION AND DECREASED MICROTUBULE BINDING. J. Busciglio*, A. Lorenzo, I. Yeh and B.A. Yankner. Dept. of Neurology, Harvard Medical School, Children's Hospital, Boston, MA 02115.

Beta amyloid (β A) causes neuronal degeneration characterized by dystrophic axons and dendrites in primary rat and human neuronal cultures (Yankner et al., 1990; Busciglio et al., 1992). The effects of aggregated forms of the β A (1-40) peptide were examined in rat E18 hippocampal and human fetal cortical cultures. Biochemical and immunocytochemical analysis was performed with the monoclonal antibody PHF-1, which recognizes a phosphorylated form of tau present in paired helical filaments. Treatment with β A resulted in marked induction of the PHF-1 antigen which preceded and accompanied neuronal degeneration. Pre-treatment with alkaline phosphatase completely abolished immunocytochemical staining of neurons with PHF-1 and PHF-1 immunoreactivity in Western blots, and increased immunoreactivity with the tau-1 monoclonal antibody, confirming the identity of this antigen as phosphorylated tau. Detergent extraction of β A-treated neurons under microtubule-stabilizing conditions demonstrated that most of the phosphorylated tau induced by β A is not bound to microtubules. In contrast, MAP-2 and non-phosphorylated tau were recovered in the detergent-resistant cytoskeletal fraction. These results suggest that β A induces tau phosphorylation which results in decreased binding of tau to microtubules. Abnormally phosphorylated tau in the AD brain has been reported to show decreased microtubule binding. These findings suggest a model in which β A causes cytoskeletal disruption and neuronal degeneration by inducing tau phosphorylation.

EXOGENOUS AMYLOID A β STIMULATES THE ACCUMULATION OF AMYLOIDOGENIC FRAGMENTS OF APP IN TRANSFECTED CELLS.

Austin J. Yang, Debra Burdick, Joseph Kosmoski, and Charles G. Glabe. Department of Molec. Biol. and Biochem., Univ. of Calif., Irvine, CA 92717

Results of our previous investigations demonstrated that exogenous amyloid beta peptide, A β 1-42, is internalized and accumulates intracellularly in late endosomes or lysosomes in human cells and is resistant to degradation. We have analyzed the effect of internalized A β on the metabolism of APP in stably transfected 293 cells by ³⁵S-methionine metabolic labeling, followed by immuno-precipitation. We found that the amounts of C-terminal, amyloidogenic fragments (particularly a 16 kDa fragment), are dramatically enhanced by treatment of the cells with A β 1-42, but not A β 1-28, which does not accumulate in cells. The amount of this fragment is greatly reduced in control, non-transfected cells incubated with A β 1-42. The stimulatory effect is not due to an increase in APP synthesis or an inhibition of the non-amyloidogenic processing of APP, since the amounts of soluble, N-terminal APP products secreted into the medium and non-amyloidogenic C-terminal fragments associated with the cell are the same in peptide-treated and control cells. The 16 kDa C-terminal fragment is highly enriched in the insoluble fraction of the cell lysate, and is colocalized with internalized ¹²⁵I-labeled A β 1-42. The continued internalization of exogenous A β 1-42 from the medium is not required for the stimulatory effect. Pretreatment of cells with A β 1-42, followed by removal and replacement with medium lacking peptide also results in accumulation of the amyloidogenic fragments. Our results suggest that the β -peptide stimulates its own accumulation by aggregating with newly synthesized amyloidogenic fragments, thereby protecting the A β domain from degradation. Amyloid accumulation could be a "run away" process once amyloid aggregates have nucleated inside the cell. Supported by the American Health Assistance Foundation and NIH NS31230

AMYLOID BETA-PROTEIN INTERFERES WITH THE UBIQUITIN-DEPENDENT PROTEIN DEGRADATION PATHWAY. L. Gregori, R. Bhasin*, and D. Goldgaber. Dept. of Psychiatry and Behav. Sci., School of Medicine, SUNY at Stony Brook, Stony Brook, NY 11794.

Amyloid β -protein (A β) and ubiquitin are both components of amyloid plaques associated with Alzheimer's disease (AD) pathology. Abnormally high levels of ubiquitin and ubiquitin conjugates in AD brains are well documented. However, the significance of this observation is still unknown. One of the functions of ubiquitin is to target proteins for degradation. In our studies we found that A β_{1-28} inhibits the ubiquitin-dependent degradative pathway. This effect was characterized using radiolabeled exogenous proteins such as lysozyme. The results showed that A β interferes with the step of ubiquitin conjugates degradation, catalyzed by the multisubunits 26 S proteasome. We also tested the ability of A β_{1-28} fragments to inhibit degradation. We found that the amino-terminal-containing peptides were effective, although not to the same extent as A β_{1-28} . In addition, three new ubiquitin conjugates containing A β were detected on gel electrophoresis. We are currently investigating the function and significance of these ubiquitinated proteins. Our results suggest that impairment of ubiquitin-dependent protein degradation by A β may explain the accumulation of ubiquitin and ubiquitin conjugates in brain of AD patients.

AMYLOID β -PROTEIN INDUCES THE EXPRESSION AND CELLULAR ACCUMULATION OF THE AMYLOID β -PROTEIN PRECURSOR IN CULTURED CEREBROVASCULAR SMOOTH MUSCLE CELLS. William E. Van Nostrand*, Judianne Davis-Salinas, Michael Wessel, and Susan M. Saporito-Irwin. Department of Microbiology and Molecular Genetics, College of Medicine, University of California, Irvine CA 92717-4025.

Deposition of the amyloid β -protein (A β) in senile plaques in the neuropil and in the media of intracortical and leptomeningeal blood vessels are hallmarks of Alzheimer's disease (AD) and related disorders including hereditary cerebral hemorrhage with amyloidosis-Dutch type. Cerebrovascular A β deposits are also accompanied by degeneration of the smooth muscle cells in the affected vessels. Moreover, cerebrovascular smooth muscle cells have been implicated in the expression of A β PP and the production of A β . In light of these suggestions, we investigated the effects of various length synthetic A β peptides on the cellular degeneration and expression of A β PP in primary cultures of cerebrovascular smooth muscle cells. The cerebrovascular smooth muscle cell cultures were incubated alone or with 25 μ M of various length A β peptides for six days. Similar to untreated controls, cells that were incubated with 25 μ M A β_{1-39} , A β_{1-40} , or a scrambled A β_{1-42} peptide exhibited no signs of cellular degeneration nor any effect on the levels of A β PP. In contrast, cells incubated with 25 μ M A β_{1-42} showed signs of extensive cellular degeneration and a striking increase in the levels of cell-associated A β PP, however, no increase in the levels of secreted A β PP were observed. The levels of cell-associated, carboxyl terminal A β PP fragments were also markedly increased when the cerebrovascular smooth muscle cells were incubated with 25 μ M A β_{1-42} peptide. These studies suggest a cyclic mechanism whereby A β can induce cellular degeneration and concomitant increased expression of cell-associated A β PP and potentially more A β peptide leading to a spread of the cerebrovascular pathology of AD and certain related disorders.

CELL MIGRATION AND DIFFERENTIATION V

GnRH NEURONS MIGRATE ALONG THE MEDIAL TELENCEPHALON IN CLOSE ASSOCIATION WITH A SUBSET OF OLFACTORY NERVE AXONS.

R. B. Norgren, Jr.*¹, C. Gao¹, and B. Fritsch². ¹Dept. Cell Biol. & Anat., Univ. Nebraska Med. Ctr., ²Dept. Biomed. Sci., Creighton Univ., Omaha, NE

Several studies indicate that GnRH neurons of the septal-preoptic area and hypothalamus originate in the nasal area and migrate to the brain on the olfactory nerve. Previously, we found that GnRH neurons migrate dorsally and caudally along the medial edge of the telencephalon to the septal area in close association with a N-CAM and Ng-CAM enriched fiber bundle. In order to determine whether this fiber bundle was an extension of the olfactory nerve or another fiber bundle, we performed two experiments. First, we unilaterally ablated the olfactory placode on an E3 chick embryo, which prevented olfactory nerve outgrowth to the brain (and GnRH migration). We waited until E7 and then sacrificed the embryo and immunostained sections for N-CAM. N-CAM immunostaining was absent along the medial edge of the telencephalon on the operated side but was clearly visible on the unoperated side. Second, we applied filter strips impregnated with Df to the olfactory nerve distal to the telencephalon to trace its full extent in an E7 chick embryo. Although most labeled axons appeared to terminate in the presumptive olfactory bulb, a small subset of labeled axons continued along the medial edge of the telencephalon in a location similar to that followed by GnRH neurons. These findings are consistent with the idea that GnRH neurons are delivered to the septal area on a transient extension of a subset of olfactory nerve axons. We are currently attempting to determine which cells in the olfactory epithelium give rise to these axons. This work was supported by NIH grant NS30047 (RBN).

682.2

CELL MIGRATION DURING DEVELOPMENT OF THE OLFACTORY SYSTEM IN THE NEWBORN OPOSSUM, *MONODELPHIS DOMESTICA*, IN VIVO AND IN VITRO. G. Tarozzo, P. Peretto, Z. Varga^o, C. Andreone, A. Fasolo*. Dept. Animal Biology, University Turin, 10123 Turin, Italy; ^oDept. Pharmacology, BioCenter, University of Basel, Basel, 4056 Switzerland.

The olfactory system of the short-tailed opossum, *Monodelphis domestica*, develops almost entirely after birth. Here, we have studied the migration of cells which originate in the olfactory region during the first 10 postnatal days. Antisera to gonadotropin releasing-hormone (GnRH), to olfactory marker protein (OMP) and carnosine (both specific to olfactory cells) were used as markers. During the first postnatal days, migration of GnRH positive cells could be followed along the terminal and olfactory nerve and on the medio-lateral aspect of the forebrain. A second population of cells, which expressed both OMP and carnosine, was contiguous, but separated from GnRH cells. For further analysis, explants of whole brain attached to their intact olfactory region from 3 day old opossum pups were cultured for up to 3 to 7 days. The explants showed a high preservation of the structures and of the immunoreactivities. Growth and maturation, although delayed, took place in culture and GnRH cells and OMP/carnosine positive cells followed the routes taken *in vivo*. The results demonstrate successful culture of whole-brain preparations with the intact olfactory system for studying cell differentiation and migration during development. SIMULTANEOUS MIGRATION AND PROLIFERATION OF NEUROBLASTS ORIGINATING IN THE ANTERIOR SUBVENTRICULAR ZONE OF THE NEONATAL RAT FOREBRAIN. J.R.L. Menezes*, K. Nelson and M.B. Luskin. Dept. of Anatomy and Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA 30322.

It has recently been shown using a retroviral lineage tracer encoding lacZ that the anterior part of the postnatal telencephalic subventricular zone (SVZa) is a discrete source of neurons destined for the olfactory bulb (OB), and that while en route to the OB the SVZa-derived cells traverse a highly restricted pathway (Luskin, *Neuron*, 11:173, 1993). In addition, the number of lacZ-positive cells along the full extent of the pathway, resulting from injections of retrovirus into the SVZa, increased as a function of the post-injection survival time, suggesting that the SVZa-derived cells divide as they migrate. In this study we examined the phenotype of the SVZa-derived cells and investigated whether they undergo cell division during their migration. Cells migrating to the OB were tagged by injections of retrovirus into the SVZa of neonatal rat pups and the lacZ(+) cells detected histo- or immunohistochemically in cryostat sections 3-4 days later. To determine if the SVZa-derived cells express a neuronal phenotype we used an antibody against neuron-specific tubulin (TuJ1), which is usually present in postmitotic neurons (Menezes & Luskin, *J. Neurosci.*, Aug. '94). The cell proliferation marker, BrdU, administered 1-5 hr prior to sacrifice of the injected pups was used to identify S-phase cells. We found that the vast majority of lacZ(+), SVZa-derived cells were TuJ1(+), indicating their neuronal identity. Approximately 10% of the lacZ(+), SVZa-derived cells incorporated BrdU throughout the migratory pathway, indicating that some SVZa-derived cells proliferate while en route to the OB. Furthermore, some cells were triple-labeled by lacZ, TuJ1 and BrdU, directly demonstrating the presence of neuroblasts in the process of mitosis as they migrate. Thus, the SVZa-derived cells in the pathway are highly atypical of most other CNS neurons, which become postmitotic before migrating to their final position. MOLECULAR CLONING OF ASTROTACTIN. C. Zheng, N. Heintz, M. E. Hatten*. Rockefeller Univ., New York, NY 10021

Using affinity-purified anti-astrotactin antibodies, we have isolated a novel adhesion molecule from cDNA expression library of postnatal day 5 granule cells. The deduced amino acid sequence starts with a signal peptide, followed by an extracellular domain containing 3 EGF repeats and 2 fibronectin type III repeats in alternative orders, but no Ig C2 domains. Screening of genomic library yielded another novel gene with 50% homology, suggesting a new gene family.

By Northern analysis, the expression of this genes is restricted to developing brain, and appears to be neuron-specific. *In situ* hybridization demonstrates a specific temporal and spatial pattern of expression in immature neurons undergoing glial-guided migration and assembly into neural layers of cerebellum, hippocampus and cortex. Antibodies against a GST-fusion protein recognize a neuronal membrane protein with an apparent molecular weight of 100 kd on Western blot. *In vitro* functional assays with this antiserum demonstrate blocking of neuron-glia interactions and neuronal migration in microcultures of developing cerebellar cells. These results suggest that we have cloned the astrotactin molecule, which belongs to a new class of membrane signaling molecules, functioning in CNS neuron-glia interactions, including glial-guided neuronal migration. Supported by NIH grant NS 15429 (MEH).

MULTIPOTENT IMMORTALIZED NEURAL PROGENITORS DIFFERENTIATE INTO GLIA & NEURONS FOLLOWING ENGRAFTMENT INTO THE SUBEPENDYMAL GERMINAL ZONE (SEZ) OF ADULT MICE. J.D. Flax, L. Villa-Komaroff* & E.Y. Snyder Depts. of Neurology & Neonatology, Harvard Medical Sch., Children's Hospital, Boston MA 02115.

It is becoming evident that CNS progenitors & germinal zones persist into adulthood. The SEZ in adult rodent brain contains progenitors capable of neuronal & glial differentiation *in vitro*. The function of adult SEZ cells *in vivo* remains controversial. Recent reports suggest they differentiate into "glioblasts" that migrate into parenchyma & replace lost astrocytes &/or oligodendrocytes, as well as olfactory bulb (OB) neurons &, perhaps, a small subset of other neurons. However, other reports suggest that SEZ cells are a self-renewing proliferative population that do not migrate out of the SEZ. Previously, we demonstrated that clonal immortalized CNS progenitor cell lines, following transplantation at various developmental time points, are capable of extensive cytoarchitectural integration, & of neuronal & glial differentiation along the neuroaxis, in a regional & temporal appropriate manner. The progenitors appear to differentiate appropriately in response to local microenvironmental developmental cues. The present study utilizes engraftment of these clonal neural progenitors into the SEZ or OB of adult animals as a tracer for the possible fate of endogenous SEZ progenitors & as an *in situ* biological assay for the signals that might regulate their fate. We found that engrafted progenitors differentiated into both glia & OB granule cell neurons when implanted into the SEZ. The results suggested that microenvironmental signals for inducing cell type specific differentiation (including neuronal) exist in some regions of the adult brain. The demonstration that immortalized CNS progenitors can differentiate & continue to express an exogenous gene (LacZ) following migration, suggests that this strategy may be useful for the repair (cell replacement) &/or delivery of exogenous gene products for gene therapy in the adult brain.

A NEUROGENIC SUBPOPULATION OF NEURAL CREST CELLS DEPENDS UPON TIMELY EXPOSURE TO ENVIRONMENTAL CUES.

P. D. Henion¹, K. S. Vogel², S. L. Rogers^{3*}, and J. A. Weston¹.

¹Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403,

²NCI-Frederick Cancer Research and Development Center, P. O. Box B, Frederick, MD 21702, ³Department of Anatomy, Univ. of New Mexico, School of Medicine, Albuquerque, NM 87131.

We have previously proposed that distinct neurogenic and non-neurogenic neural crest subpopulations segregate very soon after crest cells arise from the neuroepithelium. We predicted that the putative neurogenic precursor subpopulation would be differentially responsive to and/or dependent upon specific environmental cues. We have tested the potential of the neural crest population to give rise to neurons both *in vivo* and *in vitro*. We have found that the lateral migratory pathway *in vivo* is unable to support neurogenesis among crest-derived populations with known neurogenic ability, and that neurogenesis among neural crest cell populations *in vitro* requires the timely availability of specific growth/instructional factor activities. These results support the notion that an apparently undifferentiated but developmentally distinct neurogenic subpopulation exists in the premigratory neural crest. Supported by NS29438.

ATP-MEDIATED EFFECTS ON NEURONS DURING ONTOGENY *IN VITRO*: FROM NEUROBLASTS TO PRIMARY NEURONAL CULTURES. D.C. Spray, R. Rozental¹, M.F. Mehler, M. Morales, D. Vieira and J.A. Kessler, Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Extracellular ATP plays an important role in cell proliferation and survival of hemopoietic stem cells even in the absence of cytokines. Since our previous studies suggested that cytokines that modulate hematopoiesis also govern neurogenesis (Mehler *et al.*, Nature 362: 62, 1993) we evaluated the effects of extracellular ATP on neuroblasts as they underwent morphological and functional changes *in vitro* using dye-transfer (Lucifer yellow; L.Y.), Ca^{2+} imaging (Fura-2 AM) and double whole cell voltage clamp techniques. In naive neuroblasts maintained at 39°C (nonpermissive for T antigen expression), ATP (10-100 μ M) transiently increased the steady-state $[Ca^{2+}]_i$ levels from ~100 nM to 10 μ M without changing the internal pH. In parallel, ATP transiently uncoupled these cells as evidenced by a decrease in the extent of L.Y. spread and by a reduction in the strength of electrotonic coupling between naive neuroblasts. These responses were observed during a neuronal developmental stage in which chemosensitivity to glutamate, GABA and acetylcholine were not observed (outside out patches and Ca^{2+} imaging). In contrast to the latter neurotransmitters, the magnitude of ATP-mediated responses progressively decreased as these cells underwent morphological maturation and were dramatically lower in primary neurons. Since uncoupling has been correlated with cellular differentiation and ATP-mediated events seem to be developmentally regulated, we are currently investigating whether ATP elicited responses are implicated in the expression of membrane excitability during neuronal ontogeny.

RE-EXPRESSION OF THE RADIAL GLIAL CELL MARKER, RC2, IN YOUNG ADULT MOUSE CORTEX FOLLOWING TARGETED NEURONAL DEATH. C.S. Hermit-Grant* and J.D. Macklis Dept. Neurology, Prog. Neuroscience, Harvard Med. Sch., Children's Hosp. Boston 02115

Embryonic neurons transplanted into regions of targeted photolytic neuronal cell death in neocortex of juvenile or adult mice selectively migrate into the neuron-deficient regions up to 800 μ m over a period of 1-2 weeks (Macklis, J. Neurosci., 13(9), 1993). Here we study this migration directly in living slice preparations and investigate the potential role of radial glial cells as a structural substrate via re-emergence from postdevelopmental astrocytes.

Latex nanospheres conjugated to the cytotoxic chromophore chlorin a_8 were unilaterally injected into somatosensory cortex of 2-week old mice. Two weeks later, contralateral homotopic cortex received transcranial 674 nm laser illumination resulting in selective photolysis of retrogradely labeled callosal pyramidal neurons in layer II-III. After 2 weeks, mice received transplants of E17 neocortical cells pre-labeled with Di-I and PKH26. Three to seven days after transplantation fresh brains were cut at 150 μ m, and the region containing the transplant was microdissected out, cultured, observed under fluorescence, and images collected with a digital confocal microscope. Transplanted cells displayed bipolar morphologies characteristic of migrating neurons and moved at speeds of up to 10 μ m/hr. To study the potential role of radial glial cells, brains from another group were processed for fluorescence, RC2 and GFAP immunocytochemistry 3, 7 and 14 days after transplant. Glial cells outside the injection site reacted positively for RC2 or GFAP at all ages studied, and a small number reacted for both. RC2 reactive cells resembled the GFAP-positive reactive astrocytes, but had fewer processes and were fewer overall. GFAP positive reactive astrocytes in controls receiving transplants only or a sham injection of HBSS were found at all ages studied, but RC2 positive glia were present only within the injection site and only at 3 and 7 days and not at 14 days. These results suggest a role for RC2 positive glia during the selective migration of transplanted embryonic cells into neuron-deficient regions of young adult cortex. Further experiments are needed to determine if neurons associate closely with RC2 positive glia while migrating and whether these glia are of host or donor origin. Supported by HD28478, The Alzheimer's Assoc., MR Center Grant HD18655, The Rita Allen Foundation, and an NSF Postdoctoral Fellowship to CHG.

CELL MIGRATION AND NOVEL DERIVATIVES OF CRANIAL NEURAL CREST AND PLACODES IN *XENOPUS LAEVIS*. A. Collazo*, J. Rubero, M. Bronner-Fraser, P. M. Mabey and S. E. Fraser, Beckman Institute 139-74, California Institute of Technology, Pasadena, CA 91125.

Our previous work has shown that neuromasts, the mechanoreceptors of the lateral line system of teleost fishes (zebrafish and *Betta*) and *Xenopus*, are derived from both neural crest and epidermal placodes (Collazo *et al.* Science 264:426, 1994). We expand our analyses for *Xenopus* by using Dil [(3) or (5)C18] to label small populations of neural crest, head mesoderm or placodal cells, and lysinated rhodamine dextran (LRD) to label individual neural crest cells. We used *in vivo* time lapse imaging of Dil labeled cells to study the migration of neural crest and placodes. Neural crest forming the first two branchial arches (mandible and hyoid) and last three arches originates, respectively, from midbrain and hindbrain. Crest fills the arches from ventral to dorsal with those cells contributing to the dorsal portion of the arch migrating later. We observe labeled neural crest cells in cartilage, neuronal, glial, connective tissue and neuromast cells. The first neural crest cells to migrate tend to form mostly cartilage not neural structures. The anterior-most neural tube did not form neural crest; instead, labeled cells migrated within the neural tube to positions in the hindbrain. Our study reveals some interesting differences from previous studies of neural crest in *Xenopus* (Sadaghiani and Thiébaud Dev. Biol. 124:91, 1987). We are unable to observe migration of neural crest before stage 18 and, at stage 15-16, the lateral population of "neural crest" is mostly head mesoderm. Development of the posterior and occipital lateral lines begins after stage 34. We observe labeled cells moving from one primordium (after the placode breaks up) to another along the lateral line nerve. We show primordia form hair cells by double labeling with the hair cell dye 4Di2Asp. By iontophoretically injecting single cells with LRD we are able to demonstrate that, unlike in zebrafish, cranial neural crest cells in *Xenopus* do appear to be multipotent. Single cell labeling of LRD also confirms our result that neural crest cells contribute to neuromasts. Support: MDA & NIMH.

GAP JUNCTIONS ARE PREVALENT IN THE DEVELOPING CEREBRAL CORTEX. J. G. Parnavelas* and B. Nadarajah.

Department of Anatomy, University College London, Gower Street, London WC1E 6BT, U.K.

The neurons and glia that make up the mammalian cerebral cortex arise from neuroepithelial cells surrounding the lateral ventricles. These epithelial cells are linked with different types of specialized junctional complexes. The present study examines the distribution of gap junctions (patch-like membrane appositions with a gap of 2nm) during pre- and postnatal development of the rat cerebral cortex. Brains from rats of a number of embryonic stages and of postnatal animals up to 35 days were fixed with a mixture of aldehydes and processed for electron microscopy. Analysis of coronally-cut ultrathin sections showed that early in corticogenesis (E12-14), gap junctions were restricted to a monolayer of epithelial cells bordering the ventricle. At this stage, many gap junctions were seen between the opposing membranes of elongated cellular processes directed towards the ventricle. At later embryonic stages and in early postnatal life, this band of gap junctions appeared to move away from the ventricular zone and was observed in the regions between the intermediate zone and the deep part of the cortical plate including the subplate. Later in postnatal life, gap junctions were distributed throughout the cortical thickness with a conspicuous concentration in the deeper cortical layers at day 35. These junctions were formed predominantly between neuronal elements including the apical dendrites of pyramidal neurons. These observations suggest that gap junctions may provide a means of communication between proliferating, migrating and differentiating cells in the developing cerebral cortex.

D2 CYCLIN GENE FUNCTION IS IMPLICATED IN DIFFERENTIATION OF SPECIFIC NEURAL PRECURSORS IN BRAIN. ME Ross*, C.J. MacNabb, and M. Risken, Dept. of Neurology, Univ of Minnesota, Minneapolis, MN 55455

Cyclins are regulatory proteins which promote the progression of dividing cells through the cell cycle. D type cyclins mediate the transition from G1 into S phase and are thought to be widely expressed in mitotically active tissues. Their responsiveness to growth factors and their oncogenic capability supports the likely relationship of D cyclin regulation with cell growth and differentiation. We have isolated a cerebellar cDNA, MN20, which corresponds to a D2 cyclin message form, highly restricted to brain. DNA sequence data reveals that MN20 corresponds to a message containing 5 kb of 3' untranslated region (UTR) and 0.9 kb of open reading frame encoding D2 cyclin protein. Northern data reveal differential expression of MN20 using probes from either the extreme 3' UTR or a more 5' region. At postnatal day 6 the 3' probe hybridizes to a 7 kb message seen only in cerebellum while the 5' probe hybridizes to a 6 kb message found at varying levels in P6 cerebellum and 6 other tissues, raising the possibility that there are alternatively processed forms of D2 cyclin mRNA with distinct anatomic expression patterns. In situ hybridization using the 3' probe reveals that MN20 is not ubiquitous in brain, but is expressed in restricted neuronal precursor populations, e.g., in proliferating granule neuroblasts of P6 cerebellum but not hippocampus. Strikingly, the 3' MN20 probe labels presumed postmitotic neuronal precursors in embryonic cerebral cortex, but not dividing cortical neuroblasts. Data suggest that: 1) developing neuroblasts can select which components of the cell cycle machinery they employ, 2) post transcriptional regulation of D2 cyclin protein expression may be used to shape the development of particular brain regions, and 3) the D2 cyclin gene has additional functions beyond promoting the G1/S transition in the cell cycle. (Supported by NIH and the March of Dimes)

INTRACELLULAR RECORDINGS FROM PURKINJE CELLS IN ORGANOTYPIC CEREBELLAR CULTURES EXPOSED TO ARA C. R. Drake-Baumann^{1,2} and F.J. Seil^{1,2,3}, Neurology Research¹, VA Medical Center and Departments of Neurology² and Cell Biology & Anatomy³, Oregon Health Sciences University, Portland, OR 97201.

Previous studies have shown that exposure of explant cultures of neonatal mouse cerebellum to the DNA synthesis inhibitor, cytosine arabinoside (Ara C), for the first 5 days *in vitro* (DIV) drastically reduced the granule cell population and compromised glial function (Seil, F.J. *et al.*, Brain Res. 186:393-408, 1980; Blank, N.K. *et al.*, Neuroscience 7:1509-1531, 1982). Myelination was absent and astrocytes failed to ensheath Purkinje cells (PC). Purkinje cells sprouted recurrent axon collaterals that hyperinnervated other PC somata and projected to PC dendritic spines.

Electrophysiological studies show that Purkinje cells of untreated (control) and Ara C treated explant cultures develop spontaneous electrical activity. Intracellular recordings from Purkinje cells of cerebellar explants between 13-21 DIV exhibit spike activity consisting of a mixture of complex and simple spikes. The complex spikes contain a fast rising action potential followed by a depolarizing potential on which a plateau and several spike-like components are superimposed. This type of activity has been observed in mature Purkinje cells *in vivo* and in slices *in vitro*. By contrast, Ara C treated Purkinje cells have mainly simple spike activity reminiscent of the type of activity seen in immature Purkinje cells. These observations suggest that the electrophysiological maturation of PC is arrested in Ara C treated explants. The lack of glial ensheathment of PC and/or the absence of parallel fiber input may play a role in the failure to develop complex spikes. (Supported by the U.S. Department of Veterans Affairs and NIH grant NS 17493).

DEGENERATIVE DISEASE: ALZHEIMER'S—MECHANISMS OF CELLULAR INJURY II

683.1

TEA AND Ca^{2+} SENSITIVITY OF K^{+} CHANNELS IN OLFACTORY NEUROBLASTS FROM ALZHEIMER'S AND NORMAL DONORS. M. Boakye, R. Eicheberg, V. Luberman, B. Wolozin, and D. L. Alkon. L45, NINDS and SGP, NIMH, National Institutes of Health, Bethesda, MD 20892.

Our laboratory has identified K^{+} channel's regulation as one of the critical steps in associative memory storage. Because memory loss is the principal and earliest sign of Alzheimer's disease (AD), and because AD may be systemic, we studied K^{+} channels in peripheral tissues. Using human fibroblasts, we have found that a 113 pS, tetraethylammonium (TEA)-sensitive channel is functionally absent in fibroblasts from AD patients. The present report extends our previous findings to human olfactory neuroblasts (HON), which make direct synaptic contacts with the central nervous system (CNS) and express neuronal markers. Patch-clamp techniques were used to study K^{+} channels in HON from 8 AD patients and from 6 age-matched control individuals. In the cell attached mode, 57% of the control patches ($n=70$) and 56% of patches from AD cells ($n=81$) exhibited channel activity. Classified by conductance, we identified three types of K^{+} channels of ≈ 25 pS (K-1), ≈ 115 pS (K-2) and ≈ 170 pS (K-3). Each channel type was found with about the same frequency in active patches from AD and control individuals (%AD/%control): K-1 = 52/62; K-2 = 35/25; K-3 = 41/35. Clear TEA sensitivity differences were observed, however, between AD and normal cells for the K-2 channel. The K-2 channel was blocked by 10 mM TEA in all 9 control cells explored, while the activity of the same channel from AD cells remained unchanged even after 100 mM TEA addition ($n=6$), $p < 0.001$, Fisher's test. Initial results indicate that in AD cells, the K-2 channel requires significantly elevated $[Ca^{2+}]_i$ (2 mM) facing the inner side of the membrane, since its activity is dramatically reduced by EGTA addition. No activity was observed at $[Ca^{2+}]_i$ below 2 mM. EGTA removal (or Ca^{2+} elevation) restores K-2 activity. In contrast, the K-2 channel from control cells was unaffected by Ca^{2+} removal, remaining active in high as well as in low $[Ca^{2+}]_i$. These results indicate important differences in K^{+} channel regulation in AD HON as compared to HON from control individuals. Worth noting is the lack of TEA sensitivity in AD cells. These results, together with our previous observations in fibroblasts, further indicate alterations of K^{+} channel function in Alzheimer's, that could also occur in the CNS and thus contribute to memory loss early in the course of the disease.

SSCP ANALYSIS OF TRANSFORMING GROWTH FACTOR BETA 3 IN THE CHROMOSOME 14 LINKED FAD PEDIGREES

S.M. Gaston^{1,2}, W.H. Pettingelf¹, B. Pierre-Louis², R.G. Feldman¹, P. St. George-Hyslop¹, R.E. Tanzi²

¹Dept of Neurology, BU School of Medicine, Boston MA, ²Laboratory of Genetics and Aging, MGH, Charlestown, MA and ³Tanz Neuroscience Institute, Univ. Toronto

Chromosome 14-linked Familial Alzheimer's Disease represents a genetically well defined form of AD, with early onset of symptoms and autosomal dominant transmission. However, this FAD is identical to the more common "sporadic" AD in its pathology and clinical course. Because the Chr 14 mutation primarily affects age of onset rather than significantly reshaping the pathology, transcripts from the minimal candidate region known to regulate cell status are particularly good candidate genes. One such gene, TGFB3, is located just within the distal boundary of the minimal candidate region, between D14S76 and D14S61. SSCP analysis was used to scan the seven TGFB3 exons, 1101 bp of non-translated 5' transcript and 711 bp of sequence 5' to transcriptional start site, followed by sequencing of conformational polymorphisms. Rare non-pathogenic sequence polymorphisms were detected in both affected and control cases, each of these leading to silent substitutions. However, in three of the major Chr 14-linked FAD kindreds (FAD 1, 2, and 4), we found no evidence for potentially pathogenic mutations.

β -AMYLOID NEUROTOXICITY IN HYBRID NEUROBLASTOMA CELLS: ROLE OF NITRIC OXIDE. W.D. Le*, W.J. Xie, L. Colom, R.G. Smith and S.H. Appel, Dep. of Neurology, Baylor College of Med., Houston, TX 77030.

Despite many recent studies have focused on the molecular events associated with β -amyloid-mediated neuronal cell death *in vitro*, the involved mechanisms remain unknown. Data have been reported emphasizing alterations in calcium homeostasis, activation of EAA receptors, substance P receptors and serine proteases in β -amyloid-mediated neurotoxicity. In the present paper we document that nitric oxide (NO) plays an important role in synthetic β -amyloid 1-40 mediated neurotoxicity in our hybrid neuroblastoma cell line MES 23.5. Cytotoxicity was evaluated by FDA/PI vital staining and morphological assessment. Confocal microscope and the calcium sensitive dye Fluo-3 were employed to visualize changes in intracellular calcium concentration. Clear calcium increases were observed by dye Fluo-3 imaging in some cells four hours after the addition of β -amyloid to the culture. Inhibitors of VGCC had no effect on β -amyloid cytotoxicity. Removal of calcium from the medium partially reversed the toxic effects of β -amyloid as did antagonists of the NMDA receptor MK-801 and AP4. Interestingly, β -amyloid (20-40 μ M) increased NO production in the cells by 3-4 fold as measured by cGMP formation. The effects of β -amyloid on NO production were calcium dependent and partially attenuated by NMDA receptor antagonist MK-801. Furthermore, NO scavengers (hematin and reduced hemoglobin) and NO synthase inhibitors (L-NMMA and L-NIO) significantly blocked β -amyloid induced NO production as well as neurotoxicity. Inhibitors of the neutral cysteine proteinase calpain, however, had no effect on β -amyloid neurotoxicity. These results suggest a critical role for a calcium-activated, possibly mediated by NMDA receptors, increased synthesis of NO as a significant mechanism in the β -amyloid induced apoptotic cell death *in vitro*.

INDUCIBLE NITRIC OXIDE SYNTHASE (iNOS) EXPRESSION IN ALZHEIMER'S MICROVESSELS. M.A. Dorheim*, W.R. Tracey, and P. Grammas, Department of Pathology, Univ. of Oklahoma HSC, Oklahoma City, OK 73104, Pharmaceutical Products Division, Abbott Labs, Abbott Park, IL 60064.

The vascular production of NO, which is potentially neurotoxic, may have important pathophysiological consequences in the central nervous system. We have previously shown increased NO production and elevated expression of endothelial cell NOS in isolated microvessels (MVs) in Alzheimer's disease (AD). Since iNOS provides quantitatively more NO over a longer period, its expression could be important in AD. The objective of this study was to determine if iNOS can be induced in the cerebral microcirculation and whether its expression is altered in AD. MVs were isolated from rat brains and human cortices from AD patients and age matched non-demented controls. MVs were homogenized and the soluble protein fraction isolated for slot blot analysis with iNOS antibody. iNOS recognizes the 130 kD and does not cross react with the constitutive isotype. Immunodetection was completed using chemiluminescence and relative iNOS expression was quantitated by scanning densitometry. Isolated rat MVs treated with IL1 β , interferon- γ , and lipopolysaccharide expressed a 3 fold increase in iNOS. AD MVs expressed twice the amount of iNOS compared to control. These data suggest that iNOS expression in brain endothelium could be a significant source of NO in AD brains. (Supported by NS grant 30457, OCAST and the Glenn Foundation).

RELATIONSHIP OF PROTEASE-RESISTANT PROTEIN, AMYLOID AND TUBULOFILAMENTOUS PARTICLES TO THE AGENT OF SPONGIFORM ENCEPHALOPATHY. H. Narang¹, Dept Psy. SUNY Stony Brook NY 11794.

Senile plaques, hallmarks of Alzheimer's disease (AD), are also seen in Down's syndrome, and some transmissible spongiform encephalopathies (TSEs). Histochemical studies have revealed: i) amyloid β -protein (APP) plaques, both in AD and TSEs; ii), Protease-resistant protein (PrP) plaques observed only in TSEs. The APP and PrP are coded by two different normal genes. Unique tubulofilamentous particles (TP) seen in all TSEs have a novel three layer structure; a ssDNA lying sandwiched between two layers of protein, the inner being the PrP. Narang (Res Virol 143, 381, 1992) suggested that in the infected cell the ssDNA may code an "accessory" protein which has an ability to cleave and bind precursor PrP 33-35 into a chain of PrP 27-30. As the modified PrP molecules are added into the chain, assembly of scrapie-associated fibrils (SAF) takes place while ssDNA wraps around SAF/PrP. After an outer protein coat has been added it forms the TP. The SAF which do not acquire ssDNA and the outer protein coat accumulate to form PrP plaques.

Interlinking of ssDNA or part of a viral DNA with the host PrP or the amyloid gene can lead to the post-translation modification of the PrP or APP. An unusual palindromic six base (TACGTA)_n repeat sequence was obtained from ssDNA from scrapie and bovine spongiform encephalopathy. During sequencing of the ssDNA, about 280bp of the APP751 mRNA gene was also sequenced from two of the clones. The over expression of the APP gene appears to be a critical requirement that actually contributes to AD pathology. Activation of the interlinked viral DNA with the amyloid or PrP gene would initiate excess production of APP and PrP. This would occur in transformed cells and gradually lead to plaque formation. The expression of the APP gene might be influenced by point mutations, environmental stimulus, stress and injury.

DEGENERATIVE CHANGES IN BRAIN MICROVASCULATURE AND AMYLOID β PROTEIN IN ALZHEIMER'S DISEASE (AD)

R.N. Kalaria*, D.R.D. Premkumar and P. Hedera. Departments of Neurology and Pathology, Case Western Reserve University and UH Alzheimer Center, Cleveland, Ohio 44106, USA

Considerable evidence suggests cellular abnormalities in the brain vasculature in AD. While it is unclear whether these abnormalities are a consequence of amyloid deposition, it is likely they affect perfusion or permeability functions. We used immunocytochemical markers to examine changes in the cerebral endothelium and basement membrane (BM) in relation to the presence of amyloid β protein (A β) and apolipoprotein E (APOE) in AD and non-AD aging control subjects. Double immunostaining with antibodies to vascular markers, CD34 and CD31, revealed absence of endothelial staining in many capillary profiles that appeared to retain their BMs stained by antibodies to collagen IV. Such differential labelling suggested capillaries with collapsed or degenerated endothelium. In addition, BMs were often seen to contain circular bodies that did not appear to be pericytes. These peculiar features were largely restricted to the neocortex and lacking in brain regions free of A β deposits. The abnormalities, also apparent in Down's syndrome, were largely absent in other non-AD disorders. We suggest this profound vascular phenomenon is relatively specific to brain amyloidosis that implies anomalies in integrity of brain microvasculature in AD. Supported by grants from NIA and ADRDA.

DISTRIBUTION OF APOLIPOPROTEIN E PHENOTYPES IN ALZHEIMER'S DISEASE.

Dale M. VanderPutten^{1,2}, Ginger S. Johnson³, Carl R. Merrill¹. ¹Laboratory of Biochemical Genetics, NIMH, Washington, DC 20032, ²Monoclonetics Int. Inc., Houston, TX 77027, ³Molecular Geriatrics Inc., Lake Bluff, IL 60044

We have confirmed a risk of developing Alzheimer's disease (AD) associated with the apolipoprotein E4 (apoE4) allele by phenotypic analysis of apoE4 protein in plasma, cerebrospinal fluid (CSF) and brain ($z = 4.6$). We have found significantly ($p < 0.001$) lower levels of apoE in AD patients' CSF but not in plasma, frontal cortex or hippocampus. ApoE4 levels in apoE 4/4 homozygotic AD CSF were not different from normal control levels. Analysis of apoE 3/4 heterozygotic individuals showed differences between apoE 3 and 4 levels in AD CSF but not AD plasma or normal CSF. Quantitative RT-PCR analysis suggested the variation in relative amounts of apoE 3 and 4 in CSF results from differential metabolism apoE 3 and 4 proteins in the AD CNS. We hypothesize this difference in apoE metabolism may be an important factor in the development of AD.

PROPENTOFYLLINE INTERFERES WITH ALZHEIMER'S DISEASE-AMYLOID- AND OX ANTIBODIES' RECOGNITION OF ACTIVATED MICROGLIA

A. McRae^{1*}, K. Rudolph², Y. Nakamura³, P. Schubert³
¹University of Göteborg, Dept Anat & Cell Biol Göteborg, Sweden 41390, ²Hoechst AG, Frankfurt a.M., Germany, ³Max Planck Institute of Psychiatry, Martinsried, Germany

Propentofylline (PPF) has been shown by our groups to exert neuroprotection and to depress the ischemia-induced immunostaining of microglial antigens in the gerbil brain upon in vivo treatment. In view of the presumed relevance of a pathological microglial activation for neuronal damage, we attempted to investigate possibilities of pharmacological interference and the underlying mechanisms under defined in vitro conditions. Microglial cell cultures collected from 2-3 weeks old mother cultures of newborn rats were replated and further cultivated in FCS-DMEM for 7 days in the presence or absence of 50 M PPF. Immunostainings were performed with antibodies against OX 18, OX 42 and amyloid precursor protein (APP) and with CSF from AD patients (AD CSF). Non treated microglia were intensely stained with OX 18, OX 42 and AD CSF. PPF treated microglia displayed a loss of OX 18 and AD CSF immunoreactivity. In contrast, APP immunoreactivity was slight in the non treated microglia cultures but was enhanced in PPF treated cultures. The findings indicate that prolonged exposure of activated microglial cells in culture with PPF influences their antigen properties, possibly by favoring A2 adenosine actions. Thus PPF treatment could provide a neuroprotective therapy for AD in which an ongoing activation of microglial cells is considered to be relevant for nerve cell death.

VITAMIN E DELAYS ONSET OF NEUROLOGIC DISORDER IN TRANSGENIC (TG) MICE EXPRESSING HUMAN AMYLOID PRECURSOR PROTEIN (APP) VARIANTS.

K. K. Hsiao, R. Johansson, W. Yunis, and H. B. Clark^{*}. Departments of Neurology and Pathology, University of Minnesota, Minneapolis, MN 55455

We created Tg mice expressing human APP variants that exhibited a progressive neurologic disorder manifesting as an increase in behaviors characteristic for fear and apathy, accompanied by hypertrophic astrocytic gliosis with diminished glucose metabolism in the hippocampal formation, parahippocampal area, amygdala, and cerebral cortex. No extracellular amyloid deposition, neurofibrillary tangle formation, or neuronal loss was observed. Although the morphological substrate for neural dysfunction in these mice has not yet been defined, their behavioral and pathologic abnormalities resembled the age-dependent changes that we observed in some aged non-Tg mice within the same FVB strain, suggesting that aberrant expression of APP in Tg mice may accelerate age-dependent neural dysfunction in a manner characteristic for the specific strain of mouse under study. Vitamin E was administered intraperitoneally to animals in two affected Tg lines. Animals receiving vitamin E remained healthy significantly longer than control mice ($p < 0.001$). Since vitamin E is a free-radical scavenger, these results indicate that free-radical formation may be involved in the pathogenesis of then neurologic disorder in these Tg mice. Whether the protective effect of vitamin E is due to its ability to ameliorate a harmful activity of APP or cause a general deceleration of the aging process is unknown.

NEURONAL APOLIPOPROTEIN E IMMUNOREACTIVITY IS INCREASED IN PICK'S DISEASE.

N.W. Kowall^{1,2}, C. Abraham² and A.C. McKee^{1,2}. ¹Geriatric Research Education Clinical Center, Bedford VAMC, Bedford MA 01730; ²Depts. of Pathology, Medicine, & Neurology, Boston U. Sch. of Med.

In the normal central nervous system, apolipoprotein E (ApoE) is synthesized and secreted by astrocytes, taken up by neurons and transported down axons. One of the characteristic histological features of Pick's disease is the presence of ballooned Pick cells that may develop as a result of impaired axonal transport. We defined the distribution of ApoE in samples of affected cerebral cortex from 13 patients with Pick's disease using specific anti-human ApoE antibodies. In some cases prominent ApoE immunoreactivity was present in neurons – including ballooned Pick cells and Pick bodies which contain phosphorylated tau and neurofilament. Staining was confined to astrocytes in cases with profound neuronal loss. ApoE immunoreactivity was also associated with parenchymal and vascular amyloid deposits when present. The accumulation of ApoE within damaged neurons, its association with phosphorylated cytoskeletal proteins, and the over-representation of the E4 allele in these patients, strongly supports a role for apoE in the pathogenesis of Pick's disease.

APOLIPOPROTEIN E EXPRESSION AND EFFECTS OF DENERVATION AT NEUROMUSCULAR JUNCTIONS IN MOUSE SKELETAL MUSCLE. M. Akaaboune, M. Villanova, B.W. Festoff, M. Verdière-Sahuqué and D. Hantai*. INSERM U.153 and Université Paris VI, 75005 Paris, France; KCVAMC and KUMC, Kansas City, MO 64128 and KS 66160.

Apolipoprotein E (ApoE) allele E4 has been associated with late onset familial Alzheimer's disease (AD). In AD brain, ApoE is localized to the cerebrovascular amyloid plaque and neurofibrillary tangles. In a previous study we demonstrated that β -amyloid protein precursor and α_1 -antichymotrypsin, found accumulated in senile plaques in AD brain, were localized at neuromuscular junctions (NMJ). In the current study we asked whether ApoE was also localized at NMJ and was affected by denervation, using immunocytochemistry and Western blotting. The results indicate that ApoE was present in normal muscle at the NMJ, within intramuscular nerves, and on endothelial cell surfaces. Following axotomy, ApoE disappeared rapidly from intramuscular nerves. However, at the NMJ, ApoE lingered several days before disappearing. Such experiments in muscle after denervation may shed light on the mechanism of synapse loss as well as plaque deposition in AD.

OVERREPRESENTATION OF CYP2D6B MUTANT ALLELE IN LEWY BODY VARIANT OF ALZHEIMER'S DISEASE. Tsunao Saitoh*, Yu Xia, Xiaohua Chen, Eliezer Masliah, Richard DeTeresa, Michael Alford, Douglas Galasko, Clifford Shults, Leon J. Thal, Lawrence Hansen, and Robert Katzman. Department of Neurosciences, University of California, San Diego, 9500 Gilman Drive, La Jolla, CA 92093-0624

Approximately one-quarter of neuropathologically confirmed cases of Alzheimer's disease (AD) also have brainstem and neocortical Lewy bodies, constituting a Lewy Body Variant (LBV) of AD. Since Lewy bodies are a pathologic hallmark of idiopathic Parkinson's disease (PD), this sub-population of AD patients may have the risk factors shared by PD patients, in addition to the risk factors for AD. Analyses of cytochrome P450 CYP2D6-debrisoquine 4-hydroxylase mutant B allele (CYP2D6B), susceptibility gene for PD, revealed an association of this allele with the LBV of AD. Further, it was found that patients with the CYP2D6B allele have less developed AD neuropathology than those with the wild type CYP2D6 allele. On the other hand, analyses of apolipoprotein E allele 4 (ApoE ϵ 4), susceptibility gene for AD, revealed an association of this allele with the LBV of AD. Thus, genetically, LBV is like AD and PD at the same time. The association of CYP2D6B with the LBV of AD and its effect on neuropathology implies that this subpopulation of AD patients may require therapeutic strategies different from those applied to pure AD.

OXIDATIVE DAMAGE TO MITOCHONDRIAL DNA IS INCREASED IN ALZHEIMER'S DISEASE. M.F. Beal*, U. MacGarvey, and P. Mecocci. Neurology Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Oxidative damage to DNA may play a role in both normal aging and in neurodegenerative diseases. The mitochondria are the major source of free radicals in the cell, and recent evidence has shown decreases in cytochrome oxidase activity in Alzheimer's disease (AD), both in platelets and in cerebral cortex. Cytochrome oxidase inhibition leads to increased free radical generation in isolated mitochondria. Prior studies showed evidence for increased lipid peroxidation in AD postmortem brain tissues. We examined whether AD is associated with increased oxidative damage to both nuclear DNA (nDNA) and mitochondrial DNA (mtDNA) in postmortem brain tissue. We measured the oxidized nucleoside, 8-hydroxy-2'-deoxyguanosine (OH⁸dG), in DNA isolated from 3 regions of cerebral cortex and cerebellum in 13 AD and 13 age-matched controls. There was a significant 3-fold increase in the amount of OH⁸dG in mtDNA in parietal cortex of AD patients as compared with controls. In the entire group of samples there was a small significant increase in oxidative damage to nDNA and a highly significant 3-fold increase in oxidative damage to mtDNA in AD as compared with age-matched controls. These results confirm that mitochondrial DNA is particularly sensitive to oxidative damage, and they show that there is increased oxidative damage to DNA in AD, which may contribute to the neurodegenerative process.

DRUGS OF ABUSE: ADDICTION/TOLERANCE

684.1

THE RELATIONSHIP BETWEEN OPIOID AGONIST INTRINSIC EFFICACY AND TOLERANCE. Alokesh Duttaroy, Ka Wa Chan, Sukrut Shah and Byron C. Yoburn*. College of Pharmacy, St. John's University, Queens, NY 11439.

Tolerance is a reliable consequence of repeated exposure to opioid agonists. Furthermore, the magnitude of tolerance has been shown to be dependent upon agonist intrinsic efficacy. Continuous infusions of high intrinsic efficacy compounds (e.g., fentanyl) produce less tolerance than infusions of lower intrinsic efficacy drugs (e.g., morphine). However, it has been reported that when opioid analgesics are administered intermittently the degree of tolerance is not significantly affected by intrinsic efficacy (Duttaroy *et al.*, *FASEB J.*, 7: A704, 1993). In the present study the role of intrinsic efficacy was investigated by comparing intermittent and continuous administration dosing protocols using 3 opioid agonists (morphine, etorphine and fentanyl). In the continuous administration study, mice were infused s.c. (osmotic minipumps) with 5 - 40 times the ED₅₀ of each drug for 168hrs; the pumps were removed and 24hrs later mice were tested for analgesia (tailflick) in cumulative dose-response studies. Controls were implanted s.c. with inert placebo pellets. With increasing infusion doses, the magnitude of tolerance increased for all three analgesics. However, maximal tolerance of \approx 3 fold was observed for fentanyl and etorphine at 40 times the ED₅₀; whereas \approx 4 fold tolerance was produced by an infusion 10 times the ED₅₀ for morphine. In another study, the effect of intermittent administration of morphine and etorphine on analgesic tolerance was examined. Mice were injected s.c. once per day for 7 days with saline or 10 times the ED₅₀ for morphine or etorphine; 24hrs following the last injection mice were tested for analgesia. Although both morphine and etorphine produced tolerance, the degree of tolerance was similar for both drugs. Intermittent morphine produced a 1.7-fold shift in the ED₅₀, while intermittent etorphine produced a 2.1-fold shift in the ED₅₀. These results indicate that under conditions of continuous administration intrinsic efficacy is a determinant of the magnitude of tolerance to opioid analgesics. However, when opioid agonists are administered intermittently, intrinsic efficacy appears to have little impact on tolerance. (Supported by NIDA DA 04185)

684.2

COMPARISON OF THE ATTENUATION OF THE OPIOID WITHDRAWAL SYNDROME BY 7-NITROINDAZOLE, A BRAIN-SPECIFIC NITRIC OXIDE SYNTHASE INHIBITOR, WITH THAT OF OTHER NITRIC OXIDE SYNTHASE INHIBITORS. A.S. Kimes*¹, D.B. Vaupel¹, and E.D. London^{1,2,3}. NIDA IRP, NIH, Balto., MD, 21224; ²Dept. Radiology, Johns Hopkins Sch. Med., Balto., MD 21204; and ³Dept. Pharmacol. Exp. Ther., Univ. MD Sch. Med., Balto., MD 21201.

Inhibitors of nitric oxide synthase (NOS) attenuate some signs of opioid withdrawal (Kimes *et al.*, *Psychopharmacology* 112:521, 1993). The purpose of the present study was to compare the potency of a brain-specific NOS inhibitor, 7-nitroindazole (7-NI) with that of less selective NOS inhibitors, L-NG-nitroarginine (L-NNA), L-NG-nitroarginine methyl ester (L-NAME), and N(5)-(1-iminoethyl)-L-ornithine (L-NIO). We also compared the attenuation of the withdrawal by NOS inhibitors to that produced by clonidine. Morphine dependence was produced by the subcutaneous implantation of 1 morphine pellet (75 mg) on Day 1. On Day 4, the following drugs (doses in mg/kg) were administered 1 h before naloxone challenge (0.5 mg/kg): L-NNA (1, 3, 10, 18 & 30); L-NAME (10, 18, 30, & 56); 7-NI (1.8, 5.6, 18, 30, 56, & 100); L-NIO (1, 10, 56, 100 & 300); clonidine (0.01, 0.03, & 0.1). All of the NOS inhibitors decrease wet dog shakes, weight loss, diarrhea, and grooming. The selective NOS inhibitor, 7-NI also attenuates the expression of other signs (mastication, salivation, and penis licks/ejaculations), the expression of which are either unchanged or increased by the less selective NOS inhibitors. The expression of many signs are affected similarly by clonidine and 7-NI (weight loss, diarrhea, wet dog shakes, grooming and mastication), but clonidine uniquely attenuates the expression of abnormal posturing. The potencies of the NOS inhibitors to reduce the frequency of wet dog shakes during opioid withdrawal were similar for 7-NI and L-NAME. L-NNA was almost 4-fold more potent, and L-NIO was less than half as potent as either 7-NI and L-NAME. In conclusion, our results show that NOS inhibitors attenuate withdrawal at least as effectively, but not as potently, as clonidine, and suggest that 7-NI, which does not increase blood pressure, may be a good candidate for human use.

684.3

NALOXONAZINE PRETREATMENT IMPAIRS MORPHINE-INDUCED ACQUISITION OF PLACE-PREFERENCE BUT NOT STIMULATION OF DOPAMINE RELEASE Tanda G., R. Longoni, L. Spina, E. Carboni* and G. Di Chiara Dpt. of Toxicology Univ. of Cagliari (Italy)

Although opiates stimulate dopamine (DA) release and the firing activity of DA units, the role of DA in opiate reinforcement is debated. We now report that naloxonazine (15 mg/Kg i.p. 20 h before) fails to modify the stimulation of DA release in the n. accumbens elicited by morphine (1.0 and 5.0 mg/kg s.c.) but prevents the acquisition of place-preference induced by a single pairing with morphine. The results suggest that DA does not mediate the primary reinforcing properties of opiates. However, since naloxonazine fails to extinguish heroin self-administration (Negus et al. JPET, 265, 1249, 1993) DA might act as a secondary reinforcer to maintain opiate self-administration.

684.5

EVIDENCE THAT IBOGAINE INHIBITS DOPAMINE RELEASE VIA A KAPPA RECEPTOR MECHANISM. Malcolm S. Reid*, Kang Hsu, Patricia Broderick+, S. Paul Berger UCSF/VAMC, Substance Abuse Treatment Research 116W, 4150 Clement St., San Francisco, CA 94121; +Pharmacology Dept., CUNY Medical School, 138th St and Convent Ave., New York, NY 10031.

Ibogaine has been proposed as a clinical treatment for stimulant and opiate addiction. In the present study *in vivo* microdialysis was used to determine the effects of ibogaine on the extracellular levels of dopamine in the nucleus accumbens and striatum of freely moving Sprague-Dawley rats. In addition, the effects of the non-selective opiate antagonist naloxone and the kappa receptor opiate antagonist norbinaltorphimine (NorBNI), alone and in combination with ibogaine, were also studied. All drugs were tested locally by perfusing them through the microdialysis probe. Ibogaine was tested at several doses (10-6M to 10-3M) and it was found that it produced a biphasic dose-response curve, whereby lower doses (10-6M to 10-4M) produced a dose-dependent decrease in dopamine levels while higher doses (5x10-4M and 10-3M) produced an increase in dopamine levels, seen in both the nucleus accumbens and striatum. Naloxone and NorBNI (10-6M to 10-4M) had no effects on dopamine, except the highest dose of naloxone (10-4M) which produced an increase in dopamine levels. Co-administration of naloxone or NorBNI (10-6M or 10-4M) with ibogaine (10-4M) blocked the decrease in dopamine levels produced by ibogaine alone, suggesting that the ability of ibogaine to inhibit dopamine release is mediated by kappa opiate receptors. Further studies on the dopamine stimulatory properties of ibogaine are underway.

DELETION OF β -ENDORPHIN IN THE MOUSE BY TARGETED GENE MUTAGENESIS. M. Rubinstein, M. Japón, E. C. Chan, R. Allen*, and M. J. Low, The Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201, U.S.A.

The endogenous opioid peptides are proposed to modulate neuroendocrine circuits, autonomic reflexes, analgesia, memory, and learning through binding to a family of G-protein coupled receptors. Our laboratory has initiated a program to test the function of the individual components of the endogenous opioid system by gene targeting in embryonic stem cells. β -endorphin is produced in three discrete areas; the arcuate nucleus, the nucleus tractus solitarius, and the pituitary by the posttranslational processing of proopiomelanocortin (POMC). Because POMC is also important as a precursor for ACTH and melanocyte stimulating hormones (MSH), we designed a gene targeting vector that encodes a truncated POMC prohormone selectively deficient in the β -endorphin peptide sequences (Nucleic Acids Research 21:2613-2617, 1993). Mice homozygous for the mutated POMC allele are developmentally normal, grow to maturity and reproduce. HPLC chromatography and RIA of hypothalamic and pituitary extracts show that the truncated POMC prohormone is authentically processed to ACTH and MSH in the total absence of β -endorphin-like immunoreactivity. As a result, the mice have normal hypothalamic-pituitary-adrenal function under basal and restraint-stress induced conditions. The neurons that normally produce β -endorphin are intact and the wide-spread fiber distribution from these neurons is also normal and detectable with an antiserum to ACTH on brain sections. Preliminary data suggest that swim-stress induced analgesia is unaltered in the β -endorphin deficient mice. Additional behavioral tests are ongoing. We conclude from these studies that β -endorphin is not an essential neuropeptide for development of the nervous system or organization of the neuroendocrine circuits controlling the hypothalamic-pituitary-gonadal and adrenal axes. The lack of an obvious nociceptive phenotype suggests that enkephalins, dynorphins, and possibly nonopioid mechanisms are either sufficient for analgesia or can compensate for the loss of β -endorphin in the 129SV/EV X C57Bl/6N genetic background.

ANABOLIC ANDROGENIC STEROIDS: AN ASSESSMENT OF THEIR ADDICTIVE POTENTIAL. A.R. Lumia, S.T. Diekman and M.Y. McGinnis* Biopsychology Program, Skidmore College, Saratoga Springs, NY 12866 and Dept. of Cell Biology and Anatomy, Mount. Sinai School of Medicine, New York, NY 10029.

We employed a three-chambered place preference test apparatus to examine the reinforcing and addictive potential of anabolic androgenic steroids (AAS) in adult Long-Evans male rats. Testing consisted of three phases. First, all rats received a pretest which allowed each animal 20 min to explore all three chambers and establish a place preference. For the second (conditioning) phase, the animals were divided into two groups: an experimental group receiving twelve daily injections of 1mg testosterone propionate (TP) alternating with propylene glycol (PG), and a control group receiving only PG. Injections were given 15 min prior to placement in a chamber associated with either TP or PG for 45 min. In the third phase the rats received two place preference tests. In the first test all rats received PG and time spent in each chamber was recorded. In the second test they were given either TP or PG and tested again for place preference. Results showed that rats receiving TP paired with a particular chamber spent significantly more time in that chamber. PG-treated rats did not show a place preference. The potential for AAS addiction is suggested by the findings that 1) rats can discriminate the presence of AAS from a control substance, and 2) that AAS are positively reinforcing in a place preference test. (supported by a grant from the Harry Frank Guggenheim Foundation)

Δ^9 -TETRAHYDROCANNABINOL AND THE SYNTHETIC CANNABINOID CP-55,940 INDUCE EXPRESSION OF *c-FOS* mRNA IN STRESS-RESPONSIVE NUCLEI OF RAT BRAIN. M. Herkenham* and L. S. Brady. Section on Functional Neuroanatomy, Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892.

Little is known about the functional consequences of acute cannabinoid (marijuana) intoxication. Rats were injected acutely i.p. with Δ^9 -tetrahydrocannabinol (10 mg/kg) or the synthetic cannabinoid CP-55,940 (1, 3, or 10 mg/kg) and sacrificed 40 min later. Brains were processed for *in situ* hybridization of the riboprobe for the immediate-early gene *c-fos*. Induction of *c-fos* mRNA expression occurred in a set of structures that comprise the central effectors of the stress response—paraventricular nucleus of the hypothalamus, anterior lobe of the pituitary, locus coeruleus, ventral lateral septum, central nucleus of the amygdala, and paraventricular nucleus of the thalamus. The two drugs produced similar patterns of responses, and responses to CP-55,940 were somewhat dose-dependent. Motor structures, notably those containing dense cannabinoid receptors, did not show elevated *c-fos* mRNA levels. Thus the activated structures reflect the animals' psychological (cannabinoids elevate plasma corticosterone and appear to be stressors in rats) and motoric states (cataleptic) and not the primary sites of action of the drug.

685.1

EXCITOTOXIC-TYPE NECROSIS IN THALAMUS PRECEDES MOTOR SEIZURES IN A RAT MODEL OF WERNICKE'S ENCEPHALOPATHY. P.J. Langlais*, S.X. Zhang, G.S. Weilersbacher, T. Corso, and J.W. Olney. Psychology Dept., San Diego State University, San Diego, CA, 92182 and Psychiatry Dept., Washington University, Sch. Med., St. Louis, MO, 63110.

In the pyridoxamine-induced thiamine deficient (PTD) rat model of Wernicke's encephalopathy, thalamic necrosis has been linked to elevated extracellular glutamate (Langlais & Zhang, 1993) and activation of the NMDA glutamate receptor (Langlais & Mair, 1990). Motor seizures are frequently observed in late stages of PTD treatment. We undertook the current study to determine the role of seizures in thalamic necrosis. In PTD rats perfused prior to onset of motor seizures, electron microscopic evaluation revealed cytomorphologic changes of neurons in the anteroventral (AV) and gelatinous (Ge) thalamic nuclei that are consistent with a glutamate excitotoxic process. In PTD rats administered thiamine prior to seizures and recovered for 7 days there was significant neuronal loss in the ventroposterolateral (VPL), AV, and Ge nuclei. In animals given thiamine after onset of seizures, necrosis was more severe in VPL and was evident in midline and intralaminar regions. These observations demonstrate that seizures may aggravate but are not prerequisite to excitotoxic necrosis and early administration of thiamine can prevent more widespread damage. We propose that the critical events leading to excitotoxic necrosis are thiamine deficiency-induced reductions of energy production, elevated glutamate levels, and histamine-enhanced NMDA receptor activity. Supported by AA 07466, AG05681, MH14677, NS29481, and RSA MH38894.

ABNORMAL MITOCHONDRIAL MEMBRANE POTENTIAL IN HUMAN NEUROLOGICAL DISORDERS. S.D. Handran*, A.M. Moudy, M.P. Goldberg, D.C. DeVivo*, S.M. Rothman. Center for the Study of Nervous System Injury, Washington University School of Medicine, St. Louis, MO 63110 and *The Neurological Institute of New York, NY 10032.

Several neurodegenerative diseases are characterized by selective neuronal losses which may result from a defect in energy metabolism. A working hypothesis states that an underlying impairment of mitochondrial function may result in decreased ATP production, increased glutamatergic receptor activation, and loss of intracellular calcium homeostasis (Beal et al, *TI/NS* 16:125, 1993). We investigated human fibroblasts obtained from patients with mt-DNA mutations that directly result in impaired energy metabolism. We have previously shown (*Soc. Neurosci. Abstr.* 19:1502, 1993) abnormal calcium homeostasis in fibroblasts from patients with MELAS syndrome (mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes). We have extended this investigation by measuring mitochondrial membrane potential with the dual emission fluorescence dye JC-1 and confocal microscopy. Ratio images were analyzed by dividing the 590 nm emission (potential sensitive) by the 527 nm emission (potential insensitive). MELAS fibroblasts had significantly decreased mitochondrial membrane potential relative to control patients ($p=0.002$, Mann-Whitney) as determined by measuring the area of polarized membrane (having ratio values ≥ 1) to total mitochondrial area. This decreased membrane potential may compromise the ability of the mitochondrion to contribute to cytosolic calcium homeostasis, possibly through diminished calcium uptake. Chronic impairment in the neurons of patients with these and other neurodegenerative disorders may result in the disease phenotype. Supported by NS19988 and NIH5-T32NS07057-15.

STRIATAL TOXICITY OF 3-NITROPROPIONIC ACID PREVENTED BY THE AMPA ANTAGONIST NBQX. L. Turski* and H. Ikonomidou*. Research Labs of Schering AG, Berlin, Germany and St. Louis Children's Hospital, St. Louis, USA.

3-Nitropropionic acid (3-NP), which irreversibly blocks succinate dehydrogenase (complex II), is reported to be a selective striatal neurotoxin in rodents and primates. Chronic systemic administration of 3-NP to rats leads to low grade metabolic disturbances in the striatum and to striatal neuron damage (sparing NADPH-diaphorase containing neurons). These observations support the hypothesis that disturbances in mitochondrial energy metabolism can lead to axon-sparing glutamate-like toxicity in the brain and that such processes may be involved in the pathogenesis of chronic neurodegenerative disorders in humans.

Aged (18-24 months old) Wistar rats were subjected to a chronic (over 28 d) continuous treatment with 3-NP (24 mg/kg/d) or with 3-NP and the competitive AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate) antagonist NBQX (6-nitro-7-sulphamoyl-benzof[quinoxaline-2,3-dione; 24 mg/kg/d) by means of osmotic minipumps implanted i.p. Seven days after discontinuation of the treatment with 3-NP or 3-NP and NBQX, the rats were sacrificed by transaortic perfusion-fixation and the brains were serially sectioned and prepared for light microscopy. Two out of eight 3-NP and vehicle treated rats died in the course of chronic treatment. Morphological analysis of the brains from six remaining rats treated with 3-NP and vehicle showed consistent damage in the striatum and less damage in the hippocampus and cortex of three animals. Treatment of seven additional rats with 3-NP and concurrently with NBQX did not produce lethality and brain damage. These observations suggest that AMPA antagonists may be of benefit for preventing chronic degeneration triggered by 3-NP.

HYPERACTIVATION OF GLUTAMATE PATHWAYS INDUCES THALAMIC CYTOPATHOLOGY RESEMBLING WERNICKE-KORSAKOFF ENCEPHALOPATHY. J.W. Olney*, N.B. Farber, T. Corso, J. Labryere, S.X. Zhang, P.J. Langlais. Washington Univ., St. Louis MO 63110 and San Diego State University, San Diego, CA 92182.

Wernicke-Korsakoff encephalopathy (WKE) is a brain damage syndrome associated with alcoholism and thiamine deficiency (TD). Feeding a thiamine deficient diet to rats and treating them simultaneously with pyridoxamine induces a TD brain damage syndrome that closely resembles both the pattern and type of cytopathology seen in WKE. Acute neuron-necrotizing lesions in various thalamic nuclei is a conspicuous feature of WKE in humans and of the TD syndrome in rats. Langlais et al (1990,1993) have shown in the TD rat that there is a striking elevation of extracellular glutamate (Glu) in vulnerable thalamic regions as the lesions are developing, and that these lesions can be prevented by pretreatment with MK-801, a powerful antagonist of NMDA Glu receptors. Collins & Olney (1982) have shown that acute lesions can be induced in the ventral posterolateral (VPL) nucleus of the thalamus by hyperactivation of cerebrocortical neurons that project to VPL and use Glu as transmitter; these lesions can be prevented by MK-801 pretreatment (Clifford et al., 1989). In the present study, we have performed an electronmicroscopic analysis of the acute cytopathology induced in VPL of the TD rat and compared it with acute cytopathology induced in VPL by hyperactivation of Glu-ergic corticothalamic afferents to VPL. In both of these syndromes the cytopathological reaction was found to have the characteristic features of Glu-induced excitotoxicity. Acute edematous swelling of presynaptic dendrites and neuronal cell bodies, degenerative changes in mitochondria and endoplasmic reticulum and clumping of nuclear chromatin typifies both syndromes, as does sparing of presynaptic axon terminals. These findings are consistent with the hypothesis that brain damage in human alcoholics may be mediated by an unleashing of the excitotoxic potential of endogenous Glu. A LYSO GM1 DERIVATIVE (LIGA20) GIVEN ORALLY AFTER CORTICAL THROMBOSIS REDUCES INFARCT SIZE AND ASSOCIATED COGNITION DEFICIT. Guidotti, A*, Khramov, A., Zivkovic, I. and Costa, E.; FGIN, Georgetown University Medical Center, 3900 Reservoir Road, N.W., Washington, D.C. 20007

A bilateral, photochemically induced thrombotic lesion of rat sensorimotor cortex (approximately 3 mm in diameter and 25 mm³ in volume) is associated with a persistent cognition (learning and memory) deficit which was evaluated with water maze tasks. The semisynthetic N-dichloroacetyl sphingosine derivative of lyso GM1 (LIGA20) administered after the lesion either i.v. or p.o. reduced the infarct size by 30 to 40% and attenuated the associated cognition deficit by limiting the extent of damage of neurons at risk located in the area surrounding the infarcted core (i.e., area penumbra). The LIGA20 protection was dose and time dependent. Maximal protection was afforded by a single injection of 34 μ mol/kg of LIGA20, i.v., 1 hr after lesion or by 270 μ mol/kg, p.o. administered 1 and 24 hr after the lesion. The protective effect of LIGA20 was observed when the drug was administered i.v. up to 6 hr after the lesion. The protective efficacy of the oral administration of LIGA20 may be related to its physicochemical properties (molecular area, surface potential, collapse pressure, dipole moment) which, unlike those of GM1, allow absorption from the gastrointestinal tract. LIGA20 given orally reaches the brain promptly and is rapidly inserted into the neuronal membranes. In the brain LIGA20 does not reduce Ca²⁺ influx but selectively inhibits the pathological amplification of Ca²⁺ signalling elicited by persistent stimulation of ionotropic glutamate receptors in the area penumbra by a yet unknown molecular mechanism.

TRAUMA CAUSES GLUTAMATE-TYPE CYTOPATHOLOGY IN INFANT RAT BRAIN. C. Ikonomidou*, Y. Q. Qin, J. Labryere and J. W. Olney. Depts. of Psychiatry and Pediatric Neurology, Washington University, St. Louis, MO 63110.

Glutamate (Glu) is an excitatory neurotransmitter in the mammalian CNS, but it also has neurotoxic properties when administered systemically to infant animals. In rats we have shown that infants are much more susceptible than adults to the excitotoxic actions of exogenous Glu, NMDA or to hypoxia-ischemia, and that peak sensitivity to these conditions occurs between postnatal days 6 and 10. In this study we explored the neuropathologic changes that follow contusion injury to the infant rat brain at the age of peak sensitivity to Glu excitotoxicity. The contusing device consisted of a perforated stainless-steel tube 40 cm long that guided a falling weight onto a footplate resting upon the infant skull (at 3mm anterior and 2 mm lateral to lambda). A 1 mm footplate diameter, a 2.5 mm depression of the skull surface and a force of 165 g/cm were the selected conditions. Animals were anesthetized and pericardial perfusion fixed at 0, 2 and 6hrs after trauma. Histologic analysis revealed focal damage at the point of impact and this was surrounded by a zone of neuronal necrosis that progressively expanded over a period of 6 hrs. The cytopathologic changes consisted of swollen dendrites, degenerating neurons with pyknotic nuclei and markedly swollen cytoplasm (bull's eye profiles), and dark cells with vacuolated cytoplasm. Electronmicroscopic analysis revealed that these lesions were of the axon-sparing type and resembled in all aspects lesions caused by exogenous Glu. The NMDA antagonist MK-801, when administered 15 min before or 15 min after the trauma, significantly inhibited development of Glu-type pathology around the trauma site. We conclude that traumatic injury in the infant rat brain triggers excessive release of endogenous Glu followed by a cascade of events resulting in excitotoxic neuronal degeneration. Glu antagonists may prove beneficial in preventing brain damage associated with head trauma in pediatric patients. Supported by AA 07466, RSA MH 38894 (JWO) and a grant from Schering AG.

EXCITATORY AMINO ACID ANTAGONISTS DECREASE GANGLION CELL DEATH FOLLOWING OPTIC NERVE TRANSECTION IN ADULT RATS. R.E. McKittrick¹, P. Tempesti, D.T. Ross². Head Injury Center, Div Neurosurg, Univ of Pennsylvania, Philadelphia, PA 19104 and ¹ Brown University School of Medicine, Providence RI 02906.

Damage to the adult mammalian optic nerve produces retrograde degeneration of >95% of all retinal ganglion cells (RGCs) within four weeks. Work from our laboratory suggests that axotomy induced degenerative processes may include an excitotoxic component. This study tested the excitotoxic hypothesis of RGC death by examining the neuroprotective efficacy of the NMDA antagonist MK-801 and the AMPA/kainate antagonist CNQX on RGCs following optic nerve transection. RGCs were retrogradely labeled by injection of the carbocyanine dye Dil in their lateral geniculate nuclei. Four days later both optic nerves were transected in two groups, one that received 5µl intravitreal injections of MK-801 and CNQX, and a 2nd group received saline injections. RGC density 28 and 90 days after transection was determined from whole mounts at 400X for n=6 retina per group. Fluorescent double labeling by SMI-31 phosphorylated neurofilament immunohistochemistry was used to examine the reaction of the ganglion cell fiber layer in retina from each group.

MK-801/CNQX treatment did not induce abnormal intra-retinal RGC axon sprouting. Treatment with MK-801/CNQX did provide significant protection of RGCs at 28 days (9% to 33.5% of all RGCs), but by 90 days the RGC density in treated cases was identical to that in non-treated optic nerve transection (ONX) cases.

28 days	RGCs / mm ²	% Lost	% Spared
Normal	1209 ± 312	-	-
ONX	61 ± 25*	95%	5.0%
MK-801 + CNQX	239 ± 120 ^{1,2}	80.2%	19.8%

*ONX < Normal, p<.0001; Normal > MK801/CNQX > ONX, p<.0001

These results are consistent with the presence of an excitotoxic component in the process of axotomy induced retinal ganglion cell death which may involve both NMDA and AMPA type EAA receptors. (Supported by NS 28852 and NS 08803).

GLUTAMATE-ELICITED [Na⁺]_i INCREASE IMPAIRS NEURONAL CALCIUM BUFFERING BY MITOCHONDRIA. L. Kiedrowski* and E. Costa. Fidia-Georgetown Institute for the Neurosciences, Georgetown University, Washington, DC 20007.

An exposure of primary cultures of cerebellar granule cells to glutamate (50 µM) applied in a Mg²⁺-free medium for 4 min increases somatic [Na⁺]_i up to 100 mM and after glutamate removal [Na⁺]_i fails to decrease promptly. In contrast, [Ca²⁺]_i after an initial increase to about 5 µM, decreases to 1.5 µM during glutamate exposure. Moreover, a sudden drop in [Ca²⁺]_i to 350 nM is observed immediately after glutamate removal when [Na⁺]_i is still elevated. These data indicate that mechanisms other than the plasmalemmal Na⁺/Ca²⁺ exchanger are responsible for these decreases in somatic [Ca²⁺]_i. Thapsigargin (1 µM) fails to affect the [Ca²⁺]_i decrease during and after glutamate exposure indicating that intracellular Ca²⁺ stores controlled by endoplasmic Ca²⁺ ATPase do not contribute significantly to Ca²⁺ buffering. In contrast to thapsigargin, mitochondrial inhibitors CCCP (1 µM) and antimycin A1 (1 µM) evoke large increases in [Ca²⁺]_i up to several µM, when applied during or immediately after glutamate exposure. Both CCCP and antimycin A1 fail to affect [Ca²⁺]_i when applied without glutamate or 15 min after glutamate removal when the basal [Ca²⁺]_i is restored. When after glutamate removal [Na⁺]_i is artificially decreased to 5 mM, by application of external Na⁺ (5 mM) with gramicidin (5 µM), [Ca²⁺]_i drops to 150 nM and then increases to 350 nM when 100 mM Na⁺ is applied. These [Na⁺]_i-dependent changes in [Ca²⁺]_i are observed also in a Ca²⁺-free medium. Our data suggest that the glutamate-evoked [Na⁺]_i increase, which seems to be associated with a decrease in [K⁺]_i, reduces the efficacy of Ca²⁺ buffering by mitochondria.

GLUTAMATE RECEPTOR MEDIATED DOPAMINERGIC TOXICITY DUE TO SDH INHIBITION G.D.Zeevalk¹, E.Derr-Yellin and W.J.Nicklas. Neurology, UNDNJ-RWJ Med. Sch., Piscataway, N.J. 08854. Metabolic deficiencies have been detected in patients with Huntington's, Parkinson's and Alzheimer's Diseases suggesting a metabolic defect as a common etiological feature. Several laboratories have shown that intrastriatal administration of an irreversible succinate dehydrogenase (SDH) inhibitor, 3-nitropropionic acid (3-NPA), or reversible SDH inhibitor, malonate, produced lesions that were "excitotoxic", further suggesting that compromised metabolism could trigger an excitotoxicity (J. Neurochem. 61:1147 & 1151, 1993; J. Neurosci. 13:4281, 1993). In this study, we examined the possible involvement of glutamate receptors in metabolic stress-induced loss of dopaminergic (DA) neurons from rat mesencephalic (MN) culture. MN neurons were plated in DMEM plus 10%FBS/10%horse serum. Previous studies showed that DA neurons were sensitive to medium change but could be maintained for up to 3 weeks if fed with conditioned medium (CM; obtained from MN cultures at 6 days in vitro (div)). Prior to metabolic stress studies, glutamate receptor mediated toxicity was assessed. At 12div, 10-500µM NMDA or kainate (KA) was added to the cultures. After 24 hr, the medium was replaced with CM, allowed to recover for 48 hr and then examined for ³H-DA uptake. NMDA and KA caused a dose dependent loss of DA uptake (EC₅₀ 16 and 26µM, respectively). Staining for tyrosine hydroxylase positive cells confirmed cell loss. In metabolic stress studies, cultures were treated with 0.1-0.5mM 3-NPA. Inhibition of SDH produced a dose dependent loss of ³H-DA uptake (EC₅₀ 0.18mM). Coincubation with the NMDA antagonist MK-801 (1µM) provided nearly complete protection vs. 0.25mM 3-NPA and significant, but less, protection vs. 0.5mM 3-NPA. The nonNMDA antagonist, CNQX (15µM), was not protective. These studies demonstrate the sensitivity of cultured neurons to NMDA and KA toxicity and further show that metabolically stressing DA neurons results in neurotoxicity that is mediated in part by the NMDA receptor.

685.10

INHIBITION OF GLUTAMATE UPTAKE IN VIVO IS NOT SUFFICIENT FOR INDUCING NEURONAL DAMAGE. L.Massieu, A. Morales-Villagrán and R. Tapia*. Instituto de Fisiología Celular. UNAM. México D.F. México.

Exposure of neurons to high concentrations of glutamate cause their degeneration and death. The clearance of this amino acid from the synaptic cleft depends on their transport by high affinity uptake mechanisms. We have studied by microdialysis the effect of the administration of two inhibitors of the glutamate transporter, L-trans-pyrrolidine-2,4-dicarboxylate (PDC) and dihydrokainate (DHK), on the extracellular concentration of endogenous amino acids in the rat striatum in vivo. We have correlated the changes in the concentration of glutamate and aspartate with injury to striatal cells, evaluated 5-7 days after drug administration by determination of glutamate decarboxylase (GAD) and choline acetyltransferase (ChAT) activities as well as by histological examination. DHK (50 mM) and PDC (25 mM) produced similar remarkable increases in the extracellular concentration of glutamate (12-fold) and aspartate. However, the former induced also elevations in the concentration of other amino acids. When glutamate transport inhibitors were directly injected in the rat striatum, clear neuronal damage was observed only after DHK (400 nmol/µl) administration, which produced a significant reduction of both ChAT (46%) and GAD (44.5%) activities, relative to the contralateral striatum. This decrease was partially prevented by administration of the NMDA antagonist, MK-801 (1 mg/kg ip. 30 min before), and the non-NMDA antagonist, NBQX (50 nmol/µl) co-injected with DHK). Neither PDC nor two other inhibitors of glutamate uptake, DL-threo-β-hydroxyaspartate and L-aspartate-β-hydroxamate, induced striatal cell damage. The neurotoxic effects of DHK could be explained by direct activation of glutamate postsynaptic receptors rather than by the increased glutamate concentration.

GASTRIC BRANCH VAGAL AFFERENT AND EFFERENT CONTRIBUTIONS TO GASTRIC MACRONUTRIENT EMPTYING. A. Baldessarini, T.H. Moran, C.F. Salorio, P.R. McHugh*, and G.J. Schwartz. Dept. of Psychiatry & Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The gastric branch of the vagus nerve plays a critical role in the control of gastric macronutrient emptying, because gastric branch vagotomy results in significantly accelerated emptying of all liquid macronutrients. This effect of gastric branch vagotomy could reflect the loss of vagal afferent input, vagal efferent output, or both. The gastric emptying of a range of caloric concentrations (0.2 - 0.8 kcal/ml) of 5 ml macronutrient loads was evaluated at 5, 10, 20 and 40 minutes in rats with: 1) selective afferent gastric branch vagotomy, 2) selective efferent gastric branch vagotomy, and 3) in sham controls. In control rats, increasing caloric concentration slowed gastric emptying of carbohydrate (glucose), protein (peptone) and fat (oleic acid) loads. In addition, equicaloric loads of peptone and oleic acid (0.2 kcal/ml) emptied more slowly than glucose, demonstrating some macronutrient-specific control of emptying. Gastric emptying in selective gastric branch de-afferented rats, although accelerated, still revealed both caloric and macronutrient-specific controls. Selective gastric branch de-efferentation, however, resulted in much more significant acceleration of gastric emptying, similar to that seen in total gastric branch vagotomized rats. These results suggest that while gastric branch vagal afferent fibers play some role in the control of nutrient emptying, other non-gastric vagal and spinal afferents, and gastric efferents may be more critical for the control of gastric emptying and food intake. Supported by DK19302.

686.2

SUBDIAPHRAGMATIC VAGAL AFFERENT CONTRIBUTIONS TO THE MICROSTRUCTURE OF LIQUID MEAL INTAKE. G.J. Schwartz*, C.F. Salorio, and T.H. Moran. Dept. of Psychiatry & Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The vagus nerve provides the major neuroanatomical pathway linking gastrointestinal and central nervous system sites involved in food intake control. Surgical transection of this link during total subdiaphragmatic vagotomy has profound effects on meal size and body weight. Because these vagotomies involve transection of both sensory and motor vagal fibers, they do not reveal the specific contributions of afferent and efferent vagal components to feeding. Electrophysiological studies have shown that vagal afferent fibers with gastrointestinal receptive fields are responsive to mechanical and chemical gut stimulation with short latency, suggesting that vagal afferents signals may have the ability to modulate ingestive patterns within a meal. Using automated lick analysis, we evaluated the pattern of licking of milk diet over the first 2.5 hours of the dark cycle in male Sprague Dawley rats with and without selective subdiaphragmatic vagal rootlet deafferentation, before and after surgery. Although both sham and afferent vagotomized rats showed equivalent total numbers of licks, vagotomized rats showed longer bursts of licking, fewer bursts, and faster initial cumulative rates of licking than sham controls. These results demonstrate that removal of vagal afferent input from the gut alters the pattern of food intake in ways that suggest the removal of potential negative feedback signals, and underscore a role for vagal afferent neurophysiological signals in determining the moment-to-moment control of feeding behavior. Supported by DK19302 and the Whitehall Foundation.

BOMBESIN INHIBITION OF SODIUM APPETITE BUT NOT WATER INTAKE IN RATS WITH LESIONS CENTERED ON THE AREA POSTREMA (AP). G.L. Edwards*, T. Wang and J.D. Power. Dept. of Physiol. & Pharmacol., Coll. of Vet. Med., Univ. of Georgia, Athens, GA 30602.

Recent studies indicate that bombesin acts to inhibit sodium appetite caused by depletion of sodium (Soc. Neurosci. Abstr. 19: 1263, 1993; Soc. Neurosci. Abstr. 19: 1822, 1993). Rats with lesions centered on the AP (AP-lesions) are reported to consume increased amounts of saline (Am. J. Physiol. 264: R1242, 1993). Since the AP is a circumventricular organ and lacks a blood-brain barrier it is possible that bombesin acts in the AP to inhibit sodium appetite. When treated with 4 µg/kg bombesin I.P., rats with AP-lesions decreased their 2h "need-free" intake of 2% saline compared to 2% saline intake when injected with sterile physiological saline I.P. ($P < 0.02$). In addition, bombesin (4 µg/kg I.P.) reduced sodium depletion-induced 2% saline intake in both AP-lesioned and unlesioned rats ($P < 0.05$). Conversely, water intake induced by isoproterenol (25 µg/kg) was not reduced by bombesin in either rats with lesions of the AP or intact control rats ($P > 0.05$). These data indicate that bombesin is effective at reducing sodium appetite in rats with AP-lesions. Thus, sites other than the AP are capable of mediating the effects of peripherally administered bombesin on sodium appetite. (Supported by NIH DK 42533)

UNCONDITIONED AND CONDITIONED EXPRESSION OF cFOS TO AMPHETAMINE AND LITHIUM CHLORIDE IN RAT BRAIN DURING TASTE AVERSION LEARNING. M.W. Swank, G.E. Schafe, and J.L. Bernstein*. Department of Psychology, University of Washington, Seattle, WA 98195.

Amphetamine and lithium chloride (LiCl) are both effective unconditioned stimuli (USs) in the formation of learned taste aversions. However, the mechanism of action of these drugs is quite different with the area postrema and related emetic circuitry critical to the response to LiCl but not amphetamine. Induction of Fos-like immunoreactivity (FLI) in rat brain was examined two hours following *ip* injection of either d-amphetamine sulfate (3 mg/kg) or LiCl (6 mEq/kg). Amphetamine strongly induced FLI in striatum while LiCl did not. In most other regions where FLI was detected (e.g. nucleus tractus solitarius (NTS); lateral septum; paraventricular nuclei of the thalamus and hypothalamus) substantially more FLI was noted in animals treated with LiCl than in those treated with amphetamine. In the lateral pontine parabrachial nucleus (PBN), however, amphetamine and LiCl induced comparable, significant elevations of FLI. After a single prior pairing with either LiCl or amphetamine, exposure to a saccharin solution induced significant taste aversions and significant FLI in intermediate NTS relative to unpaired controls. Overall, these results indicate that PBN is a site of common activation by these two very different drugs during acquisition. The response to taste re-exposure points to a population of cells in intermediate NTS which have a common role in taste aversion expression despite different US activation patterns.

Gastric emptying of corn oil emulsions during oral, gastric, or concurrent oral/gastric infusions. J.M. Kaplan*, W. Siemers and H.J. Grill. Dept. Psychology, U. Pennsylvania, 19104.

We showed previously that substantially less corn oil emulsion empties from the stomach when ingested orally than when infused gastrically. In the first experiment, we sought to determine whether the full inhibitory effect can be achieved when only a portion of the total load is orally delivered. Gastric contents were recovered after 6-min single or concurrent infusions across which the intraoral:intragastric infusion ratio [100:0, 0:100, 50:50, 25:75; net infusion rate = 1.0 ml/min] was varied. Half as much oil emptied during exclusively oral infusions as during exclusively gastric infusions. The concurrent infusions were equally effective at slowing oil emptying as the exclusively oral infusion. Preliminary results of a second experiment indicate that oil emptying is equally rapid following gastric infusions (@ 1.0 ml/min) of either 50% corn oil or pre-ingested 50% corn oil (recovered from donor rats). These two experiments show that oral inhibition of oil emptying does not depend on the amount ingested, the number of swallowing actions, or on enzymatic alteration of the corn oil. Supported by DK-42284 and DK-21397.

DISTRIBUTION OF FOS-LIKE IMMUNOREACTIVITY IN RAT BRAIN FOLLOWING ISOPROTERENOL TREATMENT AND THE EFFECTS OF CONVERTING ENZYME INHIBITION OR ANGIOTENSIN II BLOCKADE. M.J. McKinley, B.J. Oldfield*, Howard Florey Institute of Experimental Physiology and Medicine, Univ. of Melbourne, Parkville, 3052, Vic., Australia.

Subcutaneous (s.c.) administration of the β -adrenergic agonist isoproterenol causes copious water drinking in rats which is blocked by angiotensin inhibition. The aim of the present experiment was to map the distribution of neurons in the brain of the rat which increased Fos production in response to isoproterenol and to test the effect of the angiotensin II antagonist losartan or the converting enzyme inhibitor captopril (at 2 different doses) on this response. Rats were injected with isoproterenol (Winthrop, 50 µg/kg s.c.) and killed 2h later. Immunohistochemistry was used to detect Fos-like immunoreactivity (Fos-LI) in paraformaldehyde-fixed sections of brain. Fos-LI was increased in neurons in the lamina terminalis, in particular those in the subfornical organ (SFO), median preoptic nucleus (MnPO), and organum vasculosum of the lamina terminalis (OVLT). It increased also in the hypothalamic supraoptic and paraventricular nuclei, bed nucleus of the stria terminalis, central nucleus of the amygdala, locus ceruleus, parabrachial nucleus, nucleus tractus solitarius, ventrolateral medulla and area postrema, but not in control rats injected with s.c. isotonic saline. Losartan (Dupont-Merck, 100mg/kg, intraperitoneal) or captopril (Bristol-Myers Squibb, 50mg/kg s.c.) which block isoproterenol induced drinking, also blocked Fos-production in the lamina terminalis, but not in the other regions, whereas a lower dose of captopril (0.5mg/kg s.c.) which potentiates isoproterenol-induced drinking, potentiated the increase in Fos-LI in the lamina terminalis. Thus, isoproterenol results in the activation of neurons in the SFO, OVLT and MnPO secondary to the action of Ang II. Activation of these neurons in the lamina terminalis appears to be crucial for the induction of thirst.

686.6

IS THE NMDA RECEPTOR INVOLVED IN THE RESPONSES TO AMINO ACID IMBALANCED DIETS? D.W. Gietzen*, B.G. Truong AND B. Dang. Dept. VM: Anat., Physiol., Cell Biol. and Food Intake Lab., Univ. California-Davis, Davis CA 95616.

The anorectic responses to imbalanced amino acid diets (IMB) have been associated with neural activity in the prepiriform cortex (PPC), an area essential for the initial depressed feeding response to IMB. Because the principal neurons of the PPC contain glutamate, we measured the intake of IMB after acute injection of the NMDA receptor antagonist, D(-)-2-Amino-5-phosphonopentanoic acid (AP5), into the PPC. After stereotaxic placement of bilateral guide cannulae aimed at the PPC and prefeeding a low-protein basal diet (BAS) for 10 days, rats were given 0.5 µl of either AP5 (4 nM in artificial CSF, N=11) or vehicle (aCSF, N=8) just before feeding IMB at the onset of darkness. BAS intake on the day prior to injections was taken as control for each rat. Coordinates for the PPC were: A 11.4, L 3.7, D 6.5 (Paxinos and Watson, 1982). Intake of IMB was increased to 88% of control in the AP5 group ($p = 0.024$ vs aCSF group, that ate 55% of control) at 6-9 hr after introduction of IMB, a crucial time period in the feeding responses. Intake values for 6-9 hr were: AP5 group = 3.59 ± 0.41 g, aCSF group = 2.29 ± 0.38 g, $p = 0.038$. Although feeding at other time points was not affected, the 6-9 hr increase was sufficient to increase intake of IMB nearly to a significant level at 24 hr ($p = 0.058$). We conclude that the NMDA receptor in the PPC may have a role in mediating the anorectic responses to IMB diets. Supported by USDA CSRS 90-37200-5440, NIH DK35747 & DK42274.

FEEDING RELATED ELEVATION IN PLASMA CORTICOSTERONE LEVELS IN INTACT AND CHRONIC DECEREBRATE RATS. R.J. Seeley,***, R.R. Sakai, J.C.K. Donahue, B.S. McEwen, and H.J. Grill* Depts of Animal Biology and Psychology University of Pennsylvania, **Neuroendocrinology Lab, Rockefeller University, ***Dept of Psychology, University of Washington, Seattle WA, 98195.

The neural basis for the feeding-related increase in corticosterone (CORT) was explored using the chronic decerebrate (CD) rat in which the caudal portion of the brainstem is neurally isolated from the forebrain by a complete transection of the neuraxis. Tail blood samples were taken before and after a gastric intubation of either 8 ml milk-diet or water following overnight deprivation. Pre-intubation baseline CORT levels were comparable in CD and intact controls. In intact rats, CORT levels increased significantly after the water intubation (110% above baseline). By contrast, no water response was observed in the CD rat. Both groups, however, showed a dramatic elevation in CORT following the nutritive load (intacts: 250% above baseline; CD: 440% above baseline). Additionally, tail blood samples were taken 1 hr after each of 5 intubations of milk diet spread evenly throughout the 12 hr light cycle. CD rats showed CORT levels that were slightly elevated from those of the intact controls, but the rise and fall of CORT levels through the light cycle in CD rats exactly paralleled those of the intact controls. The CD rat's normal-like CORT profile may reflect the competence of the HPA axis in the transected brain to mediate neuroendocrine responses. If so, the current results indicate that the function of the HPA axis can be modulated by humoral signals associated with food deprivation and caloric loads. Alternatively, the CD rat's CORT profile may have been mediated by the autonomic nervous system without a significant forebrain contribution.

STIMULATION OF FEEDING BEHAVIOR IN THE RAT BY INTRA-HYPOTHALAMIC INJECTION OF 8-BR-cAMP. E.R. Gillard*, A.M. Khan, A.U. Haq, R.S. Grewal, and B.G. Stanley. Departments of Neuroscience & Psychology, University of California, Riverside, CA 92521, USA.

Although several neurotransmitters acting in and around the lateral hypothalamus (LH) have been implicated in the control of eating, it is unknown which, if any, second messengers mediate their effects. To begin to address this, food intake was measured 1, 2, and 4 hrs after injection of 8-bromoadenosine 3',5'-cyclic monophosphate (8-BR-cAMP, a membrane-permeant cAMP analogue) into the perifornical hypothalamus (PFH) of freely feeding adult male Sprague Dawley rats. Each dose of 8-br-cAMP (0, 1, 10, 50 and 100 nmol, dissolved in artificial cerebrospinal fluid vehicle) was administered in a final injection volume of 0.3 μ l. Dose-dependent stimulation of eating was observed, with doses of 50 nmol and 100 nmol eliciting average 2 hr intakes of 5.9 and 15.7 g, respectively. To determine the locus of this effect, we compared the effects of 8-br-cAMP injected into the PFH and six other areas bracketing the PFH (LH, anterior and posterior LH, paraventricular nucleus of the hypothalamus, amygdala, and thalamus). Consistent eating-stimulatory effects were observed in the LH and PFH at doses \geq 50 nmol (2 hr intakes \geq 3.4 g). Thalamic injections resulted in a more variable feeding response which achieved significance only at 100 nmol. In contrast, injections into all other sites failed to stimulate eating. These results suggest anatomical specificity of 8-br-cAMP's effects, with likely sites of action being the LH/PFH and/or thalamus. It is possible that neurotransmitters known to influence eating in the hypothalamus may do so via the cAMP second-messenger system.

THE RELATIONSHIP OF AMOUNT OF SOUP IN THE STOMACH TO THE CONTROL OF TEST MEAL INTAKE IN MEN AND WOMEN. H. R. Kissileff*, T. Wentzlaff, R. N. Pierson, and F. X. Pi-Sunyer. New York Obesity Research Center, St. Luke's-Roosevelt Hospital and Columbia Univ., 1111 Amsterdam Ave. New York, NY 10025.

If a critical level of gastric tension, induced by volume, triggers the cessation of eating, graded volumes of preloads should lead to proportional reductions in intake of a subsequent test meal, thereby preserving constancy of total (preload + meal) volume, as preload size increases. This hypothesis holds only if meals and preloads empty at the same rates. To test this hypothesis, five women and six men in good health, nonobese and without medical problems, ate a yogurt shake test meal 30 min after tomato soup preloads. Emptying of the preload from the stomach was measured by radionuclide scintigraphy (see table for the volume of soup remaining at the start of the test meal.) The preloads and test meals were given with at least two days between. Preload sizes ranged from 160 to 800 ml in 160 ml steps. A no preload condition was included.

Test meal intake was reduced as a function of preload size in a linear fashion only between 320 g and 640 g in women and only at the 160 g compared to 0 and 800 g compared to 640 g preloads volume in men (see Table below for details).

Preload (g) ----	0	160	320	480	640	800	LS
WOMEN intake (g)	896	809	771	627	482	431	137
preload in stomach (g)	0	59	89	245	235	445	83
MEN intake (g)	1032	837	825	822	792	482	192
preload in stomach (g)	0	23	65	194	265	285	110

Unless the preloads of soup differentially affect test meal emptying, gastric tension, induced by volume, by itself, is not a critical signal for normal meal termination in humans. (Support: NIH - DK36507 & DK26687)

EATING SUPPRESSION AND BODY WEIGHT LOSS BY LATERAL HYPOTHALAMIC (LH) NMDA RECEPTOR BLOCKADE WITH D-AP5. B.G. Stanley*, V.L. Willett III, H.W. Donias and M.G. Dee II. Departments of Neuroscience & Psychology, University of California, Riverside, CA 92521.

We have recently shown that intense eating is elicited by LH injections of glutamate, N-methyl-D-aspartic acid (NMDA), or non-NMDA receptor agonists (Brain Res. 1993, 613, 88-95 & 630, 41-49). To examine whether LH glutamate and NMDA receptors might mediate natural eating, LH injection of the competitive NMDA receptor antagonist D-AP5 (10 nmol/0.3 μ l of artificial CSF) was tested for anorectic effects in adult male Sprague-Dawley rats. First, we examined whether pretreatment with LH injection of D-AP5 would suppress eating elicited by LH NMDA (10 nmol) and found a dose-dependent effect, with 10 nmol of D-AP5 suppressing the 9.8 gm NMDA-elicited eating response by 71%. In separate groups, the effects of bilateral LH injection of this dose of D-AP5 were tested on eating elicited by 24 hrs of food deprivation or by the onset of the nocturnal eating period. With food deprivation, the 11.9 gm eating response 30 min after vehicle injection was reduced 61% by D-AP5. For nocturnal eating, the 4.1 gm response 30 min after vehicle was reduced 34% by D-AP5. Some other behavioral effects were also noted. Finally, to determine the effects of long-term treatment, D-AP5 was bilaterally injected into the LH at the onset and midpoint of the dark-phase for 8 consecutive days. Compared to vehicle injection, D-AP5 produced marked and prolonged reductions of daily food intake and loss of body weight. Food intake normalized when the injections were stopped. These findings suggest that endogenous LH glutamate may act in part via NMDA receptors to influence eating behavior and body weight.

HYPOTHALAMIC GALANIN IN RELATION TO CIRCULATING INSULIN AND FAT INGESTION. S.F. Leibowitz*, J.I. Koenig and A. Akabayashi. The Rockefeller University, N.Y., N. Y. 10021 and The Immunobiology Research Institute, Annandale, N.J. 08801

Galanin (GAL) is densely concentrated in neurons of the hypothalamic paraventricular nucleus (PVN). When injected into the hypothalamus, GAL reduces insulin secretion and stimulates feeding behavior, causing a preferential increase in fat ingestion. The present studies in albino rats reveal an inverse relationship between endogenous GAL peptide (measured via RIA), specifically in the PVN, and circulating levels of insulin, while GAL and fat ingestion are positively related. Three experiments were conducted: 1) With measurements taken at several intervals across the light/dark cycle (8 time points, n=7/time), GAL levels in the PVN, as opposed to other hypothalamic nuclei, increased significantly during the middle phase of the feeding cycle, while insulin levels were declining and natural fat ingestion increased. PVN GAL and circulating insulin levels were inversely correlated ($r = -0.32$, $p < 0.05$) across the feeding cycle. 2) In rats (n=28) on macronutrient diets, GAL levels in the PVN, but not other hypothalamic areas, were inversely correlated with circulating insulin levels ($r = -0.41$, $p < 0.05$) but positively related to daily fat intake ($r = +0.64$, $p < 0.01$). 3) In rats (n=11) given 5 daily injections of GAL antisense oligonucleotides into the PVN, GAL levels and daily fat intake decreased by 35% ($p < 0.05$ compared to sense controls), while circulating insulin levels tended to rise (+46%, $p < 0.10$). This inverse relation between endogenous GAL and insulin under natural feeding conditions is consistent with another report at this meeting (Tang et al.) showing insulin in diabetic rats to reduce GAL gene expression and peptide levels, specifically in the area of the PVN.

686.12

METABOLIC REGULATION OF FOOD INTAKE IN THE WHITE-CROWNED SPARROW. R. D. Richardson, T. Boswell, R. J. Seeley, M. Ramenofsky, J. C. Wingfield, and S. C. Woods*. Depts of Psychology and Zoology, University of Washington, Seattle, WA. 98195.

Migratory birds rely on increased fat storage and fatty acid utilization to meet seasonal changes of energy expenditure and as a result increase food intake and fat stores before migration. To determine if their feeding behavior is sensitive to carbohydrate utilization, white-crowned sparrows (*Zonotrichia leucophrys gambelii*) maintained on short daylength (9L15D) were injected IP with 2-deoxy-D-glucose (2-DG), 2,5-anhydro-D-mannitol (2,5-AM), or insulin, drugs that elicit feeding in mammals. Low doses of 2-DG (25 or 50 mg/kg) had no effect on food intake and higher doses (100 or 300 mg/kg) significantly suppressed feeding after 1 and 2 hours. No dose of 2-DG increased meal size. Analogously, low doses of 2,5-AM (25, 50 or 100 mg/kg) had no effect on food intake, and higher doses (300 and 600 mg/kg) significantly suppressed intake. Low doses of insulin (0.5 or 1.0 U/kg) also had no effect on food intake and higher doses (2.0 or 4.0 U/kg) significantly suppressed feeding and induced hypoglycemia after 1 and 2 hours. These data suggest that decreased carbohydrate metabolism does not elicit feeding in this species. Importantly, all of these drugs may increase plasma fatty acids in birds. The fatty acid tributyrin (100, 300, 600 or 2000 mg/kg IP) significantly suppressed 60-min and 120-min intake dose-dependently in these birds, and equicaloric glucose (1200 mg/kg) had no effect. We conclude that white-crowned sparrows are unresponsive to manipulations of carbohydrate metabolism, but are responsive to increases of plasma lipids.

CNTF ENHANCES SPROUTING IN PARTIALLY DENERVATED MUSCLE. S.G. Siegel*, A.W. English, Dept. of Anatomy & Cell Biology, Emory University, Atlanta, GA 30322.

Following partial denervation of skeletal muscles, the remaining intact motoneurons develop sprouts which innervate a limited portion of the denervated fibers. In adult rats, each neuromuscular compartment of the lateral gastrocnemius (LG) muscle receives innervation from precisely one branch of the muscle nerve. After partial denervation by transection of the branch to the medial compartment (LGm) of the LG muscle, newly formed sprouts do not cross the compartmental border. To investigate whether exogenous ciliary neurotrophic factor (CNTF) can augment the natural sprouting response, rat LGm fibers were denervated. CNTF was administered by intramuscular injection (2-20 µg/kg) into the LG muscle once daily for 7 days. Animals were sacrificed one day after the last injection, and the tissue was analyzed for sprouts. The motor end plates and nerve terminals were visualized immunohistochemically by the presence of clustered fluorescent alpha-bungarotoxin and FITC-conjugated antibody to the 200kd neurofilament protein, respectively. Sprouts from intact motoneurons were identified as thin offshoots from the nerve terminals or preterminal axon. CNTF administration resulted in an increase in the proportion of end plates with sprouts, suggesting that the natural sprouting response to partial denervation can be enhanced. However, sprouting from motoneurons in the intact compartment did not lead to reinnervation of fibers in the denervated compartment.

CNTF was provided by Regeneron Pharmaceutical, Inc.

EFFECT OF SCIATIC NERVE SECTION ON SPROUTING BY SPARED ROOTS IN DORSAL HORN OF ADULT RATS. B. Zhang*, I. Fischer and M. Murray, Dept. Anatomy and Neurobiology, Medical College of Pennsylvania, Phila., PA 19129.

Lumbosacral dorsal rhizotomy, sparing one root, induces sprouting by that root in adults (Polistina, et al., '90). Sciatic nerve section enhances regeneration of the central process of crushed dorsal root in adults (Richardson, et al., '87). Sciatic nerve lesions are also accompanied by decreased synthesis of CGRP and SP by DRG neurons and depletion of these peptides from the dorsal horn (Nothias et al., '93; Himes and Tessler, '89). In neonates sciatic lesion induces sprouting by central processes into the dorsal horn unaccompanied by depletion of peptides (Reynolds and Fitzgerald, '92). We combined unilateral sciatic nerve section with bilateral spared root preparation to determine whether the peripheral lesion would enhance sprouting by the spared root in adult rats. The immunocytochemical staining was compared on the two sides using antibodies against neuromodulators and cytoskeletal proteins. CGRP and SP levels increased on the sciatic nerve lesioned side at 3 days and the CGRP projection was expanded, SP returned to normal (or less) at 10 days and CGRP returned to normal (or less) at 20 days, indicating a transient effect of sciatic lesion in this paradigm. The sprouting of central projections however blocks or delays the downregulation of peptide synthesis normally evoked by peripheral nerve lesion. Immunocytochemical staining of cytoskeletal proteins high molecular weight (HMW) tau, MAP 1B and phosphorylated MAP 1B showed no significant differences, suggesting that central sprouting in this paradigm is not associated with axonal elongation.

PROGRESSIVE ENTORHINAL LESIONS ACCELERATE HIPPOCAMPAL SPROUTING IN RATS. T.S. Carrigan, M.L. McQuilkin, and J.J. Ramirez*, Neuroscience Program and Department of Psychology, Davidson College, Davidson, NC 28036.

Entorhinal cortex (EC) lesions are known to induce sprouting by the crossed temporodentate pathway (CTD) in rats. Previous evidence from our laboratory indicates that two-stage (progressive) lesions of the entorhinal area accelerate recovery from spatial alternation deficits associated with unilateral EC lesions and increase the synaptic efficacy of the CTD by 250% in as little as 6 days postlesion.

The purpose of this study was to determine anatomically whether progressive lesions accelerate CTD sprouting. Animals were assigned to one of four groups: progressive lesion, control, priming lesion, or one-stage lesion. The postlesion proliferation of the CTD was analyzed using quantitative autoradiography. ³H-proline was injected into the intact EC at the time of the one-stage or secondary lesion of the contralateral homologue. Six days later the rats were killed and the brains were prepared for autoradiographic analysis. The CTD sprouting response was quantified by creating a ratio of the silver grain density evident in the outer molecular layer of the dentate gyrus contralateral and ipsilateral to the ³H-proline injection (C/I ratio). Neither the priming lesion nor the one-stage lesion resulted in a significant sprouting response at 6 days postlesion. Progressive lesions increased the C/I ratio by approximately 300% in both the dorsal and ventral leaves of the dentate gyrus. The lesion sizes of the one-stage and progressive treatment conditions were similar.

We conclude that progressive entorhinal lesions enhance the rate of sprouting by the crossed temporodentate pathway. Taken together, the anatomical, electrophysiological, and behavioral results indicate that CTD sprouting is functionally significant and behaviorally meaningful.

ANTEROGRADE INFLUENCES ON COLLATERAL NEURONAL SPROUTING IN THE SYMPATHETIC NERVOUS SYSTEM.

G. A. Kuchel*, C. Richard and M.C. Bastien, Montreal General Hospital Res. Inst., 1650 Cedar, Montreal, Quebec, Canada H3G 1A4

In contrast to retrograde signals for collateral sprouting (ie. target-derived NGF), anterograde influences on this form of plasticity are less well delineated. Using a NE-uptake assay, Dornay et al. (*J.Nsc.* 5:1522) concluded that an intact preganglionic innervation was essential for the development of collateral sprouting in the rat pineal gland after a unilateral denervation. This target receives bilateral innervation from the two superior cervical ganglia (SCG). We have quantified fluorescent immunohistochemistry for tyrosine hydroxylase (TH) as an index of collateral sprouting (*Exp.Neurol.* 124:381).

As shown earlier, 1 day after a unilateral denervation (R-ICN cut) the rat pineal gland exhibited a 50% decrease in the area fraction representing TH immunoreactive profiles (TH-IR). Collateral sprouting then took place with an increase to 78% and 76% of control values at 3 and 10 days, respectively. When this lesion was immediately preceded by a decentralization of the "intact" SCG (L-CSTx), TH-IR was 71% and 72% of control values at 3 and 10 days, suggesting that much of the collateral sprouting response was still intact. Further studies will be required to evaluate the possibility that degenerating preganglionic neurons "releasing" neurotransmitters during critical periods of signaling supplant usual anterograde signals for lesion-induced postganglionic collateral sprouting.

687.4

SPROUTING OF INTACT AFFERENTS INTO THE DENERVATED CUNEATE NUCLEUS OF ADULT RATS AFTER DORSAL RHIZOTOMY. P.E. Garraghty^{1,2*}, D.R. Sengelaub^{1,2}, A.C. Mills³, and N. Muja¹. ¹Dept. Psych. and ²Prog. Neural Sci., Indiana Univ., Bloomington, IN 47405; ³Dept. Biol., Middle Tenn. St. Univ., Murfreesboro, TN 37132.

In 1991, Pons et al. (*Science*, 252, 1857) reported a remarkably extensive topographic reorganization in SI (area 3b) of macaque monkeys that had undergone dorsal rhizotomies extending from the second cervical (C2) to the fifth thoracic (T5) level some years earlier. Here, we evaluate the hypothesis that this reorganization was due to the formation of new connections between intact afferents and neurons that had been denervated by the rhizotomies. Thus, we have performed comparably extensive, dorsal rhizotomies in adult rats followed by anatomical tracing and electrophysiological mapping experiments. Using peripheral skin injections of a conjugate of cholera toxin subunit B and horseradish peroxidase, we have observed aberrant expansions of gracile projections into the cuneate nucleus within 3 months of the deafferentation. Moreover, this new growth apparently forms functional connections because cortical recordings in forelimb regions of SI in these same animals reveal neurons that are responsive to stimulation of hindlimb skin surfaces innervated by afferents that normally project to the gracile nucleus. These results suggest that substantial new growth is possible in the mature central nervous system, and that such new growth may well account for the substantial functional recovery detected in earlier experiments in the so-called "Silver Springs monkeys." (Supported by SO7 RR07031)

THE ENTORHINAL CORTEX REDUCES GRANULE CELL COLLATERAL SPROUTING IN ORGANOTYPIC SLICE CULTURES OF MOUSE HIPPOCAMPUS. B.W. Colman*¹, F.E. Dudek², and C.F. Ide¹.

¹Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118 and ²Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523

Organotypic slice cultures of murine hippocampal tissue provide an *in vitro* model system for the controlled study of mossy fiber collateral sprouting into the dentate molecular layer (DML). We hypothesized that the presence of afferent innervation would decrease the degree of mossy fiber collateral sprouting in the DML. Alternate slices derived from the mid-hippocampal region were cultured either with or without attached entorhinal cortical tissues. Bodian silver staining confirmed the presence of fiber tracts between the dentate gyrus and entorhinal cortical tissues. Timm's heavy metal staining and densitometry were utilized to assay the degree of mossy fiber sprouting. Attached entorhinal cortex significantly reduced the degree of mossy fiber sprouting in the DML after ten days *in vitro* ($p < 0.001$; $n = 30$ pairs). To confirm that damage to mossy fiber axons was not responsible for mossy fiber sprouting in the DML, alternate pairs of hippocampal slices were subjected to either complete transection of their mossy fiber projection (at the point where the fibers leave the hilus) or left undisturbed. Slices receiving mossy fiber lesions displayed no significant increase or decrease in mossy fiber sprouting into the DML as compared to adjoining control slices receiving no mossy fiber lesions ($n = 10$ pairs). Therefore, mossy fiber collateral sprouting into the dentate molecular layer is not a consequence of damage to mossy fibers, but rather, may be regulated by the presence of afferents from the entorhinal cortex *in vitro*. Supported by DOD grant #2-89/116/88-150.

687.7

DELAYED DEGENERATION DIFFERENTIALLY AFFECTS THE TIME COURSE OF SPROUTING BY AFFERENT SYSTEMS REMAINING IN THE MOLECULAR LAYER OF THE DENTATE GYRUS FOLLOWING LESIONS OF THE PERFORANT PATH. B. Shi* and B. B. Stanfield. Lab. of Neurophysiology, NIMH, NIH Animal Center, Poolesville, MD 20837.

Axons in peripheral nerves and in certain central pathways have been shown to undergo very slow Wallerian degeneration in WLD mutant mice. It has recently been shown that in WLD mutant mice there is a delay in the intensification of acetylcholinesterase histochemical staining in the molecular layer of the dentate gyrus following lesions of the entorhinal cortex. The intensification of the acetylcholinesterase staining is indicative of sprouting of septohippocampal fibers in the dentate molecular layer. Thus, it appears that delayed post-lesion reactive sprouting is associated with the delayed degeneration of cut central axons in this mutant. We have studied the time course of changes in the septohippocampal and the hippocampal commissural projections following interruption of the perforant path in WLD and normal (C57BL/6J) mice by injecting wheat germ agglutinin conjugated horseradish peroxidase into the septum or contralateral hippocampus and processing the tissue sections for TMB histochemistry. In normal mice changes in the distribution of labeled septal and commissural axons indicative of sprouting in the dentate molecular layer are seen as early as three days post-lesion. The earliest similar changes are found in WLD mutant mice is seven days post-lesion, when an increase in the density of labeled septal axons begins in the outer molecular layer. The delay in the sprouting of commissural axons in the mutant is even longer. Changes in the distribution of labeled commissural axons in the dentate gyrus of WLD mice are first seen twelve days post-lesion. These results confirm that post-lesion reactive axonal sprouting can be delayed in the CNS of WLD mutant mice. In addition, our results indicate that the extent of this delay may differ among axonal fiber systems. These findings are consistent with the notion that various CNS axonal systems may respond differentially to sprouting cues and are reminiscent of differences found in the regenerating response exhibited by sensory and motor axons in the WLD mutant after peripheral nerve cuts.

687.9

DEVELOPMENTALLY REGULATED LOCALIZATION OF A PURKINJE CELL-SPECIFIC TRANSCRIPT IN DENDRITES. F. Bian^{1,3}, K. Schilling⁴, G. Cole^{2,3}, and J. Oberdick^{2,3}. ¹Ohio State Biochemistry Program, ²Department of Cell Biology, Neurobiology and Anatomy, and ³The Biotechnology Center, The Ohio State University, Columbus, OH 43210. ⁴Abteilung Anatomie und Zellbiologie der Universität, 89069 Ulm, Germany.

Several mRNAs thought to be important for neuronal growth and plasticity have been found to be localized in dendrites. Cerebellar Purkinje cells (PCs) are ideal for studying the role such transcripts play due to both the size and monopolar orientation of their dendrites. *In situ* hybridization has been performed for three PC-specific transcripts known to encode proteins highly concentrated in PC dendrites. Of the mRNAs coding for these three markers, L7, PEP-19 and CaBP28K, only that for L7 is abundantly detectable in PC dendrites. In addition, it appears that the amount of L7 mRNA in dendrites is much greater during the early postnatal period than in adulthood, suggesting that direct translation of the L7 protein in dendrites may be particularly important during dendritic outgrowth. This is consistent with several observations made of Purkinje cells in primary dissociated cultures of embryonic cerebellum. Under conditions of high K⁺, PC dendrites consistently take on a more elongated morphology relative to their stunted appearance in normal medium. Under the same high K⁺ conditions, expression of both the L7 protein and β -galactosidase driven from an L7-*lacZ* fusion gene, are qualitatively higher based on histological assay. In particular, in immature cultures, PC dendritic processes are L7 positive only in the high K⁺ condition. Thus, the L7 protein may be important for the growth and continuing plasticity of PC dendrites.

ROLE OF THE HYALURONAN RECEPTOR RHAMM IN NEURITE EXTENSION AND MOTILITY IN PRIMARY NEURONS AND NEURONAL AND GLIAL CELL LINES. U. N. Frankenstein*, J. Hacking, M. Z. Hossain, E. A. Turley and J. I. Nagy. Department of Physiology and Manitoba Institute of Cell Biology, University of Manitoba, 770 Bannatyne Avenue, Winnipeg, Manitoba CANADA R3E 0W3.

RHAMM (Receptor for Hyaluronan Mediated Motility) has been identified as a receptor for the extracellular matrix component hyaluronan (HA) and was recently shown to be essential for the locomotion of normal and transformed peripheral cells. In view of similarities in molecular processes that govern cell locomotion and growth cone migration, we investigated whether RHAMM also contributes to cell migration of CNS-derived cells *in vitro*. Immunohistochemical studies of cultured primary neurons, astrocytes and microglia as well as of several neuronal and astrocytic cell lines revealed a punctate form of RHAMM labelling in cell bodies, along processes and at growth cones. By Western blot analyses, neuronal cell lines such as PC12, NG108-15 and NSC-34 cells were found to express major RHAMM forms with apparent MW of 75 and 116 kDa, while glial cells contained 50 and 72 kDa forms with HA binding capacity. Treatment of NG108-15 cells with dibutyryl-cAMP led to enhanced expression of RHAMM with a clear increase in RHAMM immunolabelling in these cells. Monoclonal and polyclonal anti-RHAMM antibodies as well as peptides corresponding to the HA binding domains of RHAMM significantly inhibited neurite migration, glial cell process elongation and motility. An antibody directed against a repeat sequence present in RHAMM significantly stimulated neurite migration of NSC-34 cells and rat primary neurons. Collectively these results demonstrate the presence of RHAMM in neural cells and suggest a critical role for HA/RHAMM interactions in the mediation of neurite migration and glial cell locomotion.

AXONAL GROWTH AND TERMINAL SPECIALIZATION OF MOSSY FIBERS IN DEVELOPING RAT PUPS: AN NCAM-H AND NEO-TIMM'S STUDY. J.P. Leite*, T.L. Babb, G.W. Mathem, J.K. Pretorius and T. Seki. UCLA School of Medicine, Los Angeles, CA 90024-1769.

The postnatal axogenesis and synaptogenesis of mossy fibers (MF) were studied in normal Sprague Dawley rats between 2 and 120 days of age. Axonal growth was demonstrated by the transient expression of the embryonic form of neural cell adhesion molecule (NCAM-H). NCAM-H was broadly expressed throughout the hippocampal formation at postnatal (PN) day 2. Overall staining was decreased at PN 7, with preferential labelling of the MF pathway. Maximum expression was observed at PN 16, and a decrease of staining was observed at PN 30 and 120.

The Neo-Timm method was used to identify the progressive incorporation of the histochemically active zinc in maturing MF synapses. At PN 2 there was almost no zinc in granule cells or MFs; however, a very slight staining was observed in the highly cellular area of the hilus. At PN 7 some fibers and puncta were observed in the subgranular zone and in stratum lucidum and CA3 pyramidal. By PN 16, the distribution of MF puncta was qualitatively similar to adult hippocampus (PN 120) although Timm staining was less intense and puncta appeared smaller. Maximum accretion of MF terminals in the CA3 stratum lucidum occurred between PN 14 and PN 24. This study demonstrates that during development NCAM-H expression precedes the period of maximum incorporation of MF terminals. Increasing amounts of zinc in MF boutons might regulate the final maturation of MF synapses. Supported by NS 02808, KO8-NS 01603, NIH-FIC and CNPq (Brazil).

RHAMM-LIKE IMMUNOREACTIVITY IN RAT BRAIN AND RHAMM-DEPENDENT INHIBITION OF TYROSINE HYDROXYLASE-POSITIVE FIBER OUTGROWTH FROM INTRAOCULAR BRAINSTEM TRANSPLANTS. A-Ch Granholm¹, M.L. Price, W.A. Staines², E.A. Turley³, and J.I. Nagy⁴. Dept. Basic Science, Univ. Colorado HSC, Denver, Colorado, ²Dept. Anatomy, Univ. Ottawa, Ontario, ³Dept. Physiology, Univ. Manitoba, Winnipeg, Manitoba, Canada. Studies *in vitro* have suggested that RHAMM (Receptor for Hyaluronan Acid Mediated Motility) plays a role in neurite extension and motility. Anti-RHAMM antibodies (A-R) were found to label axons with a distribution similar to the efferents of the locus coeruleus (LC). We investigated if RHAMM plays a role in the outgrowth of LC fibers from fetal brainstem grafts. Adult rats received intraocular transplants of fetal brainstem tissue containing LC. The fetal tissue was treated with A-R, control antiserum, RHAMM mimicry peptide (RMP) corresponding to one of the hyaluronan binding domains, or control peptide with a scrambled amino acid sequence - at grafting and weekly for 5 weeks postgrafting. Transplants treated with A-R or RMP grew significantly less than the controls, and contained fewer tyrosine hydroxylase-immunoreactive neurons. The graft innervation of the host iris was also significantly reduced in both the A-R and RMP treated groups. Nerve fibers showing strong staining with A-R in the adult brain were also immunoreactive for dopamine beta hydroxylase (DBH). Three weeks following treatment with moderate doses of DSP-4 there was depletion of these double stained fibers but other populations of single-labelled, central DBH-positive fibers remained. Collateral sprouts induced in DBH-positive fibers following DSP-4 treatment were intensely labelled with anti-RHAMM antibodies. Confirmation that the immunoreactivity seen represents a true isotype of RHAMM is under investigation. The results suggest the participation of RHAMM in nerve fiber growth *in vivo*. The Time Course of Axon Elimination in the Splenium of the Rat Corpus Callosum. J.H.Y. Kim* & J.M. Juraska. Neuroscience Program, Univ. of Illinois, Champaign, IL 61820

We have previously reported preliminary data indicating that axon number changes in the rat corpus callosum after 15 days of age (Kim & Juraska, 1990). In adult rats, we found significant dorso-ventral and rostro-caudal variations in axonal density within the splenium, which could potentially influence axon number calculations if the splenium is not sampled extensively. Therefore, we re-examined axon number in the rat splenium at 15, 25 and 60 days of age. The posterior fifth of the corpus callosum, which contains the axons from the visual cortex at all of these ages (Kim et al., 1992), was extensively sampled with electron microscopy. Axon density was multiplied by the area of the posterior fifth from adjacent 1 μ sections to determine axon number.

There was a significant decrease in axon number between day 15 and 25, and also between day 25 and 60. Thus, axon withdrawal in the rat splenium continues after the adult-like distribution of callosal projections within the visual cortex is established (Olavarria & Van Sluysers 1985). Preliminary results indicate that there is a sex difference in the timing of axon withdrawal in the rat splenium which will be further investigated. Supported by NSF IBN 9310945.

THE POSTNATAL DEVELOPMENT OF THE ABERRANT LONGITUDINAL BUNDLE AND THE CORPUS CALLOSUM IN BALB/cWah1 MICE. S.L. Schmidt, D. Wahlsten* and N. Parra. Department of Psychology, University of Alberta, T6G 2E9, Canada.

The BALB/cWah1 mouse strain has approximately 50% callosal defective animals. In the brains of these acallosal mice, an aberrant longitudinal bundle (LB) is consistently found. This study was designed to investigate the distribution of cells and terminals of the LB and the corpus callosum (CC) during postnatal development. At ages ranging from 1-20 postnatal days (PND), 36 BALB/cWah1 mice were anesthetized and intracardially perfused with phosphate-buffered saline followed by 4% paraformaldehyde (PFA). Carbocyanine dyes, Dil or DiA, were inserted into the CC of normal animals or the LB of callosal defective mice. The brains were stored in 4% PFA, in darkness, for 3-9 months. After the appropriate time, each brain was embedded in gelatin and sectioned. The sections were stained with bis-benzamide and examined in an epifluorescence microscope. Analysis was focused on the parietal cortex. The distribution of cells and terminals of normal and callosal defective animals (totally or partially absent CC) did not differ. At PND 5 and PND 10 axons were seen traveling through the neocortex and terminating in layer I. At PND 10 the granular layer was clearly identified and it was found devoid of callosal or LB projections. From 15-20 PND the gaps in layer IV were confirmed and the callosal and LB cells were mainly found in layers III and V. From 10-20 PND the pattern of callosal and LB projections corresponded to those portions of the parietal cortex which did not contain dense aggregates of granule cells. It was concluded that the distribution of cells and terminals of the LB resembled a normal ipsilateral CC. This indicates that the appropriate targets are being located by the LB axons.

CALLOSAL AGENESIS IS SECONDARY TO DEFECTS IN HIPPOCAMPAL COMMISSURE FORMATION IN MOUSE EMBRYOS. D.J. Livy*. Dept. of Zoology, Univ. of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

Pioneer axons of the corpus callosum (CC) use the hippocampal commissure (HC) as a guiding substrate to cross the telencephalic midplane in normal mice. In mice with callosal agenesis, CC axons arrive at their proper location on time to cross midplane, but HC development is delayed, preventing its use by the CC axons as a guiding substrate. The routing and timing of hippocampal axon growth through the HC was studied in Balb/cWah1 (Wah1-50% CC defect), 129/J (129-70% CC defect), and a sixth generation cross of Wah1x129 (C129F₁-100% total CC absence) mouse embryos using perfusion fixation and the insertion of crystals of the carbocyanine dyes Dil and DiA into the hippocampal fimbria. Specimens ranged from 0.300g to 0.600g body weight or 15 to 17 days chronological age. Selected sections were also stained using bis-benzamide to show background morphology.

In Wah1 embryos, the first crossing of HC axons was seen at about 0.450g-0.480g which is about 1 day later than that seen in normal B6D2F₁/J hybrid embryos. In 129 embryos, first crossing was not seen until about 0.520g - 0.550g, about 2 days later than in normal hybrids. No HC axons were seen to cross midplane in the C129F₁ embryos prior to 0.600g. The arrival and movement of axons in all three strains appeared normal, but their traverse of midplane was blocked by the presence of a cleft which extended deep in the septal region.

EARLY DEVELOPMENT OF THALAMO-CORTICAL AND GANGLIONIC EMINENCE PROJECTIONS IN THE HAMSTER. C. Métin and P. Godement*. Institut A. Fessard, CNRS, 1 av. de la terrasse, 91190 Gif/Yvette, FRANCE

The formation of long-range projections in the brain requires that axons navigate along precise paths and recognize their final targets. In mammals, the thalamus and the neocortex are connected via reciprocal connections and are separated by the ganglionic eminence. We have studied the development of these projections, from embryonic day E11 to E14 in hamster embryos, corresponding to stages when these fibers begin their growth. Small injections of carbocyanine dyes (Dil, DiA) were done in fixed hamster embryo brains to label anterogradely and retrogradely the projections from small territories of the thalamus, cortex and ganglionic eminence.

Anterograde labeling shows that at E11.5, thalamic fibers reach the medial ganglionic eminence (GE), and cortical fibers reach the lateral GE. Surprisingly, retrogradely-labeled neurons are found in close proximity to the growth cones of thalamic and cortical fibers in the medial and lateral GE, respectively. Thus, at this age, there are reciprocal connections between the GE and the thalamus and neopallium. Injections into the ganglionic eminence confirm the existence of this early projection. At E12.5, thalamic fibers accumulate at the frontier between the lateral GE and the neopallium. They cross into the intermediate zone of the neopallium one day later, at E13.5. The most advanced reach the dorso-medial region of the parietal subplate and few or no fibers are found in more rostral or caudal levels. From E11.5 to E12.5, corticofugal fibers grow to and within the GE. At the frontier between the neopallium and GE, they make a right-angle turn. The first cortical fibers reach the dorsal thalamus at E13.5. At this age, retrogradely labeled cells are observed in the lateral part of the parietal cortical plate, and in the ventro-basal region of the dorsal thalamus, suggesting that these regions are the first that establish reciprocal connections.

These observations show that thalamic and cortical fibers project to the ganglionic eminence before reaching their targets. At early stages, the GE interconnects the diencephalic and neopallial compartments of the brain. Therefore, interactions of thalamic and cortical fibers with the GE and/or its projections could be involved in the establishment of thalamo-cortical connectivity during early development.

PEP-19 IMMUNOHISTOCHEMISTRY REVEALS THE DEVELOPING DIRECT PURKINJE-VESTIBULAR COMPLEX PROJECTION IN THE RAT
J. J. Velier¹, A. B. Scheibel^{2,3*}, R. S. Fisher^{2,3}, and H. V. Vinters^{1,3}
Depts. of ¹Pathology (Division of Neuropathology), ²Anatomy and Cell Biology, and the ³Brain Research Inst., UCLA, Los Angeles, CA 90024

We performed an immunohistochemical examination of the developing direct purkinje-vestibular complex projection in the embryonic rat. The antibody utilized to discriminate Purkinje cell axons from others within the developing metencephalon was a rabbit polyclonal antibody produced against the Purkinje cell enriched antigen, PEP-19, identified as a 7.6 kDa peptide containing regions of similarity to a number of proteins thought to interact with calcium, including S100b, calpain, and calmodulin. A previous immunohistochemical examination of PEP-19 in the adult rat showed immunolocalization to purkinje cells and a minor proportion of neurons within the dorsal cochlear nucleus. The earliest age we have so far examined, embryonic 17 (E17), shows no immunopositive axonal profiles within the vestibular complex (superior and lateral vestibular nuclei). At E20, well organized fascicles are seen passing through the deep cerebellar nuclei and the pontocerebellar isthmus. These axons are observed to enter into the vestibular complex and apparent synaptic contacts upon cells of all sizes within the lateral vestibular nucleus are seen. From these initial findings we conclude that the direct purkinje-vestibular complex projection is established between E17 and E20.

MULTIPLE GUIDANCE CUES ARE INVOLVED IN THE SEGREGATION OF PIONEERING PATHWAYS IN THE CORTEX AND INTERNAL CAPSULE: EVIDENCE FROM REELER A.R. Bicknese*, W. Wang, A. Sharma Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY 11794

We compared pathway formation during cortical development in normal and reeler mutant mice using the carbocyanine dyes Dil and DiA to trace axons in fixed tissue, and immunolabeling with antibodies to chondroitin sulfate proteoglycans (CSPG) to identify the extracellular matrix (ECM). By embryonic day (E)11, neurons begin extending axons from the preplate zone (PPZ) which has intense CSPG labeling. By E12, cortical plate (CP) neurons begin splitting the PPZ into the marginal zone (MZ) and subplate (SP), which retain dense CSPG labeling. CP axons transverse the SP, turn and then obliquely cross the intermediate zone (IZ), exiting the cortex close to the VZ. Reeler retain the PPZ, and their IZ and CP are mixed in one layer. Axons of "CP" neurons extend obliquely across this layer and exit near the VZ. In both normal and reeler, pioneer efferents hesitate in a zone above the forming striatum. If later arriving (E12-13) thalamic axons encounter the waiting efferents, they fasciculate. The time period of co-extension is brief. In normal neocortex, thalamic axons selectively extend within the subplate and its CSPG. As the striatum matures, thalamic axons extend laterally around expanding striatum, to enter the subplate and its CSPG. CP axons continue to exit the cortex near the VZ. Thus the two systems are physically separated and axons do not encounter each other after E14. Reeler E14 "CP" develops streaks of CSPG intermingled with efferent neurons and axons allowing reeler thalamic afferents to encounter cortical axons. Thalamic axons selectively extend within the streaks of CSPG, rarely fasciculating with cortical axons. Our evidence indicates that if thalamic and cortical axons guide each other in development, it occurs in a limited number of axons. Multiple guidance cues produce pathway segregation in the forming cortex and internal capsule.

POTENTIAL ROLES OF THE CEK5 AND CEK8 RECEPTOR TYROSINE KINASES IN THE DEVELOPMENT OF NERVOUS SYSTEM ARCHITECTURE. J.A. Holash* and E.B. Pasquale. La Jolla Cancer Research Foundation, La Jolla, CA 92037.

Many receptor-tyrosine kinases have been shown to play important roles in nervous system development as they transduce the effects of extracellular "growth factors" with neural activity. The Eph subclass represents a major branch of receptor tyrosine kinases that are highly expressed in the developing nervous system. We have examined the spatial distribution of two Eph-related kinases, Cdk5 and Cdk8, in the embryonic peripheral nervous system and visual system. At Hamburger and Hamilton stage 24, both Cdk5 and Cdk8 appear to be expressed in outgrowing motor axons. High levels of phosphotyrosine immunoreactivity correspond to the sites of Cdk5 and Cdk8 immunoreactivity. At 6 days *in ovo*, Cdk8 expression becomes restricted to a subset of spinal neurons, while Cdk5 is expressed throughout spinal nerves. By 8 days *in ovo*, Cdk5 expression in peripheral nerves decreases, but appears high perineurally, whereas Cdk8 expression remains high within the nerves themselves.

Cdk5 and Cdk8 are also expressed in the developing visual system. The pattern of Cdk8 expression suggests that it plays a role in the formation or maintenance of the ganglion cell pathway from retina to optic tectum. Cdk8 is expressed first in the undifferentiated retinal neuroepithelium, and subsequently, as the retina differentiates, becomes restricted to ganglion cell axons. By 8 days *in ovo*, Cdk8 expression is apparent throughout the optic nerve, and by 10 days *in ovo*, Cdk8 immunoreactivity outlines the optic tract. Cdk5 appears to play a role in the development of retinotectal specificity. It is highly expressed in the ventral portions of the developing retina and optic nerve, but only weakly expressed in the dorsal portions of these structures. Immunostaining of retinal explants demonstrates that Cdk5, Cdk8 and phosphotyrosine immunoreactivities can be localized to neuronal processes. This work was supported by NIH Grant HD26351.

AXONAL ARBORIZATIONS OF THE PRIMARY AFFERENTS SERVING DIFFERENT VESTIBULAR END-ORGANS IN ZEBRAFISH EMBRYOS. S.E. Fraser* and B. Chapman, Division of Biology, 139-74, Caltech, Pasadena, CA 91125.

In adult vertebrates, primary vestibular afferents serving the different semi-circular canals and otolithic organs form distinct though overlapping regions of axonal arborization in the vestibular nuclei. While there is an obvious role for this specific connectivity in sensory processing, little is known about the developmental mechanisms which are responsible for establishing the connections. In particular the relative contributions of inherent positional cues, trophic factors, and patterns of neuronal activity to the development of specificity have not previously been examined.

As a first step in answering these questions we have studied the axonal arborization patterns of primary vestibular afferents in normal zebrafish embryos. In order to label the afferents we used iontophoretic injections of lipophilic dyes into the cristae and maculae in the inner ears of fixed zebrafish specimens. After allowing time for the dyes to diffuse along the axons, we examined the patterns of arborization in area octavolateralis in the hindbrain using confocal microscopy of whole mounts of the labeled embryos.

We find that the primary afferents serving the different vestibular end-organs have recognizably different projection patterns. The pattern of axonal arborization of afferents from a given end-organ, however, is highly stereotyped and reproducible between animals at a given age. Double labeling experiments using Dil (C3) and Dil (C5) injected into different canal cristae in the same animal have shown that there is good separation of the arbors of the populations of axons serving different end-organs.

Further experiments are currently underway to test whether the development of normal patterns of axonal arborization in the vestibular system depend on the presence of normal neuronal activity, as has previously been shown to be true in the visual system.

COMMISSURE FORMATION IN THE EMBRYONIC BRAIN OF THE GRASSHOPPER. G.S. Boyan* and H. Reichert, Zoology Institute, University of Basel, Rheinsprung 9, CH-4051 Basel, Switzerland

A fundamental event in the normal development of the insect brain is the establishment of correct bilateral connections between the brain hemispheres. We have studied the formation of the very first commissural fiber pathways in the embryonic grasshopper brain using immunocytochemical and intracellular dye injection techniques. During early embryogenesis a set of approximately 130 neuroblasts differentiates from the neuroepithelium of the head to form the bilaterally organized proto-, deuto- and tritocerebral brain segments. In the midline of the brain itself, however, an additional set of precursor cells differentiates from the neuroepithelium anterior to the stomodaeum, and ventrally between the pars intercerebral lobes of the protocerebral segment. We have identified one large central cell flanked symmetrically on each side by a pair of smaller neuroblasts. At 29% of embryonic development the processes of cells expressing the glial antigen Annulin are seen surrounding all these midline cells as well as many of their progeny. By 30% the most lateral neuroblast on each side has produced a lineage of progeny from which a clearly recognizable pair of cells can be shown to direct the first axonal processes medially across the midline of the brain. These pioneer cells have been morphologically identified via intracellular dye injection and anti-HRP immunostaining, and express the antigen to fasciclin II as they fasciculate with one another across the midline. The pathway established by these midline pioneers provides a scaffold first for fibers originating from lineage-identified cells at the posterior-medial border of the pars intercerebralis, and then for fibers from the optic lobes. Each subsequent group of fibers crossing the brain reiterates a pattern of antigen expression and fasciculation similar to that described for the midline pioneers. Supported by the Swiss NSF.

CORTICOSPINAL TRACT IN THE DEVELOPING RAT SPINAL CORD: THE PARENT AXONS AND PROJECTION COLLATERALS. M. Nagashima* and Y. Inoue. Department of Anatomy, Hokkaido University School of Medicine, Sapporo 060, Japan.

A detailed morphogenesis of the corticospinal tract of the rat neonate ranging from postnatal day 1 (P1) to P11 was investigated using anterograde labeling with fluorescent dye, DiI, optimized by confocal laser scanning microscopy (MRC-500, Bio-Rad). The parent axons constituted a compact bundle which was constantly enclosed in the ventral part of the dorsal funiculus. The trajectories of individual axons were not parallel to each other within the bundle. In addition, there was an aberrant fascicle which ran ventrally along the main bundle in the sacral segments. The parent axons could be divided into two categories; pioneer axons and follower axons. In contrast with the pioneer axons which progressed by regular time course, the growth cones of follower axons were distributed over a wide range. The majority of the projection collaterals toward the target area emanated from the rectangular branching, however, a number of them ran in various directions. Multiple collaterals from the single parent axon were often observed. The projection fibers repeated branching and their arbors terminated onto the preferential phenotype of the target neurons within the dorsal horn, the intermediate substance or the ventral horn in the spinal gray matter.

AXONOGENESIS AND THE EARLY APPEARANCE OF GABA-IMMUNOREACTIVE NEURONS DURING DEVELOPMENT OF THE CNS IN A TELEOST.

L. Ohlin and P. Ekström*, Dept. of Zoology, Univ. of Lund, Sweden.

During early CNS development, a small number of neurons give rise to pioneer axons that form an axonal scaffold. It is not known at which stage these neurons acquire neurotransmitter phenotype, or which transmitter(s) they utilize. In an attempt to approach this question we have studied the early development of the axonal scaffold in embryos of a teleost fish, the three-spined stickleback, with immunocytochemical techniques. We used monoclonal antibodies against acetylated α -tubulin (MAB 6-11B-1) that labels the axons of the early axonal scaffold, and polyclonal antibodies against γ -aminobutyric acid (GABA). GABA is known to exert various neurotrophic actions in the developing nervous system. The antibodies were applied to semithin Araldite sections and to wholemount embryos. Both single and double labeling experiments were performed. Hatching occurs between 144-168 h postfertilization (PF). At 36h PF, two 6-11B-1 immunoreactive (6-11B-1ir) ventral tracts are located in the mesencephalon. At 48h PF, two 6-11B-1ir ventral tracts extend from the mesencephalon throughout the spinal cord. At 51h PF, the first GABA-immunoreactive (GABAir) neurons appear in the ventral prosencephalon, ventral mesencephalon and in the spinal cord. At 60h PF, the 6-11B-1ir ventral tracts were connected by numerous commissures all along between the mesencephalon and the spinal cord. Also, an additional lateral ventral tract appeared. At 66h PF, the first GABAir cell groups have grown by addition of GABAir neurons, and GABAir cell bodies and fibers are closely associated with the 6-11B-1ir tracts that constitute the axonal scaffold. Thus, GABAergic neurons appear only when the axonal scaffold is established. We suggest that the first pioneer neurons are not GABAergic but that GABAergic neurons make an important contribution to the formation of the early neuronal network.

MOLECULAR MECHANISMS OF EMBRYONIC BRAIN DEVELOPMENT IN *DROSOPHILA MELANOGASTER*.

S. Therianos, S. Leuzinger, F. Hirth, C. S. Goodman and H. Reichert*. Dept. of Zoology, University of Basel, CH-4051 Basel, Switzerland, and HHMI, Dept. of Molecular and Cell Biology, University of California, Berkeley, California 94720

We are using the powerful genetic and molecular genetic techniques that are available for the study of embryonic development in *Drosophila* to investigate the molecular mechanisms involved in building a complex brain. Embryonic development of the *Drosophila* brain is comparable to that of other insects. During the period of embryogenesis in *Drosophila*, complex cerebral hemispheres are formed. These cerebral hemispheres are interconnected by the brain commissure, which is pioneered by a pair of axons that navigate along a midline intercerebral bridge. The differentiation of this brain commissure depends on the *com* gene. In *com* mutants the brain commissure is severely reduced, and only a small subset of commissural fascicles are formed. The cerebral hemispheres are linked to the ventral nerve cord by paired brain connectives, which interconnect the initially separated procephalic and ventral neurogenic regions. The formation of these paired brain connectives depends on the *sim* gene. In *sim* mutants paired connectives do not form, and aberrant ectopic midline interconnections between brain and ventral nerve cord are established by axons which navigate along the midline stomatogastric nervous system structures. Our future goal is to carry out a comprehensive molecular genetic analysis of the set of genes involved in brain development. (Supported by SNSF and HHMI).

688.13

ESTABLISHING FUNCTIONAL RELATIONSHIPS BETWEEN GENES IN ABL-REGULATED PROCESSES BY ANALYSIS OF *DROSOPHILA* MUTANT PHENOTYPES. J.-L. Juang*, F. M. Hoffmann. McArdle Laboratory for Cancer Research, University of Wisconsin-Madison, Madison, WI 53706

The function of the *Abl* protein tyrosine kinase in *Drosophila* is of interest because it relates to the transforming oncogene in Abelson murine leukemia virus. *Drosophila* provides a well characterized system in which to analyze the developmental consequences of specific mutations by examining mutant phenotypes. Five genes, *disabled (dab)*, *enabled (ena)*, *failed axon connections (fax)*, *fasciclin I (fasI)* and *fasciclin III (fasII)* have been examined to analyze their functional interaction with the *Abl*. We have observed defects in axon outgrowth and/or pathfinding in embryonic CNS of these mutants. We also used enhancer trap lines to visualize a small subset of axons. Our preliminary data suggests the axon tract defects observed in mutant embryonic CNS are due to defects in cell adhesion mechanisms critical to growth cone pathfinding. Antibody staining of CNS-derived cell lines have indicated that the *Abl*, *dab*, and *ena* proteins are present in the neuronal cytoplasm, neurites, and the growth cone regions.

DEVELOPING RAT CORTICOTHALAMIC FIBRES DEFASCICULATE WHEN THEY REACH THE PERIRETICULAR NUCLEUS. N.C. Adams and R.W. Guillery*. Department of Human Anatomy, University of Oxford, South Parks Road, OX1 3QX, England.

Corticothalamic fibres undergo extensive reorganisation between the cortex and the thalamus. To examine this reorganisation as connections are being formed, we placed small crystals of the lipophilic dyes DiI and DiA in the cortex of aldehyde fixed brains of rats between embryonic day (E)15 and postnatal day (P)1. After 4 to 8 weeks the brains were sectioned, counterstained with DAPI and viewed with epifluorescence and confocal microscopy.

At E15 the first axons from the cortex can be seen entering what will later be the internal capsule. At this age, there is no discernable order in the direction that the fibres take, with many growing fibres crossing each others' paths. At E16, there is a denser fibre projection, with fibres aggregating into bundles as they leave the cortex. Fibres at E17 leave the parietal cortex and form distinct fascicles which pass in a relatively straight path towards the thalamus. On reaching the area of the internal capsule occupied by the perireticular nucleus these bundles break down. Defasciculation is accompanied by a dramatic change in the course taken by the corticofugal fibres, which form a characteristic lattice-work of fibres. The lattice continues to the inner border of the reticular nucleus, where the fibres adopt an almost direct approach towards their thalamic targets.

Perireticular cells, with their cortically projecting axons (N.C. Adams *et al* (93) *Soc. Neurosci. Abs.* 19, p45) and their position in the path of growing fibres to and from the neocortex are uniquely placed to have a role in the reorganisation of axons between the cortex and the thalamus. Perireticular cells are thus likely to be involved in guiding the corticothalamic axons to their correct destination, and in so doing, create the lattice.

NEUROTROPHIN-3 HAS A CHEMOTROPIC EFFECT ON CORTICAL NEURONS. D.D.M. O'Leary* and M.M. Daston. Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA.

NT-3 promotes the regrowth of transected corticospinal axons in adult rat spinal cord (Schnell *et al* *Nature* 367:170, 1994) and has been speculated to have a tropic effect on developing corticospinal axons. To address this potential role, we have utilized a chemotaxis chamber which is normally used to study cell migration. The chamber has 48 wells that are separated into upper and lower compartments by a membrane containing small pores. Dissociated cells are placed in the upper compartment and normally remain on the membrane's upper surface. When a soluble chemotrophic agent is added to the lower chamber cells pass through the pores onto the membrane's bottom surface. By reducing the pore size, we have been able to study directed neurite growth, rather than cell chemotaxis, since neurites, but not cells can pass through the membrane.

The tropic effect of NT-3 containing medium or medium conditioned with explants of basilar pons, cerebellum or olfactory bulb on cortical neurites was tested. Cortical cells dissociated from P1 rats were plated on the top surface of the membrane. 24 hrs later, neurites on the bottom surface of the membrane were visualized immunohistochemically and counted. The number of neurites on the bottom surface of the membrane was increased 2 to 5 fold by the explant conditioned medium compared to normal unconditioned medium. NT-3 containing medium resulted in a 10 fold increase in the number of neurites on the bottom surface of the membrane. The NT-3 effect is completely abolished when the gradient is eliminated by adding NT-3 containing medium to both the upper and lower chambers, suggesting that the effect is due to chemotropism and not simply enhanced neurite outgrowth. Experiments are in progress to determine if corticospinal neurons are among the NT-3 responsive population and whether these neurons express *trkC* in situ.

NEUROTRANSMITTER SYSTEMS AND CHANNELS: CHANNELS

689.1

MUSCLE ACETYLCHOLINE RECEPTOR CHANNEL FUNCTION DURING NERVE REGENERATION. R.A. Magelli*, E.J. Lane, T.L. Ashton, M. Lee, and M. Chao. Lab. of Neurology, University of California, Davis, CA 95616.

Two distinct types of acetylcholine receptor (AChR) channels are present at the synaptic membrane of vertebrate skeletal muscle. One type is characterized by high conductance (HC) fast kinetics, and the other type is characterized by low conductance (LC) slow kinetics. In an effort to define the role of innervation in the expression of these two classes of AChR channels we performed crush injuries to the sciatic nerves of adult mice. This was followed by sequential single channel recordings performed in freshly dissociated fibers from the flexor digitorum muscle. Up until two days after crush the percentage of LC channels were less than 1% of the total observed events and similar to the controls. At three days post crush the percentage of LC channels started to rise, and by day five more than 80% of the openings were the LC type. This was followed by a progressive decrease of the percentage of LC type, and by eight days post crush less than 40% of the opening were LC type. We conclude that neural factors are important to regulate the expression of either type of channels and that single channel recordings are useful to monitor the course of reinnervation.

689.2

DECREASED ACTIVITY OF Na CHANNELS IN PITUITARY MELANOTROPES FOLLOWING THE ONSET OF DOPAMINERGIC INNERVATION. J.C. Gomora*, A. Navarrete, A. Marin and G. Cota. Dept. of Neurosciences, Cinvestav, Mexico, DF 07000.

High-threshold Ca^{2+} currents in rat melanotopes undergo a drastic inhibition during the early postnatal period, concomitant with the onset of dopaminergic innervation (Gomora *et al.*, *Soc. Neurosci. Abstr.* 19:1128, 1993). We have now investigated whether the long-term effects of innervation include regulation of other voltage-gated ion channels. Melanotopes were dissociated from non- and fully-innervated rat intermediate pituitary lobes (postnatal days, PN, 3 and 11, respectively), kept in culture for 5-24 h, and then subjected to whole-cell patch clamp. Standard recording solutions and activating pulses to +20 mV (HP -80 mV) were used. Peak Na^{+} inward current decreased from -543 ± 54 pA (mean \pm SE, n=11) in PN3 cells to -283 ± 46 pA (n=14) in PN11 cells. In contrast, the average values for cell capacitance and K^{+} outward current amplitude did not significantly differ between these two sets of cells. Thus, the dopaminergic innervation of melanotopes reduces Na^{+} current density, but does not seem to affect the long-term activity of K channels.

689.3

FUNCTIONAL EXPRESSION OF Ca^{2+} -ACTIVATED K^{+} CURRENTS IN EMBRYONIC CHICK SYMPATHETIC NEURONS DEVELOPING *IN SITU* AND *IN VITRO*. M. E. Wisgirda*, S. Raucher & S. E. Dryer. Program in Neuroscience, Florida State University, Tallahassee, FL 32306

We have examined the expression of whole-cell $\text{I}_{\text{K}(\text{Ca})}$ in embryonic chick sympathetic neurons developing *in situ* and *in vitro*. $\text{I}_{\text{K}(\text{Ca})}$ first appears relatively late in embryonic development (E13) and reaches its mature density at E18. Voltage-activated Ca^{2+} currents (I_{Ca}) are present throughout these stages. When sympathetic neurons are isolated at E13 and maintained in cell culture for an additional five days, they do not express $\text{I}_{\text{K}(\text{Ca})}$ although I_{Ca} is expressed at normal density. Culturing sympathetic neurons in the presence of 5 ng/ml NGF caused a significant ($p < 0.05$) increase in $\text{I}_{\text{K}(\text{Ca})}$ expression, although this effect appeared to be restricted to a subpopulation of cells (17 out of 34 neurons). Similarly, co-culture of sympathetic neurons with ventricular myocytes stimulated $\text{I}_{\text{K}(\text{Ca})}$ expression ($p < 0.05$ compared to controls). By contrast, co-culture of sympathetic neurons with spinal cord explants, which make functional contacts with sympathetic cells, did not promote $\text{I}_{\text{K}(\text{Ca})}$ expression. The developmental expression of $\text{I}_{\text{K}(\text{Ca})}$ is dependent upon extrinsic factors, possibly including target-derived trophic factors. Supported by NIH Grant NS-27013.

A NOVEL CALCIUM-DEPENDENT OSCILLATION IN POST-NATAL MOUSE LATERAL GENICULATE NEURONES. Nikki MacLeod, Alex Johnston & Gavin Swanson*. Physiology Dept., University of Edinburgh & TINS, Cambridge*, UK.

Underlying the bursting behaviour of adult thalamic neurones is a 5 Hz oscillation which is generated by alternating activation and deactivation of two steeply voltage-dependent currents I_{T} , a transient calcium current and I_{H} , a slowly inactivating current carried by both sodium and potassium ions. Both of these currents and the consequent membrane oscillation are activated by membrane hyperpolarisation, induced by synaptic inhibition or intracellular current injection.

In a recent series of experiments investigating the properties thalamic neurones in brain-slices prepared from mice between P7 and P17 we have discovered a voltage and calcium-dependent membrane oscillation which is activated by membrane depolarisation. The oscillation is usually present at the cells' resting potential (-35 to -50mV) and induces spontaneous firing of complex action potentials, which often have an initial fast, TTX-sensitive component and a later slow component which is blocked by bathing the slice in low Ca medium containing cadmium ions. Neither the wide part of the action potential or the underlying membrane oscillation are affected by adding TTX, but are enhanced by low concentrations of 4AP which is known to facilitate calcium entry into neurones. The oscillatory behaviour is stopped by small membrane hyperpolarisations, while small depolarisations increase the frequency and ultimately lead to inactivation of the associated action potentials. Large hyperpolarisations induced by inward current injections do not induce the classical 5Hz oscillation described above, even though the cells showing the HT oscillation have a well developed LTS and I_{H} . However, in some of the younger neurones (P7-P8) showing the depolarisation-induced oscillation, membrane hyperpolarisation reveals TTX & bicuculline-sensitive giant depolarising potentials of up to 60 mV which can lead to fast spike generation if threshold is reached.

Localization of Rse, a Novel Tyrosine Kinase Receptor, in the Mammalian CNS; Comparison with Other Tyrosine Kinase Receptors. Mark Armanini*, Lanway Ling, Klaus Beck, Franz Heftli, Melanie Mark, Paul Godowski, Siao Ping Tsai, Arnon Rosenthal, Paul Moran, Ingrid Caras, and Heidi Phillips. Depts. of Neuroscience and Cell Genetics, Genentech Inc., 460 Point San Bruno Blvd., S.F., CA.

Rse is a novel tyrosine kinase receptor isolated from rat and human brain RNA. Rat and human Rse share 90% amino acid identity, containing extracellular, transmembrane, and intracellular domains. Northern analysis reveals Rse expression to be most abundant in brain. Here, in-situ hybridization was performed to identify specific neuronal structures expressing this gene.

In-situ hybridization revealed Rse to be widely expressed throughout the adult rat brain, but restricted to specific regions. Expression in the hippocampus was observed primarily in CA1, to a much lesser extent in CA3 and CA4, and undetectable in the dentate gyrus. High levels of expression were observed in the cortex, caudate, olfactory bulbs, and cerebellar granule cells, but undetectable in the midbrain, brainstem, and medial septum. Sections from the adult human cortex and hippocampus also revealed high levels of Rse expression in these structures.

In the E15.5 mouse and 8 week human embryo, expression of Rse was undetectable in the CNS. Thus, expression appears to be turned on later in development, with highest levels being maintained in the adult. The regulation of Rse expression in response to a combination fimbria-fornix/enterohinal lesion was also investigated.

The localization, developmental patterns, and response of Rse expression to injury were compared with other recently described tyrosine kinase receptors of the mammalian CNS.

TRANSIENT EXPRESSION OF N-TYPE CALCIUM CHANNELS IN THE FOREBRAIN OF HUMAN INFANTS IDENTIFIED WITH [^{125}I] ω -CONOTOXIN GVIA. K. E. Ward*, J. M. McIntosh, B. M. Olivera, and F. Filloux. Depts. of Neurology, Pediatrics, Psychiatry, and Biology, University of Utah, Salt Lake City, UT 84132.

Presynaptic voltage-gated Ca^{2+} channels (N-type) are thought to play an important role in the mature brain by regulating Ca^{2+} -dependent neurotransmitter release. However, little is known of their role in the developing brain. Recently, members of our group have described transient expression of N-type Ca^{2+} channels in discrete regions of postnatal rat brain (Filloux et al., *Dev. Brain Res.*, 78:131-136, 1994). We now describe the transient expression of N-type Ca^{2+} channels during human brain development. Postmortem human brain samples from the cerebellum and dorsolateral prefrontal cortex were obtained from 11 postnatal subjects, ages 1-6 months, and 8 adults, ages 26-66 years old. Slide-mounted, 10 μm -thick tissue sections from each area were radiolabeled with [^{125}I] ω -conotoxin GVIA. Autoradiograms were generated and intensities of binding were quantitated using computerized image analysis.

Results showed no qualitative differences in the intensity of [^{125}I] ω -conotoxin GVIA binding in cortical or cerebellar gray matter between infants and adults. However, there was a striking difference when comparing forebrain white matter in these ages. Specifically, infants had significantly higher binding intensity in cortical white matter when compared to adults (infants=1.60 fmol/mg, adults=0.25 fmol/mg; $p < 0.005$). Hence, it would appear that transient expression of N-type Ca^{2+} channels also occurs in at least some discrete regions during human brain development. The increased expression of N-type Ca^{2+} channels in early development of forebrain white matter may be a useful parameter in identification of certain forebrain neurodevelopmental pathologies.

POSTNATAL CHANGES IN FIRING PROPERTIES OF NEURONS IN THE NUCLEUS TRACTUS SOLITARIUS. A. Vincent, F. Tell* and A. Jean. Dept. Physiologie, URA CNRS 1832, Neurobiologie et Neurophysiologie Fonctionnelles, Fac. S¹ Jérôme 13397 Marseille cedex 20, France.

Whole cell recordings of NTS neurons were carried out on rat brainstem slices at different postnatal ages (P0-3, P5-10, P15-21 and P>30 days). Resting potential remained unchanged while input resistance decreased from P0-3 to adulthood. Duration of action potentials (APs) shortened with age. APs amplitude increased from birth to P>30 with a peak at P5-10. The percentage of cells that possessed an A-like potassium current augmented with age. Although IA amplitude did not increase significantly, IA decayed more rapidly at P0-3 than in the adulthood. Thus, unlike previously reported, IA is present at birth but is significantly altered postnatally. Therefore, firing properties of NTS neurons are not fully mature at birth. Depending on the age, processing of synaptic inputs by NTS neurons would be different and therefore generation of integrative processes such as the control of autonomic functions might be altered.

K-252a INDUCES TYROSINE PHOSPHORYLATION OF THE FOCAL ADHESION KINASE AND NEURITE OUTGROWTH IN HUMAN NEUROBLASTOMA SH-SY5Y CELLS. Anna Coco Maroney*, Lorraine Lipfert, M. Elizabeth Forbes, Marcie A. Glicksman, Nicola T. Neff, Robert Siman and Craig A. Dionne. Cephalon Inc., 145 Brandywine Parkway, West Chester, PA 19380

The protein kinase inhibitor K-252a has been shown to promote cholinergic activity in cultures of rat spinal cord (Glicksman et al., *J. Neurochem.*, 61: 210-221, 1993) and neuronal survival in chick dorsal root ganglion cultures (Borasio, *Neurosci. Lett.* 108: 207-212, 1990). To determine the mechanism by which K-252a acts as a neurotrophic factor, we examined the effects of this molecule on a human neuroblastoma cell line, SH-SY5Y. K-252a induced neurite outgrowth in a dose-dependent manner. Coincident with neurite outgrowth was the early induction of 125 and 140 kDa tyrosine phosphorylated proteins. Inhibition of protein kinase C with GF-109203X did not prevent K-252a induced tyrosine phosphorylation or K-252a dependent neurite outgrowth suggesting that the neurotrophic effects mediated by K-252a are independent of protein kinase C inhibition. We have identified one of the phosphosubstrates as the pp125 focal adhesion protein tyrosine kinase (Fak). Induction of phosphorylation coincided with increased Fak activity and appeared to be independent of ligand/integrin interaction. The induction of Fak phosphorylation, by K-252a, was also observed in LA-N-5 cells and primary cultures of rat embryonic striatal cells, but not in PC12 cells. The protein kinase-C independent induction of tyrosine phosphorylation and the identification of Fak as a substrate of K-252a-induced tyrosine kinase activity suggests that this compound mediates neurotrophic effects through a novel signaling pathway.

LPA, A NEURITE OUTGROWTH INHIBITOR, ACTIVATES MAP KINASE IN N1E-115 NEUROBLASTOMA CELLS. G.J.A. Ramakers* and W.H. Moolenaar. Division of Cellular Biochemistry, Netherlands Cancer Institute, Plesmanlaan 121, Amsterdam, The Netherlands.

The phospholipid lysophosphatidic acid (LPA) has recently been identified as an albumin-bound serum factor, that induces DNA synthesis and stress fiber formation in fibroblasts by activating both classic and novel signaling pathways through a putative 40 kD receptor coupled to heterotrimeric G-proteins (Moolenaar, Trends Cell Biol. 4: 213; 1994). The 40 kD LPA receptor is highly expressed in brain and in the neuroblastoma cell line N1E-115, which differentiates to a sympathetic phenotype upon serum withdrawal. In differentiated N1E-115 cells LPA induces rapid neurite retraction through a novel signaling pathway independent of classic second messengers (Jalink et al., Cell Growth Differ. 4: 247; 1993). As protein tyrosine kinase and phosphatase inhibitors interfere with LPA-induced neurite retraction in N1E-115 cells, we investigated protein tyrosine phosphorylation in N1E-115 cells by LPA after serum-starvation, using anti-phosphotyrosine immunoblotting.

LPA (at 100 nM and higher), thrombin and insulin, but not FGF, EGF or glutamate transiently stimulated the phosphorylation of p42 MAP kinase with a peak at 2 min. LPA-induced MAPK phosphorylation was inhibited by pertussis toxin and various suppressors of protein kinase C (PKC), indicating an involvement of the heterotrimeric G_i protein as well as PKC. A model will be presented in which LPA-induced MAP kinase parallels, but is independent of neurite retraction, and serves as a trigger to drive N1E-115 cells back into the cell cycle.

GAP-43 IN THE SUPERIOR CERVICAL GANGLIA AND IRIDES OF THE RAT AFTER DECENTRALISATION. X-E. Hou and A. Dahlström*. Dept. of Anatomy and Cell Biology, Göteborg University, Göteborg, S-413 90, Sweden.

The distribution of GAP-43-like immunoreactivity (LI) in the superior cervical ganglia (SCG) and irides of adult SD rats was studied using confocal laser scanning microscopy (CLSM). In the SCG of control rats, GAP-43-LI was mainly located in the nerve terminals around, but not inside, the principal neurons and very little in nerve bundles. After 24 hours decentralization the GAP-43 positive nerve terminals disappeared, while the principal neurons became weakly GAP-43-LI positive. Three days after decentralization, GAP-43-LI was again observed in nerve terminals, and also appeared in axon bundles, while principal neurons appeared negative. SIF cells did not show clear changes after decentralization. In the irides of control rats, GAP-43-LI was present and distributed in a patchy pattern in axon bundles, around blood vessels and in the terminal network. Double immunolabeling showed that GAP-43-LI colocalized with TH-LI, but appeared to distribute differently from SP-like (SP-LI) in the subcellular structures. A semi-quantification of GAP-43-LI in the irides was performed using CLSM. The intensity and density of the nerve terminal network in the dilator plate were registered. After 3 days of decentralization, the intensity and density of the GAP-43-positive nerve terminal was significantly increased.

The results indicate that GAP-43-LI is normally present in nerve fibers and terminals of the post-ganglionic adrenergic SCG neurons in adult rats. The modulations in GAP-43-LI observed in cell bodies and nerve terminals after decentralization suggests that these autonomic neurons have a capacity for remodelling and plasticity which may partly be regulated via the pre-ganglionic neurons.

INTERLEUKIN-18 EXPRESSION DURING DEVELOPMENT OF THE MOUSE BRAIN. J.L. Sclafner* and C.F. Ide. Neuroscience Training Program and Department of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118

Interleukin-18 (IL-18) is a cytokine which modulates inflammation and immune responses in the periphery. Expression of IL-18 has been demonstrated in the adult brain after trauma and may be regulated during cell death. Since normal development of the brain involves programmed cell death, we investigated the developmental profile of IL-18 immunoreactivity (ir) in the perinatal mouse brain using antiserum to human recombinant IL-18 for immunocytochemistry on E18, P0, P3, P6 and >P30 animals. We also synthesized a 447-bp cDNA probe to murine IL-18 mRNA for use in *in situ* hybridization studies on E18, P0, P6, P10 and >P30 mouse brains. Grains were counted and immunoreactivity was analyzed using quantitative image analysis. At E18, moderate to high expression of mRNA, but no detectable IL-18ir, was present. At P0, peak mRNA levels were observed and IL-18ir was found in cells of all brain areas, especially in the cerebral cortex. At P6, mRNA levels declined and IL-18ir was equivalent to levels and areas found at P0 and P3. Importantly, at P10, IL-18 mRNA declined in all brain regions except the olfactory bulb and the CA1 region of the hippocampus. In adults there was no detectable IL-18 mRNA except in the olfactory bulb; IL-18ir was present in scattered cells throughout the brain at low levels, prominently in the temporal cortex and the cerebellar granule cell layer. Thus, IL-18 is regulated during the early perinatal period and may be involved in the neural immune response associated with natural cell death in the developing CNS. Supported by DOD grant #2-89/116/88-150 to the Tulane/Xavier Center for Bioenvironmental Research.

CONDITIONED MEDIA FROM A TRANSFORMED GLIAL-LIKE CELL LINE ENHANCES NEURITE OUTGROWTH AND GAP-43 EXPRESSION. J.B. Madsen*, O. Weisfeiler, A. Greenspan and L.I. Benowitz. Dept. Neurosurgery, Children's Hospital; Program in Neuroscience, Harvard Medical School, Boston, MA, 02115.

The glial environment exerts a profound effect upon neuronal development and regeneration. To identify molecules that enhance or suppress axonal outgrowth, we have been coculturing primary neurons from postnatal day 3 rat cerebellum with two closely related transformed glial-like cell lines (C27 and C17). The neuronal response was quantitatively assayed by measuring the expression of the neuronal growth-associated protein, GAP-43, using Western blotting. As reported previously, neurons grown on the C27 line expressed considerably higher levels of GAP-43 than when grown on C17 cells. To determine whether secreted factors contribute to this difference (rather than cell-to-cell contact), we examined neurite outgrowth in the presence of conditioned medium (CM) from C27 and C17 cells. Again, neurite outgrowth was significantly higher in cultures containing C27 CM as compared with C17 CM. The neurite-promoting activity of the C27 cells is detectable in serum-free as well as serum-containing CM, and can be concentrated by ultrafiltration with a size cutoff > 10kD. The C27 and C17 CMs do not differ in immunoreactive laminin, but do show other differences in protein composition by HPLC. Several of the monoclonal antibodies developed in this laboratory to identify epitopic differences between surface molecules of C17 and C27 also identify specific differences between the CM proteins of the two cell lines by Western analysis. Further work is directed towards identifying the CM antigens which these antibodies recognize and to determine which molecules in CM or on the cell surface contribute to the control of neurite growth.

IDENTIFICATION OF INTERLEUKIN-6-EXPRESSING NEURONS IN DIFFERENT REGIONS OF RAT BRAIN. R.A. Gadiant* and U.H. Otten. Dept. Physiology, Univ. Basel, CH-4051 Basel, Switzerland

Interleukin-6 (IL-6) belongs to a family of neurotrophic cytokines which includes ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M and IL-11. This family of multifunctional proteins shares a common signal-transducing receptor subunit (gp130). We focused on IL-6, which promotes neuronal survival, differentiation and ameliorates the effects of excitotoxins. In a recent study using reverse transcription-polymerase chain reaction (RT-PCR) we showed that both IL-6 and IL-6 receptor (gp80) transcripts are found in normal rat brain in a region-specific manner and are developmentally regulated. To identify the cellular origin of IL-6 and its receptor, we established a sensitive non-radioactive *in situ* hybridization technique. In line with our RT-PCR data the most pronounced IL-6 mRNA signals were observed in hippocampus and hypothalamus. Low expression was seen in the striatum. The IL-6 mRNA signal was predominantly located in neuronal cells, such as the pyramidal and granular cells of the hippocampus and the Purkinje cells of the cerebellum. These findings implicate IL-6 in the regulation of so far unidentified neuronal functions. This study was supported by the Swiss National Foundation for Scientific Research (Grant 31-39121.93) and by the BMFT (Grant 01KL9303).

EFFECTS OF INTERLEUKIN-1 AND INTERLEUKIN-2 ON RAT HIPPOCAMPAL NEURONS IN CULTURE. F.Z. Wang*, H. Yao and A.S. Ding. Dept. of Neurobiology, Institute of Basic Medical Science, Beijing 100850, China

As it was reported that of various brain regions the hippocampus has the greatest abundance of interleukin-1 (IL-1) and interleukin-2 (IL-2), as well as their receptors, we first examined the neurotrophic effect of recombinant human interleukin-1 β (rhIL-1 β) and recombinant human interleukin-2 (rhIL-2) on cultured hippocampal neurons *in vitro*. The results showed that in the presence of rhIL-1 β (100U/mL) or rhIL-2 (100U/mL), the numbers and length of neurite outgrowth were markedly increased as compared with that seen in the control cultures. From long-term cultures, the cell size and the number of surviving neurons were high than those observed in the parallel series grown with non-rhIL-1 β and non-rhIL-2 medium. Then the effects of rhIL-1 β and rhIL-2 on the cultured rat hippocampal neurons were studied using intracellular recording. Experimental results showed that all of the neurons tested with rhIL-1 β (100U/mL) exhibited a 4.20 ± 1.86 mV membrane hyperpolarization. 50% of the neurons perfused with rhIL-2 (100U/mL) showed a depolarization of 11.12 ± 2.71 mV in amplitude accompanied by bursting activity. However, a 3.25 ± 0.63 mV hyperpolarization was observed in the neurons perfused with rhIL-2 in higher concentration (1000U/mL). These results indicate that the cytokines IL-1 β and IL-2 can affect not only on the neuronal survival but also on the excitability of hippocampal neurons, by which the immune system may influence the function of neurons in CNS.

EFFECTS OF ENDOTHELIN-1 ON THE EARLY DEVELOPMENT OF CHICK EMBRYOS. L.Hsu* and A.Y.Jeng. Department of Biology, Seton Hall University, South Orange, NJ 07079 and Research Department, Ciba Pharmaceuticals, Summit, NJ 07901.

Endothelin-1 (ET-1) is a potent vasoconstrictive peptide originally isolated from conditioned medium of porcine aortic endothelial cells. We have previously found that ET-1 enhances neurite outgrowth from phorbol ester-treated dorsal root ganglion explants. The purpose of the present study was to examine the effects of ET-1 treatment on the development of the nervous system in chick embryos. Eggs were incubated at 37°C and treated with ET-1 (50 pmol) through a window in the shell. A single dose of ET-1 on day 1 or 3 did not affect brain development. However, about 12% of the treated embryos had eye malformations (smaller or absent). Repeated treatment with 50 pmol ET-1 from days 2-4 resulted in significantly larger heads and trunks when observed on day 7, while the size of the eyes and limbs were comparable to the controls. The overall lengths of the diencephalon and the telencephalic and optic lobes in the treated groups were increased. Similar effects on brain development were also noted when embryos were treated with a single dose of 50 pmol ET-1 on day 5. These results suggest that ET-1 has growth-factor-like effects on brain development and that embryos are most responsive to treatments around day 5.

690.11

LOCALIZATION OF RETINOIC-ACID-BINDING PROTEINS AND RETINOIC ACID RECEPTORS SUGGESTS A FUNCTION FOR RETINOIC ACID IN DEVELOPING AND ADULT DOPAMINE-INNERVATED BRAIN AREAS. RH Zetterström,¹ A Tomac,¹ M Eriksson,² J Nennesmo,² U Eriksson,³ L Olson.¹ Depts. of ¹Neuroscience and ²Pathology, Huddinge Hospital, Karolinska Institute, and ³Ludwig Institute for Cancer Research, Stockholm Branch, Stockholm, Sweden.

Retinoic acid, the active metabolite of retinoids (vitamin A compounds), is thought to act as a gene regulator via ligand-activated transcription factors. These are retinoic acid receptors (RAR's) and retinoid X receptors (RXR's), both existing in three forms α , β and γ . In the intracellular regulation of retinoids there are also four binding proteins involved: cellular retinol binding protein (CRBP) type I and II and cellular retinoic acid binding protein (CRABP) type I and II. We have used in situ hybridization to localize the possible presence of the mRNA for CRBP I, CRABP I, RAR β and RXR γ in the developing and adult rat brain and immunohistochemistry to also investigate CRBP I- and CRABP I-immunoreactivity (IR). RAR β and RXR γ are extremely highly expressed in the dopamine-innervated areas caudate putamen, nucleus accumbens and tuberculum olfactorium in the newborn. This expression seems to decline during postnatal development. The striatum of the newborn rat is strongly CRBP I-IR in a patch+marginal zone manner, sparing the intervening "matrix," while at the same time containing many evenly distributed CRBP I-IR neurons. In the adult striatum there is much less CRBP I-IR while a population of evenly distributed strongly CRABP I-IR neurons remain. These CRBP I- and CRABP I-patterns are also seen at the mRNA level. Preliminary studies of human postmortem tissue suggest that a similar population of CRABP I mRNA positive- and CRABP I-IR neurons are present in the human caudate and putamen. Our data suggest that retinoids are important in the development and adult dopamine-innervated areas of the brain.

690.13

CHARACTERIZATION OF SOLUBLE FACTOR ACTIVITIES IN DEVELOPING CHICK CILIARY GANGLION - IRIS SYSTEM. B.A. Link, W.R. Woodward*, and R. Nishi. Dept. of Cell Biology and Anatomy, Oregon Health Sciences Univ., Portland OR 97201.

The differentiation of the developing avian iris and innervation by ciliary ganglion neurons is as an excellent system to study neuron-target influences. The developing chick iris is composed of two muscle groups, the myoepithelial or smooth-type muscle constrictor and the striated-type muscle dilator. Myoepithelial cells are believed to further differentiate to the striated-type muscle and give rise to a contractile dilator at E13. Previous studies (Landmesser and Pilar, 1974 J. Physiol. 241:737) have shown that the iris is initially innervated by the ciliary ganglion at embryo day 8 (E8). Coincident with innervation of the iris is a period of cell death in the ciliary ganglion which results in a 50% loss of the neurons. To investigate potential reciprocal influences, we have utilized mitogenic and neurotrophic assays to identify soluble activities from the ciliary ganglion and the target iris. Soluble extracts from E8 to E19 irises were prepared and applied to a heparin-agarose column. Heparin binding and non-binding fractions were tested for ³[H]-thymidine incorporation in murine AKR-2B cells in the presence or absence of exogenous heparin. Neurotrophic activities (+/- heparin) were determined by the ability to support survival of cultured E8 ciliary ganglion (CG) neurons. Soluble extracts from E8 to E14 CGs were assayed for mitogenicity as described. From iris extracts we observed developmental increases in mitogenic activity with the greatest activity in the heparin binding - heparin dependent fraction. We observed iris neurotrophic activity to increase with development in both heparin binding - heparin dependent and non-heparin binding fractions. As in the developing iris, heparin binding - heparin dependent mitogenic activity was found in the ciliary ganglion, but with a less dramatic developmental increase. In vitro differentiation of iris explants is currently being used to assess the roles of these soluble extracts on iris ontogeny.

RELATIONSHIP OF *c-neu* ONCOPROTEINS AND THE EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR) IN DEVELOPING RAT CEREBRAL CORTEX. P.E. Kuhn* and M.W. Miller. Cell. and Devel. Biol., Rutgers Univ., Piscataway NJ 08854, Res. Serv., V.A.M.C., Iowa City IA 52242, and Depts. of Psychiatry and Pharmacology, Univ. of Iowa Coll. of Med., Iowa City IA 52242.

Similarities between *c-neu* oncoproteins and EGFR were examined with antibodies directed against the carboxyl ends of the oncoprotein and the EGFR. During the first two postnatal weeks, both antibodies identified neuronal cell bodies distributed throughout cortex. Hence, both proteins may be interrelated. The transient pattern of oncoprotein immunostaining correlated with the transient expression of a 35 and a 300 kDa protein. The anti-EGFR identified a 50 kDa protein which was expressed transiently during the first two postnatal weeks. After immunoprecipitating cortical tissue with the anti-oncoprotein antibody, evidence of the EGFR + 50 kDa protein in the supernatant was eliminated; the precipitate retained all of the immunolabeling. In the reverse experiment, tissue was immunoprecipitated with the anti-EGFR; the 35 and 300 kDa proteins remained unprecipitated in the supernatant. Immunoprecipitation with either antibody did not affect detection of the oncoprotein + or EGFR + proteins with different profiles of temporal expression. The EGFR + 50 kDa protein shares an epitope with a *c-neu* oncoprotein(s). Thus, the 50 kDa protein (a) forms a heterodimer with a *c-neu* oncoprotein or (b) is a component of a larger *c-neu* oncoprotein (e.g., the 300 kDa protein). Supported by the V.A. and N.I.H. (DE07734, AA06916, and AA07568).

DEVELOPMENTAL INTERACTIONS BETWEEN CHOROID NEURONS AND THEIR SMOOTH MUSCLE TARGET CELLS D.C. Darland, G.G. Leblanc*, and R. Nishi. Department of Cell Biology and Anatomy and †Department of Biological Structure and Function, Oregon Health Sciences University, Portland, OR 97201.

The choroid neurons of the avian ciliary ganglion innervate the smooth muscle cells surrounding the arterial vasculature of the choroid layer of the eye. These neurons are cholinergic and express somatostatin as a neuropeptide. When grown in culture, the smooth muscle cells secrete Activin A (AA), which has been shown to increase the expression of somatostatin in the neurons of the ciliary ganglion. We have characterized the target cells to determine expression of smooth muscle markers over time in culture. The cells lose expression of smooth muscle specific actin (SMA) when placed in culture, but redifferentiate over time. Treatment with bFGF increases proliferation of the cells while suppressing the expression of muscle markers. In contrast, TGF β rapidly increases expression of SMA while suppressing proliferation. We have used RT/PCR to isolate and clone a fragment of AA from E12 choroid, showing that AA is present in vivo, as well as being expressed in vitro. We have initiated studies to examine the time course of AA expression during choroid smooth muscle cell differentiation in culture in addition to parallel studies of AA expression in the choroid layer in vivo.

Transforming Growth Factor alpha immunoreactive nerve fibers in the rat and mouse intestinal tract P. Hoffmann, J. Lakshmanan, J.M. Zeesh, L. Liu, M. Sottili, L. Barajas, M.G. Ervin*, and V.E. Eysselein Harbor UCLA Medical Center, Torrance, CA 90509

Epidermal Growth Factor (EGF) and Transforming Growth Factor α (TGF α) have been shown to modulate mucosal blood flow, mucus production and secretion, and motility in gastrointestinal tissues in addition to their mitogenic actions. These effects are important since they may mediate EGF/TGF α 's capability to protect intestinal mucosa against acute injury. The aim of the present study was to show morphological evidence of the involvement of TGF α in the regulation of the enteric nervous system by demonstrating TGF α immunoreactivity in nerve fibers of stomach and colon in rats and mice. Tissue specimens were fixed in Zamboni's solution, frozen in OCT compound and cut with a cryostat. A polyclonal antibody, raised against conjugated rat TGF α , was used to perform immunohistochemistry. Binding was visualized using an avidin biotin peroxidase technique as described previously. Beaded nerve fibers were detected in the muscle and submucosal layers of stomach and colon in rats and mice. A weak immunoreactivity was also detected in neurons of the myenteric plexus of both species. Detection of TGF α immunoreactivity in neural structures of intestinal tissues gives morphological evidence that TGF α released from these nerve fibers may be the endogenous source to induce EGF/TGF α 's nonmitogenic actions in vivo.

THE EFFECTS OF TRANSFORMING GROWTH FACTOR- α (TGF α) ON NEURONAL AND GLIAL CELLS ON THE DEVELOPING MEDIAL SEPTAL AREA.

I.E. Mazzoni* and R.L. Kenigsberg, Centre de Recherche Pédiatrique, Hôpital Ste-Justine, Montreal, Quebec, CANADA, H3T 1C5.

We have examined the effects of TGF α on different neuronal and glial cell populations in primary cultures of dissociated fetal rat medial septal cells. TGF α , like epidermal growth factor (EGF), was found to induce a dose-dependent decrease in choline acetyltransferase (ChAT) activity which was accompanied by a parallel decrease in the number of acetylcholinesterase positive neurons. The effects of TGF α on ChAT enzymatic activity were first evident after 4 days of continuous exposure to this growth factor. However, although the dose-response profiles of TGF α and EGF on ChAT enzymatic activity were similar (i.e. maximal inhibition evident around 10 ng/ml), TGF α consistently produced a more pronounced inhibition of ChAT activity when compared to EGF in sister cultures. When we combined maximal effective doses of TGF α with those for EGF, the decrease in ChAT activity was not additive, thus suggesting a common mechanism of action for both growth factors. In addition, like EGF, TGF α induced a marked proliferation of astrocytes and microglial cells in the fetal septal cultures without affecting the number of oligodendrocytes. The inclusion of the antimetabolic 5-fluorodeoxyuridine completely abolished both the glial cell proliferation and the decrease in ChAT enzymatic activity induced by TGF α . Consequently, TGF α is indirectly affecting cholinergic cell differentiation via responsive glial cells. Competitive binding studies on different cell populations from the medial septum showed that TGF α is more effective in displacing EGF binding to its high affinity receptor, while the opposite is seen for the low affinity EGF receptor. Finally, although TGF α when applied in the absence or presence of an antimetabolic did not appear to affect the number or glutamic acid decarboxylase (GAD) immunoreactive neurons (GABAergic) as assessed by GAD immunocytochemistry, the intensity of the immunoreaction appeared to be somewhat higher in TGF α -treated cultures when compared to controls. Quantitative effects of TGF α on GABAergic neurons will be examined by measuring GAD activity radiometrically. These results suggest that TGF α can differentially affect neuronal and glial cell populations in the developing rat medial septal area both directly and indirectly.

DOES TGF- β REGULATE CHROMAFFIN CELL PROLIFERATION? N. Wolf, S. Bieger, K. Unsicker* and K. Kriegstein, Dept. of Anat. & Cell Biol., Univ. Heidelberg, D-69120 Heidelberg, Germany.

Transforming growth factor- β s (TGF- β s) are pleiotropic cytokines with prominent roles in the regulation of cell proliferation, migration, differentiation, and extracellular matrix. We have previously found (Flanders et al., Development 113: 1991; Bieger et al., SN Abstr. 19:1993) that sympathoadrenal progenitor cells in the embryonic mouse adrenal gland as well as adult rat and bovine chromaffin cells synthesize and release TGF- β s. Western blotting using an antibody to the TGF- β receptor type II indicates that preparations of bovine adrenal medullary cells also have a TGF- β receptor component. Chromaffin cells of the rat adrenal medulla are capable to divide, in a decreasing fashion, from birth to adulthood (Tischler et al., Int. J. Devl. Neurosci. 7: 1989), and NGF, FGF, and IGFs are known to stimulate synergistically chromaffin cell proliferation in vitro (Frödin and Gammeltoft, PNAS 91:1994). Since a physiological role for the chromaffin cell-derived TGF- β s has not been established as yet, we were interested whether TGF- β would interfere with the capacity of chromaffin cells to divide and respond to various mitogens. Chromaffin cells were dissociated from P6 rat adrenal medullae as previously described and cultured for 7 days under serum-free conditions. Cultures received FGF-2, IGF-II, retinoic acid (RA), and TGF- β 1 in various concentrations and combinations. BrdU was added at 10 μ M during the final two days. Cultures were then processed for the co-visualization of BrdU- and tyrosine hydroxylase immunoreactivities. FGF-2, IGF-II and RA, applied single or in combinations, caused up to 30-fold increases in chromaffin cell proliferation. TGF- β 1, applied at 1, 2.5, or 10 ng/ml, significantly reduced the factor-mediated increases in proliferation. This suggests that TGF- β , released by chromaffin cells, together with glucocorticoids and PACAP (Frödin and Gammeltoft, 1994), which is released from intramedullary nerve terminals, must be considered as negative regulators of chromaffin cell division.

RECOMBINANT HUMAN IGF-1 AND IGF ANALOGUES PROMOTE SURVIVAL OF CEREBRAL CORTICAL AND CEREBELLAR NEURONES IN HYPOGLYCAEMIC CONDITIONS. S.J. Harper, T. Priestley, A. Macaulay, M.A. Cascieri, G.G. Chicchi & R.G. Hill.* Merck Sharp & Dohme Ltd, Terlings Park, Harlow Essex. UK. & Rahway, New Jersey.

Insulin and insulin-like growth factors (IGF-I, IGF-II) are closely related polypeptides which are found in the CNS and which promote neuronal survival and neurite outgrowth. They are each associated with specific cell surface receptors and several soluble binding proteins (IGF-BPs) which are involved in regulating function and availability. The two analogues of IGF-1 were produced by site directed mutagenesis: [Gln3, Ala4, Tyr15, Leu16]IGF-1 and a B chain analogue in which the first 16 amino acids of IGF-1 were replaced by the first 17 amino acids of insulin. These analogues have significantly reduced binding affinity for IGF-BPs. Neuronal cultures were established using embryonic (E15 - E17) rat cortex and Pnd4 rat cerebellum in order to determine whether these IGF analogues were as effective as native recombinant human IGF-1 in protecting against cell death induced by hypoglycaemia. Cultures were maintained in DMEM +10% FCS in the presence of mitotic inhibitors for 5 days (cerebellum) and 6-8 days (cortex). DMEM was then replaced with Lockes solution, a minimal salt solution containing no glucose, or Lockes containing IGF-1 or analogues. After 48 hours, Lockes solution was removed and this and the remaining cells were assayed for LDH, an established method for assaying cell survival. Results are expressed as percentage released LDH of total. In the presence of either IGF-1 or either of the IGF-1 analogues the percentage LDH released from cortical and cerebellar neurones was significantly reduced (approx. 50%) indicating that these growth factors promote survival. More importantly, these data show that the IGF analogues with reduced affinity for IGF-BPs are as effective as IGF-1 in promoting cell survival and their reduced affinity for IGF-BPs has no deleterious effect on their neuroprotective function.

TRANSFORMING GROWTH FACTOR (TGF)- β 1 REGULATES RAT BRAIN TGF- β TYPE II RECEPTOR mRNA LEVELS. T.E. Morgan*, D.K. Sarkar†, W. Vale‡, and C.E. Finch. Andrus Gerontology Center, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191; †Department of VCAPP, Washington State University, Pullman, WA 99164-6520; ‡Salk Institute, San Diego, CA 92186-5800.

TGF- β 1 is a multifunctional peptide that plays an important role in peripheral wound healing. Numerous laboratories have found TGF- β 1 in the damaged and diseased brain and its potential activities are being explored. Three distinct TGF- β receptors are detected in the mammalian central nervous system. Previously, we showed that TGF- β 1 mRNA levels increase in hippocampal microglia after partial deafferentation by unilateral perforant path transection of adult rats. We now report a several fold increase of radioimmunoassay detectable TGF- β 1 peptide in the ipsilateral hippocampus after perforant path transection; moreover, a cRNA probe specific for TGF- β type II receptor detected increased type II receptor mRNA levels in the ipsilateral cortex (area including wound site) and hippocampus after transection. The predominant cell type expressing TGF- β type II receptor mRNA is OX-42 immunopositive (macrophage/microglia). Cultured microglia contain TGF- β type II receptor mRNA. Treatment of cultured microglia with human recombinant TGF- β 1 caused TGF- β type II receptor mRNA levels to increase in a dose-dependent fashion. These results suggest autocrine features in the activities of TGF- β 1 in the rodent brain and continue to implicate microglia/macrophage as a major mediator of TGF- β 1 function in the brain. Supported by Alzheimer's Association Los Angeles Chapter (Turken Award - TEM) and AG-07909 (CEF).

ANALYSIS OF ASTROCYTE PCR PRODUCTS OBTAINED WITH DEGENERATIVE PRIMERS TO TGF β /GDNF. D.O. Dean*, D.G. Schaar, C.E. Dreyfus & J.B. Black. Dept. of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, UMDNJ, Piscataway, NJ 08854.

One of the characteristic features of Parkinson's Disease is degeneration of midbrain dopaminergic neurons. Recently, a new trophic factor, Glial cell line-derived neurotrophic factor (GDNF), which rescues these neurons, has been described. It shares homology with members of the Transforming Growth Factor- β (TGF- β) superfamily through the number and spacing of cysteine residues. Previously, our laboratory has shown that GDNF is expressed by cultured type 1 astrocytes from a number of brain regions. We now report the use of degenerative PCR to isolate TGF- β /GDNF-related cDNAs from two of these regions.

Degenerate PCR primers directed towards amino acid sequences conserved among members of the TGF- β superfamily (and in particular GDNF) were synthesized. RT-PCR was performed, utilizing these highly degenerate primers with total RNA isolated from cultured substantia nigra and cortex type 1 astrocytes as a template. The PCR products were subcloned, classified by insert size and representatives of each sequenced.

We obtained seven different inserts (4 from substantia nigra and 3 from cortex), of which five showed no significant homology to any nucleotide sequence in either the Genebank, or EMBL databases. Four of these sequences also had potential open reading frames. The remaining two sequences were highly homologous (92-96%) to either mouse TFE3 (a transcription factor), or mouse heat shock protein 86 (a member of the hsp90 family). These clones apparently represent the rat homologues of the aforementioned genes.

In sum, we have isolated two previously described and five novel cDNAs. We are presently characterizing the trophic and growth activities of these novel clones, using different brain neuronal populations. Supported by NICHD Program Project HD23315

AURINTRICARBOXYLIC ACID (ATA), A NEUROPROTECTIVE COMPOUND, INDUCED THE TYROSINE-PHOSPHORYLATION CASCADE IN PC12 CELLS.

N. Okada, S. Koizumi*. International Research Laboratories, Ciba-Geigy Japan Ltd., Takarazuka 665, Japan.

ATA is known to protect neurons from apoptotic cell death by inhibiting of calcium-activated endonucleases. With PC12 cells, a neuronal model cell line, ATA prevents cell death under serum free condition. However, direct inhibition of endonucleases by ATA was not observed in isolated nuclei of PC12 cells.

The western blot analysis of PC12 cell lysate with anti-phosphotyrosine antibodies revealed that pre-treatment with 100 μ M ATA for 2 minutes induced phosphorylation of the tyrosine residues of some proteins. The major tyrosine-phosphorylations induced by ATA were not observed in PC12 cells treated by NGF or EGF. However, ATA, as well as NGF or EGF, induced the tyrosine-phosphorylations of PI3 kinase and SHC in PC12 cells. The induction of tyrosine-phosphorylation by ATA was not observed in NIH3T3 cells. Moreover, ATA did not protect NIH3T3 cells from cell death under serum free condition.

These results suggest that the neuroprotective action of ATA is mediated by the activation of a membrane receptor and the subsequent stimulation of the tyrosine-phosphorylation cascade.

CO-ADMINISTRATION OF VASOACTIVE INTESTINAL PEPTIDE (VIP) AND EPIDERMAL GROWTH FACTOR (EGF) ELICITS NEURONAL MORPHOLOGIC DIFFERENTIATION OF PC12 CELLS. D.W. Fink, Jr.* Div. Cytokine Biol., Lab Cell Biol., Center for Biologics Evaluation and Research, FDA, Bethesda, MD 20892.

Cultured PC12 cells possess receptors for and respond to an array of peptide growth factors including nerve growth factor (NGF) and EGF. Addition of either NGF or EGF to PC12 cells elicits activation of cognate tyrosine kinase (TK) receptors resulting in rapid, enhanced tyrosine phosphorylation of a series of substrates that is similar for both NGF and EGF. While NGF promotes neuronal differentiation of PC12 cells, EGF invokes a mitogenic response. The vasoactive peptide, VIP has been reported to promote a partial neuronal differentiation in neuroblastoma cells, an effect attributed to VIP-mediated increases in cAMP levels. The possibility that a combination of EGF-stimulated TK activity and the cAMP-stimulating effect of VIP could support an NGF-like neuronal differentiation response in PC12 cells was investigated.

Co-administration of EGF and VIP to PC12 cell cultures for up to 6 days results in robust neuritic outgrowth. The neurites approximate, in length, those obtained by NGF treatment for comparable periods of time, but are less complex in their arborization. In the presence of 500 nM VIP, the neurite outgrowth response can be obtained with concentrations of EGF as low as 1 ng/ml. The neuronal morphologic differentiation induced by EGF + VIP is not inhibited by the NGF-selective inhibitor, K-252a. These results suggest that peptides such as VIP and EGF which are partial, or ineffective neurotrophic agents may interact cooperatively eliciting a neuronal morphologic differentiation similar to that observed for the identified neurotrophin, NGF. One possible inference suggested by these data is that together, cAMP-dependent protein kinase and tyrosine kinase activities are sufficient to support neurite outgrowth, a characteristic feature of neuronal differentiation.

CSF-1 AND ITS RECEPTOR ARE EXPRESSED IN DEVELOPING BRAIN AND MUTATION OF CSF-1 IMPAIRS BRAIN DEVELOPMENT. M.D. Michaelson*, P. Bieri, J.W. Pollard, M.E. Mehler, H. Xu, J.C. Arezzo, and J.A. Kessler. Depts. of Neuroscience and Dev. & Mol. Biology, Albert Einstein College of Medicine, Bronx, NY 10461.

Colony stimulating factor-1 (CSF-1) was originally identified as a specific growth factor for cells in the mononuclear phagocyte lineage, and subsequently was also found to be an important factor in maternal-fetal regulation. We find that CSF-1 is a growth factor in the nervous system as well. Nuclease protection studies demonstrate that CSF-1 mRNA is expressed *in vivo* in developing and adult mouse brain in various regions, including hippocampus, striatum, cerebellum and cortex. CSF-1 mRNA is found in whole brain samples as early as embryonic day 13, and is detectable through adulthood with some temporal variation. RT-PCR analysis shows splice variants of CSF-1 mRNA are expressed which encode soluble, and not membrane-bound, growth factor. Additionally, mRNA for *c-fms*, which encodes the CSF-1 receptor, is readily detectable in the developing and adult CNS. Regional studies correlate *c-fms* expression with CSF-1 mRNA expression. Treatment of primary cultured neurons from five brain regions with CSF-1 promotes survival and process outgrowth.

To define the role of CSF-1 *in vivo*, electrophysiologic techniques were employed on *ap/op* mice, which are homozygous for an inactivating CSF-1 mutation. These animals display aberrant visual and auditory evoked potentials, using both extracranial and intracranial recordings, indicative of abnormal cortical function. The expression of CSF-1 and its receptor *in vivo*, the effects of CSF-1 on neurons *in vitro*, and the neurological deficits in *ap/op* mice suggest that CSF-1 is an important factor in CNS development.

EFFECT OF DIFFERENTIATION AGENTS ON CHOLINERGIC CHARACTERISTICS OF A HUMAN NEUROBLASTOMA CELL LINE. R.D. Crosland*, Toxinology Div., U.S. Army Med. Res. Inst. Infect. Diseases, Frederick, MD 21702.

LA-N-2 is a cell line derived from a human peripheral neuroblastoma. It has a partially cholinergic phenotype and is a potential *in vitro* model of peripheral cholinergic neurons. It does not demonstrate, however, depolarization-stimulated, Ca^{2+} -dependent release of acetylcholine (ACh). The object of this study was to induce Ca^{2+} -dependent release of ACh in LA-N-2 cells with various differentiation agents.

Cells were treated with 1 mM dibutyryl cAMP (dibucAMP), 0.25 nM leukemia inhibitory factor (LIF) and/or 3.8 nM nerve growth factor, or 10 μ M retinoic acid (RA) for 9-14 days in F12/EMEM with FBS. Treated cells were loaded with [3 H]choline for 30 min at 37° and washed. The amounts of cellular and released (5 min, RT), labeled and unlabeled ACh and choline were determined by HPLC. None of the differentiation agents induced Ca^{2+} -dependent release of [3 H]ACh. Some of them, however, had marked effects on other aspects of cholinergic function. LIF increased [3 H]choline uptake, [3 H]ACh synthesis, and ACh content 250% and Ca^{2+} -independent release of [3 H]ACh 70% compared to untreated cells. RA increased [3 H]choline uptake, [3 H]ACh synthesis, and ACh content 30% and basal release of [3 H]ACh 130%. DibucAMP increased [3 H]choline uptake 20% and decreased ACh content 60%. LA-N-2 cells may be a good model for studying aspects of peripheral cholinergic function.

INHIBITION OF HUMAN NEUROBLASTOMA GROWTH BY A SPECIFIC VIP ANTAGONIST

G. Lilling*, Y. Wollman, M.N. Goldstein, D.E. Brenneman, M. Fridkin and I. Gozes. Sackler Med. Sch., Tel Aviv Univ.; Tel Aviv Med. Cent., Israel; Barnes Med. Sch., Washington Univ., St. Louis MO; SDMP, LDN, NICHD, NIH, Bethesda, MD; Weizmann Inst. Rehovot, Israel.

Vasoactive intestinal peptide (VIP), was shown to be a mitogen for sympathetic neuroblasts (Pincus et al., Nature 343,564,1990), and for human neuroblastoma (cell line-NMB), a tumor of the sympathetic nervous system (Wollman et al., Brain Res. 624,339,1993). Northern blot analysis revealed VIP mRNA transcripts in the neuroblastoma (cell line-NMB) suggesting an autocrine growth factor role for VIP in neurogenesis and tumor propagation. Measurements of thymidine incorporation and cell numbers now showed that a potent VIP hybrid antagonist (neurotensin₁₋₆-VIP₇₋₂₈; Gozes et al., Endocrinology 125,2945,1989) inhibited cell division in this neuroblastoma cell line. The hybrid VIP antagonist also inhibited lung cancer growth (Moody et al., Proc. Natl. Acad. Sci. USA 90, 4345, 1993), indicating a new therapeutic strategy against prevalent cancers including neuroblastoma, the most common solid malignancy of children less than 5 years of age.

PERIOSTEUM ALTERS THE TRANSMITTER PHENOTYPE OF SYMPATHETIC NEURONS. S.E. Asmus*, R.J. Scholtzinger and S.C. Landis. Dept. of Neuroscience, Case Western Reserve Univ., Cleveland, OH 44106.

Factors released by sweat glands induce a phenotypic switch in the sympathetic neurons that innervate the glands. To determine if other sympathetic neurons undergo a target-regulated transmitter switch, the innervation of periosteum, the connective tissue covering of bone, was examined. Adult rat periosteum contained sympathetic fibers characterized by choline acetyltransferase (ChAT) activity and staining for acetylcholinesterase (AChE) and vasoactive intestinal peptide (VIP). Prenatally, however, periosteal innervation displayed noradrenergic properties - catecholamine (CA) fluorescence and tyrosine hydroxylase (TH). During the early postnatal period, periosteal fibers exhibited both TH and VIP. Between postnatal days (P) 14 and 21, the phenotypic transition was complete; CA and TH decreased, while the number of fibers stained for AChE and immunolabeled only for VIP increased. Neonatal treatment with the adrenergic neurotoxin, 6-hydroxydopamine, reduced both the developmental expression of noradrenergic traits and VIP and AChE in the adult, confirming that a transmitter switch had occurred. To determine if periosteum induces the neurochemical switch, periosteal flaps from P2 rats were transplanted under P1 rat hairy skin, which receives only noradrenergic sympathetic innervation. One and two weeks after surgery, TH- and CA-containing fibers were present in the transplants. Four to six weeks after transplantation, no CA were detected, but VIP-containing fibers were observed. To examine possible factors governing the switch, periosteum of transgenic mice with a disruption in the gene for leukemia inhibitory factor (LIF), a cholinergic differentiation factor, were assayed. Identical distributions of VIP and AChE fibers were observed in transgenic and control mice, indicating that LIF is not required for the switch to occur. These results suggest that periosteum, in addition to sweat glands, regulates the neurochemical differentiation of sympathetic neurons and supports the hypothesis that target tissues influence the transmitter expression of their innervating neurons.

690.26

EFFECTS OF 2-CHLOROADENOSINE AND FGF ON MYENTERIC NEURONS IN DISSOCIATED CELL CULTURE. M.J. Saffrey, K.H. Schäfer¹ and G. Burnstock. Dept. Anat. Dev. Biol., Univ. Coll. London, UK and ¹Dept. Anat., Univ. Saarland, Homburg, Germany.

Purines have been reported to have trophic actions in the nervous system, and may act synergistically with growth factors. We have investigated the effects of basic FGF and the stable adenosine analogue, 2-chloroadenosine (2-CA) on neurite outgrowth and survival of enteric neurons in dissociated cell culture. Myenteric ganglia were obtained from postnatal day 7 rat small intestine by a novel method using a combination of enzymatic digestion and mechanical agitation and then dispersed by further enzyme treatment. The resulting cells (neurons and glia) were grown in serum-free medium. After 48 hr, cultures were immunolabelled for the neuronal marker, protein gene product 9.5 (PGP 9.5). The numbers of PGP 9.5 positive neurons were counted and neurite lengths measured using an image analysis system. FGF (10ng/ml) caused a 45% increase in neuronal survival, and an increase in neurite length of 94.8%. 2-CA (10^{-5} - 10^{-7} M) had no effect on neuronal survival, but increased neurite outgrowth in a dose-dependent manner. This increase was maximal (36.9%) at 10^{-5} M and was blocked by the P₁ purinoceptor antagonist, 8-sulphonyl-phenyltheophylline. When 2-CA was added together with bFGF, a greater increase in neurite outgrowth was seen at 2-CA concentrations of both 10^{-5} (158%) and 10^{-6} M (157%). FGF-induced neuronal survival was unchanged upon addition of 2-CA. The proportion of process-bearing neurons increased in the presence of both agents. The ratio of neurons to glial cells was similar in all conditions. These observations indicate that bFGF promotes both survival and neurite outgrowth of enteric neurons and that purines may not only directly influence neurite outgrowth, but also possibly act synergistically with FGF on neurite outgrowth in this system. Thus interactions between purines and trophic factors may be of importance in the development and regeneration of enteric neurons.

691.1

EFFECTS ON DEVELOPMENTAL AND ADULT NEUROCHEMISTRY OF CHRONIC NEONATAL TREATMENT WITH AN INHIBITOR OF ORNITHINE DECARBOXYLASE IN THE RAT. A. Contestabile, M. Sparapani, M. Virgili, F. Facchinetti and E. Ciani (Spon: European Neuroscience Association), Dept. of Biology, Univ. of Bologna, Italy.

Neonatal rats were treated from postnatal day 0 to 24 with daily s.c. injections of the suicide ornithine decarboxylase inhibitor, DFMO. In addition to some somatic effects, the treatment resulted in permanent decrease of brain weight which was mainly due to a 40% decrease of the cerebellum. While ornithine decarboxylase inhibition was only effective during the first phase of the treatment, the levels of putrescine and spermidine were decreased in the cerebellum and forebrain up to 3 days after the end of the treatment. Significant alterations of neuronal and glial chemical markers were measured in the cerebellum of treated rats once adults. Developmental treatment with DFMO activates some mechanism able to keep low levels of putrescine and spermidine even in the presence of a progressive lack of ornithine decarboxylase inhibition. Furthermore, low developmental levels of the two polyamines mainly affect regions where substantial neurogenesis does occur during the treatment, such as the cerebellum.

691.3

MOTOR ABNORMALITIES INDUCED BY X-IRRADIATION AT BIRTH ARE DELAYED BY PERINATAL GM1 TREATMENT.

L. R. Guelman, A. M. Dopico, D. E. Thierer* and L. M. Zieher. Departamento de Farmacología, Facultad de Medicina, U.B.A. Paraguay 2155 piso 15 (1121) Buenos Aires, Argentina.

Since GM1 was reported to enhance neurite formation after damage of central neurons by different agents, we study its effects on motor abnormalities and neurochemical changes in cerebellum (CE) induced by a 5 Gy single dose of X-rays (X) applied to rats up to 72 h after birth. GM1 30 µg/g were s.c. injected using different protocols: 1) 4 daily doses after X; 2) 1 dose 1 h before and other immediately after X; 3) 3 daily doses before and 3 daily doses after X. Noradrenaline (NA) was assayed fluorimetrically and motor function was quantified using an "ad-hoc" test.

At postnatal day (PN) 30, indicators of motor function in X-treated rats that received GM1, no matter the protocol used, returned to nonirradiated values. However, at PN 90 no differences in motor function were found between GM1-treated and uninjected exposed rats, except for protocol 1. None of the protocols modified the changes in NA levels induced by X.

Then, GM1 (in particular, when repeatedly administered after X) may produce a long-term delay in the appearance of X-induced motor abnormalities, probably due to an action(s) on central pathways involved in motor output.

691.5

RECOMBINANT HUMAN GLIAL GROWTH FACTOR: TEMPORAL KINETICS AND SIGNAL TRANSDUCTION IN SCHWANN CELLS.

C.J. Hoban, J. Sudhalter, N. Mahanthappa, S. M. Goldin*, D. Gwynne and C. Kirk. Cambridge Neuroscience Inc. One Kendall Square, Building 700, Cambridge, MA 02139.

Glial growth factors (GGFs) are products of the neuregulin gene family that are expressed in the nervous system (Marchionni *et al.*, Nature 362:312-318, 1993). Recombinant human GGF2 (rhGGF2) is a potent mitogen for Schwann cells. We examined two aspects of rhGGF2 action on Schwann cells *in vitro*: the temporal kinetics of DNA synthesis and activation of signal transduction pathways. Purified rhGGF2 stimulates DNA synthesis in both a dose and time dependent manner. Exposure to rhGGF2 for various time periods before the addition of ³H-thymidine labeling media stimulates DNA synthesis maximally when added at 22 hr, 50% when added at 7 hr and 20% when added at times less than 2 hr (to 5 min).

In addition, we have used compounds that inhibit either tyrosine kinases or protein kinase C (PKC) to determine if the signal for DNA synthesis is acting through these signal pathways. We show that induction of DNA synthesis by rhGGF2 is inhibited by either staurosporine, a PKC inhibitor, or genistein, a tyrosine kinase inhibitor. Our data suggest that rhGGF2 can stimulate DNA synthesis in Schwann cells through two different signal transduction pathways, a PKC-mediated as well as a receptor-tyrosine kinase pathway. We also examined the early events stimulated by rhGGF2 on second messenger pathways that signal directly to the nucleus. Within 1 hr of treatment, rhGGF2 activates several transcription factors to bind to DNA. These data describe some of the earliest events that are initiated through the binding of rhGGF2 to high affinity cell surface receptors on Schwann cells that lead to the generation of a mitotic signal.

Because rhGGF2 is an important growth regulator for several distinct cell types, our goal is to determine the biochemical basis for these pleiotropic responses induced by rhGGF2 effects in different cell types and tissues.

691.2

NEUROTROPHIC EFFECTS OF PIGMENT EPITHELIUM-DERIVED FACTOR (PEDF) ON CEREBELLAR GRANULE CELLS IN CULTURE. T. Taniwaki*, S.P. Baccera †, G.J. Chader †, J.P. Schwartz. Clinical Neuroscience Branch, NINDS, and †Laboratory of Retinal Cell and Molecular Biology, NEI, NIH, Bethesda, MD 20892

Pigment epithelium-derived factor (PEDF) is a neurotrophic agent identified and purified from conditioned medium of retinal pigment epithelium cells. PEDF has been shown to enhance neurite outgrowth and neuronal differentiation in human Y-79 retinoblastoma cells. It became of great interest to determine whether PEDF has neurotrophic effects on neurons in primary culture from central nervous system regions other than the eye. Cultures of cerebellar granule cells, prepared from 8-day postnatal rats, were treated with 5-500 ng/ml recombinant human PEDF. The PEDF-treated group contained more cells compared to the control group, when assayed either by the MTS assay (aqueous soluble tetrazolium formazan assay) or by immunocytochemistry for neuron-specific enolase. The difference became larger with longer culture times (up to 7 days) and was dependent on the dose of PEDF. Furthermore, the effect was 10-20 fold larger in the absence of serum than in its presence. PEDF had no effect on incorporation of BrdU (mitosis). Use of an enzyme-linked immunoadsorbent assay to measure neurite outgrowth showed no effect of PEDF on neurite extension. Fragments of rPEDF lacking the reactive site for serine protease inhibitor (serpin) still possess neurotrophic activity. These results demonstrate that PEDF has a neurotrophic survival effect on cerebellar granule cells in culture which is not related to serpin activity such as is seen with the glia-derived nexins.

691.4

RECOMBINANT HUMAN GLIAL GROWTH FACTOR SUPPORTS THE PROLIFERATION OF HUMAN SCHWANN CELLS *IN VITRO*. J. L. Rutkowski¹, C. J. Kirk², M. Lemer¹, R. Toms², A. G. Knapp², and G. I. Tennekoon¹.

¹Dept. of Pediatrics, Univ. of Michigan, Ann Arbor, MI 48109, and ²Cambridge NeuroScience, One Kendall Square, Bldg. 700, Cambridge, MA 02139.

Glial growth factors (GGFs) belong to a family of growth factors including the heregulin and neu differentiation factor that arise from the same gene by alternative splicing. Products of this gene initiate diverse biological functions in different cell types. Human and bovine cDNA clones encoding several mRNA isoforms have been identified, and a recombinant human protein (rhGGF2) was shown to stimulate the proliferation of rat Schwann cells *in vitro*. We examined the mitogenic activity of rhGGF2 on human Schwann cells by bromodeoxyuridine (BrdU) incorporation using an ELISA. Whereas rat Schwann cells respond similarly to either human or bovine GGF, an increase in BrdU uptake could only be observed in human Schwann cells when treated with rhGGF2. The EC50 for rhGGF2 was approximately 170 pM in both species. Due to the possibility of fibroblast contamination, stimulation of DNA synthesis was confirmed in human Schwann cells by double-labeling with antibodies to s-100 and BrdU. Moreover, rhGGF2 was effective in expanding human Schwann cell cultures in the presence of cAMP-elevating drugs which both synergize with rhGGF2 and suppress fibroblast growth. The population doubled every 5-7 days, and the cells have been carried at least 10 passages. The ability to generate large numbers of human Schwann cells *in vitro* will facilitate studies on nervous system transplantation and mechanisms of human peripheral nerve disease. (Supported by NS21700 and the Johns Hopkins Center for Alternatives to Animal Testing.)

691.6

A ROLE FOR SCHWANN CELL-ASSOCIATED HEPARAN SULFATE IN MODULATING THE ACTIVITY OF THE NEUREGULIN, rhGGF2.

J. Sudhalter, N. K. Mahanthappa, J. Lucas, E. Gamzu*, and M. A. Marchionni. Cambridge NeuroScience, 1 Kendall Sq., Bldg. 700, Cambridge, MA 02139.

Glial growth factor 2 (GGF2) is a potent Schwann cell mitogen, which is expressed in neurons and is one of several products of the neuregulin gene (Marchionni *et al.* 1993, Nature 262: 312-318). Previously Ratner and co-workers (PNAS 85: 6992-6996, 1988) described a neuronally-associated Schwann cell mitogen bound to cell surface heparan sulfate proteoglycan (HSPG) whose mitogenic activity can be inhibited by heparin. Several products of the neuregulin gene have been purified using heparin affinity chromatography, and Schwann cells have HSPG associated with both their plasma membrane and their basement membrane (Carey *et al.* 1987, JCB 105: 1013-1021). We have thus investigated the effects of heparin on the biological activity of rhGGF2. We show that heparin inhibits the mitogenic activity of rhGGF2 and blocks p185 receptor tyrosine kinase activation on Schwann cells. In contrast, D-glucuronic acid and chondroitin sulfate A had no effect. Heparin added to other known Schwann cell mitogens (bFGF, PDGF-BB) produced little or no inhibition. When Schwann cells were treated with 4-methylumbelliferyl-B-D-xyloside to inhibit proteoglycan assembly, we observed a nearly total loss of mitogenic response to rhGGF2. We hypothesize that rhGGF2 may contain a heparin binding domain and acts through cell-surface HSPGs to mediate its effects. This co-receptor model of biological activation, which consists of HSPG and a high affinity tyrosine kinase receptor for maximal activity is well-supported for other heparin-binding growth factors (Rapraeger *et al.* 1991, Science 252:1705-1707; Higashiyama *et al.* 1993, JCB 122: 933-940).

PROMOTION OF PERIPHERAL NERVE REGENERATION BY A SOLUBLE NEUREGULIN, rhGGF2: STUDIES OF AN ENTUBULATION MODEL *IN VITRO*. N. K. Mahanthappa*. Cambridge Neuroscience, One Kendall Sq., Bldg. 700, Cambridge, MA 02139.

Glial growth factors (GGFs) comprise a group of proteins, first identified in bovine pituitary extract, that promote the proliferation of Schwann cells *in vitro* (Marchionni et al. 1993, Nature 362:312-318). Recombinant human GGF2 (rhGGF2) is one of several differentially-spliced products of the neuregulin gene. We have previously shown that rhGGF2 promotes Schwann cell proliferation without significantly affecting the expression of a number of Schwann cell associated proteins (Birmingham-McDonogh et al. 1993, Soc. Neurosci. Abstr. 19:1098). The proliferative activity may be of therapeutic utility in peripheral nerve damage and disease. Since Schwann cells are known to provide trophic support for a variety of neural populations, simple expansion of the resident Schwann cell population in a site of disease or damage may promote regeneration and survival.

The goal of the current study is to examine the therapeutic utility of GGF2 in the promotion of nerve regeneration by analyzing an *in vitro* model of the entubulation surgery commonly used to treat peripheral nerve gap injuries. In the current model, a fragment of neonatal rat superior cervical ganglion is placed in one end of a segment of polyethylene tubing (1.9 mm x 10mm) that has been filled with culture medium containing bovine dermal collagen \pm rhGGF2. The collagen is allowed to gel and the tubes are maintained in culture for up to 10 days. Preliminary results suggest that rhGGF2 promotes Schwann cell proliferation, and Schwann cell invasion of the tube in a dose-dependent manner.

691.9

GLIAL GROWTH FACTOR 2, A NOVEL MUSCLE TROPHIC FACTOR. B. M. Sklar, G. Gao, C. Kirk, I. Isaacs, D. Gwynne*, R. McBurney, M. Marchionni, Cambridge Neuroscience, One Kendall Square, Bldg. 700, Cambridge, MA 02139

Recently, the expression of one or more products of the neuregulin gene in peripheral and motor neurons has been described by *in situ* hybridization (Marchionni, et al., Nature 1993;362:312-318). One of these neuregulins, acetylcholine receptor-inducing activity (ARIA), has been shown to stimulate the expression of several genes encoding components of the developing neuromuscular junction in chick muscle culture (Falls, et al., Cell 1993;72:801-815; Corfas & Fischbach, J. Neuroscience 1993;13:2118-2125). A secreted form of neuregulin, rhGGF2, has been cloned, based on its mitogenic activity on Schwann cells, and expressed in CHO cells. The possibility that rhGGF2 may have trophic effects on muscle cells in culture was investigated. rhGGF2 was mitogenic for subconfluent quiescent human myoblasts, but did not inhibit myoblast fusion. Differentiation of clonal human myoblasts in the continuous presence of rhGGF2 resulted in greater numbers of myotubes after six days of differentiation (Sklar, et al., J. Cell. Biochem. 1994;18D:540). The increase in myotube numbers was the result of an inhibition of myotube death as measured by propidium iodide uptake. rhGGF2 effects on muscle culture suggest that this neuronal-derived factor may regulate muscle growth *in vivo*.

β -A ACTIVIN IS REGULATED BY SYNAPTIC ACTIVITY AND IS EXPRESSED IN THE DEVELOPING RAT BRAIN. K. I. Andreasson*, C. A. Barnes and P. F. Worley. Depts of Neurology and Neuroscience, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205, and Depts. of Neurology, Psychology and Div. of Neural Systems, Univ. of Arizona, Tucson, AZ 84724

β -A activin is a member of the transforming growth factor β superfamily of secreted proteins. By differential screening, we have identified it to be rapidly regulated by neuronal activity. β -A activin mRNA is induced in the dentate gyrus with a single maximal electroconvulsive shock within one hour and peaks at two hours. β -A activin mRNA is induced in NMDA dependent synaptic stimulation. In chronically implanted animals, β -A activin mRNA is strongly induced in hippocampal granule cells ipsilateral to high frequency LTP stimulus one hour after treatment. This induction is eliminated with pretreatment of the animals with MK-801. In adult brain, β -A activin is expressed at basal levels in layers II/III and V/VI of the cortex and in the dorsal striatum. Treatment with MK-801 abolishes basal expression in layers II/III and significantly reduces expression in layers V/VI, indicating that expression of β -A activin mRNA is dependent on excitatory glutamatergic synaptic activity. Deafferentation of the visual cortex with the intraocular injection of tetrodotoxin reduces basal expression of β -A activin in monocular visual cortex in layers II/III and V/VI. In developing brain, β -A activin mRNA is expressed in cortical plate of fetal and post-natal brain, as well as in the differentiating neurons of the developing striatum. Expression is maximal in cortical plate around the time of birth and steadily decreases until baseline levels are reached between post-natal days 10-15. The expression of β -A activin is an example of differential regulation of an immediate-early gene in developing and synaptically active adult brain. Supported by HD00992, AG09219, and EY09347.

CONTROLLED RELEASE OF rhGGF2 FROM A MICROPOROUS COLLAGEN/COMPOSITE MEMBRANE. S. M. Goldin, C. Kirk, L. J. Martin*, R. Toms, E. M. Taylor, F. R. Wason, and J. Sudhalter. Cambridge Neuroscience, 1 Kendall Square, Bldg. 700, Cambridge MA 02139.

To optimize the therapeutic potential of growth factors in nerve regeneration, it is desirable to control their delivery to the site of nerve repair. Recombinant human glial growth factor 2 (rhGGF2), a product of the neuregulin gene, stimulates rat Schwann cell proliferation and DNA synthesis in cell culture [Marchionni et al. 1993, Nature 362:312]. The half-life of biological activity is less than 24 hours when soluble rhGGF2 is added to a polyethylene nerve guide tube reconnecting the two cut ends of rat sciatic nerve. The initial goal of this study was to determine whether rhGGF2 can be immobilized and released in quantities sufficient to enhance Schwann cell proliferation within a nerve guide tube. This technology will then be employed in a rat sciatic nerve model of nerve repair. A composite microporous structure incorporating collagen has been developed for this purpose. RhGGF2 was exposed to this microporous membrane (thickness 150 μ m) under mildly acidic conditions. Under these conditions secondary bonds within the collagen matrix are broken, and reform when the pH is raised in a manner that incorporates rhGGF2 within the membrane.

Employing stimulation of Schwann cell [125 I]-uridine incorporation *in vitro* as a marker for release of rhGGF2, the rate of release was determined to exceed 0.5×10^{-6} pmole/hr per mm² of membrane surface over a period of at least two weeks. A mathematical model of a 1.4 mm diameter nerve guide tube lined with this membrane predicts that at the aforementioned release rate, [rhGGF2] would increase at a rate of >10 pMolar per hour. Based on preliminary estimates of the half-life of soluble rhGGF2 within a nerve guide tube *in vivo* in rats, and an EC50 of ~ 100 pM for stimulation of Schwann cell proliferation ([125 I]-uridine incorporation) *in vitro*, the model predicts that by this means of controlled release, [rhGGF2] will exceed that required for stimulation of Schwann cell mitogenesis for a two week period.

NEUREGULIN, rhGGF2, STIMULATES TRANSCRIPTION OF THE AChR DELTA SUBUNIT GENE. S. A. Jo*, M. A. Marchionni², I. J. Isaacs², and S. J. Burden¹. ¹Biology Department, Massachusetts Institute of Technology, Cambridge, MA 02139 and ²Cambridge Neuroscience Inc., One Kendall Square, Building 700, Cambridge, MA 02139.

Motor neurons induce the aggregation of acetylcholine receptors (AChR) at neuromuscular synapses. We have shown that a signal in the synaptic basal lamina at the neuromuscular synapse stimulates transcription of the AChR δ subunit gene in the synaptic nuclei of skeletal myofibers (Jo and Burden, Development 115: 673-680, 1992). Because the neuregulin gene is known to encode an AChR-inducing activity, ARIA (Fall et al., Cell 72: 801-815, 1993), we were interested in determining whether products of the neuregulin gene might be the basal lamina signal. We treated C2 myotubes, which were stably transfected with a gene fusion between 1.8 kb of 5' flanking DNA from the AChR δ subunit gene and the human growth hormone (hGH) gene, with neuregulin (rhGGF2, Marchionni et al., Nature 362: 312-318, 1993), and we found that neuregulin causes a 2.4 fold increase in hGH expression. In contrast, neuregulin did not increase hGH expression from C2 myotubes stably transfected with a metallothionein promoter-hGH gene fusion. Thus, neuregulin activates transcription of the AChR δ subunit gene. Moreover, RNase protection assays show that neuregulin increases the level of endogenous δ and ϵ subunit mRNAs by 2-fold and 4-fold, respectively. Neuregulin induces the rapid tyrosine phosphorylation of a p185 protein in C2 myotubes, indicating that neuregulin regulates transcription of AChR gene through tyrosine phosphorylation. In addition, we show that the *cis*-acting elements for neuregulin-mediated stimulation of δ subunit gene expression are contained in the same 181 bp of 5' flanking DNA from the AChR δ subunit gene that confers synapse-specific expression *in vivo*.

TRANSMISSION ELECTRON MICROSCOPY REVEALS A REDISTRIBUTION OF MAP2 IN NEURO-2A NEUROBLASTOMA CELLS AFTER GANGLIOSIDE TREATMENT. L.-J. Wang, G. Yorke*, R. Colella and F. J. Roisen. Dept. of Anat. Sci. & Neurobiol., Univ. of Louisville Sch. of Med., Louisville, KY 40292.

Our previous immunofluorescent studies of Neuro-2a cells exposed to ganglioside GM1 demonstrated enhanced microtubule (MT)-dependent neuritogenesis, increased microtubular network density, and a redistribution of MAP2 from the perikarya to the distal neuritic processes. In the current study, immunogold-labeled specimens were analyzed with computer assisted morphometry. Neuro-2a neuroblastoma were grown *in vitro* with or without GM1 (150 μ g/ml) for 24 hr and embedded in Lowicryl. Thin sections were incubated with anti-tubulin and anti-MAP2 and colloidal gold labeled second antibody, 10 and 20 nm respectively. The number of gold particles per μ m² was determined in the microspines, neuritic processes and perikarya of a minimum of 50 cells per treatment group. The results demonstrate that: (a) GM1 enhances the area of spine-like projections ($p < 0.05$); (b) more MAP2 per unit area was found in spine-like projections after GM1 treatment ($p < 0.001$); (c) more MAP2 was found in neurites after GM1 exposure ($p < 0.05$); and (d) MAP2 seems more closely associated with actin-rich subcortical cytoplasm than with MT. In contrast, the location of tau protein, another MAP, was not changed after GM1 treatment. These results are consistent with previous qualitative studies demonstrating that GM1 increases the spine-like projections. Since MAP2 is associated with actin in dendritic spines, perhaps GM1 shifts MAP2 from interactions with MT to actin-filaments which form the basis of growth cone development. This suggests that gangliosides may be involved in the determination of axonal or dendritic fate by selectively changing the distribution of MAP2 and thus regulating microtubule stability and actin-mediated growth cone activity. Studies are in progress to determine the effect of GM1 on the synthesis of MAP2 and tau protein. Supported by a grant from Alliant Community Trust Fund, Louisville, KY.

ANTIBODY TREATMENT IN VIVO AS A MEANS OF BLOCKING PROTEIN ACTIVITY: EFFECTS ON INTRAOCULAR GRAFTS OF ANTI-INSULIN LIKE GROWTH FACTOR-1 AND ANTI-CELLULAR-CELL ADHESION MOLECULE ANTIBODIES. **MB Giacobini¹, VR Sara², B Öbrink³, L Olson¹**. ¹Dept of Neuroscience, ²School of Life Science, QUR Karolinska Institutet, Stockholm, Sweden, ³School of Life Science, QUR Gardens Point Campus, Brisbane, Australia.

Blocking antibodies can be used in order to study the normal roles of proteins such as trophic factors and cell adhesion molecules in the developing brain by reducing or eliminating the effects of these factors. The role of IGF-1 in olfactory bulb maturation was studied using the technique of intraocular transplantation. Olfactory bulbs from E15-E17 fetuses were transplanted into the anterior chamber of the eye of adult host rats. Transplants were treated with either 300 ng truncated IGF-1, two different IGF-1 polyclonal antisera, two different non-immune sera, 15 µg IGF-1 binding protein, or vehicle alone. Treatments were administered by preincubation just prior to grafting and by 5 µl injections into the anterior chamber on days 5, 10 and 15 postgrafting. Olfactory bulb grafts grew significantly larger after treatment with IGF-1 antisera treatment than after any of the other treatments. Similar anti-IGF-1 antibody treatment of grafts of cerebral cortex had no such effect. Immunohistochemical studies of the olfactory bulb grafts revealed no detectable differences between treatments with regard to several markers tested. These studies have established a system for studying the endogenous effects of trophic factors on developing brain tissue by antibody treatments. Studies of the role of the cell adhesion molecule C-CAM during brain development is currently under progress using a similar experimental paradigm.

691.15

EXPRESSION AND REGULATION OF ESTROGEN RECEPTOR (ER) AND ITS MRNA IN A SUBPOPULATION OF RAT DORSAL ROOT GANGLION NEURONS **M.M. Oblinger*, J. Pickett, N. Taleghany, L. DonCarlos¹** Dept. Cell Biol. and Anat., Chicago Med. School, North Chicago, IL and ¹Dept. Anat. and Neurobiol., Loyola Univ., Chicago, IL

While considerable information is available on estrogen receptors (ER) in brain, very little is known about the expression and functional roles of ER in peripheral neurons. A recent study using in situ hybridization histochemistry with oligonucleotide probes reported that virtually all dorsal root ganglion (DRG) neurons in rat express ER mRNA (Sohrabji et al., 1994, J. Neurosci. 14:459). In the present study, we re-examined this issue using immunocytochemistry to study ER protein localization in the DRG, in situ hybridization with ³³P-labeled cRNA probes to examine ER mRNA in various lumbar (L3-6) DRG, and PCR to amplify ER mRNA sequences from the DRG. DRG were harvested from adult female Sprague Dawley rats 21 days after ovariectomy with either continuous hormone replacement via implants of 17β-estradiol-filled capsules (+E), or with no hormone replacement (ovx). Immunocytochemistry revealed robust nuclear staining for ER in many of the small-sized DRG neurons, but only infrequent staining of large and medium-sized cells. In situ hybridization also showed that ER mRNA expression was significant in the small, nociceptive DRG cells but less apparent in large neurons. ER labeling in the DRG was higher in the ovx than in the +E group, and more ER-positive neurons were apparent in L6 DRG compared to other lumbar ganglia. Preliminary findings on ER function in the DRG indicate that the expression of several proteins localized to small cells, such as peripherin, varies with the estrogen status of the animal.

EXPRESSION OF THE MONOCYTE CHEMOATTRACTANT JE/MCP-1 FOLLOWING CEREBRAL CORTICAL LESIONS.

R.M. Klein*, W.-L. Liu, E. Hausmann, and N.E.J. Berman. Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS 66160-7400

Monocyte chemoattractant protein-1 (MCP-1), the product of the mouse early response gene JE, is a chemokine which is stimulated by the cytokine, tumor necrosis factor alpha (TNF-α) and by IgG. In previous studies, we have shown that injured neurons express TNF-α and Fc receptors, suggesting that they may provide signals which direct CNS repair processes. In the present studies, we examined expression of JE/MCP-1 following lesions of the visual cortex. Aspiration lesions of posterior cortex were made in mice. Following a 2 day survival, RNA was extracted from the lesioned and nonlesioned hemisphere. RNA from intact mouse brain was used as a negative control, and RNA from LPS-stimulated J774 cells was used as a positive control. Northern analysis was performed to detect JE/MCP-1 transcripts. Samples from injured cortex showed expression of JE/MCP-1, which was absent from intact brain and from the uninjured hemisphere. Taken together, our results suggest that injured neurons produce signals such as TNF-α which stimulate expression of chemoattractant factors such as JE/MCP-1. This chemokine attracts cells of the monocyte-macrophage lineage to the site of injury where they function in phagocytosis and direction of tissue remodeling. Supported by MH38399, HD02528 and NS32202.

EFFECT OF THROMBIN AND 14-AMINO ACID PEPTIDE AGONIST OF THROMBIN RECEPTOR ON PURE OR MIXED GLIAL CO-CULTURES OF SEPTAL NEURONS. **Th. Debeir, J. Benavides and X. Vigé.** Synthelabo Recherche, Preclinical Research Department, BP 110, 92225 Bagneux Cedex, France.

A role of thrombin in neuropathological processes is suggested by the fact that this protease is secreted by glial cells. An imbalance between thrombin and PN-1 (its natural inhibitor) seems to be involved in the pathogenesis of several neurological diseases including Alzheimer's disease. In vitro thrombin alters neurite outgrowth and, at low concentrations, increases choline acetyl transferase (ChAT) activity in a mixed neurons/glia culture of septal cells. To characterize further the effect of thrombin on cholinergic neurons we have compared the effect of thrombin and of the 14-amino acid peptide agonist of the thrombin receptor on a pure culture of septal neurons and on co-cultures of septal neurons/glia. Septal cells were grown in defined medium, onto a monolayer of glial cells for co-cultures. Cells were treated one day after plating. ChAT activity and MTT reduction (index of cell viability) were assayed at the 5th day in vitro.

In pure septal neurons, low concentrations of thrombin (up to 30 nM) did not affect ChAT activity or MTT reduction. However, 100 nM thrombin decreases ChAT activity and MTT reduction by 44% and 17%, respectively. In co-cultures, thrombin displayed a biphasic effect. Low concentrations (1 nM) increased ChAT activity by two fold whereas high concentrations (100 nM) decreased it (-83%). At the high concentration, thrombin was neurotoxic, as indicated by a large decrease in MTT reduction (-90%). Thrombin effects on ChAT activity were partially mimicked by the 14-amino acid peptide both in septal cells (no effect at 0.1 µM and -63% at 100 µM) and in co-cultures (+17% at 0.1 µM and -28% at 100 µM). This peptide did not affect MTT reduction. Thus, thrombin's effects on cholinergic neurons seem to be mediated, at least in part, by thrombin receptors and glial cells seem to play a major role in thrombin action.

STEROID AND NEURONAL REGULATION OF THE INDEPENDENT FATES OF NUCLEI OF MUSCLE DEO1 DURING METAMORPHOSIS IN *MANDUCA SEXTA*. **C. D. Wright* and J. W. Truman.** Department of Zoology, University of Washington, Seattle WA 98195

Metamorphosis in the moth *Manduca sexta* involves a dramatic reorganization of the skeleton and neuromuscular system. To understand the regulation of this reorganization, we have focused on the fate of a larval, abdominal body-wall muscle, DEO1. This muscle degenerates after pupal ecdysis and then regrows to become the adult muscle DE5. Examination of the muscle at the time of pupal ecdysis revealed 2 classes of nuclei. Using the terminal deoxynucleotidyl transferase method to detect degraded DNA, we found that one class of nuclei undergo degeneration starting on day 2 after ecdysis. At the same time, the other set of nuclei show incorporation of bromodeoxyuridine indicating the initiation of mitogenesis and the start of growth of muscle DE5. Both nuclear degeneration and nuclear proliferation require the rise in the titer of steroid hormones, the ecdysteroids, which occurs after pupal ecdysis. In addition, axotomy experiments show that intact innervation is required for the mitogenesis but not for the nuclear degeneration. Hence, the muscle regrowth requires a local cue from the motoneuron as well as the systemic cue provided by the steroid.

PURIFICATION OF CRANIN, A MUCIN-LIKE LAMININ BINDING MEMBRANE PROTEIN, FROM ADULT SHEEP BRAIN. **N. R. Smalheiser* and E. Kim.** Dept. of Pediatrics, MC 5058, Univ. of Chicago, Chicago, IL 60637.

Cranin is a 120 kDa integral membrane glycoprotein which binds the long arm of laminin in a calcium-dependent manner, and which expresses carbohydrate chains susceptible both to N-glycanase and O-glycanase (J Neurosci Res 36: 528 '93). Because of its extremely low abundance in brain membranes, we have undertaken to purify cranin from adult sheep grey matter. Tissue (2 kg) was homogenized, crude pellets rinsed with high salt/urea buffer, and solubilized in NP40 buffer. After sequential elutions from DEAE, con A and Jacalin lectin columns, material was passed over laminin affinity beads (at physiologic ionic strength) and eluted with 10 mM EDTA/EGTA. Repeating the last step purified cranin nearly to homogeneity, with a yield of ~100 µg as assessed by amino acid analyses. Aliquots of cranin which are detected strongly by laminin-binding and lectin blotting assays (con A, Jacalin or PNA) do not stain well by Coomassie Blue or silver stains. Cranin isolated from either E14 chick or adult sheep brain exhibited charge heterogeneity in 2-D blots, with pI centered at 5.7. It was readily digested by O-sialoglycoprotease, which selectively attacks proteins with a high density of sialylated O-linked saccharides. Though cranin appears to be distinct from dystroglycan (pI = 3.7), it closely resembles a set of low abundance selectin-binding proteins described in the immune system, both in their mucin-like modifications as well as similarities in binding their respective ligands (calcium dependent, inhibited by periodate oxidation, inhibited by fucoidin and sulfatides). Supported by NIH NS 26055, HD 09402.

CHARACTERIZATION OF HCNP PROCESSING ENZYME.

Y.Otsuka, K.Ojika*, Y.Tsugu and N.Matsukawa. 2nd Dept. of Int. Med., Nagoya City Univ. Med. Sch., Nagoya 467, Japan.

HCNP is a peptide which stimulates acetylcholine synthesis in medial septal nuclei explant culture. The peptide consists of eleven amino acids located at N-terminal lesion of its pro-protein, and suggested to be processed by the cleaving enzyme. We characterized the HCNP processing enzyme in Wistar rat hippocampus. Hippocampus from 10-11 day old rats were sonicated in 50mM MES-NaOH buffer (pH6.0) containing 150mM NaCl, 3mM KCl, 1mM EDTA and 1mM DTT, and centrifuged at 15000rpm for 20min. The supernatant was incubated at 37°C with purified HCNP pro-protein or synthetic peptide which consisted of 26 amino acids from N-terminal of the HCNP pro-protein. The reaction was terminated by adding TFA and subjected to HPLC equipped with C18 column to measure the enzyme activity. The activity was determined by the height of the peak with retention time identical to that of de-acetylated HCNP (free-HCNP) in the HPLC. The peak was also analyzed by amino acid sequencer and mass spectrum, and confirmed it as free-HCNP. The enzyme was eluted between 58-100kDa in the molecular sieving column, and retained on DEAE column at pH7.6 and G-Butyl column at pH6.0. Optimal pH of the enzyme activity was 5-6, and the activity was inhibited by Chymostatin and E-64.

CLONING AND CHARACTERIZATION OF A NEW FACTOR RELATED TO ARIA/NDF/GGF. H.Chang and W.Gilbert*. Dept. of Cell. and Mol. Biol., Harvard Univ., Cambridge, MA 02138.

Alternative spliced products of the ARIA/Neu differentiation factor (NDF)/Glial growth factor (GGF) gene have a wide range of activities, including stimulation of glial cell proliferation and regulation of acetylcholine receptor synthesis in muscle. Early experiments suggested that NDF is the ligand for the Her2 receptor, a member of the EGF receptor family. But more recent results indicated that NDF directly interacts with the Her4 receptor, another member of the EGF receptor family, raising the possibility that additional factors similar to ARIA/NDF/GGF may be the ligand for Her2. We used a PCR-based strategy to identify new factors related to ARIA/NDF/GGF, and cloned a new gene from an adult rat brain cDNA library. The new factor contains both the Ig-like domain and the EGF-like domain, and has a domain structure very similar to the ARIA/NDF/GGF proteins. At least two more alternative spliced forms of the new factor are also cloned. We expressed one form of the new factor in COS-7 cells, and our preliminary results show that the recombinant protein induces tyrosine phosphorylation of a 185 kD protein in the MDA-MB 453 cells. The phosphorylated protein could be the Her2 receptor or another member of the EGF receptor family. We are currently characterizing the new ARIA/NDF/GGF related gene and trying to determine the identity of the 185 kD phosphorylated protein.

NUTRITIONAL AND PRENATAL FACTORS

692.1

POST-TERM PATTERNS OF CARDIAC RATE AND VARIABILITY IN PREMATURELY-BORN INFANTS SUFFERING FROM APNEA OF PREMATURITY. V.L. Schechtman*, J.A. Henslee, M.Y. Lee & R.M. Harper. Brain Research Inst., UCLA Sch. of Med., Los Angeles, CA 90024; and Southwest SIDS Research Inst., Lake Jackson, TX 77566.

Prematurely-born infants have higher heart rates and reduced heart rate variability at term relative to fullterm neonates (Eiselt et al., 1993), suggesting that prematurity may have long-lasting effects on cardiovascular control. In the present study, we assess post-term development of heart rate and its variability in prematurely-born infants who continue to suffer from apnea of prematurity (AOP).

Six-hour recordings of EKG and respiration were obtained from infants with AOP born at gestational ages of 24 to 35 weeks. Heart rate and its variability were assessed during three periods of regular respiration in each recording of the premature infants and similar recordings of fullterm infants at comparable post-conceptual ages.

At term, infants suffering from AOP showed higher heart rates and reduced heart rate variability relative to fullterm neonates. Over the first month of postnatal life, however, the fullterm infants showed an increase in heart rate and a reduction in variability, such that by 1 mo after term, there were no significant heart rate differences between fullterm infants and prematurely-born infants suffering from AOP. The two groups of infants continued to show comparable heart rates and variabilities at all ages up to 6 mo after term. Thus, neither prematurity nor AOP appears to have a long-lasting effect on cardiac rate or overall cardiac variability.

EFFECTS OF CORN-BASED DIET ON THE DEVELOPMENT OF THE GABAergic INNERVATION OF THE SOMATOSENSORY CORTEX IN THE RAT. IMMUNOCYTOCHEMICAL STUDIES. S. Orozco-Suárez, A. Ferio-Velasco* and A. Del Angel. Unidad Invest. Med. Patol. Exptl., Hosp. de Oncología, ON, S-XXI, IMSS, México, D. F. and Div. de Biol. del Desarrollo, Unidad de Invest. Bioméd. de Occidente, IMSS, Guadalajara, Jal. MEXICO.

Restriction of specific nutrients interferes with growth and development of central nervous system producing alterations in physiology, biochemistry and morphology of brain and cerebellum. To determine the effect of corn-based diet on the development of GABAergic innervation of cerebral cortex, female Wistar rats, 60 days old were fed for 6 weeks with 1) corn-based diet (with 8% protein), and 2) normal diet (commercial diet for rodents, 23% protein). The morphometric studies were performed in the pups at 1,7,14,21,30 and 60 days after birth, and postnatal development of GABAergic elements was analyzed by GABA and GAD-immunocytochemistry. Radial distribution of cells and laminar numerical densities were calculated at each stage of development by substantial qualitative observations. Results of morphometric studies showed that body and brain stem weight, and thickness of cerebral cortex of the corn-fed group, were significantly reduced compared to their controls. At postnatal stages the maturation of GABA-immunoreactive elements showed a reduction in cell number, cell size and different cell development at each postnatal stage in the corn-fed rats. Results suggest that protein restriction plays an important influence on development and differentiation of the GABAergic system in cerebral cortex. Moreover, as corn is restricted in tryptophan and lysine, it is important to further investigate to which extent this restriction also participates in the results obtained in the present work.

692.3

LONG-LASTING CHANGES IN DOPAMINE RECEPTOR DENSITIES IN THE NUCLEUS ACCUMBENS OF PRENATALLY STRESSED RATS. C. Henry, J. Arsaut, A. Sarrieau*, M. Le Moal, J. Demotes-Mainard. INSERM U-259 and U-394, 33077 Bordeaux, France.

Restraint stress applied to pregnant rats during late pregnancy results in offspring exhibiting some behavioral and neurobiological alterations. Particularly, this procedure of prenatal stress can cause long-lasting changes in the hypothalamo-pituitary-adrenal axis of the offspring, that persist in adult animals. Moreover, prenatally stressed rats show an increased propensity to develop amphetamine self-administration. For this reason, we studied by quantitative autoradiography the densities of D1, D2 and D3 dopamine receptor subtypes in the striatum and nucleus accumbens at postnatal day 90 in either prenatally stressed or control rats, using [3H]-SCH23390, [3H]-sulpride and [3H]-7-OH-DPAT as ligands, respectively. Our results show that in adult offspring, the prenatal stress significantly induce i) a mild increase in D1 receptor binding in both striatum and nucleus accumbens; ii) an increase of D2 receptor binding in the nucleus accumbens; iii) a decrease of D3 receptor binding in the nucleus accumbens. These data indicate that prenatal stress induces long-lasting changes in the dopamine sensitivity in nucleus accumbens, which possibly could participate in the increased propensity to amphetamine self-administration. The mechanism responsible for this alteration remains to be elucidated, but the impaired control of corticosterone could possibly be involved in long-term changes in the mesolimbic dopamine system.

692.4

EFFECTS OF PRENATAL PROTEIN MALNUTRITION ON LTP AT THREE AGES OF DEVELOPMENT. P.J. Morgane*, R.J. Austin-LaFrance, J.D. Bronzino and J.R. Galler. Dept. of Engin. and Comp. Sci., Trinity College, Hartford, CT 06106 and Cntr. for Behav. Dev. and Mental Retardation, Boston Univ. Med. Cntr., Boston, MA 02118.

The effects of gestational protein malnutrition on the establishment, maintenance, and decay of LTP across the perforant path/dentate granule cell synapse were examined in freely-moving rats at 15, 30, and 90 days of age. Measures of population spike amplitude (PSA) and EPSP slope were used to assess the magnitude and duration of LTP. Significant enhancement of both measures was obtained from all malnourished (6/25) and control (25/25) animals at 15 days of age. The magnitude of enhancement obtained 6/25 rats was significantly below that of controls over the first 24 hrs. post-tetanzation. Beyond 24 hrs., both groups showed continuous rise in these measures. To determine what percentage of this rise was the result of tetanization and what percentage resulted from normal development, input/output (I/O) curves were obtained daily from PND 16-30 from non-tetanzated pups of both diet groups. Subtraction of developmental increases revealed that tetanization effects decayed to baseline between days 4 and 5 post-tetanzation. At 30 days of age, approximately 50% of 6/25 animals showed no significant change in PSA measures, while EPSP slope enhancement was delayed 1-3 hrs. The remaining 50% of 6/25 animals did not differ from controls, i.e., initial enhancement of both measures was maintained for 5-18 hrs., decaying to baseline by 24 hrs. Approximately 50% of 90 day old 6/25 animals showed a decrease in both measures ≥ 1 hr. after tetanization. At 3 hrs., enhancement was comparable to initial levels obtained from the remaining 6/25 animals and controls. Results indicate an inverse relationship between the impact of the dietary insult and age, and suggest that altered GABAergic interneuronal activity may underlie the LTP deficits obtained from 6/25 rats.

OXIDATIVE STRESS RISKS WITH HIGH POLYUNSATURATED FATTY ACID DIETS IN BRAIN/HEART/KIDNEY/MAMMARY/LIVER OF FEMALE SHR RATS R.S. Mehta, C.A. Gunnett and D.K. Hartle. Dept. of Pharmacol. and Toxicol., College of Pharmacy, Univ. of Georgia, Athens, GA 30605-2356.

Aging can be increased by accelerating the rate of initiation of random free radical reactions or by increasing ingestion of easily oxidized dietary components. Dietary polyunsaturated fatty acids (PUFA) of omega-3 and omega-6 type, known to have some beneficial cardiovascular effects, are susceptible to peroxidation under multiple conditions that encourage oxidative free radical formation. We studied the effects of long-term feeding with dietary omega-3 and omega-6 PUFAs on 1) blood pressures and 2) in vitro tissue lipid peroxidation in female spontaneously hypertensive rats. After 16 weeks of feeding with either control (5% corn oil, AIN) or high fat diet (19% Menhaden oil; MO and 20% Corn oil; CO), no differences in blood pressure were observed among groups. In whole brain homogenates, autooxidation averaged 282% and iron-ascorbate catalyzed peroxidation 1225% compared to baseline oxidation in all diet groups. Marked differences occurred between the omega-3 and omega-6 (MO and CO respectively) high PUFA diets on baseline oxidation, autooxidation and iron-ascorbate catalyzed oxidation in various tissues. MO caused a 675% increase in basal oxidation, 2624% increase in autooxidation and 4244% increase in iron-ascorbate catalyzed oxidation in mammary gland compared to the CO diet. Similarly, a 400% increase in iron-ascorbate catalyzed oxidation occurred in liver, 225% in heart, 120% in kidney and 50% in aortae in MO compared to CO, respectively. The results indicate that 1) brain is extremely susceptible to iron-catalyzed peroxidation; 2) neither high omega-3 nor high omega-6 PUFA diets afford protection from hypertension in female SHRs and 3) high omega-3 fatty acid diets markedly increase the oxidative aging risk of multiple organs.

692.7

EFFECTS OF PROTEIN DEFICIENT DIETARY REGIMENS, PRE-TERM BIRTH AND HYPERTENSION ON RAT NEONATAL BEHAVIOR. F. Drago*, F. Di Leo, M. F. Di Grazia, L. Lo Presti. Institute of Pharmacology, University of Catania Medical School, 95125 Catania, Italy.

The effect of various metabolic factors on the development of neonatal reflexes and on learning and memory capacity in adulthood was studied in the rat. Female rats of the Wistar strain were subjected to protein deficient dietary regimens (commercial animal food at a reduced weight regimen of 80% or a diet containing casein 6% as the only protein component). Another group of animals was subjected to a caesarean cut at day 19 of pregnancy in order to induce a pre-term birth of pups. Spontaneous hypertensive rats (SHR) were used to examine the possible influence of gestational hypertension on rat brain maturation. We found that protein deficient dietary regimens were accompanied by a retardation in the development of neonatal reflexes and a reduction in learning and memory capacity in adulthood. Differences were also found between control animals and pups born by caesarian cut or from SHR mothers, above all for eye opening time and body weight.

692.9

REPRODUCTIVE SUCCESS IS COMPROMISED IN RATS OVERFED AS NEONATES. E. Taylor* and L. Diaz. Dept. of Psychology, University of Washington, Seattle, WA 98195.

On postnatal day 4, Long-Evans female rat pups were randomly assigned to one of three groups: 1) mother reared in litters of 9 (MR), 2) gastrostomy-fed for ten days to match the growth of the MR group (WM), and 3) gastrostomy-fed with excess formula to accelerate growth (OF). On day 14 the gastrostomy-fed animals were returned to lactating dams in litters of 8 pups each. All animals were weaned on day 22 and maintained thereafter on laboratory chow. On day 170, plasma glucose readings were taken using tail blood. The animals were bred the following day. On day 190 glucose readings were again recorded.

6 of 9 MR females (67%), 5 of 11 WM females (45%), and 4 of 11 OF females (36%) produced litters. Pregnant glucose levels of the successful females were significantly lower than glucose levels of females who failed to produce pups ($p < .001$). Pre-pregnant glucose levels were significantly higher in OF females and an analysis of variance also indicated that pre-pregnant glucose levels were different among the three groups ($p < .01$, ANOVA; OF x WM, $p < .05$, t test; OF x MR, $p < .01$, t test).

These findings support the hypothesis of several researchers that high fuels experienced in early development can permanently alter adult metabolism. The issue of whether or not central regulatory control systems were altered in addition to peripheral metabolic systems by these nutritional manipulations in early development remains to be determined.

692.6

ELEVATED BLOOD COPPER:ZINC RATIOS IN ASSAULTIVE YOUNG MALES W. Walsh, F. Rahman, R. Isaacson, A. Hall, Health Research Institute, Naperville, IL 60563 & I.J. Young* Edward Hines Jr. Hospital, Hines, IL 60141

There has recently been increased research in studying the association between chemical imbalances and violent behavior. In the treatment of over 3000 assaultive young males, The Carl Pfeiffer Treatment Center has observed elevated blood copper:zinc ratios. The objective of this study was to determine if violent and non-violent patients had significantly different copper and zinc levels and copper:zinc ratios. The sample consisted of all male subjects of the Center and for an 8 week period that were 3 to 18 years old. The test subjects had a history of frequent assaultive incidents, while the control subjects had an absence of such incidents. There were 135 violent and 18 non-violent patients. The mean copper:zinc ratios of 1.40 for violent and 1.02 for non-violent were shown to be significantly different ($p < 0.05$). The mean serum copper levels were 98.5 and 86.6 mcg/dl and plasma zinc levels were 75.4 and 87.4 mcg/dl for violent and non-violent subjects, respectively. These relationships suggest a strong correlation between assaultive behavior and abnormal metal metabolism. Clinical studies are underway to determine if correcting these chemical imbalances will result in improved behavior.

BIOMAGNETIC ASSESSMENT OF THE INTEGRITY OF THE FETAL CENTRAL NERVOUS SYSTEM. J.D. Lewine*, W.W. Orrison, P. Shaw, P. Wiest, G. Joffe, K. Argubright, L. Morrison, M. Williamson, S. Provencal, J.T. Davis, K. Paulson. Magnetic Source Imaging Facility, New Mexico Regional Federal Medical Center and the University of New Mexico, 2100 Ridgecrest Drive, SE, Albuquerque, NM, 87108.

Perinatal identification of infants at risk for neurological dysfunction is a challenging but important clinical problem. At present, ultrasound evaluation of CNS-mediated cardiac reactivity to external stimuli or spontaneous movement is the dominant technique for assessing the fetal nervous system. Beat-to-beat variability is also believed to be a good index of fetal well-being, but this is not easily assessed by ultrasound. Biomagnetic techniques offer an attractive alternative to ultrasound examination. The fetal magnetocardiogram (MCG) is readily recorded as early as 14 weeks, and in some cases it is possible to directly record fetal brain activity via magnetoencephalography. Using a 37-channel biomagnetometer we have demonstrated centrally-mediated, stimulus-evoked fetal heart-rate accelerations in a 34-week old fetus. Heart-rate increased to presentation of external sounds and spontaneous movements. Interestingly, the heart-rate returned to baseline when the auditory stimuli were left on for an extended period of time. Examination of "habituation-time" may provide novel insights into fetal CNS function. MCG also provided data on inter-beat variability and morphology of the fetal PQRS waveform. Auditory-evoked brain activity was also recorded successfully from a 34-week old fetus. The data demonstrated clear brain reactivity with an onset latency of 130 milliseconds.

PRENATAL MALNUTRITION ON THE DEVELOPMENT AND MATURATION OF CA3 HIPPOCAMPAL PYRAMIDAL CELLS IN THE RAT.

S. Diaz-Cintra*, L. Parra G., M. Garcia-Ruiz, T. Kemper and P.J. Morgane. Centro de Neurobiología, UNAM, México, D.F. 04510. Boston Univ. School of Med. Center of Behav. Dev. and Retardation. M921, 80 East Concord Street Boston, MA 02118.

The effects of postnatal malnutrition (6% casein diet) in the somatic size, length of the apical dendrite, number of dendritic branching and the thorny excrescence area of CA3 hippocampal pyramidal cells were studied in rats of two ages (30 and 90 days old). A total of 144 cells impregnated with rapid-Golgi were selected for morphometric analysis. Results showed that postnatal malnutrition produced significant decreases ($p < 0.05$) in the all parameters studied. These findings indicate that postnatal malnutrition produces severe alterations in the maturational and development patterns which in these cells occurs during postnatal life. We have found similar results in pre and postnatal malnutrition studies (García-Ruiz M et al., Brain Res. 625: 203, '93). Thus, only postnatal malnutrition can affect these maturation patterns in CA3 pyramidal cells, as well as, chronic malnutrition. These anatomical deficits could be affect the functional integrity of the intrahippocampal activity of the CA3 field. Supported by DGAPA IN-204892, IN-204093 and CONACYT fellowship 83601.

692.11

PRENATAL MALNUTRITION ON THE BASKET (GABAergic) DENTATE GYRUS CELLS IN THE RAT.

A. Aguilar V*, S. Díaz-Cintra, A. González, M. A. Morales, T. Kemper and P.J. Morgane. Centro de Neurobiología, UNAM, UISSI-IMP, SSA, c.p.14410, IBM, México, D.F. 04510 and Boston Univ. School of Med. Center of Behav. Dev. and Retardation. M921, 80 East Concord Street Boston, MA 02118.

The effect of prenatal malnutrition (6% casein diet) on the somatic size, in basket cells was measured in the fascia dentata in rats of 30 days of age, using the Golgi technique. The density of GAD-like immunoreactive cell was studied in the fascia dentata and hippocampal formation, divided into three levels (rostral, medial and caudal). Results showed a significant reduction in the major axis (-15%), perimeter (-16%) and area (-20%) in fusiform cells. In all three levels, numbers of GAD-immunoreactive cells were significantly increased in the hilus of fascia dentata in relation with the hippocampus. The bigger amounts of those cells were localized in the middle part of the fascia dentata. In addition, preliminary data showed increased number of these cells in an older age (i.e. 220 days). The morphological alterations observed in these cells may affect at least in part, the functional integrity of the hippocampal formation, since they have inhibitory activity on the granule cells. Supported by DGAPA IN-204892 and IN-204093.

692.13

THE SEVERITY OF NEONATAL ALCOHOL-INDUCED CEREBELLAR PURKINJE CELL LOSS IN RATS DEPENDS ON THE TIMING OF ALCOHOL EXPOSURE: A STEREOLOGICAL STUDY. J.D. Thomas¹*, C.R. Goodlett², E.A. Wasserman¹, & J.R. West³. ¹University of Iowa, ²IUPUI, ³Texas A&M.

Short term binge-like alcohol exposure during the brain growth spurt in rats depletes Purkinje cells in the cerebellum, but the severity of loss depends on the timing of exposure. Two consecutive days of binge-like alcohol exposure beginning before, but not after, postnatal day (PD) 7 significantly reduces the density of Purkinje cell profiles in the cerebellar vermis (Hamre & West, *Alc. Clin. Exp. Res.*, 1993). Those findings, however, were based on biased counting methods from which estimates of total Purkinje cell number could not be obtained. The present study investigated the effects of two-day alcohol exposure on Purkinje cell number using a stereological method (the optical fractionator) which provides an unbiased estimate of total cell number. Sprague-Dawley rat pups were randomly assigned within litter to five treatment groups. Three alcohol-exposed and one control group were gastrostomized and artificially reared from PD 4 through 9. All alcohol-exposed groups received 6.6 g/kg/day of alcohol, producing peak blood alcohol concentrations of 390 mg/dl. One group was exposed to alcohol on PD 4 & 5 (4/5), a second group on PD 8 & 9 (8/9), whereas a third group was exposed during both periods (Comb). Control groups included the gastrotomy control (GC) and a normally reared suckle control (SC). On PD 55, subjects were perfused, the cerebellum was sectioned, and Purkinje cell number was determined with an Olympus/BICO computerized stereological system. Purkinje cell numbers were reduced in all alcohol-exposed groups (Comb: 53% of GC; PD 4/5: 57% of GC; PD 8/9: 83% of GC). The PD 4/5 group did not significantly differ from the Comb group and both had significantly more severe cell loss than the PD 8/9 group. These results confirm the greater susceptibility to alcohol-induced Purkinje cell loss early in the neonatal brain growth spurt. Moreover, these unbiased methods now show that the severity of cell loss is greater than previously estimated and that even exposure late in the brain growth spurt can produce significant reductions in Purkinje cell number. Supported by Grants AA05523 (JRW) & AA09596 (CRG).

INCREASED LOOK DURATION IN PAIRED COMPARISONS BY RHESUS MONKEY INFANTS WITH N-3 FATTY ACID DEFICIENCY (N-3 FAD). S. Reisbick*, M. Neuringer and E. Gohl

Oregon Health Sci. Univ., Portland, OR 97201 and Oregon Reg. Primate Res. Center, Beaverton OR 97006

N-3 fatty acids are integral components of neural and retinal membranes. Perinatally deficient primate and human infants show low levels of n-3 fatty acids in cerebral cortex and retina, delayed development of visual acuity and abnormal electroretinograms.

Nine infants deficient both pre- and postnatally and 8 standard nursery infants received paired comparison tests at 2, 5, 9 and 13 weeks with both 6 pattern-pairs and 6 face-pairs, each set presented on a separate day. Familiarization consisted of 30 sec of fixation. Tests (familiarized vs novel card) were 10 sec on each side, semi-randomized. For each stimulus set, tests were conducted both immediately and after 24-hours.

Fixations by deficient infants were consistently longer in both the immediate and 24-hr tests for patterns (p<.05) and approached significance for faces (p<.08).

Table 1	Pattern Sets (6 pairs)		Face Sets (6 pairs)	
	Immediate*	24-Hour*	Immediate	24-Hour
Standard	1.18 + .05	1.18 + .06	1.20 + .05	1.1 + .05
Deficient	1.52 + .05	1.43 + .06	1.48 + .05	1.4 + .05

Look duration has been inversely associated with speed of visual processing. N-3 FAD may slow processing.

692.12

POSTNATAL MALNUTRITION ON THE DEVELOPMENT AND MATURATION OF GRANULE DENTATE GYRUS CELLS IN THE RAT.

I. Granados*, A. Díaz, L. Cintra, A. Aguilar, M. García-Ruiz, and S. Díaz-Cintra. UISSI-IMP, SSA, 14410 and Centro de Neurobiología, UNAM, México, D.F. 04510.

The effects of postnatal malnutrition (6% casein diet) in the somatic size, number of dendritic branching and the spine density of granule cells were studied in rats of 30 days old. A total of 115 cells impregnated with rapid-Golgi were selected for morphometric analysis. Results showed that postnatal malnutrition produced significant decreases (p<0.05) in the number of spines in proximal and middle dendritic segments as well as dendritic density in the 7 of the 8 intersected rings, studied. These findings are similar to those found in the study of CA3 pyramidal cells and indicate that postnatal malnutrition produces severe alterations in the maturation and development patterns which in these cells occurs during postnatal life. Thus, these anatomical deficits may be affect the functional integrity of the intrahippocampal activity initiated in these granule cells. Supported by DGAPA IN-204892, and IN-204093, IN-202891.

OFFSPRING OF A SECOND MATING SHOW AN ENHANCED ANALGESIC RESPONSE TO MORPHINE. M.L. Pilati*, S.H. Trull, D.L. Tio and A.N. Taylor. Department of Psychology, University of California, Los Angeles, CA 90024.

It has been demonstrated that sensitivity to opiates declines as a function of multiparity in the rat. The impact of this maternal change on offspring sensitivity has not been studied. In order to determine if parity has an impact on offspring responsiveness to opiates, female Sprague-Dawley offspring from a first and second breeding were tested for their analgesic responsiveness to morphine. At 30-36 days of age subjects were tested for their hotplate latency 30 and 60 min after administration of 5mg/kg morphine. Prior to drug administration baseline latency was established. There was a significant effect (p<.01) of parity on baseline and 30 min latencies, due to offspring from the second mating showing higher latencies. The significance at 30 min was still present after correcting for baseline differences. It is not clear whether the observed difference is a result of maternal age (dams were 3 months old at first breeding and seven at the second) or parity. The data do, however, indicate that maternal history may significantly alter offspring sensitivity to drugs and possibly other aspects of behavior. (Supported by NIH-HD07228, UCLA Psychoneuroimmunology Program, and VA Medical Research Service.)

EEG POWER SPECTRA ANALYSIS OF MALNOURISHED LACTATING RATS. L. Cintra*, S. Ramirez, F. Mena, P. Durán and C. Escobar. Centro de Neurobiología, UNAM. A.P.70228, México, D.F., 04510.

Cerebral activity of normal (N) and malnourished (M) lactating female Sprague-Dawley rats was registered during a 24h period, during and after suckling and without their pups. Rats were malnourished 5 weeks before mating, throughout gestation and lactation. N rats showed a synchronized pattern during milk ejection. Using power spectra analysis in N rats, we found a significant increase of theta activity in the first third of the lactation period, an increase of delta waves in the second third and a significant increase of theta activity in the last third of this period. M rats showed a significant increase of theta activity during the last lactating days, however during the first third of the period they showed increase in delta waves. In both groups N and M delta waves increased when pups were retired from the nest. We also found ultradian rhythms in delta, theta and high frequency activity; N rats showed 4 main peaks and M rats presented 8 peaks, with phase advance in respect to N rats. These results suggest that protein malnutrition installed 5 weeks prior to conception, can produce alterations in the electrical activity of lactating rats (Supported by DGAPA IN-202891).

692.17

SLEEP-WAKE PATTERNS IN MALNOURISHED, REHABILITATED AND CONTROL RATS OF 60 DAYS OF AGE. A. Galván*, L. Cintra and A. Alfaro. Centro de Neurobiología, UNAM, México D.F. 04510.

This study was designed to evaluate the sleep-waking cycle of 6% protein malnourished, postnatally rehabilitated and control male Sprague-Dawley rats at 60 days of age. Malnutrition was established before mating and was continued throughout gestation and postnatal life. Rats were rehabilitated by the "cross fostering" method switching at birth malnourished pups to well nourished dams. Occipital EEG and neck muscles EMG activity were obtained with bipolar stainless steel electrodes. Polygraphic vigilance states were obtained for a 24h period and scored visually in 12 second epochs. Postnatally rehabilitated rats showed a similar distribution of their vigilance states as their controls during the light and dark phase, as well as in the 24h period. In contrast, malnourished rats showed an increased proportion of SWS during the dark phase and in the total 24h period and a phase shift in the distribution of REM-sleep. These data reveal that malnutrition affects the mechanisms that regulate sleep-wake patterns and suggest that postnatal nutritional rehabilitation can prevent those alterations. (Supported by DGAPA IN-202891 and PADEP 30383).

692.19

EFFECTS OF CHRONIC UNDERNUTRITION ON THE AMPLITUDE AND LATENCY OF THE N13 AND N20 COMPONENTS OF THE SEP IN CHILDREN. H.Hesse, M.F.Rivera, M.A.Zavala, I.Díaz, W.Mejía*, G.J.Quirk. Dept. Physiology, National Autonomous University of Honduras and Odontopediatric Center, Ministry of Health, Tegucigalpa, Honduras and Center for Neural Science, New York University, NY, NY 10003.

An estimated 50% of Honduran children suffer from chronic undernutrition. To assess the consequences of such deprivation on CNS physiology, we measured the central conduction time (CT), using the somatosensory evoked potential (SEP), of 14 children ages 7-10 with heights below the 3rd percentile for their age and 17 age-matched controls. The two groups also differed significantly in nutritional intake, socioeconomic variables, achievement in Bender's neurointegrative test and hematocrit (control mean=39; undern.=36; $p<0.01$, Scheffe F-test), but not birth weight. The children were stimulated over the median nerve with 0.3ms shocks at a rate of 2-3Hz and a voltage sufficient to produce a just visible abduction of the thumb (motor threshold, MT). The cervical N13 and cortical N20 components were recorded over positions C5S-EPc and C3-A1, respectively. In addition to motor threshold, recordings were also taken at .75MT and 1.25MT to assess the response to varying stimulation intensities. Mean CT (N20 latency-N13 latency) for the undernourished group (6.64ms) did not differ significantly from the controls (6.38ms, $p=.3$), nor was there a difference in the amplitudes of the N13 and N20 waves with intensity. However, in 5/14 undernourished subjects whose hematocrit was extremely low the CT was 1.8 standard deviations greater than controls ($p<.001$, t-test). Thus, CT may be affected in a proportion of subjects by a postnatal dietary lack, while the CNS of others may be "protected".

692.18

EARLY OLFACTORY LEARNING IN UNDERNOURISHED RATS. C. Escobar*, J. Caldeas and L. Cintra. Centro de Neurobiología, UNAM, Ado. Postal 70-228 México D.F. 04510.

Rat pups are attracted to odors experienced in the nest, emanating from the dam or litter mates. The acquisition of this preference to odors is associated to maternal care and is considered an early associative learning process. When different odors are presented to the pups in a two-choice test they exhibit enhanced orientation to those experienced in the nest. Morphological studies have reported that undernutrition in the rat retards cellular migration and functional maturation in the olfactory bulb. The present study examined the olfactory behavioral response of prenatal- (U-R), postnatal (U), pre- and postnatally undernourished- (U-U) and control (C) Wistar rat pups ($n=30$) in a two-choice olfactory test. Undernutrition during gestation was induced by restricting the mother's food intake to 50% of the diet, two weeks before mating and during gestation. At birth U-U and U pups were postnatally undernourished by daily removing the pups for 12 h and placing them in an incubator. Pups were tested on postnatal days 1 to 12 using maternal shavings and fresh shavings' odor. The latency to show a response was lower in the U-U and U ($p<0.01$) than U-R and C. Also, the proportion of pups that exhibited a preference to maternal odor was higher in U and U-U ($p<0.01$), although all groups showed a significant preference to maternal odor in contrast to fresh odor. Our data suggest that undernutrition does not restrict the pups ability to establish early olfactory associations, nor to express an olfactory preference, however, postnatal undernutrition exerted an important influence by motivating the pups to respond faster to the maternal odor source. (Supported by PADEP DCCH9151).

PATTERN FORMATION, COMPARTMENTS, AND BOUNDARIES III

693.1

THALAMOCORTICAL AXON MORPHOLOGY IN NEONATAL RAT SOMATOSENSORY CORTEX IS RAPIDLY ALTERED BY PERIPHERAL DAMAGE. S. Catalano*, R.T. Robertson* and H.P. Killackey*. Depts of 'Psychobiology and of 'Anatomy and Neurobiology, University of California, Irvine, CA 92717; *Dept. Molecular and Cell Biology, University of California, Berkeley, CA 94720

Jensen and Killackey ('87, J. Neurosci. 7:3544) reported that infraorbital nerve section on the day of birth alters both the somatotopic pattern within S1 and the morphology of thalamocortical terminal arbors in the adult. Given the close relationship between individual thalamic terminations and the cortical pattern in the adult rat, we sought to examine whether neonatal infraorbital nerve section would alter the initial development of individual thalamocortical terminal arbors. We therefore examined the morphology of individual axons on P 3 in rats subject to infraorbital nerve section on the day of birth and compared them to axons of the same age from normal rats. Axons were labeled with Dil and photoconverted axons were later reconstructed from coronal vibratome sections. In normal animals at P 3, terminal arbors within layer IV are relatively restricted, spanning an average of 144.0 μ m. Following infraorbital nerve section on the day of birth, P 3 arbors are significantly wider, spanning 249.2 μ m ($t[5]=3.66$, $p=0.015$). The number of branches per terminal arbor does not differ from normal animals. Our observations suggest that the role of the periphery in guiding terminal arbor formation is exerted both very rapidly and at the level of the single thalamic axon. Further, these results imply that there is a tight coupling between individual axon terminal arbor morphology and pattern formation in rat somatosensory cortex. Supported by NSF BNS90-22168, NIH NS07351 and NIH NS30109.

693.2

PRENATAL DELINEATION OF THE STRIOSOMAL SYSTEM BY SELECTIVE TRANSCRIPTION FACTOR EXPRESSION. E. Fusco*, J.D. Milbrandt*, M.J. Iadarola*, and A.M. Graybiel. Dept. Brain & Cognitive Sciences, MIT, Cambridge, MA 02139; *Dept. Pathology, Washington Univ. Sch. of Medicine, St. Louis MO 63110; *Neurobiol & Anesthesia Br, NIDR, NIH Bethesda MD 20892.

Transcription factors (TFs) are proteins that can bind to DNA and regulate the transcription and therefore the expression of other genes. Selective TF expression is thus key for the differential gene expression that controls developmental fates. We have analyzed the prenatal expression of several TFs by immunocytochemical techniques to determine their expression in the mouse forebrain and, in particular, in the striatum. We report that the TFs: NGFI-A (zif268, egr1, krox24), Fos/FRA (OGS lot no. 392051), and FRA have a remarkably restricted expression in embryonic forebrain, and that, over a prolonged period of development, they are selective markers for the striosomal system of the striatum. The general spatial and temporal patterns of expression of these TFs are similar, especially in the striosomal system, but they are not identical. NGFI-A & Fos/FRA expression is first detectable at E16 and largely restricted to the striatum and olfactory amygdaloid regions. FRA immunoreactivity, which should represent several members of the Fos family, has more intense and broader expression. At E15, FRA is already clearly detectable in the striatum and also in other well circumscribed forebrain regions (as major examples: olfactory, limbic and hippocampal regions). Within the striatum, these TFs are all first expressed by scattered cells. Patches of TF-positive neurons are present by E18 and persist until after birth. To determine whether these patches were protostriosomes, we marked cells destined for striosome fate by injecting BrdU at E11 and by double-labeling for BrdU and FRA at E19 (by which time BrdU-positive protostriosomes are clearly detectable). Almost all the striosomes marked at E11 by BrdU injection, were, at E19, double-labelled with FRA. The expression pattern showed by these TFs suggest that they may function in relation to the development of the striosomal system. Supported by NIH 5R01 HD28341.

RECIPROCAL INFLUENCES OF NIGRAL (DOPAMINE) NEURONS AND STRIATAL PATCH NEURONS IN DISSOCIATED CO-CULTURES. E. Aronica*, L. Costantini, and A. Snyder-Keller. Wadsworth Center for Laboratories and Research, N.Y. State Dept. Health, and S.U.N.Y. School Public Health, Albany, NY 12201.

In our previous studies of transplants of nigral tissue into dopamine (DA)-depleted rats, we found that the inclusion of embryonic striatal tissue increased the efficacy of these transplants, and this effect was greatest with the youngest striatal tissue containing primarily patch neurons (Costantini et al., *Exp. Neurol.* 1994). We have now employed dissociated cultures to examine whether the survival of DA neurons, as well as striatal patch neurons, is increased in co-cultures of nigral and striatal cells taken from different age embryos. Striatal patch neurons were labelled by *in vivo* BrdU injection on E13 + E14. The number of BrdU-labelled neurons was much higher in E14 striatal cultures (58%) as compared to E18 (10%) or E20 (4%) striatal cultures at 1 DIV, and the percentage in all cultures decreased over the next two weeks. The inclusion of E14 nigral cells attenuated this decline. Similarly, the number of DA (TH-immunoreactive) neurons in E14 nigral cultures decreased with time *in vitro* (10% at 1 DIV to 3% at 15 DIV), and this decline was attenuated by the inclusion of E14, but not E18 or E20, striatal cells. Thus, the survival of nigral DA neurons and striatal patch neurons in culture appears to be enhanced in the presence of the other. These reciprocal influences may be relevant to the *in vivo* development of the nigrostriatal system, as well as the possible potentiation of transplanted cells. (Supported by MH46577.)

TRANSIENT *c-fos* EXPRESSION IN RESPONSE TO DOPAMINE D1 AGONISTS IN THE DEVELOPING STRIOSOMES. E. Arnault, J. Arsaut, R.M. Bluthé*, J. Demotes-Mainard. INSERM U-394, 33077 Bordeaux, France.

In intact adult mice, dopamine D1 receptor activation only induces *c-fos* in the most caudal region of the striatum. In contrast, when dopaminergic receptors are previously sensitized by lesion of the nigro-striatal pathway, the expression of *c-fos* in response to D1 agonists is present throughout the striatum. Therefore, *c-fos* induction by D1 agonists requires a state of altered responsiveness of dopamine receptors. Since the D1 receptors develop in the striatum prior to the D2 subtype, we further examined in intact animals the postnatal ontogeny of the *c-fos* response to D1 agonists. *In situ* hybridization of *c-fos* messenger ribonucleic acid (mRNA) in the developing mouse striatum showed that during a transient developmental period extending from postnatal days 3 to 12, injection of the D1 agonist SKF 38393 results in a *c-fos* expression scattered throughout the striatum and observing a patchy distribution. After postnatal day 15 the D1 receptor-mediated *c-fos* hybridization signal had almost disappeared and lost its patchy distribution, except in the most caudal division of the striatum where a strong expression appeared at postnatal day 3 and persisted in adults. Since this transient response of *c-fos* gene to D1 dopamine agonist parallels the developmental pattern of striatal dopamine innervation, of D1 dopamine receptor distribution and the delineation of the striosomal compartment, this study raises the questions of: i) the possible role of D1 receptor-mediated gene expression in the ontogeny of striatal compartments, and ii) the significance of a persisting D1-induced *c-fos* expression in the most caudal part of the adult caudate-putamen.

REGULATION OF PHENOTYPE EXPRESSION IN THE STRIATUM. William F. Silverman*, Yaakov Pollack¹ and Yoram Solberg. Center for Brain Research and ¹Unit of Microbiology & Immunology, Ben-Gurion University, Beer Sheva, 84105 ISRAEL.

We have previously reported an increase in the expression of the gene coding for tyrosine hydroxylase (TH) in subsets of dopamine (DA) neurons, related to the establishment of synaptic connections with their target cells in the striatum. We have also observed that certain gene products in the striatal neurons are expressed at the same time that TH mRNA is up-regulated, suggesting that DA projections from the SN are simultaneously conducting regulatory messages in both anterograde and retrograde directions. In order to test this, we injected 6-hydroxydopamine unilaterally into the SN of newborn rats. Forty-eight hours later this treatment had effectively eliminated the DA innervation to the striatum on the injected side, but failed to reduce the expression of neurotensin or calbindin, leading us to formulate an alternate hypothesis: Induction of these striatal phenotypes is a function of afferent innervation from non-DA areas. Postmortem injections of the carbocyanine dye DiO into the striatum has subsequently demonstrated that at birth and through the first day, virtually all striatal afferents originate from nigral DA neurons. At P2, when activation and peptide expression are first observed in the striatum, a robust afferent innervation was observed to arrive from both cerebral cortex and ventral thalamus, in addition to the midbrain DA group, raising the possibility that input from these areas might influence expression of specific striatal phenotypes in the perinatal rat. Supported by the Israel Institute for Psychobiology (WFS) and the Clore Foundation (YS).

AGGREGATION OF STRIATAL PATCH AND MATRIX NEURONS IN DISSOCIATED CULTURES: INFLUENCE OF CO-CULTURED NIGRAL CELLS. A. Snyder-Keller*, L. Costantini, and E. Aronica. Wadsworth Center for Laboratories and Research, N.Y. State Dept. Health, and S.U.N.Y. School Public Health, Albany, NY 12201.

The relative importance of intrinsic and extrinsic factors in the formation of striatal patch/matrix organization is still a matter of debate. Krushel et al (1989) reported that striatal patch neurons selectively reassociate *in vitro*. We pursued this observation using striatal tissue dissected from E14, E16, or E20 rat embryos, dissociated with trypsin, plated on coverslips placed in 24-well culture dishes, and grown under different culture conditions. Striatal patch neurons were labelled by *in vivo* BrdU injection on E14 or E13 + E14. Aggregation was influenced by a variety of culture conditions: substrate, medium, whether grown face-up in the wells or on inverted coverslips, etc. On polylysine-coated inverted coverslips, striatal neurons from all ages were fairly evenly distributed when grown in defined medium. Under these conditions, aggregation was most notably increased when striatal neurons were grown in the presence of nigral cells. However, within these aggregates BrdU-labelled patch neurons were not obviously associated with one another, and were just as frequently seen outside the aggregates. These findings indicate that the aggregation of striatal cells in culture is greatly influenced by "extrinsic" conditions, including the presence of nigral cells. Although these influences were not specific to striatal patch neurons, they may nonetheless relate to the clustering of patch neurons *in vivo*. (Supported by MH46577.)

DEVELOPMENTAL AND GENETIC ANALYSIS OF *hyh*, A MUTANT WITH ABNORMAL CEREBRAL CORTICAL MORPHOGENESIS.

K.M. Allen¹, H. Sweet², M. Davisson², R. Bronson², and C. Walsh¹.

¹Dept. of Neurology, Beth Israel Hospital, Harvard Medical School, Boston, MA.

²The Jackson Laboratory, Bar Harbor, ME.

Whereas the most striking features of the mouse mutant hydrocephalus with hop gait (*hyh*) are massive lethal dilation of the lateral ventricles, a large third ventricular cyst, and an abnormal "hopping" gait (Bronson and Lane, *Dev. Brain Res.* 54:131, 1990), our preliminary examination of adult and neonatal *hyh* brains has shown several disorders of cerebral cortical development that were not previously noted. Firstly, there are morphogenetic abnormalities and disruptions of laminar patterning of the medial cortical regions including dentate gyrus, Ammon's horn, subiculum, and cingulate cortex. Secondly, the migration of some cerebral cortical neurons is disrupted forming islands of heterotopic cells along the lateral ventricles. The presence of large islands of ectopic cerebral cortical neurons has not been observed in other inherited forms of hydrocephalus. These heterotopias may reflect a specific effect of *hyh* on cortical neuronal migration or may be a secondary effect of hydrocephalus.

In order to more precisely map *hyh* on Chromosome 7, the coinheritance of several simple sequence length polymorphism (SSLP) markers and the mutant phenotype was analyzed in over 300 mice from a backcross and two independent F2 populations. Localization of the recombination breakpoints allowed the definition of an approximate 2 cM candidate region between *D7Mit75* and *D7Mit56*. This corrected location of *hyh* is about 10 cM proximal to the proposed location based on a smaller cross. High resolution mapping places *hyh* near several potential candidate genes on proximal Chromosome 7 which are being analyzed for involvement with *hyh*. Furthermore, closely linked genetic markers will allow prenatal diagnosis of *hyh* mutant animals before they display gross abnormalities. A comparison of brain development in mutants and normal littermates will facilitate an understanding of the specific abnormalities of forebrain morphogenesis present in the *hyh* mice.

STAINING FOR ACETYLCHOLINESTERASE REVEALS DIFFERENT PATTERNS IN THE THALAMUS AND CORTEX OF PERINATAL RATS, MICE, AND HAMSTERS. R.W. Rhoades*, N.L. Chiaia, and C.A. Bennett-Clarke. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Acetylcholinesterase (AChE) is a marker for thalamocortical axon terminals in perinatal rats and has been used extensively to study the development of these fibers. Studies in which we attempted to use this marker in developing mice and hamsters demonstrated striking differences in the expression of this enzyme in the three species. In developing rats, AChE staining heavily labels neurons in the ventral posterolateral (VPL) and ventral posteromedial (VPM) thalamic nuclei and reveals a somatotopically organized pattern of clusters in the developing cortex. In both hamster and mouse, VPM neurons were relatively lightly labelled and heavy staining in VPL appeared to be contained in afferent fibers. This was confirmed by its disappearance after medial lemniscus lesions. AChE staining in the cortices of both of these species resulted in a negative image of the distribution of thalamocortical afferents. This image appeared to result from reduced AChE cortical neuronal staining and was first apparent as a crude representation of the body in lamina V and VI and then as a more precise image in lamina IV. Staining for both AChE and Nissl substance in developing mice indicated that the dense AChE staining was located in the septae. These results demonstrate a dramatic species difference in AChE expression by thalamic and cortical neurons and prompt caution in the general use of this enzyme as a marker for developing thalamocortical axons.

INFRAORBITAL NERVE TRANSECTION AND AXOPLASMIC TRANSPORT BLOCKADE HAVE SIMILAR EFFECTS UPON PRIMARY AFFERENT AND SECOND ORDER NEURONAL MARKERS IN THE RAT'S TRIGEMINAL BRAINSTEM COMPLEX. C.A. Bennett-Clarke, N.L. Chiaia, R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Transection of the infraorbital nerve (ION, the trigeminal [V] branch that supplies the mystacial vibrissae follicles) has specific effects on the chemistry of both primary afferent and second-order neurons in the V brainstem complex. Such lesions cause a marked upregulation of galanin in the central arbor of damaged primary afferent axons and reductions in the staining of second-order cells for both cytochrome oxidase (CO) and the calcium binding protein, parvalbumin (PA). Blockade of axoplasmic transport has less severe effects on the population of fibers in the developing ION than transection and it does not disrupt peripheral activation of V brainstem cells. Nevertheless, such blockade produces changes in V primary afferent and second-order neuronal markers that closely mimic those observed after nerve transection. Transport blockade causes a marked up-regulation in galanin in V primary afferents and, in V nucleus principalis, V nucleus interpolaris, and the magnocellular part of V nucleus caudalis, these galanin-positive axons are arrayed in a clustered and somatotopic fashion which matches that of the mystacial vibrissae follicles. Transport blockade also causes reductions in the density of both CO and PA staining in the brainstem and a loss of the normally observed patterning that corresponds to that of the vibrissae follicles.

693.11

TRANSECTION OF, AND AXOPLASMIC TRANSPORT BLOCKADE IN, THE INFRAORBITAL NERVE IN NEWBORN RATS REDUCE EXPRESSION OF ACETYLCHOLINESTERASE BY SOMATOSENSORY THALAMOCORTICAL AXONS. N.L. Chiaia, C.A. Bennett-Clarke, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Acetylcholinesterase (AChE) is transiently expressed by thalamocortical axons in perinatal rats and it has been used extensively to study the development and plasticity of these axons. The use of AChE as a marker for thalamocortical fibers in plasticity studies requires that its expression not be significantly altered by manipulations employed in such experiments. The present results demonstrate that transection of the infraorbital nerve (ION) or blockade of axoplasmic transport in this nerve with colchicine or vinblastine markedly reduces the expression of AChE in developing thalamocortical fibers. Newborn rats sustained either transection of the ION or application of a vinblastine- or colchicine-impregnated implant to this nerve and were killed on postnatal day 7. The cortex was either stained for AChE or Di-I was used to label thalamocortical afferents. Staining with AChE in experimentally manipulated animals revealed very light bands of labelling in the portion of the cortex representing the vibrissae follicles contralateral to the treated nerve. In some animals no periphery-related AChE staining was visible in the experimental hemisphere. AChE staining demonstrated dense somatotopically organized patches in the cortex that retained its normal input. Tracing with Di-I revealed a banded pattern of thalamocortical afferents in the experimental cortices of all animals evaluated.

DIFFERENTIAL AFFINITY OF HOST SEROTONIN AXONS FOR INTRASTRIATAL GRAFTS OF DIFFERENT ANATOMICAL ORIGIN. P. Pierret*, H. Moukhtes, G. Campistron and G. Doucet. Département de pathologie et Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

Grafts of fetal striatal or cortical tissue have been shown to be innervated by host serotonin (5-HT) neurons following implantation into ibotenic acid-lesioned striatum of adult rat. In contrast, very few 5-HT axons were visualized in grafts of fetal substantia nigra after implantation into the unlesioned striatum of adult rat, suggesting a differential affinity of 5-HT axons for CNS grafts of different anatomical origin. Nevertheless, we have recently demonstrated that implantation into newborn rat results in strong 5-HT innervation of grafted mesencephalic tissue, indicating a developmental regulation of this affinity. To test this hypothesis further, we compared the 5-HT innervation of fetal striatal and mesencephalic grafts after implantation into the unlesioned striatum of rats aged 1 to 25 d. Immunocytochemistry for 5-HT, tyrosine hydroxylase and DARPP-32 was performed 2 months after transplantation, to visualize 5-HT axons and assess mesencephalic and striatal grafts, respectively. Numerous 5-HT-immunoreactive axons were present inside ventral mesencephalic transplants (devoid of 5-HT cell bodies) only after implantation into recipients less than 14 d old. In contrast, striatal grafts were richly 5-HT-innervated in older as well as newborn recipients. Interestingly, 5-HT fibers invaded only DARPP-32-positive areas, i.e. true striatal portions of the "striatal" grafts, even in newborn recipients. Therefore, the affinity of 5-HT axons for "striatal" grafts was not affected by the age of the recipient. Furthermore, 5-HT axons showed a differential affinity for striatal and non-striatal portions of the "striatal" grafts. We conclude that a postnatal developmental regulation in the affinity of host 5-HT axons is a special feature of their relationship with ventral mesencephalic tissue. EFFECTS OF AXOPLASMIC TRANSPORT BLOCKADE ON MYELINATED AXON NUMBER IN THE INFRAORBITAL NERVE, AND CENTRAL VIBRISSEAE-RELATED PATTERNS. S. Zhang*, N.L. Chiaia, R.S. Crissman, C.A. Bennett-Clarke, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Axonal transport was blocked in the developing infraorbital nerve (ION) the trigeminal branch that supplies the mystacial vibrissae) between P-0 and P-6 by application of implants impregnated with varying amounts of colchicine or vinblastine. Effects upon numbers of myelinated fibers in this nerve were assessed by light microscopic examination of toluidine blue-stained sections and effects upon central vibrissae-related patterns were evaluated by histochemical and immunocytochemical staining. The average number of myelinated axons in the normal ION (N=20) on P-6 was $9,931 \pm 1,241$. The average percentage of myelinated axons that remained in the ION of animals subjected to transport blockade (N=18) ranged from $14.1 \pm 3.7\%$ for the animals that received implants with high colchicine concentrations to $51.7 \pm 17.7\%$ for the rats that received low doses of vinblastine. Regardless of the number of myelinated axons that were preserved in the ION, the effects on central vibrissae-related patterns were the same. The cytochrome oxidase (CO)-dense patches in the brainstem corresponding to the vibrissae follicles were absent and the density of staining was markedly reduced. The vibrissae-related CO pattern in the thalamus was also absent, but the density of staining was not markedly decreased. In cortex, staining for serotonin or labelling axons with Di-I revealed a banded pattern similar to that observed after nerve transection.

NMDA RECEPTOR MEDIATED MOTOR NEURON DENDRITE GROWTH Robert G. Kalb*, Yale University, New Haven CT. 06510

Adult mammalian motor neurons receive 20,000-50,000 synaptic inputs and this innervation is a function of the size and geometry of the neuronal dendritic arbor. We performed a quantitative examination of the postnatal growth of rat motor neuron dendrites until the adult architecture is achieved. Motor neuron cell body cross sectional area and dendritic growth in the radial and rostrocaudal axes increase monotonically while the growth of dendritic arbor/motor neuron and the number of dendritic branches is biphasic. These later features undergo overabundant growth in the first three weeks of life then regress to the adult pattern.

The timing and organization of afferent ingrowth into the spinal cord have been proposed to regulate dendrite growth during development. We have examined the participation of synaptic activity in dendritogenesis. We find that blockade of the NMDA subtype of glutamate receptor in neonates with either MK-801 or aminophosphonopivalic acid inhibits the growth of dendritic arbor/motor neuron by predominantly inhibiting dendritic branching. Blockade of the NMDA receptor in adult animals has no effect on dendritic geometry. Thus NMDA receptor activation promotes the development of a more complex motor neuron dendritic tree during the naturally occurring remodeling period in early postnatal life. The activity-dependent maturation of the dendritic tree is likely to influence the quantitative and qualitative aspects of convergent innervation to motor neurons and have lifelong effects on their computational capabilities.

ENGINEERING OF ARTIFICIAL HIPPOCAMPAL NETWORKS. J.L. Hickman, K.E. Foster, D.A. Stenger¹, A.E. Schaffner^{2*}, Yong-Xin Li² and J.L. Barker². Science Applications International Corporation, McLean, VA 22102; ¹Center for Biomolecular Science and Engineering, Naval Research Laboratory, Washington, D.C. 20375 and ²Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

The creation of chemically defined, patterned surfaces has allowed us to study the development of neuronal networks *in vitro*. We are using patterned, self assembled monolayers (SAMs) to control the adhesion and direct the neurite outgrowth of hippocampal neurons. Controllable variables in the preparation of *in vitro* networks such as surface composition, growth media and cell preparation all play important roles in determining neuronal viability and pattern fidelity. The patterned surfaces have been characterized by XPS, imaging XPS and contact angle measurements both before and after cell culture. We have begun electrophysiological recordings from cells grown on SAMs. We will apply what we learn from this study to an understanding of embryonic neuronal development and circuit formation as well as to the repair of damaged neuronal systems *in vivo*.

694.1

EFFECTS OF INFRAORBITAL NERVE TRANSECTION ON THE ORGANIZATION IN INTRACORTICAL CONNECTIONS WITHIN THE RAT'S PRIMARY SOMATOSENSORY CORTEX. T.D. King, C.A. Bennett-Clarke, N.L. Chiaia, H.P. Killackey, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Intracortical projections within lamina IV of the vibrissae representation of the rat's primary somatosensory cortex (the barrelfield) are generally restricted to the septal regions and avoid the dense aggregates of lamina IV neurons referred to as the barrels. In the present study, anterograde and retrograde tracing with biotinylated dextran amine (BDA) was used to determine whether transection of the infraorbital nerve (ION), the trigeminal branch that supplies the vibrissae follicles) on either the day of birth (P-0) or P-7 altered the organization of intracortical connections in layer IV of the barrelfield. In rats that sustained ION transection on P-0 and survived to adulthood, there was a marked reorganization of intracortical connections in lamina IV of the barrelfield. Both retrogradely labelled cells and anterogradely labelled axons were present within the dense aggregates of granule neurons that remained in this lamina. In contrast, the pattern of intracortical connections in layer IV of rats with ION transections on P-7 appeared normal. Labelled cells and anterograde labelling was largely restricted to the septae and formed a negative image of the clusters of granule cells. These results suggest that altered input to the barrel cortex must be achieved very early in postnatal development to alter intracortical connections in this lamina.

694.3

ANATOMICAL AND FUNCTIONAL REORGANIZATION OF THE CUNEATE NUCLEUS AFTER NEONATAL FORELIMB REMOVAL IN THE RAT. R.D. Lane, N.L. Chiaia, H.P. Killackey, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699 and Dept. of Psychobiology, Univ. of California, Irvine CA 92717

Most previous anatomical studies have shown that large caliber, low-threshold primary afferents exhibit only limited central sprouting after peripheral nerve damage in either neonatal or adult animals. In this study, forelimb removals were carried out in newborn rats that were then allowed to survive until adulthood and used in terminal anatomical or physiological experiments. Sciatic nerve afferents to the brainstem were labelled with a combination of WGA-HRP and CT-HRP in 6 normal rats and 8 animals that sustained neonatal forelimb removals. All of the experimental rats and none of the controls had dense HRP labelling that extended out of the gracile nucleus into the cuneate nucleus. Multi-unit recordings demonstrated the presence of hindlimb-related activity in the cuneate nuclei of all manipulated rats. Single unit recordings demonstrated the existence of cuneate neurons (49% of 49 recorded) that responded to hindlimb stimulation. Most of these (67%) had split receptive fields that also included the stump of the forelimb. Electrical stimulation of the sciatic nerve and brachial plexus demonstrated that 18 (37%) of 49 cells tested could be activated from both sites. These results are consistent with the conclusion that low-threshold, hindlimb-related primary afferents invade the cuneate nucleus after neonatal forelimb removal and make functional contacts with neurons in this nucleus.

CHRONOTOPIC ORGANIZATION OF PRIMARY AFFERENTS IN THE RAT'S TRIGEMINAL SPINAL TRACT. R.S. Crissman, F.A. White, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Trigeminal (V) ganglion cells with different phenotypes have different birthdates. Larger neurons positive for neurofilament protein (NF) and which give rise to large myelinated axons are born early in V ganglion neurogenesis with 27.3% born on E-10.5, 30.3% born on E-11.5, and 37.0% born on E-12.5. In contrast, CGRP-positive ganglion cells are born later, 51.5% on E-13.5 and 42.1% on E-14.5. The difference in birthdates for these two classes of V ganglion cells is reflected by the position of their axons in the V spinal tract. NF-positive axons are located throughout the depth of the V spinal tract, but are more dense in its deeper portion. In contrast, CGRP-positive fibers are largely restricted to the superficial portion of the tract. Ganglion cells that bind the lectin *Bandiera simplicifolia-I* (BS-I) are also born late with 70.9% being generated on E-13.5. BS-I-positive axons are also restricted to the superficial V spinal tract. Immunocytochemical results were supported by electron microscopy. The larger myelinated axons are located in the deep portion of the V spinal tract and there are relatively few unmyelinated fibers in this region. The percentage of myelinated axons is reduced superficially. These results are consistent with the conclusion that axons are added just below the pia surface in the developing V spinal tract with the earliest arriving axons eventually forming its deepest part and later arriving fibers forming its superficial portion.

CENTRAL PROJECTIONS OF INTER-WHISKER PRIMARY AFFERENTS SHORTLY AFTER BIRTH AND IN ADULTHOOD: GALANIN AND SINGLE AXON STAINING PATTERNS. P.H. Young, N.L. Chiaia, C.A. Bennett-Clarke, R.W. Rhoades, P.J. Shortland & M.F. Jacquin. Anatomy & Neurobiology, St. Louis Univ. Sch. Med., St. Louis MO 63104; Anatomy, Medical College of Ohio, Toledo OH 43699; Neurology, Washington Univ. Sch. Med., St. Louis MO 63110.

Mechanisms subserving pattern formation in the rat whisker-barrel system are unknown, although most believe peripheral connections are necessary. In part because NGF can preserve excess ganglion cells and alter pattern formation, Henderson et al. (*J. Neurosci.* 14, '94) suggest that patterns form as a result of a neurotrophically specified, disproportionate death of ganglion cells that project to inter-whisker surfaces. If such cells project centrally to regions intervening between surviving and neighboring whisker projections, their death would form "septa", i.e. somatotopic patches. For this hypothesis to be tenable, inter-whisker and whisker ganglion cells should have central projection patterns that are mirror images of each other; one should resemble a "honeycomb", the other should resemble barrels. To test this, inter-whisker surfaces were selectively denervated at birth (by electrocautery of the skin between rows of whiskers) and their central projections stained by galanin histochemistry (White et al., *Dev. Brain Res.* 72, '93) on postnatal days 3 or 6. Alternate sections were stained for cytochrome oxidase to reveal whisker patches. At both ages, galanin immunoreactive terminals were sparse in brainstem whisker regions, although they occurred most often between whisker patches, sometimes to the extent that the stained fibers produced a honeycomb pattern. However, in normal adults, primary afferents with inter-whisker receptive fields had collaterals that usually ended in whisker patches; on rare occasion they terminated between whisker patches. Thus, staining patterns in neonates, but not adults, support the above-stated hypothesis.

EFFECTS OF FORELIMB DAMAGE AT DIFFERENT AGES ON PEPTIDE DISTRIBUTION AND LECTIN BINDING IN THE CERVICAL DORSAL HORN. W.H. Bauer, B. Hoeflinger, N.L. Chiaia, C.A. Bennett-Clarke, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Rats that sustained forelimb removal on either embryonic day (E-) 16 or the day of birth (P-0), or transection of the brachial plexus as adults had sections through the cervical dorsal horn stained for galanin, calcitonin gene-related peptide (CGRP), or the lectin *Bandiera simplicifolia-I* (BS-I) >30 days after these lesions. There were age-related differences in the effects of peripheral nerve damage upon each of these markers. Damage to the brachial plexus in adulthood caused a significant increase in the density of galanin immunoreactivity in the medial portion of layers I and II and the appearance of galanin immunoreactivity in layers III and IV of the cervical dorsal horn. Such lesions resulted in significant reductions in the density of CGRP immunoreactivity in layers I and II and decreased BS-I binding in lamina II. Forelimb removal at birth resulted in no significant change in the density of galanin immunoreactivity in layers I and II, but in the appearance of galanin-immunoreactive fibers in layers III and IV. Neonatal forelimb removal resulted in no significant change in the density of CGRP immunoreactivity in layers I and II, but in a significant reduction in BS-I binding in the medial portion of lamina II. Forelimb removal on E-16 increased galanin immunoreactivity in layers III and IV, but had no effect on either CGRP immunoreactivity or BS-I binding in the cervical dorsal horn.

IMMATURE THALAMOCORTICAL SYNAPTIC RESPONSES IN NEONATAL MOUSE BARREL CORTEX. A. Agmon¹ and Diane K. O'Dowd^{1,2}. Depts. of ¹Anatomy and Neurobiology and ²Developmental and Cell Biology, University of California, Irvine, CA 92717.

We have extended our previous study of the development of thalamocortical synaptic responses in mouse barrel cortex (*J. Neurophys.* 68, 345, 1992) to include the first 3 postnatal days (P0-P2) and the deep cortical layers. Using the thalamocortical slice preparation, whole-cell recordings were obtained from neurons in all cortical layers, and synaptic currents evoked by electrical stimulation of the thalamocortical pathway. To study the morphological basis of these responses, selected cells were stained with Lucifer Yellow, and in the same slices (after fixation) thalamocortical axons were labeled with DiI(5). Synaptic responses were evoked in deep (layers V/VI) neurons as early as P0, and in the incipient layer IV by P2. Responses were exclusively excitatory; they were highly labile and were often irreversibly depressed after a small number of stimuli. Current-voltage relationships indicated that the dominant component in these responses was mediated by non-NMDA glutamate receptors. In P2 animals, a single electrical stimulus to the thalamus evoked a prolonged sequence of small synaptic events lasting up to 400 ms, apparently due to temporally-dispersed transmitter release. Supported by NS30109.

PRENATAL DEVELOPMENT OF THE RAT CORTICOTRIGEMINAL TRACT. D.A. Randall* and W.E. Rehehan. Division of Gastroenterology, Henry Ford Health Sciences Center, Detroit, MI 48202

The rodent trigeminal system has served as a model of somatosensory development and plasticity for over two decades. It is interesting to note, however, that most investigations have focussed entirely on the ascending trigeminal pathways, with little attention paid to the maturation of the descending inputs to the trigeminal nucleus or the developmental interactions between the ascending and descending projections. We have addressed this issue by using the carbocyanine dye Dil to study the prenatal development of the corticotrigeminal (CT) projection in the rat. Crystals of Dil were placed in the region of the barrelfield cortex of fixed brain tissue from rats that had been sacrificed on embryonic (E) days 18 and 20 and postnatal (P) day 0 (the day of birth). Numerous labeled CT axons were clearly visible in the ipsilateral medullary pyramid at E18. At this age, CT fibers could be seen approaching the medial border of the rostral ipsilateral trigeminal brainstem nuclear complex (TBNC), but no terminals were identified within the confines of the trigeminal subnuclei. At E20, however, numerous CT axon terminals were visible in the rostral ipsilateral TBNC. A lesser number of axons were also identified in the caudal aspect of the ipsilateral TBNC. In addition, labeled axons were seen in the rostral portion of the contralateral TBNC. The disposition of labeled CT axons in P0 animals was similar to that noted in adult animals, with the density of the terminals in the contralateral TBNC exceeding that seen in the ipsilateral brainstem. These results indicate that the CT pathway in the rat develops in an ipsilateral-to-contralateral, rostral-to-caudal sequence in the late prenatal period. Supported in part by DE07734.

DO DENDRITES RESPECT WHISKER PATCH BORDERS IN THE DEVELOPING NUCLEUS PRINCIPALIS? CONFOCAL ANALYSIS. P. Robinson, J.A. DeMaro, J.J.A. Arends, J. Christensen, G.J. Bailey, T.A. Woolsey & M.F. Jacquin. Dept. Neurology and Neurological Surgery, Washington Univ. Sch. of Med., St. Louis, MO 63110; Dept. Anatomy and Neurobiology, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

In the developing somatosensory cortex, granule cell dendrites come to be largely confined to individual barrels by selective pruning and reorientation relative to thalamocortical patch boundaries. In the developing VPM thalamus, the opposite appears to occur (Brown et al., *Soc. Neurosci. Abstr.* 19:47, '93). To study this issue in trigeminal nucleus principalis (PrV), the brainstem link in the whisker-barrel neuraxis, rats were sacrificed on postnatal days 0-6. Single PrV cells were stained with Lucifer yellow in aldehyde-fixed transverse slices and the resultant labeling and whisker patch-related autofluorescence were reconstructed manually and by confocal microscopy. The extent to which a single cell's dendritic tree was confined to its patch of origin was determined by computer-assisted merging of the dendrite and patch images. We find that at birth, almost all PrV cell dendrites are restricted to their "home" patch, although there appear to be a greater number of proximal dendrites per cell, less polarity in the dendritic tree as a whole, and a greater number of dendritic appendages per cell than at later ages. By postnatal day 6, a greater number of cells have dendrites that span multiple patches, and other features also more closely approximate the adult-like morphology. However, in the adult PrV, most dendrites do not span beyond their "home" patch. These data suggest that PrV dendrites develop according to a different set of rules than those operating in the VPM thalamus and layer IV of barrel cortex. This may reflect the fact that primary afferent projections are quite mature in the newborn PrV when large numbers of PrV cells have yet to die of natural causes, and that PrV dendrites serve a different function than VPM dendrites in adults. NIH DE07734, NS17763.

THE TIME-COURSE OF PLASTIC CHANGES IN THE BARREL CORTEX OF ADOLESCENT RATS. S. Glazewski* and K. Fox. Dept. Physiology, University of Minnesota, MN 55455

Long-term deprivation (60 days) of all but the D1 vibrissae in adolescent rats (P28), results in expansion of the D1 representation in layers II/III of the barrel cortex. To test how rapidly this expansion occurs, we assayed plasticity in rats deprived for 5-7 days and compared the results with those obtained from rats deprived for 60 days. Two kinds of deprivation were used: one group had their vibrissae trimmed every day (VT), the other group had their vibrissae carefully pulled out every two days (VP). The receptive fields of 298 layer II/III cells located above barrels immediately surrounding the D1 barrel were measured using post-stimulus time histogram analysis. We found that functional plasticity occurred in both long- and short-term deprived animals but that the underlying processes were different. Short-term deprivation resulted in suppression of deprived vibrissae input (0.55 ± 0.13 spikes per stimulus in VT and 0.43 ± 0.28 in VP vs. 1.22 ± 0.25 for age matched controls), without a change in the spared D1 vibrissa input. In contrast, long-term deprivation did cause potentiation of the spared vibrissa input (0.96 ± 0.17 spikes per stimulus versus 0.45 ± 0.15 at P28 and 0.41 ± 0.15 in adults). These results suggest that attenuation of deprived vibrissae input might be a prerequisite for expansion of the spared vibrissae representation. Supported by NS27759.

EFFECTS OF WHISKER DEPRIVATION OR CORTICAL IMPULSE BLOCKADE ON THE DEVELOPING CORTICOTRIGEMINAL PROJECTION. W.E. Rehehan* & M.F. Jacquin. Lab. of Gastro., Gust. & Somatic Sensation, Henry Ford Hospital, Detroit, MI 48202; Anatomy & Neurobiology, St. Louis Univ. Sch. Med., St. Louis MO 63104; Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110.

We know that daily whisker trimming from birth alters the receptive field size and character of many trigeminal (V) brainstem cells without affecting primary afferent responses or projection patterns, brainstem cytochrome oxidase staining patterns, or brainstem somatotopy (Jacquin et al., *J. Comp. Neurol.* '94). Deprivation-induced response alterations may then reflect disrupted inhibitory mechanisms, the preservation of immature circuitry, altered V brainstem circuitry due to altered activity-based competitive interactions, use-dependent plasticity of existing circuits, and/or an indirect effect of direct changes in cortical circuits (Simons & Land, *Nature*, '87) that are imposed on V brainstem neurons by more effective cortico-V projections. The latter is particularly compelling because the patterning and extent of the cortico-V projection is altered by V nerve injury at birth, and cortical inputs contribute to V brainstem receptive fields in normal rats. To further evaluate the cortical substrate hypothesis, 2 experiments were done. In 1-2 month old rats whose mystacial whiskers were trimmed daily from birth, WGA-HRP injections into the barrel cortex labeled cortical fibers whose extent, density and pattern were normal in ipsilateral and contralateral V brainstem nuclei. However, the incidence of cells in V nucleus interpolaris that were discharged by electric shocks in the contralateral internal capsule was significantly higher. This suggests that whisker deprivation impacts on "subtle" aspects of cortico-V circuits. To determine whether these changes are prompted by the brainstem or cortex, slow-release polymers containing TTX are being applied to the newborn cortex. Effects on the cortico-V projection will be reported. Supported by NIH DE07734.

PLASTICITY AT THALAMOCORTICAL SYNAPSES REVEALS A SYNAPTIC BASIS FOR DEVELOPMENTAL CRITICAL PERIODS. M. C. Crair* and R. C. Malenka. Departments of Psychiatry and Physiology, University of California, San Francisco, CA 94143.

It has long been suspected that there could be a synaptic basis for the developmental critical period seen in the cortical representation of the sensory periphery. We present evidence that LTP and LTD-type phenomena might be responsible for one such developmental critical period in the somatosensory cortex of the rat. Using an *in vitro* thalamocortical slice preparation we tested the lability of monosynaptic response in the barrel cortex of rats to stimulus of the somatosensory thalamus and found that under a pairing protocol (depolarization to -10 ± 5 mV with 100 stimuli at 1 Hz using a blind whole-cell patch), animals beyond the critical period did not display significant plasticity (1 out of 10 cells from animals P8-P14 potentiated more than 10%), whereas thalamocortical synapses in younger animals potentiated easily ($150 \pm 20\%$ in 9 out of 10 cells from animals age P3-P7). Elucidation of the mechanisms responsible for this developmental switch would aid not only our understanding of critical periods *per se*, but also add to the growing body of evidence suggesting that synaptic plasticity commonly seen *in vitro* may have important *in vivo* ramifications as well.

694.12

AUGMENTATION OF NEURAL ACTIVITY AND CORTICAL GROWTH IN ENUCLEATED RATS D. Zheng* and D. Purves. Dept. of Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

We have examined the metabolic activity and size of the adult rat primary somatosensory cortex (S1) after neonatal eye removal to ask whether altered neural activity affects the growth of the neocortex. Activity in S1 was analyzed by comparing the cortical vascularization of enucleated rats with littermate controls; postnatal growth was determined by direct measurement of S1 and its component parts. The overall density of blood vessels in the enucleated animals was 11% greater in the primary somatosensory cortex, and 16% greater within the cortical barrels that represent the whisker pad. In parallel with this change, measurements of S1 and its component parts in the enucleated animals showed that cortical regions with increased levels of ongoing activity were larger than their counterparts in the littermate controls. Thus there was an increase in the average size of both S1 (11%) and of the barrels in the whisker pad representation (20%) in the experimental rats. This correlation of increased metabolic activity and cortical growth provides evidence that neural activity stimulates the elaboration of cortical circuitry during postnatal development. Such activity-modulated cortical growth during maturation may be the mechanism by which early experience encodes information in the developing central nervous system.

THE EXPRESSION OF DIFFERENT CYTOCHEMICAL MARKERS IN NORMAL AND AXOTOMIZED NUCLEUS GRACILIS PROJECTING DORSAL ROOT GANGLION CELLS IN THE ADULT RAT.

J.K.E. Persson¹*, B. Lindh¹, R. Elde², B. Robertson¹, C. Rivero-Melán¹, N.P. Eriksson¹, T. Hökfelt¹ and H. Aldskogius¹. ¹Department of Neuroscience, Karolinska Institutet, S-171 77 Stockholm, Sweden. ²Department of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455.

The aim of this study was to analyze the expression of a number of cytochemical markers in normal and axotomized nucleus gracilis projecting dorsal root ganglion cells. L4 and L5 lumbar dorsal root ganglion neurons projecting to the nucleus gracilis were retrogradely labeled with Fluoro-Gold (FG) and analyzed immunohistochemically for their content of substance P (SP), calcitonin gene-related peptide (CGRP), nitric oxide synthase (NOS), galanin, galanin message-associated peptide (GMAP), neuropeptide Y (NPY) and carbonic anhydrase as well as affinity to RT97, choleragenoid and to griffonia simplicifolia lectin I - isoelectin B₄ (GSL-B₄). The analysis was made in uninjured rats and in rats which had been subjected to unilateral sciatic nerve transection and partial resection three weeks earlier.

Six and nineteen percent, respectively, of the FG-labeled cells showed SP- and CGRP-like immunoreactivity. Following nerve injury none of the cells showed immunoreactivity for either SP nor CGRP. NOS-like immunoreactivity was found in two percent of the cells normally and in ten percent after injury. Galanin- and GMAP-like immunoreactivity were found in two and three percent, respectively, of the cells normally and in 22 and fourteen percent, respectively, after injury. Thirty-four percent of the cells were carbonic anhydrase positive normally, and 42 percent after injury. Seventy-five percent of the cells showed RT97-immunoreactivity normally and twelve percent after injury. Choleragenoid-like immunoreactivity was found in 99 percent of the cells normally and in 81 percent after injury. Two percent of the cells were labeled by GSL-B₄ in the normal cases. After injury, however, no double-labeling was found. No NPY-like immunoreactivity was found in these cells normally, but after nerve injury 96 percent of the cells showed NPY-like immunoreactivity.

These results show that peripherally axotomized nucleus gracilis projecting neurons undergo marked alterations in their cytochemical characteristics, which may be significant for the structural and functional plasticity of somatosensory systems after injury.

ALTERED PATTERNS OF EYELID MORPHOGENESIS FOLLOWING LESIONS OF THE TRIGEMINAL GANGLIA B.L. Munger* and J.M. Crook
Department of Anatomy, University of Tasmania, Hobart, Tasmania, 7001

In order to test the hypothesis that the afferent nervous system plays a role in the differentiation of ectodermal derivatives, the left trigeminal ganglion was cauterized in opossum pups at day 1 post-natal. Morphogenetic abnormalities were compared with the equivalent stages of normal development. Neurolectomies were carried out using procedures described by Morohunfolu et al (1992 The Anat. Rec., 232, 599). Mother and pups were anaesthetized with halothane (Keller et al. 1988 Lab. Anim., 22, 269). Pups were taken for histologic analysis 2-20 days following surgery. Pups were given intraperitoneal nebutal, and fixed in formalin, serial paraffin sections stained with silver. The development of the eyelid neural non-neural constituents occurs post-natally and the lower eyelid lags behind the upper eyelid. Eyelid innervation precedes mesodermal maturation and hair follicle formation suggesting a possible neural role in cutaneous differentiation. Trigeminal ganglionic lesions only involved the sensory component of the nerve sparing the motor root. Trigeminal lesions resulted in altered spatial and temporal patterns in the eyelid that included abnormal eyelash symmetry, delayed follicle formation deletions of eyelashes and delayed dermal maturation. Sham operated pups (skin cauterized but lacking a neural lesion) showed normal development in all parameters of eyelid morphogenesis. These findings support the earlier findings of Morohunfolu, et al, (1992 a & b), based on lesions of lumbo-sacral dorsal root ganglia and spinal cord. The present study involves a purely sensory lesion and clearly implicates afferent nerves in the formation of their targets in skin, i.e. the cutaneous appendages.

TEMPERATURE-DEPENDENT BEHAVIORAL CHANGES AND CEPHALIC WOUNDS IN CAPSAICIN NEONATALLY TREATED RATS. P. Carrillo*, M. Camacho, M. Salas and P. Pacheco. INE, Univ. Veracruzana; Centro de Neurobiología e Inst. de Invest. Biomédicas, UNAM, México, D.F. México.

Neonatal administration of Capsaicin (CAP) in the rat interferes with eye-opening, scratching frequency and is also associated with skin ulcers emergence. Here we investigate, a) if the wounds emergence is a trophic effect or is produced by the increased cephalic scratching and, b) how the behavior of CAP rats was modified by the warm environmental exposure. We used control and neonatally (day 2 pp) CAP treated (50 mg/kg s.c.) Wistar male rats. In experiment a) rats were using (n=20) or not (n=20) a plastic collar fitted around the neck to prevent head scratching. The control group (n=10) were left undisturbed. In experiment b) the behavioral patterns of control or experimental rats were visually recorded in an isolated chamber at 24 °C or 35 °C of temperature (120 measurements/ 30 min). In both CAP groups the head wounds appeared around the 23 days of age and the progression in the number and extension of the lesions were also similar. Data indicate that wounds emergence is not provoked by the increment in the scratching frequency. Moreover, a significant reduction in self grooming frequency (p< 0.05) and relaxed extended posture (p< 0.01) in CAP animals was observed. Data showed that neurotoxic is primarily related with trophic skin lesions and has also a long term interference with the behavioral response associated to heat exposure.

POSTNATAL DEVELOPMENT AND PLASTICITY OF TERMINALS AND SYNAPSES IN SUPERFICIAL MEDULLARY DORSAL HORN: STEREOLOGICAL ANALYSIS. J.P. Golden*, J.A. DeMaro, P. Robinson & M.F. Jacquin. Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104; Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Mature receptive fields in the superficial dorsal horn develop later than in other "second-order" somatosensory nuclei (Fitzgerald, J. *Physiol.* 364, '85), and associated critical periods for deafferentation-induced plasticity differ. To further our understanding of the bases for these observations, EM stereology was applied to developing connections and morphology in laminae I and II of nucleus caudalis in normal rats. At birth, postnatal (P) days 1, 4, 17 and 90 there were 6.4 ± 4.6 , 13.2 ± 6 , 16.3 ± 2.7 , 22.6 ± 1.3 and 35.2 ± 6.6 synapses per $100 \mu m^2$, respectively. At corresponding ages there were 12.5 ± 2.9 , 18 ± 8.5 , 18.9 ± 2.3 , 31.8 ± 13.3 and 29.6 ± 2.5 terminals; 4.1 ± 4.6 , 10.5 ± 4.0 , 4.4 ± 2.0 , 2.3 ± 0 and 0.2 ± 0.2 degenerating profiles; 9.2 ± 1.9 , 5.1 ± 2.1 , 5.5 ± 3.4 , 0.3 ± 0.1 , and 0 growth cone-like profiles per $100 \mu m^2$. Thus, there is a gradual and protracted accretion of connections and terminals through P17, and a corresponding attrition of degenerating and growth cone-like profiles. After infraorbital nerve section at birth, at P1, 4, 17 and 90 there were 10.5 ± 6.9 , 9.8 ± 3.7 , 21.8 ± 2.6 and 38.7 ± 5.2 synapses per $100 \mu m^2$. At corresponding ages there were 16.0 ± 7.8 , 16.9 ± 4.8 , 36.2 ± 12 and 34.6 ± 4.7 terminals; 14.7 ± 1.4 , 5 ± 1.7 , 4.6 ± 1.4 and 0.3 ± 0.1 degenerating profiles; 4.5 ± 0.5 , 3.3 ± 1.9 , 0.1 ± 0 and 0 growth cone-like profiles per $100 \mu m^2$. Thus, after deafferentation, normal numbers of terminals and synapses develop in the face of altered temporal patterns of degeneration and growth. These are hallmark signs of injury-induced pre- and postsynaptic degeneration and axonal sprouting. The source of the latter remains to be determined, although additional areal fraction data suggest that "replacement" terminals are not of primary afferent origin. Supported by NIH DE07734, NS17763.

ISOLATION AND CHARACTERIZATION OF THE CHICK NMDA RECEPTOR cDNA L.K. Garner*, A. Shalash, B. Mendelson* and B. M. Davis. Dept. of Anatomy and Neurobiology, University of Kentucky Medical Center, Lexington KY 40536; ¹Dept. of Anatomy, University of Arkansas Med. Sch., Little Rock AR 72205

A chick brain cDNA library was screened using a ³²P radiolabeled oligonucleotide that corresponds to the first transmembrane region of the rat NMDAR1 subunit. A fragment (approx. 0.5 kb) was isolated and subcloned into pGEM 4Z and used for double stranded sequencing (United States Biochemical). Preliminary results show that the first 200 nucleotides of the isolated fragment are homologous (80%) to the rat and human NMDAR1 subunit at the 5' end of the open reading frame. This region corresponds to the amino terminal end of the NMDA receptor and codes for the extracellular domain that precedes the first transmembrane region. Comparison of the chick cDNA to other NMDA subunits shows no homology. This cDNA fragment has been used to make cRNA probes to determine the normal ontogeny of the NMDA receptor mRNA in the chick spinal cord. Preliminary *in situ* hybridization results show high levels of the NMDA receptor mRNA located primarily in the dorsal horn of the spinal cord (stage 39; E13). We are currently determining the distribution of NMDA receptor mRNA in the spinal cord following administration of curare and various NMDA receptor antagonists.

695.1

SYNAPTIC VESICLE PROTEIN 2 (SV2) LOCALIZATION IN THE DEVELOPING HAMSTER PRIMARY VISUAL PATHWAY. AnnaMaria Confaloni* and K. L. Moya. INSERM U334 and CNRS URA 1285, S.H.F.J.-C.E.A., Orsay, France; Istituto Superiore di Sanità, Rome, Italy.

A number of proteins whose synthesis and rapid axonal transport coincide with specific developmental stages of axonal growth have been characterized *in vivo*. One of these rapidly transported proteins has electrophoretic properties similar to SV2, a synaptic vesicle glycoprotein (Buckley and Kelly, *J. Cell Biol.* 100: 1284, 1985). We used the anti-SV2 monoclonal antibody, 10H, to examine 2-D Western blots containing metabolically labeled rapidly transported proteins of the hamster retinofugal pathway in parallel with immunohistochemical localization of SV2 in brain.

Western blotting showed that the 10H antigen did not correspond to a rapidly transported protein, while immunohistochemistry revealed marked developmental changes in SV2. In the neonate hamster (day of birth = P0) fiber fascicles in the superficial optic tract (OT) over the hamster lateral geniculate nucleus (LGN) were SV2 immunoreactive (IR). At this age many retinal ganglion cell axons are still elongating over the LGN and superior colliculus (SC). At P1 and P2 immunoreactive fascicles in the position of the internal OT were more evident, and at P5 when retinal axons are arborizing, SV2 IR was more distributed in the neuropil. By P8, few SV2 IR fascicles could be observed. In the adult, the neuropil-like IR had diminished considerably and the OT was devoid of SV2 IR. A similar pattern was observed in the SC: fascicles in the stratum opticum/superficial gray were intensely labeled in the neonate and then the IR shifted to the neuropil at P5 - P6. The retinal origin of these fascicles was confirmed by their disappearance after eye enucleation.

These results show that SV2 is distributed along retinal axons as fibers reach their central targets and begin to arborize. Later, SV2 is distributed in the target neuropil and then diminishes. In addition, it appears that SV2, like other synaptic vesicle proteins such as rab3A and synapsin I, are not transported rapidly and are conveyed to axon terminals in a slow component of axonal transport.

We thank Dr. Buckley for the gift of mab10H. Supported by INSERM and CNRS.

NEONATAL ADMINISTRATION 5,7-DIHYDROXYTRYPTAMINE RESULTS IN SYNAPTIC REORGANIZATION IN THE SUPERFICIAL GRAY LAYER OF THE HAMSTER'S SUPERIOR COLLICULUS E.A. Arce, R.D. Mooney, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Neonatal subcutaneous administration of the neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) to hamsters results in a marked depletion of serotonin (5-HT) in cortex and a dramatic increase in the concentration of this amine in the superior colliculus (SC). In order to determine whether this increase was associated with an alteration in the synaptic organization of 5-HT-containing axons in the superficial gray layer of the SC, immunocytochemistry was combined with electron microscopy. In normal adult hamsters, only 4.4% of 250 5-HT-immunoreactive profiles made synaptic contacts in the superficial gray layer of the hamster's SC. Most of these contacts were axodendritic. In 5,7-DHT-treated animals, examination of 400 individual profiles indicated that 25.5% of 5-HT-positive profiles made synaptic contacts. Like the case in normal hamsters, most (63%) 5-HT-positive profiles in the treated animals were axoaxonic; 35% were axodendritic, and 2% were axosomatic. 5,7-DHT treatment had no significant effect on the diameter of 5-HT-positive profiles in the superficial SC laminae. The average for the normal animals was 0.84 ± 0.36 μ m and that for the treated hamsters was 0.67 ± 0.24 μ m. Given the recently demonstrated effect of 5-HT on retinotectal transmission in this species, these results suggest that the functional SC organization may also be markedly altered in animals that sustain neonatal 5,7-DHT administration.

NMDA RECEPTOR BINDING IN TECTUM OF DEVELOPING XENOPUS. S.B. Udin* & L. G. Murakami. Dept. of Physiology, SUNY, Buffalo, NY 14214.

The ipsilateral visual input to Xenopus tectum comes into register with the contralateral map during development. The initial map is established via chemoaffinity cues, while the final order is determined by a Hebbian mechanism involving binocular visual input. The role of visual input is normally confined to a 3-month critical period starting at about 1 month post-metamorphosis. The role of NMDA receptors in the process of organization of the ipsilateral map is demonstrated by the ability of NMDA receptor blockers to prevent matching of the ipsilateral map to the contralateral map during the critical period. Moreover, application of NMDA itself before or after the critical period confers activity-mediated plasticity during periods when visual input normally has no effect on ipsilateral map formation.

We have investigated whether the changes in plasticity are correlated with changes in NMDA receptor density in the superficial layers of the tectum. These layers contain the axons of the contralateral and ipsilateral visuotectal projections. NMDA receptor numbers in brains from tadpoles and of frogs of ages 1, 3 and 8 months post-metamorphosis were assessed by receptor binding studies in which tritiated glutamate, with or without NMDA as competitor, was applied to tectal slices. Autoradiographs were assessed densitometrically using Image software from NIH. The results show that NMDA receptors are present at all ages.

FUNCTIONAL PROPERTIES OF OPTIC AXONS REGENERATING INTO THE PRIMARY OLFACTORY CORTEX OF THE FROG. F. Scalia*, M. Reyes, A. Grant and J.Y. Lettvin. Dept. of Anatomy and Cell Biology, SUNY Health Science Center at Brooklyn, Brooklyn, New York 11203 and Dept. of Biomedical Engineering, Rutgers University, Piscataway, New Jersey 08855.

When the optic nerve of *R. pipiens* is cut and deflected into the telencephalon, the regenerating fibers form a coherent terminal field in the primary olfactory cortex (OC) (Scalia, '87, '91). Electrophysiological study 2 mo to 1 yr after surgery showed unit visual activity of types I-IV (Maturana et al., '60) in the superficial neuropil of OC (Layer I). Although the projection did not form a precise map of the visual field, all the units recorded in the neuropil of the more readily exposed anterior end of OC responded only to stimuli in the frontal 45° of the visual field. These stimuli also evoked responses at the level of the OC cell layer deep to the superficial neuropil. No visual responses were observed in OC in normal controls.

At 2 mo, only the small A waveform (as observed in the neuropil of the optic tectum [OT] by Grant and Lettvin, '91) characterized the visual responses in the neuropil of OC. After 5 mo, the B and C waveforms also appeared. They were much larger than any transients found in the neuropil of OC in normal controls, but somewhat smaller than those found in OT. The individual receptive fields in a multiunit receptive field in OC were usually fewer in number and distributed over wider angular areas than in OT.

The novel development of B and C waveforms in the superficial neuropil of OC suggests that the morphology and electrogenic properties of the dendrites are affected by maturation of the aberrant projection. (Supported by NIH Grant EY 05284)

EFFECTS OF NEONATAL 5,7-DIHYDROXYTRYPTAMINE TREATMENT ON RETINAL GANGLION CELL AND OPTIC NERVE FIBER NUMBER IN THE ADULT HAMSTER. T. Crnko, R.S. Crissman, L. Zheng, R.W. Rhoades, and R.D. Mooney. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

A single subcutaneous injections of 5,7-dihydroxytryptamine (5,7-DHT) at birth results in a 50% increase in the concentration of serotonin in the superficial layers of the hamster's superior colliculus and a marked increase in the density of 5-HT-positive axons in this structure. This change is associated with abnormalities in both the crossed and uncrossed retinotectal projections. In the present experiment, Nissl staining, electron microscopy, and retrograde labelling with HRP were employed to compare numbers of neurons in the ganglion cell layer, numbers of optic nerve fibers, and numbers of retinal ganglion cells in normal adult hamsters and adult hamsters that received neonatal 5,7-DHT injections. The average number of neurons in the ganglion cell layer of the normal hamsters (N=5) was $128,383 \pm 25,584$ and that in the treated animals (N=5) was $150,208 \pm 7,455$. The average numbers of retrogradely labelled ganglion cells in the two groups (N=7 normal and N=8 5,7-DHT-treated hamsters) were $72,731 \pm 11,125$ and $74,669 \pm 8,120$, respectively. The average numbers of axons in the optic nerves of the normal (N=11) and 5,7-DHT-treated animals (N=12) were $102,649 \pm 13,660$ and $89,992 \pm 5,480$, respectively. Multivariate analysis of these results indicated that the changes in the retinotectal projections of 5,7-DHT-treated hamsters do not result from effects of this manipulation on retinal ganglion cell or optic nerve fiber number.

THE ROLE OF RETINOCOLLICULAR AXONS IN THE DEVELOPMENT OF THE CORTICOCOLLICULAR PROJECTION OF MICE. M. Khachab* and L.L. Bruce. Department of Biomedical Sciences, Creighton University, Omaha, NE 68178.

Corticocollicular (CC) axons are believed to use retinocollicular (RC) axons as their primary guiding cue in the development of their topographic specificity in the superior colliculus (SC). Therefore, the development and specification of the CC and RC projections were studied in normal mice and compared to that of the CC projection in anophthalmic (129SV/C_{Por}) mice. Injections of fluorescent dyes (DiI and DiA) were made in the visual cortex and/or the retina of normal and anophthalmic mice (E15 to adult). In normal mice, both RC and CC axons had reached the rostral pole of the SC by E15. By birth, they had reached the caudal pole of the SC. In mice that completely lacked a RC projection, the CC axons were confined to the rostral pole by P0 and reached the caudal pole by P6. In normal mice, RC and CC axons developed short side branches by P0, as did CC axons in anophthalmic mice. Transneuronal diffusion of DiI, indicating the development of immature synapses, was associated with CC axons of normal and anophthalmic mice at similar ages. Because the growth of the CC projection was delayed in mice that lacked a RC projection, the presence of RC axons may play a critical role in target finding by the CC projection. Furthermore, the elaboration of short side branches and appearance of transneuronal labeling in RC, normal and anophthalmic CC projections at approximately the same age suggests that the initiation of synaptogenesis depends on cues within the colliculus rather than the RC projection.

EXPRESSION OF CONSTITUTIVELY ACTIVE CaMKII IN XENOPUS TECTAL CELLS MODIFIES RETINAL GANGLION CELL AXON MORPHOLOGY. D.J. Zou*, D. Pettit, R. Malinow and H.T. Cline. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724

NMDA receptor activity is essential in the plasticity of the developing frog retinotectal projection. Ca^{2+} entering through the NMDA receptor may act through a Ca^{2+} /Calmodulin-dependent protein kinase II (CaMKII) pathway. We are studying this possibility by combining recombinant viral technology with *in vivo* imaging techniques. Vaccinia virus containing the DNA sequences encoding truncated constitutively active CaMKII and β -galactosidase (β G) (T.Virus) or β G alone (β G.Virus) was injected into the ventricles of stage 48 albino *Xenopus* tadpoles. Intense infection throughout the CNS, as indicated by the expression of β G, occurred by day 3. To examine RGC axon morphology, a small amount of 0.5% Dil was injected to the retina of stage 46-47 tadpoles. Animals were screened the next day to select those with a single brightly labeled RGC axon. Three days later, when tadpoles were stage 48, the axon morphology was observed *in vivo* by using a confocal microscope. The extent of viral infection was verified by checking β G expression. Single axons were reconstructed. In the animals infected with T. Virus and constitutively active CaMKII was expressed, the average total length of 13 RGC axons was $373 \pm 49 \mu m$ (\pm SE) and the average number of axon branches was 13 ± 2 . These values are smaller than those in the control animals with no virus injected ($n=15$) and those infected with β G Virus ($n=12$), where the average total axon length was 523 ± 67 and $616 \pm 116 \mu m$, the average number of axon branches was 27 ± 3 and 24 ± 2 , respectively. Thus constitutively active CaMKII expressed in the tectal cells reduced the RGC axon total length and the branch numbers in 3 days. These results indicate that CaMKII activity in the postsynaptic tectal neurons is likely to be involved in the control of the growth of presynaptic RGC axons. We are taking time-lapse images of growing axons to study the mechanism by which their morphology is modified.

EFFECTS OF SEROTONIN ON PATCH-CLAMPED NEURONS IN THE OPTIC TECTUM OF THE FROG. Malayev A.A. and E.A. Debski*. Sch. of Bio. Sciences, University of Kentucky, Lexington, KY 40506.

Recent immunocytochemical studies have shown that serotonergic retinal ganglion cells project to the optic tectum of frogs (Liu & Debski, J. Comp. Neurol. 338:391-404, 1993; Liu & Debski, Neurosci. Abstr. 19:452, 1993). The role of serotonin in the functioning and/or development of the tectum is unknown. We are investigating the effects of external application of serotonin on tectal cells in tadpoles and juvenile bullfrogs by applying whole-cell patch-clamping techniques to brain slices. Perfusion of the slices with $100 \mu M$ serotonin induced a sustained outward current of $3.0 \pm 2.0 pA/pF$ ($n=4$) in 27% of the tadpole cells voltage-clamped at $-60 mV$. Under these conditions 50% of the cells recorded in juvenile frogs to date have shown this serotonin-evoked current ($1.1 \pm 0.7 pA/pF$; $n=2$). Stepping the membrane potential to between -50 and $0 mV$ from a holding potential of $-70 mV$ revealed serotonin-induced outward current in 50% of the tadpole cells and in 75% of the juvenile frog cells. Preliminary experiments conducted in current-clamp mode indicated that exposure of the cells to serotonin resulted in a cell hyperpolarization of approximately $10 mV$. In addition to an evoked outward current, in some cells serotonin also increased the frequency of synaptic inputs. Cells that responded to serotonin also responded to NMDA. External application of $33 \mu M$ NMDA in the presence of TTX resulted in the activation of an inward current at a holding potential of $-60 mV$. Our data suggest that serotonin may modulate NMDA receptor activity in the optic tectum by changing the potential of the membrane upon which these NMDA receptors sit. Supported by NSF grant IBN-9209651.

THE DEVELOPMENT OF THE RETINO-COLLICULAR MAP IN THE SYRIAN HAMSTER. I.D. Thompson and P.M. Cordery. (SPON: Brain Research Association). Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, UK.

Previous studies applying Dil to the retinae of foetal rats revealed considerable topographic disorder in the retinal projection to superior colliculus (SC; Simon & O'Leary, 1992, J. Neurosci. 12:1212). We have used two retrograde tracers, red and green fluorescent latex microspheres, to examine the development of topography in the retino-collicular projection of the hamster. Small (25-50 nl) injections of tracers were made in all four quadrants of the SC in neonatal hamsters. Both the separation and the orientation (rostrocaudal vs mediolateral) of the paired red-green injection sites was varied. Single injections of tracer on P2 produced labelling over approximately one third of the retina, even though the injection sites occupied a very much smaller proportion of SC. When injections were separated by $400 \mu m$ or less and irrespective of their orientation, there was considerable overlap in the populations of red and green labelled cells. Large ($700-800 \mu m$) mediolateral separations resulted in very little overlap between the red and green labelled populations of ganglion cells whereas similarly large rostrocaudal separations produced much more overlap. Similar numbers of ganglion cells were labelled following injections into caudal or into rostral SC. By P6, single injections labelled ganglion cells in much more restricted regions of retina and pairs of injections separated by $400-500 \mu m$ produced discrete foci with relatively little overlap. Older animals displayed increasing precision in the retino-collicular projection such that, at P21, injections separated by less than $200 \mu m$ could produce two non-overlapping foci of labelled ganglion cells.

These results reveal that a crude retinal topography exists for the mediolateral axis of the SC in neonatal hamsters and that the overall topography refines during the period of ganglion cell death.

Production of monoclonal antibodies to bullfrog brain and localization in optic tectum. Lex C. Towns*, Melissa Stuart, Patricia Sexton, and Nandor Uray. Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

Two thousand hybridoma lines were generated from mice immunized with homogenized brain of *Rana catesbeiana*. Of these lines, 79 were positive by enzyme-linked immunosorbent assay (ELISA) against brain homogenates and subsequently assayed against brain tissue immunohistochemically utilizing a biotin-conjugated secondary antibody and visualized with AEC. Thirteen lines were chosen for further analysis based on tissue staining patterns and the hardness of the hybridomas under *in vitro* culture and storage conditions. Monoclonal antibodies from all 13 lines were analyzed by ELISA and western blotting against various developmental stages of *R. catesbeiana*. Three interesting lines - 1B3, 4B8, and 1H12 - recognized all developmental stages in the ELISA. Western blot patterns of denaturing gels were unique for each antibody, but all three recognized a 100-kDa *R. catesbeiana* component. Antibodies 1B3 and 4B8 reacted with elements in the ependymal/subependymal zone. The labeling was dense adjacent to the entire ventricular lumen in premetamorphic animals, and the labeling became restricted posteriorly in the tectum in older animals. Antibody 1H12 was visualized as a dense, uniform reaction product lying in the middle third of lamina 9 of optic tectum. The antibody labeling in lamina 9 was not continuous across the entire optic tectum at all ages. In early premetamorphic animals, 1H12 labeling of lamina 9 extended from the anterior limit of the optic tectum to approximately mid-tectum. At later premetamorphic ages, the labeling extended further posteriorly; more of lamina 9 was labeled at successively later premetamorphic and metamorphic ages. One speculation is that this labeling in lamina 9 parallels the ingrowth of optic nerve fibers, although this hypothesis awaits experimental analysis.

THE DEVELOPMENT OF NORMAL AND ABNORMAL GENICULO-CORTICAL TOPOGRAPHIES IN THE SYRIAN HAMSTER. A.L. Smith, K.Krug and I.D. Thompson (SPON: Brain Research Association). Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, UK.

The orderly mapping of the lateral geniculate nucleus (LGN) onto area 17 in the adult hamster is disrupted by unilateral eye removal on the day of birth. Ipsilateral to the remaining eye, single injections of tracer into area 17 can produce dual foci of retrogradely labelled geniculate neurons (Trevelyan & Thompson, 1992, Eur. J. Neurosci. 4:1104). We have studied the development of both the normal and the aberrant geniculo-cortical projections.

Separate injections of red and green fluorescent latex microspheres, spaced mediolaterally, were made in visual cortex of neonatal hamsters that had been monocularly enucleated on the day of birth (P0). No topographic order was discernible in animals injected on P2 when a single cortical injection labelled neurons throughout the LGN. With two injections, the populations of red and green labelled cells overlapped completely. At P6, cortical injections contralateral to the remaining eye produced an essentially adult pattern: most of the LGN was unlabelled and there were distinct foci of red and green labelled cells. The pattern in the ipsilateral geniculate was different with more overlap between the populations of red and green labelled cells, however the projection was much more restricted than that seen at P2. The characteristic double focus seen in adult deafferented LGNs appeared later.

The emergence of geniculo-cortical topography between P2 and P6 in the hamster coincides with the invasion of cortical plate by the majority of geniculate axons, as revealed by transneuronal tracing. Preliminary experiments placing MK801-containing Elvax on visual cortex failed to disrupt this early phase of topographic refinement.

TRANSIENT CHANGES IN THE DEVELOPMENT OF SPONTANEOUS ACTIVITY IN THE NEONATAL RAT SUPERIOR COLLICULUS. S. Fortin, S. Molotchnikoff, and S.K. Itaya*. Dept. Sci. Biol., Univ. Montréal, Montréal, Que. Canada H3C 3J7, and Dept. Biomed. Sci., Univ. South Ala., Mobile, AL 36688.

We have found that there are four major events in the functional development of the neonatal rat superior colliculus. (1) Spontaneous discharges are the earliest recordable activity, becoming manifest on postnatal day 5 (P5). (2) The first evoked response to electrical stimulation of the optic nerve is detectable on P10, and (3) the first flash evoked responses in the superior colliculus occur on P12/13. (4) On P14/15, eye opening occurs. Since spontaneous activity occurs first and may influence the development of visual pathways, we examined this function more closely. We measured the frequency of spontaneous spikes at different postnatal ages; interval histograms were constructed between P5-P15. Preliminary data, based on 28 animals, suggests an interesting trend. On P5, P6, P10, and P13, there are unimodal distributions of intervals, indicating clustering of shorter intervals and a relatively high frequency of spontaneous discharges compared to other ages. These ages may be pivotal days, since they precede each of the four major events in the development of the superior colliculus by 24-36 hours. Our data suggests that there is a transient increase in spontaneous activity coinciding with the initiation of each new functional capability. To further characterize the source of the spontaneous activity, we injected 2% xylocaine into the optic nerve head, silencing optic nerve activity at P6-P11. There was no change in the spontaneous activity in the superior colliculus during the blockade. These results indicate that spontaneous discharges in the superior colliculus are independent of the retina. Supported by grants from NATO, NSERC, and USARC.

A KERATAN SULFATE PROTEOGLYCAN THAT MARKS THE FUNCTIONAL SUBDIVISIONS OF FERRET LGN DURING DEVELOPMENT. E.E. Geisert*¹ and J.A. Robson². ¹Dept. of Anatomy and Neurobiology, University of Tennessee, Memphis TN 38163; ²Dept. of Anatomy and Cell Biology, SUNY HSC, Syracuse, NY 13210.

Monoclonal antibody (TED15) identifies a keratan sulfate proteoglycan (ABAKAN) that concentrates along the boundaries between thalamic nuclei during development and blocks cell attachment and neurite outgrowth in culture. In the lateral geniculate nucleus (LGN) of the developing ferret, TED15 transiently labels the borders between laminar subdivisions while retinal axons segregate and laminae form. At birth the LGN is relatively undifferentiated and axons from both eyes overlap. TED15 labeling outlines the nucleus. By postnatal day 10 (P10), retinal axons segregate into eye-specific laminae and interlaminar zones appear. TED15 labeling concentrates in these interlaminar zones. At P20 interlaminar zones are clearly labeled as the borders between ON and OFF leaflets within laminae A and A1. As development continues labeling becomes relatively uniform throughout the nucleus. To test whether ABAKAN distribution depends on normal laminar development, one eye was removed from young kits causing axons from the intact eye to cross laminar borders into denervated laminae. The animals were killed around P20, the age when TED15 maximally labels laminar borders in normal ferrets. In one-eyed animals the boundaries between laminae are less distinct and TED15 no longer labels interlaminar zones. However, the borders between ON and OFF leaflets within non-denervated laminae remain labeled. These results are consistent with the hypothesis that ABAKAN plays a role in LGN lamination. Supported by the Hendricks Fund (JAR).

SIGNAL TRANSMISSION IN THE LATERAL GENICULATE NUCLEUS OF MONKEYS WITH SURGICALLY INDUCED ESOTROPIA. E.L. Smith III*¹, Y.M. Chino¹, H. Cheng¹, Y. Sasaki¹, M.L.J. Crawford², R.S. Harwerth¹ and G.K. von Noorden³. College of Optometry, University of Houston¹; University of Texas at Houston², Department of Ophthalmology, Baylor College of Medicine, Houston, TX³.

Early strabismus, a form of abnormal visual experience which often leads to permanent vision anomalies, produces dramatic alterations in the response properties of neurons in the monkey's visual cortex. In addition, the morphology of monkey LGN neurons is clearly altered by strabismus, but it is not known whether the functional status of LGN neurons is also affected. We investigated the effects of early strabismus on the transmission properties of LGN neurons in 3 monkeys reared with surgically induced esotropia by using microelectrode recording techniques to compare the responses of individual LGN neurons with those of their retinal inputs (S-potentials). For well-isolated S-potential and LGN action potential pairs (n=65), we measured orientation, spatial frequency, temporal frequency and contrast response functions using drifting sine-wave gratings. Contrary to our previous findings in strabismic cats, there were no obvious differences between the transfer characteristics of control and treated-eye neurons. The results suggest that, in comparison to the cat, the physiological status of the primate LGN is less susceptible to environmental influences.

695.14

GLYCINE IN THE VISUAL SYSTEM OF YOUNG AND ADULT FERRETS. Kathrin Herrmann*, Lab. Neurophysiology, NIMH, Poolesville, MD 20837, USA.

It is well established that glycine is an inhibitory neurotransmitter in the brainstem and spinal cord. Glycine, however, is also present in retinal ganglion cells both in adult and developing mammals, and glycine receptors are abundant in the early postnatal mammalian neocortex. In the present study the lateral geniculate nucleus (LGN) and the visual cortex were examined in adult and developing ferrets for the presence of glycine employing immunohistochemical procedures using a rabbit anti-glycine antibody. In adults, glycine-positive cells were present in both the LGN and visual cortex. In adults, immunopositive cells in the LGN were mainly large or medium sized neurons, and glycine positive cortical cells were found in all layers, but occurred in greater frequency in the infragranular layers. By birth, glycine-positive cells were already plentiful in the LGN. In the developing cortex, however, glycine-positive neurons were sparse in the cortical plate, although abundant in the subplate (SP) and marginal zone. In addition, the SP/intermediate zone contained a dense plexus of glycine-positive fibers, perhaps representing thalamocortical axons. To determine whether the glycine occurs in relay neurons of the LGN, I injected HRP and/or fluorescent latex beads into visual cortex of adult (\geq P85) ferrets. Most if not all retrogradely labeled LGN cells were also glycine-positive. Since the relay neurons of the LGN are likely to use an excitatory neurotransmitter, the presence of glycine in LGN projection neurons strongly suggests that glycine within thalamocortical axons acts on the glycine site of the NMDA receptor, mediating the appropriate excitatory thalamocortical response. The presence of glycine by birth, before the onset of synaptogenesis, might indicate an additional role for glycine perhaps as a neurotrophic factor.

695.16

THE EFFECT OF NEONATAL MONOCULAR APHAKIA OR OCCLUSION ON THE EXPRESSION OF CAT-301 ANTIGEN, PARVALBUMIN AND CALBINDIN IN THE LATERAL GENICULATE NUCLEUS OF MACAQUE MONKEYS. N. Jain*, M. Tigges, V. Rama and J. H. Kaas. Dept. of Psychology and Inst. for Developmental Neuroscience, Vanderbilt University, Nashville, TN, and Yerkes Research Center, Emory Univ., Atlanta, GA.

Macaque monkeys (*Macaca mulatta*) were reared from birth to about one year of age either with surgically induced monocular aphakia, resulting in a blurred retinal image, or with a black occluder lens on one eye, which prevents visual experience. Levels of expression of the Cat-301 antigen, parvalbumin (PV) and calbindin (CB) were examined with immunohistochemical techniques in the lateral geniculate nucleus (LGN). Both types of deprivation resulted in a marked reduction of Cat-301 staining in both parvocellular and magnocellular LGN layers connected to the deprived eye, with deprived magnocellular layers retaining a relatively higher level of staining than the deprived parvocellular layers. PV and CB immunoreactivity, however, was reduced only moderately in the deprived layers, with a more pronounced reduction ipsilaterally to the deprived eye. These results show that changes in the expression of the Cat-301 antigen, and PV and CB are similar, whether produced by aphakia or occlusion. Remarkably, alterations can be more pronounced in the layers receiving inputs from ipsilateral than the contralateral deprived eye. (Supported by NIH EY02686, EY09737 and RR-00165)

MOTOR FUNCTION ANALYSIS OF NORMAL AND TRANSPLANTED MUTANT MICE USING A ROTAROD DEVICE. P.L. Kuhn¹, J.L. Cantrell¹, E. Petroulakis², J.L. Norman¹ and R.D. McKinnon². California State U., Chico, CA 95926¹ and R.W. Johnson Med. School, UMDNJ, Piscataway, NJ 08854².

We examined motor control in normal and shiverer (shi) mutant mice using the rotarod assay, a forced motor activity which tests for balance and coordination. Shiverer mice carry a deletion in the myelin basic protein (MBP) gene, resulting in CNS dysmyelination and characteristic motor dysfunction. Shiverers were evaluated at 6-7 weeks of age in order to avoid the tonic seizures seen in older shi adults, and all animals were acclimated to the test apparatus prior to testing at 3 rpm and 6 rpm each for 1 min. Homozygous mutant mice had a significant increase in cumulative falls (5.05 ± 0.6 , n=44) relative to wild-type and heterozygous (shi/+) mice (0.11 ± 0.11 , n=9). Comparable results were obtained at speeds of 12 and 18 rpm, 1 min each. Non-acclimated animals showed learning curves with progressive improvement in performance when tested daily for four days, although the shi/shi animals consistently had more falls than normal control animals.

We also examined the potential for the rotarod assay to detect differences in motor performance of shi/shi animals in a transplantation paradigm. Postnatal day 2 animals received thalamic transplants of either rat cortical oligodendrocyte-type 2 astrocyte (O-2A) progenitor cells, or the O-2A line Central Glial-4 (CG-4) cells. Shi/shi transplant recipients showed a significant improvement in rotarod performance (1.72 ± 0.3 falls, n=18) although they continued to demonstrate a gross phenotype, indicating that the recovery measured in the rotarod represents a mild degree of functional restoration. Immunohistochemical analysis of tissue harvested after rotarod analysis revealed the expression of MBP in the CNS of transplanted shi/shi mice. A group of transplant recipients had a decline in motor performance relative to nontransplanted shi/shi mice (9.8 ± 1.8 falls, n=5). RNA analysis of two of these animals showed no evidence of MBP transcripts, consistent with the interpretation that the grafts were not successful in these recipients. Our results demonstrate that the rotarod is a sensitive measure of motor function in dysmyelinated mice, and suggest that transplantation can lead to an improvement in motor function. The cell and molecular basis for this motor recovery in shi/shi transplant recipients remains to be elucidated.

KINEMATIC AND EMG ANALYSES OF CONTROL AND SPINAL CORD TRANSECTED RATS DURING TREADMILL LOCOMOTION. J.G. Broton*, X.-M. Xu, M.B. Bunge, and B. Calancie. The Miami Project to Cure Paralysis and the Department of Neurological Surgery, University of Miami, Miami, FL.

We previously demonstrated that mid-thoracic spinal cord transections bridged by Schwann cell-filled guidance channels open at both ends (OPEN CHANNEL) promoted a greater number of axons growing into it than do channels closed at the distal end. The following studies were undertaken to determine if behavioral or electrophysiological correlates of this increased growth exist.

Unoperated control rats were studied to determine the normal walking pattern on a treadmill. These data were then compared to spinal cord transected, closed channel and OPEN CHANNEL groups. Rats were studied 1-4 weeks post-surgery. For the kinematic analysis, limb positions were taken at 30 frames/s during 7.5-30s of regular forepaw movement while rats were suspended in a sling over a treadmill which was moving at 0.05-0.15m/s. In conjunction with the kinematic study, EMG experiments were done, in which periods of activity ranging from 7.5-120s were collected from forelimb and hindlimb muscles, digitized at 2000Hz, rectified, and analyzed.

OPEN CHANNEL rats displayed significantly more hindlimb EMG than did rats with closed channels. Further, alternating hindlimb movements were sometimes seen which closely matched appropriate forelimb movements at some treadmill speeds, but which deteriorated at lower or higher speeds. To determine if this movement was under some voluntary control, we also calculated the cross-covariance functions of forelimb vs. hindlimb movements (kinematic analysis) and muscle activations (rectified EMG analysis).

Because involuntary reflex hindlimb movements can confound currently available behavioral measures of motor function, this analysis may prove useful in the assessment of motor deficit and subsequent restoration of movement after complete or incomplete spinal cord injury.

696.3

EFFECTS OF FETAL SPINAL CORD (FSC) IMPLANTS AND EXERCISE ON MUSCLE ATROPHY IN CHRONIC SPINAL RATS. N.B. Reese*, J.D. Houle, C.A. Peterson, C.M. Gurley, C.L. Berry, R.D. Skinner and E. Garcia-Rill. Depts. of Anatomy and Medicine, University of Arkansas for Medical Sciences, Little Rock, AR 72205

The potential for interventional procedures to influence the characteristic atrophy of hindlimb skeletal muscle following spinal cord injury was examined. Adult Sprague-Dawley rats sustained a complete spinal cord transection (Tx) by aspiration at the T12 level. Four groups of animals were prepared: Tx only, Tx followed by transplantation of FSC tissue, Tx followed by passive exercise or Tx with transplantation and exercise. A fifth group of non-injured animals served as controls. Exercise began 5 days after injury, consisting of two 20-minute sessions on a motorized cycler, 5 days/wk for at least 2 months. Animals were sacrificed after 2-3 mos. and tissue blocks from the gastrocnemius (G) and tibialis anterior (T) muscles were prepared for measurement of cross-sectional area of individual myofibers or for immunocytochemical analysis of myosin heavy chain (MyHC) components. Mean myofiber area was reduced by 45-55% of control in both G and T muscles after Tx alone. With passive exercise only, the extent of myofiber reduction was less severe (40% in G and 30% in T), while greater maintenance of fiber size was attained with FSC transplantation alone (65% of control for G and 90% of control for T). Combined FSC transplantation and exercise gave similar results to FSC transplantation alone. These results indicate that FSC transplants help maintain muscle fiber size to a greater degree than with exercise alone.

Analysis of MyHC components demonstrated an increase in myofibers expressing type IIb (fast, fatigable) and a decrease in those expressing type I (slow) after Tx. With exercise, fewer type IIb fibers were evident, while type IIa (fast, fatigue resistant) fibers were more prominent. These results suggest that the shift in expression towards type IIb fibers caused by spinal cord Tx is reduced by exercise by increasing the proportion of type IIa fibers. Supported by NSF Grant RII 8922103 and NIH Grant NS 29328.

EFFORTS TO REINNERVATE ADULT RAT GASTROCNEMIUS MUSCLE BY EMBRYONIC SPINAL MOTOR NEURONS TRANSPLANTED INTO PREDEGENERATED TIBIAL NERVE. D.E. ERB*, L. LIPSON, and R.P. BUNGE. The Miami Project to Cure Paralysis, Un. of Miami School of Medicine, Miami, FL 33136

Motor innervation is required for effective contraction and maintenance of skeletal muscle. If motor innervation is lost the muscle becomes denervated and undergoes progressive atrophy which ultimately leads to degeneration. Efforts to illicit muscle contraction or significantly retard muscle atrophy by direct electrical stimulation of the muscle are relatively ineffective without a nerve supply. Previously, we have reinnervated denervated adult rat gastrocnemius muscle by transplanting a heterogeneous neuronal population of dissociated cells, from E14 ventral spinal cord, into the adult rat tibial nerve, which was then transected proximal to the transplant site (Exp. Neurol. 1993. 124:372-376). Currently, we seek reinnervation by transplanting into nerve 1, 2, and 3 weeks after axotomy. Within six weeks posttransplantation large multipolar cells, resembling alpha motor neurons, were observed within the transplant site. Axons originating from these transplanted cells were identified within the nerve stump and within the previously denervated gastrocnemius muscle. Transplanted motor neurons survived up to 10 weeks (the longest survival) and could be retrogradely labeled with the retrograde tracer fast blue. This study demonstrates that embryonic spinal motor neurons, transplanted into the predegenerated adult peripheral nerve, are able to survive and extend axons into the denervated target muscle. This approach may provide the innervation necessary to artificially control muscle contraction by functional electrical stimulation, thus making previously unavailable therapies available to the muscle. (The Hollfelder Foundation, The Miami Project to Cure Paralysis, NRSA NS09144-01).

PHARMACOLOGIC MODIFICATION OF TRANSPLANT MEDIATED BEHAVIORAL RECOVERY IN NORMAL, SPINAL AND SPINAL+TRANSPLANT RATS. M.Murray*, A.Tessler, K.Simansky and D.Y.Miya. Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Fetal tissue transplanted into spinal cord will promote development of locomotor function in cats (Howland et al., 1993) and in rats transected as neonates (Miya et al., this volume). Specifically, interlimb coordination across the graft develops in transplanted but not spinal rats, shown by both behavioral and physiological methods. Transplants may improve interlimb coordination by promoting connectivity across the lesion, by increasing weight support through mechanisms operating at a segmental level or by a combination of both mechanisms. Because regenerating 5-HT axons have been shown to cross grafts in neonates, descending serotonergic systems might contribute to behavioral recovery. Trained normal, spinalized and transplanted rats were studied for the effects of serotonergic agonists. Quadrapedal treadmill locomotion was videotaped both before and after drug administration and analyzed. The non-specific 5-HT receptor agonist quipazine, produced a marked increase in the step cycle duration and augmented markedly the amplitude and duration of hindlimb extensors, flexors and axial muscles in transplanted animals. Quipazine did not effect either normal or transected rats at the doses used indicating that the descending 5-HT system may be involved in transplant enhanced locomotion. Immunocytochemical and fluorogold results also indicate the possible contribution of both the descending 5-HT and NE systems in the improved function. Supported by NIH NS24707 and VA Research Service.

696.4

CERVICAL SPINAL CORD INJURY (SCI) IN THE ADULT RAT: FORELIMB FUNCTION AFTER INTRASPINAL TRANSPLANTATION OF TROPHIC FACTOR-TREATED FETAL SPINAL CORD CELLS. S.M. Onifer*, J.F. Rodriguez, J.C. Benitez, D.H. Hesse, D.T. Kim, J.T. Pacheco, J.V. Perrone, D.I. Santiago, A. Martinez-Arizala. The Miami Project, Dept. of Neurological Surgery & Neurology, University of Miami School of Medicine, Miami, FL, 33136.

Traumatic contusion injury to the human spinal cord most frequently occurs at the cervical level and produces varying degrees of chronic tetraplegia. The deficits in the hands and arms result in part from cervical spinal motor neuron degeneration. Using our adult rat model of incomplete cervical SCI and forelimb behavior tests, the present study begins investigations of motor neuron replacement after cervical SCI as a means of ameliorating forelimb dysfunction. Cervical SCI was produced by dropping a 10 gm weight 2 cm onto the C7 spinal cord segment. Between 1-4 weeks post-SCI, SCI rats (n=11) had significant forelimb deficits compared to sham-injured rats (n=4) as shown by: 1) decreased grades for proximal (elbow) and distal (wrist and digits) extension and flexion (grasp) with a modified Tarlov scale and during Forelimb Placing Tests, 2) reduced forelimb grip strengths in the Grip Strength Test, and 3) reduced pellet retrievals and well clearance scores in the food retrieval Staircase Test. At 5-6 weeks, CNTF (Regeneron Pharmaceuticals, Inc., 5 µg/day) (n=4) or saline (n=3) was administered at the C7 segment of SCI rats through an intrathecal cannula. At 5 weeks, some SCI rats received transplants at C7 of diamidino yellow-labeled, E14-15 rostral spinal cord cell suspensions (1.05×10^6 viable cells) incubated for 60-90 min in $10.5 \mu\text{g}$ CNTF (n=2) or saline (n=2). At 10 weeks, forelimb function of all SCI rats had not improved. Nissl-stained cells with motor neuron morphology and ChAT-immunoreactive cells were found in similar small numbers in all transplants. The results show that improving survival and outgrowth of transplanted motor neurons needs to be further examined. Supported by The Miami Project to Cure Paralysis.

TRANSPLANT MEDIATED BEHAVIORAL RECOVERY OF WEIGHT SUPPORT & INTERLIMB COORDINATION IN NORMAL, SPINAL AND SPINAL+TRANSPLANT RATS.

D.Y.Miya*, B.Clark, A.Tessler and M.Murray. Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Transplanted fetal spinal cord tissue into verified lesion sites can support locomotion in newborn spinal cats (Howland et al., 1993). Surgical procedures and a battery of quantitative behavioral tests were developed to extend these results to a neonatal rat model. Blocks of E14 cervical spinal cord tissue were placed into the newly transected rat thoracic spinal cord on/after the day of birth. Reflex and locomotor behavior was studied in normal rats, spinal rats and in spinal rats with a transplant beginning at 4 weeks of age. Tests examined posture, weight support and interlimb coordination and included reflex bipedal and quadrapedal treadmill locomotion, motivated locomotion over a variety of terrains and stair climbing. Transplanted animals demonstrate coordination and weight supported steps on all types of locomotion but also exhibit marked hypermetria in the hindlimbs (HL's). EMG recordings taken from each limb during locomotion also demonstrate intersegmental communication across the graft in transplanted, but not spinal rats. Spinal rats demonstrate coordinated HL stepping only during tests of supported, reflex bipedal locomotion. Stair climbing, a task requiring complex postural adjustments and adaptive changes in weight support and interlimb coordination, was completed differently by each of the 3 groups of trained rats. Supported by NIH NS 24707 and VA Research Service.

COMPARISONS BETWEEN TYROSINE HYDROXYLASE AND PREPROENKEPHALIN mRNA IN RAT ADRENAL MEDULLARY EXPLANTS IN VITRO AND IN CNS TRANSPLANTS. X.-T. Wang*, J. Unnerstall, G.D. Pappas and J. Sagen. Dept. of Anat. & Cell Bio., Univ. of Illinois at Chicago, Chicago, IL 60612.

Our previous work has indicated that pain sensitivity can be reduced by transplanting adrenal medulla into the rat spinal subarachnoid space. To further elucidate the mechanism of this pain alleviation, the expression characteristics of tyrosine hydroxylase (TH) mRNA and preproenkephalin (PPEnk) mRNA were investigated using *in situ* hybridization in rat adrenal medullary explants in culture and transplants in the spinal subarachnoid space. ³²S-labeled oligonucleotide probes and anti-TH monoclonal antibody were applied to 10-µm cryostat sections. The relative mRNA levels and immunoreactivity (IR) were quantified by image analysis. Both TH mRNA and PPEnk mRNA levels in explants started to increase after 4 days in culture, and reached a peak at 7 days. At 14 and 28 days in culture, levels of TH and PPEnk mRNA decreased, but were still significantly higher than that of intact normal adrenal medulla and than at 1 and 4 days in culture. The TH-IR significantly increased by 1 day, and continued to increase up to 4 days in culture. Thereafter, it remained constant at a high level. Similar to adrenal medullary explants, adrenal medullary transplants contained numerous TH mRNA labeled cells at 1, 2 and 12 weeks after transplantation. However, only a few cells expressed PPEnk mRNA by 2 weeks post-transplantation. These results indicate that, while surviving chromaffin cells can still synthesize catecholamines when transplanted to the CNS, the synthesis of opioid peptides may remain low. In addition, these findings suggest that the regulatory mechanisms of TH mRNA and PPEnk mRNA expression in rat adrenal medullary cells differs under the environmental influence of culture and the CNS. Supported by NIH grant NS25054.

ANALGESIA INDUCED BY IMPLANTATION OF ENCAPSULATED GENETIC ENGINEERED CELLS SECRETING β -ENDORPHIN. Y. Saitoh*, T. Taki, N. Arita, T. Ohnishi, T. Hayakawa. Dept. of Neurosurgery, Osaka Univ. Med. Sch., 2-2 Yamadaoka, Suita, Osaka 565, Japan

The purpose of this study was to assess whether genetic engineered, xenogeneic tumor cells immunologically isolated in polymer capsules could survive and continue to reduce pain when transplanted into the spinal CSF space of rats. The mouse neuroblastoma cell line, pro-opiomelanocortin gene transfected Neuro2A (gift from Dr. Boileau, Montreal) which secretes β -endorphin, was enclosed in polymer capsules (AMICON Co., diameter: 500 μ m, length: 15mm) at the density of 5x10⁶/ml, and transplanted into the spinal CSF space from the occipito-atlantal junction of male Sprague-Dawley rats. Three analgesiometric tests; tail pinch test, hot plate test, and electrical stimulation test, showed that the rats with encapsulated Neuro2A (n=6) were significantly less sensitive to pain 2 and 4 weeks after transplantation in comparison with control animals (n=8) and pre-transplanted animals (ANOVA; p<0.05). The analgesia induced by encapsulated cells secreting β -endorphin could be attenuated by naloxone (1mg/kg; body weight, i.m.), which suggested the involvement of opiate in mediating this response. Morphological study revealed that the cells in polymer capsules survived a month after implantation in the CSF space. A month after the implantation of capsules in the rat CSF space, some of them were removed and immersed in culture medium. Peptides secretions from encapsulated Neuro2A cells were confirmed. The result of this study suggest that immunologically isolated, genetic engineered xenogeneic tumor cells can secrete opiate in the CSF space, and this method may be applied to the treatment of cancer pain.

THE ADRENAL MEDULLAE AUTOTRANSPLANTED INTO THE THALAMI FOR 8 MONTHS STILL PRODUCE ENKEPHALINS

Q. Liu¹, G. Cao², H. Liu¹ and C. Yu²

¹Division of Pharmacology, Lushan Pharmacy Institute, Lushan, Henan 467300, ²Department of Histology and Embryology, West China University of Medical Sciences, Chengdu, Sichuan, 610041, P. R. China, and ³Department of Physiology and Biophysics, University of Cincinnati College of Medicine, Cincinnati, OH 45267-0576.

Enkephalin, an endogenous opioid peptide, plays an important role in pain modulation. As enkephalin is produced by the adrenal medulla, a possible treatment for reduction of refractory pain is by adrenal medullary transplantation. One possible target for this transplantation is within the thalamus, a major site for processing ascending and descending nociceptive information. In the present study, L-enkephalin and M-enkephalin contents were determined in homogeneous adrenal medullae transplants after eight months survival. Male guinea pigs (eight weeks old) were used. Right adrenal medullae were used as control. Following a eight month survival time, animals were perfused with Zamboni's fixative. Thirty micron sections were cut through the thalamic grafts and the left adrenal medulla and the tissue processed immunocytochemically for L-enkephalin and M-enkephalin. Following a eight month survival time, L-enkephalin and M-enkephalin were still detected in the grafts of the thalami of the guinea pigs. This result suggests that L-enkephalin and M-enkephalin were produced by the grafts transplanted into the thalamus after a relatively long period time of survival.

696.13

EFFECTS OF FETAL SEPTAL GRAFTS ON MEMORY AND LEARNING PERFORMANCE WITH HIPPOCAMPAL ACETYLCHOLINE METABOLISM IN FIMBRIA TRANSECTED RATS. Z. Ipekoglu, L. Ruyukcuysal, I. Iluluz*, E. Korfali. Department of Neurosurgery and Pharmacology, Uludağ Univ. Sch. of Med., BURSA 16059

The fimbria of Sprague-Dawley rats was transected unilaterally. A group of rats with fimbria lesion received septal graft two weeks after the lesion surgery. The grafts were obtained from ventral forebrain of 13-15 days old fetuses of the same outbred strain. Lesion of the fimbria led to impairments in step-through passive avoidance and Morris' water maze tasks. Such impairments were partially ameliorated by graft tissue but it did not reach to a statistically significant level. Fimbrial lesion produced significant decline in both stimulated acetylcholine (ach) release from the hippocampal slices and in tissue ach levels. Septal grafts both ameliorated hippocampal ach levels (p<0.01) and stimulated release of ach (p<0.01) although we were unable to show its reflection on behavioral tests appropriately.

696.10

XENOTRANSPLANTATION OF ENCAPSULATED BOVINE CHROMAFFIN CELLS FOR THE TREATMENT OF INTRACTABLE PAIN: A PHASE I CLINICAL STUDY

P. Aebischer*, E. Buchser, J.M. Joseph, B. Heyd, V. Padrun, A. Zum, J. Favre, N. de Tribolet, M. Goddard. Lausanne University Medical School, Lausanne, Switzerland, CytoTherapeutics, Providence, RI, USA.

Chromaffin cells are known to release a cocktail of analgesic substances such as catecholamines and opioids. Transplantation of allogeneic and xenogeneic chromaffin cells has been shown to alleviate pain in rodent models. To circumvent the problem related to the shortage of human cadaver donors, we are investigating the possibility of transplanting encapsulated xenogeneic cells in humans suffering from intractable pain. Chromaffin cells are isolated from surgically harvested calf adrenal glands and encapsulated in a tubular (5cm long, 950 μ m OD) semipermeable membrane which allows diffusion of nutrients and neurotransmitters but prevents rejection of the graft by the host immune system. Bacteriologic analysis and capsule catecholamine release studies were performed before implantation.

Ten patients suffering from chronic pain related to advanced cancer or deafferentation were transplanted with cell loaded capsules in the lumbar subarachnoid space (n=8) or lateral ventricle (n=2) using minimally invasive techniques. No evidence of serious complications or significant host tissue reaction related to the capsules was observed. Viable cells positive for tyrosine hydroxylase and methionine enkephaline immunostaining were observed in all but one of the nine explanted capsules. Seven of the ten patients showed improvement in their chronic pain on the basis of decreased narcotic intake (4/6 opioid responders) or improvement in pain scores (3/3 non-responders to narcotics).

696.12

POLYMER-ENCAPSULATED CELLS GENETICALLY MODIFIED TO SECRETE HUMAN NGF IMPROVE COGNITIVE FUNCTION FOLLOWING INTRAVENTRICULAR IMPLANTATION INTO AGED RATS. M.D. Lindner*, E.E. Baeige, J.P. Hammang, S.R. Winn, E.J. Gentile, E. Doherty, C.E. Krams, B. Frydgi, and D.F. Emerich. Dept. of Neuroscience and BioEngineering, CytoTherapeutics, Inc., Two Richmond Square, Providence, RI, 02906.

Exogenous NGF has been reported to improve cognitive function in rats with age-related cognitive deficits. However, as a potential treatment for Alzheimer's disease, concerns have been expressed about the risks involved with supplying NGF to the CNS. Recent work in our laboratories has suggested that the beneficial effects of exogenous NGF may be obtained with doses much smaller than those used previously. In this study, baby hamster kidney cells were genetically-modified to secrete human NGF (hNGF), encapsulated in semipermeable membranes, and implanted intraventricularly. hNGF production was less than 10% of doses previously reported to be effective. Performance in a working-memory version of the Morris water maze spatial learning task was improved in more impaired 20.6 and 26.7 mo rats; yet, in contrast to results with higher doses of NGF, there was no evidence that hNGF impaired performance in the youngest 3.3-5.4 mo rats. Other measures support the safety of this potential treatment. More than 30% of the oldest rats died during the 6 days before being implanted, but analyses of the survival distribution functions failed to detect significant increases in mortality rates related to either the implantation procedure or the hNGF produced by the capsules. Body weights, collected weekly throughout the study, also failed to reveal even transient deleterious effects of the surgical procedure or the hNGF produced by the capsules. Exogenous hNGF administered peripherally produces hyperalgesia, but the intraventricular capsules in the present study did not produce statistically significant effects in the hot plate analgesiometric test. Activity levels monitored throughout the light:dark cycle revealed statistically significant but small increases in activity in the young and middle-aged rats receiving hNGF, but no change in the oldest rats receiving hNGF. Somatosensory function, assessed using von Frey hairs, was not affected by hNGF in the young or middle-aged rats. Old rats are significantly less responsive to light touch than young rats, but hNGF treatment increased the responsiveness of the oldest rats to light touch to the level of young rats. These results suggest that CNS-implanted semipermeable membranes, containing genetically-modified xenogeneic cells continuously produce hNGF that improves age-related cognitive deficits in nonimmunosuppressed rats, and that both the surgical implantation procedure and long-term exposure to low doses of hNGF appear safe in rats.

A MODEL OF FETAL NEURAL TISSUE TRANSPLANTATION INTO A SITE OF TRAUMATIC BRAIN INJURY. G.Sinson, E.S. Flamm*, and T.K. McIntosh. Division of Neurosurgery, University of Pennsylvania, Philadelphia, PA 19104.

Fetal rat cortical cells have been shown to survive when transplanted to the edge of the central core of ischemia induced by middle cerebral artery occlusion. The present study was designed to examine the feasibility of transplanting fetal rat cortical cells into the area of damaged cortex in a clinically relevant model of fluid-percussion head injury in the adult rat. This injury results in a reproducible cavity with glia limitans in the parietal cortex. Male Sprague-Dawley rats (300-400g) received later (parasagittal) fluid-percussion brain injury of moderate severity (2.1-2.3 atmospheres). At 24 hours after injury timed pregnant female Sprague-Dawley rats (E16) were anesthetized (sodium pentobarbital), the fetuses were removed, and the fetal cortical cells were surgically dissected. These fetal rat cortical cells were stereotactically transplanted with a glass pipette into the site that the injury cavity would form.

Memory testing using the Morris Water Maze and examination of post-traumatic motor dysfunction at 48 hours after transplantation demonstrated that these animals did not have worsened deficits when compared to animals which only received a fluid-percussion injury of similar severity. Histologic evaluation with Nissl stain 48 hours and 7 days after transplantation demonstrated survival of fetal cells. It is concluded that fetal cortical cells can be safely and successfully transplanted into the traumatically injured cortex of the adult rat. (Supported in part by NIH grants NS2618 and NS08803).

Host Brain Modulation of Intra-Retrospinal Transplants of Cholinergic Septal Neurons. *Ying J. Li*, and Walter C. Low.* Depts of Neurosurgery and Physiology, and Program in Neuroscience, University of Minnesota Medical School, Minneapolis, MN, U.S.A.

Previous studies from our laboratory have demonstrated that cholinergic-rich grafts derived from fetal septal nucleus can re-establish the cholinergic innervation in the retrosplenial cortex (RSC) of rats with lesions in both fornix and cingulate pathways. Concurrently, a significant amelioration of spatial memory deficits in these animals was observed. In the present study we postulated that the grafts can become functionally incorporated with the neural circuitry of the host brain, and can thus be regulated by activity from the host brain. To test this hypothesis we evaluated the effect of the animals' performance in a 6-arm radial maze task on high affinity choline uptake (HACU). Three groups of rats were used: 1) normal control rats (NC), 2) rats with lesions of the fornix and cingulate pathways, and 3) lesioned rats with fetal septal grafts in the RSC (RSCsep-TPL). Animals in each group were further randomly divided into two subgroups: 1) rats that performed the maze before the determination of HACU levels (BEH), and 2) rats that were kept in their home cage (NON-BEH) and paired with a BEH mate for HACU assessment. In NON-BEH animals, the HACU values (pmol/4 min/mg protein) were 21.2 ± 0.9 (mean \pm SEM) for the NC, 9.9 ± 1.0 for the FX, and 17.7 ± 0.7 for the RSCsep-TPL animals. The BEH subgroups had HACU values of 29.8 ± 0.8 for the NC, 9.1 ± 1.0 for the FX, and 22.9 ± 0.9 for the RSCsep-TPL. In comparing HACU levels with their NON-BEH counterparts, *t*-test indicated significant increases in the NC ($p < 0.001$) and RSCsep-TPL ($p < 0.005$) groups, but not in the FX animals ($p = 0.565$). These results suggest that fetal septal graft in the RSC can become functionally incorporated with the host neural circuitry, and that the activity of the implanted cholinergic neurons can be modulated by the host brain. (Supported by NIH grant RO1-NS-24464).

INDUCED RAPID PATH FORMATION OF FETAL DOPAMINE NEURONS GRAFTED IN NIGRA AND REINNERVATION OF STRIATUM WITH FUNCTIONAL IMPROVEMENT. *F.C. Zhou*, and Y.H. Chiang.* Dept. Anatomy, Indiana Univ. Sch. Med., Indianapolis, IN 46202

Excitatory neurotoxin ibotenic acid (IB) or kainic acid (KA) injection in the brain in one way causes death of excitable neuron, but they also induce a neurotrophic environment for neuronal growth. The lesion effects when confined in a tract, provides a trophic throughway for the axonal outgrowth of transplanted neurons and reinnervation of 5-7 mm distal target in 3 weeks.

Sprague-Dawley rats were unilaterally injected with 6-hydroxydopamine (6-OHDA, 12 μ l, 5 μ g/ μ l) in medial forebrain bundle. 1-2 weeks later, KA (1 μ g/ μ l) or IB (10-20 μ g/ μ l), or phosphate buffer (PB) were microinjected through a glass-pipet to make a 5-7mm long tract between nigra and striatum, followed by graft of E-14 brainstem cells into nigra. Animals were either perfused and stained with tyrosine hydroxylase immunocytochemically (TH-im) 3-4 weeks later, or injected with HRP in the striatum and their brains were stained 24 hours later in the graft regions.

The 6-OHDA degenerated DA neurons in nigra and completely denervated the striatum. (n=13). Unilateral turning was evident after amphetamine challenge. Traceable TH fibers from grafts grew distinctly in a bundle along the entire length of KA/IB tract (n=5), but not into the PB tract (n=5). The TH-im fibers did not leave the KA tract when coursing through the globus pallidus, but quickly spread out when reaching the striatum. Reinnervating TH-im fibers were distributed in patches in the striatum near pallidum but non-discriminately in rostral striatum. HRP tracing reveals labeled neurons in the graft (n=3). Behavioral studies show that amphetamine challenged unilateral turning was reduced by about 40%-50% after the bridging method of transplant.

ENHANCED SURVIVAL OF NEURAL XENOGRAFTS AFTER MASKING OF DONOR MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I. *P. Pakzaban*,^{1,2} T.W. Deacon,¹ L.H. Burns,¹ J. Dinsmore,³ and O. Isacson.^{1,2}* Neuroregeneration Laboratory¹, McLean Hospital, Belmont, MA, 02178; Neurosurgery and Neurology Services², Massachusetts General Hospital, and Program in Neuroscience, Harvard Medical School, Boston, MA 02114; and Diacrin Inc.³, Charlestown, MA 02129.

To determine the role of major histocompatibility complex class I (MHC-I) in immunological rejection of neural xenografts, fragments of a monoclonal antibody (Fab) directed against porcine MHC-I were used to mask this complex on porcine striatal neuroblasts transplanted into the rat striatum. Adult rats previously lesioned with quinolinic acid in the striatum received stereotaxic intrastratial injections of cell suspensions prepared from the lateral ganglionic eminence of E35 porcine telencephalon. The presence of MHC-I on the surface of these cells was confirmed by fluorescence-activated cell sorting. Transplanted rats were divided into 4 groups based on immunosuppressive treatment: group I, no immunosuppression; group II, pretreatment of porcine neuroblasts with anti-MHC-I Fab; group III, daily subcutaneous injections of cyclosporine A (CsA; 10 mg/kg/d); group IV, Fab pretreatment plus CsA administration. Rats were sacrificed after 3 - 4 months, and xenograft survival and integration were assessed by species-specific immunostaining of donor neuronal and glial elements. Xenograft survival rates in the 90 surviving rats were 1/14 in group I, 15/29 in group II, 23/31 in group III, and 13/16 in group IV. MHC-I masking with Fab produced a significant increase in xenograft survival compared to the non-immunosuppressed controls ($P < 0.005$, $\chi^2 = 9.39$, df = 1). The difference in graft survival between groups II, III, and IV was not statistically significant, but grafts in group II were smaller and relatively depleted in neuronal elements compared to groups III and IV. Grafts undergoing rejection were infiltrated by host immune cells and were intensely immunoreactive for donor MHC-I. In addition to confirming the importance of MHC-I-restricted immune mechanisms in neural xenograft rejection, these results encourage future application of molecular-level immunoprotection strategies to neural transplantation.

696.18

PROTEOLYTIC ENZYMES INVOLVED IN GLIAL CELL MIGRATION FOLLOWING TRANSPLANT OF FETAL RABBIT BRAIN TISSUE INTO MOUSE BRAIN. *M.R. Del Bigio*, J.-L. Tchelingirian, C.M. Jacques* INSERM U134, Hôpital de la Salpêtrière, Paris 75675 France

Following grafting of fetal (E25) rabbit brain fragments into the striatum of shiverer mouse (a mutant lacking MBP) brain, glial cells migrate predominantly along white matter tracts. Differentiated astrocytes can be identified by the antibody TpGFAP1 which recognizes rabbit but not mouse GFAP. Transplanted oligodendrocytes produce myelin which contains MBP. Immunoelectron microscopy shows that transplanted astrocytes are well integrated into host brain in both perivascular and perineuronal positions. To study the role of proteolytic enzymes in the migration of transplanted glial cells 3 days to 4 weeks after transplantation we used immunohistochemistry and non-radioactive ISH. Transplanted astroglial cells are often immunoreactive for tissue plasminogen activator (tPA). Some immature transplant cells at the graft nidus show urokinase PA-like immunoreactivity. In sham-grafted controls, reactive astroglia exhibit tPA and inflammatory cells show UPA. Immature transplanted cells express the mRNA for matrix metalloproteinases (MMP) type 1 and type 3 for up to 4 weeks. Transient expression of MMP3 is occasionally observed at a distance from the graft in sites associated with cell migration. We conclude that some proteolytic enzymes may be associated with the migration of transplanted glial cells. However, they are not unambiguous identifiers of migrating glial cells.

CHRONIC ADMINISTRATION OF GM1 GANGLIOSIDE ENHANCES CHOLINERGIC PARAMETERS IN THE AGED BRAIN. *M. Hadjiconstantinou*, T.G. Fong and N.H. Neff.* Depts. of Psychiatry, Pharmacology and The Neuroscience Program, The Ohio State University College of Medicine, Columbus, Ohio 43210

Although the mechanism(s) of action of GM1 ganglioside is unresolved, it has been postulated that it might enhance the action of endogenous trophic factors by augmenting their synthesis and/or release, and/or by altering trophic factor receptor characteristics. We now provide evidence that GM1 has a synergistic action with NGF in the brain of aged animals. Chronic intracerebroventricular administration of GM1 increases choline (Ch) uptake and choline acetyltransferase (ChAT) activity in the striatum and hippocampus of old rats. When a low ineffective dose of GM1 (0.5 mg/day for 4 wks) is co-administered with various doses of NGF (0.2, 0.5 and 1 μ g/day for 4 wks) there is enhancement of the response to NGF on Ch uptake and ChAT activity. Our results are consistent with apparent potentiation by GM1 of the effect of NGF on cholinergic parameters in aged animals.

697.2

Cholesterol Protects Against NO- or OH-Induced Oxidative Stress in Perfused Striatal Slices Irrespective of Age. *J.A. Joseph*, R. Villalobos, J. Strain and N. Jimenez.* ARS-USDA Human Nutrition Ctr. on Aging, Boston, MA 02111.

Previously, cholesterol (Cho) decreased oxotremorine (Oxo) enhancement of K⁺-evoked dopamine release (K⁺-ERDA), suggesting that Cho, which accumulates in membranes during aging alters signal transduction. However, present findings suggest that such accumulation may actually serve to protect neuronal tissue from oxidative damage. Striatal slices (6, 24 mo rats) were incubated in 1 mM cholesterol (30 min) followed by H₂O₂ (7.5 μ M, 30 min). Perifusions with 30 mM KCl with, and without 500 μ M Oxo, indicated no H₂O₂ reductions in K⁺-ERDA in Cho-incubated tissue in either age group (e.g., no Oxo, young K⁺-ERDA Δ from HiKCl alone H₂O₂ = -69.48 \pm 10 Cho+H₂O₂ = 60.34 \pm 14.34 p moles/mg protein, $t = 17.9$ df = 8 $p < 0.0001$). Similar protection was observed under Oxo conditions as well. Cho also antagonized nitroprusside (NI 150 μ M) decreases in K⁺-ERDA (young Ni Δ = -79.30 \pm 10.41, Ni + Cho 6.07 \pm 22.96 p moles/mg protein, $t = 7.57$ $p < 0.001$). Interestingly, Cho comparisons with other antioxidants (e.g., α -tocopherol) on OH⁻ or NO⁻ reductions indicated comparable protection.

697.3

LONG-TERM TREATMENT WITH A MONOAMINE OXIDASE-B INHIBITOR SELEGILINE OF AGEING RATS: EFFECTS ON AMINO ACID AND MONOAMINE NEUROTRANSMITTERS. P. Saransaari, J. Suhonen, S.M. Lillrank, A. Hervonen and S.S. Oja. Tampere Brain Res. Ctr., Univ. of Tampere, FIN-33101 Tampere, Finland.

Long-term treatment with the monoamine oxidase type B inhibitor L-deprenyl (selegiline) prolongs both mean and maximum survival and improves cognitive functions in aged rats. The effects of this drug on amino acid and monoamine neurotransmitters in different brain regions (cerebral cortex, cerebellum, hippocampus, striatum) were investigated in male Wistar rats treated with selegiline (0.5 mg/kg/d in drinking water) from the third postnatal week up to 10 months or from 12 months to 24 months of age. There were no significant differences between selegiline-treated and control rats in the basal and K⁺-stimulated (50 mM) release of labeled preloaded dopamine, noradrenaline and GABA from brain slices. Ageing did not either affect the release parameters. The binding constant K_D of GABA_A sites increased with age in the cerebral cortex and cerebellum but the maximal binding capacity B_{max} for GABA remained about the same. In the selegiline group K_D decreased in the cortex and striatum but increased in the cerebellum during ageing, while B_{max} was affected less. Selegiline treatment thus alters both affinity and number of binding sites. The binding parameters of GABA_B sites remained unaltered during ageing and selegiline treatment until 17 months of age. There were no marked changes in the properties of dizocilpine (MK-801) binding to the cortical NMDA receptor complex. The results show that long-term selegiline treatment affects the receptor binding but not the release of the above transmitters in the brain regions studied.

CYSTAMINE-INDUCED ASTROCYTE CYTOPROTECTION: ROLE OF INTRACELLULAR ANTIOXIDANT DEFENSES. F. Manganaro and H.M. Schipper. Dept. of Neurology and Neurosurgery, McGill Univ., Bloomfield Centre for Research in Aging, Jewish General Hospital, Montreal, QC, Canada, H3T 1E2

Background: The aminothiol compound, cysteamine (CSH), induces gliosis *in situ* and the appearance of peroxidase-positive cytoplasmic granules in cultured astroglia identical to glial inclusions which progressively accumulate in the aging periventricular brain. In addition CSH-pretreatment protects cultured astroglial from subsequent H₂O₂ and mechanosensory stress. **Objective:** To determine whether changes in antioxidant defenses mediate cytoprotection in CSH-treated astroglia. **Methods and Results:** CSH treatment (880 μM) induced a 5 fold increase in glutathione (GSH) concentrations and a persistent augmentation of manganese superoxide dismutase (MnSOD) activity in cultured astroglia. In contrast, astroglial catalase and glutathione reductase activities and whole cell lipid peroxidation were suppressed by CSH treatment while copper-zinc superoxide dismutase activity remained unchanged. Glutathione peroxidase activity was increased after 3 and 48 hrs of CSH treatment but declined thereafter to below control levels. **Conclusions:** Elevations in intracellular GSH concentrations and sustained augmentation of MnSOD activity may be responsible for astrocyte cytoprotection resulting from CSH exposure. CSH-treated astrocytes may serve as a useful model for stress-related (dys)regulation of MnSOD and other antioxidant defenses which have been documented in the aging and degenerating nervous system. In the latter, astrocyte cytoprotection may facilitate the establishment of reactive gliosis in the face of concomitant neuronal depletion.

697.7

EFFECTS OF AGE ON THE DISTRIBUTION OF VISUOSPATIAL ATTENTION. S. Panicker, P.M. Greenwood & R. Parasuraman. Cognitive Science Lab., The Catholic University of America, Washington, D.C. 20064. Assessment of the component operations and brain systems mediating shifts of visuospatial attention, both in normal aging and in dementia (Panicker et al., *Soc. Neurosci. Abst.*, 1993), requires further analysis of the processing of non-informative or neutral spatial cues. To determine age effects in the distribution of visuospatial attention following informative and neutral spatial location cues, young and old Ss performed a cued discrimination task in which choice RT was measured. Cues were informative (60% valid, 20% invalid) or neutral (20%) and preceded discrimination targets ("+" or "x") by 100, 200 or 500 msec. The distance between invalid cues and targets was systematically varied. There were two types of neutral cues: a small diamond in the center of the screen; a large rectangle outlining the periphery of the screen. Old and young produced similarly steep slopes relating RT to invalid cue-target distance and similarly shallow slopes relating RT to neutral cue-target distance for both types of neutral cues. These results indicate: (a) age has no effect on the shifting of attention over a large range of distances; (b) while a narrow focus of attention is induced by informative peripheral cues, a broad and fairly even distribution of attention is induced by both discrete and diffuse neutral cues. This suggests attention is diffusely distributed following a neutral cue, irrespective of the cue's physical attributes. Supported by Alzheimer's Association/Ana M. Buchanan Memorial Investigator-Initiated Research Grant to PMG and NIA grant AG07569 to RP.

METAL-CATALYZED OXIDATION OF BOVINE NEUROFILAMENTS (NF) IN VITRO. JC Troncoso^{1,3}, JH Kim², AC Costello², and GVW Johnson¹. Departments of ¹Pathology and ²Neurology, ³Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD; ⁴University of Alabama, Birmingham, AL.

NF are important determinants of the shape and size of nerve cells. The oxidation of NF, potentially relevant to aging, neurodegenerative disorders, and Wallerian degeneration, has not been studied. In this investigation, we combined biochemical and ultrastructural methods to study the metal-catalyzed oxidation (MCO) of bovine NF using an ascorbate/Fe³⁺/O₂ system. The oxidation of NF proteins was documented by significant increases in carbonyl content, which were time and concentration dependent. Polyacrylamide gel electrophoresis and immunoblot analyses revealed fragmentation of oxidized NF proteins, predominantly NF-H and NF-M. Electron microscopy showed that oxidized NF formed dense aggregates and bundles of laterally aggregated filaments. Finally, we also demonstrated that oxidized NF proteins were more susceptible to calpain proteolysis. In view of the growing evidence to support increased oxidative stress of the nervous system in aging and the report of the Cu/Zn superoxide dismutase mutation in familial motor neuron disease, the oxidative injury of NF may be of relevance to the atrophy and degeneration of nerve cells and the formation of abnormal cytoskeletal structures in neurodegenerative disorders.

AGE-RELATED IMPAIRMENT OF THE CARDIAC SYMPATHETIC AND VAGAL COMPONENTS OF THE BAROREFLEX ARC IN FISCHER 344 RATS. Eugene W. Shek*, Julianna E. Szilagyi. Department of Pharmacological & Pharmaceutical Sciences, University of Houston, Houston, Texas 77204-5515.

Ageing is associated with progressive deterioration of baroreflex sensitivity (BRS). The present study was undertaken to examine whether the impaired BRS observed in aging was due to the change in the relative contribution of the cardiac sympathetic (CS) and cardiac vagal (CV) components of the baroreflex arc (BRA) in 6, 12 and 18-month-old male Fischer 344 rats. Rats were anesthetized with methoxyflurane and α-chloralose. BRS was determined by calculating the slope of a regression line relating changes of heart period to mean blood pressure in response to randomized doses of phenylephrine (PE). The CS and CV components of the BRA were determined after vagal (2mg/kg atropine) and sympathetic (2mg/kg propranolol) blockade, respectively. There was no significant change in basal blood pressure with age. The basal and intrinsic heart rate (HR) of 12 & 18-month-old rats were significantly lower than 6-month-old rats. In addition, the 18-month-old rats had an augmented CS heart rate compared with the younger rats. The CV heart rate appeared to be unaltered with age. The BRS of 18-month-old rats was significantly attenuated compared with 6 & 12-month-old rats (1.1±0.1 vs 1.8±0.1 & 1.7±0.1 msec/mmHg, respectively; p<0.0005). There was a significant increase in the CS component of BRA with age (12%, 13% & 46%, respectively; p<0.001) with only a gradual decline in the CV components (61%, 55% & 49%, respectively). The vascular responsiveness to PE was significantly decreased in 18-month-old rats compared with 6 & 12-month-old rats. Thus, these results demonstrated that 1) the reduced basal HR in aged rats was primarily due to the reduced intrinsic HR, 2) the impaired BRS with age was due to the augmented CS contribution of the BRA in responses to an increase in blood pressure, 3) baroreflex function was changed from being primarily a CV mediated response in younger rats to a response equally mediated by CV and CS in the aged rats, and 4) the reduced vascular responsiveness to α-adrenoceptor agonist (PE) suggested a possible change in vascular α-adrenoceptor number, affinity or second messenger system in aged rats. (Supported by: AG09542)

AGE-RELATED DIFFERENCES IN DOPAMINE MEDIATED BEHAVIORS AND FOS IMMUNOREACTIVITY IN FISCHER 344 RATS. C.A. Crawford* and M.S. Levine. Mental Retardation Research Center, University of California, Los Angeles, CA 90024.

Decreases in dopaminergic function are known to occur in the nigrostriatal and mesolimbic systems during aging; however, the neurobiological substrates that underlie these changes have not been determined. Therefore, in the present study, the behavioral and neuronal response to amphetamine were assessed in aged (24 mos) and young (2 mos) Fischer 344 rats. Rats were first habituated for 30 min in a test chamber and then injected with amphetamine (5 mg/kg, i.p.). They were then placed in the testing chamber for 90 min and behavioral data were recorded for a 2 min period at 10 min intervals. Behavioral stereotypes induced by amphetamine were rated on an intensity scale. Low-intensity stereotypes included rearing and line crossing while high-intensity stereotypes included licking and chewing. Following behavioral testing, rats were sacrificed and tissue was processed for Fos immunoreactivity using standard techniques. Behavioral results showed that aged rats had significantly fewer low-intensity stereotypes than young rats. In contrast, the number of high-intensity stereotypes were significantly enhanced in the aged group. Aged rats had fewer Fos-positive nuclei in the lateral neostriatum and nucleus accumbens than young rats. The number of Fos-positive nuclei in the medial neostriatum, piriform cortex and olfactory tubercles did not vary consistently according to age. Supported by AG 10252.

PARANODAL ACCUMULATION OF LIPOPIGMENTS IN AGING MOTOR AND SENSORY AXONS. K.P. Gatzinsky*, R.H.M. King and P.K. Thomas. Dept. of Neurosci., Royal Free Hospital Sch. of Med., London NW3 2PF, UK.

The aim of this study was to explore if paranodal axon-Schwann cell networks (ASNs), which are entities assumed to take part in removal and degradation of worn-out organelles in large myelinated PNS axons, can serve as depots for non-degradable materials with increasing age. We addressed this issue by examining the occurrence of autofluorescent lipopigments in large myelinated motor and sensory axons of rats aged 2-25 months. After fixation with 4% paraformaldehyde, 10 μ m thick longitudinal sections were cut from the lumbar ventral (VR) and dorsal (DR) roots and examined with a Zeiss fluorescence microscope equipped with phase-contrast optics and a FITC filter set. From each root, 200 randomly selected node-paranode regions in nerve fibres 8-12 μ m in diameter were searched for autofluorescent granules. Orange-yellow granules situated in close apposition to the paranodal myelin sheaths started to appear in both VR and DR axons from 3-4 months of age. Both the percentage of paranodal regions of this type and the number of granules increased with age. Up to 1 year of age, VR axons showed the highest granular contents. From this age, >90% of the paranodes in both the VR and the DR showed autofluorescent granules. Some paranodes in the oldest animals contained >15 granules, which generally appeared in clumps and often were of larger sizes in VR than DR axons. In both axon types, the vast majority of the granules were situated distal to the nodal mid-level. EM analysis showed that most granules were lipofuscin bodies associated with ASNs. The progressive age-related accumulation of indigestible materials within ASNs may serve a function to shield the aging perikarya mainly of motor neurons from being crammed with retrogradely transported worn-out organelles from the axon.

EFFECT OF A CONDITIONING LESION ON AXONAL OUTGROWTH RATES IN MATURE AND AGED F344 RATS. Zhong Huang* and Jane M. Jacob. Dept. of Anatomical Science, Univ. of Oklahoma HSC, Oklahoma City, OK 73190.

The conditioning lesion paradigm in which a first, or conditioning, lesion is followed by a second, or testing, lesion, has been shown to accelerate axonal outgrowth rates and to require the cell body reaction in young rats (Jacob and McQuarrie, 1993). While it is known that regeneration rates are slowed in the old animal, it is not known how a conditioning lesion affects axonal outgrowth rates in these animals. In this project, we used the conditioning lesion paradigm to determine if axonal outgrowth rates can be accelerated in old animals in a manner analogous to young animals.

Outgrowth rates were measured in 6 mo and 24 mo male F344 rats 15-19 d after a 20 sec crush lesion (conditioning lesion, CL) of the sciatic nerve at the level of the knee. Tritiated proline was microinjected into the corresponding ventral horn 4 or 8 d after the testing lesion (14 or 18 d after the CL). Rats were killed 1 d later. Using linear regression analysis, outgrowth rates were determined in control and experimental animals. These data suggest 24 mo F344 rats respond less robustly to a conditioning lesion than do 6 mo rats.

LACK OF CORRELATION BETWEEN NGF LEVELS AND ALTERED NERVE FIBRE DENSITY IN PERIPHERAL TISSUES OF AGEING RATS. I. Gavazzi, T. Cowen* and K. A. Crutcher. Dept. of Anatomy and Developmental Biology, Royal Free Hospital School of Medicine, London, UK and Dept. of Neurosurgery, University of Cincinnati Medical Center, Cincinnati, Ohio 45267-0515.

Studies have shown that target tissues undergo age-changes that apparently induce degenerative changes in their innervating sympathetic neurons. In contrast, ageing sympathetic neurons appear to retain a considerable degree of plasticity. In an attempt to identify the target-associated factors that might be responsible for this regulatory role, 2-site ELISA assays for NGF were carried out on tissues from young (6wk) and old (24m) Sprague Dawley rats. Superior cervical ganglia (SCG) and tissues, some innervated by the SCG, with known and contrasting age changes in their innervation were assayed using established techniques. Cerebral arteries of the Circle of Willis, which exhibit a loss of about 50% in their overall innervation with age (including reductions in sympathetic and sensory nerve fibres), showed no significant alteration in NGF levels expressed as pg/mg wet weight of tissue. The sympathetic innervation of the iris increases slightly with age, whilst the sensory innervation decreases. However, NGF levels increased significantly ($p < 0.01$) in the aged iris. The non-innervated common carotid artery showed levels of NGF comparable to those in the Circle of Willis, and exhibited no changes with age. In the old SCG, NGF levels showed a small but significant ($p < 0.05$) decrease when NGF levels per ganglion (the preferred method of expression because neuronal numbers are unaltered in the ageing rat SCG) were compared. These results suggest that absolute NGF levels in ageing target tissues may not dictate the density of innervation by sympathetic and NGF-sensitive sensory nerves. Changes in the SCG suggest that neuronal uptake and/or transport of NGF may be impaired with age. Supported by the British Heart Foundation (TC and IG) and the NIH (NS17131, KAC).

REGRESSIVE CHANGES IN STEROID ACCUMULATION IN AGING ANDROGEN-SENSITIVE RAT SPINAL NUCLEI. M.B. Widows, A.K. Finn and D.R. Sengelaub*. Program in Neural Science, Indiana University, Bloomington, IN 47405.

Motoneurons in the rat spinal nucleus of the bulbocavernosus (SNB) are sensitive to androgens throughout life. Androgen titers decline with normal aging in male rats, and we have previously reported concomitant regressive changes in SNB dendritic length, soma size, and target muscle weight. Using steroid autoradiography, we determined whether regressive changes in the ability of these motoneurons to accumulate steroids might also occur in aging.

Male rats (12, 19 and 25 months old; $n = 4$ per age) were castrated 48 hours prior to injection with tritiated testosterone (s.c.; 1.5 μ Ci/g body weight) and killed 1.5 hours later. Accumulation was assessed in the steroid sensitive, sexually dimorphic SNB and dorsolateral nucleus (DLN), as well as in the non-sexually dimorphic retrodorsolateral nucleus (RDLN) from each rat (at least 50 cells per nucleus). The number of SNB and DLN motoneurons reaching criteria (Poisson) was reduced by as much as 21% at 25 months, while no changes were observed in RDLN. The density of labeling also declined with age in all motor nuclei and was particularly pronounced in the SNB. At 12 months of age, 55% of SNB motoneurons were labeled at more than 8 times background levels, but less than 30% were labeled at this density by 25 months. Thus, declines in androgen accumulation by steroid-sensitive motoneurons reflect age-related declines in circulating androgen titers. Regressive changes in motoneuron morphology could result from a reduced ability of androgen to act directly on these motoneurons. (Supported by NIH AG09309)

AGE DIFFERENCES IN MEMBRANE FLUIDITY AND LOW Km GTPase ACTIVITY DUE TO CHOLESTEROL INCORPORATION IN RAT BRAIN. R. Villalobos-Molina*, N.D. Jimenez and J.A. Joseph. USDA ARS Human Nutrition Research Center on Aging at Tufts University, 711 Washington St., Boston, MA, 02111.

Alteration in second messenger generation during aging, after receptor occupancy, has been documented in recent years. Decrements in the production of IP_3 (and cytosolic Ca^{2+} mobilization), in cAMP levels and in low Km GTPase activity, have been reported. The suggested mechanism is an alteration in the coupling/uncoupling between the receptor and the G protein in the signal transduction pathway. In order to address if membrane composition alters this mechanism, brain slices or membranes (cortex, hippocampus and striatum), from 6 or 22 mo male Fischer rats, were incubated with cholesterol (water soluble), at 37 C for 60 min. Fluidity (DPH) and carbachol-stimulated GTPase activity were measured after treatment. The results showed that although graded concentrations of cholesterol (up to 1 mM), reduced the fluidity in: cortex [$F(3,36) = 5.12$, $p = 0.005$], striatum [$F(3,30) = 3.14$, $p = 0.04$], hippocampus [$F(3,30) = 3.99$, $p = 0.02$], from both young and old tissues to the same extent, the carbachol-stimulated GTPase activity lowered more in the young compared to old striata. The data suggest that cholesterol can alter the coupling/uncoupling between receptor and G protein by modifying the membrane composition.

DORSAL ROOT FIBERS IN THE AGED CAT. C. Bertolotto*, J. Yamuv, F. R. Morales, and M. H. Chase. Department of Physiology, Department of Anatomy and Cell Biology and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA. 90024-1746.

Nerve impulse conduction in primary afferent fibers is greatly impaired in aged cats as indicated by a decrease in action potential conduction velocity (Exp. Neurol., 100: 583-595, 1988). The present study was designed to examine morphological changes that may underlie this functional disturbance. For this purpose, dorsal roots were studied using light and electron microscopic techniques in two aged cats (17 and 19 years old) and a control cat (2 years old). Many of the dorsal root fibers exhibited clear pathological abnormalities. These included disruption of the myelin sheaths characterized by splitting and ballooning of myelin lamellae which created spaces containing either loops and segments of damaged myelin or a granular matrix. There were abnormal spaces intercalated between myelin and axon cylinders. Retraction of the lateral myelin loops from the paranodal axolemma at the nodes of Ranvier were observed. In addition, axons showed degenerative changes. The fibers which did not exhibit these changes seemed, nevertheless, to also be affected. For example, in spite of the fact that in many fibers the axon appeared to be structurally intact, the myelin was markedly thin. The endoneurial space was increased and there was macrophage infiltration; macrophages were filled with myelin fragments and debris. In conclusion, afferent fibers in the aged cat exhibit demyelination and axonal degeneration or an abnormally thin myelin sheath. These morphological changes may be the basis for the marked decrease in afferent fiber conduction velocity. Supported by USPHS Grant AG 04307.

LOSS OF MOTONEURONS INNERVATING NORMAL AND HYPERTROPHIED MEDIAL GASTROCNEMIUS MUSCLE IN AGED RATS. K. Kanda, K. Hashizume and K. Iwata*. Dept. of Central Nervous System, Tokyo Metropol. Inst. of Gerontol., Tokyo 173, Japan.

Our previous experiments showed that long-term swimming exercise retarded loss of motoneurons in aged rats. To clarify the role of an augmented activity of neuromuscular system itself, we investigated the effect of removal of synergistic muscles, which may cause an increase in activity of remaining muscle with minimal systemic changes, on motoneuron survival in the aged rat. Male Fischer 344 rats aged 17 months were anesthetized with pentobarbital sodium (45 mg/kg, i.p.), and the lateral gastrocnemius, soleus and plantaris muscles were removed unilaterally. Unoperated, intact side was served as control. The rats were raised under usual laboratory conditions until the final experiment was performed at the age of 24 or 28 months. Horseradish peroxidase (40%) was injected into the medial gastrocnemius (MG) nerve bilaterally under halothane anesthesia. Two days later, the animal was reanesthetized and perfused transcardially with cold fixative (1.25% glutaraldehyde and 1% paraformaldehyde in phosphate buffer, pH 7.4). Serial sections (40 µm in thickness) were cut horizontally from the spinal cord block including L4 to S1 segments, and processed with TMB method. Each labeled motoneuron was identified under a microscope, and counted. There was no sign of contracture or ankylosis in the operated leg, and the MG muscle in the operated side was consistently heavier than that in contralateral, intact side (29.3% for 24-month-old rats and 32.3% for 28-month-old rats). The mean number of labeled motoneurons decreased with advancing age: 126.5 ± 10.5 (n=4) and 116.8 ± 6.6 (n=12) for intact side of 24- and 28-month-old rats. The values for hypertrophied side of 24- and 28-month-old rats were 127.8 ± 7.0 and 115.4 ± 8.4 . There was no difference in the numbers of labeled motoneurons between the intact and the operated sides for both age groups (Wilcoxon signed-rank test, $p>0.6$). The results suggest that an increased motoneuronal activity is not the major factor causing retardation of motoneuronal loss in the exercising rats.

ELEVATED ADRENOMEDULLARY TYROSINE HYDROXYLASE WITH AGE MAY NOT BE INTRINSIC TO THE GLAND: POSSIBLE ROLE FOR DEXAMETHASONE. N. Tümer* and J.S. LaRochelle. GRECC VA Medical Center and Department of Pharmacology, University of Florida, Gainesville, Florida 32608-1197.

Aging is associated with elevated tyrosine hydroxylase (TH) expression in the rat adrenal medulla (AM). To determine whether this increased TH activity is intrinsic to the gland or dependent on endogenous factors, we assessed TH activity in AM explants from young (3 mo) and old (24 mo) F-344 rats. In addition we examined the ability of dexamethasone (Dex) to stimulate TH. We have previously shown that TH activity in noncultured AM tissues from old was 2-fold higher compared with young rats. Medullas were cultured in RPMI-1640 media supplemented with 5% fetal calf serum, 10% horse serum and 25 µg/ml gentamicin. TH activity at time zero in culture in old AM explants was also 2-fold higher compared with young (119 ± 5 and 59 ± 6 nmol/mgprotein/h, respectively; $p<0.001$) which was similar to our findings in noncultured tissues. After 12h in culture TH activity in explants was no longer different with age (26 ± 2 young and 23 ± 2 nmol/mgprotein/h, old; $p>0.2$). Following 2h with 10 µM Dex, TH activity was not significantly different in young AM explants (4488 ± 435 control vs. 3877 ± 546 nmol/hr/adrenal, Dex; $p>0.40$). In contrast in old AM explants, TH activity was significantly higher compared with aged matched controls (8046 ± 322 control vs. 12057 ± 1253 nmol/hr/adrenal, Dex; $p<0.02$). These data indicate that the increased TH activity in senescent rat AM may be dependent on endogenous factors, and one of those factors may be glucocorticoids. TWO LOCI ENCODE SNAP-25 IN ZEBRAFISH AND GOLDFISH. C. Risinger*, E. Salanek, and D. Larhammar. Dept of Medical Genetics, Box 589, Uppsala University, S-751 23 Uppsala, Sweden.

SNAP-25 (synaptosome-associated protein of 25 kDa) is a presynaptic protein involved in vesicle docking and release (Söllner et al., Nature 362, 1993, and Blas et al., Nature 365, 1993), as well as neurite extension (Osen-Sand et al., Nature 364, 1993). We have previously shown that SNAP-25 has remained highly conserved from mammals to *Drosophila* (Risinger et al., JBC 268, 1993). We initially isolated cDNA clones for SNAP-25 from goldfish because we intended to study this protein in the model system provided by the regenerating nervous system of this species. Although SNAP-25 is evolutionarily conserved we discovered sequence variability within the goldfish. This was found to reflect a gene duplication early in bony fish evolution, leading to *SnappA* and *SnappB*, followed by the tetraploidization 15-20 Myr ago (Risinger and Larhammar, PNAS 90, 1993). However, the tetraploid status of the goldfish makes this animal less appropriate for molecular genetic studies. Instead, the closely related diploid zebrafish provides an excellent system for these purposes. Zebrafish cDNA clones have been isolated for both *SnappA* and *SnappB*. The predicted protein sequences are highly similar between zebrafish and goldfish, and are approximately 90% identical between zebrafish and mammals. Interestingly, the zebrafish clones reveal two alternative splicing variants of exon 5. The existence of these two variants have previously been shown for chicken (Bark, JMB 233, 1993) and humans (Bark and Wilson, Gene 139, 1994). The expression of *SnappA* and *SnappB* and the alternatively spliced exons will be studied in zebrafish.

THE MAMMALIAN SEC1P-HOMOLOGUE IS A CHROMAFFIN GRANULE-BINDING PROTEIN. T. Schaefer, A. Hodel, C. Heuss, A. Matus* and M. M. Burger. Friedrich Miescher-Institute, PO Box 2543, CH-4002 Basel, Switzerland

Membrane proteins of the synaptic vesicle and the presynaptic plasma membrane together with soluble proteins form a secretory fusion complex conserved from yeast to neurons (Söllner et al. (1993) Nature 362, 318-324). We have localized three of these membrane proteins in chromaffin cells, which secrete catecholamines stored in chromaffin granules. Syntaxin (1A and 1B) and SNAP-25 are found in a plasma membrane-enriched fraction, whereas VAMP/synaptobrevin is concentrated on the granules. Recombinant syntaxin 1A has been used in an affinity chromatography assay to isolate syntaxin receptor proteins of the chromaffin granules. Solubilized granule membranes contained a single protein with high affinity for syntaxin 1A, the mammalian homologue of Sec1p, mSec1 (Hodel et al. (1994) J.Biol. Chem. 269, 8623-8626). In yeast, this hydrophilic protein acts late in the secretory process. Genetic suppressor analyses predicted the interaction of Sec1p with Sso1p, a yeast homologue of syntaxin 1A, and with Sec4p, a homologue of rab3A (Aalto et al. (1993) EMBO J. 12, 4095-4104). Although rab3A is present on chromaffin granules, we did not detect it bound to syntaxin 1A together with mSec1. Western blot analysis of subcellular fractions revealed three pools of mSec1 in chromaffin cells: on plasma membrane vesicles, in the cytosolic terminal fraction, and on the chromaffin granule membranes. mSec1 can be detached from the latter by high salt-treatment. It binds back to its receptor upon addition to granules at physiological salt concentrations. The characterization of both the attachment of mSec1 to the granule and its binding to syntaxin 1A should help to elucidate the interaction of transmitter vesicles with the plasma membrane in docking and fusion.

UNIFORM QUANTAL RELEASE MAY BE REGULATED BY THE SYNAPSE-SPECIFIC CLATHRIN ASSEMBLY PROTEIN F1-20/AP-3. W. Ye and E.M. Lafer*. Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, and *Institute of Biotechnology / Program in Molecular Medicine and Dept. of Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX, 78245.

We reported the characterization and cloning of the synapse-specific phosphoprotein F1-20. We overexpressed F1-20, and reported that F1-20 is identical to the clathrin assembly protein AP-3. At the nerve terminal, clathrin mediated endocytosis is involved in the biogenesis and recycling of synaptic vesicles. Here we characterize the ability of bacterially expressed F1-20/AP-3 to bind and assemble clathrin cages. We find that bacterially expressed F1-20/AP-3 can bind and assemble clathrin as efficiently as preparations of F1-20/AP-3 from bovine brain. This establishes that the clathrin assembly activity found in F1-20/AP-3 preparations from brain extracts is indeed encoded by the cloned gene for F1-20/AP-3. It also demonstrates that post-translational modification is not required for activation of the clathrin binding or assembly function of F1-20/AP-3. Ultrastructural analyses of the clathrin cages assembled by bacterially expressed F1-20/AP-3 reveals a strikingly narrow size distribution. Because mature synaptic vesicles are derived from precursor clathrin coated vesicles, we hypothesize that an important function of the synapse-specific clathrin assembly protein F1-20/AP-3 is to limit the range of vesicle sizes, and therefore increase the uniformity of quantal release. We also expressed the 33 kD NH₂-terminus of F1-20/AP-3 in *E. coli* and measured its ability to bind and assemble clathrin. It has been suggested that the 33 kD NH₂-terminus of F1-20/AP-3 constitutes a clathrin binding domain. We found that while the bacterially expressed 33 kD NH₂-terminus of F1-20/AP-3 binds to clathrin triskelia, it fails to bind to preassembled clathrin cages and is not sufficient for clathrin assembly.

698.4

CELLULAR AND SUBCELLULAR LOCALIZATION OF SYNTAXIN IMMUNOREACTIVITY IN THE RAT CORTEX AND STRIATUM. S.R. Sesack* and C. L. Snyder. Departments of Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260

Syntaxin is a membrane-bound protein that concentrates in axon terminals and may participate in synaptic vesicle docking prior to Ca²⁺-mediated fusion events. We sought to characterize the cellular and subcellular distribution of immunoreactivity for syntaxin in the rat forebrain using both a polyclonal antibody directed against a bacterially expressed syntaxin protein (Bennett et al., Science, 257:255) and a monoclonal antibody against the identical membrane-derived protein, HPC-1 (Barnstable et al., Dev. Brain Res., 20:286). Whether labeled by immunoperoxidase or immunogold methods, syntaxin and HPC-1 proteins were localized exclusively to axons and terminal varicosities in the rat dorsolateral striatum and frontal cortex. Immunoreactive terminals made exclusively asymmetric synapses, primarily on dendritic spines, while unlabeled terminals in the adjacent neuropil made either symmetric or asymmetric synapses on somatodendritic targets. Immunogold labeling for syntaxin or HPC-1 was localized primarily to non-synaptic regions of the plasma membrane. These results suggest that syntaxin is an integral membrane protein localized to a subpopulation of forebrain terminals that use excitatory amino acids as neurotransmitters. The apparent exclusion of syntaxin immunolabeling from the presynaptic active zone must be considered in light of potential limitations in antibody penetration or epitope recognition at junctional specializations. Conversely, the non-synaptic localization of syntaxin implies that its functional role may not be limited to synaptic vesicle docking. This work was supported by USPHS grant MH50314.

698.5

SPECIFICITY AND REGULATION OF PROTEIN INTERACTIONS MEDIATING SYNAPTIC VESICLE DOCKING. Jonathan Pevsner*, Shu-Chan Hsu, Janice E. Braun, Nicole Calakos, Anthony E. Ting and Richard H. Scheller, Dept. of Mol. & Cell. Physiol., HHMI, Stanford U. Med. Center, Stanford CA 94305.

Synaptic vesicle (SV) docking is thought to be mediated by the binding of two SV proteins, VAMP and synaptotagmin, to two plasma membrane proteins, syntaxin and SNAP-25. We have identified n-sec1, a soluble neural-specific 68 kDa protein, and demonstrated its high-affinity binding to syntaxin ($K_D=5.7$ nM). Recombinant n-sec1 binds syntaxin in a complex distinct from the docked SV complex, based upon immunoprecipitation and glycerol gradient centrifugation studies. N-sec1 inhibits VAMP and SNAP-25 binding to syntaxin immobilized on agarose beads. In the absence of n-sec1, VAMP binds the syntaxin 1 and 4 (but not 2 and 3) isoforms. This VAMP binding to syntaxin 1 (but not syntaxin 4) is potentiated ten-fold in the presence of SNAP-25, suggesting a mechanism for achieving both specificity and high affinity binding of VAMP-containing SVs to the appropriate syntaxin on target membranes. The proposed pathway of SV docking and fusion includes the displacement of synaptotagmin by the soluble protein α SNAP, and subsequent binding of NSF to syntaxin, SNAP-25 and VAMP in a 20S complex *in vitro*. We have reconstituted this pathway with recombinant proteins binding to immobilized syntaxin.

698.7

DIFFERENTIAL RESPONSES OF PROTEIN KINASE C SUBSTRATES (MARCKS, NEUROMODULIN, AND NEUROGRANIN) PHOSPHORYLATION TO CALMODULIN AND S100. F.-S. Sheu*, F.L. Huang and K.-P. Huang, NICHD, NIH, Bethesda, MD 20892.

Phosphorylation of three physiological substrates of protein kinase C (PKC), MARCKS, neuromodulin (Nm), and neurogranin (Ng), present in a mixture was analyzed to determine their relative efficacies as substrates of PKC α , β , and γ and relative sensitivities to inhibition by calmodulin (CaM) and S100. The rationale for these experiments was to mimic the *in vivo* conditions where these substrates and inhibitor proteins co-exist. In addition, since PKC and these substrates are all phospholipid-binding proteins, the presence of all these components and phospholipids in the same reaction mixture may create an environment to allow selectivity for each PKC isozyme. Based on the kinetics parameters (V_{max}/K_m) of the phosphorylation of each individual substrate, we estimated the order of efficacy as PKC substrate was MARCKS>Nm>Ng. The rates of PKC α -catalyzed phosphorylation of Nm and Ng in a mixture containing MARCKS were significantly reduced as compared to that phosphorylated individually by this isozyme, especially at a higher level of MARCKS. Although phosphorylation of MARCKS, Nm, and Ng individually by PKC are known to be inhibited by CaM, when present in a mixture, both CaM and S100 preferentially inhibited MARCKS phosphorylation over those of Nm and Ng. Protease-activated catalytic fragment of PKC (PKM) was used to determine the effect of Ca^{2+} on the CaM- and S100-mediated inhibition of PKC substrate phosphorylation. CaM and S100 inhibited the PKM-catalyzed phosphorylation of MARCKS only in the presence of Ca^{2+} while phosphorylation of Nm and Ng by PKM were inhibited more prominently by CaM in the absence than in the presence of Ca^{2+} ; S100 was relatively ineffective in inhibiting the phosphorylation of these two substrates even in the presence of Ca^{2+} . The results presented here demonstrate that MARCKS is likely the most preferred substrate of PKC in the brain and its phosphorylation by PKC is most sensitive to inhibition by CaM and S100.

INTERACTION OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II WITH MEMBRANES: STUDIES WITH PURIFIED SYNAPTIC VESICLES AND LIPOSOMES. S. Hilfiker-Rothenfluh, J.J. Cheetham, A.A. Fienberg*, P. Greengard and A.J. Czernik, Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, 1230 York Ave., New York, NY 10021

Purified small synaptic vesicles possess a form of Ca^{2+} /calmodulin-dependent protein kinase II (CaM kinase II) which serves as a binding protein for synapsin I [Benfenati *et al.* (1992) *Nature*, 359, 417-420]. The interaction between synaptic vesicle-associated CaM kinase II and the synaptic vesicle membrane was studied using hydrophobic photoaffinity labeling. Purified synaptic vesicles were labeled with 3-(trifluoromethyl)-3-(*m*-[^{125}I]iodophenyl) diazine ([^{125}I]-TID). Upon photolysis, synaptic vesicle-associated CaM kinase II was labeled, suggesting that part of the molecule is embedded in the lipid bilayer. To further characterize this interaction, we performed liposome binding studies to determine if purified soluble CaM kinase II could bind to liposomes, using a sedimentation assay. We found that soluble CaM kinase II bound to sucrose-loaded liposomes and that the binding was dependent on the presence in the liposome membrane of anionic lipids, such as phosphatidylserine. Binding of CaM kinase II to liposomes was also dependent on salt concentration, suggesting that electrostatic interactions may contribute to the interaction. Soluble CaM kinase II bound to liposomes was also labeled using [^{125}I]-TID, indicating that some portion of the protein may be embedded in the membrane. [Supported by USPHS grant MH 39327 to P.G., MRC of Canada Postdoctoral Fellowship to J.J.C. and David Rockefeller Fellowship to S.H.]

AUTOPHOSPHORYLATION OF POSTSYNAPTIC DENSITY-ASSOCIATED CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE. A. Dosemeci* and H. Jaffe, Laboratory of Neurobiology and Protein/Peptide Facility, NINDS, NIH, Bethesda, MD 20892.

The major postsynaptic density protein (mPSDp) is similar or identical to the α -subunit of calcium / calmodulin-dependent protein kinase II (α -CaM Kinase II). Previous studies indicated that when an endogenous phosphatase in the postsynaptic density (PSD) preparation is inhibited, the mPSDp can be autophosphorylated in the presence of calcium to a degree comparable to that observed for the cytosolic CaM Kinase II (Dosemeci and Reese, 1993, *J. Neurochem.* 61, 550-555). We now show that inhibiting the phosphatase also allows extensive calcium-independent autophosphorylation of mPSDp. In analogy to the cytosolic kinase, prior incubation in calcium, presumably to phosphorylate a distinct site, is necessary for calcium-independent autophosphorylation to occur. In order to identify sites of phosphorylation, peptides generated by endoproteinase Lys-C digestion of mPSDp were separated by reverse phase HPLC. Comparison of phosphopeptide elution profiles of digests of mPSDp following autophosphorylation in the presence and absence of calcium, showed differences, indicating that certain distinct sites are involved. The major phosphopeptide peak, however, eluted at the same position in both cases. Sequence analysis of this peak revealed a threonine corresponding to Thr-253 of the α -CaM Kinase II as the site of phosphorylation of mPSDp either in the presence or in the absence of calcium. Thus, for the PSD-associated kinase, autophosphorylation of this site appears to be facilitated and is able to continue after the removal of calcium.

IDENTIFICATION OF PHOSPHOLIPID BINDING SITES IN SYNAPSIN I USING HYDROPHOBIC PHOTOAFFINITY LABELING. J.J. Cheetham, S. Hilfiker-Rothenfluh, A.J. Czernik, A.C. Naim* and P. Greengard, Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, 1230 York Ave., New York, NY 10021

Synapsins Ia and Ib (synapsin I) are peripheral membrane phosphoproteins, associated with the cytoplasmic surface of small synaptic vesicles [Greengard *et al.* (1993) *Science*, 259, 780-785]. It is thought that synapsin I regulates neurotransmitter release by tethering synaptic vesicles to actin filaments and restricting the availability of vesicles for fusion with the presynaptic membrane. Synapsin I binds to both actin filaments and synaptic vesicles *in vitro*, and these interactions are regulated by phosphorylation of synapsin I by Ca^{2+} /calmodulin-dependent protein kinase II (CaM kinase II). Synapsin I also binds with high affinity to liposomes containing anionic lipids and induces rapid and extensive liposome aggregation. To further characterize the interaction of synapsin I with membrane lipids, we have attempted to identify the sites in synapsin I that directly interact with phospholipids using a hydrophobic photoaffinity labeling approach. Purified bovine synapsin I was bound to liposomes containing 3-(trifluoromethyl)-3-(*m*-[^{125}I]iodophenyl)diazine ([^{125}I]-TID). Upon photolysis, membrane-embedded segments of the protein were crosslinked to the [^{125}I]-TID. [^{125}I]-TID-labeled synapsin I was digested with CNBr and peptides were separated using reverse phase HPLC. Radiolabeled peptides were further purified by Tris/Tricine PAGE, transferred to Immobilon and subjected to gas-phase protein microsequencing. Several peptide sequences, each located within the central region of synapsin I (domain C) interact with the phospholipid bilayer. SPATIAL DETECTION OF AUTOPHOSPHORYLATION OF Ca^{2+} /CaM-DEPENDENT PROTEIN KINASE II IN HIPPOCAMPAL SLICES. S. Kindler*, E.M. Schuman, C. P. Hung, and M.B. Kennedy, Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

Ca^{2+} /calmodulin-dependent protein kinase II (CaM KII) is highly concentrated in mammalian forebrain. About half is located throughout the neuronal cytoplasm; the rest is associated with the particulate fraction, including postsynaptic densities. It has been hypothesized that Ca^{2+} entering through NMDA receptors activated during induction of long term potentiation (LTP) may activate CaM KII. Activation of CaM KII leads to autophosphorylation of a threonine residue neighboring the CaM-binding domain. Even after a decrease of Ca^{2+} levels the autophosphorylated kinase remains in an active state until it is dephosphorylated. This process may enable CaMKII to remain active after a short Ca^{2+} transient for a time that is dependent on local phosphatase activities. Biochemical methods have failed to show strong activation of the kinase during induction of LTP. This finding may reflect the fact that transient rises in Ca^{2+} during induction are restricted to relatively small cell areas. To visualize local changes in CaMKII autophosphorylation we have used a monoclonal antibody that recognizes CaM KII only in its autophosphorylated form, and a polyclonal rabbit serum that reacts only with the non-phosphorylated form (Patton *et al.* (1993) *Mol. Biol. Cell* 4, 159). We double-labeled 50 μ m sections cut from acute hippocampal slices fixed after exposure to different treatments. Antigen distributions were visualized by LS confocal microscopy using two different fluorophores. Images were analyzed with the program MacPhase. When compared to control slices, neurons in slices incubated with EGTA show a dramatically reduced ratio of staining with anti-phosphokinase to staining with anti-dephosphokinase. We are presently examining changes in autophosphorylation produced by activation of specific receptors and by stimulation paradigms that induce LTP.

NITRIC OXIDE STIMULATES BINDING OF NAD TO GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE (G3PD) IN POSTSYNAPTIC DENSITY FRACTIONS FROM PORCINE BRAIN. P. Sikevitz¹, A.A. Rogalski-Wilk², R.S. Cohen² and K. Wu³. ¹Dept. Cell Biology, The Rockefeller Univ., New York, NY 10021; ²Dept. Anatomy and Cell Biology, Univ. of Illinois at Chicago, Chicago, IL 60612; ³Dept. Neuroscience and Cell Biology, UMDNJ/RWJ Med. Sch., Piscataway, NJ 08854

Nitric oxide (NO), a messenger molecule produced in the brain from the metabolism of L-arginine to L-citrulline, appears to play a key role in a variety of synaptic processes, including long-term potentiation. Recently, both nitric oxide synthase (NOS) (Aoki et al., *Brain Res.* 620, 97-113, 1993) and G3PD (Rogalski and Cohen, *J. Cell Biol.* 111, 163a, 1990), enzymes that produce NO and ATP, respectively, were found to be intrinsic components of the postsynaptic density (PSD). NO has been shown to stimulate the apparent auto-ADP-ribosylation of G3PD in whole brain extract (Zhang and Snyder, *PNAS USA* 89, 9382-9385, 1992). However, the reaction has been found to be binding of the entire NAD molecule to the G3PD (McDonald and Moss, *PNAS USA* 90, 6238-6241, 1993). We proposed that one locale of this reaction is the PSD. Subcellular fractions of porcine cerebral cortex, including whole homogenate, synaptosomes, synaptic plasma membranes, crude synaptic vesicles and PSDs were incubated at 37°C for 1 hour with (adenylate-³²P)NAD in the presence of calmodulin and calcium with and without sodium nitroprusside as the source of NO. The mixtures were then subjected to SDS-PAGE and were analyzed autoradiographically. NO significantly enhanced binding of NAD to a 37 kDa protein in all the above subcellular fractions examined, with the PSD showing the greatest enhancement. Western blot analysis using affinity purified antibodies to human G3PD (Rogalski et al., *J. Biol. Chem.* 264, 6438-6446, 1989) identified this protein as G3PD. Because G3PD is an actin binding protein and actin is present in the PSD, we propose that NO may alter G3PD-actin associations, thereby leading to structural alterations in the PSDs. PHARMACOLOGY OF SYNAPTIC TRANSMISSION II

699.1

A ROLE OF NITRIC OXIDE IN GANGLIONIC TRANSMISSION OF RAT SUPERIOR CERVICAL GANGLIA. H. Tang* and N. J. Dun. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43614

Immunoreactivity to nitric oxide synthase (NOS-I) was localized to nerve fibers opposing the majority of rat superior cervical ganglion (SCG) neurons. NOS-I was either too low to be detected or absent in the postganglionic neurons. The hypothesis that nitric oxide (NO) may modulate synaptic transmission in SCG neurons was examined by evaluating the effects of agents that elevate tissue NO levels on synaptic responses and on depolarizations induced by pressure application of acetylcholine (ACh). Intracellular recordings were made from neurons in isolated rat SCG. Superfusion of L-arginine (10-300 μ M) dose-dependently increased the amplitude of excitatory postsynaptic potentials (EPSPs) evoked by stimulation of cervical sympathetic trunk in approximately 50% of ganglion cells studied. The membrane depolarization induced by pressure application of ACh was also increased in some but not in all ganglion cells. D-arginine in comparable conc. caused no significant change of the EPSPs. Sodium nitroprusside (10-300 μ M) reversibly increased the EPSPs in a concentration dependent manner. The present study shows that NOS-immunoreactivity is present in nerve fibers presynaptic to postganglionic neurons and in SIF-like cells and that NO when released from these neural elements may potentiate synaptic transmission. (Supported by NS18710 & NS24226).

PRESYNAPTIC cGMP PRODUCES ACTIVITY-DEPENDENT LONG-LASTING POTENTIATION IN HIPPOCAMPAL CELL CULTURES. O. Arancio*, E.R. Kandel, and R.D. Hawkins. Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, NY, NY 10032.

Previous results suggest that cGMP is involved in long-term potentiation (LTP) in the CA1 region of hippocampal slices, perhaps as the presynaptic effector of a retrograde messenger (Zhuo et al., 1994). Consistent with this idea, the membrane-permeable analog 8-Br-cGMP also produces activity-dependent long-lasting potentiation of evoked postsynaptic currents (EPSCs) in dissociated cultures of hippocampal neurons (Arancio et al., 1993). This potentiation is paralleled by a decrease in the coefficient of variation and an increase in the frequency but not the amplitude of spontaneous miniature EPSCs, suggesting that cGMP acts presynaptically. However, a postsynaptic increase in cGMP might indirectly produce presynaptic effects. To attempt to distinguish between these possibilities, we injected substances directly into the pre- or postsynaptic neuron. Injection of cGMP into the presynaptic cell paired with weak presynaptic activity produced a long-lasting increase in the amplitude of the EPSC. cGMP alone or either vehicle or cAMP paired with activity produced no potentiation. Injection of cGMP into the postsynaptic cell paired with presynaptic activity also did not produce potentiation. Similarly, postsynaptic cGMP did not cause any increase in the amplitude or the frequency of spontaneous miniature EPSCs. In preliminary experiments, injection of the membrane-permeable guanylyl cyclase inhibitor LY83583 into either cell blocked the induction of long-term potentiation by repeated tetanic stimulation. These results demonstrate that a presynaptic increase in cGMP produces activity-dependent long-lasting potentiation that may contribute to LTP.

699.2

SPERMINE AFFECTS NEUROTRANSMISSION IN SLICES OF STRIATUM AND HIPPOCAMPUS: EFFECT OF CALCIUM. P.A. Ferchmin*, DiScenna, P.G., E.M. Rivera, Vesna A. Eterović and T.J. Teyler. ¹Center for Molecular and Behavioral Neuroscience, Department of Biochemistry, Univ. C. del Caribe, Bayamón, Puerto Rico 00960 and ²Department of Neurobiology, College of Medicine, Northeastern Ohio Universities, Rootstown, OH 44272

Spermine inhibited neurotransmission in slices from rat striatum and hippocampus. In the latter, spermine increased paired-pulse facilitation in stratum pyramidale and to a lesser extent in s. radiatum of the CA1 area. A similar pattern was observed in the presence of ω -conotoxin (ω -CTX), a blocker of voltage-sensitive Ca^{++} channels (VSCC). In addition, a decreased Ca^{++} concentration in the perfusing solution also increased paired-pulse facilitation. Spermine effect was larger at 1 mM Ca^{++} than at 2 mM and was almost nil at 3 mM Ca^{++} . Addition of APV, an NMDA antagonist, did not interfere with spermine effect on paired-pulse facilitation. These results support the hypothesis that spermine is an endogenous neuromodulator that decreases the release of neurotransmitters by blocking presynaptic VSCC and perhaps also by blocking VSCC on dendrites and soma of pyramidal cells. (Supported by NSF-EPSCoR and NIH-RCMI RR03035)

699.4

DELAYED ENHANCEMENT OF SCHAFFER COLLATERAL-COMMISSURAL SYNAPTIC TRANSMISSION BY PROLINE. S.M. Cohen* and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

Many, but not all, glutamate terminals express a high affinity, Na^{+} -dependent transporter for L-proline. Proline may play a role in synaptic transmission at these sites. This idea was tested by recording Schaffer collateral-commissural synaptic potentials extracellularly in area CA1 during superfusion of hippocampal slices with proline. Two concentrations of proline were used: a concentration typical of normal CSF (3 μ M) and a concentration present in CSF of persons with hyperprolinemia type II (30 μ M). Neither proline concentration altered synaptic transmission when testing was performed 15 min after its addition to the superfusion medium. However, both concentrations enhanced synaptic transmission when they were continuously present in the medium from the time of slice preparation, as indicated by a statistically significant upward shift in the plot of field EPSP slope against fiber volley amplitude. In another series of experiments, proline was added to control medium and the field EPSP was recorded for the next 4 h. In the presence of proline, EPSP slope began to increase in about 40 min and reached a plateau in 80-90 min. The plateau values of EPSP slope were $24 \pm 9\%$ and $35 \pm 10\%$ greater than baseline for 3 and 30 μ M proline, respectively. In contrast, EPSP slope in control slices declined by $8 \pm 10\%$.

These results suggest that concentrations of proline normally present in CSF enhance transmission at the Schaffer collateral-commissural synapse. The presynaptic proline transporter may serve to regulate this process. Finally, the childhood seizures associated with hyperprolinemia type II may result from excessive facilitation of glutamate transmission.

PROMINENT DEPRESSION OF DENDRITIC GLUTAMATE (GLU) EXCITABILITY BY COLLATERAL RELEASE OF NOREPINEPHRINE (NE): RECORDINGS FROM LOCUS COERULEUS (LC) NEURONS IN VITRO. A. Ya. Ivanov and G. Aston-Jones.* Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann Univ., Philadelphia, PA 19102.

Early evidence *in vivo* indicated that spontaneous and postactivation activity of LC neurons was strongly influenced by collateral release of NE. However, more recent studies in brain slices do not support this view, finding instead that calcium-dependent potassium conductance may be the main mechanism which regulates such activity in LC cells. We examined the possibility of local collateral inhibitory control of LC activity with intra- or extra-cellular recordings from LC neurons in brain slices from rat. Glu (20 mM) was ejected by pressure from a micropipette situated in the rostromedial peri-LC dendritic zone. In all 12 LC neurons tested Glu ejection increased impulse activity; the location of the Glu pipette was critical for this response and small adjustments within the dendritic zone resulted in no response. This indicates that such Glu-evoked activation was not due to diffusion of Glu to the LC soma area, but apparently reflected direct activation of extracellular LC dendrites of the recorded cell. Glu-evoked responses were increased in amplitude after blockade of α_2 receptors with yohimbine (1 μ M). A similar increase in Glu-evoked response was obtained with superfusion of 20 mM Mg^{++} and 2 mM Co^{++} . Yohimbine increased the spontaneous activity of 6/12 neurons about 30%, but had no effect on the activity of the other 6 cells. Intracellular recordings revealed that dendritic application of Glu elicited a slow depolarization with impulse generation. After yohimbine, the Glu-evoked depolarization increased in duration resulting in a greater number of impulses generated than after Glu alone. In contrast, the afterhyperpolarization following impulses did not change in amplitude or duration after yohimbine. The slow IPSP evoked by electrical stimulation in the peri-LC area was consistently blocked by yohimbine. Together, these results indicate that NE released from LC neurons is a potent influence on responses of these neurons to excitatory dendritic inputs. Supported by PHS grant NS24698.

PRESYNAPTIC DEPRESSION OF GABA-MEDIATED SYNAPTIC RESPONSES OF CA1 PYRAMIDAL CELLS BY METABOTROPIC GLUTAMATE RECEPTORS IN RAT HIPPOCAMPAL SLICES. A. Jouvenceau, P. Dutar* and J.M. Billard. INSERM U161, 75014 Paris, France.

Evidence indicate that the glutamatergic synaptic transmission is modulated by presynaptic metabotropic glutamate receptors (mGluR) but a participation of mGluR in the control of GABAergic neurotransmission in the CNS remains poorly documented. To address this question, we studied the sensitivity of the GABA-mediated responses to the mGluR agonists trans-ACPD (50-200 μ M) or 1S-3R-ACPD (10-50 μ M) using intracellular recordings from CA1 neurons in the rat hippocampal slices. Bath application of mGluR agonists rapidly caused a membrane depolarisation, an increase in membrane resistance and a loss of the postburst afterhyperpolarization. Stimulation of the str. radiatum elicited an early excitatory postsynaptic potentials (EPSPs) followed by fast GABA_A (fIPSP) and slow GABA_B (sIPSP)-mediated inhibitory postsynaptic potentials. At low concentration, trans-ACPD (50-100 μ M) or 1S-3R-ACPD (10 μ M) reduced the EPSP by 49% and 42% respectively. The fIPSP was slightly affected (15% and 12% depression) while the sIPSP was consistently decreased (41% and 28%). Increasing the concentration of the mGluR agonists to 200 μ M and 50 μ M respectively further depressed the EPSP (65% and 79%) and dramatically reduced both IPSPs (70% for the fIPSP and 79% for the sIPSP for both agonists). Monosynaptic IPSPs evoked in the presence of APV (30 μ M) and CNQX (10 μ M) were also depressed by the mGluR agonists. In contrast, preliminary experiments suggest that the discharge frequency of spontaneous miniature IPSPs is rather increased. Besides, the postsynaptic hyperpolarization caused by the GABA_B agonist baclofen was not affected in the presence of the mGluR agonists.

These results suggest that besides the control the excitatory neurotransmission, mGluR also modulate GABA release through the activation of receptors located on GABAergic terminals. This mechanism may contribute to the facilitatory effect of mGluR in the induction of long term potentiation.

PRESYNAPTIC INHIBITION OF INHIBITORY SYNAPTIC TRANSMISSION MEDIATED BY METABOTROPIC GLUTAMATE RECEPTORS IN MONOSYNAPTICALLY ISOLATED PAIRS OF CULTURED HIPPOCAMPAL NEURONS. R. Maki¹ and M. A. Dichter.^{1,2} ¹David Mahoney Institute of Neurological Sciences, ²Depts. of Neurology and Pharmacology, Univ. of Pennsylvania School of Medicine and Graduate Hospital, Philadelphia, PA 19104.

Whole-cell patch clamp recordings were performed to elucidate the effects of the metabotropic glutamate receptor (mGluR) agonist ACPD and the recently described mGluR antagonist (RS)- α -methyl-4-carboxyphenylglycine (MCPG) on inhibitory synaptic transmission in low density cultures of hippocampal neurons. Application of ACPD (100 μ M) resulted in a reversible decrease in the amplitude of IPSCs (33.6 \pm 24.6% decrease; n=9). Coapplication of MCPG (500 μ M) completely reversed the effects of ACPD (n=7); MCPG alone had no effect on IPSC amplitude. Examination of miniature IPSCs (n=5) indicated that changes in postsynaptic GABA_A receptor sensitivity did not account for the decrease in evoked IPSC amplitudes; therefore, inhibition of the IPSCs was due to a presynaptic mechanism. Application of the glutamate uptake inhibitor L-trans-PDC (250 μ M) led to a reduction in 8 out of 13 pairs tested; these 8 inhibitory pairs also exhibited an increase in baseline NMDA-receptor mediated noise, indicating an increase in the ambient concentration of glutamate. The reduction of IPSC amplitude by application of L-trans-PDC could also be blocked by the mGluR antagonist MCPG (1 mM). Based on these and other previously reported results (Maki, Robinson and Dichter, J Neurosci, in press) we concluded that (1) all inhibitory neurons in our very low density cultures express functional mGluRs responsive to ACPD, and (2) inhibition of glutamate uptake by L-trans-PDC results in the activation of mGluRs by increased ambient glutamate concentrations, and that this occurs only in the cases where there was a source for glutamate. Modulation of the activation of presynaptic auto- and heteroreceptors may serve to tightly regulate the balance of inhibitory and excitatory synaptic transmission in the CNS. Supported by GM-34781 (MAD) and AG-12003-01 (RM).

VASOPRESSIN (VP) AND VP 4-8 IN FEMTOMOLAR CONCENTRATION AUGMENT EPSPs IN CA1 NEURONS OF THE VENTRAL HIPPOCAMPUS. I.J.A. Urban*, A. N. Cherkova¹, D. De Wied, A.H. Ontskul and G.M.J. Ramakers. Rudolf Magnus Institute, P.O. Box 80040, 3508 AT Utrecht, The Netherlands. ¹Institute of Brain Research, Per. Obukha 5, Moscow, Russia.

Effects of 10^{-10} M vasopressin (VP) and VP(4-8) on passive properties and synaptic excitability of neurons in the CA1 layer in slices from the ventral hippocampus were studied with sharp, KAc or KCl microelectrodes. The medium contained (in mM): NaCl (125); KCl (3.5) CaCl₂ (2.5); MgSO₄ (1.2); NaHCO₃ (26) and D-glucose (10). Stimuli of 35.9 ± 18.6 μ A (S.E.) were applied to the stratum radiatum to evoke EPSPs in CA1 neurons. Nearly 70% of the impaled neurons showed an 10-200% increase in the amplitude and/or the slope of the EPSPs. The EPSPs started to rise at the end of the 15 min VP application. In more than 50% of these neurons the EPSPs increase outlasted the washout of the peptide by more than 60 min. In the remaining cells, the EPSPs declined to the baseline within 60-90 min after the VP application. No treatment-related change was seen in either the resting membrane potential (RMP) and/or input resistance R_{in} . However, the threshold for action potentials (APs) by depolarizing current injection (DCI) often decreased and the number of APs generated increased. Neither picrotoxin alone nor picrotoxin in combination with an NMDA receptor antagonist prevented the effect of VP on EPSPs. Also, VP (4-8) (10^{-10} M) elicited a similar long-lasting increase the amplitude and/or slope of EPSPs without changing the RMP and/or R_{in} of the neurons. The threshold for firing APs was also frequently decreased by VP (4-8). Thus, both peptides appeared to facilitate the excitatory, presumably glutamatergic transmission in the CA1 layer of the ventral hippocampus for a period of time outlasting markedly the peptide application. The mechanism of this long-lasting peptide action may be complex, including changes in transmitter release, postsynaptic glutamate receptors and/or postsynaptic conductances.

699.8

METABOTROPIC GLUTAMATE RECEPTORS ATTENUATE INSPIRATORY-MODULATED SYNAPTIC CURRENT IN PHRENIC MOTONEURONS. X-W. Dong*, D. Morin & J.L. Feldman. Systems Neurobiology Lab., Dept of Physiological Science, UCLA, Los Angeles, CA, 90024-1527

Metabotropic glutamate receptors (mGluRs) modulate synaptic transmission at many glutamatergic synapses. We examined the effects of activation of mGluRs on synaptic transmission of endogenous excitatory amino acid-mediated inspiratory drive to phrenic motoneurons (PMNs) in the isolated brainstem-spinal cord preparation of neonatal rat. PMN activity was recorded under whole cell patch-clamp conditions. Drugs were applied via pressure ejection from micropipettes positioned over the PMN pool. The mGluR agonist 1S,3R-ACPD (0.5 mM, 3 sec) reversibly reduced PMN peak inspiratory-modulated synaptic current (I_{insp}) to $76 \pm 3\%$ (n=5) of control and increased excitability via a tonic inward current (see Morin *et al.*, this volume). This effect on I_{insp} was antagonized by the mGluR antagonist (R,S)- α -methyl-4-carboxyphenylglycine (MCPG). To elucidate underlying mechanisms, we examined records from cells with few enough events during inspiration that unitary peaks could be resolved. ACPD produced a prominent decrease in the number of unitary events; this finding suggests a decrease in transmitter release. We had observed a similar action of AP4 (Liu *et al.*, J Neurophysiol., 64:423, '90). MCPG antagonized the action of AP4, indicating that the action of AP4 is mediated by mGluRs. However, whether the effects of the agonists ACPD and AP4 are mediated by same or distinct receptors remains unclear. We conclude that presynaptic mGluRs modulate transmission of endogenous inspiratory drive to PMNs, consistent with our hypothesis of an autoregulatory site for glutamate release modulating inspiratory drive to PMNs. Supported by NIH Grant NS 24742.

ACPD-INDUCED LONG-TERM DEPRESSION IN IMMATURE CA1 REQUIRES BOTH mGluR AND NMDAR ACTIVATION L. S. Overstreet, J. F. Pasternak, N. T. Slater, J. W. Cozzens, B. L. Trommer* Pediatric Neurology Research Laboratory, Northwestern Univ. Medical School, Evanston Hospital, Evanston, IL 60201

Activation of the mGluR by 1S,3R-ACPD produces long-term potentiation (LTP) in mature hippocampal area CA1, and long-term depression (LTD) in immature CA1. The latter is blocked by the mGluR antagonist (+)MCPG (500 μ M). We studied the effects of NMDA receptor (NMDAR) blockade on ACPD-induced LTD. Field EPSPs were recorded in the stratum radiatum of CA1 in response to stimulation of the Schaffer collateral path in hippocampal slices from 9-12 day rats (n=13). In the presence of the NMDAR antagonist D-AP5 (20 μ M), bath application of ACPD (10 μ M, 20 min) did not produce LTD, although a reversible depression (-18%) of EPSP slope was seen in 8 slices. After ACPD wash, EPSP slope remained near baseline (n=8) or showed LTP (+27%, n=5). With subsequent AP5 wash (20, 60, or 120 minutes following ACPD wash), a persistent decrease (-20%) in EPSP slope occurred in all slices. Subsequent ACPD application produced further decrease in EPSP slope (-25%); subsequent tetanus reversed LTD and/or produced LTP (+31%). Thus LTP, the dominant effect in mature CA1, is seen in immature CA1 only with NMDAR blockade; when both mGluR and NMDAR are active in immature CA1, LTD is produced. Moreover, the depression of synaptic activity in immature CA1 consists of 2 components: one that is reversible and depends only on mGluR activation and a second that is long-lasting and requires concomitant, but not necessarily coincident, NMDAR activation. mGluR activation alone creates a "depression primed" state that is subsequently expressed as LTD after return of the NMDAR-associated current produced by background synaptic activity. It is likely that this "priming" effect results from a long-lasting change in intracellular 2nd messenger system modulation induced by mGluR activation in developing brain/CA1.

DISTRIBUTION AND PHARMACOLOGICAL CHARACTERIZATION OF DOPAMINE RECEPTORS IN THE SUBTHALAMIC NUCLEUS OF THE RAT. A. E. Johnson*, H. Coirini, L. Källström and E. -A. Wiesel. Department of Psychiatry, Ulleråker Hospital, Uppsala University, S-75017 Uppsala, Sweden.

The display of neuroleptic-dependent movement disorders is thought to be due to a disruption in the balance of neurotransmission between the "direct" and "indirect" pathways connecting the striatum with the major output nuclei of the basal ganglia. Classical neuroleptics are thought to initiate this imbalance through the blockade of striatal dopamine (DA) D₂-receptors resulting in a cascade of neurochemical events throughout the basal ganglia and thalamo-cortical motor circuitry. However, classical neuroleptics may also interfere with DA transmission within a key intermediate structure of the indirect pathway, the subthalamic nucleus (STh). While DA receptors are located in the STh, their distribution and pharmacological identity is unclear. The purpose of the following experiments was to describe the distribution and to pharmacologically characterize the DA-receptors in the STh. For these experiments, brain sections were incubated with either D₁- or D₂-receptor selective ligands (¹²⁵I-SCH23982 or ¹²⁵I-NCQ298, respectively) in the presence or absence of a wide range of unlabelled dopaminergic compounds and binding was analyzed using receptor autoradiographic techniques. Results of distribution experiments showed that ¹²⁵I-NCQ298 exhibited moderately high binding in the STh and that the binding was uniform throughout the region. Contrary to previously published data, ¹²⁵I-SCH23982 binding was not observed in the STh. However, DA displaceable ¹²⁵I-SCH23982 binding was observed ventral to the STh in the internal capsule. Subsequent competition studies confirmed that STh DA receptors are of the D₂-subtype. These data suggest that D₂-receptor mediated DA neurotransmission may be an important modulator of STh neural activity and that the blockade of STh D₂-receptors may influence the display of neuroleptic-dependent movement disorders. Supported by grant #8318 from the Swedish MRC.

PROPERTIES OF MIPSCS IN CULTURED RAT SPINAL CORD AND MEDULLARY NEURONS. C. A. Lewis* and D. S. Faber. Dept. of Anatomy and Neurobiology, Med. College of Penn., Philadelphia, PA 19129.

We previously concluded there are at least 3 populations of inhibitory receptors present on cultured rat embryonic neurons, those activated only by glycine or GABA or by either one (Neurosci. 52:83-96, 1993). Also, whole-cell current responses to bath-applied agonist have both desensitizing and nondesensitizing components, with the former being more sensitive to block by antagonists.

To determine which of these postsynaptic receptors are involved in inhibitory synaptic transmission, whole-cell patch recordings were obtained from neurons voltage clamped at -70 mV and perfused with NaCl Ringer's solution containing 300 nM TTX, 10 μ M APV, and 8 μ M CNQX. Spontaneous miniature inhibitory postsynaptic currents (mIPSCs) were digitized at 2 kHz and analyzed using a peak detection program (Ankri, N., et al. Neurosci. Meth., in press), which calculates the peak amplitude and an exponential decay time constant (τ) for each event.

Amplitude distributions were skewed, and frequently showed no discernible peaks. The effects of different antagonists on the amplitude distributions were complex and did not provide insights concerning the involved inhibitory receptors. On the other hand, the decay distributions were consistently best fitted by the sum of 4 Gaussians with τ s of: $\tau_1 = 8.11 \pm 0.96$ (\pm S.D., $n = 22$), $\tau_2 = 13.6 \pm 2.8$ ($n = 24$), $\tau_3 = 25.9 \pm 2.3$ ($n = 22$) and $\tau_4 = 49.3 \pm 6.8$ ($n = 25$) ms. These 4 classes of decay times have different pharmacological sensitivities to antagonists. The results of experiments using different concentrations of strychnine and bicuculline lead to the following conclusions: τ_1 is mediated by the nondesensitizing GABAR, τ_2 by the nondesensitizing GlyR, and τ_3 and τ_4 by the desensitizing Gly/GABAR. However, since all four decay components are seen in cell-attached patches that exhibit mIPSCs, it is possible the responses are generated by one receptor with complex binding affinities and sensitivities to block by antagonists.

SYNAPTIC INHIBITION AND FACILITATION IN RABBIT PANCREATIC GANGLIA. J. A. Love* and C. Owyang. Dept. of Internal Medicine, University of Michigan, Ann Arbor, MI 48109.

The intrinsic ganglia of the pancreas receive innervation from vagal, sympathetic, myenteric and primary afferent nerves while providing the postganglionic parasympathetic innervation to pancreatic endocrine and exocrine cells. Presently little is known of the synaptic mechanisms and neurotransmitters which regulate the firing of pancreatic neurons. We have performed the first intracellular recordings from rabbit pancreatic ganglia to study these questions. Portions of the pancreas, with or without the duodenum attached, were removed and intracellular recordings were made from neurons in single or interconnected ganglia. Stimulation of nerve fibers elicited multiple nicotinic fast EPSPs (fEPSPs) and action potentials. At low stimulus frequency (0.5 Hz) fEPSP activity decreased with time until frequent synaptic failures were observed. This phenomenon was antagonized by atropine. At higher stimulus frequencies (1-10 Hz), facilitation of fEPSP activity, resulting in synaptic action potentials, was observed. Conditioning (10Hz) trains also delayed the onset of synaptic failures observed at low frequency stimulation. Superfusion with norepinephrine (NE) or the α_1 agonist phenylephrine (5-10 μ M) depolarized (8 ± 1 mV) 8/19 neurons and facilitated synaptic transmission while 7/15 neurons responded to NE with a hyperpolarization (8 ± 1 mV) and synaptic inhibition. Thus, the postganglionic output to the endocrine and exocrine pancreas can be extensively regulated at the level of pancreatic ganglia by intrinsic synaptic mechanisms as well as by cholinergic and adrenergic neurotransmitters. Supported by NIH.

REGULATION OF [3H]RX821002 BINDING TO ALPHA-2 ADRENOCEPTORS BY G-PROTEIN IN RAT BRAIN. J. Chung, G. Chen, H. K. Manji, J. Crawley*, W. Z. Potter, D. Pickar. Experimental Therapeutics Branch, NIMH, NIH, MD 20892.

In recent years, it has become increasingly clear that for a number of neurotransmitter systems, receptors can exist in a precoupled to G-proteins state even in the absence of agonists. This has been demonstrated by the effects of antagonists or GTPase activity. We have sought to examine the coupling of alpha-2 adrenoceptors in rat brain by the use of the highly selective alpha-2 antagonist, [3H]RX821002. Saturation experiments showed that [3H]RX821002 binding to alpha-2 adrenoceptors is saturable, highly specific and best fitted to a one-site model by iterative Scatchard analysis. Non-specific binding defined by the addition of 0.1 mM epinephrine was less than 10 % of total binding. Interestingly, we found that the addition of 0.1 mM Gpp(NH)p increased both the affinity and the density of sites recognized by the antagonist [3H]RX821002 (paired T-test, $P < 0.01$ and $P < 0.05$, respectively). Similar effects on the density of alpha-2 sites were observed by pretreatment of rat membranes with pertussis toxin. Taken together, these results suggest that a percentage of alpha-2 adrenergic receptors exists in a precoupled state in rat cortex, and guanine nucleotides regulate antagonist affinity to these sites as well.

These findings of the coupled state of empty alpha-2 adrenoceptor in rat cortex have important implications for basic and clinical studies using alpha-2 antagonists.

VOLTAGE DEPENDENCE OF THE EPSC AND DESENSITIZATION OF AMPA RECEPTORS BY TRANSMITTER. S. Zhang* & L. Trussell. Dept. of Neurophysiology, Univ. Wisconsin - Madison, 53706.

Chick VIIIth nerve fibers form somatic synapses in the nucleus magnocellularis and generate large EPSCs. A previous study of brain slices showed that the neurotransmitter, presumably glutamate, activates and then desensitizes AMPA receptors (Trussell et al., Neuron 10, 1185). The kinetics of glutamate and kainate responses in these cells are voltage dependent (see abstract by Otis, Raman, & Trussell, this meeting). We examined changes in the time course of the EPSC with postsynaptic potential to see whether voltage sensitivity might reveal further information about the transmitter's lifetime and receptor desensitization. The decay of the AMPA receptor EPSC could be described by two exponentials, of 0.7-1 ms and 6-40 ms. With depolarization from -65 to +125 mV, both components slightly lengthened, but the relative magnitude of the slow component increased 5-fold, resulting a marked overall slowing of the EPSC. Such a large slow component could not be explained by a long channel burst duration or desensitization time course. The increase with depolarization in the magnitude of the slow phase is consistent with an increased receptor affinity. We propose that there is a prolonged phase of transmitter removal from the synaptic cleft. Synaptic depression, monitored with EPSC pairs, was reduced at positive holding potentials. Since receptor desensitization is reduced by depolarization, depression may in part result from desensitization, a consequence of the slow clearance of transmitter.

CHOLINERGIC MODULATION OF POSTSYNAPTIC RESPONSES ELICITED FROM RAT MAGNOCELLULAR CHOLINERGIC BASAL FOREBRAIN NEURONS. J. A. Sim*, W. H. Griffith* & D. A. Brown*. ¹Dept. of Pharmacology, Univ. Coll. Lond., London WC1E 6BT & ²Dept. of Medical Pharmacol. and Toxicol., Coll. of Medicine, Texas A & M Univ., College Station, TX 77843.

Basal forebrain nuclei, which form the main cholinergic projection to cortical and subcortical regions of mammalian brain, receive afferents from various brain regions. In the present study, a thin-slice preparation was used to study the postsynaptic currents of basal forebrain nuclei. Coronal sections (200 μ m) were prepared from 10-14 day-old rat pups, incorporating the horizontal limb of the Diagonal Band of Broca and substantia innominata. Whole-cell recordings were made from visually identified magnocellular neurons, using a potassium acetate-based internal solution. Neurons with diameter > 20 μ m were selected, as they stained positive with acetylcholinesterase histochemistry, and thus were considered to be cholinergic. In most cells, spontaneous synaptic responses could be recorded, displaying sensitivity to either bicuculline (Bic) or 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). These events were not readily blocked by tetrodotoxin (TTX). Following bipolar stimulation within a 50-100 μ m radius of the recorded cell synaptic responses, both CNQX- and bicuculline-sensitive evoked-responses could be recorded. The mean time constant for decay (τ) for CNQX-sensitive epscs was approximately 3.03 ± 0.31 ms and was 27.5 ± 2.4 ms for Bic-sensitive ipscs (as measured at 20-23 °C). Carbachol (CCh; 0.3-10 μ M) reduced the amplitude of these epscs in a dose-dependent manner. In addition to reducing the amplitude of these postsynaptic events, inhibition by CCh was frequently observed as failures of synaptic events.

In summary, synaptic connections within basal forebrain nuclei have been preserved in thin-slice preparations and that excitatory and inhibitory afferents to the magnocellular cholinergic basal forebrain express presynaptic muscarinic receptors. [Supported by Wellcome Travel Award (W.H.G.) and M.R.C. (JAS,DAB)].

SYNAPTIC CONNECTIONS BETWEEN CELL PAIRS IN RAT HIPPOCAMPAL SLICE CULTURES.

D. DEBANNE*, N.C. GUÉRINEAU, B.H. GÄHWILER and S.M. THOMPSON.
Brain Research Institute, University of Zurich, 8029 Zurich Switzerland

Pairs of individual neurons were recorded in rat hippocampal slice cultures with sharp electrodes or in whole-cell configuration. Unitary synaptic connections were studied between pre- and postsynaptic cells in CA3 and CA1 hippocampal fields by eliciting single action potentials in the presynaptic cell. Monosynaptic excitatory connections were highly probable between CA3 and CA1 pyramidal cells ($p=0.76$, $n=125$) with almost no feed-forward inhibition ($p=0.024$). By contrast, disynaptic IPSPs, blocked by CNQX or bicuculline, were observed with a very high probability ($p=0.43$) between CA3 pyramidal cells. Monosynaptic excitation was found in 56% of cases between CA3 neurons ($n=91$) but only between 16% of CA1 pyramidal cell pairs ($n=25$). AMPA- and NMDA-components of EPSPs could be identified pharmacologically at both CA3/CA3 and CA3/CA1 cell synapses, with kinetics similar to those seen with extracellular stimulation. Single action potentials evoked in interneurons resulted in monosynaptic, bicuculline sensitive IPSPs only in pyramidal cells within the same region. Paired-pulse facilitation of unitary EPSPs and paired-pulse depression of unitary IPSPs, were observed. Probability of transmitter release, studied in recordings where failures could be unambiguously distinguished from spontaneous or small PSPs, was found to be close to 100% at both excitatory and inhibitory synapses. Bath application of the inhibitor of glutamate release, adenosine, reduced the amplitude of unitary EPSPs in a graded manner, indicating that the release at excitatory synapses is multiquantal.

CHARACTERIZATION OF INTRACELLULAR CALCIUM OSCILLATION IN RAT HIPPOCAMPAL NEURONS IN THE PRESENCE OF MAGNESIUM IONS. T.Tanaka*, H.Saito, and N.Matsuki. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., Univ. of Tokyo, Tokyo 113, Tokyo

It is widely known that the embryonic neurons can develop morphologically and functionally in culture and form the synaptic network. In Mg^{2+} -depleted condition the cultured neurons show spontaneous and periodical oscillations of intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$), which are synchronized among the cells. In the present study the spontaneous oscillatory changes of $[Ca^{2+}]_i$ were observed even in the presence of physiological concentration of magnesium and characterized pharmacologically. The hippocampal cells from embryonic day 18 rats were cultured for 10-16 days and changes in $[Ca^{2+}]_i$ of single cells were measured by a microfluorimetric technique with fura-2. The spontaneous oscillation was blocked completely by application of $1 \mu M$ tetrodotoxin. CNQX ($10 \mu M$) and nicardipine ($10 \mu M$) blocked the oscillation completely while APV showed only a partial depression of the increase in $[Ca^{2+}]_i$. This contracts with the results in Mg^{2+} -free condition, in which either APV or CNQX alone inhibits the oscillation completely. The inhibitory neurotransmitter GABA ($10 \mu M$) suppressed the spontaneous oscillation, whereas bicuculline ($3 \mu M$), a GABA_A antagonist, slightly enhanced the amplitude. Basic fibroblast growth factor (bFGF) also had depressant effect on the oscillation, and this effect was encountered by suramin. These results suggest that excitatory and inhibitory transmission is involved in the formation and maintenance of the intracellular Ca^{2+} oscillation.

GABA-MEDIATED OUTWARD CURRENTS IN HERMISSENDA PHOTORECEPTORS. E. Yamashita* and A. Kuzirian. Marine Biological Laboratory, Woods Hole, MA 02543.

GABA is the inhibitory neurotransmitter at the mechanosensitive-hair cell-photoreceptor synapse in *Hermisenda*. In addition, GABA induces a transient rise in intracellular Ca^{2+} . It has been proposed that such induction may play a role in plasticity in *Hermisenda*. Here we report GABA-induced outward currents in photoreceptors of *Hermisenda* using whole-cell patch-clamp technique. Individual photoreceptors were isolated as previously described. Inward Na^+ and Ca^{2+} currents were minimized by substitution of Na^+ with choline and using low external Ca^{2+} ($1 mM$). Outward K^+ currents were blocked by $5 mM$ 4-aminopyridine and $100 mM$ tetraethylammonium. BAPTA ($10 mM$) was added to the internal solution to block I_{KCa} . Under these conditions, minimal inward or outward currents were recorded. However, an outward current could be recorded upon the application of $10 nM$ GABA (fig 1a & b). Desensitization to GABA occurred after prolonged exposure. Current was blocked by bicuculline ($100 \mu M$), a known blocker of GABA_A receptor. The properties of the GABA-mediated outward current were consistent with those of Cl^- current: (1) The current magnitude and the estimated reversal potential were altered dependent on the external and internal Cl^- concentrations. (2) The current was reduced by DIDS ($100 \mu M$), a known blocker of Cl^- current. The inhibitory post synaptic potential at the hair cell-photoreceptor synapses may be mediated by the Cl^- current.

IDENTIFICATION AND CHARACTERIZATION OF PROTEIN TYROSINE PHOSPHATASES AT THE NEUROMUSCULAR JUNCTION. L. Mei* and R.L. Huganir. Department of Neuroscience, HHMI, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Protein tyrosine phosphorylation is prevalent throughout the nervous system suggesting that it may be involved in the regulation of neuronal function. The phosphorylation of proteins is regulated by the balance of protein kinases and protein phosphatases. Although protein tyrosine kinases in the brain have been characterized, much less is known about neuronal protein tyrosine phosphatases. We have been using the neuromuscular junction as a model to study the role of protein tyrosine phosphatases in the regulation of synaptic transmission and plasticity. Twelve individual protein tyrosine phosphatases were isolated from the rat skeletal muscle based on the consensus sequence of previously characterized tyrosine phosphatases, including three novel ones. Previously we have shown that PTP1D, a cytoplasmic phosphatase containing two SH2 domains, appeared to be abundant in the brain and muscle at the mRNA level and its phosphatase activity was down-regulated by a four amino acid insert generated by RNA splicing. Using affinity-purified antibodies, PTP1D was identified as a 68-kDa protein most abundant in the brain and heart, moderate in the skeletal muscle, lung, and liver, least in the kidney. Its expression in the brain appeared to increase continually during the development: from barely detectable on embryonic day 10 to maximal on postnatal day 60. The catalytic domain of PTP1D could be phosphorylated by protein kinase C but not by cAMP-dependent kinase. Phosphoamino acid analyses indicated that PKC phosphorylation of PTP1D was on serine residues. GST fusion proteins containing SH2 domains of PTP1D were made to study its interaction with other proteins. The SH2 domains were found to bind to several tyrosine-phosphorylated proteins *in vitro*, including nicotinic acetylcholine receptors in the skeletal muscle. Studies are under way to investigate the effects of PKC phosphorylation of PTP1D on the phosphatase activity and to identify the proteins that interact with PTP1D.

HYPERPOLARIZING AND DEPOLARIZING ACTIONS OF GLYCINE ON RAT ROSTRAL VENTROLATERAL MEDULLA NEURONS. H. H. Lin* and N. J. Dun. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43614

Intracellular recordings were made from rostral ventrolateral medulla (RVLM) neurons of brain stem slices ($500 \mu m$) of immature (12-16 days) rats. Pressure application of glycine from a micropipette containing $100 mM$ glycine to 37 RVLM neurons evoked 3 types of responses: a depolarization ($n=24$), a hyperpolarization ($n=6$) and a biphasic response consisting of a hyperpolarization followed by a depolarization ($N=2$). The hyperpolarizing and depolarizing responses were associated with a marked decrease of membrane resistance. Increasing and decreasing the membrane potential reduced and increased the glycine hyperpolarization; the reversal potential was between -60 and $-70 mV$. The glycine depolarization was reduced by depolarizing and increased by hyperpolarizing the membrane from the resting potential of $-60 mV$. Strychnine ($1 \mu M$) blocked the glycine-induced hyperpolarization, whereas it partially suppressed the glycine-induced depolarization in 3 cells and had no effect in the other 5 cells. The results indicate that there are two pharmacologically distinct types of glycine receptor, the activation of which initiates a strychnine-sensitive hyperpolarization and a depolarization that is less susceptible to blockade by strychnine in the immature rat RVLM neurons. ACTIVATION OF A CATIONIC CONDUCTANCE BY METABOTROPIC GLUTAMATERGIC AND MUSCARINIC AGONISTS IN CA3 CELLS IN HIPPOCAMPAL SLICE CULTURES.

N.C. Guérineau*, B.H. Gähwiler and U. Gerber

Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland

An increase in a membrane cationic conductance in response to metabotropic glutamatergic or muscarinic agonists was characterized in CA3 pyramidal neurons using the patch-clamp technique. When $[K^+]_o$ was raised above 5 mM, 1S,3R-ACPD (50 μ M) or methacholine (MCh, 5 μ M) induced a biphasic inward/outward current. The initial inward component was associated with an increase in membrane conductance, displayed no apparent voltage sensitivity over the range -120 to -50 mV, and had a mean extrapolated reversal potential in 16 mM $[K^+]_o$ of -9.1 ± 21.2 mV and -3.3 ± 24.0 mV for 1S,3R-ACPD and MCh, respectively. Decreasing $[K^+]_o$ or $[Na^+]_o$ reduced the current amplitude and shifted the reversal potential to more negative values. The response to 1S,3R-ACPD or MCh was reduced by extracellular Ba^{2+} (1 mM), Cd^{2+} (200 μ M), Mg^{2+} (10 mM) or TEA (20 mM) whereas extracellular Cs^+ (2 mM) or loading cells with BAPTA (20 mM) or Cs^+ (140 mM) did not affect the current. The effects of 1S,3R-ACPD persisted unchanged in the presence of 20 μ M CNQX and 40 μ M DAPV, but were reversibly inhibited by bath-applied MCPG (1 mM). The outward component of the 1S,3R-ACPD- and MCh-induced response was associated with a decrease in membrane conductance, reversed close to E_{K^+} , varied linearly with membrane potential and may correspond to $I_{K,leak}$. Thus, in addition to a reduction in K^+ conductance, both 1S,3R-ACPD and MCh activate a non-selective cationic conductance mainly permeable to K^+ and Na^+ ions that is more prominent upon elevating $[K^+]_o$.

CALCIUM PERMEABILITY AND CYCLIC NUCLEOTIDE MODULATION OF THE HYPERPOLARIZATION ACTIVATED CATION CURRENT, I_h , IN N1E-115 NEUROBLASTOMA CELLS. C. Mathes* and S.H. Thompson. Hopkins Marine Station of Stanford University, Pacific Grove, CA 93950.

We recorded I_h in a neuronal cell line derived from mouse sympathetic ganglion. This time and voltage dependent current is activated at hyperpolarized potentials and tail current measurements give a reversal potential of -30 mV. The instantaneous (I_{inst}) and steady-state (I_{ss}) $I(V)$ curves are inwardly rectifying. The activation curve of I_h is fit by a single Boltzmann function with $V_{1/2} = -85$ mV and the slope factor $z = 3$. Like $I_{h(f)}$ in cardiac and other cells, the inward current is inhibited by Cs but not by Ba which distinguishes this inward current from the fast inward rectifying K current. I_h amplitudes increase by about 144% when $(Ca)_{out}$ is elevated and when Mn or Co are added. These results suggest that I_h is permeable to divalents, including Ca, Mn and Co. Single channel currents have been measured with Ca as the carrier that have a similar $I(V)$ curve and extrapolated reversal potential to I_h . The slope conductance is ~ 50 pS. In nystatin patch experiments, cAMP (1 mM 8-bromo cAMP) increases I_h by 400% (I_{inst}) and 151% (I_{ss}) at -95 mV. Cyclic GMP (1 mM 8-Br cGMP) inhibits I_h by 36% (I_{inst}) and 46% (I_{ss}) at -95 mV. Cyclic AMP increases I_h amplitudes at all voltages, while the inhibition of I_h by cGMP occurs only at negative potentials. This cyclic nucleotide modulation of I_h may be the mechanism by which muscarinic receptors suppress I_h . Muscarinic agonist application reduces I_h amplitudes by 35% at -90. Muscarinic inhibition of I_h should decrease spike frequency and counteract the slow EPSP during synaptic transmission. [NIH NS14519 to S.H.T., MH10425 and AFAR to C.M.]

ACTIVATION, PERMEABILITY AND INHIBITION OF THE LARGE-CONDUCTANCE SWELLING-INDUCED ANION CHANNEL IN ACUTELY ISOLATED RAT CORTICAL ASTROCYTES. T.O. Jalonen*, C.J. Charniga, A.J. Popp, and H.K. Kimelberg. Department of Surgery, Albany Medical College, Albany, N.Y. 12208.

We have used GFAP(+) cortical astrocytes within 1-8 hours after their isolation from postnatal day 3 to day 28 rats to study the characteristics of a large-conductance (over 300 pS), swelling-induced anion channel (LA^-) found in astrocytes. Hyposmotic solutions activate this channel and we have now found that both isosmotic and hyperosmotic 50 mM EtOH solutions also induce its activation. Since hyperosmotic EtOH does not swell the cell, this also indicates a direct, osmolarity-independent effect of ethanol on channel activity. Contrary to results in rabbit kidney cells (Mills et al., 1994; J. Exp. Zool. 268:111), cytochalasin D (0.3-1 μ M in DMSO, added into the bath in a cell-attached recording configuration) did not activate the astrocytic LA^- channel, indicating that possible disruption of actin filaments during swelling is not responsible for this channel's activation in astrocytes. Though Gray and Ritchie earlier showed that in normal (non-swollen) conditions glutamate does not permeate astrocyte Cl^- channels in whole-cell recordings from primary astrocytes (1986; Proc. R. Soc. Lond. B. 228:267), we now find in single-channel recordings that high concentrations of glutamate (20-137 mM) permeate the LA^- channel when the channel is first activated by hypotonic solutions. This supports the idea that this is one possible pathway for amino acids to permeate the membrane during astrocytic swelling. The anion transport inhibitor, 4,4'-diisothiocyanatobiphenyl (DIDS, 100 μ M), blocks the LA^- channel at 0.1-0.6 mM concentrations, but has no inhibitory effect on K^+ channel activities. These findings give new information on possible functions of the anion channel in astrocytic swelling during traumatic head injury and ischemia. (Supported by BRSG NIH507R005394-31 (T.O.J.), H. Schaffer Foundation (A.J.P.) and NS 30303 (H.K.K.)).

PROPERTIES OF A NOVEL VOLTAGE-DEPENDENT CATION CURRENT IN RAT NEOCORTICAL NEURONS. C. Alzheimer*. Department of Physiology, University of Munich, Pettenkoferstr. 12, D-80336 Munich, Germany.

Pyramidal neurons acutely isolated from rat sensorimotor cortex were found to express a nonlinear cation current (I_{CAT}) which could not be explained using established categories of channel classification. The ionic nature and the voltage dependence of this current were investigated using the whole-cell configuration of the patch-clamp technique. Experimental conditions were chosen to block Na^+ currents (1 μ M TTX), Ca^{2+} currents (0.4 mM Cd^{2+}), and K^+ currents (internal Cs^+ instead of K^+). Recordings were performed at room temperature.

In symmetrical high Cs^+ solutions, depolarizing pulses applied from a holding potential of -70 mV evoked sustained currents that were inward between -40 and 0 mV (peak amplitude -300 to -400 pA at -20 mV) and became outward at positive command potentials. I_{CAT} displayed outward rectification in the depolarizing direction. Upon repolarization to -70 mV, I_{CAT} slowly decayed producing a prominent inward tail current (τ : 40 - 60 ms). At a given potential, the time constant of tail current decay was independent of prepulse potential. In contrast, when repolarization potentials were varied along the voltage axis (-120 to -60 mV) after a prepulse to 30 mV, deactivation kinetics of I_{CAT} showed a strong voltage dependence, the decay time constant substantially increasing with depolarization.

Ion substitution experiments revealed that the channel producing I_{CAT} was permeable to a number of monovalent cations including K^+ , Cs^+ , Na^+ , and choline, but not to the anion Cl^- . I_{CAT} was reduced by TEA at high concentrations (35 mM), but not by 4-AP, and proved to be insensitive to cation channel blockers such as Cs^+ , amiloride, or gadolinium. Activation of I_{CAT} did not require Ca^{2+} influx nor cytosolic Ca^{2+} rise.

Due to its slow deactivation kinetics, I_{CAT} is likely to contribute to the sequence of afterpotentials following a depolarizing event in electrically active neurons.

MOLECULAR AND FUNCTIONAL CHARACTERIZATION OF AN INWARDLY RECTIFYING CONDUCTANCE IN RAT BRAIN. R.L. Smith, K.J. Staley, G.H. Clayton, and C.L. Wilcox*. Dept. of Neurology, UCHSC, Denver, CO 80262 and Dept. of Microbiology, CSU, Fort Collins, CO 80523

A voltage sensitive inwardly rectifying chloride channel is present in hippocampal pyramidal neurons but not dentate gyrus neurons. This conductance has electrical properties similar to a chloride channel (designated $ClC-2$) that has been cloned and functionally characterized in a xenopus expression system, and has been shown to have a significant role in modulation of neuronal responses to GABA_A-mediated mechanisms (K. Staley, JNP 7/94; in press). Therefore, defining the CNS distribution of $ClC-2$ is of interest to understanding the neuron-specific mechanisms that can modulate GABA_A response. Using *in situ* hybridization methods to detect the $ClC-2$ mRNA, we have demonstrated that expression of $ClC-2$ mRNA was restricted to the same population of neurons in the hippocampus that contain a voltage sensitive inwardly rectifying Cl^- conductance. In rat brain, expression of $ClC-2$ was restricted to neurons and choroid plexus but was not detectable in glial cells. Although $ClC-2$ mRNA was widely expressed in cortical neurons, significant differences in signal intensity were observed regionally and in different cell layers. In subcortical structures $ClC-2$ expression was restricted to specific regions and neuronal cell types. These results suggest that in brain $ClC-2$ may have neuron specific functions in modulation of the chloride gradient that differ significantly from the proposed role in volume regulation of non-neural tissues.

RAPID AND REVERSIBLE INHIBITION OF GAP JUNCTIONAL DYE TRANSFER USING 18 α -GLYCYRRHETINIC ACID AND 18 α -CARBENOXOLONE IN CELL CULTURE. G.S. Goldberg, J.F. Bechberger, and C.C.G. Naus*. Dept. of Anatomy, University of Western Ontario, London, ON N6A 5C1, CANADA.

Gap junctions are intercellular conduits, made up of proteins called connexins, through which molecules may pass from one cell into another - a process referred to as gap junctional intercellular communication (GJIC). GJIC appears to play crucial roles in the control of cell growth and differentiation. Therefore, the ability to effectively inhibit GJIC, without causing cytotoxic or other side effects, would be extremely useful for investigating the functional significance of GJIC in a variety of systems. Others have shown the glycyrrhetic acid family of compounds to have great promise in this respect. We describe here a simple method for determining concentrations of 18 α -glycyrrhetic acid and 18 α -carbenoxolone which are able to completely and reversibly inhibit GJIC in cell culture, as assayed by dye transfer, with no detectable cytotoxic effects. This procedure should prove useful in many other cell types and systems.

SENSITIVITY TO OSMOTIC CHANGES OF VOLTAGE-GATED CALCIUM CURRENTS IN RAT ANTERIOR PITUITARY CELLS.

O. Matzner & I. Nussinovitch*. Dept. of Anatomy, Hebrew University Sch. of Med., Jerusalem, Israel.

In a recent study it has been shown that voltage gated calcium currents, in pituitary cells, are flow sensitive (Ben-Tabou, Keller and Nussinovitch, J. Physiol. 476.1, 1994). This finding raised the possibility that local deformation of pituitary cell membranes can affect influx through voltage sensitive calcium channels. We tested this possibility by exposing pituitary cells to solutions with different osmolarities, causing deformation of pituitary cell membranes by swelling or shrinking. In this study, pituitary somatotrophs were exposed to hypotonic solutions (165-200 mosmol) or hypertonic sucrose containing solutions (400-520 mosmol) by bath perfusion. The osmolarity of the standard extracellular solution was 320 mosmol. Calcium currents were recorded with the whole-cell mode of the patch-clamp technique.

Exposure to hypo-osmotic solutions resulted in two major effects: 1. Block of T-type calcium currents with no change in their voltage dependence of activation. 2. Negative shift (of about 10 mV) in the activation curve for high voltage activated (HVA) calcium currents. HVA calcium currents which were activated at negative test potentials (-50 mV to -10 mV) increased in size whereas those activated at more positive test potentials (0 mV to +30 mV) decreased in size. Similar results were observed when the cells were exposed to hyper-osmotic solutions except that the block of HVA currents was not always associated with a shift in activation curve. These findings suggest that deformation of pituitary cell membrane by osmotic changes can regulate influx through voltage sensitive calcium channels.

NITRIC OXIDE SYNTHASE (NOS) DOES NOT MEDIATE CURRENT-DEPENDENT INACTIVATION OF N-TYPE Ca^{2+} CHANNELS BUT IT DOES SOMETHING TO I_{Ca} . J.L. Kenyon*

Dept. of Physiol., Univ. of NV School of Med., Reno, NV 89557

I tested the hypothesis that Ca^{2+} entry via I_{Ca} inhibits I_{Ca} by stimulation of NOS and production of nitric oxide (NO). N-type I_{Ca} was measured in chick dorsal root ganglion neurons using amphotericin perforated patches at 35-36°C. I_{Ca} was reduced by low $[\text{Cl}^-]_o$ and 100 μM niflumic acid. Inactivation of I_{Ca} during 250 ms conditioning steps (-70 to +40 mV) was monitored by 50 ms test steps (-8 mV). 10 s intervals separated the conditioning steps. As conditioning voltages were made less negative, test I_{Ca} decreased then recovered as expected for current-dependent inactivation of I_{Ca} (Tillotson, PNAS 76:1497, 1979). Inactivation was not reduced by 100 μM Nitro-L-arginine (L-NNA) suggesting that synthesis of NO by NOS is not required for this process. Curiously, I_{Ca} during the conditioning step to -8 mV was larger than I_{Ca} in the first test step (4 of 5 cells, left panel).

This effect was abolished by L-NNA (right panel) implying an NO-dependent potentiation of I_{Ca} during the train of conditioning and test steps. NS 32144

PHARMACOLOGY OF LOW-THRESHOLD CALCIUM CURRENTS IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS. R.B. Avery* and D. Johnston, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Hippocampal neurons possess multiple types of voltage-gated calcium channels (Fisher et al., J. Neurophys. 64:91). The contribution of specific channel types to cellular functions, however, is not well-established. Low-threshold calcium currents are thought to support complex firing patterns in CA3 pyramidal cells. Since the pharmacology of low-threshold calcium channels varies among neurons, we wish to screen potential blockers of these channels in CA3 cells.

Recordings were made from CA3 pyramidal neurons acutely isolated from rats 7 to 14 days old. Cell-attached patches confirmed the presence of low-threshold calcium channels on the somata of these cells. In 110 mM barium, single channel openings could be evoked from potentials as low as -60 mV. The slope conductance of single channels was less than 10 pS. Patches with several channels exhibited a rapidly inactivating macroscopic current.

To screen putative blockers of these channels, we made whole-cell recordings in 5 mM calcium. From hyperpolarized holding potentials, calcium currents activated at potentials more positive than -60 mV. We assayed low-threshold calcium currents with test pulses to -40 mV from a holding potential -80 mV. The current at -40 mV was slowly activating and inactivating. The amplitude was about a third of the peak whole-cell current, which occurred between -10 and 0 mV. High-threshold currents were isolated by holding at -50 mV to inactivate low-threshold channels. Steps from -50 mV to 0 mV elicited a slightly inactivating current. The amplitude was about half that compared to currents evoked from a holding potential of -80 mV. 50 or 100 μM nickel strongly reduced the low-threshold component but only slightly blocked the high-threshold currents. CALCIUM-DEPENDENT INHIBITION OF HUMAN N-TYPE CALCIUM CHANNELS. C. J. Grantham, P.S. Chard, P.T. Toth, J. Jordan†, G. Ghadge, R. Roos, R.J. Miller and D. Bleakman, Lilly Research Centre Ltd, Surrey GU20 6PH U.K. and Depts. of Pharmacol. Physiol. Sci. & Neurology, Univ. of Chicago, Chicago, Illinois 60637, U.S.A.

Voltage-dependent calcium channels (VDCC) can undergo both voltage and current-dependent inactivation. We have investigated the modulation of human N-type VDCC by changes in $[\text{Ca}^{2+}]_i$. Ca^{2+} and Ba^{2+} currents were measured in HEK 293 cells which had been transfected with the human neuronal α_{1B} - α_{2B} - β_3 subunits. Using whole cell voltage clamp recordings, prepulse protocols were employed to examine current-dependent reductions in N-type VDCC currents. Voltage-dependent inactivation was minimized (<10%) by utilizing a double pulse protocol with P1 (V_h = -90mV, V_t = +10mV, dur. = 200ms) and P2 (V_h = -90mV, V_t = +10mV, dur. = 200ms) separated by a 1200ms pulse interval (at V_h = -90mV). Under low Ca^{2+} buffering conditions (100 μM Fura-2 in the patch pipette), the P2/P1 ratio was significantly reduced when Ca^{2+} ions replaced Ba^{2+} ions as the charge carrier (0.48 ± 0.28 , $n=6$ & 0.83 ± 0.07 , $n=6$ respectively. $p < 0.02$). However, when 15mM BAPTA was added to the patch pipette, the P2/P1 ratio for Ca^{2+} ions was significantly increased (0.89 ± 0.01 , $n=6$, $p < 0.01$).

HEK 293 cells were infected with a replication defective calbindin D28k (AdCABP-1), or β -galactosidase (Ad β GAL), expressing adenovirus. 24 hrs following infection, immunocytochemical staining confirmed expression of these proteins. Ca^{2+} -dependent inhibition was also attenuated in calbindin D28k expressing cells. Using simultaneous electrophysiological (nystatin perforated patch)/fura-2 based microfluorimetric recordings, we assessed increases in $[\text{Ca}^{2+}]_i$ (per pC charge influx) for the AdCABP-1 and Ad β GAL infected HEK 293 cells. Increases in $[\text{Ca}^{2+}]_i$ (per pC charge influx) were significantly lower in AdCABP-1 infected cells compared to Ad β GAL infected cells and abolished in BAPTA containing cells. These experiments demonstrate that N-type VDCC can be inhibited by a process involving increases in $[\text{Ca}^{2+}]_i$. †Supported by NATO grant.

PROTON-INDUCED CURRENT CHANGES IN ION SELECTIVITY DURING CULTURE OF EMBRYONIC RAT SPINAL CORD NEURONS. Y.X. Li, A.E. Schaffner, H.R. Li, R. Nelson*, and J.L. Barker. Laboratory of Neurophysiology, NINDS, NIH, Bethesda, Maryland 20892

Rapid increases in protons (H^+) induce Na^+ conductance in a variety of cell types (Gen. Physiol. Biophys. 11:39, 1992). Here we report that H^+ can trigger a cation selective conductance in cultured embryonic (E) rat spinal cord neurons that changes over time in culture. Experiments were performed on neurons dissociated at E15 and cultured for 1-4 weeks. All recordings were carried out at 22-25°C with conventional whole-cell patch clamp techniques using CsCl-filled pipettes. An inward current exhibiting a rapid decay phase (≤ 6 seconds) in many of cells and requiring several minutes to recover after complete inactivation, was triggered by brief application of saline buffered to $\text{pH} \leq 6.5$. More modest decreases in pH, which by themselves failed to activate this current, depressed those triggered by effective changes in pH. The currents recorded from the cells cultured for up to one week could be abolished completely in the absence of Ca^{2+} and persisted in Na^+ -free solution and in Ba^{2+} , Mn^{2+} and Co^{2+} -containing solutions. The currents were blocked by 1mM Ni^{2+} or 2mM Mg^{2+} . The reversal potential was about +55mV, similar to the Ca^{2+} equilibrium potential, consistent with the Ca^{2+} -dependency of the current. After ~10 days in culture protons induced an inward current with similar kinetic properties, but Na^+ -dependency. Thus, proton-activated cation conductance changes ion selectivity in culture.

REGULATION OF VOLTAGE-DEPENDENT CALCIUM CHANNELS OF MOUSE DRG NEURONS BY CHRONIC ELECTRICAL STIMULATION IN CULTURE. M.X. Li, M. Jia, R.D. Fields*, and P.G. Nelson. NICHD and NINDS, NIH, Bethesda, MD 20892.

Previous research has shown that influx of calcium through voltage-sensitive calcium channels is responsible for the arrest of growth cone motility in mouse DRG neurons in culture. After chronic electrical stimulation, growth cones recover and become insensitive to repeated stimulation. (Biphasic stimulation was delivered at 6V in 0.5 s bursts at 10 Hz every 2 s for 40 - 70 hrs.) To understand the mechanism of growth cone accommodation, whole cell voltage clamp experiments and calcium imaging using fura-2 were performed on mouse DRG neurons cultured in multi-compartmental chambers. The electrically-induced increase in calcium was significantly slower in the growth cones and cell bodies of DRG neurons after chronic stimulation ($\tau = 3.2\text{s}$ vs. 1.4s , $p < 0.001$). High-threshold-activated (HVA) whole-cell calcium currents were reduced in chronically stimulated neurons from 3.2 nA to 0.59 nA ($p < 0.02$), measured at the end of a 200 ms stimulation pulse. Low-threshold-activated (LVA) were reduced from 0.74 nA to 0.095 nA ($p < 0.02$). The membrane potential of the peak current was shifted from -15 mV in the control neurons to +9.1 mV ($P < 0.0002$). There was no difference in the mean diameter of neurons in the control and stimulated groups. The HVA calcium currents inactivated more rapidly in the stimulated group. Our results suggest that development of the nervous system could be influenced by activity-dependent regulation of calcium conductance through VSCC, by ensuing effects on growth cone motility, and other calcium-dependent processes.

MODULATION OF RYANODINE RECEPTORS BY MITOCHONDRIAL CALCIUM IN DORSAL ROOT GANGLION NEURONES. D. Bowie*, P. Feltz and R. Schlichter, *Laboratoire de Physiologie Générale, Université Louis Pasteur, Strasbourg, France.*

An extensive repertoire of ionic channels are modulated by changes in the concentration of cytosolic calcium ($[Ca^{2+}]_i$) which, in many cases such as for ryanodine receptors¹, exerts a bell-shaped dependency on channel activity. As yet, these observations have not been demonstrated in an intact neurone nor has the Ca^{2+} -signalling pathway which modulates receptor function been identified. In single, intact nociceptive sensory neurones pre-loaded with fura-2, we have attempted to identify the Ca^{2+} -signal which modulates ryanodine receptors using a variety of receptor agonists which elevate $[Ca^{2+}]_i$ through known pathways². The sensory neurone excitant, capsaicin (500nM-2µM) and 50mM KCl evoked biphasic elevations in $[Ca^{2+}]_i$ consisting of a peak and plateau component. The peak Ca^{2+} -rise was due to entry of extracellular Ca^{2+} which was attenuated and sustained at a plateau level for long periods by the mitochondria; identified using 10µM FCCP to selectively inhibit Ca^{2+} -uptake into the organelle. The amplitude of the plateau was greater following application of capsaicin than 50mM KCl. Activation of ryanodine receptors by 10mM caffeine elicited transient Ca^{2+} rises that were reversibly inhibited during the Ca^{2+} -plateau evoked by capsaicin but unaffected by the plateau to 50mM KCl. Selective inhibition of the mitochondrial Na^+/Ca^{2+} exchanger with 2µM CGP37157 lowered the plateau amplitude observed with capsaicin and restored the Ca^{2+} rises evoked by caffeine. These observations support a novel role of the mitochondria as a long-term modulator of intracellular Ca^{2+} stores as well as a prospective regulator of other Ca^{2+} -dependent events in the cytoplasm.

CALCIUM INFLUX THROUGH P-TYPE CHANNELS ACTIVATES CLOSELY ASSOCIATED CALCIUM DEPENDENT POTASSIUM CHANNELS AT THE MOUSE MOTOR NERVE TERMINALS.

D.A. Protti and O.D. Uchitel*, Faculty of Medicine, University of Buenos Aires, Paraguay 2155 (1121), Buenos Aires, Argentina.

Transmitter release is commonly shortened by the repolarization of the membrane, due to the onset of diverse potassium currents. At the mammalian motor nerve terminals, two main potassium conductances have been described, a voltage dependent K^+ current, blocked by 3,4-diaminopyridine (3,4-DAP) and a calcium activated potassium current (IK_{Ca}) sensitive to TEA and to Charybdotoxin. We have previously reported that FTX and ω -Aga-IVA, two P-type calcium channel blockers, inhibit neuromuscular transmission, diminish quantal content and block calcium currents at the mouse motor nerve terminals (PNAS 89,3330-3333, 1992; Neuroreport 5, 333-336, 1993).

We studied the activation of the (IK_{Ca}) in the levator auris muscle-nerve preparation of the mouse by means of perineural recordings in the presence of 3,4-DAP (1mM). We have found that the (IK_{Ca}) is abolished in the presence of FTX (1:10,000) and ω Aga-IVA (10 nM). This (IK_{Ca}) was also inhibited after loading the nerve terminals with the fast calcium chelators BAPTA-AM and DM-BAPTA-AM (25 µM) but not when loaded with EGTA-AM (25 µM), a slow calcium chelator.

These results indicate that calcium influx through P-type calcium channels is responsible for the activation of the calcium-dependent potassium channels. Moreover, the ability of BAPTA-AM and DM-BAPTA-AM of preventing (IK_{Ca}) activation and the lack of effect of EGTA-AM suggest that both types of channels are closely associated at the release sites.

STIMULUS-INDUCED SECRETION AND VESICLE ACIDIFICATION IN SEROTONERGIC PARANEURONS (PARAFOLLICULAR CELLS): THE ROLE OF VOLTAGE-GATED Ca^{2+} CHANNELS. H. Tamir*, K.P. Liu, M. Heath, M. Adlersberg, and M. D. Gershon, D. Anat. & Cell Biol., & D. Anesth. Columbia Univ. P&S New York, NY 10032

Thyroid parafollicular (PF; "C") cells are neural crest-derived endocrine cells that resemble neurons. These cells synthesize 5-HT and co-store it with calcitonin in secretory vesicles. The pH within these vesicles is regulated by gatable membrane Cl^- channels. These channels open and permit the vesicles to acidify in response to secretagogues, which include $\uparrow[Ca^{2+}]_i$ and $\uparrow[K^+]_e$. We now report that a Cl^- channel (p64), identical to that found in epithelial cells, is present in the membrane of PF vesicles. The opening of this channel is associated with an increase in its state of phosphorylation. Secretagogues, in concentrations that also cause secretion, induce an increase in $[Ca^{2+}]_i$. Secretion in response to $\uparrow[Ca^{2+}]_i$ was partially inhibited by the L-type channel blocker, nimodipine (NIM; 0.5 µM) and by tetrodotoxin (TTX; 10 µM), which were additive when combined. Secretion in response to $\uparrow[K^+]_e$ was unaffected by TTX, but abolished by NIM. Antagonism of secretion by NIM was reversed by the L-type channel agonist, Bay K8644 (10 µM). In contrast to NIM, neither the N-type channel blocker, Ω -conotoxin (0.1 µM), nor the P-type channel blocker, Ω -agatoxin (0.1 µM), affected secretion. Vesicle acidification in response to $\uparrow[Ca^{2+}]_i$ was partially inhibited by both NIM (0.5 µM) and Ω -conotoxin (0.1 µM), but was unaffected by Ω -agatoxin (0.1 µM). Vesicle acidification induced by $\uparrow[K^+]_e$ was inhibited by NIM (1.0 µM), Ω -conotoxin (0.1 µM), Ω -agatoxin (0.1 µM), and by TTX (1.0 µM). These data suggest that Ca^{2+} entry through L-type voltage-gated Ca^{2+} channels is involved in coupling stimulation to both secretion and vesicle acidification; however, N-type channels (and P-type channels when cells are stimulated with $\uparrow[K^+]_e$) contribute only to vesicle acidification. THAPSIGARGIN DISCHARGES INTRACELLULAR Ca^{2+} ($[Ca^{2+}]_i$) STORES IN MOUSE CORTICAL ASTROCYTES. J.A. Edwards*, H.H. Wolf and H.S. White. Anticonvulsant Drug Development Program, Department of Pharmacology and Toxicology, University of Utah, SLC, UT 84112.

Thapsigargin stimulates Ca^{2+} release from $[Ca^{2+}]_i$ stores by selectively inhibiting the Ca^{2+} -ATPase on the intracellular storage membrane. By poisoning the Ca^{2+} pump thapsigargin treatment produces a release of Ca^{2+} from the thapsigargin-sensitive Ca^{2+} stores. The present investigation was initiated to assess the $[Ca^{2+}]_i$ storage capacity of mouse cortical astrocytes. In an attempt to deplete $[Ca^{2+}]_i$ stores varying concentrations of thapsigargin (10, 30 & 100 nM) were bath applied to a confluent monolayer of astrocytes for 10 minutes. Changes in the $[Ca^{2+}]_i$ of type-1 mouse cortical astrocytes (21-28 days in culture) were measured using an indo-1 based microfluorometry imaging system. Treatment with thapsigargin resulted in a dramatic increase (417, 646 & 621% at 10, 30 & 100 nM, respectively) in the $[Ca^{2+}]_i$ over basal levels. This effect was only partially reversible upon subsequent wash-out with drug-free buffer. Of particular interest was the finding that the increase in $[Ca^{2+}]_i$ was highly dependent on the concentration of $[Ca^{2+}]_o$. These results suggested that depletion of $[Ca^{2+}]_i$ stores was producing Ca^{2+} influx across the plasma membrane. Additional studies with dantrolene and ryanodine (to block $[Ca^{2+}]_i$ release) and nimodipine (to block voltage-sensitive Ca^{2+} channels) were unable to attenuate the thapsigargin-induced influx of Ca^{2+} and subsequent increase in $[Ca^{2+}]_i$. These data support the hypothesis that the decrease in Ca^{2+} stores may release some type of intracellular messenger (e.g., calcium influx factor) which would initiate refilling of $[Ca^{2+}]_i$ stores. SINGLE CHANNEL BASIS OF THE MULTIPLE FUNCTIONAL COMPONENTS OF MACROSCOPIC L-TYPE Ca^{2+} CHANNEL CURRENT IN CLONAL PITUITARY CELLS. D.M. Fass* & E.S. Levitan.

Depts. of Neuroscience and Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

In the presence of the dihydropyridine agonist BAY K 8644 (1 µM), whole cell L-channel Ba^{2+} currents in GH₃ cells consist of two functional components. These two components differ in their rate of deactivation, voltage dependence, sensitivity to BAY K 8644, and sensitivity to inhibition by the neuropeptide TRH. The simplest hypothesis which may account for these two components is one which invokes two populations of L-channels. To test this hypothesis, single channel recordings were obtained from cell-attached patches. To control the potential of the membrane outside the patch, the K^+ ionophore valinomycin (10 µM) was applied to the cells. This treatment stabilized V_m at ~-60 mV. In addition, rundown was much less pronounced (channel activity remained stable for hours) than when the typical high K^+ external solution was used. Ensemble tail currents derived from recordings from multi-channel patches were fit by two exponentials, indicating that the two components were detectable in the presence of valinomycin. Two exponentials were also required to fit the ensemble tail current derived from one of two single-channel patches obtained thus far. The other single-channel patch had an ensemble tail fit well by one exponential. Obtaining more single channel patches will allow us to determine whether individual L-channels display the behaviors of one or both components of macroscopic L-current.

LEAD ATTENUATES L-TYPE CALCIUM CHANNEL INACTIVATION IN BOVINE CHROMAFFIN CELLS. L. Sun, J. B. Suszkiw, and N. Sperelakis*. Dept. of Physiology and Biophysics, Univ. of Cincinnati, Cincinnati, OH 45267-0576.

Using whole-cell voltage clamp, we investigated the effects of inorganic lead (Pb^{2+}) on the voltage-gated calcium channel currents recorded from bovine adrenal chromaffin cells. Currents were evoked by 200ms voltage step pulse to +10mV from a holding membrane potential of -80mV. Extracellularly-applied Pb^{2+} (0.05, 0.1, 0.5, 1.0 µM) depressed calcium currents in a dose-dependent manner and acted as a potent and reversible blocker of Ca^{2+} channels, which is consistent with a competition by Pb^{2+} with Ca^{2+} at a binding site within the calcium channel. However, intracellular application of Pb^{2+} (0.001, 0.01, 0.1 µM) showed a facilitation of calcium currents. This effect was dose-dependent, could be blocked by 10 µM nifedipine, and appears to reflect reduced rate of calcium current rundown. It has been indicated that the Ca^{2+} -dependent inactivation of L-type channels involves an activation of protein phosphatase and the channel dephosphorylation. These results suggest that Pb^{2+} may attenuate Ca^{2+} channel inactivation by maintaining Ca^{2+} channel in phosphorylated status.

ACUTE EXPOSURE TO LOW LEVELS OF LEAD ALTERS CALCIUM CURRENT AMPLITUDES IN RAT PC-12 CELLS. C.C. Hegg & V. Miletic. Dept. Comp. Biosci. & Environmental Toxicology Center, Univ. Wisconsin, Madison, WI 53706.

Lead is a known neurotoxin with varied and poorly understood mechanism(s) of action. We employed the whole-cell patch-clamp technique to examine the effects of low levels of lead on high-threshold voltage-dependent calcium currents in rat pheochromocytoma (PC-12) cells. PC-12 cells were placed in NGF-containing media for 4, 8, or 12 days prior to recording. During recordings, the cells were first perfused for 5 minutes with lead-free solution, then switched to a 1 or 10 μ M lead-containing solution for another 5 minutes, and finally washed again with lead-free solution. As previously reported, acute low-levels of lead caused a decrease in calcium current amplitude without an obvious change in activation or deactivation kinetics in some cells ($n=7$). However, unlike previous reports, acute exposure to the same low levels of lead also produced increases in calcium currents in other cells ($n=12$). In both situations, the effect of lead was only partially reversible with washing. There was no systematic difference in the effects of lead among the 4, 8 or 12 day cultures. These data suggest complex interactions of lead with calcium channels in PC-12 cells. (Supported by NIH NS21278).

SELECTIVE MODULATION OF T- and L-TYPE CALCIUM CURRENTS BY STIMULATION OF m3 AND m4 MUSCARINIC RECEPTOR SUBTYPES IN TRANSFECTED 3T3 CELLS. K.E. Pemberton* and S.V.P. Jones. Molecular Neuropharmacology, Departments of Psychiatry and Molecular Physiology and Biophysics, University of Vermont College of Medicine, Burlington, VT 05405.

Calcium currents were recorded from NIH 3T3 cells transfected with the m3 and m4 muscarinic receptor subtypes. Whole cell patch clamp recordings were made with (mM): NaCl 150, MgCl₂ 1, BaCl₂ 20, Hepes 10 and Glucose 5. Patch pipettes (4-6M Ω) were filled with (mM) NMGC1 120, MgCl₂ 4, EGTA 10, Hepes 10, ATP 4, GTP 0.1, creatine phosphate 5, and creatine kinase 50 units/ml. Using a variety of stimulation protocols two types of voltage dependent calcium current were observed. A low voltage activated, transient, nifedipine-insensitive calcium current (T-type) and a slowly inactivating, high voltage activated calcium current that was dihydropyridine-sensitive (L-type). Stimulation of cloned m4 receptors resulted in a pertussis toxin-sensitive reduction in amplitude of the L-type calcium current but appeared to be without effect on the amplitude of the T-type calcium current. Conversely, activation of the m3 muscarinic receptor produced an increase in the amplitude of the T-type calcium current. The respective mechanisms of action of these muscarinic receptor subtypes will be addressed.

Noradrenergic potentiation of a low-voltage-activated calcium current in dissociated nucleus basalis neurons. S. Williams*, A. Pegna, M. Mühlethaler and L. Bernheim Dept. of Physiology, CMU, 1211 Geneva 4, Switzerland.

Nucleus basalis (NB) neurons provide an important cholinergic input to the cerebral cortex and receive a prominent innervation from noradrenergic (NA) neurons of the locus coeruleus. Previous studies have indicated that cholinergic neurons of the NB are endowed with the capacity to emit action potentials in bursts. These bursts are thought to be mediated by a potent low-voltage-activated (LVA) calcium current. We have studied the NA modulation of the LVA current in dissociated NB neurons using whole-cell voltage-clamp recordings. In the presence of TTX (0.5 μ M), TEA (20 mM) and 4-AP (4 mM), NB neurons recorded with an internal solution containing (in mM) 130 Cs acetate, 20 Cs Cl, 5 HEPES, 5 MgCl₂, 0.1 BAPTA, 3 Na₂ATP and 0.1 NaGTP, consistently displayed a transient LVA current. From a V_H of -90 mV, the LVA current was activated at potentials near -50 mV, had a peak amplitude (measured at -30 mV) of 223 ± 60 pA ($n=8$, mean \pm SD) and was reduced by amiloride (300 μ M, $n=3$) or cadmium (200-400 μ M, $n=8$). Perfusion of NA (50 μ M) produced a long lasting (>15 min) increase of 44 ± 32 % ($n=4$) in the peak amplitude of the LVA current. The addition of prazosin (1 μ M, $n=3$), an α_1 receptor antagonist, prevented this effect. Perfusion with L-phenylephrine (40 μ M), an α_1 receptor agonist, mimicked the NA induced potentiation, producing an increase of 52 ± 23 % ($n=7$). These results suggest that NA, through the activation of an α_1 receptor, can potentiate the LVA current and could therefore in certain conditions, favour the propensity of NB neurons to generate rhythmic bursts. (Canadian MRC and Swiss FN).

CALCIUM MOBILIZATION IN RESPONSE TO IRON, HEMIN AND PROTOPORPHYRIN IX: MULTIPLE PATHWAYS OF ACTIVATION. DL Kraemer*, AH Cornell-Bell. Neurosurgery* and Cell Biology Yale University School of Medicine, New Haven, CT 06510

Intracranial hemorrhage is associated with stroke, reperfusion injury, trauma, and epilepsy. Abnormalities in calcium metabolism have been reported with all of these disease processes, and have been attributed to iron-induced Fenton chemistry. The relative contribution of inorganic and organic blood breakdown products upon intracellular calcium physiology was investigated to determine whether multiple factors might be involved. Cultured rat hippocampal astrocytes were exposed to varying concentrations of FeCl₂, hemin and protoporphyrin IX. Relative changes in intracellular calcium were measured using Fluo-3 and time-lapse video confocal laser microscopy. FeCl₂ induced intracellular oscillations and long-range regenerating calcium waves in a dose dependent manner ($r=0.85$, $EC_{50}=1\mu$ M). Hemin produced similar changes ($r=0.95$, $EC_{50}=5\mu$ M), except that a late, sustained calcium elevation was also noted. Protoporphyrin IX induced a slow rise in intracellular calcium, with minimal wave generation. Removal of extracellular calcium from the bathing medium abolished the response seen to 50 μ M FeCl₂, ($p<.0001$), but had no effect on the calcium rise induced by 50 μ M protoporphyrin IX. ($p>.05$, NS). These results suggest that blood breakdown products mobilize different sources of calcium, and that multiple pathophysiologic mechanisms may be induced after hemorrhage.

701.16

ACTIVATION OF GABA_B AND μ -OPIOID RECEPTORS MODULATE DIFFERENT TYPES OF Ca²⁺ CURRENTS IN RAT NODOSE GANGLION NEURONS. K.I.Rusin* and H.C.Moises. Dept. of Physiology, Univ. of Michigan, Ann Arbor, MI 48109-0622.

Whole cell patch clamp recordings were obtained from nodose neurons acutely dissociated from 10-24 day old rats to characterize the Ca²⁺ channel types that are modulated by GABA_B and μ -opioid receptors. Five components of high-threshold current were distinguished on the basis of their sensitivity to blockade by ω -CgTxGVIA, nifedipine, ω -AgaIVA and ω -CTx MVIIIC. Administration of the μ -opioid agonist H-Tyr-D-Ala-Gly-Phe(N-Me)-Gly-ol (DAGO, 0.3-1 μ M) or the GABA_B agonist baclofen (30 μ M) suppressed high-threshold Ca²⁺ currents by 51.5 ± 2.7 % ($n=51$) and 20.7 ± 2.4 % ($n=24$), respectively. Blockade of N-type channels by ω -CgTxGVIA eliminated current suppression by baclofen in all cells tested ($n=11$). The inhibitory effect of DAGO was completely abolished by ω -CgTxGVIA in 12 of 30 neurons and partially reduced in the remaining 18 neurons. Administration of ω -Aga IVA in saturating concentrations failed to completely eliminate the μ -opioid sensitive current component which persisted after blockade of N-type channels. This ω -CgTxGVIA/ ω -AgaIVA-resistant component of the μ -opioid sensitive current was blocked by ω -CTxMVIIIC in 9 neurons. The remaining neurons ($n=9$) contained an unidentified component of Ca²⁺ current that was resistant to blockade by ω -CgTxGVIA, dihydropyridines, ω -AgaIVA and ω -CTxMVIIIC. This toxin-resistant component was reduced by DAGO. Dihydropyridine-sensitive (L-type) current was unaffected by μ -opioid or GABA_B receptor activation. These data suggest that μ -opioid receptors in nodose ganglion neurons are negatively coupled to N, P, Q and unidentified toxin-resistant Ca²⁺ channels, whereas GABA_B receptors are coupled only to N-type channels. (Supported by DA03365 to HCM).

701.18

Serotonergic and GABAergic modulation of HVA calcium currents in dissociated nucleus basalis neurons. A. Pegna, L. Bernheim, M. Mühlethaler, M. Serafin*, and S. Williams. Dept. of Physiology, CMU, 1211 Geneva 4, Switzerland.

A major source of cholinergic input to the cerebral cortex arises from nucleus basalis neurons (NBn). In addition to a low-voltage-activated Ca²⁺ current, NBn exhibit an important high-voltage-activated (HVA) Ca²⁺ current. The inhibition of the HVA current by baclofen and 5-HT was studied in guinea-pig acutely isolated NBn using the whole-cell voltage-clamp technique. The HVA current was isolated with TTX (0.5 μ M), TEA (20 mM) and 4-AP (4mM), and recorded with patch pipettes containing (in mM), 130 CsAc, 20 CsCl, 5 HEPES, 5 MgCl₂, 0.1 BAPTA, 3 Na₂ATP and 0.1 NaGTP. A voltage step to 0 mV for 40 ms, from a V_H of -90 mV, activated a HVA current with a peak amplitude of 1.46 ± 0.47 nA ($n=9$, mean \pm SD). The HVA Ca²⁺ current could be dissociated pharmacologically into three components (L, N and P). The total HVA current was reduced by 20 ± 14 % ($n=9$) with the application of nifedipine (3-5 μ M), an L-type blocker, by 38 ± 20 % ($n=10$) with ω -conotoxin GVIA (100 nM), an N-type blocker, and by 35 ± 20 % ($n=5$) with ω -aga-IVA (100 nM), a P-type blocker. The application of 5-HT (10 μ M) or the 5-HT_{1A} agonist 8-OH-DPAT (10 μ M) reduced the peak amplitude (at 0 mV) of HVA currents by 34 ± 8 % ($n=3$) and 29 ± 3 %, respectively. In the presence of ω -conotoxin GVIA (100 nM), 8-OH-DPAT ($n=2$) did not affect remaining HVA currents suggesting that 8-OH-DPAT reduces only the N-type Ca²⁺ current. The GABA_B agonist baclofen (10 μ M) produced a 33 ± 10 % ($n=5$) reduction of HVA currents. We are presently determining which HVA current(s) is (are) modulated by baclofen. Taken together, these results suggest that, in NBn, the HVA Ca²⁺ current is composed mainly of types L, N and P. Serotonin and GABA may selectively modulate only one component of the HVA current.

SEROTONIN (5HT) MODULATES HVA CALCIUM CURRENTS IN RAT NEOCORTICAL PYRAMIDAL NEURONS. **Foehring, R.C.***, Dept. of Anatomy & Neurobiology, Univ. of Tenn., Memphis, TN 38163.

Neocortical pyramidal cells were acutely-dissociated from the sensorimotor cortex of rats (P7-adult) and whole cell voltage-clamp recordings were obtained. 5HT reduced HVA currents in a reversible and dose-dependent manner. In a given cell, 10-40% of the whole cell current was modulated by 5HT, with no change in voltage-dependence. The 5HT effect was mimicked by the 5HT_{1A} agonist 5-CT and by the 5HT_{1A} agonist R(+)-8OHDPAT. The 5HT effect was blocked by the 5HT_{1A} antagonist NAN-190, but not by the 5HT₂ antagonists mianserin or ketanserin. These data suggest that the modulation is mediated by 5HT_{1A} receptors. Under our standard internal Ca²⁺ chelation conditions (10 mM EGTA or 20 mM BAPTA), the modulation was unaffected by 5 μ M nifedipine and partially occluded by saturating doses of ω -CgTx GVIA (1 μ M) or ω -AgTx IVA (100 nM). The combination of these two agents completely blocked the modulation, suggesting that N- and P-type channels were modulated. The modulation of N- and P-type current by 5HT was rapid in onset (τ of several hundred ms) and partially reversed by prepulses to +120 mV. In the presence of GTPyS, the modulation was irreversible. These data indicate the involvement of a G protein in the modulation and suggest utilization of a membrane-delimited pathway. When the internal solution contained 0.1 mM BAPTA as the only chelator, L-type current was reduced in addition to N- and P-type. This modulation appeared slower in onset than that of N- and P-type currents. Under all chelation conditions, 5HT reduced the slow tail currents generated by L-type channels in the presence of Bay K 8644. Supported by NINDS grant #R29NS27180. ω -AgTx IVA was a gift from Pfizer, Inc.

BIOPHYSICAL PROPERTIES OF PHARMACOLOGICALLY-DEFINED HVA Ca²⁺ CURRENTS IN NEOCORTEX. **Lorenzon, N.M.* and Foehring, R.C.**, Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38163.

Neocortical pyramidal cells were acutely-dissociated from the sensorimotor cortex of rats (P7 or adult) and whole cell voltage-clamp recordings were obtained. We defined L-, N-, and P-type Ca²⁺ currents as those blocked by saturating doses of nifedipine (5 μ M), ω -CgTx GVIA (1 μ M), and ω -AgTx IVA (100 nM), respectively. Currents were isolated by subtracting the current obtained in the presence of one of the blockers from control records. We measured: (1) The voltages at which currents were first observable and at peak current. (2) Time-to-peak current activation (at -10 mV). (3) Deactivation time constant (at -55 mV). (4) The steady-state voltage-dependence of activation was estimated by transformation of currents obtained with a voltage ramp (the GHK equation was used to generate a driving force term) or from the amplitude of tail currents (at -50 mV) following steps to various potentials. The conductance vs. voltage relationship was fit by a single Boltzmann function. We found good agreement between the two methods. (5) Time constant of inactivation (at -10 mV), and (6) Percent inactivation at 2.7 s (at -10 mV). In cells from adult rats, we found no significant differences between L-, N-, and P-type currents for any of these parameters. Similarly, in cells from 1 week-old animals (P6-10), we found no significant differences between the various current types. The voltage-dependence of activation and percent inactivation differed between immature and adult cells. Currents in young cells activated at voltages ~5-10 mV more positive than in adult cells and exhibited slightly more inactivation. Supported by NINDS grant #R29NS27180 (R.C.F.) and an NIMH predoctoral fellowship to N.M.L. ω -AgTx IVA was a gift from Pfizer, Inc.

702.1

INDUCTION OR PROTECTION OF LIMBIC SEIZURES IN MICE FOLLOWING INTRACEREBRAL INJECTIONS OF METABOTROPIC GLUTAMATE RECEPTOR AGONISTS. **L.P. Tizzano*, K.I. Griffey, J. Goldworthy, S.R. Baker, and D.D. Schoepp**, Lilly Research Laboratories, Eli Lilly and Company, Greenfield, IN 46140.

Metabotropic glutamate receptors (mGluRs) are a heterogeneous family of receptors coupled to multiple second messenger systems via G-proteins. We have previously described that the mGluR selective agonist 1S,3R-1-aminocyclopentane-1,3-dicarboxylic acid (ACPD) induces limbic seizures in mice. In this study, other mGluR selective agonists were evaluated for effects in this model. 3,5-dihydroxyphenylglycine (DHPG), which like ACPD activates phosphoinositide (PI) coupled mGluRs (mGluR1 and/or mGluR5), was found to be about equipotent to ACPD in inducing seizures. Other mGluR agonists such as L-2-amino-4-phosphonobutanoate (L-AP4) and L-serine-O-phosphate (L-SOP) which are highly selective for the negatively-linked cAMP coupled mGluR subtypes (mGluR4, mGluR7) were inactive at doses of up to 3200 nmol. In contrast, these agonists blocked seizures induced by either ACPD or DHPG in a stereoselective manner. (2S,3S,4S)-a-(carboxycyclopropyl) glycine (L-CCG I) which has some selectivity for cAMP linked mGluRs (mGluR2 and mGluR3), also protected against ACPD or DHPG at lower doses. However, higher doses of this agonist induced seizures that were qualitatively similar to ACPD or DHPG. These data suggest that induction of mGluR mediated limbic seizures in mice are a result of activating PI linked in situ mGluRs. In contrast, mGluR agonists which act to decrease cellular cAMP do not induce seizures, but can functionally antagonize the effects of other mGluR agonists which induce seizures through activation of the PI pathway.

702.3

FUNDAMENTALLY DIFFERENT MECHANISM UNDERLIE THE LOCOMOTOR STIMULATORY ACTIONS OF DOPAMINE AGONISTS AND MK-801. **A. Mele*, D.N. Thomas and A. Pert**, Dip. Biol. Molec., Univ. Roma "La Sapienza", P.le Aldo Moro, 5, 00185, Roma and Biological Psychiatry Branch, NIMH, Bldg. 10, Rm 3N212, Bethesda, MD 20892

The actions of dopamine (DA) agonists in the nucleus accumbens (Acb) are thought to be translated into locomotor activation through decreases in ventral pallidum GABA. Blockade of glutamate function in the Acb by non-competitive glutamate antagonists such as MK-801 also increases locomotor output. Some have suggested that MK-801 produces locomotor stimulation through mesolimbic DA, although support for this proposition is equivocal. For example, we have previously failed to find significant increases in Acb DA overflow by pharmacologically relevant doses of MK-801. The present behavioral studies also failed to provide support for a role of Acb DA in the stimulatory effects of this glutamate antagonist. DA depleting lesions of the Acb significantly attenuated the locomotor activating effects of amphetamine applied focally to this structure while the stimulatory actions of MK-801 were not altered. The second series of studies was directed at evaluating the role of pallidum GABA in mediating the motoric actions of DA agonists and MK-801. Using *in vivo* Microdialysis procedures, apomorphine was found to decrease pallidum GABA while MK-801 failed to have an effect despite producing pronounced increases in locomotor activity. Injections of muscimol (10ng) into the ventral pallidum prevented the excitatory effects of amphetamine but not MK-801. The locomotor activating effects of MK-801 do not appear to involve Acb DA nor pallidum GABA.

702.2

KETAMINE-INDUCED ALTERATION OF NITRIC OXIDE SYNTHETASE ACTIVITY IN RAT CAUDATE NUCLEI. **R.A. Mueller, M.D., Ph.D.* and R.D. Hunt, B.S.**, Departments of Anesthesiology and Pharmacology, UNC-Chapel Hill, Chapel Hill, NC 27599-7010

It has previously been reported that pretreatment with inhibitors of nitric oxide synthetase (Type 1) (NOS) can antagonize the anesthetic effects of ketamine in rats, but the effect may be due to decreased delivery of ketamine to its site of action. In the present study *in vivo* NOS synthetase activity was used to assess caudate NOS during the onset, maintenance and disappearance of ketamine anesthesia.

Rats (60-120 g) given saline (2 ml/kg) or ketamine (75 mg/2 ml/kg) i.m. at zero time were used to study NOS activity *in vivo* 15 (onset) 30 (maintenance) or 60 (disappearance) minutes after IM saline or ketamine. Each rat received 5-10 μ Ci of ³H-arginine i.v. and as killed by decapitation 5 minutes later, with rapid removal of plasma, liver, parietal cortex, cerebellum, and caudate nuclei samples. ³H-citrulline was measured by ion exchange and HPLC with all tissue values corrected for contamination of the tissue by plasma ³H-citrulline calculated to be within the tissue.

Synthesis of caudate ³H citrulline was increased 50% in rats that received ketamine 15 minutes previously ($p < 0.05$), but not at 30 or 60 minutes. No significant changes were noted in the cerebellum or parietal cortex.

These results suggest that after ketamine, the NOS activity is briefly increased acutely but returns to normal even though analgesia persists. NOS activity changes do not parallel the time course of anesthetic effects.

702.4

PHARMACO-EEG PROFILES OF SELECTIVE LIGANDS FOR DIFFERENT BINDING SITES ON THE NMDA-RECEPTOR COMPLEX. **D.F. Sisson*, D.H. Snyder, J.M. Goldstein**, Zeneca Pharmaceuticals Group, Wilmington, DE 19897.

Selective ligands for sites on the NMDA-receptor were administered to unanesthetized, unrestrained rats by infusion into chronic, indwelling, jugular catheters. Drugs were infused at a rate of 1 ml-hr⁻¹ for four hours. Each rat received one dose of 5, 10 or 20 mg-kg⁻¹-hr⁻¹ of either the competitive NMDA antagonist CGS19755, the non-competitive NMDA antagonist CNS1102 or the glycine-site antagonist ACEA1021. EEG activity was monitored from chronic transcranial screws implanted bilaterally over frontal and parietal cortices. CGS19755 produced a profound elevation of EEG spectral power in the 0-4 Hz (delta) band starting 15 min into the infusion and reaching a plateau in 30-60 min. A further increase in delta-band power was observed at 4 hr with the 10 mg-kg⁻¹-hr⁻¹ dose. Stereotypy and ataxia were observed after about 3 hr infusion at 10 mg-kg⁻¹-hr⁻¹. CNS1102 produced a profound increase in delta activity 15 min into infusion, reaching a phasic peak at 30 min and declining to a plateau by 60 min. Almost full recovery was observed by 60 min post-infusion. Ataxia and stereotypy were observed starting about 45 min into the infusion at 10 mg-kg⁻¹-hr⁻¹. The effects of ACEA1021 on EEG were subtle. Rats maintained a sleep wake cycle throughout the infusion, although sleep was somewhat disrupted in the first hour of infusion. This is reflected in a decrease in delta band power at 30 min. At a dose of 10 mg-kg⁻¹-hr⁻¹, this decrease continued for the duration of the infusion; at the higher dose, delta activity exhibited an initial decrease and then an increase. Mild ataxia was observed during infusion; no stereotypy was observed. Quantitative EEG is a useful tool not only in determining the time course of central action of NMDA ligands, but is also capable of discriminating between ligands for different sites on the NMDA-receptor complex.

ANTAGONISM OF STRIATAL QUINOLINATE TOXICITY BY L-4-CL-KYNURENINE IN VIVO. P. Guidetti¹, H.-Q. Wu and R. Schwarcz². Md. Psych. Res. Ctr., Baltimore, MD 21228.
7-Cl-kynurenic acid (7-Cl-KYNA), a selective and potent antagonist of the glycine co-agonist site of the NMDA receptor, can be produced from L-4-Cl-kynurenine (4-Cl-KYN) by the action of kynurenine aminotransferase, a glial enzyme which catalyzes the biosynthesis of kynurenic acid from L-kynurenine (KYN) (J. Med. Chem. 37: 334, 1994). The anti-excitotoxic effect of 4-Cl-KYN was now studied in the rat striatum using glutamic acid decarboxylase (GAD) as a marker of neuronal death. Infusion of 120 nmol quinolinic acid (QUIN) into the striatum (over 2 hrs) resulted in a $45 \pm 3\%$ decrease in GAD in the injected striatum after one week (N=11). Combined pre- and co-infusion with a total of 135 nmol 4-Cl-KYN (over 4 hrs) prevented the QUIN-induced decrease in GAD activity. The production of 7-Cl-KYNA from 4-Cl-KYN was verified by HPLC analysis of brain extracts. 181 ± 15 pmol/mg prot 7-Cl-KYNA were recovered from a normal striatum infused with 135 nmol 4-Cl-KYN for 4 hrs (N=14). The production of 7-Cl-KYNA was decreased by 51% after astrocytic impairment by flurocitrate (1 nmol/1 μ l, i.str.; N=13), but was increased by 204% in the astroglial striatum, i.e. seven days after an intrastriatal QUIN (300 nmol) injection. These data indicate that astrocytes can produce neuroprotective quantities of 7-Cl-KYNA from 4-Cl-KYN in the rat striatum in vivo. Supported by a grant from the Huntington's Disease Society of America (to P.G.).

LEARNING IMPAIRMENT INDUCED BY CHRONIC INFUSION OF QUINOLINIC ACID - PROTECTION BY MEMANTINE. W. Danyś¹, M. Misztal¹, R. K. Filipkowski², L. Kaczmarek² and J. Skangiel-Kramska². Dept. Pharmacol., Mierz+Co, 60318 Frankfurt/Main, Germany¹; Nencki Institute, 02-093 Warsaw, Poland².

A few studies only have aimed to mimic the chronic nature of neurodegeneration, involving possibly glutamate receptors, which is believed to take place in senile dementia of the Alzheimer's type (SDAT). In the present study, NMDA agonist quinolinic acid (9 mM), was infused icv by ALZET osmotic minipump for 2 weeks (Yamada et al. 1990, Neurosci. Lett., 1118, 128-131). This treatment produced a persistent, short-term memory deficit in T-maze, developing over 2 weeks. In the hippocampus, induction of c-fos mRNA was observed 1 day, but not 1 hour and 3 or 7 days after the start of quinolinic acid infusion. Autoradiography revealed a decrease in the density of muscarinic receptors and choline uptake sites. Parallel s.c. infusion of an uncompetitive NMDA antagonist memantine (1-amino-3,5-dimethyladamantane), 20 mg/kg/day by another minipump prevented the learning deterioration induced by quinolinate. The treatment with memantine resulted in steady-state plasma levels of 1.2 μ M which should assure inhibition of NMDA receptors and is similar to levels seen in demented patients treated with this agent. Hence, if the glutamate hypothesis of dementia is accepted the neuroprotective activity of memantine in SDAT patients might be expected.

702.9

NMDA, BUT NOT AMPA, BLOCKADE REDUCES MONOSODIUM GLUTAMATE (MSG) INDUCED DAMAGE IN NEONATAL RATS. B. Milburn, J. Parks, T. Bambrick, R. Telford, D. Bannerman and M. Saari^{*}. Neuroscience Research Unit, Nipissing University, 100 College Dr., North Bay, Ontario, Canada, P1B 8L7.

In two experiments we investigated whether NMDA and/or AMPA receptor blockade mitigates the physiological and behavioural damage associated with neonatal MSG injections in the rat. In the first experiment, Wistar rat pups received two injections on postnatal days 2, 3, 5, 7 and 9. The first injection was either saline (SAL) or MK-801 (0.1 mg/kg; sc.) while the second injection was either saline or MSG (4 g/kg; sc.). This yielded 3 treatment groups: MK-801/MSG, SAL/MSG and SAL/SAL. In the second experiment, we tested the protective effects of MK-801 and/or NBQX injection prior to MSG administration. Behavioural testing revealed the expected SAL/MSG induced learning deficit in the water maze and reduced pain sensitivity as measured by the tail flick test. Postmortem analyses revealed organ weight reductions in MSG treated rats. We conclude that MK-801, but not NBQX, protects against damage associated with neonatal MSG treatment. ACKNOWLEDGEMENT: The authors thank NOVO NORDISK for their contribution of NBQX.

COMPETITIVE NMDA ANTAGONISTS DECREASE STRIATAL 3-METHOXYTYRAMINE LEVELS IN THE MOUSE. M.L. Carlsson^{*}. Dept. of Pharmacol., Univ. of Göteborg, Medicinarg. 7, S-413 90 Göteborg, Sweden.

The present study was aimed at investigating the effect of the competitive N-methyl-D-aspartate (NMDA) receptor antagonists D-CPPene and CGS 19755 on mouse brain 3-methoxytyramine levels, as an indirect measure of dopamine release. In some experiments, the animals were treated with the monoamine oxidase inhibitor pargyline as to accumulate 3-methoxytyramine. The mice were sacrificed at a time point when the NMDA antagonist-induced locomotor stimulation in previous studies has been shown to be maximal. D-CPPene and CGS 19755 were found to decrease mouse striatal 3-methoxytyramine levels, whereas in general 3-methoxytyramine levels in the limbic forebrain were not significantly altered. Both D-CPPene and CGS 19755 have been observed to produce psychotic symptoms in man. The present results suggest that these symptoms are not a result of enhanced central dopaminergic transmission, but rather depend on the primary action of these compounds, i.e. an interference with central glutamatergic neurotransmission.

The results obtained in the present study are in agreement with observations made in rats receiving CGS 19755 (N Waters, personal communication): In vivo microdialysis experiments showed that CGS 19755 decreased extracellular dopamine levels in the striatum.

702.8

NON-AMINERGIC MECHANISMS INVOLVED IN NMDA-INDUCED MOTOR ACTIVATION IN RODENTS. E. Martínez, L. Giménez-Llort and S. Ferré. Dept. of Neurochemistry, C.S.I.C., 08034 Barcelona, Spain.

The systemic administration of NMDA in mice induced an initial motor depression followed by a sustained dose-dependent increase in motor activity. With similar doses (25-100 mg/kg i.p.), NMDA induced a dose-dependent motor activation in reserpinized mice (reserpine 5 mg/kg s.c. 20 h prior to NMDA administration), which was counteracted with a dose of the non-competitive NMDA antagonist MK-801 which was associated with motor activation in non-reserpinized mice (0.5 mg/kg i.p.). On the other hand, MK-801 induced motor activation in reserpinized mice at very high and toxic doses (about 2 mg/kg i.p.), which were associated with motor depression in non-reserpinized mice. The NMDA-induced motor activation was still present after a stronger catecholamine-depleting pretreatment (reserpine 10 mg/kg s.c. plus α -methyl-p-tyrosine 200 mg/kg s.c.). These results suggest that, instead of NMDA receptor antagonists, as it is being recently claimed in the literature, NMDA receptor agonists could counteract motor deficits in dopamine-dependent motor disorders.

A more specific and long-lasting effect of NMDA on motor activity was found when studying exploratory activity in non-convulsant rats. Fast movements (FM), slow movements (SM) and rearings (R) were analyzed during both the light and dark periods of the light-dark cycle. A single systemic administration of NMDA (100 mg/kg i.p.) produced an acute short-lasting depressant effect on FM, SM and R, followed during the next two days by a long-lasting increase in exploratory activity, only significant for FM during the dark period. These results could represent a behavioural correlate of the NMDA-induced changes in synaptic plasticity. (Supported by FISS-93/0350).

702.10

MUSCLE RELAXANT ACTION OF FLUPIRTINE: EVIDENCE FOR AN INVOLVEMENT OF α_2 ADRENERGIC AND N-METHYL-D-ASPARTATE (NMDA) RECEPTORS? M. Schwarz¹, F. Block¹, G. Pergande², J. Noth^{1*}. ¹Department of Neurology, RWTH, 52057 Aachen, Germany; ²ASTA Medica, 60314 Frankfurt, Germany

The aim of the present study was to characterize the pharmacological mechanisms involved in the central muscle relaxant action of flupirtine, a novel non-opioid centrally acting analgesic agent. For this purpose in urethane-chloralose anaesthetized rats the action of flupirtine was investigated on the mono-synaptic Hoffmann-(H) reflex recorded from plantar foot muscles and on polysynaptic flexor reflexes recorded from tibialis muscle. Intraperitoneal (1-10 mg/kg) and intra-theal (33-330 nmol) administration of flupirtine depressed poly-synaptic flexor reflexes in a dose-dependent manner without affecting monosynaptic H-reflexes. The effect of intrathecal injection of flupirtine was prevented by co-administration of the mixed α_1 - α_2 adrenergic antagonist yohimbine (10 nmol) and the excitatory amino acid N-methyl-D-aspartate (NMDA; 1nmol), but neither by co-administration of the α_1 adrenergic antagonist prazosin (10 nmol), the GABA_A antagonist bicuculline (1 nmol), the GABA_B antagonist phaclofen (100 nmol) and the non-NMDA agonist amino-3-hydroxy-5-tert-butyl-4-isoxazole-propionic acid (ATPA; 0.1 pmol) nor by pre-treatment with the benzodiazepine antagonist flumazenil (5 mg/kg). These observations suggest that α_2 and NMDA receptors are involved in the mediation of the muscle relaxant activity of flupirtine.

702.11

EFFECTS OF MK 801 AND FLUPIRTINE ON ISCHEMIC RETINAL DYSFUNCTION. F. Block¹, M. Schwarz¹, G. Pergande², S.W. Schoen^{*1}; ¹ Dept. of Neurology, RWTH, 52057 Aachen, Germany; ² ASTA Medica, 60314 Frankfurt, Germany.

Electrophysiological data suggest that flupirtine exerts a muscle relaxant effect via antagonistic action at the NMDA receptor (Schwarz et al, present meeting). Transient occlusion of both common carotid arteries (24 minutes) in normotensive rats induces retinal ischemia as reflected by a reduction in amplitude of the b-wave of the electroretinogram (Neurosci. Lett. 144:124-126; 1992). In the present study the effect of flupirtine on the reduction in amplitude during ischemia and on the recovery during reperfusion of the b-wave was compared to that of the NMDA antagonist MK 801. The electroretinogram was recorded from pentobarbital-anesthetized rats before, during and after transient occlusion of both common carotid arteries. The drugs were administered intraperitoneally 20 minutes before or at the onset of occlusion. MK 801 (1 mg/kg) significantly reduced the depression of the b-wave during occlusion and accelerated the recovery during reperfusion when given 20 minutes before or at the onset of occlusion. Flupirtine (5 mg/kg) led to an attenuation of the reduction of the b-wave during occlusion and to an enhancement of the recovery during reperfusion at either time point of application. The present results demonstrate that the NMDA antagonist MK 801 and flupirtine which seems to interact also with the NMDA receptor provide protection against ischemic retinal dysfunction.

702.12

KETAMINE-INDUCED DISTRACTIBILITY & THOUGHT DISTURBANCE REDUCED BY HALOPERIDOL IN HEALTHY SUBJECTS. J.H. Krystal*, L. Karper, A. Bennett, A. Abi-Dargham, D.C. D'Souza, K. Morrissey, D. Abi-Saab, D.S. Charney. Dept. Psychiatry, Yale Univ. Sch. of Med., VA Medical Center, West Haven, CT 06516

The NMDA antagonist, ketamine, produces psychosis and cognitive impairments in humans. Because ketamine effects resemble endogenous psychoses, the effects of antipsychotic pre-treatment on ketamine responses might provide insights into glutamate-dopamine interactions relevant to psychosis and its treatment. This study evaluated the effects of haloperidol pretreatment on ketamine effects in healthy humans. **METHODS:** In an ongoing study, healthy subjects (n=8) completed 4 test days under double-blind conditions in which haloperidol (placebo or 5 mg. p.o.) was administered prior to ketamine (placebo or 0.26 mg/kg i.v. bolus & i.v. infusion of 0.65 mg/kg/hr). Behavioral ratings were made periodically during the test day. Plasma prolactin, cortisol, and HVA responses were assessed. **RESULTS:** Ketamine produced psychosis and "negative symptoms" on the Brief Psychiatric Rating Scale, increased distractibility on a continuous performance test, impaired learning, increased perseverative error on the Wisconsin Card Sorting Test, and produced bizarre and concrete proverb interpretations in the healthy subjects. Haloperidol had few behavioral effects on its own. However, it reduced ketamine-induced distractibility and bizarre and concrete proverb interpretations.

GABA RECEPTORS: FUNCTION III

703.1

AN OPEN PROBABILITY ESTIMATE FOR CNS GABA_A CHANNELS. M.V. Jones* and G.L. Westbrook. The Vollum Institute for Advanced Biomedical Research, Portland, OR 97201.

Inhibitory synaptic transmission in the CNS is shaped, in part, by the probability (P_0) that postsynaptic GABA_A receptor channels will open once they have bound GABA. In the past, P_0 has been estimated by examining the proportion of time spent open during long bursts in steady-state single channel records. (Newland et al., 1991). At synapses, however, the GABA concentration is not at steady state. Dissociation of GABA and receptor desensitization may play a role in determining time-dependent changes in P_0 that shape the synaptic current. To assess P_0 after pulses of GABA, we examined the variance of GABA-activated currents (by the method of Sigworth, 1980). Outside-out patches from cultured postnatal rat hippocampal neurons were voltage-clamped, and currents were activated by rapid applications of a saturating GABA concentration (10mM, 1 to 100ms duration, <1ms solution exchange time, 25°C). Sampled currents ($f_c=2kHz$, 100μs/point) activated rapidly (~2ms, 10-90%), showed multiphasic desensitization ($\tau=20ms$ and ~1s) and multiphasic deactivation ($\tau=10$, ~50 and ~200ms). For a series of up to 100 currents in each patch, the variance of each sampled data point about its mean was calculated using local averaging of every three currents to compensate for rundown. Plots of variance (σ^2) vs mean (I) were fit by $\sigma^2=iI-I^2/N$, where N is the number of independent channels and i is their apparent conductance, i , but not N , varied with potential (0.74±0.1pA (n=5), 1.6±0.3 (8), 2.9±0.8 (5) at -30, -60 and -90mV), giving a slope conductance of 30pS, close to the 26-28pS main conductance obtained by direct single channel measurements from these neurons. The mean peak current divided by the maximum current possible (I_{peak}/N_i) gave a mean P_0 between 0.56 and 0.67, independent of potential. Our estimate of P_0 at the peak of responses to saturating pulses of GABA is ~25% lower than that found within long bursts of steady-state single channel activity (Newland et al., 1991). These results predict that inhibitory postsynaptic currents in the CNS represent the opening of not more than ~60% of the channels that are present opposite the sites of GABA release.

Supported by NIH grants T32-DA07262 (M.V.J.) and NS26494.

703.2

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF RECOMBINANT GABAR ISOFORMS COMPRISING THE MAIN CEREBELLAR GABARS EXPRESSED IN L929 MOUSE FIBROBLAST CELLS. N.C. Saxena* and R.L. Macdonald. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI-48104.

Recent immunoprecipitation studies using mixtures of subunit-specific antibodies have provided valuable evidence for the subunit composition of GABAR isoforms in the rat cerebellum (C.I. Ragan et al. 1993. Biochem. Soc. Trans. 21:622-626). Based on their findings, three main GABAR isoforms comprise approximately 90 % of total rat cerebellar GABARs. These are $\alpha 1\beta\gamma 2L$ (28% of total cerebellar GABARs), $\alpha 6\beta\gamma 2L$ (36% of total cerebellar GABARs) and $\alpha 6\beta\gamma\delta$ (23% of total cerebellar GABARs). This study seeks to characterize the electrophysiological and pharmacological properties of corresponding recombinant cerebellar GABAR isoforms expressed in L929 cells transfected with $\alpha 1$, $\alpha 6$, $\beta 3$, $\gamma 2L$ and δ subunits. Transfections with all three subunit combinations yielded a high percentage of GABA-responsive cells suggesting that GABAR isoforms predicted by immunoprecipitation studies of Ragan et al do indeed constitute functional GABARs in these cells. The concentration-response (CR) curves for $\alpha 1\beta 3\gamma 2L$, $\alpha 6\beta 3\gamma 2L$ and $\alpha 6\beta 3\delta$ GABAR isoforms indicate that the substitution of the $\alpha 1$ subunit for the $\alpha 6$ subunit and the substitution of the γ subunit for the δ subunit decreases the EC_{50} values for GABAR isoforms. $\alpha 1\beta 3\gamma 2L$ whole-cell currents were enhanced by diazepam and pentobarbital while the $\alpha 6\beta 3\gamma 2L$ and $\alpha 6\beta 3\delta$ whole-cell currents were insensitive to diazepam but enhanced by pentobarbital. The three different GABAR isoforms displayed differences in their response to divalent and polyvalent cations and to the inverse agonist DMCM but displayed similar block by picrotoxin. Therefore, cerebellar GABAR isoforms show different electrophysiological and pharmacological properties depending on subunit composition and could offer potential therapeutic specificity in the action of drugs in the cerebellum. Single channel characteristics of these GABAR isoforms are under investigation.

703.3

γ -AMINO BUTYRIC ACID INCREASES INTRACELLULAR CALCIUM CONCENTRATION IN CULTURED RAT CORTICAL NEURONS.

M. Takebayashi, N. Motohashi*, T. Hayashi, Y. Okamoto, H. Shinno, A. Kagaya, S. Yamawaki Dept. Psychiat. Neurosci., Hiroshima Univ. Schl. Med., 1-2-3 Kasumi, Minami-ku, Hiroshima 734, Japan.

Recent reports suggest that a major inhibitory neurotransmitter, γ -aminobutyric acid (GABA) increases intracellular calcium concentration ($[Ca^{2+}]_i$) in neonatal hippocampal neurons. In this study, we examined GABA-induced Ca^{2+} mobilization in cultured rat cortical neurons by using calcium indicator, fura-2/AM. Frontal cortex was isolated from Wistar rat pups at embryonic day 18 and cultured for 5-6 days. $[Ca^{2+}]_i$ in single cells was measured with fluorescence microscope/video camera systems. GABA and GABA_A agonist, muscimol, applied for 30 sec transiently, increased $[Ca^{2+}]_i$ dose-dependently. The increase was inhibited by GABA_A antagonists, bicuculline and picrotoxin, but not by GABA_B antagonist, phaclofen. Because the $[Ca^{2+}]_i$ increase was inhibited by EGTA and a Ca^{2+} -channel blocker, nifedipine, the $[Ca^{2+}]_i$ increase could be explained by Ca^{2+} influx through voltage-gated Ca^{2+} -channel. These results suggest that GABA increases $[Ca^{2+}]_i$ chiefly through GABA_A-receptor and voltage-gated Ca^{2+} -channel in immature cortical neurons.

703.5

GABA-A MEDIATED CALCIUM RESPONSE IN GT1-7 NEURONS IS DEPENDENT UPON THE CHLORIDE GRADIENT ACROSS THE MEMBRANE. S. Yagodin*, Q.Y. Liu, L.A. Holtzclaw, J.L. Barker and J.T. Russell, LCMN, NICHD, and LN, NINDS, NIH, Bethesda, MD 20892

It is known that activation of GABA-A receptors in LHRH secreting GT1-7 neurons results in membrane depolarization and calcium entry via voltage dependent calcium channels resulting in a calcium signal. We have analysed this calcium signal using fura-2 based calcium imaging and the perforated patch-clamp technique. Instantaneous replacement of chloride ions in the medium with isethionate, resulted in a significant increase in the muscimol-induced calcium response. This increase, however, was transient and after 15 min of perfusion in zero chloride medium, the signal amplitude was only 50% of the normal chloride condition. Replacement of chloride with gluconate dramatically reduced the calcium response since gluconate chelated extracellular calcium ions. Under current clamp, muscimol application induced a depolarizing response of 26 ± 10.0 mV with a few TTX-sensitive action potentials. In the absence of external chloride, the amplitude of muscimol-induced depolarization was smaller but the frequency of spikes was increased. Muscimol-induced depolarization and calcium increase were abolished in cells treated with furosemide (0.1mM) for 20 min. Ethacrynic acid (0.3mM) also reduced the calcium signal by 70%. Depletion of intracellular calcium stores by thapsigargin (100 nM) decreased the calcium response by 60% suggesting that release from stores contributes to the GABA-A mediated cellular calcium response. The data demonstrate that a cooperative action of furosemide- and ethacrynic acid-sensitive Cl⁻ pumps maintain outwardly directed driving force for chloride ions.

CHARACTERIZATION OF GABA_A AND GABA_B RECEPTORS IN TURTLE RETINAL GANGLION CELLS. Y. Liu and E.M. Lasater*, Moran Eye Center, Univ. of Utah, Salt Lake City, UT 84132.

We recently reported that turtle retinal ganglion cells express both GABA_A and GABA_B receptors coupled to Cl⁻ channels. Experiments were carried out to further characterize the kinetic and pharmacological properties of these channels. Standard whole-cell patch clamp recordings were made from isolated, cultured turtle retinal ganglion cells. Test agents were applied by a superfusion system. Application of GABA (1–100 μ M) induced a prominent inward current with two components in all ganglion cells tested. The decay of the GABA response could be perfectly fit with a single exponential time course plus a steady state. The time constant of the transient current is about 3 sec, while the steady state current is about 1000 pA. Cis-4-aminocrotonic acid (CACA, 100 μ M–1 mM) activated only a sustained current, which is very similar to the steady state current induced by GABA. Bicuculline (10–100 μ M) inhibited the transient but not the sustained current induced by GABA. Picrotoxin (PTX, 100 μ M) totally blocked both components of GABA response. Surprisingly, when PTX was washed out, subsequent application of GABA only activated the sustained current. It took another application of GABA to induced both components. To further test if PTX blocks the two types of GABA receptors via different mechanisms, lower concentration of PTX (1–10 μ M) was applied twice (interval, 2 min). It was found that the second application of PTX inhibited more transient current as compared to the first application of PTX. This is consistent with the mechanism of open channel block. On the other hand, the percentage of the sustained GABA response inhibited by PTX is constant regardless of how many times PTX was applied, which indicates that the inhibition of the sustained GABA response is mediated by some other mechanisms than open channel block. Our data suggest that the GABA_A and GABA_B receptors in turtle retinal ganglion cells are coupled to Cl⁻ channels with different kinetic and pharmacological properties. Moreover, we first report that PTX may regulate the GABA_A and GABA_B receptors via different mechanisms.

CHLORIDE-DEPENDENT EXCITATORY ACTION OF γ -AMINO BUTYRIC ACID ON ISOLATED IDENTIFIED NEUROSECRETORY CELLS. U. García*, J. Garduño, E. Becerra and H. Aréchiga*. Dept. Fisiología, Biofísica y Neurociencias, CINVESTAV, IPN México and *División de Estudios de Postgrado e Investigación, Facultad de Medicina, UNAM, México.

A sub-population of neurosecretory cells in the X organ of the crayfish was identified by using a monoclonal anti-Leu-enk antibody (Amersham). Only eight cell bodies with diameters between 35 to 50 μ located in the most superficial layer of the X organ were immunopositives. These cells may be the same found to react to an antibody against the Crustacean Hyperglycemic Hormone (Van Herp & Van Buggenum, *Experientia* 35: 1527, 1979).

The isolated X organ cells were kept in culture several days. GABA was applied in micropulses onto different regions of the neuron. A dose-dependent depolarization was elicited, resulting in the firing of action potentials. This effect was reversibly blocked by Picrotoxin and Bicuculline and was mimicked by Muscimol. Under voltage-clamp conditions, the reversal potential for the GABA-induced current was found at -20 mV. When chloride was substituted by methanesulfonate in the external solution, the reversal potential for the GABA-induced current was shifted to more positive values. This suggest that chloride mediates the effect of GABA on X organ cells.

GABA-INDUCED GABA RELEASE IN CULTURED EMBRYONIC RAT THALAMIC NEURONS IS Ca^{2+} -DEPENDENT AND TTX-INSENSITIVE. Q.Y. Liu*, J. Vautrin, A. Schaffner, K.M. Tang, W. Ma and J.L. Barker, Lab. of Neurophysiology, NINDS, NIH, Bldg 36/Rm 2C02, Bethesda, M.D. 20892.

In embryonic and early postnatal stages, GABA has excitatory effects on most if not all neurons expressing functional GABA_A receptor-coupled Cl⁻ channels. Due to a depolarizing Cl⁻ gradient, activation of GABA_A receptor-coupled Cl⁻ channels depolarizes neurons, which in turn may activate voltage-dependent Ca^{2+} channels and lead to increases in cytosolic Ca^{2+} (Ca^{2+}_i). But in some cells GABA induced increase in Ca^{2+}_i does not appear to be mediated by classical Cl⁻ channel-coupled GABA_A receptors. In culture embryonic (E17) rat thalamic neurons, we found that 10 μ M GABA induced or increased the frequency of miniature synaptic-like transients (minis) superimposed on persistent Cl⁻ current response. The minis reversed polarity at E_{Cl} , were blocked by bicuculline and decayed with kinetics similar to GABA-activated Cl⁻ channels suggesting they were GABAergic. The agonist concentration that induced minis was lower than that required to activate Cl⁻ channels. Interestingly, the GABA_A receptor/Cl⁻ channel agonist muscimol readily induced Cl⁻ current response but failed to mimic GABA in triggering minis. GABA-induced GABA release was dependent on extracellular Ca^{2+} and insensitive to 2 μ M TTX. We conclude that GABA can trigger GABA transients in cultured embryonic rat thalamic neurons through an action of GABA that does not involve classical GABA_A receptor/Cl⁻ channels.

SELECTIVE SUPPRESSION OF INTRINSIC BUT NOT AFFERENT FIBER SYNAPTIC TRANSMISSION BY BACLOFEN IN THE PIRIFORM CORTEX. Akaysha C. Tang* & Michael E. Hasselmo, Dept. of Psychology, Harvard Univ., Cambridge, MA 02138.

The GABA_B agonist baclofen has been shown to suppress synaptic transmission in subregions of the hippocampus and in the piriform (olfactory) cortex. Here we report a laminar selectivity of suppression of synaptic potentials in the olfactory cortex. In brain slice preparations (n=37), baclofen suppresses extracellularly recorded field potentials at the intrinsic fiber synapses proximal to the superficial pyramidal cell bodies (layer Ib) while leaving the afferent fiber synaptic potentials recorded at the distal dendrites (layer Ia) little affected. The suppression of synaptic potentials was significantly stronger in layer Ib (n=5) than in layer Ia (n=3) at each of the following concentrations: 0.1, 1.0, 10, 100 and 500 μ M. At the concentration of 100 μ M, suppression in layer Ia was $5.1 \pm 6.3\%$ (n=5); suppression in layer Ib was $68.8 \pm 6.7\%$ (n=5). Suppression of intrinsic fiber synaptic transmission in layer Ib had an $IC_{50} = 9.2$ μ M. This dose dependent selective suppression of intrinsic fiber synaptic transmission is also correlated with an increase of paired-pulse facilitation. These results suggest that afferent and intrinsic synaptic inputs may be differentially modulated by the activation of GABA_B receptors and that this selective suppression is at least partially mediated via a presynaptic mechanism.

A LATE, GABA_A RECEPTOR-MEDIATED, BICARBONATE-DEPENDENT, DEPOLARIZING SYNAPTIC POTENTIAL IN CA1 PYRAMIDAL CELLS K.J. Staley*, W.R. Proctor, and P.J. Whiting, Neurology and Pharmacology Depts., University of Colorado Health Sciences Center, Denver, CO 80262

In the many reports describing a depolarizing component of the GABA_A receptor-mediated synaptic response in hippocampal pyramidal cells, two consistent experimental features have been 1) the use of extracellular (EC) HCO₃⁻ / CO₂ buffer, and 2) prolonged GABA_A receptor activation.

Only a monophasic hyperpolarizing membrane potential response was seen during 4-second GABA_A receptor activation by muscimol application to patch-clamped adult rat CA1 pyramidal cells when both the electrode and EC solutions were buffered with HEPES (n=12) and electrode [Cl⁻] was 8 mM. However, when HCO₃⁻ / 5% CO₂ was used to buffer the incubating and EC solutions, a large, late depolarizing component was consistently seen with onset 65 ms after the start of the hyperpolarizing response and peak amplitude of 9.4 mV at 1.8 seconds (n=7).

Monophasic responses to GABA were also seen in voltage-clamped fibroblasts expressing $\alpha_1 \beta_1 \gamma_2$ GABA_A receptor subunits when using EC HEPES buffer and electrode solutions containing KHCO₃ / HEPES (pH 7.2 using mM ratios 0:10, 16:36, and 32:72) and 8 mM Cl⁻ (n=9). No significant shifts in the reversal potential were seen during 10-second GABA applications. The ratio of HCO₃⁻ to Cl⁻ permeability calculated from the HCO₃⁻ effect on the GABA reversal potential was 0.6.

These results indicate that an outward HCO₃⁻ flux is responsible for the late depolarizing component of the GABA_A synaptic response, which may be important in activity-dependent disinhibition. The kinetics of the response are not due to an interaction between the HCO₃⁻ anion and the GABA_A receptor. Supported by NIH NS15173 and HD27827.

GABA ACTIVATES TWO DISTINCT GABA_B POSTSYNAPTIC RESPONSES IN CA1 PYRAMIDAL CELLS OF RAT HIPPOCAMPAL SLICES. T.M. Pham* and J.-C. Lacaille, Center for Research in Neurological Sciences and Department of Physiology, University of Montréal, Montréal, Qc, Canada H3C 3J7.

The aim of this study was to characterize pharmacologically and electrophysiologically the non-GABA_A postsynaptic responses elicited by GABA in rat hippocampal CA1 pyramidal cells. GABA (5mM) and CGP11973A (L-baclofen [BAC]; 0.25mM) were applied by micropressure (drop diameter 50-100 μ m) in s. radiatum to dendrites of CA1 pyramidal cells during intracellular recordings. In the presence of antagonists of GABA uptake and of GABA_A, NMDA and non-NMDA receptors, GABA hyperpolarized cells (-4.2 \pm 0.1mV [mean \pm sem], n=29) and reduced membrane resistance (n=5). The equilibrium potential (E_{rev}) of GABA responses was -90.1 \pm 3.1mV (n=9). GABA responses were heterogeneous: a component was antagonized by Ba²⁺ (1mM, n=5), leaving a residual Ba²⁺-insensitive response (amplitude 59.5 \pm 5.6% of control; n=5) with an E_{rev} of -75.7 \pm 3.0mV (n=3). Ba²⁺-sensitive and insensitive components were mediated by GABA_B receptors because GABA responses were totally blocked by the GABA_B antagonist CGP55845A (5 μ M, n=7). BAC hyperpolarized cells (-3.9 \pm 0.2mV, n=38) and reduced membrane resistance (n=5). BAC responses reached equilibrium at -88.4 \pm 1.9mV (n=8) and were completely blocked by Ba²⁺ (n=15). GABA elicited hyperpolarizations with KCl-filled (3M, n=7) electrodes, and depolarizations with CsCl (3M, n=9) and LiCl (3M, n=7) electrodes. These results suggest that GABA activates 2 distinct postsynaptic GABA_B responses coupled to G proteins in hippocampal cells: the first response, also elicited by baclofen, involves a Ba²⁺-sensitive K⁺ conductance, and the second response, only induced by GABA, is mediated by a Ba²⁺-insensitive K⁺ conductance.

STIMULUS-INDUCED INHIBITORY POSTSYNAPTIC POTENTIALS IN REGULAR-SPIKING NEURONS OF THE HUMAN ASSOCIATION NEOCORTEX IN VITRO. GGC Hwa*, A. Olivier, J-G Villemure and M. Avoli, Montreal Neurological Inst., McGill Univ., Montreal, Canada

Intracellular recordings with K-acetate-filled microelectrodes were made from regular-spiking neurons in slices of temporal and frontal neocortex that was obtained during epilepsy surgery. Electrical focal stimuli were applied within the neocortical layers. At resting membrane potential of -56 to -72 mV, single stimuli could induce: (i) an initial excitatory postsynaptic potential (EPSP), (ii) an early hyperpolarizing inhibitory postsynaptic potential (IPSP_{early}, peak latency 10-25 ms), (iii) an intermediate depolarizing component (peak latency 50-100 ms) and (iv) a late, hyperpolarizing IPSP (IPSP_{late}). Increasing the stimulus strength by small increments demonstrated that the EPSP was the first potential to appear, followed by the IPSP_{early}, the IPSP_{late} and the depolarizing component were seen only at high-strength stimulation. Application of the NMDA antagonist APV (100 μ M) reduced the amplitude of both hyperpolarizing IPSPs to a greater extent than the amplitude of the initial EPSP. A response similar to that recorded in control could be seen in the presence of APV by increasing the stimulus strength. Application of CNQX (4 μ M) blocked the initial EPSP and also caused a reduction of the IPSP_{early}, depolarizing component, and IPSP_{late}. Under this experimental condition both IPSP_{early} and depolarizing component were reduced and eventually blocked by the GABA_A-receptor antagonist bicuculline methiodide (10 μ M). These results indicate that human neocortical cells generate an inhibitory postsynaptic sequence that includes both hyperpolarizing IPSPs and a depolarizing component. We propose that as in the rat hippocampus, the latter potential might be caused by an outward-directed Cl⁻ movement due to the activation of GABA_A receptors located on the dendrites of regular-spiking neurons. DEPOLARIZING AND HYPERPOLARIZING GABA RESPONSES IN THE XENOPUS SPINAL CORD ARE MEDIATED BY GABA_A RECEPTORS. J. Rohrbough and N.C. Spitzer*, Department of Biology, UCSD, La Jolla, CA 92093.

Rohon-Beard (RB) sensory neurons in the *Xenopus* spinal cord are depolarized by GABA throughout their development, unlike the majority of other GABA-sensitive CNS neurons. The GABA reversal potential (E_{rev}) recorded intracellularly from RB cells is near -30 mV, which is not at an equilibrium potential expected for any single ion. While brief reduction in external [Cl⁻] was not observed to shift the E_{rev} of whole cell responses to bath applied GABA (Rohrbough & Spitzer, 1993), subsequent Na⁺ and K⁺ substitutions also did not produce expected changes in E_{rev}.

We have reexamined the Cl⁻ dependence of the response to iontophoretically applied GABA in voltage clamped neurons in the spinal cord. Altering either external or pipette [Cl⁻] in whole cell recordings shifted the GABA E_{rev} in RB cells by 52 mV per 10-fold change in the [Cl_o]/[Cl_i] ratio, consistent with dependence upon Cl⁻. Bicuculline (50-100 μ M) reversibly blocked 65% to 85% of the current activated by GABA. GABA responses recorded from dorsolateral interneurons for comparison had a similar Cl⁻ dependence and pharmacology. However, in perforated patch configuration, in which internal Cl⁻ is not dialysed by the pipette, the E_{rev} for these interneurons was ~15 mV more negative in normal external [Cl⁻] than for RB cells. These results indicate that GABA_A receptors mediate the GABA responses in RB cells, as well as in other classes of differentiating spinal neurons. A simple explanation of the depolarizing GABA response in intact RB cells is an elevated level of internal [Cl⁻], as has been proposed for other developing neurons. Interestingly, replacement of external Na⁺ in perforated patch recordings from RB cells shifted E_{rev} by as much as -10 mV, raising the possibility of cation-dependent [Cl⁻] modulation. We are interested in mechanism(s) contributing to this response and in the potentially excitatory role of GABA in RB cells during this period of development.

THE INHIBITION OF PRIMATE SPINOTHALAMIC TRACT NEURONS PRODUCED BY STIMULATION IN PERIAQUEDUCTAL GRAY IS REDUCED BY SPINAL BICUCULLINE. Q. Lin*, Y.B. Peng and W.D. Willis, Department of Anatomy and Neurosciences, University of Texas Medical Branch, Galveston, TX 77555-0843.

GABA is well established as one of the inhibitory substances in the spinal cord, involved in antinociception arising from supraspinal centers. However, it is still not clear that whether the descending inhibitory effects are mediated by GABA_A or GABA_B receptors at the spinal level. Experiments were performed on anesthetized young adult monkeys (*Macaca fascicularis*). Spinothalamic tract (STT) cells were identified by antidromic activation and recorded using a carbon filament electrode. The inhibitory effects of electrical stimulation in periaqueductal gray (PAG) on cutaneous mechanical and thermal stimuli were tested before, during and after perfusion of the spinal cord with bicuculline (GABA_A antagonist) or phaclofen (GABA_B antagonist) through a microdialysis fiber placed in the dorsal horn. Infusion of bicuculline or phaclofen resulted in an increase both in background activity and responses to cutaneous mechanical and thermal stimuli. PAG-induced inhibition was significantly reduced in most of cells tested during intra-spinal administration of bicuculline. The reduction was mainly on the PAG-induced inhibition of responses to noxious mechanical stimuli. In contrast, infusion of phaclofen did not significantly alter the PAG-induced inhibition. These results indicate that GABAergic inhibitory interneurons in the dorsal horn exert a tonic control of the activity of STT neurons by acting both on GABA_A and GABA_B receptors. Stimulation of PAG results in activation of GABAergic interneurons, which may contribute to descending antinociceptive actions via GABA_A receptors in the spinal cord. This work was supported by NIH Grants NS09743 and NS11255.

GAMMA-HYDROXYBUTYRIC ACID INCREASES INTRACELLULAR Ca²⁺ CONCENTRATION AND NUCLEAR CRE- AND AP-1 DNA-BINDING ACTIVITIES THROUGH GABAB RECEPTORS IN CULTURED CEREBELLAR GRANULE CELLS. Y.Ito*, K.Ishige, E.Zaitzu and H.Fukuda, Dept. of Pharmacology, Coll. of Pharmacy, Nihon University, Funabashi, Chiba 274, Japan.

In primary cultures of mouse cerebellar granule cells, a brief stimulation by γ -hydroxybutyric acid (GHB, 0.1-3 mM) significantly increased intracellular Ca²⁺ concentration ([Ca²⁺]_i) in a concentration-dependent manner. In addition, gel-mobility assay showed that exposure of the cells to GHB also increased nuclear DNA-binding activities specific for the cAMP responsive element (CRE) and activator protein 1 (AP-1) transcriptional element. The concentration range of GHB to increase nuclear CRE- and AP-1 DNA-binding activities was the same as that of GHB to elicit an increase in [Ca²⁺]_i. The GHB-induced increases in [Ca²⁺]_i and nuclear DNA-binding activities were antagonized by CGP 35348, a specific GABAB antagonist. In addition, thapsigargin (1 μ M) suppressed GHB-induced increase in nuclear DNA-binding activities. Caffeine, which has been shown to activate Ca²⁺-induced Ca²⁺ release store sites, increased [Ca²⁺]_i in a concentration-dependent manner, and this effect was also blocked by thapsigargin. Furthermore, GHB inhibited [³H]baclofen binding to cultured cerebellar granule cells and mouse cerebellar membranes. These results suggest that stimulation of the GABAB receptors by GHB activates intracellular Ca²⁺ store sites and that increased [Ca²⁺]_i by releasing stored Ca²⁺ plays an important role in a increase in nuclear CRE- and AP-1 DNA-binding activities in primary cultures of cerebellar granule cells.

EVALUATION OF FLUORESCENCE AND ELECTROCHEMICAL DETECTION OF γ -AMINOBUTYRIC ACID IN MICRODIALYSIS SAMPLES J. Kehr*, W.T.O'Connor and U. Ungerstedt. *CMA/Microdialysis and Dept. of Pharmacology, Karolinska Inst., Stockholm, Sweden.

A technique of in vivo microdialysis has been used in number of studies to characterise extracellular release and uptake of γ -aminobutyric acid (GABA) in the brain. It was shown that at least 50% of GABA overflow in the striatum of freely moving rats is of neuronal origin. Determination of GABA requires an ultrasensitive analytical method, since GABA levels in a typical microdialysis sample are often in the range of 0.1-0.5 pmol (5-50 nmol/l). Previously we developed an isocratic HPLC method based on electrochemical (EC) detection of GABA derivatized with OPA/t-butylthiol¹. The limit of detection was 50 fmol GABA. However, the excess of thiol which is oxidised on the electrode and a high acetonitrile (50%) in the mobile phase are most probable causes of shortened life-time of the electrode, gradually increasing background signal and noise levels. The result is that a substantial portion of "research time" is spent on system maintenance.

Fluorescence detection of OPA derivatized amino acids is a more common way to determine physiological amino acid in body fluids. Normally, by using gradient elution and OPA/mercaptoethanol derivatization the limit of detection for GABA is only 0.5-1 pmol. To achieve GABA detection of 50 fmol we developed a new method based on microbore columns and optimized isocratic separation with a step gradient. The step gradient is achieved by a low pressure switching valve installed at the pump inlet. The whole system is fully automated allowing analysis of up to 80 samples/day.

Correlation between these two techniques was studied for microdialysis samples from the rat. Advantages and limitations of both methods are discussed. Ref.1. Kehr J. and Ungerstedt U., J. Neurochem. (1988) 51, 1308.

703.17

HETEROGENEITY OF ALLOSTERIC COUPLING IN GABA_A RECEPTORS REVEALED BY α SUBUNIT SPECIFIC ANTIBODIES. K.H. Huh*, S. Endo and R.W. Olsen. Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

GABA_A receptors are composed of multiple binding domains which are allosterically coupled with each other in a functionally relevant manner. Differential degrees of coupling observed in different brain regions have been interpreted as the existence of receptors with diverse subunit combinations. In the present study, the subunit specificity of allosteric interaction between GABA and benzodiazepine binding sites was studied using α subunit specific antibodies. In the TX-100 soluble extract from rat whole brain, GABA_A receptors immunoprecipitated with $\alpha 1$ antibodies had a significantly lower maximal enhancement of [³H]flunitrazepam binding by GABA than those immunoprecipitated with $\alpha 2$ or $\alpha 3$ antibodies (35 \pm 2 % for $\alpha 1$, 75 \pm 4 % for $\alpha 2$ and 63 \pm 1 % for $\alpha 3$). On the other hand, receptors containing $\alpha 1$ or $\alpha 3$ subunits had higher affinities for the enhancement (32 \pm 10 nM and 36 \pm 20 nM, respectively) as opposed to those containing $\alpha 2$ subunits (142 \pm 27 nM). These differential coupling efficiencies endow unique functional and structural properties to different α subunit containing receptors in addition to the previously identified benzodiazepine pharmacology. It would be of interest to see if this heterogeneous binding profile can also be translated into the differential coupling with the channel gating domain. Supported by NIH grant NS 28772.

703.16

GABA_A-MEDIATED INHIBITION IN NEOCORTEX IS EVOKED VIA AMPA (BUT NOT NMDA) RECEPTORS ON INHIBITORY INTERNEURONS. D.S.F. Ling¹ and L.S. Benardo^{1,2}. Depts. of Pharmacology¹ and Neurology², SUNY-HSCB, Brooklyn, NY 11203.

Previous studies from our laboratory have suggested that recruitment of GABA_A-mediated inhibition is limited in the neocortex, regardless of the level of excitation. The specific mechanisms underlying this effect are unknown. Whole-cell patch recordings of layer V neurons in coronally sectioned slices (400 μ m) of somatosensory cortex were used to examine the excitatory amino acid receptor subtypes involved in the recruitment of evoked GABA_A-inhibitory postsynaptic currents (IPSCs). Stimulus-response characteristics of evoked, isolated IPSCs were recorded by holding cells at the excitatory postsynaptic current (EPSC) reversal potential (0 mV), while stimulating in either layer VI or deep white matter.

Under physiological conditions, the fast IPSC reached a maximum magnitude at a stimulus strength of approximately 1.5-2X the threshold stimulus. Modulation of NMDA-mediated transmission by exposure of slices to either magnesium-free solution or to CPP (10 μ M) did not affect the maximal IPSC. However, blockade of AMPA receptors with CNQX (5 μ M) reduced the magnitude of the maximal IPSC by >50%, with subsequent blockade or enhancement of NMDA-mediated activity having no effect. From the results of this study, we conclude that neocortical interneurons are activated by glutamatergic afferents terminating on AMPA, but not NMDA, receptors. (Supported by NS01386 and NS09534)

OPIOID RECEPTORS: TOLERANCE AND REGULATION

704.1

ALTERATION OF MU-OPIOID RECEPTORS AND G-PROTEINS IN BRAINS OF MORPHINE TOLERANT RATS. M. Szűcs, G. Fábián, B. Tombor, B. Bozó, M. Szikszay. Biol. Res. Center Hung. Acad. Sci., Szeged, Hungary (SPON: European Neuroscience Association)

Previous studies detected high affinity opioid binding sites in synaptic plasmamembrane (SPM) and microsomal (MI) fractions of rat brain. Since they were found to be uncoupled from G-proteins in the latter, they were postulated to be desensitized sites. To explore this hypothesis, female Wistar rats were s.c. injected by increasing doses of morphine twice daily for 5 days. Western-blotting with specific antisera, pertussis toxin catalysed ADP-ribosylation and photoaffinity labeling studies all showed that prolonged exposure to morphine elevated the amount of G-proteins which was calculated 63% and 30% in SPM resp. MI in [³⁵S]GTP γ S binding studies. The B_{max} for the μ -opioid agonist [³H]DAMGO nearly doubled in MI after morphine treatment. These up-regulated sites displayed profound sensitivity to GTP unlike the μ -sites detected in MI of untreated rats. These results suggest that regulation of G-proteins represent part of the molecular changes that underlie morphine effects in brain, and further emphasize the significance of intracellular events.

REGIONAL CNS DISTRIBUTION OF MU OPIOID RECEPTOR (MOR) mRNA IN NAIVE, MORPHINE TOLERANT AND MU DEFICIENT RODENTS. C.E. Inturrisi*, M. Brodsky, K. Elliott and A. Hynansky. Dept. of Pharmacology, Cornell U. Med. Coll., New York, NY.

The steady-state levels of MOR mRNA were measured by solution hybridization in samples microdissected from rodent brain and spinal cord. In adult male rats, a 7 day treatment with morphine (2 x 75 mg pellets, implanted sc on days 1 and 4), which produces an 11-fold shift in morphine dose-response curve, did not alter MOR mRNA levels in the dorsal horn of spinal cord (SpC), nucleus raphe magnus (NRM), periaqueductal gray (PAG), medial thalamus (Thal), hypothalamus (Hyp) or somatosensory cortex (Ctx) of treated rats as compared to placebo controls. The MOR mRNA levels ranged from 0.7 pg/ μ g RNA in Ctx to 15.0 pg/ μ g RNA in Thal. The CXBK (MU deficient) mice were found to be 7-fold less sensitive to systemic morphine than CD-1 mice, as assessed using the tailflick test (ED₅₀ estimates were 29.4 and 4.2 mg/kg sc, respectively). CXBK mice were also found to have lower MOR mRNA levels than CD-1's in SpC (by 28%), NRM (by 43%), PAG (by 35%), Hyp (by 49%) and Thal (by 15%), but not in Ctx. The CD-1 MOR mRNA levels ranged from 0.04 pg equiv./ μ g RNA in Ctx to 0.52 pg equiv./ μ g RNA in Thal. Thus, while no change in MOR mRNA levels occurs in morphine tolerant rats, the low levels in CXBK mice may result in fewer opioid binding sites and contribute to the functional difference between CD-1 and CXBK strains. Supported by DA07274, DA01457, DA00198 and VZV Research Foundation.

704.3

CHRONIC OPIOID AGONIST TREATMENT DOES NOT ALTER DELTA OPIOID RECEPTOR (DOR) mRNA LEVELS IN THE CNS OF MICE. B. Kest, S. Jenab, M. Brodsky, K.J. Elliott and C.E. Inturrisi. Dept. of Pharmacology, Cornell U. Med. Coll., NY, NY. 10021.

The steady-state levels of DOR mRNA were measured in male CD-1 mice rendered tolerant to the antinociceptive effects of the selective DOR opioid [D-Ala⁵]Deltorphin II (DELT II) and morphine (MOR). After tid administration of MOR (10-40 mg/kg, sc) for 3 days or DELT II (10 ug, icv) for 4 days, the ED₅₀ values for MOR and DELT II were increased 5- and 8-fold, respectively, relative to saline controls. DOR mRNA levels were measured by solution hybridization in samples obtained by microdissection of CNS regions of tolerant and control mice. DOR transcript levels, in pg/ug of total RNA, were highest in the caudate/putamen (0.42) and frontal cortex (0.32). Moderate levels were observed in n. accumbens (0.26), olfactory cortex (0.20), PAG (0.2), and hippocampus (0.14). The medial thalamus (0.05) and cerebellum (0.04) displayed relatively low levels of DOR mRNA. The DOR mRNA levels in the CNS regions of MOR or DELT II tolerant mice did not differ significantly from controls in any CNS region studied. These data suggest that altered steady-state DOR mRNA levels are not one of the adaptive changes observed in mice tolerant to the antinociceptive effects of MOR or DELT II. Supported by DA07274, DA01457, DA00198, the VZV Research Foundation and a grant from the Aaron Diamond Foundation.

Modulation of Rat Brain Opioid Receptors by the Novel Pyrrole Resorcyate, (+) RTI-14: An Autoradiographic Study. C.B. Goodman¹, B. Emilien^{1,2}, J.S. Partilla¹, J.L. Cadet², E.L. Carroll³, B. Blough³, K.F.A. Soliman⁴ and R.B. Rothman¹. ¹CPS and ²MPS, NIH/NIDA, Addiction Research Center, Baltimore, MD 21224, ³Research Triangle Institute, Research Triangle Park, NC 27709-2194, ⁴Florida A&M University, College of Pharmacy and Pharmaceutical Sciences, Tallahassee, FL 32307.

The utilization of various agents to pharmacologically manipulate the opioid receptor system has been extensively studied using several radiolabeled techniques. In the present study, in vitro receptor autoradiography was used to characterize the anatomical distribution of [125I]-DAMGO binding sites in discrete brain nuclei of rats treated chronically i.c.v. with (+)RTI-14, a novel PCP site 2 ligand with moderate amine uptake inhibition activity, and of other potent amine uptake inhibitors. ALZET 2002 osmotic minipumps (0.5 µl/hr for 13 days) were filled with saline, (+)RTI-14 (6 mg/ml), cocaine hydrochloride (5 mg/ml) or imipramine (5 mg/ml). Regional brain sections (14 µm) at the striatal level were used to assess treatment effects on the mu opioid receptors. Initial findings demonstrate that (+) RTI-14 significantly decreased [125I]-DAMGO binding distribution in each specific nuclei measured. Chronic cocaine increased [125I]-DAMGO binding in caudate patches and matrix, while the imipramine-treated animals showed no changes from controls. Studies are in progress to confirm and extend these observations.

704.7

DEVELOPMENTAL EXPRESSION OF THE DELTA OPIOID RECEPTOR IN THE MOUSE Y. Zhu*, B. Anton, M. Zheng, C. J. Evans, J. E. Pintar. Dept. Neurosci. & Cell Biol., UMDNJ Robert Wood Johnson Med. Sch., Piscataway, NJ 08854 and Dept. Psychiatry, UCLA Sch. of Med., Los Angeles, CA 90024.

To characterize the establishment of opioid systems during development, we have begun to examine the distribution of δ receptor mRNA at early postnatal stages of mouse development using in situ hybridization. In the developing nervous system, we have thus far detected restricted δ receptor gene expression as early as postnatal day 1 (p1) in the pons, caudate-putamen, and nucleus accumbens, and have localized particularly intense hybridization to a band of cells near the boundary between the superior colliculus and tegmentum. By p4 and p5, δ receptor expression has expanded to include subpopulations of neurons in the cerebral cortex (especially in the retrosplenial cortex), amygdala, hippocampus, olfactory bulb, thalamus, hypothalamus, and substantia nigra. The cellular resolution afforded by in situ hybridization has provided additional anatomical detail that complements prior receptor binding studies. In the hypothalamus at p4, for instance, δ receptor expression is detected in specific cells of the lateral hypothalamic area, in addition to the expression in the ventromedial hypothalamic nuclei similar to reported results from opioid binding studies. In addition, the pattern of high δ receptor expression in subgroups of adult CA3/CA4 hippocampal neurons is already established at early post-natal ages. Although the levels of δ mRNA/cell are significantly lower in most, if not all, cell groups than in adult brain sections hybridized equivalently, the initiation and significant increase in δ receptor expression observed in the perinatal period indicate a rapid maturation process for the δ receptor system in early postnatal development. Supported by DA-08622 and DA-05010.

MOLECULAR LESIONING OF OPIOID DELTA-NCX BINDING SITES IN RAT BRAIN BY ANTISENSE OLIGODEOXYNUCLEOTIDES. X.Y. Cha¹, H. Xu¹, K.C. Rice², F. Porreca³, J. Lai³, and R.B. Rothman^{1*}. ¹CPS, IRP, NIDA, NIH Baltimore, MD 21224. ²LMC, NIDDK, NIH, Bethesda MD 20892. ³Department of Pharmacology, University of Arizona, Tucson AZ 85724.

Previous studies support the existence of two delta receptor subtypes called delta-cx and delta-ncx. Other studies have delineated the existence of additional subtypes termed delta-cx-1, delta-cx-2, delta-ncx-1 and delta-ncx-2. These sites are assayed with [3H]DADL (10 mM TRIS-HCl, pH 7.4, 100 mM NaCl, 3 mM MnCl₂, 2 µM GTP and 5 mM 2-mercaptoethanol) using rat brain membranes depleted of delta-ncx sites by pretreatment with the delta-ncx-selective acylating agent, (+)-trans-SUPERFIT or depleted of delta-cx sites by pretreatment with the delta-cx-selective acylating agent, BIT. The recent cloning of a rat brain delta receptor raises the issue of the relationship between the multiple binding sites defined on the basis of our ligand binding studies and the molecularly defined delta receptor. To determine this, the antisense oligodeoxynucleotides complementary to the 5' end of the coding sequence of the cloned delta opioid receptor (nucleotides 7 to 26) and the corresponding sense oligodeoxynucleotides were administered i.c.v. twice a day for three days. Our data demonstrate that the antisense DNA selectively inhibited [3H]DADL binding to the delta-ncx site by 50%. Studies underway will determine effect of the antisense DNA on the two subtypes of the delta-ncx binding site.

μ OPIATE RECEPTOR: DEVELOPMENTAL PROFILE AND REGULATION. Yasuo Imai¹, Jia-Bei Wang¹, Akiyoshi Moriwa¹ and George R. Uhl^{1,2,3}. ¹Molecular Neurobiology, ²Office of the Director, Intramural Research Program, NIDA, NIH and ³Dept. of Neurology and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21224

The developmental profile and regulation by morphine treatment of rat μ opiate receptor (μ OR) mRNA was investigated using a ribonuclease protection assay.

μ OR was most abundantly detected in thalamus, followed by hypothalamus, midbrain, and spinal cord in cortex, striatum, brainstem, hippocampus, but not in cerebellum or peripheral tissues in adult rats. Total RNA was isolated from whole brain of fetal rats of 11-20 days gestation, from cortex, mesencephalon, brainstem, cerebellum, spinal cord of neonatal rats, and from adult rat brain tissues dissected after 5 days morphine pellet s.c. implantation and/or withdrawal. μ OR mRNA was detectable as early as 14 days gestation, and gradually increased to plateau levels at 2-3 months after birth in cortex or mesencephalon. No mRNA was detected in cerebellum in all periods. Preliminary data reveal modest effects of withdrawal from chronic morphine treatments.

704.8

PERIPHERAL μ - OPIOID RECEPTORS DURING INFLAMMATION: ENHANCED SYNTHESIS AND ACCESSIBILITY INCREASE ANTINOCICEPTIVE EFFICACY OF OPIOIDS. M. Schäfer¹, Y. Imai², S. Mousa³, I. Antonijevic, G.R. Uhl^{2,4,5}, C. Stein^{3*}, Preclin. Pharmacol., ²Mol. Neurobiol., ⁴Off. of the Director, ARC/NIDA/NIH, ³Dep. of Anesth., ⁵Dep. of Neuroscience, Johns Hopkins Univ., Baltimore, MD 21224. This study examined the magnitude of peripheral opioid antinociception in relation to 1) the development of inflammation; 2) μ -opioid receptor (μ OR) gene expression in dorsal root ganglia (DRG); 3) the number of peripheral μ OR and 4) leakage of the perineurium of peripheral nerves. After Freund's adjuvant induced unilateral hindpaw inflammation in Wistar rats volume and temperature of the inoculated paws and, in parallel, antinociceptive effects of DAMGO (a μ -selective opioid agonist) increased significantly at 6 hrs, reached a maximum at 24 hrs and did not significantly change until 96 hrs. Doses of i.p. δ -fentanyl, an irreversible μ -receptor antagonist, required to antagonize the antinociceptive effects (IC₅₀ values) increased linearly up to 96 hrs of inflammation. Using a ribonuclease protection assay, μ OR-mRNA levels were detectable in DRG L3-L5 of noninflamed limbs and displayed a trend towards an increase on the inflamed side by 24 hrs. Perineurial leakage, assessed by horseradish peroxidase histochemistry, was apparent both at early (12 hrs) and late stages (96 hrs) of inflammation. In conclusion, gene expression, number and accessibility of μ -opioid receptors appear to be "up-regulated" during inflammation, resulting in a greater efficacy of peripherally acting opioids.

704.9

CHRONIC MORPHINE DOWN-REGULATES μ -OPIOID RECEPTORS IN GUINEA-PIG MEDIOBASAL HYPOTHALAMUS (MBH). G. Zhang*, M. A. Bosch and M. J. Kelly. Dep. of Physiology, Oregon Health Sciences Univ., Portland, OR 97201.

Electrophysiological data have shown that chronic morphine decreases the potency and efficacy of μ -agonist DAMGO mediated hyperpolarization in the subpopulation of arcuate neurons in MBH. The effect of chronic morphine on μ -opioid receptor density in MBH was investigated in the present study. MBH were dissected from ovariectomized females implanted s.c. with morphine- or placebo-pellets (4x75 mg for 2 days plus 6 more for a total of 7 days). The P₂ membrane fraction was prepared, pre-incubated in 50 mM Tris with NaCl+GTP+ EDTA and subjected to several washings to eliminate opiates from opioid binding sites. Saturation of μ -opioid receptors was performed using [³H]diprenorphine as an opioid antagonist radioligand in the presence of DPDPE and U50488 to occupy δ - and κ -receptors, respectively. B_{max} \pm S.E. was 276.4 \pm 16.3 fmol/mg protein in placebo animals (n=6). For morphine-treated animals (n=6), the μ receptor density was significantly (p < 0.05) decreased (B_{max} = 216.9 \pm 8.7 fmol/mg protein) without a change of the antagonist affinity (K_d: 0.38 \pm 0.03 nM vs 0.37 \pm 0.05 nM). Preliminary data from competition of [³H]diprenorphine by DAMGO showed no shift in the fraction of μ -receptors between high and low affinity states in morphine-treated animals. Solution hybridization assays are presently in progress to evaluate the μ -receptor mRNA expression in MBH. Therefore, this 20% down regulation of μ -receptors in MBH appears to contribute to the reduced efficacy of DAMGO in arcuate β -endorphin cells among morphine-tolerant neurons (supported by DA05158).

OPIOID RECEPTORS: LOCALIZATION

705.1

TOPOGRAPHICAL DISTRIBUTION & ULTRASTRUCTURAL LOCALIZATION OF δ -OPIOID RECEPTOR IMMUNOREACTIVITY IN RAT LIMBIC CORTEX: RELATIONSHIP WITH LEU³-ENKEPHALIN. A.L. Svingos*, P.Y. Cheng, C.L. Clarke, C.E. Inturrisi, & V.M. Pickel, Cornell University Medical College, Dept. of Neurol. & Neurosci. & Dept. of Pharmacology, NY, NY, 10021

Mediation of opioid reinforcement has been associated with δ -opiate receptors in cortical-limbic structures. We utilized an antiserum shown to be specific for the δ -opiate receptor to determine whether topographical or ultrastructural localization could demonstrate a selective cellular substrate for these actions. Light microscopic examination among cortical areas revealed immunoreactivity (IR) in limbic-associated cortex to be distinguished by 1) lack of superficial laminar staining, 2) heavier deep laminar labeling and 3) sparse to moderate labeling of varicosity-laden fibers. Ultrastructural analysis of insular cortex showed δ -opiate receptor labeling localized predominantly in small unmyelinated axons and terminals and in distal processes of astrocytes. In terminals, plasma membranes and synaptic vesicles were most intensely labeled. Additionally, dendritic labeling was detected and was most prominently associated with plasma membranes, smooth endoplasmic reticulum and occasionally postsynaptic densities. In a second portion of the study we examined the anatomical relationship between the δ -opiate receptor and endogenous opioids by combining immunoperoxidase and immunogold-silver methods, for localization of antisera directed against the δ -opiate receptor and leu³-enkephalin (ENK) in single sections. ENK labeling was principally seen in large dense core vesicles (DCV) within axon terminals. Terminals appeared more homogeneously distributed as compared to the δ -opiate receptor. In the regions thus far examined neither axon terminals nor dendrites in contact with ENK neurons have shown detectable δ -opiate IR. We conclude that in limbic cortex, δ -opiate receptors 1) are prominently presynaptic modulators and 2) may be activated by opioid peptide released more distally from DCV. Supported by DA04600, DA07274, DA01457, DA00198 and Aaron Diamond Foundation.

705.2

δ -OPIOID RECEPTOR IMMUNOREACTIVITY IN RAT SPINAL CORD: ULTRASTRUCTURAL DISTRIBUTION AND RELATION TO LEU³-ENKEPHALIN. P.Y. Cheng, A.L. Svingos, C.L. Clarke, J. Chan, & V.M. Pickel, Dept. of Neurol. and Neurosci., Cornell Univ. Medical College, New York, NY 10021.

δ -opioid receptors in the dorsal horn are thought to mediate the antinociceptive effects of enkephalins. We examined the ultrastructural localization of antiserum raised against a 15 amino acid fragment, from the amino terminus of the δ -opioid receptor in sections through the cervical spinal cord. By light microscopy, δ -opioid receptor-like immunoreactivity (δ -ORLI), observed using immunoperoxidase, was intensely localized to varicose processes in lamina I of the dorsal horn. Electron microscopy further demonstrated that δ -ORLI was mainly localized in unmyelinated axons and terminals. The most intense peroxidase product in axons was localized to the plasma membrane, smooth endoplasmic reticulum (ER), and synaptic vesicles. Less frequent, but equally intense peroxidase activity was selectively accumulated at postsynaptic densities and ER of dendrites. In sections dually labeled for the δ -opioid receptor (peroxidase) and Leu³-enkephalin (immunogold), we established that the δ -opioid receptor was present in axon terminals both with and without detectable Leu³-enkephalin-like immunoreactivity (ELI). Less commonly, the δ -opioid receptor was seen in terminals presynaptic to neurons showing ELI. We conclude that the δ -opioid receptor is mainly localized so as to modulate the presynaptic release of enkephalin and other neurotransmitters in lamina I of the spinal cord.

STUDIES TOWARD IDENTIFYING TISSUES CONTAINING δ 1 OPIOID RECEPTOR SUBTYPES. L. Fang*, I. De Leon, R. J. Knapp, E. Malatynska, E. Varga, W. Roeske, and H.I. Yamamura. University of Arizona Dept. of Pharmacology, Tucson, AZ 85724.

Delta opioid receptor heterogeneity has been well established by pharmacological studies. Recently, we cloned a human δ opioid receptor by screening human cDNA libraries. It is suggested that this human δ opioid receptor matched the δ 2 subtype, since it showed higher affinity to the δ 2 selective ligand (NTB) than that to the δ 1 selective ligand (BNTX). Other cloned mouse and rat δ opioid receptors also showed δ 2 receptor ligand binding properties. Thus, the δ 1 subtype has not been cloned in any species.

In order to obtain the δ 1 opioid receptor subtype molecular structure, one of the strategies is to find tissues containing δ 1 rather than δ 2 opioid receptor subtypes. Therefore, three interesting tissue membranes have been studied. First is the CXBK mouse brain membrane, which was suggested to have a predominant population of supraspinal δ 1 opioid receptors, rather than δ 2 opioid receptors by Raffa et al. (1992). The second is the guinea pig brain membrane, in which the δ 1 selective antagonist BNTX showed 100-fold greater affinity (K_i = 0.1 nM) for [³H]DPDPE binding sites (δ 1) relative to those of [³H]DLSLET (δ 2) (Portoghese et al., 1992). The third is the rat olfactory bulb membrane, in which the stimulation rather than inhibition of adenylate cyclase activity was observed (Oliana and Onali, 1992). Radioligand binding studies were performed in these three tissues, and the data will be presented. Supported in part by NIDA grants.

705.4

DISTRIBUTION OF DELTA (δ)- AND MU (μ)-OPIOID RECEPTORS IN SMALL SENSORY NEURONS AND AXONS. C.N. Honda*, R.J. Dado, M. Riedl, J.H. Lee, U. Arvidsson, M.W. Wessendorf, H.H. Loh, P.-Y. Law, R. Elde. Departments of Cell Biology & Neuroanatomy and Pharmacology, University of Minnesota, Minneapolis MN 55455.

We have demonstrated previously that a population of small neurons in dorsal root ganglia as well as afferent fibers and terminals in the spinal cord are immunoreactive (ir) for delta (δ)-opioid receptors (Neuroreport 5:341, 1993). Presently, we report that in part, mu (μ)-opioid receptors share a similar distribution, and that both opioid receptors are restricted to a population of sensory neurons and axons not immunoreactive for neurofilament protein.

Rabbit antisera produced against synthetic δ (DOR-) or μ (MOR-) opioid receptors were combined with a mouse monoclonal antibody (RT-97) directed against the 200 kD neurofilament protein subunit, which is a cytochemical marker for large sensory neurons with rapidly conducting axons. Dual color immunofluorescence was employed to test for the coexistence of opioid receptor- and RT-97-ir in sensory cells and axons. Within the DRG, DOR- and MOR-ir were confined almost exclusively to a population of small diameter cells and axons. In peripheral nerve, dorsal rootlets, and spinal gray matter, opioid receptor-ir was localized to small fibers. RT-97-ir was distributed to larger DRG cells and axons, and in peripheral nerve and spinal cord was found in large and small caliber fibers. Rarely did DOR- or MOR-ir coexist with RT-97-ir within the same neuronal elements, supporting the hypothesis that opioid receptors are localized to the terminals of nociceptive primary afferent neurons. Supported by NIH grant NS25658 and grants from NIDA.

705.5

THE RELATIVE DISTRIBUTIONS OF mRNAs ENCODING FOR MU AND DELTA OPIOID RECEPTORS AND FOR GLUTAMIC ACID DECARBOXYLASE (GAD) IN THE VENTRAL MESENCEPHALON. Darragh P. Devine*, Stanley J. Watson and Huda Akil, University of Michigan, Mental Health Research Institute, Ann Arbor, MI, USA 48109-0720

Radioactive *in situ* hybridization was used to characterize the distributions of mRNAs that encode for mu and delta opioid receptors, and for glutamic acid decarboxylase (GAD) in rat ventral mesencephalon. Riboprobes complementary to the mu, delta, and GAD mRNAs were labeled with ³⁵S, and applied to serial sections of rat brain. GAD mRNA was most abundant in the interpeduncular nucleus (IPN). A moderate amount of GAD mRNA was found in the Substantia Nigra pars reticulata (SNpr), and a low abundance of GAD mRNA was found throughout the Substantia Nigra pars compacta (SNpc) and Ventral Tegmental Area (VTA). Mu receptor mRNA was most abundant in the IPN, and low levels of mRNA were found in the SNpr, SNpc, and VTA. Delta opioid receptor mRNA was also most abundant in the IPN, with low levels throughout the SNpr, SNpc, and VTA. We are currently examining the possibility of cellular colocalization of these three mRNAs using double-labeled radioactive (³⁵S) and non-radioactive (digoxigenin) *in situ* hybridization.

ULTRASTRUCTURAL EVIDENCE FOR PRESYNAPTIC KAPPA OPIOID RECEPTORS IN GUINEA PIG HIPPOCAMPUS. CT Drake*, TA Patterson*, ML Simmons*, C Chavkin*, and TA Milner*, *Dept. of Neurology & Neuroscience, Cornell Univ. Med. Coll., New York, NY 10021 and *Dept. of Pharmacol., Univ. of Washington, Seattle WA 98195

Activation of kappa (κ) receptors diminishes excitatory transmission in the dentate gyrus and CA3 regions of the guinea pig hippocampal formation. Although many biochemical and physiological studies have suggested that κ receptor effects are mediated presynaptically, the anatomical localization of κ receptors to pre- or post-synaptic processes has not yet been reported. We examined the distribution of a polyclonal rabbit antibody raised against a peptide from the C-terminal portion of a mouse κ receptor. Specificity of the affinity-purified antibody was determined by Western blotting and immunolabeling of κ receptors expressed in *Xenopus* oocytes. The antibody was localized immunocytochemically in acrolein-fixed brain sections. Sections incubated in antibody preadsorbed with the antigenic peptide had no labeling by light or electron microscopy. By light microscopy, κ receptor-like immunoreactivity (κ -LI) was present in varicose processes in the dentate gyrus inner molecular layer, granule cell layer and hilus, and in CA3 stratum lucidum and radiatum. By electron microscopy, κ -LI was found in small unmyelinated axons and terminals, and was associated with large vesicular structures, cytoplasmic surfaces of small vesicles and plasma membranes. In the dentate gyrus, axons and terminals with κ -LI contacted large dendrites and perikarya of presumed granule cells. In hilus and in stratum radiatum of CA3, axons with κ -LI were apposed to unlabeled dendrites or other axons. In stratum lucidum, axons with κ -LI were found occasionally in bundles of mossy fibers. Thus our ultrastructural data support physiological and biochemical evidence that κ opioids modulate transmitter release from axons in guinea pig hippocampus. Supported by DA08259, DA07274, DA04123.

DELTA OPIOID RECEPTOR- AND ENKEPHALIN-IMMUNOREACTIVITY ARE SPATIALLY RELATED IN THE MOUSE CNS. I-H Lee*, TC Breije, RI Dado, HH Loh, P-Y Law and R Elde, Departments of Cell Biology & Neuroanatomy and Pharmacology, University of Minnesota, Minneapolis, MN 55455

The cloning of a δ -opioid receptor (DOR) has permitted the raising of antisera which recognize this protein. We previously reported that immunostaining for DOR in the dorsal horn of the spinal cord is strikingly restricted to axons and their terminals, and that these terminals are closely apposed by enkephalin-immunoreactive (-ir) boutons (Dado et al., NeuroReport 5:341-344, 1993). In the present study, we have examined the spatial relationship of DOR and ENK-ir nerve fibers in other regions of the central nervous system of mice using digitally-rendered montages produced by confocal microscopy. Nerve fibers and terminals with prominent DOR-ir were observed, for example, in the islands of Calleja and olfactory tubercle, the caudate-putamen, the globus pallidus and entopeduncular nucleus (n), amygdaloid nuclei (nn), mamillary nn, substantia nigra, interpeduncular nn, raphe pontis, parabrachial nn, n of the solitary tract, lateral reticular n and spinal trigeminal n. DOR- and ENK-ir nerve fibers and terminals were interspersed in most of these regions, however only rarely was DOR-ir found on the same elements as ENK-ir. Thus, DOR is unlikely to be an autoreceptor. In some regions, DOR-ir was abundant in areas which did not contain ENK-ir, and vice versa. However, these regions of complementary staining were in many instances immediately adjacent to each other, suggesting that the opioids may participate in interneuronal communication over significant distances. Supported by grants from NIDA.

705.6

μ OPIATE RECEPTOR: IMMUNOHISTOCHEMISTRY AND IN SITU HYBRIDIZATION. A. Moriwaki*, P.S. Johnson@, D. Walther#, J.-B. Wang# and G.R. Uhl#, *Molecular Neurobiology Branch, Office of the Director, Intramural Research Program/NIDA, NIH; @Pharmacology Research Associate Program, NIGMS; #Department of Neurology and Neuroscience, Johns Hopkins School of Medicine, Baltimore, Maryland 21224.

A rabbit polyclonal antiserum was raised against a hemocyanin conjugate of the C-terminal 18 amino acids of the rat μ opiate receptor. The antiserum produced high titers (1:40,000) when analyzed by ELISA, recognized purified μ receptor protein in Western immunoblots, and stained COS cells expressing the μ OR cDNA. Microscopic examination of immunostained brain and spinal cord sections revealed that μ -opiate receptor immunoreactivity was present in fiber- and terminal patterns in amygdala, nucleus accumbens, globus pallidus, hypothalamus, thalamus, medial habenula, substantia nigra, ventral tegmental area, periaqueductal gray, nucleus raphe magnus, nucleus tractus solitarius, zona spongiosa and substantia gelatinosa, while little was observed in neocortex or hippocampal formation. Neural cell bodies were immunostained in areas including hypothalamus. In situ hybridization studies of brain regions including thalamus reveal hybridization over neurons which display little somatic immunoreactivity. No immunoreactivity was observed when preimmune or preadsorbed sera were used. These results directly show the distribution of the immunoreactive receptor in the rat central nervous system.

705.8

A MONOCLONAL ANTIBODY TO THE KAPPA₃ OPIATE RECEPTOR A.I. Brooks, K.M. Standifer, G.W. Pasternak*, The Cotzias Laboratory of Neuro-Oncology, Department of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY U.S.A. 10021

Monoclonal antibodies (mab) were raised against Be(2)-C human neuroblastoma membranes which contain μ , κ_3 , and δ opiate receptors. Over 5000 hybridoma cell lines were screened, with 2000 hybridomas testing positive against the Be(2)-C membranes. Screening against another neuroblastoma line lacking opioid receptors, left 98 positive for Be(2)-C only. Several hybridomas showed high immunoreactivity to the Be(2)-C membranes, but only five of these clones, (8D8₁, 25G11, 15F3, 7E1, and 22H1) inhibited binding to the κ_3 opioid receptor. Mab 8D8₁ inhibited up to 90% of ³H-NalBzoH (κ_3) binding with no effect on ³H-DAMGO (μ) or ³H-DPDPE (δ) binding, illustrating the selectivity of mab 8D8₁ for the κ_3 subtype. Mab 8D8₁ recognized κ_3 receptors in mouse, rat, and calf brain homogenate binding assays. In addition, mab 8D8₁ blocked the inhibition of cAMP accumulation by NalBzoH but not morphine. On Western blots, mab 8D8₁ labeled proteins consistent with the putative κ_3 receptor. Mab 8D8₁ also recognized a novel opioid receptor clone corresponding to the κ_3 receptor. In immunocytochemical studies the mab effectively labeled Be(2)-C cells but not cells lacking κ_3 receptors. Mab 8D8₁ also has been effective in labeling brain slices, demonstrating its utility in establishing the distribution of κ_3 receptors in the nervous system. Further characterization and purification of mab 8D8₁ is ongoing.

705.10

COLOCALIZATION OF SUBSTANCE P AND A DELTA OPIOID RECEPTOR IN THE RAT CENTRAL NERVOUS SYSTEM. M Riedl*, U Arvidsson, RI Dado, I-H Lee, MW Wessendorf, HH Loh, P-Y Law and R Elde, Departments of Cell Biology & Neuroanatomy and Pharmacology, University of Minnesota, Minneapolis, MN 55455

Antibodies to the δ -opioid receptor (DOR) and the μ -opioid receptor (MOR) were developed and used to map DOR- and MOR- immunoreactivity (-ir) in the central nervous system (CNS) of adult mice and rats (Lee et al., this meeting; Arvidsson et al., this meeting). In the present study, these antibodies were used to examine spatial relationships between these receptors and neuropeptides and other transmitters at the cellular level. Sera from rabbits immunized against amino acids 3-17 (Dado et al., NeuroReport 5:341-344, 1993) of the predicted sequence of DOR were used in conjunction with a monoclonal antibody to substance P (SP) for two color immunofluorescent staining and analysis. A high degree of colocalization between DOR and SP was seen in axons and terminals in many regions of the brain and spinal cord. Extensive colocalization was evident, for example, in the islands of Calleja and olfactory tubercle, the shell of n accumbens, ventral pallidum, lateral septal n, amygdaloid nn, several hypothalamic nn, interpeduncular n, substantia nigra, n of the solitary tract and the spinal trigeminal n. Controls suggested that the apparent colocalization was not artifactual. Interestingly, it has been suggested that μ -opioid receptors occur on noradrenergic fibers originating from locus coeruleus. However, a high degree of colocalization was not observed for molecules which mark these systems. In summary, a surprisingly constant relationship was observed between DOR- and SP-ir in axons and terminals, suggesting a presynaptic role for this receptor in regulating the release of SP and transmitters which coexist with it, in a wide range of systems. Supported by NIDA.

RECONSTITUTION OF A PURIFIED μ OPIOID BINDING PROTEIN WITH PURE G-PROTEINS IN LIPOSOMES

Fan, L.Q.¹, Gioannini, T.L.², Dingus, J.^{1,2}, Wilcox, M.^{1,2}, Hildebrandt, J.^{1,2}, Hiller, J.M.¹ and Simon, E.J.¹
¹Departments of Psychiatry and Pharmacology, NYU Medical Center, New York, NY, ²Department of Pharmacology, Medical University of South Carolina, Charleston, S.C.

A functionally active μ opioid binding protein (OBP), purified to homogeneity from bovine striatal membranes, has been reconstituted with purified G-proteins into liposomes containing the phospholipid, phosphatidylcholine. Liposomes were formed by precipitating the lipid-protein mixture with PEG and resuspending the liposomes in buffer. Most experiments were done with a highly purified bovine brain G-protein mixture, but individual purified G_i and G_o -proteins were also found to be effective. Functional reconstitution was evaluated by measuring stimulation of the GTPase activity of G-proteins by opioid agonists and high affinity agonist binding. Low- K_m GTPase was stimulated by the μ agonists DAGO, morphine, and levorphanol (max. 100% over basal), but not by DPDPE or U50,488H. Stimulation was reversed by naloxone and both stimulation and naloxone reversal were stereospecific. The [³H]-DAGO binding observed in the liposomes with purified G-protein mixture and OBP had a $K_d = 8$ nM, an affinity slightly lower than that seen in bovine striatal membranes, and was sensitive to inhibition by GTP γ S and sodium. No high affinity delta or kappa binding was observed in the reconstituted system. The evidence from these studies supports our previous results suggesting that OBP is a μ receptor. (supported by grant DA-00017 from NIDA to EJS).

AGONIST-INDUCED DESENSITIZATION OF THE MU OPIOID RECEPTOR COUPLED POTASSIUM CHANNEL (KGA). A. Kovoor¹, D.J. Henry¹, H.A. Lester², N. Davidson² and C. Chavkin^{1,3}

¹Dept. of Pharmacology¹, Univ. of Washington, Seattle, WA and Div. of Biology² or CNS Program³, Caltech, Pasadena, CA.

Application of mu-opioid agonists evoked an increase in K⁺ conductance in Xenopus oocytes expressing the rat mu receptor and the G-protein-gated, inwardly rectifying K⁺ channel (KGA). The amplitude of the response decayed during agonist exposure with a $\tau_{1/2}$ of 8 ± 2 min. In oocytes co-expressing the mu and 5HT1A receptors, stimulation of either receptor resulted in heterologous desensitization of the subsequent response to the other. Injection of GTP γ S (1 mM) increased the peak response to agonist but did not affect the rate of desensitization. Basal channel activity in the absence of agonist also desensitized at the same rate when the oocytes were clamped at -80 mV and bathed in high K⁺ (96 mM) solution. The above results indicate that the desensitization of the response occurred downstream of the receptor, possibly at the channel. Response desensitization occurred at the same rate if the cells were clamped either at 0 mV or with agonist in low K⁺ buffer (2 mM). The rate of desensitization was not significantly altered by any of the following treatments: removal of external Ca²⁺, preloading the oocytes with BAFTA-AM (1-10 μ M), elevation of cAMP levels, treatment with phorbol esters (1 μ M), staurosporine (0.5 μ M), or cytochalasin B (0.5 μ M). These results suggest that desensitization requires open channels but may not involve a calcium or phosphorylation-dependent mechanism or internalization of components of the transduction pathway. Supported by DA04123.

706.5

ONTOGENY OF μ -OPIATE INHIBITION OF ADENYLATE CYCLASE AND GTP MODULATION OF μ -RECEPTOR BINDING IN RAT BRAIN. P. J. Little¹ and C. M. Kuhn. Dept. of Pharmacology, Duke University Medical Center, Durham, NC 27710.

Signal transduction pathways play a critical role in opiate receptor function, especially after chronic exposure. To understand the consequences of perinatal opiate exposure, it is necessary to characterize the coupling of opiate receptors to their respective signal transduction pathways during development.

The present study investigated the inhibition of basal and forskolin-stimulated cAMP accumulation by DAMGO, a selective μ -agonist, in striatal membranes from 10 and 60 day old rats. The ability of GppNHP to shift striatal μ -receptors from high to low affinity at these ages was also assessed.

DAMGO (0.1-10 μ M) significantly inhibited basal and forskolin-stimulated cAMP accumulation by 25%, and 22%, respectively, in 60 day old rats. In contrast, DAMGO failed to inhibit significantly cAMP accumulation in 10 day old rats. Approximately 30% of striatal μ -receptors were shifted to low affinity by GppNHP in 60 day old rats, whereas only 4% were shifted to low affinity in 10 day old rats. These data suggest that μ -receptors in 10 day old rats are not coupled as tightly to effector systems as in 60 day old rats. These ontogenetic differences in μ -receptor coupling may prevent receptor function from adapting to chronic opiate exposure, making neonates especially vulnerable to the adverse consequences of chronic administration. (Supported by DA-02739 and MH-15177)

INVOLVEMENT OF GUANOSINE 5'-TRIPHOSPHATE IN μ -OPIOID RECEPTOR-ACTIVATED POSTSYNAPTIC RESPONSES IN SUBSTANTIA GELATINOSA NEURONS. S.P. Schneider* and A.R. Light. Dept. of Physiology, University of N. Carolina, Chapel Hill, NC 27514-7545.

The involvement of the nucleotide 5'-triphosphates GTP and ATP in mediating μ -opioid actions on substantia gelatinosa (SG) neurons was investigated using tight-seal whole-cell recordings from superfused transverse slices of hamster spinal cord. Bath application of the μ -opioid receptor agonist [D-Ala², N-Me-Phe⁴, Gly⁵-ol]-enkephalin (DAMGO; 1-5 μ M) caused a hyperpolarization and decrease in neuronal input resistance (R_{in}) in 62% of SG neurons when the electrode internal solution contained 100 μ M GTP and 2 mM ATP. However, at bath concentrations up to 10 μ M DAMGO had little or no effect on the transmembrane potential or R_{in} of SG neurons using electrodes without GTP and ATP. DAMGO-activated responses were attenuated in SG neurons after dialysis with internal solution containing 2 mM ATP but no GTP. DAMGO activated a non-reversing membrane hyperpolarization in SG neurons recorded with electrodes containing 100 μ M GTP- γ -S, a non-hydrolyzable GTP analogue. SG neurons were less responsive to DAMGO following intracellular application of the analogue GDP- β -S (500 μ M) which blocks G-protein activation. We conclude that intracellular GTP is necessary for μ -opioid receptor-mediated responses in SG neurons, consistent with the idea that antinociceptive effects of opioids are mediated through receptor-coupled second messenger systems involving G-proteins. The results resolve why DAMGO does not always evoke postsynaptic effects in superficial dorsal horn neurons in whole-cell recordings. Supported by NINDS grant NS25771 (S.P.S.), NIDA grant DA04420 (A.R.L.), and NIDDK grant DK475901 (E.R. Perl).

KAPPA OPIOID RECEPTORS COUPLE TO INWARD RECTIFIER K⁺ CHANNELS WHEN COEXPRESSED IN XENOPUS OOCYTES. D.J. Henry¹, N.F. Lim², H.A. Lester², N. Davidson² and C. Chavkin^{1,3}

¹Dept. Pharmacol., Univ. of Washington, Seattle, WA and Division of Biology² and CNS Program³, California Institute of Technology, Pasadena, CA.

Xenopus oocytes expressed kappa (κ) opioid specific binding sites 5-14 days following injection of mRNA prepared from a clone of the mouse κ opioid receptor (provided by David Grandy, Vollum Inst., Portland, OR). Peak expression of κ receptor (870 fmol ³H-U69,593/mg membrane protein) was observed 7 days after injection of 5 ng mRNA/oocyte. The κ receptor was previously shown to negatively couple to N-type Ca²⁺ channels. We find additionally that coexpression of κ receptor mRNA with mRNA coding for an inward rectifier channel (KGA) resulted in oocytes that expressed κ agonist-gated K⁺ currents. The κ agonist U69,593 activated a large (1.0-1.5 μ A) inwardly rectifying K⁺ current with an EC₅₀ of 220 nM. This agonist-gated K⁺ conductance was not observed in oocytes injected with mRNA for the κ receptor or KGA channel alone, and was blocked by either 300 μ M Ba²⁺ or the opioid antagonists naltorphine (1 μ M) or naloxone (1 μ M). When mRNAs (1-2 ng/oocyte) coding for G-protein subunits were coinjected with KGA and κ receptor mRNA, only G_{ai2} (but not G_{ai3}, G_{az}, G_{aoA}, $\beta_1\gamma_2$ or $\beta_2\gamma_2$) significantly potentiated the maximum response to U-69593. The acute response to U-69593 desensitized rapidly, with a $t_{1/2}$ of 4 minutes following peak response. Supported by DA 04123 and DA 05610.

CHP-212, A HUMAN NEUROBLASTOMA CELL LINE, EXPRESSES A HETEROGENEOUS POPULATION OF δ OPIOID RECEPTORS

A.M. Babey¹*, K.M. Standifer¹, J. Cheng¹, J.L. Biedler², and G.W. Pasternak^{1,3}. ¹The Cotzias Laboratory of Neuro-Oncology, ²Laboratory of Cellular and Biochemical Genetics, Memorial Sloan-Kettering Cancer Center and ³Departments of Neurology & Neuroscience and Pharmacology, Cornell University Medical College, New York, NY, USA, 10021

Identification of two δ opioid receptor subtypes, termed δ_1 and δ_2 , has been greatly facilitated by the use of specific agonists (DPDPE and deltorphin II, respectively) and specific antagonists (BNTX and naltrexone, respectively). We have recently reported that the human neuroblastoma cell line, CHP 212, expresses δ opioid receptors, but does not demonstrate binding to μ (³H-DAMGO), κ_1 (³H-U69,593) or κ_2 (³H-NalBzoH) specific ligands (Babey, et al., 1993). Competition binding assays in this cell line raise the possibility that the δ receptor population in these cells is comprised of both δ_1 and δ_2 subtypes. The K_i values for the subtype-specific agonists and antagonists against ³H-naltrindole were: DPDPE 3.45 \pm 0.56; deltorphin II 1.67 \pm 0.33; BNTX 0.92 \pm 0.24; naltrexone 0.21 \pm 0.04; while the Hill coefficients were all less than one. In order to characterize the receptor proteins, [¹²⁵I]- β -endorphin was chemically cross-linked to CHP-212 membranes using BSOES. SDS PAGE of the covalently labeled membranes reveals several specific bands. This cell line may be a useful tool in the study of the interaction between the two δ receptor subtypes.

FUNCTIONAL EXPRESSION OF THE MOUSE DELTA OPIOID RECEPTOR IN A PITUITARY TUMOR CELL LINE. E. Pinos*, P. Zaki, R.H. Edwards, C.J. Evans & T.G. Hales. Depts Psych., Neurol. & Anesth., UCLA, LA., CA. 90024

Cloning of the delta opioid receptor offers a unique opportunity to characterize its functional coupling with effector systems in different cell lineages. The rat growth hormone and prolactin secreting GH3 cell line expresses somatostatin (SRIF) receptors, G-proteins, adenylate cyclase and Ca^{2+} and K^{+} channels, but lack opioid receptors, assessed by ligand binding and cAMP assays. Therefore, GH3 cells would appear to be suitable for the expression of opioid receptors and for the investigation of their coupling to second messenger systems, channels and hormone release.

A plasmid containing the entire coding region of the mouse delta opioid receptor (DOR) was transfected into GH3 cells. Stable expression of DOR was verified by immunocytochemistry and radioligand binding with [^{125}I]-D-Ala²-D-Met⁵-enkephalin (DADLE). Twelve positive clones were analyzed for their ability to bind delta-specific ligands. One of these clones (GH3-DOR-22) was used in further analysis. [D-PEN 2,5]-enkephalin (DPDPE), etorphine and DADLE (1-1000 nM) all dose-dependently displaced [3H]-diprenorphine bound to GH3-DOR-22 cells.

The ability of the transfected delta opioid receptors to inhibit adenylate cyclase was assessed by measuring cAMP levels in GH3-DOR-22 cells. Etorphine (1-1000 nM) dose-dependently inhibited adenylate cyclase in GH3-DOR-22 cells and the effect was blocked by naloxone. cAMP levels were also reduced by SRIF (0.01-5 μ M) in both control and DOR transfected GH3 cells.

The receptor's ability to modulate Ca^{2+} channels was investigated using the whole-cell voltage-clamp recording technique in both NG108-15 cells (from which DOR was cloned) and in GH3-DOR-22 cells. While both DADLE and SRIF inhibited voltage-activated Ca^{2+} channels in NG108-15 cells, neither was effective in the GH3-DOR-22 cell line. In addition, both ligands failed to modulate K^{+} conductances in GH3-DOR-22 cells. It is concluded that the delta opioid receptor can couple to adenylate cyclase in transfected GH3 cells, although this cell line may not be a suitable model for studying cloned opioid receptor coupling to ion channels. (NIDA #DA-05010)

CHARACTERIZATION OF μ AND δ OPIOID RECEPTOR BINDING DOMAINS: SENSITIVITY TO N-ETHYLMALIMIDE. M. Shahrestanifar and R.D. Howells*. Department of Biochemistry and Molecular Biology, UMD-New Jersey Medical School and Graduate School of Biomedical Sciences, Newark, NJ 07103

It has been shown previously that opioid receptor binding is sensitive to alkylation by the sulphydryl-specific reagent, N-ethylmaleimide (Smith and Simon, PNAS 77: 281-284, 1980). As part of a more general project aimed at identifying specific amino acid residues that contribute to the opioid receptor ligand binding site, a series of experiments have been initiated to locate the cysteine residues that are involved in the inhibition of receptor binding following treatment with N-ethylmaleimide. For these studies, human embryonic kidney 293 cells were transiently transfected with μ and δ receptor expression plasmids by the calcium phosphate method, and cell membranes were harvested 48 h later. The δ receptor expression plasmid, DOR-1, has been reported previously (Evans et al., Science 258: 1952-1955, 1992). The μ receptor expression plasmid was constructed by subcloning a 1.4 kbp HindIII fragment containing the open reading frame of the μ receptor from a 4.8 kbp cDNA insert in pBluescript (Chen et al., Mol. Pharmacol. 44: 8-12, 1993). Membranes from μ and δ receptor-transfected 293 cells bind tritiated diprenorphine and bremazocine with low nanomolar affinity and high capacity (20 pmoles/mg protein), while cells transfected with expression plasmids lacking inserts did not exhibit specific binding. When μ receptor-transfected membranes were preincubated at 37°C for 15 min with 0.5 mM N-ethylmaleimide, specific binding was reduced to 25% of controls; δ receptor binding was somewhat less sensitive. Kinetic analysis of the inhibition indicated a half-life of inactivation of 8 min. Preincubation with opioid alkaloid agonists, peptide agonists, and alkaloid antagonists prior to treatment with N-ethylmaleimide partially protected against receptor inactivation, with a rank order of potency that correlated well with competitive binding affinities. We are currently using site-directed mutagenesis to identify the relevant cysteine residues that are subject to N-ethylmaleimide alkylation. Supported by DA 05819 and the Foundation of UMDNJ.

EFFECT OF FORSKOLIN/IBMX AND ROLIPRAM ON δ -OPIOID RECEPTOR mRNA LEVELS IN NEUROBLASTOMA X GLIOMA NG108-15 HYBRID CELLS. K.H. Gyllys*, K. Magendzo, P. Zaki, P. Y. Law, and C.J. Evans. Dept. of Psychiatry & Biobehavioral Sciences, University of California, Los Angeles CA 90024, and Dept. of Pharmacology, University of Minnesota, Minneapolis, MN.

Forskolin, an adenylate cyclase activator, together with the phosphodiesterase inhibitor isobutylmethylxanthine (IBMX) have previously been shown to induce cell differentiation and down-regulation of δ -opioid receptor mRNA in NG108-15 cells (Bergsbaken et al., 1993; Magendzo et al., 1993). IBMX and other xanthine-derived PDE inhibitors are notorious for their lack of selectivity; therefore, we have compared the effects of forskolin/IBMX with the selective PDE inhibitor Rolipram on δ -opioid receptor transcripts by Northern analysis. NG108-15 cells were exposed to drugs for varying lengths of time before harvesting and isolating total RNA. Rolipram treatment does not result in a similar down-regulation of δ -opioid receptor mRNA; however, like the forskolin/IBMX treated cells, all transcripts were regulated in a parallel fashion. No differential regulation was observed between the previously identified multiple δ -opioid receptor transcripts in NG108-15 cells. These results suggest that the increased selectivity of Rolipram may make it a appropriate agent to study cAMP effects in this system.

PROTEIN KINASE C INVOLVEMENT IN HOMOLOGOUS DESENSITIZATION OF OPIOID δ -RECEPTOR IN GUINEA PIG STRIATAL MEMBRANES AND *XENOPUS* OOCYTE EXPRESSION SYSTEM. H. Ueda*, T. Miyamae, N. Fukushima and Y. Misu. Dept. Pharmacol. Yokohama City Univ. Sch. of Med, Yokohama 236, Japan.

DSLET, an opioid δ -agonist showed a weaker stimulation on GTPase activities in striatal membranes of young (4-week old) guinea pigs than in mid-old (16 weeks) ones or in rat striatal ones. The responses in young guinea pigs were markedly enhanced by the addition of 0.1 μ M K252a or calphostin C, protein kinase C inhibitors, but not by 0.1 μ M KT5720, a protein kinase A inhibitor. On the other hand, the evoked currents by 0.1 μ M DSLET through an action of $G_{i\alpha}$ and phospholipase C in *Xenopus* oocytes injected with mouse δ -receptor (DOR1) and $G_{i\alpha}$ RNAs (Febs Lett.(1993) 333, 311-314) were constant upon repeated challenges of the agonist, and markedly attenuated by a bath-application of phorbol ester (10 nM, 10 min) in a protein phosphatase 2B-reversible manner. The currents by repeated challenges of higher concentration (3 μ M) of δ -agonist in the oocytes injected with DOR1, $G_{i\alpha}$ and M2 muscarinic receptor RNAs were rapidly desensitized, while there was no cross desensitization with M2-responses. Such a homologous desensitization was completely rescued by a bath-application with 2 μ M calphostin C, but not with 2 μ M KT5720. These results suggest that δ -opioid receptor is homologously desensitized through an action of protein kinase C.

706.10

$G_{i\alpha}$ AND $G_{i2\alpha}$, BUT NOT $G_{i3\alpha}$ INVOLVEMENT IN RECEPTOR-MEDIATED PHOSPHOLIPASE C ACTIVATION IN *XENOPUS* OOCYTE EXPRESSION SYSTEM. T. Miyamae*, H. Ueda, N. Fukushima and Y. Misu. Department of Pharmacol. Yokohama City Univ. Sch. of Med., Yokohama 236, Japan.

Involvement of $G_{i\alpha}$ in phospholipase C activation by metabotropic receptors in *Xenopus* oocyte expression system was studied. The currents evoked by 0.1 μ M DSLET, a δ -opioid agonist or by 10 μ M ACh in the *Xenopus* oocytes injected with mouse δ -opioid receptor (DOR1) or M2 muscarinic receptor (M2) RNA were rapidly desensitized by repeated challenges of the agonist. Such a rapid desensitization was rescued by the addition of RNA of $G_{i\alpha}$ and $G_{i2\alpha}$, but not $G_{i3\alpha}$, $G_{o\alpha}$, $G_{q\alpha}$, $G_{11\alpha}$ nor $G_{14\alpha}$. In the oocyte injected with $G_{i\alpha}$ and DOR1 or M2, the agonist-evoked currents were constant in amplitude upon at least 6 repeated challenges and these were completely abolished by the intracellular injection of 100 pmol of EGTA or 1 pmol of inositol 1,4,5-trisphosphate. When the chloride ion-concentration was reduced to one fourth, the I-V curve (or reversal potential) was shifted to the right (from -25 to 0 mV). When AlF_4^- , an activator of universal heterotrimeric G-proteins was used instead of the receptor stimulation, the rapid desensitization and its rescue by $G_{i\alpha}$ RNA injection as well as $G_{q\alpha}$ or $G_{11\alpha}$ RNA were also observed. These results provide the evidence that α -subunits of some of pertussis toxin-sensitive G-proteins are also involved in the receptor-mediated phospholipase C activation.

CO-LOCALIZED OPIOID AND GLUTAMATE RECEPTORS ON ASTROGLIAL CELLS - POSSIBLE REGULATORS OF SYNAPTIC TRANSMISSION. T. Thorlin¹, P.S. Eriksson^{1,2}, M. Nilsson¹, E. Hansson^{1,3} and L. Rönnbäck^{1,2}, Institute of Neurobiology¹ and Department of Neurology² University of Göteborg and Department of Cell Biology, Faculty of Health Sciences, University of Linköping³, Sweden.

Neurons and astroglial cells from the cerebral cortex in primary culture respond differentially to opioid receptor stimulation using selective agonists. Cultured neurons were shown to respond with a substantial decrease in the cytoplasmic free calcium after stimulation of μ , δ and κ receptors. On the other hand, stimulation of δ and κ receptors, on astroglial cells in culture using DADLE or U-50,488H resulted in a substantial increase in the cytoplasmic free calcium. Glutamate receptors were shown to be co-localized with opioid receptors on cultured astroglial cells. These effects were visualized through the use of the fluorescent calcium indicator fura-2. Astroglial cells in culture and acute dissociated astrocytes were identified by immunostaining with antibodies against glial fibrillary acidic protein (GFAP). The presence of δ -receptor mRNA was verified in cultured astroglial cells using RT-PCR and Northern blot. The present study suggest that cultured neurons from the cerebral cortex express μ , δ and κ -receptors. Cultured astroglial cells from the cerebral cortex express co-localized glutamate, δ - and κ -receptor. A method for acute dissociation of astrocytes and is under development to further investigate functional δ -receptors (i.e. calcium activating) to validate the relevance of the in vitro system. This might represent a novel mechanism contributing to the depressant action of opioids on synaptic transmission via decreasing the availability of calcium.

706.13

OPIOID RECEPTORS ARE DIFFERENTIALLY TARGETED IN THE NERVOUS SYSTEM AND IN A CELLULAR EXPRESSION SYSTEM. RJ Dado*, AH Nakano, S Chakrabarti, J-H Lee, M Riedl, U Arvidsson, M W Wessendorf, HH Loh, P-Y Law and R Elde, Departments of Cell Biology & Neuroanatomy and Pharmacology, University of Minnesota, Minneapolis, MN 55455

The δ -opioid receptor (DOR) that has been cloned appears to be enriched in axons and terminals in spinal cord, where it may function as a presynaptic receptor (Dado et al., *NeuroReport* 5:341-344, 1993). Further examination suggests that DOR may be almost exclusively targeted to axons. In contrast the μ -opioid receptor (MOR) that has been cloned appears to be targeted to the plasma membrane of dendrites and cell bodies, and, in some cases, to axons (Arvidsson et al., this meeting). Immunofluorescence studies were used to characterize this distinction more completely. COS-7 cells were electroporated with constructs which expressed DOR, MOR and the cloned κ -opioid receptor (KOR) behind a 9 amino acid epitope tag (TAG) followed by a 4 amino acid thrombin site. Cells were fixed 72 hrs after electroporation and stained with a monoclonal anti-TAG antibody. With both MORTAG- and KORTAG-transfected cells, TAG immunoreactivity (-ir) was observed in the endoplasmic reticulum, the golgi and the plasma membrane. In contrast, in DORTAG-transfected cells, TAG-ir was restricted to the endoplasmic reticulum. The targeting of these receptors in axons was examined in sciatic nerves of rats which had been previously ligated under general anesthesia. DOR- and MOR-ir accumulated both proximal and distal to ligation sites at survival times ranging from 2 - 8 hrs. Taken together these results suggest that there are consistent differences among opioid receptors in their targeting. Supported by NIDA.

PROPERTIES OF A KAPPA OPIOID RECEPTOR EXPRESSED IN CHO CELLS: ABILITY TO ACTIVATE MULTIPLE G-PROTEINS IS SIMILAR TO OTHER OPIOID RECEPTORS. P.L. Prather*, T.M. McGinn, P.A. Claude, L. Y. Liu-Chen*, H.H. Loh and P.Y. Law, Dept. of Pharmacology, Univ. of Minnesota, Minneapolis, MN 55455 and *Dept. of Pharmacology, Temple Univ., Philadelphia, PA 19140.

The purpose of the present study was to determine if the coupling pattern of a recently cloned κ -opioid receptor stably transfected in CHO cells to individual G_α subunits was different than that observed previously for δ - and μ -opioid receptors. Data presented in the current study indicate the successful stable expression of a κ -opioid receptor in CHO cells. This is supported by experiments which revealed that ligands with selectivity for κ -, but not δ - or μ -opioid receptors demonstrated high affinity for the expressed receptor and were able to potently and efficaciously produce inhibition of adenylyl cyclase activity. In addition, only κ -opioid agonists were able to induce dose-dependent increases in the incorporation of [32 P]-azidoanilido-GTP into four G_α subunits, three of which were identified as $G_{i3\alpha}$, $G_{i2\alpha}$ and $G_{o2\alpha}$. Further, the amount of κ -opioid agonists required to induce 50% maximal labeling of any individual G_α subunit was not different. Although κ -opioid agonists produced equivalent maximal labeling of $G_{i3\alpha}$, $G_{i2\alpha}$ and $G_{o2\alpha}$, significantly less agonist-induced labeling was observed for an unknown G-protein designated as $G_{? \alpha}$. These results are similar to that observed previously for both δ - and μ -opioid receptors and suggest that although all opioid receptors interact with multiple G-proteins, this coupling is not selective for any individual G_α subunit.

IDENTIFICATION OF TRANSCRIPTS ENCODING OPIOID RECEPTORS IN IMMUNE CELLS. Claire Gavériaux-Ruff, Frédéric Simonin, Katia Befort and Brigitte Kieffer*, ESBS, Univ. Louis Pasteur, 67 Strasbourg, France.

Numerous in vivo and in vitro studies have shown that opioids modulate the immune response. A direct effect of opioids on immune cells has been postulated, however pharmacological studies to demonstrate the existence of opioid receptors on these cells have been poorly convincing. We, and others, recently isolated cDNAs encoding neuronal opioid delta, mu and kappa receptors. The cloning of these receptors has provided molecular tools for the identification of the expression of opioid receptors in immune cells. We designed opioid receptor subtype-specific primers, based on the known sequence of the cloned receptors, and used Reverse Transcriptase-Polymerase Chain Reaction followed by Southern hybridization, for the detection of opioid receptor transcripts. We have tested both mouse and human cells representative of the different components of the immune system. Our results indicate that kappa receptor mRNA is undetectable in several mouse T cell lines. We found low level of delta receptor mRNA in some human T and monocyte cell lines. In all the human B cell lines tested, substantial amounts of kappa receptor transcript, as well as low level of delta and mu receptor transcripts are present. Our data suggest that the cloned mu, delta and kappa receptor subtypes are not only present in nervous tissues, but also are expressed in immune cells.

706.14

NUCLEAR MATRIX OPIOID BINDING IS ABOLISHED UNDER DESENSITIZATION CONDITIONS. M.M. Belcheva*, S. Gucker*, D.-M. Chuang*, W.G. Clark*, R.J. McHale*, G. Toth*, A. Borsodi*, C.J. Goscia*, *Dept. Biochem. & Mol. Biol., St. Louis Univ. Sch. Med., St. Louis, MO, *Biol. Psych. Branch, NIMH, Bethesda, MD, *Biol. Res. Center, Szeged, Hungary.

Opioid binding sites were found in nuclear matrix preparations from NG108-15 neurohybrid cells. The opioid antagonist, 3 H-naltrindole, and 3 H-diprenorphine, display high affinity binding, while agonists bind with low affinity, if at all, to nuclear matrix preparations. Gpp(NH)p insensitivity of agonist binding and the absence of adenylyl cyclase activity suggest the occurrence of G protein uncoupled opioid sites in this fraction. Opioid inhibition of basal and forskolin-stimulated adenylyl cyclase activity was found in nuclear membrane preparations. *In vitro* preincubation with protein kinase A or desensitization of cells with etorphine elicited similar binding alterations in each of four subcellular fractions. Both treatments abolished nuclear matrix opioid binding, without affecting antagonist binding densities in membranes sedimenting at 20,000 g (P_{20}) or nuclear membrane preparations. A decrease in agonist binding affinities and densities in P_{20} fractions was also observed under these conditions, whereas treatment of cells with forskolin potentiated both P_{20} and nuclear matrix binding. Taken together our results support the hypothesis that nuclear membrane opioid receptors are newly synthesized molecules enroute to the cell surface, whereas nuclear matrix contains internalized δ -sites.

706.16

KAPPA OPIOID INHIBITION OF STIMULATED PHOSPHOINOSITIDE HYDROLYSIS IS NOT MEDIATED BY A DECREASE IN INTRACELLULAR CALCIUM. Dennis Paul*, Lerna Minor and Naili Duan, Department of Pharmacology and Centers for Neuroscience and Alcohol and Drug Abuse, LSU Medical Center, New Orleans, LA 70112.

Kappa opioid agonists close N-type Ca^{2+} channels and attenuate stimulated phosphoinositide (PI) hydrolysis in neural tissue. PI hydrolysis is Ca^{2+} dependent. Accordingly, we assessed the possibility that the kappa attenuation of stimulated PI hydrolysis is due to reduced intracellular Ca^{2+} . Rat hippocampal slices labelled with 3 H-myoinositol were incubated with or without the Ca^{2+} ionophores, BayK 8644 (10 μ M) or A23187 (10 μ M). These doses of ionophores blocked the nifedipine induced attenuation of PI hydrolysis. KCl (27.5 μ M) or NE (30 μ M) were added to stimulate PI hydrolysis. In addition, various concentrations of the kappa agonist U-50,488 were added. One hour later, the assays were stopped and PI hydrolysis was measured as the ratio of dpm released / dpm incorporated. U-50,488 dose dependently attenuated KCl-, NE- and carbachol stimulated PI hydrolysis. Assurance of high intracellular Ca^{2+} levels with BayK 8644 or A23187 did not affect kappa agonist attenuation of stimulated PI hydrolysis. Additional studies assessed kappa agonist effects on heart ventricle slices, a tissue in which kappa agonists increase intracellular Ca^{2+} . EKC and U-50,488 inhibited NE-stimulated PI hydrolysis dose-dependently. Together, these results provide evidence that kappa agonists do not attenuate PI hydrolysis by reducing intracellular Ca^{2+} .

706.18

OPIOID-DEPENDENT TYROSINE PHOSPHORYLATION IN NEURONS. D. A. Mangoura*, Department of Pediatrics, The University of Chicago Chicago, IL 60637.

In primary neuronal cultures derived from 6-day-old chick embryo cerebral hemispheres (E6CH) met-enkephalin elicits a transient activation of phospholipase D (PLD), which precedes a 2-fold increase in PKC- ϵ activity. Opioid-dependent PLD activation is blocked by the tyrosine kinase (TK) inhibitor herbimycin A, strongly indicating that the mechanism of opioid-dependent PLD activation involves tyrosine phosphorylation. Western blot analysis and immunoprecipitations with anti-phosphotyrosine antibodies revealed that 10 $^{-7}$ M met-enkephalin caused increases in protein tyrosine phosphorylation in E6CH. Among the reactive protein bands, three proteins of Mr 170K, 125K and 35K had the highest level of phosphorylation. Immunocytochemical analysis with anti-phosphotyrosine antibodies revealed that neurons are stained throughout their cell body, processes, and growth cones and the bases of filopodia in particular. In an effort to identify these TK substrates we have initiated studies on a tyrosine kinase, localized in focal adhesions, termed FAK. FAK is tyrosine-phosphorylated by neuropeptides that act through G protein-linked receptors. In our studies we compared abundance and level of tyrosine phosphorylation between E6CH neuronal cultures and total tissue of corresponding age, using immunoprecipitation with the 2A7 mAb to FAK. Neuronal cultures were enriched in FAK (>3fold by blot densitometry). In addition, immuno-reactivity for FAK was present in all cell bodies, neurites, varicosities and growth cones, in a homogeneous way. Following post fixation permeabilization, the nuclei were no longer visible, indicating a general cytosolic localization of FAK. These data suggest that opioid peptides are linked to tyrosine kinase and possibly FAK activation (supported by HD 09402).

707.1

PERIPHERAL EFFECTS OF NALOXONE IN MICE WITH INTESTINAL INFLAMMATION. O. Pol and M.M. Puig. Anesthesiology Research Unit, IMIM, Universidad Autónoma de Barcelona, Barcelona, Spain, E-08003.

The aim of the present study is to evaluate the effects of opioid antagonists on gastrointestinal (GI) transit in mice with diarrhoea associated with intestinal inflammation.

Diarrhoea was induced by p.o. administration of croton oil (CO), and demonstrated by weight loss ($P < .01$), and increased GI transit ($P < .05$) when compared to animals treated with saline (SS). The presence of inflammation in CO, was demonstrated by electron microscopy. GI transit was evaluated with a charcoal meal used as a marker. Administration of 0.1 mg/kg i.p. naloxone (NX) or NX-methiodide, induced a significant increase ($P < .05$) in GI transit in CO but not in SS animals. The inactive enantiomer (+)NX had no effect either in CO or SS animals. The delta antagonist naltrindole (3 mg/kg) also induced an increase in transit ($P < .01$) in CO animals, while MR-2266 (κ) had no effect.

Our results suggest that CO diarrhoea induces a local release of endogenous opiates (EO) which play an inhibitory role in the physiological response to intestinal inflammation in mice. It is postulated that the EO's released, could be a μ or δ agonist.

707.3

ACTIVATION OF BRAIN OPIOIDERGIC STRUCTURES IMPROVES ADAPTATION TO CHRONIC EXERCISE STRESS IN MICE V.K. Meshavkin^{1,2}, I.D. Surkina¹, N.V. Toropov², O.B. Ilyinsky². Central Sports Research Institute (Moscow, Russia)¹, Research Center Mental Health (Moscow, Russia)², Baylor/UT Southwestern Sports Science Research Center, Dallas, TX 75246.

Injection of opioids, direct electrical stimulation of the periaqueductal grey substance and transcranial electrical stimulation (TES—"electroanalgesia") increase velocity of nerve regeneration and wound healing in rats (Ilyinsky et al. '85;86;89). Naloxone blocked the effects. Recently we demonstrated that TES improved the response to another type of stress: acute exercise stress (Meshavkin et al. '93). In this study, we investigated the effects of TES on exhaustive swim performance after chronic exercise training, consisting of 21 days of swimming 30 min/day. 72 mice (BALB/c) were divided into: Group A (n=25) received 21 days of swim training and 3 days of TES (0.6mA, 30 min) prior to a swim to exhaustion, Group B (n=23) received training and sham stimulation and Group C (n=24) received training only. The results demonstrated that swim times for mice receiving TES was 143.3±12.8 min vs. sham - 100.1±7.0 ($p < 0.01$), vs. control - 80.3±4.1 ($p < 0.001$). So, TES improved the adaptive response to chronic exercise stress. Further work revealed that the timing of TES, influenced the results. Mice (n=23) that received the last TES 30 hrs prior to swim, swam shorter than those receiving TES 6 hours prior to swim but longer than sham (n=24) or control (n=23) mice ($p < 0.01$). Difference in swim time between sham and control, which existed after 6 hrs ($p < 0.01$), disappeared after 30 hrs Naloxone (0.5 mg/kg i.p., prior to TES) blocked the effects of TES. We concluded that brain opioidergic structures participate in the adaptation to chronic exercise training.

707.5

ULTRASTRUCTURE OF DYNORPHIN IMMUNOREACTIVE PERIKARYA AND AXON TERMINALS IN THE NUCLEUS ACCUMBENS: RELATIONS TO DOPAMINE AND SUBSTANCE P. E.J. Van Bockstaele*, K.N. Gracy and V.M. Pickel. Dept. of Neurol. and Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

Dynorphin (DYN) facilitates conditioned place aversion and reduces locomotor activity through mechanisms potentially involving direct activation of target neurons or presynaptic release of catecholamines or substance P (SP) in the nucleus accumbens (Acb). We examined the ultrastructural substrates underlying these actions by combining, in single sections of rat tissue, immunoperoxidase and gold-silver labeling for dynorphin 1-8 and either the catecholamine synthesizing enzyme, tyrosine hydroxylase (TH) or SP. DYN-labeled perikarya were spherical in shape, contained unindented nuclei and were closely apposed to other perikarya and dendrites, some of which also contained DYN immunoreactivity. Smooth endoplasmic reticulum and coated vesicles could also be identified in the cytoplasm on either side of the apposed membranes. The DYN neurons received afferent input from unlabeled as well as DYN and/or SP labeled terminals. Terminals containing one or both peptides were similar in their content of small and large dense core vesicles and their prominent formation of symmetric synaptic specializations. TH-labeled terminals formed primarily symmetric synapses with small dendrites and spines. In some cases, single dendrites were postsynaptic to both DYN and TH terminals. Additionally, presynaptic interactions were suggested by close appositions between DYN terminals (n=370) and other terminals that were unlabeled (41%), TH-labeled (10%), DYN-labeled (14%) or SP-labeled (11%). We conclude that DYN neurons may (1) communicate with other neurons through non-synaptic appositional contacts, (2) are most likely inhibited by synaptic input from terminals containing DYN and/or SP and (3) may interact presynaptically through contacts with axons either containing catecholamines or SP. Supported by NARSAD to EJVB and MH 40342 and DA 04600 to VMP.

EVIDENCE FOR ENDOGENOUS OPIOID-MEDIATED INHIBITION OF MEDULLARY NEURONS THAT MODULATE NOCICEPTIVE TRANSMISSION. Z.Z. Pan* and H.L. Fields. Dept. of Neurology & Physiology, UCSF, San Francisco, CA 94143.

There are significant numbers of endogenous opioid-containing cell bodies and terminals in the rostral ventromedial medulla (RVM) and the midbrain periaqueductal gray (PAG) which control nociceptive transmission at the spinal cord. Five-barrel micropipettes were used for extracellular recording of the RVM neurons and iontophoresis. On-cells (cells that increase firing just prior to tail flick (TF)) and Off-cells (cells that pause in firing before TF) were identified in the RVM in lightly anesthetized rats *in vivo*. Microinjection of bicuculline (30-40ng) into ventrolateral PAG inhibited >95% of the spontaneous firing of the ON-cell and blocked the TF. Iontophoresis of naloxone at current levels (20-30nA) which blocked the inhibition of the On-cell firing induced by iontophoretic morphine (20-30nA), consistently reversed most of the inhibitory effect on the On-cell firing produced by bicuculline or morphine (5µg) microinjected into the PAG. Naloxone was ineffective in the inhibition of the On-cell firing induced by iontophoretic clonidine (10-20nA), an α_2 adrenoceptor antagonist. The Off-cell firing was increased to >190% of control by PAG bicuculline and was not affected by iontophoretic naloxone. These results suggest that activation of the PAG neurons (probably through disinhibition by bicuculline) that produces antinociception could elicit the release of an endogenous opioid peptide(s) (most likely enkephalin) in the RVM and that the released opioid peptide(s) selectively inhibits a specific class of RVM neurons (On-cells) which has been shown to receive enkephalin-immunoreactive inputs and has a putative permissive or facilitating action on spinal nociceptive transmission. SPINAL CORD AND BRAIN OPIATE RECEPTORS: DIFFERENTIAL EFFECTS ON LARGE-FIBER VERSUS SMALL-FIBER SOMATOSENSORY PATHWAYS. A.D. Legatt*, C.E. Schroeder, I.B. Hollinger, and L.P. Seimon. Departments of Neurology, Neuroscience, Anesthesiology, and Orthopedic Surgery, Montefiore Medical Center and the Albert Einstein College of Medicine, Bronx, New York, 10467.

During spinal instrumentation and fusion surgery for scoliosis, morphine sulfate may be injected into the spinal subarachnoid space to provide postoperative analgesia, and bolus doses of intravenous narcotics may be given as part of the anesthesia regimen. Somatosensory evoked potentials (SEPs) to posterior tibial nerve stimulation are monitored to detect spinal cord compromise during this operation. We examined the effects of the narcotics on the cortical SEPs and on the SEPs recorded over the neck. The latter, often called "cervical SEPs", are generated near the cervicomedullary junction.

Bolus doses of intravenous narcotics did not alter the cervical SEPs, but did cause transient waveshape changes and attenuation of the cortical SEPs. In contrast, intrathecal narcotics affected neither the cortical nor the cervical SEPs, though they did produce analgesia.

These SEPs predominantly reflect activity in the large-fiber (dorsal column/lemniscal) somatosensory pathways. The differential narcotic effects on the cortical SEPs demonstrates that the large-fiber afferent somatosensory pathways are influenced by opiate receptors in the brain but not by those in the spinal cord. Since intrathecal narcotics produce analgesia, spinal cord opiate receptors affect the small-fiber (pain), but not the large-fiber, somatosensory pathways within the spinal cord.

REGULATION OF DYNORPHIN (DYN), TYROSINE HYDROXYLASE (TH) AND [Met⁵]ENKEPHALIN (ME) IN NEURONAL/GLIAL CO-CULTURES FROM RAT HYPOTHALAMUS G.-C.Wu*, M.K. McMillian and J.-S. Hong LMNI/NIEHS/NIH, RTP, NC 27709

Hypothalamic neurons contain the highest concentration of dynorphin in the brain and this neuropeptide may be an important modulator of feeding behavior as well as contribute to regulation of pituitary hormone secretion. Using a mixed hypothalamic cell culture model (confluent glia from PN7 pups, neurons from E16 fetuses), we have examined the second messenger pathways involved in regulation of DYN, and have compared DYN responses to changes in TH-immunopositive (TH+) cell number and to ME release. Elevating cAMP with forskolin (FSK, 10^{-6} M) increased DYN levels and also increased TH+ cell number. Dexamethasone (DEX, 10^{-7} M) increased dynorphin production, but did not affect ME release or TH+ cell number. FSK+DEX produced a near additive effect on DYN, but had a more pronounced effect on ME release (previously shown to be glia-derived). Depolarization with KCl (45 mM) more effectively increased TH+ cell number than DYN, as did activation of PKC with phorbol ester (10^{-7} M). DYN is regulated differently than TH and ME in these hypothalamic cultures.

DEVELOPMENT OF OPIOID TOLERANCE IN THE nTS IS ASSOCIATED WITH GENERAL CHANGES IN NEURONAL RESPONSIVENESS. C.J. Malanga*, W.W. Fleming and D.A. Taylor. Dept. of Pharmacology, West Virginia University School of Medicine, Morgantown, WV 26506-9223.

Chronic morphine exposure results in non-specific changes in the sensitivity of guinea-pig nucleus tractus solitarius (nTS) neurons to inhibitory agonists. While a 5.6-fold rightward shift of the dose-response curve to muscimol was observed, no significant shift of the dose-response curve to morphine was seen with cumulative drug applications. One explanation for the lack of altered sensitivity to morphine is acute desensitization, which can be avoided by application of single drug concentrations to spontaneously-active nTS neurons. Using standard extracellular electrophysiological techniques in brainstem slice preparations from vehicle- and morphine-pellet implanted guinea pigs, application of morphine (1 μ M) resulted in an 80 \pm 7% inhibition of firing in control and a 47 \pm 13% inhibition of firing in chronically morphine-exposed neurons, indicating a significant ($P<0.05$) 41% reduction in response to morphine in the morphine-treated group. Similarly, application of muscimol (0.3 μ M) to the same nTS neurons inhibited firing 57 \pm 11% in controls and 30 \pm 8% in morphine-treated preparations, indicating a significant ($P<0.05$) 47% reduction in response to muscimol in morphine-treated animals. Furthermore, elevation of extracellular K^+ (normal aCSF=5.0 mM [K^+]_o; depolarizing aCSF=7.28 mM [K^+]_o) resulted in an excitation of 58 \pm 13% in control neurons and an excitation of 146 \pm 47% in neurons from the morphine-treated group. Together, these findings suggest that 1) the *in vitro* nTS/brainstem slice preparation is an appropriate model system in which to study the development of opioid tolerance, and 2) the development of opioid tolerance in the nTS is associated with a non-specific, general change in the physiology of these neurons. PROOPIOMELANOCORTIN EXPRESSION IS REDUCED BY AN ANTISENSE OLIGONUCLEOTIDE

S.Spampinato*, G. Campana, L. Carboni and S.Ferri. Dept. of Pharmacology, Univ. of Bologna, 40126 Bologna, Italy.

Gene expression in mammalian cells can be suppressed by oligonucleotides complementary to the target mRNA. This strategy was explored as means of arresting translation of the prohormone precursor proopiometelanocortin (POMC). The synthesis of the POMC-derived peptides adrenocorticotropin (ACTH) and β -endorphin (β -END) was markedly reduced by an oligodeoxynucleotide (ODN) complementary to a region of β -END mRNA in AtT-20 cells, which retain many of the differentiated phenotypes of corticotrophs; this treatment did not affect the steady-state levels of POMC mRNA. Antisense ODN was stable in cell culture medium for 24 h and cellular uptake was low (\approx 2.5% of the added ODN); however, the intracellular levels of the ODN were sufficient to form a ribonuclease-resistant duplex with complementary cellular mRNA. Addition of ODN to the cell culture did not affect cell viability and proliferation. Microinfusion of the antisense ODN in the rat hypothalamic arcuate nucleus (0.625 μ g/h/60 h), where the majority of POMC-positive brain penkarya are located, significantly reduced ACTH-immunopositive neurons in the medio-basal hypothalamus (1430 \pm 87 vs 2590 \pm 90 in vehicle-treated rats, $p<0.01$; $n=7$) and antisense ODN-treated rats showed substantially less of the grooming behavior usually observed in a novel environment. Changes of nociceptive threshold, body temperature and of plasma levels of anterior pituitary hormones in rats exposed to antisense oligonucleotide will be presented.

THE OPIOID-INDUCED CURRENT IN RAT LOCUS COERULEUS (LC): ELECTROTONIC CONSIDERATIONS. R.A. Travaglini, M. Wessendorf, T.V. Dunwiddie and J.T. Williams. Vollum Institute, OHSU, Portland, OR 97201.

We utilized whole cell and intracellular recordings from slices of rat brainstem to study the effects of opioids on LC cells. The amplitude of the [met⁵] enkephalin-induced outward current (I_{ME}) was larger and E_{ME} was more negative in slices cut in the horizontal than in the coronal plane. Morphological analysis with neurobiotin indicated that cells from horizontal slices had a more extensive dendritic arborization than from the coronal plane. When the pipettes were filled with Cs gluconate, I_{ME} was still outward, did not reverse polarity even at strongly negative potentials and was blocked by BaCl₂. When recordings were made from 2 neurones, BaCl₂ and TTX induced synchronous oscillations in membrane potential. LC basic properties were not affected by carbenoxolone, a gap junction blocker which reduced I_{ME} , shifted the reversal potential to the right and prevented the Ba-induced oscillations. The results suggest that I_{ME} is mediated by an increase in gK only. Deviation from Nernst predictions for K⁺ result from poor space clamp which may be due to electrotonic coupling among LC cells.

OPIATES SUPPRESS FORSKOLIN-INDUCED EXCITATION OF GABAERGIC NEURONS IN THE MEDIAL SEPTUM/DIAGONAL BAND OF BROCA (MS/DBB).

M.Alreja* Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

This study explored the electrophysiological actions of opiates in the MS/DBB as receptor autoradiography and in situ hybridization studies show that the MS/DBB is rich in the μ type of opiate receptor and its mRNA (Mansour et al, 1988, 1993). Since, opiates have been shown to inhibit adenylate cyclase in various brain regions, this study focussed on interactions between opiates and the cAMP pathway. In extracellular recordings, the opioid peptide met-enkephalin (ENK) decreased spontaneous firing and blocked forskolin (an activator of adenylate cyclase)-induced excitation in a sub-population of MS/DBB neurons. In intracellular recordings from cholinergic and non-cholinergic type cells (Griffith, 1988), forskolin (10 μ M) or 8-Br-cAMP (2 mM) increased the number of bicuculline-sensitive, depolarizing synaptic potentials (i.e. reverse GABAergic IPSPs) seen with KCl-containing electrodes. ENK decreased the forskolin-induced IPSPs in a reversible manner. A subpopulation of MS/DBB neurons were directly excited by forskolin and 8-Br-cAMP; these cells most likely represent the GABAergic neurons that give rise to IPSPs in both cholinergic and non-cholinergic cells.

These results show that opiates inhibit forskolin-induced excitation of GABAergic neurons in the MS/DBB, presumably via inhibition of adenylate cyclase.

NORADRENERGIC DRIVE ON OXYTOCIN NEURONES DURING NALOXONE-PRECIPIATED MORPHINE WITHDRAWAL. N.P.Murphy, S.C.H.Brown, S.G.J.Munro, G.Leng, R.G.Dyer*, S.J.A.Russell. Dept. Neurobiology, Babraham Institute, Cambridge, CB2 4AT, U.K. *Dept. Physiology, Medical School, University of Edinburgh, Edinburgh EH8 9AG, U.K.

Oxytocin neurones in the supraoptic nucleus (SON) develop dependence on morphine given intracerebroventricularly (i.c.v.) over five days (up to 5 μ g/h) as revealed by naloxone (NLX) precipitated morphine withdrawal which increases oxytocin neurone firing rate by 3.5 fold. We have studied the importance of the noradrenergic input for the expression of this withdrawal excitation. (1) NLX (5mg/kg) precipitated withdrawal-induced Fos expression in tyrosine hydroxylase neurones in the nucleus tractus solitarius. These neurones are known to project to the SON and mediate the response of oxytocin neurones to systemic cholecystokinin-8S (CCK). (2) Electrophysiological extracellular recording was carried out in urethane anaesthetized rats. Oxytocin neurones were identified by firing pattern, antidromic activation and response to CCK. The excitatory response to i.v. CCK injection was similar before (mean \pm s.d.: 1.06 \pm 0.39 Hz increase, over 5 mins) and after NLX in morphine-infused rats (1.18 \pm 0.46 Hz, $n=11$), though smaller than in morphine naive animals. (3) Clonidine (2.5 mg/kg i.v.), an α_2 adrenoceptor agonist, attenuated the rise in oxytocin secretion after withdrawal (mean \pm s.e.m., vehicle: 702 \pm 186 pg/ml vs. + clonidine: 303 \pm 113 pg/ml after 10mins, $n=7$, $p<0.05$, one-way t-test). (4) Electrical activity in oxytocin neurones after withdrawal was reduced by both acute (25 μ g) and continuous (0.32 to 1.62 μ g/min for >20 min) administration of i.c.v. α_1 adrenoceptor antagonists such as benoxathian. This effect could be reversed by simultaneous infusion of the α_1 adrenoceptor agonist phenylephrine. These results indicate that an excitatory, or permissive, noradrenergic input to oxytocin neurones drives the expression of opiate withdrawal-induced excitation.

PAIN-PRODUCING SUBSTANCES AUGMENT I_h IN NODOSE GANGLION NEURONS. S. L. Ingram*¹ and J. T. Williams², Department of Pharmacology¹ and Vollum Institute², Oregon Health Sciences University, Portland OR 97201.

Our previous work in the nodose ganglion has shown opioid inhibition of forskolin-stimulated I_h in a small subpopulation of nodose neurons. Pain-producing substances which are known to increase cAMP levels (PGE₂, bradykinin, and 5-HT) also elicit an inward current (at -60 mV) in a subpopulation of neurons. The mean amplitude of the inward currents are as follows: PGE₂ (1 μ M), 120 \pm 39 pA ($n=4$); bradykinin (1 μ M), 263 \pm 88 pA ($n=2$); and 5-HT (10 μ M), 122 \pm 12 pA ($n=5$). Cs⁺ (2 mM) blocked the currents in 7/7 neurons regardless of drug applied. Thus, we have preliminary evidence that agents other than forskolin are effective in augmenting I_h . In an attempt to further identify responsive neurons on the basis of conduction velocities, intracellular recordings from guinea pig isolated nodose ganglion preparations were made. In 75% of neurons with conduction velocities <1.5 m/s ($n=28$), only 35% expressed an I_h current. In contrast, 83% of the neurons with conduction velocities >1.5 m/s had an I_h current. These results suggest that A δ neurons may be regulated by both pain-producing substances and opioids through opposite actions on adenylate cyclase. INTERACTION OF MK-801 WITH THE DEVELOPMENT OF MORPHINE TOLERANCE AND DEPENDENCE IN THE ISOLATED SPINAL CORD OF THE NEONATAL RAT. J.A. Bell* and C.L. Beglan. Neuroimaging and Drug Action Section, Intramural Research Program, National Institute on Drug Abuse, Baltimore, MD 21224.

Chronic co-treatment of rats with opioids and MK-801 (MK) inhibits the development of tolerance and physical dependence in intact animals. The mechanism of this phenomenon is obscure. Use of the isolated spinal cord from neonatal rat eliminated the potential interference from behavioral effects. Newborn rats were treated with either morphine (M) or MK + M in incrementally increasing doses for 3 days. The spinal cord was set up in a superfusion bath. Nociceptive reflexes elicited by electrical stimulation or capsaicin were inhibited by M (10 nM - 10 μ M) in controls ($18 \pm 10.5\%$ S.E.M. depression of capsaicin response at 10 nM to $81 \pm 3.4\%$ at 10 μ M). In cords of neonates treated with chronic M, additional doses of M did not depress nociceptive reflexes indicating the development of tolerance. Combination of MK (0.3 mg/kg) with M did not inhibit the development of tolerance. The development of dependence evidenced by increases in naloxone-induced spontaneous activity was not affected by co-treatment with MK. Thus, MK combined with chronic treatment with M failed to block the development of tolerance and physical dependence in this model.

We conclude that the spinal cord has to be mature and/or act in synergy at least with the periphery (spinal) for MK inhibition of development of tolerance and physical dependence to be realized.

707.15

EFFECTS OF DAMGO, NALOXONE AND ACETYLCHOLINE ON THE FIRING OF MEDIAL PREFRONTAL CORTICAL NEURONS. J. L. Giacchino* and S. V. Henriksen. Dept. of Neuropsychology, The Scripps Research Institute, La Jolla, CA 92037.

Extracellular recordings were made from fifty-six spontaneously firing neurons of the medial prefrontal cortex (mPFC) in halothane-anesthetized rats. Areas investigated include the dorsal anterior cingulate, prelimbic, and infralimbic components of the prefrontal cortex. Previous work in our laboratory demonstrated that systemic morphine decreases neuronal activity in the mPFC, and that this effect can be reversed by systemic naloxone. As the mPFC is suggested to function in reinforcement pathways and drug-related behaviors in the rat, the action of opiates, specific opioid receptor agonists and antagonists at the cellular level is of interest. Microiontophoretic application of the selective mu agonist DAMGO (1mM) decreased firing of most mPFC neurons studied. This drug effect was typically slow in onset and often prolonged (approx. 3-10 min). This effect could be blocked or reversed by naloxone (2mM). Iontophoresis of naloxone alone had no effect on most mPFC neurons. As expected, acetylcholine (1M) increased firing in the majority of spontaneously active mPFC cells. In addition, ACh pulses elicited transient increases in cell firing during DAMGO-induced depression, and also during concurrent application with naloxone. Even when mPFC neuronal firing was completely suppressed following DAMGO, ACh was able to elicit firing, implying a receptor specific effect. These results suggest that activation of mu receptors may hyperpolarize mPFC neurons and/or may function presynaptically to inhibit excitation (Supported by SDAC #3-5-94271 and NIDA #3-5-94219)

HILAR MEDIATED EXCITATION AND LTP OF THE DENTATE GRANULE CELL. GW Terman¹, ML Simmons² and C Chavkin². Departments of Anesthesiology¹ and Pharmacology², University of Washington, Seattle, WA 98195.

Kappa agonists inhibit excitatory neurotransmission and long-term potentiation (LTP) in the hippocampus via a decrease in amino acid release from both hippocampal perforant path and mossy fiber terminals. We now report a third site of kappa opioid inhibition of excitatory neurotransmission in the hilar region of the dentate gyrus.

Extracellular recordings were made in the granule cell layer of the dentate gyrus of the guinea pig hippocampal slice. The hilar pathway was selectively stimulated by making a knife cut through the molecular layer to sever the perforant path and placing the stimulating electrode in the molecular layer across the cut from the recording electrode.

In the presence of bicuculline (10 μ M), stimulation (0.3 μ s, 50-300 μ A) of the hilar pathway elicited granule cell population spikes whose amplitudes were decreased by the kappa₁ agonist, U69593 (1 μ M) in a nonbinaltorphimine (100nM) reversible manner. LTP in this pathway was blocked by the NMDA antagonist, APV (25 μ M), and by U69593. Without bicuculline, no population spikes were elicited from the hilar path and no LTP could be induced. However, following LTP, population spikes were evident with or without bicuculline.

Thus kappa opioids modulate neural excitability in at least three distinct regions of the hippocampus. Although the hilar pathway studied here is normally under strong GABA_A control, plastic changes appear capable of overriding GABA inhibition - perhaps leading to hyperexcitable states. Supported by DA04123 and the Foundation for Anesthesia Education and Research with a grant from Abbott Labs.

NEUROPROTECTIVE ACTIVITY OF THE SELECTIVE δ -OPIOID SNC-80 IN VITRO. F. Tortella*, K. Klette, S. Calderon*, K. Rice* and M. DeCoster. Walter Reed Army Inst. Res., Washington, DC 20307 and LMC, NIH, Bethesda, MD 20892.

SNC-80 is a new, highly selective non-peptide δ -opioid (Calderon et.al., J. Med. Chem. In Press, 1994). Unlike other peptide and non-peptide opioids, high i.c.v. doses of SNC-80 (up to 800 μ g) fail to elicit EEG seizures or convulsant activity in rats. In contrast, SNC-80 causes a complex behavioral response consisting of initial, brief periods of stupor followed by prolonged episodes of intense hyperactivity associated with marked EEG theta-driving (unpublished observations). We have begun to assess the effects of SNC-80 in a neuronal culture model of CNS excitotoxicity. In the present study SNC-80 was added to primary rat cortical cultures immediately prior to 80 μ M glutamate. Neurotoxicity and/or neuroprotection was assessed 18 h later. LDH measurements and morphological evaluation revealed that SNC-80 produced a concentration dependent neuroprotection. Compared to glutamate alone, 5, 20, and 40 μ M SNC-80 protected neurons to the extent of 16, 30, and 60%, respectively. Intracellular calcium ([Ca²⁺]_i) was monitored as an indicator of glutamate-induced neuronal injury in these same cultures. While glutamate consistently produced a sustained increase in [Ca²⁺]_i in 83% of the neurons analyzed, treatment with SNC-80 (50-100 μ M) resulted in a shift in the [Ca²⁺]_i dynamics such that greater than 80% of the neurons demonstrated only biphasic or transient increases in [Ca²⁺]_i, an event previously shown to correlate with less toxic concentrations of glutamate (DeCoster et.al., NeuroReport, 1992). These results demonstrate that SNC-80 is neuroprotective in vitro and suggest a potential utility of selective δ -opioids for attenuating CNS injury.

707.16

DISTRIBUTION OF DYNORPHIN mRNA IN THE CENTRAL NERVOUS SYSTEM OF THE RAT. P. Cianchetta, D.E. Lennard, D. Bronstein & I. Merchenthaler*. LMNI, NIEHS, NIH, RTP, NC 27709.

The distribution of dynorphin mRNA in brain and spinal cord of adult male rats was studied with *in situ* hybridization histochemistry. Intact or colchicine-treated animals were either (a) perfused with paraformaldehyde (PF) and sectioned with a vibratome or (b) frozen on dry ice, cut on a cryostat, thaw-mounted, and post-fixed with PF. Free-floating vibratome sections and mounted slides were treated with triethanolamine, then dehydrated with ethanol. While vibratome sections were rehydrated, cryosections were airdried after dehydration. Sections were hybridized with a ³⁵S-UTP-labeled probe (bp 100-835 of dynorphin cDNA), incubated overnight at 55 C and stringently washed to remove nonspecific label. Subsequently, vibratome sections were mounted on gelatin coated slides. Slides were dipped in liquid photographic emulsion and exposed for ten to twenty days. Evaluation of autoradiograms revealed that the location of dynorphin mRNA was in good agreement with the location of the peptide detected by immunocytochemistry. However, we were able to detect mRNA in several regions of the central nervous system in which no peptide was reported. These include the olfactory bulb, the island of Calleja, posterior thalamic nuclei, CA1 and CA2 regions of the hippocampus, optic tectum, spinal trigeminal nucleus, etc. In addition, the number of mRNA-containing perikarya was higher than the number of peptide-containing perikarya previously observed in cerebral cortex. The use of 30 μ m vibratome sections resulted in a shorter exposure time and less background than the use of 16 μ m cryosections. Colchicine-treatment had no significant effect on the level of dynorphin mRNA.

708.1

IMPLICATION OF CCK IN THE POTENTIATION OF THE NMDA RESPONSE INDUCED BY SIGMA LIGANDS IN THE RAT DORSAL HIPPOCAMPUS. N. Lavoie*, B. Gronier and G. Debonnel, Neurobiological Psychiatry Unit, McGill University, Montréal, Québec, Canada, H3A 1A1.

Sigma (σ) ligands modulate the response of pyramidal neurons to NMDA in the CA₃ region of the dorsal hippocampus. It has also been found that CCK is involved in the effects induced by σ ligands on colonic motility. The present experiments were undertaken to determine if this interaction is also present in the CNS. Using five-barrelled glass micropipettes for extracellular recordings and microiontophoresis, we evaluated the effects of different CCK₈ and CCK₆ receptor antagonists on the modulation of the NMDA response, induced by the intravenous administration of low doses of the σ ligands DTG, (+)pentazocine and JO-1784 on rat CA₃ dorsal hippocampus pyramidal neurons. The potentiation of the NMDA response induced by these σ ligands was abolished by the specific CCK₆ receptor antagonist SR 27897, but not by the CCK₈ antagonist CI-988. CCK-8S, applied with a low current, insufficient to induce an increase of the firing activity by itself, markedly potentiated the response of NMDA, without affecting that of QUIS. SR 27897 applied during the potentiation of the NMDA response by CCK-8S, markedly reduced this potentiation. In contrast, the selective CCK₆ receptor antagonists CI-988 applied microiontophoretically, and PD 135158 administered intravenously (3mg/kg), failed to abolish the effect of CCK-8S on the NMDA response.

Our results suggest that the potentiation of the NMDA response of hippocampal pyramidal neuron by σ ligands involves the activation of CCK₆ receptors. Since CCK-8S, by itself, potentiates markedly and selectively the NMDA response, these results also suggest that, in the CA₃ region, σ ligands might induce their modulatory effect on the NMDA response by promoting the release of CCK-8S.

708.3

ENDOGENOUS DYNORPHIN RELEASE IN THE GUINEA PIG DENTATE MOLECULAR LAYER IS MEDIATED BY L-TYPE CALCIUM CHANNELS.

M. L. Simmons¹, G. W. Terman², S. M. Gibbs¹, and C. Chavkin¹, Depts. of Pharmacology¹ and Anesthesiology², University of Washington, Seattle, WA 98195.

In the dentate molecular layer, dynorphins are released from granule cell dendrites and inhibit glutamate release via kappa₁ opioid receptors on perforant path afferents. In the CA₃ region, dynorphins are released from, and act upon, mossy fiber terminals. In both regions, dynorphins also have been shown to inhibit the induction of LTP. The present study investigated the roles of Ca²⁺ channel subtypes in mediating the release of endogenous dynorphins. High frequency stimulation was applied to granule cells to induce dynorphin release, which was detected as a >20% depression of the field EPSP that lasted 2-15 minutes. In the dentate molecular layer, the L-type Ca²⁺ channel blockers nifedipine (10 μ M) and PN200-110 (5 μ M) inhibited the dynorphin-mediated depression. These drugs did not alter the effect of kappa receptor activation by exogenous agonist (1 μ M U69593) application, nor did they affect the field EPSP responses themselves. Therefore, the L-type channel blockers inhibited dynorphin release without inhibiting the action of dynorphin or the release of glutamate. Furthermore, nifedipine and PN200-110 facilitated the induction of LTP in the dentate gyrus. This result is consistent with our previous studies showing that the kappa opioid receptor antagonist, norbinaltorphimine, also facilitates the induction of LTP. In contrast to the effects observed in the dentate gyrus, the L-type channel blockers had no effect on dynorphin release from mossy fibers in CA₃. Supported by DA04123.

708.5

EFFECTS OF MORPHINE ON LIVER ORNITHINE DECARBOXYLASE (ODC) ACTIVITY AND PLASMA INSULIN AND GLUCOSE LEVELS IN RAT PUPS. B. Aliche, M.B. Bartolome and J.V. Bartolome*, Department of Pharmacology, Duke University, Durham, N.C. 27710

We have previously reported that central, but not peripheral, administration of β -endorphin (BE) to infant rats markedly decreases basal levels of ODC (a key growth regulatory enzyme) activity throughout the body, as well as tissue ODC responsiveness to classical trophic factors. Based on these and other observations we have hypothesized that endogenous CNS BE plays a prime role in controlling postnatal development. The question remains as to whether perinatal exposure to exogenous opiates causes a pattern of developmental effects similar to those produced by BE.

In the current study we found that, like BE, intracerebroventricular (i.c.v.) administration of 2 μ g of morphine to 6-day-old rats decreased basal levels of liver ODC activity. In addition, hepatic ODC responsiveness to subcutaneously (s.c.) administered insulin (I) or growth hormone, two important trophic hormones, was almost totally arrested in pups pretreated i.c.v. with morphine. Also similar to BE, i.c.v. morphine increased the half-life of exogenously administered I. As expected, hypoglycemia in rats injected with morphine i.c.v. plus I s.c. was more marked than in pups given I alone. Equivalent results were obtained in animals given morphine s.c.

The data obtained suggest that the developmental disabilities commonly observed in infants born to opiate-addicted mothers could result, at least in part, from an exacerbation of the effects of endogenous opioids on tissue ODC expression and on insulin/glucose metabolism. NEUROMODULATORY EFFECTS OF SIGMA LIGANDS IN THE RAT NUCLEUS ACCUMBENS. G. Debonnel* and B. Gronier, Neurobiological Psychiatry Unit, McGill University, Montréal, Québec, Canada, H3A 1A1.

The present study was undertaken to investigate *in vivo* the effects of sigma (σ) ligands on neuronal firing activity in the dorsomedial part of the rat nucleus accumbens. Using extracellular recording and microiontophoresis, the effects of applications, or intravenous (i.v.) administration, of the selective σ ligands (+)pentazocine and JO-1784, on the neuronal firing activity induced by NMDA, were assessed. Microiontophoretic application, as well as i.v. administration (20 μ g/kg) of JO-1784 had no significant effect on the spontaneous firing activity, but produced a marked increase of the activation induced by NMDA. This potentiating effect was reversed by the i.v. administration of the selective σ antagonist JO-5220 (150 μ g/kg). (+)Pentazocine, administered i.v. at 10 or 30 μ g/kg, failed to modify significantly the NMDA-induced excitation. Since the nucleus accumbens receives a rich dopaminergic (DA) innervation, we have also explored the effects JO-1784 on the DA modulation of the NMDA response. Microiontophoretic applications of low currents of DA significantly reduced the excitatory response of accumbens neurons to NMDA. JO-1784, simultaneously applied with DA, enhanced significantly its inhibitory effect.

These findings suggest that the σ ligand JO-1784 exert a modulatory effect on NMDA-induced activation in the rat nucleus accumbens, in keeping with our previous observations in the CA₃ region of the dorsal hippocampus. The lack of effect of (+)pentazocine is in contrast with our results in the dorsal hippocampus and constitutes another argument suggesting that (+)pentazocine acts on a different subtype of σ receptor than JO-1784, not present in the nucleus accumbens. In addition, the fact that JO-1784 increases the neuronal sensitivity to DA in rat nucleus accumbens neurons suggests the existence of a functional interaction between the σ and DA receptors.

ENDOGENOUS OPIOID PEPTIDES MEDIATE THE SUCKLING INDUCED PROLACTIN INCREASE IN POST-PARTUM FEMALE RATS. S. Klosterman, D. Prunty, P. Callahan and J. Janik*, Miami University, Dept of Zoology, Oxford, Ohio 45056.

We have reported that β -endorphin is a potent stimulus for prolactin secretion in virgin female rats (Kehoe, et al., Neuroendo 57:875, 1993). Doses as low as 25 ng were capable of producing a prolactin secretory response that mimicked the prolactin response to suckling in post-partum female rats. In addition, antiserum to β -endorphin totally abolished the suckling-induced Prolactin increase in post partum, lactating female rats. The purpose of this study was to determine whether or not endogenous opioid peptides (EOP) from the enkephalin or dynorphin family were involved in the regulation of Prolactin secretion during lactation.

Lactating, female, Sprague-Dawley rats between days 8-12 post-partum were used in all experiments. Animals were surgically implanted with chronic intraventricular (ivt) cannula into the lateral ventricle on day 2 post-partum. After at least a 5 day recovery period and one day prior to the experiment, animals were implanted with chronic jugular cannula to facilitate blood withdrawal. On the day of the experiment, dams were separated from their pups for six hours prior to ivt administration of specific antisera to met-enkephalin or dynorphin. Blood samples were withdrawn immediately prior to antiserum injection and at 15 minute intervals, up to 1 hour, after the onset of suckling.

Antiserum to each one of the EOP effectively blocked the suckling-induced Prolactin increase. These results indicate that met-enkephalin and dynorphin are both important in the suckling-induced Prolactin increase. The mechanism(s) responsible for this action is not known. It is also not clear which receptor subtype mediates this response or if there is interaction among the different EOP and/or their receptor subtypes. (This work was supported by NIH grant # 1 R15 HD30375-01 to JJ and PC).

MORPHINE TOLERANCE/DEPENDENCE: REVERSAL FROM INHIBITION TO ENHANCEMENT OF cAMP FORMATION. L. Wang* and A.R. Gintzler, Dept. of Biochemistry, SUNY Hlth. Sci. Ctr. at Brooklyn, N.Y. 11203

This laboratory has previously demonstrated that sufentanil can produce a naloxone-reversible increase or decrease in the stimulated formation of cAMP in the myenteric plexus, depending on the concentration of opioid employed. Low doses of opioid (10⁻¹⁰ M) enhance whereas higher concentrations (10⁻⁸ M) inhibit the magnitude of cAMP formation. On the basis of these results, we suggested that μ -opioid receptors are positively as well as negatively coupled to adenyllyl cyclase. In the present study, the effect of chronic *in vivo* morphine exposure on the balance between opioid excitatory and inhibitory actions was investigated. In chronically morphine-treated preparations, the magnitude of stimulated cAMP formation, while in the presence of an inhibitory concentration of sufentanil, is indistinguishable from that which occurs in opiate naive preparations (in the absence of exogenous opioid). This indicates the development of tolerance to the negative modulation of stimulated enteric cAMP formation by sufentanil. However, in 'addicted', tissue the magnitude of increase in cAMP formation produced by electrical stimulation, in the presence of a previously inhibitory concentration of sufentanil, is significantly larger than in 'addicted' tissue that had been washed in morphine-free Krebs' or Krebs' solution containing naloxone. Thus, the equivalence between the magnitude of stimulation-induced increase in cAMP formation observed in naive vs 'addicted' tissue in the presence of sufentanil, is due to the ability of an originally inhibitory concentration of opioid to enhance or facilitate stimulated formation of cAMP. It is suggested that tolerance/dependence to the opioid inhibition of stimulated cAMP formation results not only from the loss of inhibitory potency but from the reversal to enhancement.

THE EFFECT OF HALOPERIDOL ON PREPROENKEPHALIN GENE EXPRESSION IN THE RAT ANTERIOR PITUITARY. E. Tang* and T.S.M. Lau. Department of Physiology, Faculty of Medicine, University of Hong Kong, Hong Kong.

To study the effect of haloperidol on the gene expression of preproenkephalin in the anterior pituitary, male SD rats weighing 250-300g were injected for 3 weeks with 2mg/Kg haloperidol i.p. The anterior pituitary was homogenized in AT buffer using RNasin as RNase inhibitor. Cytoplasmic RNA was obtained after digestion with proteinase K and the equivalent of about one-sixth of an anterior pituitary was assayed for preproenkephalin mRNA using solution hybridization - RNase protection assay. Standards and P-32 labelled riboprobes were prepared from linearized plasmid DNA's (courtesy of Dr. J. Hong), using SP6 polymerase. An actin probe (gift of Dr. D. Autelitano) was used to normalize the values, which are expressed as pg preproenkephalin mRNA per pg actin mRNA. It was found that haloperidol treatment resulted in a significant decrease of preproenkephalin mRNA contents in the anterior pituitary, and this correlates well with the decrease of met-enkephalin levels as measured by RIA. Dopamine receptor blockade may therefore lower the met-enkephalin level in the anterior pituitary through a decrease in preproenkephalin synthesis.

TREATMENT WITH ANTISENSE OLIGODEOXYNUCLEOTIDE TO THE CLONED MOUSE CCK₈ RECEPTOR PRODUCES NALTRINDOLE-SENSITIVE ENHANCEMENT OF MORPHINE ANTINOCICEPTIVE POTENCY. T.W. Vanderah, P. Peterson, R. Horvath, J. Lai, H.I. Yamamura and F. Porreca* Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

CCK may function as an endogenous anti-opioid. Thus, intracerebroventricular (i.c.v.) L365,260 (CCK₈ receptor antagonist) increases the antinociceptive potency of i.c.v. morphine. In mice, the modulatory effect of CCK₈ antagonists (but not the direct morphine antinociception) is sensitive to naltrindole (NTI, δ antagonist), suggesting the involvement of the δ opioid receptor (DOR). Furthermore, treatment with antisense raised against [Leu]⁵enkephalin, but not [Met]⁵enkephalin, blocks the L365,260 modulation of morphine. Here, the possible involvement of the DOR in this modulatory effect was further evaluated using treatments with 20-base oligodeoxynucleotides (oligos) directed towards the N-terminal portion of the cDNA of the mouse cloned CCK₈ receptor. Male, ICR mice (20-35 g) received twice daily i.c.v. injections of saline, antisense or mismatch oligo (12.5 μ g) for 3 days. Nociceptive thresholds in control or i.c.v. morphine-injected mice were determined on day 4 using the 55°C warm-water tail-flick assay. Treatment with the oligos did not alter nociceptive threshold alone. Antisense, but not mismatch, oligo displaced the morphine dose-effect curve to the left by 4.9-fold. NTI (19 mg/kg, s.c.) also did not alter nociceptive threshold alone and did not affect morphine antinociception. NTI pretreatment on day 4, however, blocked the leftward shift of the morphine dose-effect curve in antisense oligo treated mice. Decreases in CCK₈ receptor number were shown using [³H]SNF8702 (CCK₈ ligand) only in midbrain and striatum. These data suggest a tonic inhibition of enkephalin release by CCK via CCK₈ receptors. The subsequent enhancement of morphine antinociceptive potency may result by actions of enkephalins (possibly [Leu]⁵enkephalin) at the DOR.

KAPPA RECEPTOR mRNA LOCALIZATION IN THE GUINEA PIG BRAIN: COMPARISON TO [³H]BREMAZOCINE AND [³H]U69,593 BINDING. A. Mansour, C.A. Fox*, S. Burke, G. Xie, H. Akil and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Three opioid receptor types have been identified in the CNS that are referred to as μ , δ , and κ . Given the recent cloning of the guinea pig κ receptor (Xie et al, Proc. Natl. Acad. Sci. USA, in press), this study examines the mRNA distribution of the κ receptor in the guinea pig brain and compares it to the kappa binding sites defined either by [³H]U69,593 (4.3nM) or [³H]bremazocine (0.6nM, in the presence of a 300 fold excess of DAMGO and DPDPE) using *in situ* hybridization and receptor autoradiographic techniques. Kappa receptor mRNA was identified with a 35S-cRNA probe generated to Eco R1-Bam H1 fragment of the guinea pig receptor (602-1334) that spans from extracellular loop 1 to near the C-terminal end of the protein coding region. An excellent correspondence is observed between κ receptor binding sites and mRNA in the deep layers of cortex, caudate-putamen, nucleus accumbens, olfactory tubercle, dentate gyrus, and cerebellum. Differences were observed, however, in such brain regions as the substantia nigra and ventral tegmental area, where κ mRNA is localized in the substantia nigra, pars compacta and ventral tegmental area, while κ binding is predominantly in the pars reticulata. This suggests κ receptors may be synthesized in the striatum and transported to the substantia nigra, pars reticulata, or alternatively, may represent binding sites on dendrites of pars compacta neurons. Similarly, κ receptors are synthesized in the substantia nigra and ventral tegmental area and transported to the striatum. Species comparisons to the rat κ mRNA distribution will be discussed.

ROLE OF BRAIN OPIOIDS IN THE DEVELOPMENT OF HYPERTENSION IN STRESSED BORDERLINE HYPERTENSIVE RATS. A.A. Houdi* and M. Welch College of Pharmacy and THRI, University of Kentucky, Lexington, KY 40546.

Opioid peptides have been implicated in modulating autonomic function under basal and stressful conditions, but their role in regulating cardiovascular function remains unclear. The borderline hypertensive rat (BHR) is a unique and useful animal model of neurogenic hypertension because its genetic background makes it susceptible to the hypertensive effect of stress. In this study, we examined the effect of a time limited period of restraint stress in the development of hypertension and the role of brain opioids on the development and maintenance of hypertension in 8-9 week old BHR. We found that restraint stress, 2 hr daily, 5 days a week for 5 weeks, caused a significant rise in systolic blood pressure one week after beginning stress treatment. This increase in blood pressure (BP) continued throughout the period of stress (5 weeks). Moreover, stressed BHR continued to have higher blood pressure compared to the control group 10 weeks after the end of stress (182 ± 8.1 mmHg vs 158 ± 3 mmHg, $P < 0.05$, $n=10$). Pretreatment with naloxone (1 mg/kg, intra-arterially) attenuated the increase in blood pressure due to acute restraint stress (10 min) applied 5 min after naloxone. Intracerebroventricular (icv) administration of the μ -opioid receptor agonist DAMGO (5 nmole), produced an increase in BP (Δ MAP = 16.6 ± 2.3 mmHg) and heart rate (Δ HR = 89.6 ± 13.2 bpm). This increase in BP and HR peaked at 5-10 min and remained elevated. ICV administration of the delta opioid agonist DPDPE (50 nmole) or saline (4 μ l) had no effect on BP or HR. Restraint stress in saline-treated rats evoked an increase in BP and HR. Rats pretreated with DAMGO showed no further alteration in BP or HR responses to stress applied 20 min after drug treatment. These data support the involvement of μ -opioid receptors in the development and maintenance of hypertension due to stress. Supported by UKMC & KTRB.

DIFFERING ULTRASTRUCTURAL RELATIONSHIPS BETWEEN ENKEPHALIN AND GABA CONTAINING NEURONS WITHIN THE HIPPOCAMPAL FORMATION. K. Commons* and T.A. Milner, Dept. of Neurology and Neuroscience, Cornell Univ. Med. Coll., New York, NY 10021.

Electrophysiological studies have suggested that the excitatory actions of opioids in the hippocampal formation are mediated by inhibition of GABA interneurons; however, an anatomical basis for this interaction has never been demonstrated. Thus, we sought to determine the ultrastructural relationship of leu⁵enkephalin (LE)-containing terminals and GABAergic neurons using double labeling immunohistochemistry throughout the hippocampal formation. In the s. lacunosum-moleculare of CA1, LE-containing terminals ($n=99$) occasionally contacted GABA labeled perikarya and dendrites (15%) and were often in apposition to GABA labeled (13%) axon terminals. In the outer molecular layer of the dentate gyrus, LE-containing terminals ($n=65$) almost exclusively contacted unlabeled dendrites, although they were often in the same field as GABA containing terminals. In contrast, many small round LE-containing terminals and larger LE-labeled mossy fiber boutons in the infragranular hilus of the dentate gyrus ($n=119$) often synapsed on GABAergic perikarya and dendrites (40%), but were rarely in apposition to GABA containing terminals. However, LE-containing mossy fiber boutons in the s. lucidum ($n=85$) most often contacted unlabeled dendrites while GABA-labeled terminals were in the same field. These results suggest that in CA1 enkephalin may modulate GABAergic neurons directly through contacts with both dendrites and terminals, while in the hilus enkephalin may primarily modulate GABAergic neurons through contacts on dendrites. In contrast, the primary effects of enkephalin in the outer molecular layer of the dentate gyrus and in s. lucidum of CA3 may not be mediated through an interaction with GABAergic interneurons. MULTIPLE EXPRESSION OF OPIATE TOLERANCE IN HYPOTHALAMIC ARCULATE NEURONS. M.J. Kelly*, G. Zhang, A. H. Lagrange and O. K. Ronnekleiv. Department of Physiology, Oregon Health Sciences U., Portland, OR 97201

To determine if hypothalamic arcuate (ARC) neurons develop tolerance to μ -opioids, intracellular recordings were made with biocytin-filled electrodes in ARC neurons in hypothalamic slices from placebo and chronic morphine-treated (4 x 75 mg pellets for 2 d + 6 more pellets for a total of 6-8 d), ovariectomized female guinea pigs. A dose-response curve was generated measuring the hyperpolarization in response to the selective μ -opioid agonist DAMGO. β -endorphin (β END) neurons were identified using double labeling. Chronic morphine caused both a decreased potency ($EC_{50} = 245 \pm 22$ nM, $N=12$ vs. 63 ± 3 nM in controls, $N=50$), a decreased efficacy ($\Delta V_{max} = -7.1 \pm 1.1$ mV vs. -10.7 ± 0.6 mV) and a 60% decrease in ΔG_{DAMGO} in all β END neurons ($N=5$) and other ARC neurons ($N=7$). In another population of tolerant ARC neurons from morphine-treated animals ($N=11$), DAMGO was less potent ($EC_{50} = 110 \pm 4$ nM) without a change in efficacy. A third population of neurons ($N=5$) did not exhibit any signs of tolerance with morphine treatment. Morphine-tolerant neurons also exhibited a higher incidence of dye-coupling versus cells from controls (20% vs. 4%, χ^2 , $p < 0.01$). Therefore, chronic morphine uncouples μ -opioid receptors from K⁺ channels and increases dye-coupling in ARC neurons. Since β END neurons show widespread projections throughout the forebrain, this would not only affect neuroendocrine but also homeostatic and reward circuits. (supported by PHS grant DA05158)

708.13

KAPPA OPIOID RECEPTOR ACTIVATION MODULATES EXCITATORY SYNAPTIC RESPONSES OF THE RAT SPINAL DORSAL HORN NEURONS. Li, Koic*, G. Cheng and M. Randic, Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011.

To determine how κ -opioid receptor agonists affect the primary afferent neurotransmission, we examined the actions of dynorphin A_{1-17} (Dyn_{1-17}), *trans*-(\pm)-3,4-dichloro-N-methyl-N-[2-(1-pyrrolidinyl)-cyclohexyl]-benzeneacetamide (U-50,488H) and ($5\alpha,7\alpha,8\beta$)-(-)-N-methyl-N-[7-(1-pyrrolidinyl)-1-oxaspiro(4.5)dec-8-yl]-benzeneacetamide (U-69,593) on synaptic transmission between dorsal root afferents and neurons in the superficial laminae of the spinal dorsal horn (laminae I-III) by using intracellular recording in transverse slice preparation of rat (17-26 days) spinal cord. The strength of primary afferent neurotransmission was assayed by recording the size of presumed monosynaptic EPSPs that result from stimulation of L3-L6 dorsal roots with electrical shocks of 2-40V (0.01-0.5ms duration) intensity. Bath application of Dyn_{1-17} (0.01-1 μ M for 10 min) caused hyperpolarization (-4.0 ± 0.8 mV, mean \pm SEM, 11/22 cells) or depolarization (7.1 ± 3.4 mV, 7/22 cells) of the resting membrane potential accompanied by a decrease (to $79.3 \pm 4.1\%$ of control, 6/21 cells) or an increase (by $15.9 \pm 3.6\%$, 9/21 cells) in membrane input resistance. During the superfusion of 10nM Dyn_{1-17} , the peak amplitude of the presumed monosynaptic EPSPs was reversibly depressed (to $67.4 \pm 5.5\%$ of control, 7/11 cells) or enhanced (by $25.2 \pm 8.2\%$, 3/11 cells), whereas 1 μ M Dyn_{1-17} induced only potentiation (by $44.5 \pm 6.2\%$, 5/5). The Dyn_{1-17} -induced depression and enhancement of the EPSPs remained under conditions in which NMDA-, GABA_A- and glycine-mediated synaptic responses were blocked by selective antagonists D-2-amino-5-phosphonovaleric acid, bicuculline and strychnine, respectively. Similar dual modulation of EPSPs was observed with U-50,488H (n=6) and U-69,593 (n=11). The Dyn_{1-17} -induced depression of synaptic responses was reduced or abolished by a claimed selective κ_1 -receptor antagonist nor-binaltorphimine (0.1 μ M, 5/5 cells). The results indicate that distinct modulation of synaptic efficiency can be induced at primary afferent synapses with neurons in the superficial laminae of the spinal dorsal horn by κ -receptor activation and that these changes may be physiologically relevant for transmission and integration of sensory information, including pain. (Supported by NS-26352 and IBN-9209462).

INHIBITORY ACTIONS OF OPIOIDS ON SYNAPTIC TRANSMISSION IN THE RAT NEOSTRIATUM. B. Schlösser, M. Kudernatsch, B. Sutor and G. ten Bruggencate*, Department of Physiology, University of Munich, D-80336 Munich, Germany

In the neostriatum, opioid receptors exist at a high concentration. Furthermore, enkephalin is colocalized with GABA in spiny stellate cells indicating that opioids may regulate the activity in striatal synaptic circuitry. In the present study, we investigated the influence of opiate-receptor activation on neostriatal neurons *in vitro* using intracellular recordings.

Experiments were performed on rat neostriatal slices (400 μ m) with maintained corticostriatal connection. In the recording chamber the slices were kept submerged in artificial cerebrospinal fluid (ACSF). Synaptic activity was evoked by intracortical or intrastriatal electrical stimulation. Drugs were applied by addition to the ACSF.

Application of the opioid receptor agonist D-Ala²-D-Leu⁵-enkephalin (DADLE) and the selective δ -receptor agonist D-Pen^{2,5}-Enkephalin (DPDPE) (0.1-1 μ M) produced a dose-dependent decrease in the amplitude of both striatally or cortically evoked synaptic potentials. The opioids did not affect membrane potential or current-voltage relation. The effects were blocked by the opioid antagonist naloxone (1 μ M) and persisted when GABA-ergic components were abolished by the GABA_A-receptor antagonist bicuculline (20 μ M).

The data demonstrate, that activation of δ -opioid-receptors decreases synaptic transmission in the rat neostriatum mainly by reducing glutamatergic excitation. (Supported by the BMFT, 01 KL9001).

708.17

INHIBITION OF ADENYLYL CYCLASE ACTIVITY IN RAT CAUDATE PUTAMEN BY DYNORPHIN A_{1-17} . L.H. Clave, E.M. Unterwald, A. Ho, and M.J. Kreek*, The Rockefeller University, New York, NY 10021.

Adenylyl cyclase activity is used as one functional measure of opioid receptor-mediated signal transduction. The naturally occurring opioid peptide, dynorphin A_{1-17} , is thought to be the endogenous ligand of the κ opioid receptor. The aim of the present study was to investigate the effects of dynorphin A_{1-17} on adenylyl cyclase activity *in vitro*. Adenylyl cyclase activity was determined by measuring cAMP production in membranes prepared from caudate putamen of naive male Fischer 344 rats using a cAMP radioligand binding assay. Dynorphin A_{1-17} , 10^9 to 10^6 M, produced a significant dose-dependent inhibition of adenylyl cyclase activity with a maximum inhibition of 67%. The ability of norbinaltorphimine, a selective κ receptor antagonist, and naloxone to attenuate dynorphin A_{1-17} -inhibition of cyclase was determined to investigate if this effect of dynorphin A_{1-17} is opioid receptor mediated. Preliminary findings show that norbinaltorphimine, 10^5 and 10^6 M, attenuated dynorphin A_{1-17} -inhibition of cAMP production at dynorphin A_{1-17} concentrations of 10^9 to 10^6 M. Similarly, naloxone, 10^6 and 10^4 M, reversed the effects of dynorphin A_{1-17} at concentrations of 10^9 to 10^6 M. Neither norbinaltorphimine nor naloxone inhibited the actions of higher concentrations of dynorphin A_{1-17} , 10^5 and 10^4 M. These results suggest that dynorphin A_{1-17} -inhibition of cyclase activity at low concentrations is mediated by κ opioid receptors, but may not be opioid receptor mediated at higher concentrations. DYNORPHIN A MODULATES EXCITABILITY IN AMPHIBIAN AND MAMMALIAN NERVES. M.R. Luna and M.F. Pacheco*, Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Colima, Col. 28045 México.

The effects of dynorphin A 1-17 (DYN) on nerve excitability were studied in isolated sciatic nerves of the frog and rat. The amplitude of recorded diphasic action potential was gradually reduced by increasing concentrations of locally applied DYN (10 - 100 μ M). Amplitude inhibition attained, at each DYN concentration, was not modified by increasing stimulation frequency up to 10 Hz, however, higher stimulus rates reduced the degree of inhibition. DYN effect on action potential amplitude was concomitant with a decrease in conduction velocity and a 1 to 3 fold increase in threshold strength input-output curve; reaching maximum effects after 15 to 35 min of DYN application, and recovering completely (in 86% of the experiments) after 25 to 700 min of drug washout. DYN actions were antagonized by nor-binaltorphimine (50 μ M), therefore, our data are indicative of a widespread action of DYN on nerve conduction, which results in an excitability decrease through an specific interaction with κ 1-opioid receptors. Finally, these results provide an additional mechanism in order to explain reversible flaccid hindlimb paralysis and loss of reflexes, observed in rats, after intrathecal administration of DYN (Stewart & Isaac, Brain Res. 543:322-328, 1991).

EFFECT OF OPIATE ON THE *IN VITRO* RELEASE OF NEUROPEPTIDE FF FROM THE RAT SPINAL CORD. H.-Y.T. Yang* AND J. Zhu, Lab. Biochem. Genetics, NIMH, Neuroscience Center at St. Elizabeths, Washington DC 20032

Neuropeptide FF (FLFQQRamide) is an FMRamide-like peptide with opiate modulating activity. Neuropeptide FF (NPFF) is highly localized in the spinal cord where there are also specific NPFF receptors. Furthermore, there have been studies indicating that NPFF may participate in the regulation of pain threshold in the spinal cord. Thus, in this study, possible relationships between opiates and NPFF were investigated by studying the effects of various opioid receptor ligands on the K⁺-evoked release of NPFF immunoreactive material (IR) from rat spinal cords. NPFF release experiments were carried out by using an *in vitro* superfusion of isolated intact rat spinal cords. The κ -opioid agonist U50488H decreased the K⁺-evoked release of NPFF-IR in a dose dependent manner. In contrast, the μ -opioid agonist, Tyr-D-Ala-Gly-N-Me-Phe-Gly-ol (DAGO), was inactive and δ -opioid agonist, Tyr-D-Pen-Gly-Phe-D-Pen (DPDPE), exerted only a very slight inhibitory effect. The inhibitory effect of U50488H was antagonized by the κ -opioid antagonist nor-binaltorphimine (NBI). NBI was found to enhance the K⁺-evoked release of NPFF probably resulting from the concomitant release of endogenous dynorphin by the high K⁺. In view of the role of dynorphin in the antinociception, the results of this study further support that spinal cord NPFF participates in the regulation of opiate mediated antinociception.

709.1

LACK OF NMDAR1 EXPRESSION IN LUTEINIZING HORMONE-RELEASING HORMONE NEURONS OF THE MALE SYRIAN HAMSTER. G. Munro,* V. Garvillou, S.G. Kohama and H.F. Urbanski. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

There is substantial evidence demonstrating that excitatory amino acid (EAA) receptors are involved in luteinizing hormone-releasing hormone (LHRH) secretion both *in vivo* and *in vitro*. Since immortalized LHRH neurons (GT1 cells) express the NMDAR1 gene it has been proposed that EAAs may stimulate the secretory activity of LHRH neurons directly. We have used immunocytochemistry combined with *in situ* hybridization histochemistry (ISHH) in an attempt to confirm whether this particular facilitatory influence of EAAs is indeed mediated by such a direct neuronal pathway. Adult male Syrian hamsters were perfused with heparinized saline under ether anesthesia and their brains fixed with 4% paraformaldehyde. Coronal Vibratome sections (50 μ m) containing the medial preoptic area were then processed initially for immunocytochemistry using a monoclonal antibody to LHRH (HU4H) and stained with diaminobenzidine. Subsequent ISHH for NMDAR1 mRNA using a ³⁵S-labeled 450-bp antisense riboprobe (the DNA template was excised from NMDAR1 cDNA using *Pst*I and *Eco*RI) was performed on these same sections and also cultured GT1 cells. After dipping in photographic emulsion, silver grain deposition was examined microscopically to determine colocalization of NMDAR1 mRNA within the immuno-stained LHRH neurons. As expected, GT1 cells clearly demonstrated hybridization of the riboprobe. In the brain sections, a high density of silver grains was localized in the outer fringe of the cerebral cortex and within the hippocampus but not in the vicinity of the LHRH perikarya; only 1 neuron from a total of 103 neurons/3 animals showed possible colocalization. These results suggest that although GT1 cells may have an intrinsic capacity to express the NMDA receptor, in the intact animal excitation of LHRH neurons by EAAs is more likely to be mediated indirectly, by a pathway that involves interneurons.

709.3

FOS EXPRESSION IN GnRH NEURONS WITHIN PREOPTIC AREA (POA) GRAFTS IN HYPOGONADAL (HPG) MICE: EFFECT OF PROGESTERONE AND SEXUAL BEHAVIOR. M.J. Gibson*, T.J. Wu, G.M. Miller, and A.-J. Silverman. Dept. of Medicine, Mount Sinai School of Medicine, NY, NY 10029, and Dept. of Anatomy and Cell Biol., Columbia University, New York, NY 10032.

Expression of FOS, the protein product of the immediate early gene *c-fos*, is widely accepted as a marker for neuronal activation. We have shown that in normal steroid-primed, ovariectomized mice paired with an ejaculating male, FOS expression occurs in greater than 40% of GnRH neurons and is maintained at this level for a longer time than in similarly treated females paired with an unsuccessful male (Endocrinol 131:2045, 1992). HPG mice lack a functional GnRH gene and are infertile. After receiving intraventricular POA grafts containing GnRH neurons, females may enter persistent estrus, and have the capacity to ovulate reflexively or, more rarely, ovulate in response to a progesterone challenge. The present study of HPG/POA mice examined the effects of both progesterone treatment (P, 500 μ g; 0930h) and sexual behavior (introduced to an experienced male at 1400 h) on the expression of FOS in grafted GnRH neurons. In response to sexual behavior, 47.5 \pm 10.2% of GnRH neurons of P-treated HPG/POA mice expressed FOS in contrast to 0.9 \pm 0.6% of GnRH neurons in those mice that did not receive P. P treatment alone did not increase FOS expression in GnRH neurons (0.4 \pm 0.4%). These results suggest that in the presence of P, sexual behavior may serve as a stimulus of FOS expression in GnRH neurons. In addition, the present study supports the hypothesis that at least a portion of the graft-host connectivity that underlies aspects of reproductive competence in HPG/POA mice is steroid sensitive.

THE SEXUAL DIMORPHISM OF THE RAT MEDIAN EMINENCE: AN INVESTIGATION ON A MECHANISM OF DIFFERENTIATION. P. Ciofi¹*, D. Deneux¹, D. Croix¹, J.E. Krause², J.C. Beauvillain¹, A.R. Bello³, G. Tramu³ and M. Mazzuca¹. (1) U.156 INSERM, Place de Verdun, 59045 Lille (France); (2) Dept. Anat. & Neurobiol., Wash. Univ., St. Louis, Miss. 63110; (3) Lab. Neurocyto. Fonct., URA CNRS 339, Univ. Bordeaux I, 33405 Talence (France).

The hypothalamic arcuate nucleus contains a neuronal population immunoreactive (ir) for prodynorphin- (DYN) and protachykinin B- (TKB) derived peptides and giving a sexually differentiated projection to the median eminence: to the subependymal zone in females, to the gonadoliberin (GnRH)-rich regions of the palisadic zone in males (Soc. Neurosci. Abs. 17:713, 1991). This DYN/TKB neuronal system was studied in the two sexes using immunohistochemistry, (1) during normal postnatal development and (2) following alterations of the neonatal gonadosteroidal milieu.

If at birth (day 0, d0) this system is for TKB only appears immature, not different between sexes, it seems to develop faster in females in which it becomes progressively ir for DYN (d20) and seems to be established at puberty (\pm d40). In the male, the system appears to develop slowly over the first month of life and becomes ir for DYN at puberty (\pm d50). In the two sexes, gonadectomy (GX) at d0 results in adults (d120) treated or not with estradiol (d90-120) in a female type of organization, whereas in adult testosterone (T)-treated (d90-120) d0-GX animals the organization appears identically hermaphrodite in the two sexes. In males GX at d10, d15 or d20, and T-treated as adults (d90-120), the organization appears similarly hermaphrodite, resembling that of d0-GX+T males and that of females GX+T (30 days) as adults. In adults of the two sexes, both the number and the distribution in the arcuate nucleus of cell bodies ir for DYN/TKB are identical, with or without adult gonadectomy.

At this point, results suggest a postnatal androgen-driven, "non numerical", mechanism of differentiation for this neuronal system of the mediobasal hypothalamus whose organization evokes a direct involvement in the auto- or retro-control of GnRH release.

IMMUNOHISTOCHEMICAL STUDIES ON VASOTOCIN INNERVATION OF AROMATASE-CONTAINING REGIONS IN THE MALE QUAIL FOREBRAIN. C.Viglietti-Panzica*, P. Absilt, G.C.Panzica, N.Aste, and J. Balhazart. *Dept. Human Anatomy and Physiology, Univ. Torino, I-10126 Torino, Italy and †Lab. Biochemistry, Univ. Liège, B-4020 Liège, Belgium.

In the male quail forebrain, aromatase-immunoreactive (ARO-ir) elements are clustered within the sexually dimorphic medial preoptic nucleus (POM), the nucleus striae terminalis (nST), the nucleus accumbens (Ac), and the ventromedial (VM) and tuberal hypothalamus. Previous studies demonstrated that ARO-ir cells are sensitive to testosterone (T) and its metabolites: their number and size increase after exposure to these steroids. In a recent study, we demonstrated that the vasotocinergic system is also sensitive to T: the density of the vasotocin- immunoreactive (VT-ir) fiber networks located within the POM and the lateral septum is greatly reduced in gonadectomized male birds and restored to intact level by a treatment with T. We analyzed here the anatomical relationships between ARO-ir elements and VT-ir fibers. The study was performed on brains perfused with Zamboni fixative and serially sectioned with a cryostat. Sequential staining for VT, ARO, or VT+ARO was performed on adjacent 30 μ m-thick sections. High concentrations of VT-ir fibers were observed within the POM, the nST, the lateral septum, the VM and the tuberal region. In double-labelled sections, all clusters of ARO-ir cells, with the exception of those localized in the Ac, were embedded in a dense network of VT-ir fibers. Many of the VT-ir terminals appeared to end in the neuropile surrounding ARO-ir elements rather than directly on their cell bodies. However, there was a very close correspondence between the extension of the ARO-ir cells and of VT-ir fibers. This study hence supports the idea that the T-dependent ARO system is also directly innervated by a T-dependent peptidergic system. ARO could therefore be modulated by steroids both directly and indirectly through the VT system. Further studies will be needed to determine whether this VT innervation has a functional significance for the ARO-ir cells and whether these two neurochemical systems (ARO and VT) affect reproduction in an independent or coordinated manner. EFFERENT CONNECTIONS OF THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS IN THE FEMALE RAT. G.B. Gu* and R.B. Simerly. Div. of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

The anteroventral periventricular nucleus of the hypothalamus (AVPV) is thought to be a nodal point in the forebrain circuits mediating hormonal feedback on gonadotropin secretion. It contains nearly an 8-fold greater number of neurons that project to the arcuate nucleus of the hypothalamus, as well as greater numbers of tyrosine hydroxylase and dynorphin B immunoreactive neurons in female rats, relative to males. The present study was designed to clarify the organization of projections from the AVPV in female rats to facilitate a full understanding of its possible role in neural pathways underlying reproductive function. *Phaseolus vulgaris* leucoagglutinin (PHA-L) was injected iontophoretically into the AVPV and the distribution of labeled fibers evaluated immunohistochemically. The AVPV sends ascending projections through periventricular and dorsolateral pathways with dense terminal fields in the ventral part of the lateral septal nucleus, the parastria nucleus, and the vascular organ of the lamina terminalis (OVLT), including the region adjacent to the OVLT where a subpopulation of gonadotropin releasing factor (GnRH)-containing neurons are located. The majority of projections from the AVPV pass caudally through the periventricular zone and provide extremely dense terminal fields to all of the periventricular nuclei of the hypothalamus, most parts of the paraventricular nucleus, the arcuate nucleus of the hypothalamus, and the medial part of the medial preoptic nucleus. Thus, the organization of projections from the AVPV in female rats suggests that sexually dimorphic populations of neurons in this nucleus may regulate the activity of GnRH cells directly, or indirectly via projections to regions of the hypothalamus that contain hypothalamic releasing factors such as β -endorphin or NPY. Work in progress utilizing double and triple fluorescence labeling methods and confocal microscopy will confirm whether tyrosine hydroxylase and dynorphin B immunoreactivities are expressed in these pathways.

709.6

EFFECTS OF INTRAUTERINE POSITION ON METABOLIC CAPACITY OF THE HYPOTHALAMUS IN THE GERBIL:

A CYTOCHROME OXIDASE STUDY D. Jones,* F. Gonzalez-Lima, D. Crews, B.G. Galer¹ and M.M. Clark¹, Dept of Psych and Zoology, Univ of Texas, Austin TX, 78712 USA and ¹Dept of Psych, McMaster Univ, Ontario L8S 4K1, Canada.

Neural metabolic correlates of known effects of intrauterine position on behavior in the Mongolian Gerbil were investigated. Hypothalamic regions were compared in female gerbils that developed *in utero* between two female fetuses (2F) or between two male fetuses (2M) to assess differences in metabolic capacity. Taking advantage of quantitative image analysis systems we measured the cytochrome oxidase (C.O.) activity in histochemically stained brain slices of the gerbil. Due to its limiting role in oxidative metabolism, C.O. is an excellent marker of metabolic capacity: increased activity of neurons in a brain region lead to increased C.O. content in their mitochondria. The C.O. staining procedure involved metal intensification through cobalt preincubation, as well as oxygenation and heating of the reaction medium. Optical density (O.D.) of ten hypothalamic regions, including the sexually dimorphic area, were assessed using grey to white matter O.D.. Significant group differences in the metabolic capacity of three hypothalamic regions were revealed. Increases in C.O. in the anterior portion of the lateral hypothalamic area, the posterior portion of the anterior hypothalamic area and the sexually dimorphic area were seen in 2M as compared to 2F females. To our knowledge, this is the first demonstration of functional changes in hypothalamic areas related to the differences in intrauterine position. (Supported by RO1 MH43353 and OGP0037338).

THE DISTRIBUTION OF AROMATASE mRNA IN THE BRAIN OF ADULT MALE AND FEMALE RATS USING *in situ* HYBRIDIZATION
C.K. Wagner* and J.I. Morrell, Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

Many of the effects of gonadal steroid hormones in the male brain are due to the actions of the testosterone metabolite, estradiol, which is synthesized by the actions of the P450 enzyme, aromatase. Aromatase activity has been demonstrated, through the use of *in vitro* enzyme activity assays, to be present in regions of the preoptic area, hypothalamus and limbic system. Levels of aromatase activity are much higher in males than in females in some brain regions. The present study examined the distribution and cellular localization of aromatase mRNA in adult male and female rat brains using *in situ* hybridization. A 113-base ³⁵S-labelled cRNA probe, complementary to the aromatase mRNA just upstream from the heme-binding domain, was synthesized from the rat aromatase cDNA inserted into pGEM3Z (generous gift from J. Richards, Baylor College of Medicine, Houston TX), using a BstNI fragment and SP6 polymerase. Following the hybridization procedure, slides were dipped in nuclear track emulsion in order to detect aromatase mRNA at the cellular level. In the male, many heavily labelled cells were found in the encapsulated bed nucleus of the stria terminalis and the medial amygdala. A smaller number of heavily labelled cells were seen in the periventricular preoptic nucleus, the medial preoptic nucleus, the ventromedial nucleus, the cortical amygdala and the subfornical organ. Lightly to moderately labelled cells were observed in the horizontal diagonal band, the magnocellular preoptic nucleus, the median preoptic nucleus, the anterior hypothalamus, the arcuate nucleus, the piriform cortex and nuclei of the thalamus. Aromatase mRNA was found in the same brain regions in females. Sex differences and the effect of castration in males on levels of aromatase mRNA will be discussed. EFFECTS OF TRH ON THE SEMI-CIRCADIAN RHYTHMS OF DA RELEASE IN THE MBH AND PRL LEVELS IN PLASMA DURING PSEUDOPREGNANCY IN AWAKE RATS. W. Timmerman*, I. R.T. Poelman, B.H.C. Westerink² and G.A. Schuiling¹. Departments of ¹Obstetrics & Gynaecology and ²Medicinal Chemistry, University of Groningen, 9713 EZ, 9713 AW Groningen, The Netherlands.

The tuberoinfundibular dopaminergic (TIDA) neurons inhibit the prolactin (PRL) secretion from the adenohypophysis. Thyrotropin-releasing hormone (TRH) is a PRL-releasing hormone, but under certain conditions it suppresses PRL secretion. We tested the hypothesis that the inhibitory effect of TRH on PRL secretion is mediated via a stimulatory effect of TRH on DA release from TIDA neurons. To simultaneously study DA release and plasma PRL concentrations, a microdialysis probe was implanted in the mediobasal hypothalamus (MBH) together with a permanent heart cannula in pseudopregnant female rats. These animals display a diurnal PRL peak (between 1300-1800 h) and a nocturnal peak (between 0100-1200 h), with an interphase (between 1800-0100 h) during which PRL levels are low for 10 consecutive days. Dialysis experiments were performed with nomifensine (5 µmol/l) in the dialysate. This infusion increased extracellular DA to 350% of basal values. During the interphase, DA levels in the MBH were ~4 fmol/min, while during the nocturnal PRL surge period DA levels were ~1.6 fmol/min. Plasma PRL concentrations were ~35 and ~240 ng/PRL-RP-2/ml in the inter- and nocturnal phase, respectively. When the TRH analogue CG 3703 (500 and 2500 µg/kg iv) was administered at 0000 h, the PRL surge was postponed dose-dependently, which could be related to the dose-dependent increase in DA release in the MBH. These data suggest that (1) DA levels in the MBH and plasma PRL levels are inversely correlated during pseudopregnancy, and (2) the inhibitory effect of the TRH analogue on PRL secretion was mediated by a stimulatory effect of the drug on DA release from TIDA neurons. EXTRASTRIATE VISUAL CORTEX: FUNCTIONAL ORGANIZATION IV

710.1

DISTRIBUTION OF THE CALCIUM-BINDING PROTEINS PARVALBUMIN, CALBINDIN AND CALRETININ IN THE MACAQUE MONKEY VISUAL CORTEX. P.R. Hof, C.A. Sailstad, N. Archin, A.M. Edwards, W.G.M. Janssen and J.H. Morrison*. Fishberg Research Center for Neurobiology, Mount Sinai Medical Center, New York, NY 10029.

Immunohistochemical studies localizing the calcium-binding proteins (CaBPs) parvalbumin (PV), calbindin (CB), and calretinin (CR) in the monkey and human visual areas V1 and V2 have shown that these CaBPs are present within morphologically distinct groups of neurons that display specific regional and laminar distribution patterns. In order to further characterize the cellular organization of the primate visual system, we performed a quantitative analysis of the distribution of CaBPs-immunoreactive (ir) neurons in several divisions of the magnocellular (M) and parvocellular (P) visual pathways in the macaque monkey. Area V1 was characterized by very high numbers of PV- and CB-ir cells, while CR-ir neurons were less numerous. Areas V2, V3 and V3A displayed lower numbers than area V1 for the three neuronal populations. However, cell counts markedly increased in areas at higher levels in the cortical hierarchy. In particular, areas MT, VIP, V4 and TEO were characterized by very high densities of stained neurons. In addition, a subset of CB-ir pyramidal neurons located in layer III exhibited differential distribution among the cortical areas investigated, with the highest densities in areas V4 and MT and slightly lower cell counts in areas TEO, TE, VIP and LIP. These results indicate that CaBPs define neuronal populations that are differentially represented among cortical regions of known function in the M and P pathways in the primate visual system. SELECTIVITY OF AREA V2 OF THE MACAQUE TO KINETIC AND OTHER TYPES OF BOUNDARIES. V.L. Marcar*, D.-K. Xiao, S.E. Raiguel & G.A. Orban. Lab. Neuro-en Psychofysiologie, Medical School, KULeuven, B-3000 Leuven, Belgium, EEC

We have reported the presence of cells in area V2 that can signal the orientation of a boundary defined by motion cues only (Marcar *et al.*, Soc. Neurosci. Abstr. 1992, 537.5). We have extended our investigation of V2 by including boundaries defined by additional fourier and non-fourier cues.

Luminance contrast stimuli were used to determine the preferred orientation, centre of the receptive field and the optimum stimulus length. Cells in which the preferred orientation differed by less than 23° between the parallel and the orthogonal motion condition were considered orientation selective for kinetic boundaries. About 10% (9/94) of V2 cells fell into this category. Histological reconstruction placed these cells in or bordering layer V. For these boundary cells we compared the orientation selectivity and orientation preference for luminance, texture and the three types of anomalous edges. We have found that in some cells the preferred orientation and sensitivity to all types of edges was very similar.

RESPONSES TO A MOVING KANIZSA SQUARE IN AREAS V2 AND V4 OF THE MONKEY. J.I. Nelson*, P. De Weerd, R. Desimone and L.G. Ungerleider. Lab Neuropsychology, NIMH/NIH 491B80, Bethesda MD 20892

Prior physiological studies of subjective contours used patterns which induce bars or edges by line ends or corners (van der Heydt *et al.*, Science 224:1260, 1984). By contrast, we employed a more complex figure in which a Kanizsa square is induced and placed in apparent motion. The Kanizsa square moved back and forth along a double row of inducers ("PAC-Men"). This illusion is achieved by appropriately orienting neighboring inducers in successive frames of a movie and randomly orienting inducers elsewhere (Bravo *et al.*, Vision Res. 28:861, 1988).

At eccentricities equal to those tested cellularly, six observers perceived the illusory square as a darker, bounded object moving against the background. If the open quadrants of the inducers were closed by thin circular arcs, no such object was seen (control stimulus). We recorded from cells in areas V2 and V4 of one fixating rhesus monkey and sought a cellular correlate of this perceptual illusion. We attempted to place all inducing elements outside the classical receptive field.

In V2, 6/59 cells (eccentricity 3-4 deg) responded to the moving Kanizsa square but gave a reduced response or no response at all to the control stimulus. In preliminary data from V4 (eccentricity 0.5-1.5 deg), 4/13 cells showed similar behavior. Response peaks corresponded to the presence of the induced object centered on the receptive field.

Some of these cells were clearly color selective and responded to patterns in which inducers and background colors were photometrically isoluminant. In some cells we reversed inducer/background colors and could abolish the subjective square response. In another case, increasing luminance contrast to 19% but rendering background and inducers achromatic did not evoke an increased response.

These results confirm the presence of illusory contour responses in V2 and extend these findings to a more complex stimulus. In addition, we have preliminary evidence for similar responses in V4. Our results suggest the existence of figural completion mechanisms for chromatic patterns similar to the boundary completion mechanisms shown earlier for achromatic patterns.

710.4

MECHANISMS OF CONTOUR PROCESSING IN MONKEY PRESTRIATE CORTEX INCLUDE INFORMATION ON DIRECTION OF GRAVITY.

X. M. Sauvan, V. Henn, and E. Peterhans (SPON: European Neuroscience Association), Dept. of Neurology, University Hospital Zurich, CH-8091 Zurich, Switzerland.

Form perception requires a generalized representation of contours with regard to the quality defining them (e.g. luminance, color, motion, or texture) and their spatial position and orientation. We report here the effect of body tilt on mechanisms of contour processing in the visual cortex of the alert rhesus monkey.

The responses of single neurons were studied while the monkey performed a visual fixation task in either an upright position, or with its body tilted about the naso-occipital (roll) axis by ± 25-30 deg. We recorded from 106 orientation selective neurons both in striate and prestriate cortex (areas V2 and V3/V3A). For 44 neurons we could compare the preferred orientation and the position of the response field for light and dark bars or edges at 2 or 3 body positions. In striate cortex, most neurons (19/21) were of a non-compensatory type showing a change in the preferred orientation and position of the response field according to the body tilt and the estimated counterrolling of the eye (see Vision Res. 32:1341-1348, 1992). By contrast, 40% of the neurons in prestriate cortex (8/20) were of a compensatory type. These cells, although showing a change in field position, preferred similar stimulus orientations at all body tilts. This indicates that the orientation selectivity of the compensatory neurons was invariant with respect to the direction of gravity.

In conclusion, information about the direction of gravity is implemented in monkey visual cortex first at the level of area V2. This suggests that otolithic signals contribute to mechanisms of contour processing at early stages of visual processing.

Supported by ESPRIT (Insight-II 6019 and Mucom-II 6615).

710.5

TOPOGRAPHIC PATTERN OF CORTICAL CONNECTIONS TO DORSAL AND VENTRAL V2 IN MACAQUE MONKEYS. I. Stepniowska* and J.H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

We studied the connections of V2 with other extrastriate visual areas in macaque monkeys (*Macaca mulatta*) to better determine their extent and visuotopic organization. Multiple injections of different fluorescent tracers and WGA-HRP were made in dorsal V2 representing the lower central vision and in ventral V2, representing the upper central vision. After 4-7 days survival, animals were anesthetized and perfused, and visual cortex separated from the rest of the brain. Cortex was manually flattened and cut parallel to the surface. Transported label was related to architectonic boundaries identified from adjacent myelin- and cytochrome oxidase-stained sections. Injections in both dorsal and ventral V2 labeled neurons in the adjacent portion of primary visual area (V1), in the dorsomedial (DM, dorsal V3) and dorsolateral (DL, V4) visual areas as well as middle temporal area (MT, V5) in the superior temporal sulcus. This suggests that all these areas, including DM, contain complete representations of the contralateral visual hemifield. Two separate groups of labeled neurons were found in DL, indicating that this region consists of rostral (DLr) and caudal (DLc) fields, each with its own visuotopic organization. The pattern of connections suggests that DL extends less far ventrally than described in previous studies. Other areas weakly connected with V2 were located in the superior temporal (MST, FST), and intraparietal sulci. Most connections of V2 were topographically organized so that dorsomedial V2 was connected with dorsomedial locations in other extrastriate areas, and ventrolateral V2 was connected with ventrolateral portions of extrastriate areas. These results provide further information about the retinotopic organization of extrastriate areas and suggest that much of the area designated as dorsal V3 in macaque is a homologue of DM in owl monkey. (Supported by NEI Grant EY-02686)

ANALYSIS OF COLOR AND MOTION IN MACAQUE AREA V3. Gegenfurtner, K.R.*, Kiper, D.C.* and Levitt, J.B.* MPI for biological Cybernetics, 72076 Tübingen¹, Germany; Inst. of Anatomy, University of Lausanne², Switzerland; Inst. of Ophthalmology, London³, UK.

Extrastriate area V3 may represent an important site for integration of visual signals. It receives inputs from both magno- and parvocellular pathways and has prominent projections to both areas MT and V4. Therefore we investigated the representations of color and motion in V3. We recorded from single cells in area V3 of macaque monkeys (*Macaca mulatta*) using standard acute recording techniques. After measuring each cell's spatial and temporal properties, we tested its chromatic and motion properties using sinewave gratings, colored bars and plaid stimuli.

All V3 neurons were orientation selective. About 50% of our sample was selective for direction of motion. Contrary to previous reports, we also found a high proportion (about 40%) of cells that were selective for color. These two subpopulations overlapped to a large extent, and we found a significant proportion of cells highly selective for both of these stimulus attributes. An analysis of the responses of directionally selective cells to plaid patterns showed that in area V3, as in MT and unlike in V1 and V2, many cells were sensitive to the motion of the plaid pattern, rather than to the component motion. Furthermore, a third of our sample was endstopped, and many of these cells showed orientation- or direction-selective surround effects. Our results show that there is a significant interaction between color and motion processing in area V3, and that V3 cells show many of the more complex motion properties typically observed at later stages of visual processing.

710.9

CORTICOTECTAL CELLS IN AREAS 17 AND PMLS OF THE CAT. I.G. Weyand* and A.C. Gafka, Dept. Anatomy, LSU Medical Center, New Orleans, LA 70112

Using antidromic techniques, we have recorded from corticotectal (CT) neurons in primary visual cortex (area 17, $n = 21$) and a lateral visual cortical area (posteromedial lateral suprasylvian cortex, PMLS, $n = 13$) in cats trained in oculomotor tasks. Head position was fixed, and gaze was monitored using the scleral search coil technique. The cat faced a rear projection screen onto which we could project an assortment of visual stimuli. CT cells in both areas responded well to a small spot used as the target when the spot is placed in the receptive field. None of the cells in either cortical area exhibited pre-saccadic activity. At least half the CT cells in area 17 showed post-saccadic activity associated with sweeping the retina across an illuminated field. PMLS CT cells did not show post-saccadic activity. Because CT cells in PMLS do respond to visual stimuli well in excess of saccade velocities, an oculomotor signal must actively suppress visual inputs when the cat makes eye movements. In general, area 17 CT cells in the awake cat are just like their counterparts in the paralyzed, anesthetized preparation. Most are strongly directional, orientation selective and show little evidence of length summation. PMLS cells exhibit a directional anisotropy; they respond best to stimuli moving away from gaze. PMLS CT cells exhibit this same direction anisotropy. Area 17 CT cells provide detail on the spatial attributes of the visual array to the superior colliculus. This is presumably used by the colliculus to make decisions about which target to look at next. In contrast, the large receptive fields and direction anisotropy of PMLS CT cells would be consistent with a role in supporting visually-guided locomotion (Supported by NIH Grant EY06818).

710.6

THE DISTRIBUTION OF CORTICO-COLLICULAR PROJECTION NEURONS CORRELATES WITH THICK CYTOCHROME OXIDASE STRIPES IN VISUAL AREA V2 OF MACAQUE MONKEY P.L. Abel*, B.J. O'Brien, B. Lia and J.F. Olavarria, Depts. of Psychology, Physiology and Biophysics, and Ophthalmology, Univ. of Washington, Seattle, WA 98195.

Several lines of evidence suggest that the three classes of CO stripes observed in V2 (CO-dense thick and thin stripes, and pale interstripes) are related to specialized functional streams in visual cortex. One line of evidence comes from the pattern of connections that CO stripes have with ipsilateral cortical visual areas. Thus, in accordance with the idea that thick CO stripes are part of the magnocellular processing stream, these stripes have been shown to project to areas involved in the analysis of motion and spatial attributes, such as area MT. Exploring the pattern of V2 connections with subcortical nuclei that have magnocellular functions offers another opportunity for investigating the specificity of projections originating from V2 stripes. For instance, the superior colliculus (SC) receives a strong projection from V2, and available information indicates that the corticotectal pathway in the monkey is predominantly magnocellular in nature. We have therefore correlated the distribution of V2-SC projection neurons with the array of CO V2 stripes.

Guided by recordings of visually evoked potentials, multiple injections of either HRP or fluorescent tracers were made into the SC of adult monkeys (*Macaca fascicularis*). Three-four days later, area V2 was sectioned coronally or tangentially to the cortical surface, and the distribution of labeled cells in layer V was compared to the CO staining pattern in overlying cortex. The identification of stripes was aided by analyzing the distribution of CAT-301 positive cells.

We found that labeled cells accumulate in finger-like clusters which extend perpendicularly from the V1/V2 border across the width of V2. These clusters are preferentially distributed within areas of infragranular cortex underlying thick CO stripes, with fewer cells underlying thin and interstripe regions. Our results thus support current notions about the functional specificity of pathways originating from V2 stripes. Supported by NIH EY09343 and T32 EY07031.

710.8

RECEPTIVE FIELD STRUCTURE OF V2 NEURONS IN THE PROSIMIAN PRIMATE *GALAGO CRASSICAUDATUS*. J.D. Allison* and V.A. Casagrande, Dept. of Cell Biology, Vanderbilt University, Nashville, TN 37232-2175.

Visual area 2 (V2) is the second largest visual area in the primate cortex and receives input solely from V1. There is very little data on the receptive field (RF) structure of V2 cells. A key question is how the RF structure of V2 cells compares to the RF structure of V1 cells. To answer this question we measured the response amplitude of single cells in V2 of 3 galagos using standard single-unit electrophysiological techniques with both bars and drifting sine-wave gratings. All cells were classified as simple or complex and their RF size, directionality, orientation tuning, spatial and temporal frequency tuning, and contrast sensitivity were tested. After recording, the electrode tracts were marked with lesions and reconstructed to identify the location of each cell. The results showed that all cells were complex and their RFs were located within 5° of area *centralis* with large (mean = $26 \pm 5.8 \text{ deg}^2$ SE), elongated (mean = $4.1 \times 1.8 \text{ SE}$) receptive fields. The majority (71%) of the cells were binocular and directionally selective (78%). The average orientation tuning was $21.5 (\pm 9.65 \text{ SE})^\circ$, the preferred spatial frequency averaged 0.5 cycles/deg with a mean tuning bandwidth of $2.4 (\pm .68 \text{ SE})$ octaves and a mean cutoff of 1.2 cycles/deg. The mean preferred temporal frequency was 2.76 ($\pm 1.8 \text{ SE}$) Hz with a cutoff frequency of 8 Hz. The average contrast sensitivity was 20.1 ($\pm 19.32 \text{ SE}$). The RF structure of V2 cells near area *centralis* is very similar to that of V1 cells in this species. V2 cells differed from V1 cells in having larger receptive fields, being mostly binocular, and having lower spatial frequency peaks and cutoffs.

710.10

SYNCHRONIZATION OF THE SLOW (<1 Hz) OSCILLATION IN VISUAL CORTICOTHALAMIC NETWORKS. A. Núñez*, F. Amzica and M. Steriade, Lab. of Neurophysiol., Laval University, Quebec, Canada G1K 7P4; and Dept. Morfologia, Fac. Medicina, Univ. Autónoma de Madrid, Spain.

It has been shown that a slow (<1 Hz) cortical oscillation is present in various neocortical areas as well as related thalamic nuclei (Steriade et al., J. Neurosci., 1993, 13:3252-3299). It remained however unclear whether or not this oscillatory behavior is evenly distributed within different cortical areas belonging to the same sensory modality. We performed simultaneous, multi-site, intra- and extracellular recordings from cortical visual areas 17, 18, 19 and 21 and related thalamic nuclei (mainly LG and PG) of cats under ketamine & xylazine anesthesia. The extent of synchronization as well as its spectral composition was assessed by means of correlation techniques applied to spike discharges, membrane potentials in intracellular recordings, and field potentials.

The slow (<1 Hz) oscillation occurred predominantly in areas 18, 19 and 21 (90%) and was less often seen in area 17 (58%). When it appeared in area 17, it was synchronous with the same oscillation recorded from other visual areas. In 19% of area 17 cells, they were oscillating in the delta frequency (1-4 Hz) and no synchrony with slowly oscillating neurons from other visual areas was observed. PG thalamic neurons were coherent with slowly oscillating cortical cells in 89% of cases. LG cells often (58%) reflected the cortical slow rhythm and, in those instances, were synchronized with cortical cells. In other cases (31%), LG neurons displayed delta oscillation, without relation with the slow rhythm. Light stimulation disrupted the synchrony among cortical neurons or between cortical and thalamic neurons. We suggest that the appearance of the slow oscillation in the neocortex is favored by wide-range connections between association areas, while primary receiving areas reflect a balance between the ascending clock-like, intrinsic, thalamically-generated delta oscillation and the intracortical inputs of the slow oscillation.

THALAMIC AND CORTICAL CONNECTIONS OF AREA 18 OF ALBINO CATS. Marcie Pospichal*, Andrzej Wrobel, Iwona Stepniowska and Jon Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

The visual system of albino animals are abnormal in that many ganglion cells in the temporal retina are misrouted to the contralateral lateral geniculate nucleus (LGN). The consequences of this misrouting are only partially understood. We studied the organization of albino geniculocortical and corticocortical connections by injecting up to 6 different tracers in distinct rostrocaudal locations in area 18 (V2) of 4 animals. The results revealed a roughly normal rostrocaudal sequence of geniculate projections so that progressively more rostral injections in area 18 labeled progressively more rostral locations in the LGN. However, the zones of labeled cells were larger than those for comparable injections in normal cats, suggesting greater divergence and convergence of LGN projections. Layer A1, with abnormal retinal inputs, had discontinuous medial and lateral foci of labeled neurons from single injections, indicating topographic mismatching in projections. Cortical connections with areas 17 and 19 and suprasylvian regions were also roughly normal with more rostral injections labeling more rostral locations in these fields. However, again connections appeared less precise than normal with connections of central area 18 in particular being more widespread and overlapping than in normal cats. These abnormalities suggest that in albino cats, visuotopic organization is less precise and orderly. Supported by EY-02686 (JK), NSPB-FFS PD92037 (MP) & James S. McDonnell Foundation (AW).

MODULAR ASPECTS OF CORTICOCORTICAL CONNECTIVITY BETWEEN AREAS 17 AND 18 Joanne Matsubara* and Jamie Boyd Depts of Ophthalmology and Anatomy, University of British Columbia, Vancouver, British Columbia, Canada V5Z 3N9

We have previously shown that the cells projecting from area 17 of the cat to the posterior medial lateral suprasylvian area (PMLS) are clustered within regions that stain densely for cytochrome oxidase (CO). Here, we extend these findings to connections involving area 18.

Large, multiple injections of wheat germ agglutinin-conjugated horseradish peroxidase or cholera toxin conjugated to colloidal gold were made into areas 17, 18, or the PMLS. In each case, the aim was to saturate a large part of the visual field representation of the injected area. Labeled cells were charted in tangential sections of cortex and compared to the pattern of CO staining in alternate sections.

After tracer injections into the PMLS, labeled cells in area 18 were, as was previously found in area 17, arranged in patches that aligned with the CO blobs. CO blobs, and associated PMLS projecting patches, were slightly larger in area 18 (slightly greater than 1mm spacing) than in area 17 (slightly less than 1 mm spacing). In agreement with Ferrer et al. (1988), we found the projection from area 17 to area 18 to be discontinuous. Moreover, cells projecting from area 17 to area 18 are confined to the CO blobs. Surprisingly, labeled cells and terminals in area 18, following large injections in area 17, also have a patchy organization, which we are currently trying to relate to the pattern of CO activity. Preliminary evidence suggests that they too are confined to the blobs.

Thus, while both area 17 and 18 have similar PMLS-projecting blob and non-PMLS-projecting interblob compartments, it appears that connections between these two areas are made specifically to and from the CO blobs, with interblobs being unconnected corticocortically. These results are not easy to interpret within a strictly hierarchical framework classifying connections from 17 to 18 as feedforward, connections from 18 to 17 as feedback; rather, the similarities in connectional organization is consistent with suggestions that these two areas operate in parallel. TWO CORTICAL VISUAL SYSTEMS IN A RODENT. C.G. Ellard* and M. Dias, Dept. of Psychology, University of Waterloo, Waterloo, Ontario, Canada.

Although it is sometimes assumed that there are two visual cortical processing streams in non-primates, there is little evidence for such a dissociation of function in rodents. We wanted to demonstrate selective effects of lesions to either dorsal or ventral posterior cortical areas on two different types of visual information processing in the Mongolian gerbil. Gerbils received either lesions of parietal cortex, temporal cortex, or sham surgery. After recovery, they were placed at random starting locations into an open field containing an object for five one-minute trials. On each trial, the total time spent in contact with the object was recorded. On the sixth trial, the object was moved to a new location in the field and a new, different object was placed in the old location. The critical measure was the amount of time spent in contact with each of the objects on the sixth trial. Normal gerbils showed decreasing contact time with the object over the first five trials. On the sixth trial, they showed elevated contact time with both the new object and the old object at a new location, demonstrating sensitivity to both object location and identity. Gerbils with parietal lesions showed dishabituation to the new object but not the new location, suggesting a spatial deficit but intact object recognition. Gerbils with temporal lesions showed no habituation to objects in the field, suggesting a deficit in object recognition. These findings constitute evidence that lesions to two different cortical areas in the gerbil produce dissociable effects on visual behaviour reminiscent of those seen in primates. 710.12

Visual acuity of single neurons in area 21a of the adult cat. E. Tardif¹, A. Bergeron¹, F. Lepore¹, J.P. Guillemot^{1,2}. ¹Groupe de Recherche en Neuropsychologie Expérimentale, Univ. de Montréal et ²Dépt. de Kinanthropologie, Univ. du Québec à Montréal, Montréal, Québec, Canada.

The spatial selectivity of single neurons in area 21a of the adult cat was investigated using sinusoidal gratings. Extracellular activity was recorded and analyzed in the conventional manner while the animal was paralyzed and anesthetized (halothane: 0.5% and N₂O-O₂: 70:30). Receptive fields (RFs) were located in the upper part of the visual field. Most RFs were complex type but simple and end-stopped RFs type were also found. Results showed that cells responded well to drifting sinusoidal gratings. The spatial frequency tuning functions revealed both low-pass and band-pass characteristics. Visual acuity was lower than that found for cells in area 17 but comparable to that of other visual areas. Optimal spatial frequencies were low and the bandwidth of most cells was similar to that of striate cortex. For binocular cells, a positive relationship was found between the spatial properties derived from each eye. The contrast threshold was generally quite low under optimal parameters but some cells were found which responded only to high contrast. Cells were also tested for temporal selectivity and they were found to respond to a wide range of velocities.

710.14

MODULAR ORGANIZATION OF CORTICOCORTICAL INPUTS AND OUTPUTS OF AREA 19 Jamie Boyd* and Joanne Matsubara Depts of Ophthalmology and Anatomy, University of British Columbia, Vancouver, British Columbia, Canada V5Z 3N9

Our recent finding that cells in areas 17 projecting to the PMLS are confined to the CO blobs suggests that, as for primate area V1, cat area 17 may have segregated outputs to specialized extrastriate areas. In primates, CO blobs and interblobs in V1 project to thin stripes and interstripes, respectively, in V2. However, corticocortical connections between areas 17 and 18 in the cat are restricted to CO blobs (see previous abstract) begging the question of where the interblobs project.

Large, multiple injections of cholera toxin conjugated to colloidal gold (CTB-Au) were made into area 19 or the PMLS. In addition, small, focal injections of CTB-Au or unconjugated CTB were made into area 19. Labeled cells were charted in tangential sections of cortex and compared to the pattern of CO staining in alternate sections.

After large injections in area 19, labeling in areas 17 and 18 was continuous, with both blob and interblob zones labeled. Focal injections into area 19 gave rise to patches of labeled cells in areas 17 and 18 that were either confined to blobs, or confined to interblobs. In one case, after paired injections of CTB and CTB-Au, one tracer labeled blobs and the other labeled interblobs in areas 17 and 18, forming an interdigitated pattern. Interestingly, patchy, intrinsic connections in area 19 from these two injections were also partially interdigitated. These patches of local labeling in area 19 were nearly twice the size and spacing of their counterparts in areas 17 and 18. This larger spacing in area 19 was also reflected in the distribution of PMLS projecting cells in area 19, which were arranged in 0.5-1.0 mm wide bands spaced 1.5-2 mm apart and running perpendicular to the 18/19 border. We are currently studying the relationship between these output- and input-defined compartments.

These results suggest that area 19 of the cat is composed of at least two types of modules and that in cat area 19, as in primate V2, segregation of blob and interblob information is maintained, and reflected in projections to extrastriate areas. It is not clear if there is a third type of compartment in cat area 19 analogous to the division of CO stripes into thick and thin types. (This work funded by MRC 5-99150)

710.16

ENHANCED PHYSIOLOGICAL DECAY OF VISUAL NEURONS IN MULTIMODAL AND NONPRIMARY VISUAL CORTICAL AREAS OF EARLY DEPRIVED CATS. U. Yinon, I. Gershon, R. Yaka and Z. Wollberg*. *Physiol. Lab., Goldschleger Eye Res. Inst., Fac. Med., Sheba Med. CTR and Dept. Zool., Fac. Life Sci., Tel-Aviv Univ., Tel-Aviv, 69978, ISRAEL.*

The modifiability of cortical cells was studied in visual primary (VI), nonprimary (SSS: PMLS, AMLS, PLLS, ALLS and medial AI) and multimodal (MS or area 7) areas. Extracellular unit recording was made in 7 cats monocularly deprived (MD) at ages of 1-11 weeks and in 31 normal (NOR) controls. They were anesthetized and paralyzed, the receptive fields (RFs) mapped and PSTHs analyzed. While similar responsiveness was found in VI

Cortical area	Total number of cells		Responsive cells, %		Binocular cells, %	
	MD	NOR	MD	NOR	MD	NOR
VI	64	429	84.4	86.5	33.3	71.1
SSS	122	398	26.2	49.7	9.4	88.9
MS	164	362	61.0	52.2	18.0	79.9

and MS areas of MD and NOR cats, a remarkable reduction was found in the SSS areas of the MDs (see table). The binocularity is consistently reduced in all areas of MDs but more vigorously in the SSS and MS. This is in accordance with our previous results suggesting reduction in selectivity of the cells' reaction and their RFs in MDs, outside VI (Soc. Neurosci. Abstr., 18:1315, 1992). There is, thus, an internal deficiency in processing visual information in areas not exclusively dedicated to vision, which is enhanced by the partial elimination of visual exposure during development.

DIRECTIONAL RESPONSE PROPERTIES OF PURKINJE CELLS TO VESTIBULAR AND NECK INPUTS. O. Pompeiano*, P. Andre, and D. Manzoni. Dept. of Physiol., Univ. of Pisa, Pisa, Italy, I-56127.

Vestibulospinal (VS) and cervicospinal (CS) reflexes show different patterns of postural adjustments depending on the direction of head and neck displacements. This organization may require the assistance of the cerebellar anterior vermis, which integrates both the vestibular and neck inputs and influence the motor output. A prerequisite for such a proposed function is that the vermis encode the spatial coordinates of both head and neck displacements. We investigated, in decerebrate cats, the directional selectivity of the responses of vermal Purkinje (P)-cells to wobble either of the whole animal at 0.15 Hz, 10° (vestibular input) or of the body over a fixed head at 0.15 Hz, 2.5° (neck input). In both instances the direction of animal or body rotation moved at a constant speed over 360° in a clockwise (CW) or counterclockwise (CCW) direction. Bidirectional responses were represented by a vector lying midway between the maximal response directions to CW and CCW stimuli. These vectors were distributed over the entire plane of rotation for both vestibular (n=44) and neck responses (n=98), with some predominance of neck vectors in the fore-aft directions. In conclusion, the cerebellar anterior vermis provides a framework for spatial coding of vestibular and neck signals, and may intervene in the control of VS and CS reflexes during a variety of head and neck displacements.

REGIONAL DIFFERENCES IN CEREBELLAR UNIT ACTIVITY AFTER CONDITIONING A BLINK CR TO AN ACOUSTIC CS IN CATS. C. Woody*, X.F. Wang and E. Gruen. UCLA Center for Health Sciences, MRRC, BRI, Los Angeles, CA 90024.

The % of cells responding to 70 db clicks and hisses differed by region: 83% in L V/VI, 56% in flocculus, 45% in lat. ansiform lobe, and 37% in med. ansiform lobe. After conditioning with click-CS and hiss-DS, mean activity 64-192 ms after click (n=699 units) increased relative to baseline in each region. The timing of the peak response differed from region to region. Onsets of response were typically 16-24 ms except for the med. ansiform lobe (>24 ms). (Earlier onsets were found in some units and states.) After conditioning, responses to CS were greater than to DS in the med. ansiform area, and exceeded peak responses to the CS before conditioning. The ratio of CS:DS responsive cells increased and reversed from that for adaptation and sensitization. Separation of data from L V and VI also found responses after conditioning greater to CS than DS in L VI. Discriminative initiation of the blink CR appears to depend more on motor cortex and dorsal cochlear nucleus than on cerebellum even though contributions from the cerebellum may be needed for late components of the CR to develop and be performed. SELECTIVE ELIMINATION OF CEREBELLAR OUTPUT IN THE GENETICALLY DYSTONIC RAT. M.S. LeDoux*, J.F. Lorden and J. Mainzen-Derr. Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, Alabama 35294

The genetically dystonic (*dt*) rat, an autosomal recessive mutant, exhibits a progressive motor syndrome that resembles the generalized idiopathic dystonia seen in humans. Even with supportive measures, *dt* rats die by postnatal Day 35. A total cerebellectomy that includes the dorsal portion of the lateral vestibular nucleus (LVN) eliminates the dystonic motor syndrome of the *dt* rats, greatly improves overall motor function and prevents early death. After total cerebellectomy, *dt* rats survive into adulthood, mate and successfully rear their offspring.

Selective elimination of cerebellar output was performed on 15-day-old *dt* rats in order to determine the cerebellar components critical to the mutant's motor syndrome. Electrolytic and/or excitatory amino acid lesions of the medial cerebellar nucleus, interpositus cerebellar nucleus, lateral cerebellar nucleus and LVN were created in separate groups of *dt* rats. Rats were observed for the presence of abnormal motor signs (falls, twists, clasps, pivots) and tested on several measures of motor performance (activity, climbing, righting, homing) before surgery and again on Day 20. All nuclear lesions produced significant ($p < .05$) improvements in motor function and decreases in the frequency of abnormal motor signs. No individual nuclear structure appears entirely responsible for the *dt* rat motor syndrome. SPATIO-TEMPORAL CODING IN THE CEREBELLAR CORTEX. V. Perciavalle*, G. Bosco and R.E. Poppele. Dept. of Physiology, University of Minnesota, Minneapolis MN 55455

The role played by parallel fibers in coincidence detection by Purkinje cells (PC) has not been investigated under natural stimulus conditions. It has been proposed that this function would depend on a synchronous activation of mossy fiber inputs similar to that of the climbing fibers. We present evidence for such activation from 208 spinocerebellar PCs recorded in anesthetized cats during rapid passive foot rotations. The stimuli evoked synchronous patterns of simple spike activity that reflected the temporal patterns recorded in the dorsal spino-cerebellar tract (DSCT) mossy fiber projection. We showed previously that the timing of DSCT post-stimulus spike density, expressed by principal components computed across cells, is generated by spinal circuits and not by stimulus parameters because the same components result from single electrical stimuli to peripheral nerves (Osborn & Poppele, J. Neurophysiol., 1989,61:447).

Three-quarters of the total variance in post-stimulus firing patterns across PCs in all parts of the spinocerebellum could be explained by four principal component waveforms which are nearly identical to those derived from DSCT activity recorded under the same experimental conditions. Further consideration of the temporal delays between DSCT and PC responses and the locations of responsive PCs relative to DSCT terminations leads to the conclusion that the synchronous patterns of post-stimulus activity evoked in cerebellar PCs results from the detection of synchronous patterns of parallel fiber activity established by spinal circuitry and transmitted via mossy fibers. (Supported by NIH Grant NS 21143.)

SIMILAR SAGITTAL TOPOGRAPHY OF NECK AND EYE MOVEMENTS IN RABBIT CEREBELLAR VERMIS. M. Godschalk* and J. van der Burg. Dept. of Anatomy, Fac. of Medicine, Erasmus University Rotterdam, The Netherlands.

Electrical microstimulation in lobules VI and VII of monkey, cat and rabbit evokes saccadic eye movements, topographically related to the stimulation site in the vermis. In monkey and cat, the horizontal component of the saccades is directed ipsilaterally. In rabbit however, stimulation in a zone close to the midline evokes ipsilaterally directed saccades, and stimulation in a more distant zone induces saccades directed contralaterally (Godschalk et al., 1992, Soc. Neurosci. Abstr. 18:1046). To further elucidate this sagittal zonal topography, we studied the relation between evoked eye and neck movements in the rabbit.

Rabbits were prepared, under full anesthesia, for recording microstimulation-evoked eye and neck movements. Scleral search coils were implanted under the conjunctiva of both eyes and a similar coil was attached to a recording chamber, placed over the cerebellar vermis. After full recovery, electrode penetrations were made in the vermis while the head was relatively free-moving: the microdrive attached to the recording chamber was suspended from a rubber band, leaving the head in an upright position. The animal could freely rotate its head in the horizontal plane and shift the head for a limited extent in the horizontal plane and vertically.

On all sites where saccades were elicited, they were accompanied by neck movements. In all cases, the head made a rotatory movement in the horizontal plane and in the same direction as the accompanying eye movement; thus the sagittal zonal pattern of eye movements was preserved in the neck movements. The thresholds of the neck movements were similar to those of the elicited saccades and ranged between 8 and 60 μ A. Latencies for both movement types were similar after any stimulus. We conclude that the topography of neck movements in lobules VI and VII of the cerebellar vermis, similar to saccadic eye movements, is organized in two parasagittal zones: a medial zone for ipsilaterally directed movements and a lateral zone for movements directed contralaterally.

CYTOLOGY OF THE CEREBELLAR CORTEX IN THE MEANDERTAIL MUTANT MOUSE. J.A. Heckroth*, A. Akintunde, H. Grishkat, and L.M. Eisenman Indiana University School of Medicine, THCME, Terre Haute, IN, 47809 and Jefferson Medical College, Dept. of Anatomy and Dev. Biol., Philadelphia, PA 19107.

Adult meandertail mutant mice (*meal/meal*), unaffected heterozygous mice (*meal/+*), and wild-type mice (C57Bl6) were euthanized, transcardially perfused with a buffered mixture of aldehydes, and the cerebella prepared for routine transmission electron microscopy. In its anterior region the meandertail cerebellar cortex is agranular, but retains a crude trilaminar architecture. The thin superficial layer consists of neuropil composed primarily of Purkinje cell dendritic profiles. Disarranged Purkinje cell somata with intervening neuropil form an intermediate layer. The deepest layer consists of glial and small neuronal somata, and a neuropil containing myelinated fibers, Purkinje cell dendrites, and a few mossy fiber rosettes. Scattered within the agranular cortex are microneurons, a few of which appear to be ectopic granule cells. The neuropil of the agranular cortex contains large numbers of presumed Purkinje cell dendritic spines which are wrapped in glial lamellae, and are apparently not contacted by presynaptic elements. Presumptive basket cell axons are observed to impinge upon the surface of Purkinje cell somata and dendrites, and boutons with the characteristics of climbing fibers contact some spinous appendages. The cortex of the cerebellar posterior lobe is relatively normal in appearance. This "normal" cortex, however, exhibits a high frequency of ectopic granule cells located singly, and in clusters, at the surface of and within the molecular layer. An intermediate cortical region forms a gradual transition from the normal to the agranular cortical architecture. Supported in part by NIH grant NS22093 to LME.

LOSS OF PURKINJE CELLS DOES NOT ALTER THE TOPOGRAPHY OF LOWER THORACIC-UPPER LUMBAR SPINOCEREBELLAR PROJECTIONS IN THE CEREBELLAR ANTERIOR LOBE OF *SHAKER* MUTANT RATS. T.L. Knight, N.A. Connors*, and D.L. Tolbert. Depts. of Anat., Neurobiol., and Surg. (Neurosurg.), St. Louis Univ., St. Louis, MO. 63104

Lower thoracic-upper lumbar (LT-UL) spinocerebellar (SpCb) projections have a complex topography in the anterior lobe of normal rats. In adult *shaker* mutant rats, many or all of the Purkinje cells (PCs) in the anterior lobe degenerate. This study sought to determine if loss of PCs alters LT-UL SpCb topography in the anterior lobe. In *shaker* rats the distribution of WGA-HRP labeled LT-UL SpCb mossy fiber terminals were mapped in unfolded reconstructions of the anterior lobe and compared with similar reconstructions from normal rats. In *shakers*, labeled LT-UL labeled terminals were localized to clusters and sharply defined, irregularly-shaped patches surrounded by terminal free areas. The terminal patches were contained within discontinuous parasagittally oriented stripes or transversely oriented bands. The spatial distribution of LT-UL SpCb projections in *shaker* rats have numerous features of organization similar to that seen in normal rats. Based on these similarities, we conclude that PCs are not necessary for the maintenance of SpCb topography in the rat cerebellum. (Supported by NIH Grants RR07013 and NS20227).

711.9

ELECTRICAL STIMULATION OF THE INFERIOR OLIVE RESULTS IN ENHANCED ACTIVITY OF PROJECTION NEURONS IN THE CEREBELLAR NUCLEI OF THE KETAMINE ANESTHETIZED RAT. T.J.H. Ruigrok, T.M. Teune, J. van der Burg and J. Voogd*. Dept of Anatomy, Erasmus University Rotterdam, the Netherlands.

The role of the complex spike as a 'meaningful' afferent input for the cerebellar nuclei is much debated. Here, we study the response of identified neurons in the cerebellar nuclei to graded electrical stimulation of the inferior olive.

Ketamine anesthetized male Wistar rats received stimulation electrodes in the red nucleus and inferior olive. Recordings of neurons in the contralateral cerebellar nuclei and cerebellar cortex were obtained with glass micropipettes filled with 4M NaCl. Cerebellar nuclear units were identified by their antidromic action potential triggered from the red nucleus which collided with spontaneous spikes. Purkinje cells were identified by their complex spike activity. After identification, the response pattern to graded inferior olive stimulation was recorded and analyzed.

Seventy-five cerebellar nuclear neurons were analyzed. Besides a single orthodromically induced action potential in 44 units (presumably triggered by climbing fiber collaterals; latency 4.2 ± 0.4 msec), virtually all units (73) responded with an initial pause of variable duration (mean 57 ± 38 msec). Post-stimulus time histograms showed that this inhibition phase was followed by an increase in activity in 61 units. For 36 units, the chance of firing more than doubled for at least 20 and up to 500 msec (mean 125 msec). Graded stimulation learned that, frequently, the inhibition developed before the facilitation. Purkinje cell recordings indicated that it is unlikely that the facilitatory effect upon cerebellar nuclear neurons is exclusively due to a change in simple spike firing rate.

It is concluded that olivary triggered complex spikes not only cause a phasic inhibition of cerebellar nuclear neurons but, in addition, may result in a subsequent, and potentially significant, increase of their firing rate. This effect appears to be especially prominent when large numbers of olivary neurons fire in synchrony.

INHIBITORY SYNAPTIC RESPONSES IN TURTLE CEREBELLAR GRANULE CELLS. Jens Midgård*, Div. Neurophysiology, Dept. Medical Physiol., Univ. of Copenhagen, Blegdamsvej 3, DK-2200 Copenhagen N, Denmark.

Synaptic responses were investigated in a slice preparation of the turtle (*Trachemys scripta elegans*) cerebellum by current clamp whole-cell recordings. IPSPs, presumably due to Golgi cell activation, were evoked by electrical stimulation in the granule cell layer and in the molecular layer. Three types of inhibitory responses were found: the classical bicuculline and picrotoxin sensitive response with reversal potential near the Cl^- -equilibrium potential. This IPSP had a relatively short latency, lasted around 100 ms and strongly reduced the amplitude and duration of the mossy-fiber EPSP. In some cells a part of this IPSP persisted following the addition of bicuculline (50 μM) and picrotoxin (50 μM). Under these conditions glycine (focal application or 200 μM bath-applied) evoked a strychnine-sensitive (30 μM) response with a reversal potential close to the Cl^- equilibrium potential. The bicuculline and picrotoxin-resistant glycine response is consistent with the expression in granule cells of glycine-receptor β subunits, insensitive to picrotoxin (Pribilla et al). Following these short-lasting IPSPs, a slow IPSP developed, with a maximum after 500-1000 ms, and lasting some seconds. This IPSP had a reversal potential close to the K^+ equilibrium potential and was blocked by CGP 35348 (200-800 μM), consistent with a GABA_B response. This IPSP was particularly prominent in the presence of bicuculline and picrotoxin: under these conditions mossy-fiber EPSPs displayed a marked paired-pulse depression, corresponding in timecourse to the GABA_B IPSP; furthermore, the mossy-fiber paired-pulse depression was strongly reduced by CGP 35348. Thus, different IPSPs exert a strong control of the granule cell excitability on a timescale from ms to seconds.

NEW(?) PROPOSALS FOR CEREBELLAR STUDIES L.Simon*, A.Simon, J.Laczko. 1st Dept. of Anatomy, Semmelweis Univ. Medical School, 1450 Budapest, Hungary

a, The double spike generating mechanism revealed on dendritic records of Purkinje cells (Simon, 1981) suggests i, to postulate phase-related unidentical input to the (generally two) main, separated dendritic areas, which ii, due to the continuous transfolial shift of the dendritic trees (Palkovits et al. 1971), calls for a smooth, gradually changing parallel fiber input organization, rather than clearcut somatotopic maps.

b, The elementary phenomena of heterosynaptic modulating effect of climbing fiber response (CFR), demonstrated on the independent dendritic spike generator patterns (Simon, 1977, 1994) could fulfill both the heterosynaptic inhibition and facilitation proposed by Albus (1971) and Marr (1976), respectively.

c, The climbing fiber activation i, at sensorimotor conflict builds up the adaptive modifications, organizes and maintains task- and body/environment model (Simon, 1987)-related individual sensorimotor programs, ii, at need of changing for an other, formerly elaborated program, covering the incoming sensorimotor context, it will be loaded by inferior olivary bursts by means of fast (1-4 Sec) actualization of the dendritic input connections. Every individual PC can serve a plenty of programs based on overlapping sensorimotor machinery.

711.10

INACTIVATION OF RED NUCLEUS BLOCKS BURSTING IN DEEP CEREBELLAR NUCLEUS: EVIDENCE FOR A POSITIVE FEEDBACK CIRCUIT. J. Keifer*. Dept. of Anatomy and Structural Biology, Univ. of South Dakota School of Medicine, Vermillion, SD 57069.

Microelectrode recordings in behaving animals show that burst discharges in cerebellum and red nucleus correspond to discrete limb movements. Activity in the cerebellar circuit is postulated to be generated by positive feedback. An anatomical basis for a recurrent circuit is provided by tract tracing studies in a variety of vertebrate species that demonstrate connections among the red nucleus, cerebellum and precerebellar nuclei. The function of a positive feedback circuit requires that the loop be closed. To further evaluate the potential role of positive feedback in producing bursts recorded in this circuit, the loop was opened by pressure microinjections of blocking agents and the effect on bursting examined.

Experiments were performed using the *in vitro* turtle brainstem-cerebellum preparation (*Chrysemys picta*). Extracellular single-unit recordings were made from the deep lateral cerebellar nucleus. Neurons were identified by antidromic activation in response to an electrical stimulus applied to the contralateral red nucleus and were readily driven to burst by a brief stimulus applied to the spinal cord. To evaluate the role of feedback in producing these bursts, cobalt (100 mM) or lidocaine (2%) mixed with fast green (2%) was microinjected (0.4 - 2.4 μl) into the red nucleus. During inactivation of the red nucleus, ascending inputs to the cerebellum from a spinal stimulus are unaffected. Ejection of these compounds into the red nucleus either blocked completely or reduced burst discharges recorded in the cerebellar nucleus. These effects were usually reversible. Location of the ejection in the red nucleus was evaluated by histological localization of fast green. Some cells failed to show a response to the ejection. These cells could not be identified and may have been medial nucleus neurons, or ejections in these cases failed to localize in the red nucleus.

These preliminary observations provide further support for the hypothesis that burst discharge recorded in the cerebellar circuit is generated by a spatially distributed network that is mediated, in part, by positive feedback (Keifer & Houk, *Physiol. Rev.*, July, 1994). Supported by NIH grant R29 NS31930-01A1.

CONTROL OF SOMATIC SPIKING BY SYNAPTIC INPUT AND VOLTAGE-GATED DENDRITIC CURRENTS IN CEREBELLAR PURKINJE CELLS: A MODELING STUDY. D. Jaeger*, E. De Schutter* and J.M. Bower. Div. of Biology 216-76, Caltech, Pasadena, CA 91125 and U. of Antwerp - ULA*, Belgium

The level of depolarization at the soma of a Purkinje cell is strongly dependent on the inward and outward currents distributed over the large area of its dendritic tree. Here we analyze the relative contribution of synaptic and voltage-gated currents on the spiking behavior of the soma, using a previously constructed realistic Purkinje cell model (De Schutter and Bower, *J. Neurophysiol.* 71: 375-419). We find that dendritic Ca^{++} currents tend to depolarize the cell in a positive feedback loop, such that a net outward synaptic current is necessary to produce physiological somatic spiking rates (0 - 100 Hz). In the absence of inhibition, bursting behavior ensues. This modeling result is supported by intracellular recordings *in vivo* showing somatic bursting behavior when inhibition is blocked with bicuculline. The control of spike timing in the model was investigated by varying inhibitory and excitatory input rates and synaptic strength. The regularity of spiking was found to be strongly dependent on the temporal structure of both inhibitory and excitatory input.

SHORT-TERM INTERACTION BETWEEN THE COMPLEX SPIKE AND GRANULE CELL INPUTS IN A PURKINJE CELL MODEL. E. De Schutter¹* and J.M. Bower². ¹University of Antwerp - UIA, 2610 Antwerp, Belgium, ²California Institute of Technology, Pasadena CA 91125, USA.

We used a detailed compartmental model of a Purkinje cell (J. Neurophysiol. 71:375-400, 401-419, 1994) to investigate how a climbing fiber (CF) input modifies the response to subsequent granule cell (GC) inputs. We have shown that somatic responses to small synchronous GC inputs are amplified by dendritic P calcium channels (PNAS in press); the same P channels are also activated by the complex spike (CS).

A CS fired up to 160 ms before the synchronous GC input had no effect on the amplitude of somatic EPSPs. A stimulus between 160 and 140 msec after the CF input was slightly potentiated. Between 140 msec and 90 msec there was a depression of up to 17 %, but 80 to 60 msec after the CF input there was a progressive and large potentiation (90 % at 60 msec) of the EPSP. GC inputs arriving sooner after the CF input fell into the prolonged afterhyperpolarization after the CS. Similar effects were seen for simple spike (SS) firing in response to steady asynchronous parallel fiber inputs. Between 60 and 80 ms after the CS, SS frequency increased up to 50%, between 80 and 120 ms SS frequency decreased up to 35%.

These results may explain some of the conflicting results found with *in vivo* recordings. We conclude that, even without synaptic plasticity and without changes in GC firing patterns, a CS might cause either a potentiation or a depression of SS firing, depending on which time frame after the CS is investigated.

A NEW SILICON MICROELECTRODE ARRAY TECHNOLOGY FOR MULTICHANNEL EXTRACELLULAR RECORDING. D.T. Kewley^a*, D.A. Borkholder^b, C.W. Stormont^b, J.M. Bower^a and G.T.A. Kovacs^b. ^aComputation and Neural Systems and Division of Biology, California Institute of Technology, Pasadena, CA 91125, ^bDepartment of Electrical Engineering, Stanford University, Stanford, CA 94305.

We have developed a new technology for the fabrication of micromachined *in vivo* extracellular microelectrode arrays. These devices ("probes") consist of thin films deposited on a single-crystal silicon substrate which is thinned to 24 μ m. Their overall shape is comblike, with each shaft of the comb supporting several individual electrode sites. In a neurophysiological experiment, these shafts would be inserted into the brain of the experimental animal, allowing simultaneous recordings to be made from multiple locations both normal and parallel to the brain surface. Our efforts complement work on similar devices performed in other laboratories.

We are drawing on our combined experience as neurophysiologists and engineers to optimize the utility of this technology for the end users. For example, we are concentrating on providing a large number of electrode sites on a shaft of minimal width. We accomplish this by using two metal levels, one for high-resolution interconnects and the other for electrode sites. This allows us to position the electrodes over the interconnects, placing 4 electrode sites along the centerline of a shaft that is 24 μ m wide, or 8 sites on a 40 μ m shaft. Like other advanced probes, ours have iridium electrode sites, which can be used for both recording and stimulating. We are also customizing the probe geometries to meet the needs of specific experimental paradigms. For the first fabrication run, we have designed 15 different probes, including some specifically for the rat cerebellar cortex, some for the rat olfactory bulb, and some for general-purpose use. Supported by a grant from Medtronic Corporation to J.B., and an NSF NYI award to G.K.

MORPHOLOGICAL EVIDENCE FOR INTERZONAL INHIBITION BY GOLGI CELLS IN THE RABBIT VESTIBULOCEREBELLUM. C.I. De Zeeuw^{*}, D.R. Wylie, P.L. DiGiorgi, and J.I. Simpson. Dept. Physiology & Biophysics, NYU Med. Ctr., New York, NY 10016.

The complex spike (CS) and simple spike (SS) activity in individual parasagittal climbing fiber zones of the flocculus and nodulus are optimally modulated during optokinetic stimulation about approximately the same spatial axis (Kano et al., '91). Which elements of the vestibulocerebellar cortex cause the SS activity to be spatially aligned with the CS activity is not clear, because an individual mossy fiber can have rosettes in different climbing fiber zones. To investigate whether Golgi cells might be involved in the spatial alignment, we made small injections of biocytin into the granular layer to determine the orientation of Golgi cell axons with respect to the parasagittal zones. The zones were identified using acetylcholinesterase staining of the raphe that divide the white matter into zones and/or by determining the axis of visual world rotation that produced the strongest CS modulation. The majority of our sample (n = 47) of Golgi cell axons in the flocculus and nodulus was oriented perpendicularly to the zones and crossed to neighboring zones. The basket cells showed the opposite pattern; their axons were parasagittally oriented and therefore were confined to a single zone (see also Bishop et al., '91). We suggest that the Golgi cells may enhance the spatial alignment of the CS and SS modulation in the vestibulocerebellum by inhibiting the granule cells of neighboring zones.

OPTICAL IMAGING OF CEREBELLAR CORTICAL ACTIVITY *IN VIVO* USING THE pH SENSITIVE DYE, PHENOL RED. G.C. Chen and T.J. Ebner^{*}. Departments of Neurosurgery and Physiology, University of Minnesota Medical School, Minneapolis, MN 55455.

Neuronal activity is associated with intra- and extracellular pH changes. This raises the possibility of using pH as an indicator of neuronal activity, using optical detection methods. In this study we utilized phenol red as an optical indicator of neuronal activity. In anesthetized rats, Crus 1 and 2 of the cerebellar cortex were stained with phenol red (4 mg/ml) for approximately 1 hour. After wash out of the dye, these areas were imaged (100 ms exposure time, excitation 546 nm, emission > 590 nm) with and without surface electrical stimulation (single stimulus) using a Photometrics cooled CCD camera. The optical response in the cerebellar cortex to stimulation was determined by subtracting and averaging images without stimulation from images with stimulation. The optical response consisted of a discrete "beam" of increased signal which extended across the whole folium. The time course of the optical response peaked within 100 ms and was undetectable 200 ms after the onset of stimulation. Signal size correlated with the stimulation amplitude (100-300 μ A). Field potential recordings revealed a close spatial correspondence with the optical signals. Both the electrical and optical responses were reversibly blocked with TTX. One possible origin of this optical signal is the initial, brief alkalinization of the extracellular space which follows stimulus-evoked activity in cerebellum. This observation suggests that optical imaging of pH change could be a useful method for studying spatial and temporal patterns of activity in the central nervous system. Supported by NIH grant PO1 NS31318.

COMPLEX SPIKE SYNCHRONY OF PURKINJE CELLS IN THE VESTIBULOCEREBELLUM OF THE RABBIT. J.I. Simpson^{*}, D.R. Wylie, and C.I. De Zeeuw. Department of Physiology & Biophysics, NYU Medical Center., New York, NY, 10016.

By recording from Purkinje cell pairs in the ventral nodulus of ketamine-anesthetized rabbits, we showed that neurons in the same sagittal zone and having the same complex spike (CS) response characteristics, exhibit CS synchrony, that is the tendency to fire within 2 msec (Soc. Neurosci. Abs. 19:1278). In the present study we show that CS synchrony occurs between cells in spatially separated zones but with the same class of CS responses, and between cells in the same zone but with different classes of CS responses. Neurons that exhibit CS modulation in response to optokinetic stimulation (OKS) about the vertical axis are found in 4 separate zones in each half of the cerebellum, 2 in the nodulus and 2 in the flocculus (VA zones). We recorded in the nodulus from 16 Purkinje cell pairs consisting of one cell in each of the VA zones. Six of these pairs showed CS synchrony. In addition, 3 of 14 pairs consisting of a VA cell in the nodulus, and a VA cell in the flocculus showed CS synchrony. The HA zones of the flocculus and nodulus contain contra-45° and ipsi-135° cells, both of which are modulated by OKS about a horizontal axis perpendicular to the ipsilateral anterior canal. They differ with respect to (1) ocular dominance, and (2) the origin of their CF input, which is the rostral dorsal cap and ventrolateral outgrowth, respectively. Of 7 contra-45°/ipsi-135° pairs, 5 showed CS synchrony. To summarize, CS synchrony is neither limited to Purkinje cells within a single sagittal zone nor to one class of Purkinje cells within the same zone.

711.18

ZONAL PROJECTION OF THE VENTRAL NODULUS IN THE RABBIT. D.R. Wylie^{*}, C.I. De Zeeuw, P.L. DiGiorgi, and J.I. Simpson. Dept. of Physiology & Biophysics, NYU Medical Center, NY, NY, 10016.

The projections of Purkinje cells from zones in the ventral nodulus of pigmented rabbits were studied with the use of extracellularly injected biocytin as an anterograde tracer. The zones were physiologically identified according to the complex spike (CS) modulation of Purkinje cells in response to optokinetic stimulation (OKS). Purkinje cells in the most medial zone (zone NR) do not respond to OKS; they project to the fastigial nucleus, peri-fastigial white matter, peri-interposed white matter (plwm), and medial vestibular nucleus (MVN). In the adjacent zone (zone VA1) Purkinje cells respond best to OKS about the vertical axis; they project to the plwm and MVN. Purkinje cells in the next zone (zone HA) respond best to OKS about a horizontal axis approximately perpendicular to the ipsilateral anterior canal; they project to the plwm, dorsal group y, superior vestibular nucleus (mainly peripherally but also centrally), and MVN. In the most lateral zone, (zone VA2), Purkinje cells respond best to OKS about the vertical axis; they project to the plwm, dorsal group y, and MVN. Although all zones projected to the MVN, the projection from zone HA was largely to the caudal MVN, whereas the other zones projected to the parvocellular and caudal MVN subdivisions. A few terminal fields were found in the descending vestibular nucleus, magnocellular MVN, interposed nuclei, and ventral dentate nucleus. No terminals were found in the prepositus hypoglossi or lateral cerebellar nucleus. The majority of axons innervated more than one nucleus. Often, three or four different areas received terminals from a single Purkinje cell axon. The zonal projection pattern of the ventral nodulus is compared to that of the flocculus, which, with respect to the visual climbing fiber afferents, has similar zones.

712.1

MAXIMUM ACTIVATION DIRECTION AND VISUAL-VESTIBULAR INTERACTION OF FLOCCULUS PURKINJE CELLS IN ALERT CATS. K.D. Powell*, J.E. Killian, B.W. Peterson, J.F. Baker. Physiology, Northwestern Univ., Chicago, IL 60611.

We determined the maximum activation direction (MAD) vectors of 54 neurons in the vestibulocerebellum in the alert cat. The cat rotated sinusoidally at 0.5 Hz in conditions of total darkness and/or dim light. We characterized neurons during vestibular rotations about 3 - 12 axes. Of the 50 neurons recorded in dim light, 19 exhibited both simple and complex spikes and were classified as Purkinje cells (PC). As in our findings in decerebrate cats (Soc Neurosci 18:406), there was canal-canal convergence in alert cats. A total of 40/50 neurons (17/19 PC) had MAD vectors $>20^\circ$ from any single canal plane. MAD vectors of 3 neurons (1 PC) were $<20^\circ$ from ipsilateral horizontal canal, 5 neurons (1 PC) $<20^\circ$ from ipsilateral anterior canal and 2 neurons $<20^\circ$ from contralateral posterior canal. One PC recorded in dim light had a type III response and was $>20^\circ$ from any single canal plane. Other PCs had typical type I or II responses.

We recorded 11 neurons (8 PC) in total darkness, of which 8 neurons (5 PC) had MAD vectors $>20^\circ$ from any canal plane. The remaining 3 PCs each had MAD vectors $<20^\circ$ from one of the 3 ipsilateral canal planes. Of 7 neurons spatially characterized both in the dark and light conditions, 5 had MAD vectors for rotations in the dark $>20^\circ$ different from their MAD vectors for rotations in the light. The difference between MAD vectors for rotations in dark versus light indicates the presence of a visual signal with directional sensitivity different from that of the vestibular signal. The diversity of directional information represented by the Purkinje cells in the flocculus, both vestibular and visual, may support directional VOR adaptation. Supported by EY07342, EY06485.

CONTEXT-DEPENDENT MODULATION OF CEREBELLAR NUCLEAR NEURONS RELATED TO THE PERFORMANCE OF SPECIFIC MOVEMENT SEGMENTS. M.S. Milak*, V. Bracha, J.R. Bloedel. Barrow Neurological Institute, Phoenix, Arizona 85013.

This study addresses the hypothesis that the modulation of some cerebellar nuclear neurons related to the performance of a particular component of a complex movement reflects its context within the overall movement being performed. Initially cats were trained to reach for a manipulandum and move it through a template consisting of a single straight segment. Trained animals were implanted with a multiple single unit, microwire-based, recording system targeted to the anterior and posterior regions of the fastigial and dentate nuclei and the anterior and posterior interposed nuclei. After recovery, the animal was required to learn a succession of new templates, each consisting of 2 to 3 sequential, straight segments. The straight segment on which the animals were trained initially was a component of each template and was always positioned in the same location in the allocentric work space. Histograms were constructed from the activity of simultaneously-recorded units held throughout the acquisition and performance of all the templates used over one experimental day. Amplitudes of specific movement- or premovement-related unitary response components were analyzed relative to a movement segment common to all of the performed templates.

Of the 60 units recorded in seven experiments, 38% showed modulation changes dependent on the context in which the movement segment was performed. In some units these changes were related to movement components executed approximately 400 msec after the peak time of the unitary response. This finding suggests that these neurons participate in the specification and/or organization of movement sequences required for the performance of goal-directed forelimb movements. Supported by NIH grants NS30013 and NS21958.

DIFFERENTIAL TIMING OF CLIMBING FIBER DISCHARGES IN THE CEREBELLAR CORTEX DURING THE INITIATION PHASE OF THE VOLUNTARY ARM MOVEMENT IN MONKEY. J.-P. Pellerin*, M.-T. Parent, C. Valiquette and Y. Lamarre, Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal (Qc), Canada, H3C 3J7.

Climbing fiber responses of Purkinje cells (CFR) were recorded in the vermal, intermediate and lateral regions of a monkey trained to perform rapid flexions or extensions of the elbow in response to randomly presented visual, auditory and somesthetic cues. 119 of the 314 recorded cells were time-locked activated with the movement onset in all triggering modalities. Two types of CFR were defined: 1- Pre-onset CFR: CFR frequency increasing only before the movement onset (65/119 cells) with a mean latency of -59 ms ($s=18$ ms) and 2- Post-onset CFR: CFR frequency increasing at/or after the onset of the movement (54/119 cells) with a mean latency of 10 ms ($s=12$ ms). In both cases, mean latency were statistically compared. In pre-onset CFR, the results showed a significant difference in the mean latency between the three areas investigated: Crus I and II: -81 ms ($s=37$ ms); Paramedian and Vermal lobules VII-VIII: -48 ms ($s=24$ ms) ($F(2,67) = 6.3004, P<.003$). However, there is no difference in the mean latency of the post-onset CFR in any of the cerebellar regions recorded (10 ms, $s=12$ ms). We suggest that pre-onset CFR are implicated in the control of the initiation of the movement because these cells are activated well before the onset of the movement. Post-onset CFR are probably more involved in feedback signal relative to the execution of the movement. Pre-onset CFR are activated earlier in the lateral cerebellum (Crus I and II) which project to the Dentate nucleus. Lateral cerebellum may be a part of a circuit regulating the initiation of the movement according to an hierarchical organisation of the sequence of activation of the olivocerebellar fibers. Supported by MRC grant of Canada.

712.2

INVOLVEMENT OF THE CAT CEREBELLAR INTERPOSED NUCLEUS IN THE CONTROL OF CONDITIONED AND UNCONDITIONED WITHDRAWAL REFLEXES. F.P. Kolb*, K.B. Irwin, N.K. Winters, J.R. Bloedel, V. Bracha. Barrow Neurological Institute, Phoenix, AZ, 85013.

The aim of the present study was to examine the involvement of the cat cerebellar interposed nucleus (IN) in the control of the classically conditioned and unconditioned reflexes elicited in three distinct effector systems.

In food-motivated cats, instrumentally conditioned to maintain quiet stance on small platforms, three types of classically conditioned withdrawal reflexes were established: 1) eyeblink reflex; 2) forelimb withdrawal reflex; and 3) hindlimb withdrawal reflex. Each animal was chronically implanted with a matrix of guiding cannulae used for insertion of injection needles. The effects of temporarily inactivating IN subregions were systematically examined using microinjections of muscimol (1 μ l, 800 ng).

Transient inactivation of the IN affected conditioned as well as unconditioned components of the withdrawal responses in all three reflex systems. The drug injections altered both postural and phasic movement components of the limb's flexion responses. From the magnitude of the effects produced at different injection sites on the three conditioned reflexes, a topographical organization was derived. In addition, IN inactivation severely affected performance of the postural placement response in both limbs ipsilateral to the injection site and the tactile placing, hopping and magnet responses in the forelimb. The data support the view that various regions of the IN are differentially involved in the control of a variety of conditioned and unconditioned cutaneo-muscular and postural reflexes.

DIFFERENTIAL CONTRIBUTIONS OF NUCLEUS INTERPOSITUS ANTERIOR AND POSTERIOR DURING REACHING TASKS IN THE MACAQUE. C.R. Mason*, R.R. Carter, J.F. Baker, J.C. Houk. Northwestern University Institute for Neuroscience, Chicago, IL 60611.

Because the nucleus interpositus anterior (NIA) receives primarily cutaneous input from the rostral dorsal accessory olive while the nucleus interpositus posterior (NIP) receives primarily proprioceptive input from the medial accessory olive, we anticipated that the NIA and NIP might contribute to different aspects of motor control. A macaque fascicularis was trained in a pointing to target task, a reach to pull task and retrieval of fruit bits from Kluver board, bottles or experimenters' hands. The approximate locations of the NIA and the NIP were mapped out during a number of penetrations where single units were recorded and related to the target task. Inactivations were induced by pressure-injecting 2.0 μ l muscimol (0.5 μ l doses four times 2.5 minutes apart) (2 mg/ml) above the NIA or NIP. Different reaching deficits were observed depending on the site of muscimol inactivation. The NIA inactivation greatly impaired the monkey's ability to shape its hand in preparation for surface contact during the pointing task or reshaping the hand prior to grasp in a reach to pull task. Once contact was made with the surface, the monkey appeared unable to use cutaneous cues to improve hand function. The monkey was able to aim its arm and place the hand in the desired spatial location for use. NIP inactivation greatly affected the monkey's ability to aim its hand to the desired location in space or maintain the position during use of the hand. The monkey did exhibit proper hand shaping for the tasks at hand. The monkey appeared unable to use proximal forelimb proprioceptive input and attempted compensation by using visual cues or distal fixation. These observations suggest that the NIA contributes to the optimal function of the hand during tasks that require coordinated use of the fingers and hand and that the NIP contributes to the overall coordinated use of the hand by coordinating the transport of the hand to where it needs to be in space (aiming the hand) and maintaining its position once there so that the hand and fingers have a stable base to work on. Supported by N00014-90-J-1822 and 1 P50 MH48185-01.

712.6

NEURONAL CORRELATES OF DIRECTIONAL INSTRUCTION IN THE CEREBELLUM DURING PREPARATION FOR AN INTENDED MOVEMENT. L. Germalin*, Y. Lamarre, J. Kalaska. C.R.S.N. Dép. de physiologie, Univ. de Montréal.

In order to assess the activity of cerebellar nuclear and cortical neurons during an instructed delay period two monkeys were trained according to the following paradigm. A 1000 Hz or a 400 Hz tone were used as auditory instructions for right elbow flexion or extension respectively. These auditory signals were followed by a silent immobile instructed delay period of 500 to 1500 msec duration. At the end of the preparatory period a torque pulse to the manipulandum was used as a trigger signal for movement execution. Tones and duration of delay periods were randomly mixed and set-related cells were recorded while the monkeys were performing at $92 \pm 4.4\%$ and $85 \pm 5.9\%$. All neurons were recorded for approximately 100 trials and only cells which displayed a statistically significant (Student's t-test $p(0.01)$) sustained change in firing rate during the instructed delay period were included in our samples of set-related cells. Our first sample included 23 nuclear neurons and our second sample included 50 nuclear and 34 cortical neurons. Only neurons which displayed a statistically significant difference between their change in firing rate during instructed delay for flexion as compared to extension were considered as directional. The vast majority of set-related cells were directional. The mean difference in firing rate for directional nuclear set-cells were 10.88 ± 5.29 imp/sec ($n=19$) and 10.91 ± 5.64 imp/sec ($n=35$). In the cerebellar cortex this directional difference during the instructed delay was 14.35 ± 15.3 imp/sec ($n=22$). These data are consistent with a role for cerebellar neurons in the preparation for an intended movement during an instructed delay motor task (supported by MRC and FRSQ).

SPATIAL CHARACTERISTICS OF THE RESPONSES OF CEREBELLAR PURKINJE CELLS DURING A TWO-DIMENSIONAL REACHING MOVEMENT IN MONKEYS I. SIMPLE SPIKES. Q.-G. Fu*, D. Flament, J.D. Coltz and T.J. Ebner. Depts. of Neurosurgery & Physiology, Univ. Minnesota, Minneapolis, MN 55455.

We have used a direction-distance arm reaching paradigm to study the spatial characteristics of the responses of cerebellar Purkinje cells and quantitatively analyzed the simple spike response with univariate and multivariate regression models. The paradigm involved a multi-joint reaching movement in the horizontal plane from a centrally located start position to 48 targets located in 8 different directions and 6 distances. Simple spikes firing in relation to direction, distance, and target location were analyzed using regression models as previously applied to the premotor and primary motor cortex (Fu, et al., J. Neurophysiol., 70:2097-2116, 1993).

Based on a univariate model, the simple spike firing of the majority of cells (114/151, 75.5%) was modulated by movement direction, distance or both parameters. Of these cells 31/114 (27.2%) showed a cosine-tuned modulation with direction and 45/114 (39.5%) cells were linearly correlated to distance, while 38/114 (33.3%) cells were modulated by both parameters. However, the majority of cells exhibited directional modulation at only one distance or distance modulation along one direction. Multivariate analysis indicated the firing of 99/128 (77.3%) cells was correlated with either direction, distance, or target location parameters (62/99, 62.7%) or some combination of these three parameters (37/99, 37.3%). The mean total R^2 for the multiple regression model was 0.34 ± 0.15 , considerably lower than the average of 0.61 ± 0.18 obtained from the cerebral motor cortical area. Although significant correlation of simple spike discharge with kinematics occurs, still other parameters or models are needed to fully describe these cells' activity. Supported by NIH grant NS-18338.

KINEMATIC AND EMG ANALYSIS OF WRIST MOVEMENTS IN FRIEDREICH'S ATAXIA. B. Wild, T. Klockgether, J. Dichgans (SPON: European Neuroscience Association). Department of Neurology, University of Tübingen, D 72076 Tübingen, Germany

Due to the predominant degeneration of peripheral and spinal proprioceptive neuronal pathways Friedrich's ataxia (FA) can be regarded as a model of cerebellar deafferentation. Our goal was to characterize movement abnormalities in fast goal directed wrist flexions in FA patients compared to age-matched healthy subjects and patients with chronic cerebellar degeneration.

Flexion movements (5° and 30° of amplitude and fast movements without target) were performed and measured using a manipulandum. Agonist and antagonist EMG were recorded with surface electrodes.

FA patients exhibited very slow movements with increase of reaction time, time to peak acceleration and movement duration and a decrease of peak acceleration and velocity. This was similar in cerebellar patients but significantly more pronounced in FA. In both patient groups the rise of the first agonist burst was slower and the antagonist burst delayed. In contrast to cerebellar patients there was a disruption of the triphasic pattern with diminished antagonist activity and a decrease or disappearance of the second agonist burst in FA.

We conclude that cerebellar deafferentation in FA and chronic cerebellar degeneration causes similar EMG and kinematic changes, i.e. slowing of movement initiation, acceleration and velocity and a delay of the antagonist burst. We propose that the disruption of the triphasic pattern and the excessive movement slowing found in FA patients are sufficiently explained by peripheral deafferentation. Similar changes have been described in patients with peripheral neuropathy.

HUMAN BRAIN FUNCTION IN BIPEDAL GAIT STUDIED WITH PET — AGING EFFECT IN CEREBELLAR FUNCTION
K. Ishii, M. Senda*, H. Toyama, K. Oda, S. Ishii, K. Ishiwata and T. Sasaki. PET Center, Tokyo Metro. Inst. Gerontology, Tokyo, JAPAN.

We reported in the previous meeting on an approach to evaluate in vivo regional brain function during walk in human subjects by use of FDG-PET technique, in which the cerebellar vermis was significantly activated by a treadmill walk. The purpose of this study is to examine the aging effect on the brain function associated with bipedal gait. The subjects were twelve healthy volunteers without any neurological problems (ages 22 to 88). In each subject, two measurements were undertaken; in walking (30 minutes' treadmill walk at a steady velocity) and at rest (keeping supine rest). In both conditions, eyes were open and the brightness of the room light was controlled at the same level. After a transmission scan for attenuation correction, 150MBq of FDG was injected and the subject was instructed to keep one of the two conditions. Forty minutes after the injection, a 12- or 24-minute emission scan was performed with HEADTOME-IV. The two sets of PET images from each subject were three-dimensionally registered. The whole brain activity in each study was normalized and the normalized regional activities were evaluated as the indices of regional brain function. Cerebellar vermis was markedly activated with treadmill walk in all the subjects. The mean amplitude of the reaction was 38% in the younger group (under 60, $n=7$, ages 31 ± 9.4) and 27% in the elder group (over 60, $n=5$, ages 76 ± 10.6). The tendency for the elderly people to lose walking activity may be partially attributed to the reduced reactivity of the brain.

712.8

Systematic error in multi-joint coordination in cerebellar patients J. Low*, S. Massimini, B. Marinelli, M. Hallett. Human Motor Control Section, NINDS, NIH, Bethesda, MD; #Human Motor Control Laboratory, Department of Neurology, University of Rochester, Rochester, New York

Cerebellar patients have multiple deficits in motor coordination. These deficits may share common pathophysiologic mechanisms. We studied multi-joint coordination in cerebellar patients quantitatively. Two patients with olivopontocerebellar atrophy and 2 normal subjects sat in front of a chest-high table and placed the right wrist on the table 15 cm away from their chest. They reached for 3 targets in straight lines which required predominantly shoulder (direction A), synchronous elbow and shoulder (direction B), and predominantly elbow (direction C) rotation. Two infrared cameras sampled the positions of 4 diodes placed on the left and right shoulder, right elbow and right wrist at 400 Hz. The corresponding shoulder angles when elbow angles reached 1/3 of their angular trajectories were computed. At high velocities, normals deviated from straightness by making excessively synchronous elbow and shoulder rotations. In direction A, the average shoulder rotation of trials with higher velocities (AH) was 4° more than that with lower velocities (AL). In direction C, AH was 3.9° less than AL. Cerebellar patients deviated from straightness by a different systematic error. The abnormality was inadequate shoulder rotation in both direction A and C. AH was 5.3° and 7.0° less than AL in direction A and C respectively. This may be caused by inadequate torque generation at the shoulder. These findings suggest that the cerebellum may play a role in the control of force.

712.10

ANALYSIS OF INTERSEGMENTAL DYNAMICS IN CEREBELLAR LIMB ATAXIA

H. Topka, M.D*, J. Konczak, Ph.D., K. Schneider, Ph.D¹ and J. Dichgans, MD
Neurology Department, University of Tübingen, F.R.G.
¹Institute of Kinesiology, Technical University of Munich, F.R.G.

OBJECTIVE: To determine the mechanical characteristics of multi-joint arm movements in three-dimensional space in healthy subjects and patients with cerebellar degenerative disorders.

METHODS: We studied 5 patients and 5 age and sex - matched normal subjects. Point-to-point multi - joint movements at various movement velocities were recorded using an infrared tracking system (E.L.I.T.E.) with position markers attached to the shoulder, elbow, wrist, and hand. An inverse dynamics approach modeling the upper limb as three interconnected rigid links was employed to calculate net joint torques (NET), gravitational torques (GRA), interactive motion-dependent torques (MDT), and muscle torques (MUS) acting at the shoulder and elbow joint. Effects of MDT on angular kinematics of interconnected joints were estimated.

RESULTS: When moving at high velocities, peak velocity, peak acceleration and deceleration of the hand marker, as well as angular velocity, acceleration and deceleration of shoulder and elbow joints were smaller in patients. Peak NET, MUS, and MDT torques acting at the shoulder and elbow joint were similar in both groups at slow and moderate speed, but were smaller in patients when performing high velocity movements. At all movement velocities, MDT originating in shoulder and wrist joint had a more profound effect on angular kinematics of the interconnected elbow joint in patients as compared to normals. Similarly, MDT originating at the elbow and wrist joint abnormally influenced angular acceleration of the shoulder joint in the patients.

CONCLUSION: Dyscoordination of upper limb movements in cerebellar ataxia may be due to an insufficient compensation for motion-dependent interactive torques occurring during movements of a multi-segmented limb with interconnected joints. The problem may reflect a deficiency in generating appropriate levels of muscle torques at the shoulder and elbow joint.

713.1

NADPH-DIAPHORASE ACTIVITY IN DEVELOPING CEREBELLUM OF THE CHICK. C.R. Dermont*, A. Stamatakis (SPON: European Neuroscience Association) Dept. of Biology, Crete Univ., Iraklion 711 10, Crete, Greece.

A novel messenger nitric oxide (NO), has been suggested to play role in synaptic plasticity and to participate in shaping neuronal connections. In order to further investigate the role of NO, we studied the distribution of nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) positive cells and fibers in the developing chick cerebellum, during the time that cell migration occurs and while synaptic contacts are established. From embryonic day 9 (E9) until E15 day, the most prominent feature was the strong NADPH-d activity in the undifferentiated cerebellar white matter, which contained a) NADPH-d positive ascending axons, that targeted selectively the developing folia and b) Golgi like stained neurons moving outwards from neuroepithelium to cerebellar cortex. In addition, NADPH-d labeled cells were found in cerebellar nuclei from E13 day. Cerebellar cortex exhibited weak NADPH-d reactivity until E15 day, when a) NADPH-d negative immature granule cells in external granular layer, begun massive inward migration to form internal granular layer, in which differentiated granule cells and glomeruli exhibited gradually increasing NADPH-d activity, b) molecular layer contained lightly stained basket and migrating granule cells, while diffuse NADPH-d activity increased, possibly due to the development of parallel fibers and c) Purkinje cells (PC) showed transient NADPH-d activity on their somata and apical dendrites, that peaked around E17 day and then gradually decreased, until posthatching day 1 (P1) when PC were completely devoid of NADPH-d activity, phenomenon that parallels the transient appearance of PC perisomatic processes and axo-somatic synapses. From P5 day, adult patterns of NADPH-d activity were observed in the chick cerebellum. Our data support similar pattern of NO expressing neurons in the developing avian and mammalian cerebellum and we suggest that neurons forming NO are involved in the developmental processes for the establishment of connections and normal cytoarchitecture

CLONING OF A SELENOPROTEIN PREFERENTIALLY EXPRESSED IN THE CEREBELLUM. K. Saijoh^a, N. Saito^b, M. J. Lee^a, M. Fujii^a, T. Kobayashi^a, K. Sumino^a, and T. Fukunaga^c. ^aDept. Pub. Hlth and ^bDept. Pharmacol., Kobe Univ. Sch. Med., Kobe 650, Japan, and ^cDept. Leg. Med. Shiga Univ. Med. Sci., Ohtu 520-21, Japan.

In order to obtain cDNA coding proteins enriched in the bovine cerebellar cortex, a subtraction library was produced. From the subtracted library, a clone of which cDNA insert displayed high homology to selenoprotein P cDNA but contained 12 rather than TGA codons and a tandem repeat of CCCCAC and CCGCAT were isolated. Thus, its primary structure was characterized as containing 12 selenocysteines as well as an 8-fold-repeat of (Pro-His). Moreover, the tandem repeat and its adjacent region included 16 histidines and 10 prolines among 28 amino acids. This selenoprotein mRNA was expressed in all the areas of the brain but most prominently in the cerebellar cortex, hippocampus, and olfactory bulb. Expression of selenoprotein P mRNA was scant in the brain. These findings suggest the possibility that this new selenoprotein, rather than selenoprotein P, is a major selenium carrier in the brain. (This work was in part supported by Grants-in-Aid of Ministry of Education, Science and Culture, Japan.)

THE DORSAL COLUMN NUCLEI PROJECT TO THE BASILAR PONTINE NUCLEI IN THE MONKEY. G.A. Mihailoff^{1,2*} and S. Warren¹, Departments of Anatomy¹ and Neurology², University of Mississippi Medical Center, Jackson, MS 39216-4505.

The basilar pontine nuclei (BPN) have long been recognized for their role in the transfer of cerebral cortical information to the cerebellum. However, recent studies in the rat indicate that the BPN receive a more diverse array of afferent projections than previously recognized. Included among these afferent systems is a projection from the dorsal column nuclei (DCN) and the spinal trigeminal nucleus. In the present studies we seek to document the existence of DCN projections to the BPN in non-human primates. In cynomolgus monkeys, multiple, unilateral injections of an orthogradely transported axonal marker were made into the DCN. In addition, in some animals, either multiple injections of an orthograde marker or an ablative lesion was made in the hand or leg region of the primary somatosensory cortex (SI). After survival periods ranging from one to twelve days, each animal was sacrificed and its brain prepared for light and electron microscopic visualization of the orthogradely transported markers. Observations from these cases indicate that the DCN in the monkey project via the medial lemniscus to territories within dorsal, medial, ventral, and lateral regions of the BPN. Some of these DCN termination sites overlap those of SI corticopontine projections. Electron microscopic studies revealed that labeled DCN boutons form asymmetrical synapses within the BPN, and further, that these spheroidal vesicle containing boutons participate in glomerular-like arrangements similar to those described in the rat. These observations suggest that in addition to the spinocerebellar systems, peripherally derived somatosensory information might be transferred to the cerebellum via mossy fibers arising in the basilar pons. Moreover, the possibility exists that peripheral and cortical somatosensory signals are integrated in some fashion within the BPN prior to transfer to the cerebellum. Supported by NIH grant NS12644.

PURKINJE CELL HETEROGENEITY: A DIRECT COMPARISON STUDY OF TWO PARASAGITTAL BANDING PATTERNS IN THE ADULT MOUSE CEREBELLUM. A. Akintunde¹(1), J. Voogd²(2), T. J. H. Ruigrok²(2), A. J. Haroian³ and L. M. Eisenman¹(1). Depts. of Anatomy, Thomas Jefferson Univ., Philadelphia, PA 19017(1), Erasmus Univ., P.O.Box 1738, 3000 DR Rotterdam, Netherlands(2) and Hahnemann Univ. Sch. Med., Philadelphia, PA 19102(3).

Several correlational studies of the parcellation of the cerebellar cortex have been carried out in attempts to determine the "functional unit" or "cerebellar module" of the mammalian cerebellum. Purkinje cell efferents to the cerebellar nuclei have been shown to be organized into parasagittal zones as has the distribution of the zebrin II antigen. Unilateral injections of the tracer Tetramethylrhodamine ("Fluoro-Ruby") were made into the fastigial nucleus (FN) of the adult mice. Serial frontal sections of the cerebellar cortex were processed for visualization of tracer retrogradely transported from the FN injection site and for zebrin II antigenicity. Retrogradely labeled Purkinje cells were observed ipsilaterally in the posterior and anterior cerebellar vermis and in well-delineated narrow parasagittal longitudinal zones. Comparison of the banding patterns revealed the narrow longitudinal zones of retrogradely labeled Purkinje cells to be confined to a restricted portion within the boundaries of two immunonegative Purkinje cell bands. Similar observations were made in the rat (Voogd et al., Neurosci. Abstr. 17:1573, '91) NIH grant NS 16531 (LME) and NATO Grant CRG 910888 gratefully acknowledged.

ANATOMICAL TRACING REVEALS DIFFERENT VIBRISSE REPRESENTATIONS IN DIFFERENT CEREBELLAR LOBULES. J.J.A. Arends, H.P. Zeigler & M.F. Jacquin. Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis MO 63104; Psychol., Hunter Coll., New York NY 10021; Neurology, Washington Univ. Sch. Med., St. Louis MO 63110.

Prior studies suggest that the cerebellum contains multiple representations of the body surface. It is unclear, however, whether different lobules contain representations that are biased toward particular receptor organs, and whether the latter are conveyed to the cerebellum via different mossy fiber systems. The concise and reiterated map of the facial whiskers in trigeminal brainstem subnuclei interpolaris and principalis, and their projections to the cerebellum, provide an ideal system for addressing these issues. We have previously shown that the uvula, deep lobule of Crus I, and Crus II receive the heaviest inputs, in decreasing order, from whisker-related portions of the trigeminal complex. Here, in adult rats, retrograde and anterograde tracers were used with parvalbumin immunohistochemistry to correlate single whisker representations in the trigeminal nuclei with their projections to the cerebellar cortex. We find that the distribution of labeled interpolaris cells differs markedly after tracer injections in the vermis (uvula) and the hemispheres (Crus I and II) as follows. Injections in the uvula produced a relatively homogeneous distribution of labeled cells throughout ventral interpolaris. Deep Crus I injections resulted in labeled cells mostly in ventrolateral interpolaris, where the caudalmost whiskers are represented. Crus II or paramedian lobule deposits produced a somewhat different pattern of retrogradely labeled cells that most heavily represented the ventral and rostral whiskers. Such "lobular" patterning is much less apparent in principalis. Here, mossy fibers originate exclusively in the rostral 2/3 of the nucleus, from a medial location caudally and gradually including more lateral regions rostrally. This distribution represents a bias toward a rostral whisker representation in principalis. Supported by NIH NS29885, DE07662.

CONVERGENCE AND DIVERGENCE OF SPINAL AND SPINAL-CUNEATE MOSSY FIBER INPUTS TO THE RAT CEREBELLAR ANTERIOR LOBE. D.L. Tolbert* and J.M. Alisky, Depts. of Anat., Neurobiol., and Surg. (Neurosurg.) St. Louis Univ., St. Louis, MO 63104

The convergence and divergence of lower thoracic-upper lumbar (LT-UL) spinocerebellar (SpCb) and spino- and cuneocerebellar (CnCb) projections to the anterior lobe was studied in rats. Mossy fiber terminals differentially labeled with biotinylated dextran amine (BDA) and cholera toxin subunit B (CTb) were identified in the same section and quantitatively mapped in computer generated (Bioquant) unfolded reconstructions of the anterior lobe. Injections of BDA surrounded by CTb injections within a single LT-UL segment showed a higher degree of convergence than injections into rostrocaudally separated LT-UL segments. Continuing this trend, differentially labeled L₁ and L₂ SpCb terminals showed a greater degree of convergence compared to similarly labeled, but more widely separated, L₁ and L₃₋₅ projections. Differentially labeled SpCb and CnCb projections terminated preferentially in restricted non-overlapping areas but nonetheless showed a small degree of convergence. These findings indicate that there are varying degrees of convergence and divergence for different LT-UL SpCb inputs or for SpCb and CnCb inputs. However, terminal overlap or segregation of such inputs is never absolute. (Supported by NIH Grant NS20227).

BRANCHED NUCLEOCORTICAL PROJECTIONS TO THE INTERMEDIATE CEREBELLUM IN THE CAT. L. PROVINI², W. MARCOTTI¹, S. MORARA¹, A. ROSINA^{1*}. ¹Ist. Neurosci. Bioimm., C.N.R. and ²Ist. Fisiol. Gen. Chim. Biol. Univ. Milano, Milano, Italy.

Cerebellar nucleocortical projections have been reported to be topographically organized, in relation to both the olivocorticonuclear compartments and the somatotopic arrangement of the olivocerebellar input. This study was aimed to address two related questions, i.e. I) whether or not somatotopically homologous areas of the anterior lobe (PIAL) and paramedian lobule (PML) - in C1, C2 and C3 compartments - differ in the extent and topography of their nucleocortical input; and II) whether or not there are nuclear neurons that connect by way of branched collaterals these two areas, as it was previously found for the olivocerebellar system. With this aim, one of the fluorescent retrograde tracers Fast blue (FB) and Diamidino yellow (DY) was pressure injected into the forelimb-related folia (FL) of the intermediate compartments of either PIAL or PML.

The analysis of single- and double-labeling in the inferior olive complex (IO) allowed to verify that the FB and DY injected areas were centered into the FL areas, and only those experiments in which the two IO labeled populations were in register, were selected for the present study. The results show that the FL-PIAL and FL-PML areas in C1, C3 and C2 cortical zones are projected upon by neurons located in the anterior (NIA) and posterior (NIP) interposed nuclei, thus roughly reciprocating the corticonuclear organization. Within these nuclei, the two populations of labeled neurons overlap and show a topographic relation to the cortical somatotopy. In the areas of overlap, double-labeled neurons are found. A minor non reciprocal projection stemming from the fastigial nucleus, and a contralateral projection from the interposed nuclei were also observed.

These data are taken to indicate that the corticopetal fibers from the interposed nuclei to C1, C2, C3 compartments mainly operate as a closed loop feed-back system. The non-reciprocal and contralateral nucleocortical fibers may be seen as a system which allows communication among different compartments.

ORGANIZATION OF THE OLIVOCEREBELLAR PROJECTION IN THE MEANDER TAIL MUTANT MOUSE. J.A. Napieralski, H.L. Grishkat and L.M. Eisenman*. Department of Anatomy/Developmental Biology, Thomas Jefferson University, Philadelphia, PA 19107.

There is a considerable amount of evidence which demonstrates that the histologically uniform cerebellum is actually divided into anatomical, biochemical and functional zones. One of the parasagittally organized afferent systems which has been particularly well characterized in several species is the olivocerebellar system. Although the mechanism underlying the organization of this system is unknown, useful information has been obtained through the analysis of the projection in neurologically mutant mice with cerebellar defects. This study presents the results of the analysis of the olivocerebellar projection in the cerebellum of the *meander tail* (*mea*) mutant mouse. The cerebellum of the *mea/mea* is characterized by an apparently normal cytoarchitecture posteriorly with an abrupt transition to an abnormal anterior region characterized by abnormal foliation, agranularity and Purkinje cell (PC) ectopia. Injections of either wheatgerm agglutinin-horseradish peroxidase or tetramethyl rhodamine into the inferior olive of *mea/mea* mice demonstrated that the parasagittal organization of the olivocerebellar system is preserved in both the "normal" posterior and abnormal anterior regions of the cerebellum. These results suggest that neither the agranularity of the cortex nor the abnormal location of the PC, the target cells of the olivocerebellar fibers, disrupts the normal parasagittal organization of these fibers in the cortex. NIH Grant NS22093 (to LME) gratefully acknowledged.

713.11

THE PREFRONTAL CORTEX IS THE TARGET OF OUTPUT FROM THE BASAL GANGLIA AND CEREBELLUM. F.A. Middleton*¹ and P.L. Strick². ¹Research Service, VA Medical Center and Departments of ²Neurosurgery and ³Physiology, SUNY Health Science Center, Syracuse, NY 13210.

There have been a number of recent suggestions that output from the cerebellum and basal ganglia influences regions of the prefrontal cortex involved in language and higher cognitive function. To begin to examine this issue we injected the McIntyre-B strain of herpes simplex virus type 1 (HSV1) into the dorsolateral prefrontal cortex (Walker's area 46) of cebus monkeys (*Cebus apella*, n=3). This strain of HSV1 is transported transneuronally in the retrograde direction. All injection sites were confined to the principal sulcus and virus did not spread to adjacent cortical regions, such as the frontal eye field (FEF) in area 8. Five days after virus inoculation, many labeled neurons were found in both the dentate nucleus (DN) of the cerebellum and the internal segment of the globus pallidus (GPi). The size and shape of labeled neurons in DN and GPi were typical of neurons in these structures that project to the thalamus. Labeled DN neurons were located in the most ventral portion of DN and were concentrated rostro-caudally in the middle third of the nucleus. This location is clearly distinct from that of DN neurons labeled by retrograde transneuronal transport from the primary motor cortex (M1), ventral premotor area (PMv), or FEF. Labeled GPi neurons were located in the most dorsomedial region of both the inner and outer portions of GPi and were concentrated rostro-caudally in the middle-third of the nucleus. This location is clearly different from that of GPi neurons labeled by transneuronal transport from M1, PMv, or the supplementary motor area. These findings provide an anatomical substrate for the participation of cerebellar and basal ganglia output in higher cognitive function. Support: VA Medical Research Service and USPHS 2957 & 24328 (PLS).

VISUAL INPUT TO THE CEREBELLUM OF RATS. B. Mercier, E. Jenkinson, I. Kralj-Hans, C. Swales and M. Glickstein*. Dept. of Anatomy, University College London, Gower Street, London WC1E 6BT.

To trace visual pathways to the cerebellum we injected wheatgerm agglutinin (WGA-HRP) into the visual cortex or the superior colliculus of rats and plotted terminal distribution of fibres in the pontine nuclei and nucleus reticularis tegmenti pontis (NRTp). In parallel experiments we injected WGA-HRP into cerebellar lobules VII or IX of the vermis or the petrosal lobule, and plotted retrogradely filled cells in the pons. The visual cortex projects principally to a dorsolateral region in the rostral half of the pontine nuclei. Although collicular projection overlap somewhat with those from the visual cortex, they extend far more caudally. Unlike the visual cortex, the superior colliculus also projects to NRTp. We compared the location of retrogradely labelled cells following cerebellar injection with the results of studies of orthograde projections from cortex and colliculus. The petrosal lobule receives its input from the same region of the pontine nuclei which receives fibers from the primary visual cortex. The region of pontine nuclei whose cells project to lobule IX receives inputs from both visual cortex and superior colliculus. Unlike the petrosal lobule and lobule IX, lobule VII receives a major input from NRTp. The results suggest that there are two relatively independent pathways by which visual information can reach the cerebellar cortex. One originates in the primary visual cortex and projects by way of the dorsolateral pons to the petrosal lobule and lobule IX. Another originates in the superior colliculus and projects by way of NRTp to lobule VII. The pattern of organization is similar to that seen in parallel experiments with monkeys.

ANTEROGRADE LABELLING OF SPINOCEREBELLAR FIBERS IN FETAL MOUSE CEREBELLUM. H.L. Grishkat* and L.M. Eisenman. Department of Anatomy/Developmental Biology, Thomas Jefferson University, Philadelphia, PA 19107.

A large amount of information has been collected on the adult organization of the spinocerebellar projection in several different species. However, studies on the development of this projection are few and have been limited to select species such as the opossum, chick, cat and the early postnatal rat. An analysis using anterograde tracing techniques on the spinocerebellar projection in the fetal mouse (E13-E15) is presented. Biocytin crystals were applied to the cut end of the cervical spinal cord of embryonic mice. A tissue slab containing the brain stem, cerebellum and cervical spinal cord was maintained *in vitro* for 23 hrs and then fixed, sectioned and processed for biocytin revelation. Only a few labelled fibers were found in the lateral most portions of the rostral cerebellum at E13. At E14 labelled fibers were limited to rostralateral portions of the cerebellum. At E15 labelled fibers were evident coursing to the rostromedial areas of the cerebellum. These fibers were just ventral to the migrating EGL and parallel to the pial surface, although a few fibers could be seen coursing more deeply within the cellular layer. Some fibers were seen to cross the midline. No labelling was found in the posterior cerebellum at this age. These studies indicate that spinocerebellar fibers have penetrated the cerebellar anlage significantly prior to the differentiation and migration of their target, the granule cell. Supported by NIH grant NS22093 to LME.

714.1

CORTICOTROPIN RELEASING FACTOR (CRF) AXONS AND BINDING SITES IN THE REELER CEREBELLUM. J. S. King, G. A. Bishop, and P. C. Madtes, Jr.* Dept. Cell Biology, Neurobiology and Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

It is our working hypothesis that CRF functions in early development as a growth regulating factor. We previously reported in the developing opossum cerebellum that (1) CRF is present in early arriving axons and growth cones and (2) the initial CRF binding sites are expressed over Purkinje cells subsequent to their migration (King & Madtes, '93 Neurosci. Abstr. 19:1215). In this study we used an antibody to CRF and 125 I labeled CRF to describe the distribution of CRF labeled axons and CRF binding sites in the cerebellum of the mutant mouse, reeler. In the reeler cerebellum, most Purkinje cells fail to migrate to the typical monolayer and are malpositioned in either the internal granule cell layer or in three paired deep cellular masses. CRF immunoreactive axons terminate in their adult phenotypes as climbing fibers and mossy fibers, but only in the reduced molecular and granule cell layers. Punctate immunolabeling is present within the lateral and intermediate deep cellular masses, but absent in the medial cellular mass. CRF binding sites are present over Purkinje cells that have migrated to form the typical monolayer, and those that reach the internal granule layer. In contrast, CRF binding sites are absent over Purkinje cells that fail to reach the diminutive cortex and are positioned in the deep cellular masses. Taken together, these findings are compatible with our developmental data that indicate CRF receptor binding is expressed over Purkinje cells only after they reach the cortical surface, and supports our working hypothesis. (Supported by NS-08798).

714.3

PHYSIOLOGICAL EFFECTS OF CALCITONIN GENE RELATED PEPTIDE IN CEREBELLAR CIRCUITRY. G. A. Bishop*. Dept. of Cell Biology, Neurobiology and Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

Calcitonin gene related peptide (CGRP), composed of 37 amino acids, has been localized within specific populations of mossy fibers in the cat's cerebellar cortex (J. Comp. Neurol. 322:201-212, 1992). In the present study the physiological effects of CGRP on spontaneous, amino acid induced, and synaptically mediated activity were analyzed. In addition, interactions between CGRP and serotonin (5HT), another modulator of cerebellar circuitry, also were recorded. CGRP suppresses spontaneous and amino acid induced activity. However, the peptide has a more potent effect in blocking aspartate and quisqualate mediated excitation as compared to that elicited by glutamate. CGRP decreases or eliminates synaptic activity elicited by stimulation of the inferior cerebellar peduncle. 5HT also suppresses neuronal firing in the cerebellum. When CGRP and 5HT are applied together, the individual suppressive effects are potentiated. However, the potentiation is most effective if 5HT is applied prior to the application of CGRP. The results suggest that the release of amino acids from climbing and mossy fibers may not always result in excitation of their target neurons. Rather the response of the postsynaptic cell is dependent on its chemical microenvironment at a particular point in time. This chemical microenvironment may be different for each cell, thus each may have a unique response that is determined by interactions between peptides, monoamines and classic excitatory amino acids. These complex interactions between peptides, excitatory amino acids and monoamines provide evidence for functional plasticity in cerebellar circuitry. (Supported by NS18028).

17 β -ESTRADIOL ALTERS SENSORY PROCESSING IN WHISKER RESPONSIVE CELLS OF PRINCIPAL TRIGEMINAL (PrV) AND ROSTRAL DORSAL ACCESSORY OLIVARY (rDAO) NUCLEI OF THE RAT M.C. Kennedy, S.S. Smith, M.A.L. Nicoletis* and J.K. Chapin*. Depts. of Anatomy and Physiology, Inst. of Neuroscience, MCP-Hahnemann University, Broad and Vine, Philadelphia, PA 19102-1192.

The estrous cycle of the rat is associated not only with changes in reproductive function, but also with facilitation of an entire array of sensorimotor parameters, including lowered sensory detection threshold, increased whisker barrel field size and more precise limb coordination. Previous studies from this lab have demonstrated that systemic injection of 17 β -estradiol enhances synchronized rhythmic discharge from the rDAO during a variable speed treadmill paradigm. In the present study the effects of this hormone (100 ng in oil injected i.p.) were tested on sensory responses of simultaneously recorded neurons within the rDAO and PrV. For this study female rats were chronically implanted with separate bundles of 8 microwires (50 μ dia stainless steel, NB Labs) lowered independently into the whisker projection areas of the above structures. Up to 47 individual units were recorded using software from Spectrum Scientific on a Motorola computer. The whiskers were stimulated using a motor-driven wooden probe brushed in three different planes (rostral-to-caudal, dorsal-to-ventral, ventral-to-dorsal). Post-stimulus histograms were then constructed before and 30-90 min after administration of the steroid. Administration of 17 β -estradiol enhanced the signal-to-noise ratio of sensory responses to brushing in the rostral-to-caudal (7/12 rDAO; 9/11 PrV cells) and ventral-to-dorsal (14/26 rDAO; 6/9 PrV cells) direction both by enhancing the sensory response (by ~20%) and by decreasing background discharge (by 30-50%) of those neurons demonstrating an excitatory response. In contrast, only 4/24 (rDAO) and 1/11 (PrV) responses of neurons to brushing in the dorsal-to-ventral direction were enhanced by hormone treatment; the remainder were either primarily depressed (13/24 rDAO; 4/11 PrV cells) or not changed (7/24 rDAO; 6/11 PrV cells) by 20 min post-steroid. Thus, these results suggest that the reproductive hormone estradiol alters sensory processing in whisker responsive cells of both trigeminal and rDAO neurons. (Supported by USAF Grant AFOSR#93-0136 to SSS and NS26722 to JKC.)

714.2

PEPTIDE LOCALIZATION IN THE MOUSE INFERIOR OLIVE. K.V. Gregg, J.S. King* and G.A. Bishop. Neuroscience Program, The Ohio State University, Columbus, OH 43210.

Recent studies from our laboratory have defined the roles of various neuropeptides in modulating circuits in the cerebellar cortex (Prog. in Neurobiol., 39:475, 1993). A major afferent system to the cerebellum is derived from neurons in the inferior olivary complex (IOC). Modulation of this afferent system also will alter the pattern of activity in cerebellar circuits. The intent of the present study is to determine the distribution of several neuropeptides within the IOC of the adult C57BL/6J mouse using the PAP technique. These peptides are known to modulate cerebellar activity and include cholecystokinin (CCK), enkephalin (ENK), calcitonin gene-related peptide (CGRP), substance P (Sub P) and corticotropin releasing factor (CRF). Kooy's terminology is used to describe olivary subdivisions (Folia Neurobiol., 10:205, 1917). Each of these peptides, with the exception of Sub P, labeled small ($\leq 1\mu$ m) varicosities in all nuclei of the olivary complex. In addition, CGRP and CRF immunostaining were present in larger profiles ($\geq 1\mu$ m) that were restricted in their distribution. The larger CGRP varicosities were localized primarily in the lateral pole of the dorsal accessory olive (DAO), the dorsal cap of Kooy, and the dorsomedial extension of the ventral lamella of the principal olive (POv). Large CRF varicosities were exclusively found in the dorsal cap of Kooy. Substance P immunolabeling was confined to the dorsal cap of Kooy, the dorsomedial extension of the POv, and portions of the medial accessory olive (MAO). CRF was the only peptide that labeled olivary cell bodies. The overlap in the distribution of these peptides suggests that they may be colocalized with each other as well as with excitatory or inhibitory amino acids known to be present in afferents to the IOC. These findings serve as baseline data for future physiological studies designed to address the functional role of peptides in olivary circuitry. (Supported by NS08798).

714.4

COLLATERALS OF OLIVOCEREBELLAR PATHWAY SYNAPSE ONLY ONTO NON-GABAergic NEURONS OF THE DEEP CEREBELLAR NUCLEI. *T. Borsello, *F. Rossi, *J. van der Want and *P. Strata*. *Dpt. Anat. Human Physiol. Univ. of Torino, 10125 Torino, Italy and *Dpt. of Morphology, Netherlands Ophtalm. Res. Inst., 1100AC Amsterdam, The Netherlands.

Collaterals of the olivocerebellar fibres to the cerebellar nuclei have been assumed to be important to set a background excitation to allow Purkinje cells to sculpture their inhibitory action. The pattern of nuclear cell discharge to the motoneurons is important to shape movements. The discovery that the cerebellar nuclei contain cells which project back to the inferior olive and that are inhibitory (GABAergic) in nature leads to reexamine the problem as to the functional significance of these collaterals to the nuclear cells. Therefore, the question is whether such collaterals project to all types of nuclear cells or whether they are specific to a cell type. Phaseolus vulgaris leucoagglutinin (PHA-L) was injected into the inferior olive of adult albino rats, in order to identify at E.M. level collaterals to the cerebellar nuclei. GABAergic cells were identified by immunoreactivity with postembedding colloidal gold particles. Cholera toxin (CTB) was also injected into the inferior olive to label anterogradely the collaterals to the nuclei and retrogradely the nucleo-olivary projections.

Collaterals of inferior olive cells to the intracerebellar nuclei were present exclusively on non-GABAergic deep cerebellar neurons. In addition, CTB labelled retrogradely only deep nuclear cells which are GABAergic, whereas orthodromic labelling was confined to terminals ending on non-GABAergic neurons. The lack of collaterals of the olivocerebellar pathway to the GABAergic neurons which project back to the inferior olive suggests the olivo-cerebellar-olivary loop to be a closed loop circuit which contributes to motor performance with a different mechanism from the open loop circuit where the deep nuclei neurons project towards the motoneurons.

LOCAL APPLICATION OF ESTRADIOL FACILITATES SYNCHRONIZED RHYTHMIC OLIVARY ACTIVITY. Sheryl S. Smith*, Dept. of Anatomy, Inst. of Neuroscience, Hahnemann-MCP University, Phila., PA 19102-1192.

Ongoing studies in this laboratory have demonstrated that synchronized olivary oscillations are modulated by the hormone (estrous) cycle of the rat. Limb response to changes in treadmill speed is most accurate and timely on estrus, following endogenous increases in estradiol, relative to diestrus (lower hormone levels). One potential strategy by which estrous hormones might facilitate rapid limb movements is via an action on the synchronization of rhythmic olivary activity. Synchronized oscillations of this structure are thought to facilitate rapid, alternating movements of the limbs (Linás, 1991). Previous studies from this lab (Smith, 1991, 1992) have demonstrated that synchronized rhythmic olivary activity recorded during treadmill locomotion is facilitated on the night of behavioral estrus, when limb coordination is improved, or following systemic injection of estradiol and progesterone at physiological doses. For the present study, the effect of local administration of estradiol was tested for its effect on synchronized olivary activity. This study was conducted in diestrus female rats chronically implanted with arrays of microwires (50 μ dia, stainless steel, teflon-coated) to record from as many as 23 neurons simultaneously within the rDAO during treadmill locomotion. The wires encircled a 23 g. cannula implanted 1 μ m above the wire tips. Local infusion of drugs was then accomplished using fused silica capillary tubing (144 μ dia.). Local administration of 600 nM 17 β -estradiol (E₂ in 1 μ l 0.02% ETOH/saline) triggered synchronized olivary activity with a 3 Hz oscillation during treadmill locomotion using a variable acceleration paradigm by 15 min post-steroid. Local administration of vehicle had no effect on rhythmic olivary activity. Local administration of the NMDA receptor antagonist MK-801 (20 μ M) 5 min prior to administration of the steroid prevented the synchronizing effect of E₂ administration. These results suggest that E₂ can increase synchronized olivary oscillations by acting within the vicinity of the rDAO, and that this effect is dependent upon functional NMDA receptors. These modulatory effects of E₂ may underlie its reported facilitating action on rapid movements of the limbs. (Supp. by USAF Grant# 93-1-0136)

714.7

ULTRASTRUCTURE OF MUSCARINIC AND NICOTINIC RECEPTOR PROTEIN IN THE RAT, RABBIT, AND MONKEY CEREBELLUM. A.R. Caffé, R.K. Hawkins and J. Voogd, Dept. Anatomy, Erasmus University Rotterdam, The Netherlands. (SPON: European Neuroscience Association).

The cerebellum is innervated by cholinergic mossy fibres from the medial vestibular and prepositus hypoglossi nuclei, and thin varicose fibres of which the origin is still uncertain. Furthermore, cholinergic agents administered within the cerebellum evoke behavioural modifications. Physiological studies, however, have yielded conflicting results about the identity of the cholinergic elements. To characterise cerebellar cholinergic profiles at the ultrastructural level, antibodies against cholinergic receptor proteins have been used. Muscarinic receptor protein immunoreactivity has been found in astrocytes. In the granular layer some Golgi cells, mossy fibre terminals, and granule cell bodies also express this staining. Some Purkinje cell somata display cytoplasmic labelling but most of these perikarya receive labelled axon terminals. In the molecular layer prominent muscarinic receptor immunolabelling has been observed in some Basket cells, Bergmann glia and parallel fibres. Nicotinic receptor protein is differently expressed. Some granule and Golgi cells, but no astrocytes or mossy fibre terminals, express immunoreactivity. Most Purkinje cells and their dendrites show strong staining. In the molecular layer parallel fibre varicosities, but no Bergmann glia fibres, express nicotinic receptor protein. Species differences exist in topography of both muscarinic and nicotinic stained cerebellar profiles. The results indicate that muscarinic and nicotinic receptors are synthesised by multiple and distinct cerebellar cells. Combined with the species differences this might explain the present inconsistent data on the identity of cerebellar cholinergic profiles.

SPATIOTEMPORAL STUDY OF FOS ACTIVITY IN THE INFERIOR OLIVE AND CEREBELLUM FOLLOWING SYSTEMIC HARMALINE. D.W. Saxon* and A.J. Beitz, Department of Vet. Pathobiology, University of Minnesota, St Paul, MN 55108

The tremorogenic alkaloid, harmaline when given systemically produces repetitive synchronous activity in neurons of the inferior olive (IO) and presumably release of excitatory amino acid neurotransmitter at the olivopurkinje cell synapse. Following subcutaneous injection (25 mg/kg in saline) and survival times between 15 minutes and 24 hours, rats were perfused with paraformaldehyde, sectioned and reacted for FOS protein immunocytochemistry. The results indicate that as early as 15 min following harmaline there are detectable levels of FOS in caudal subdivisions of IO (i.e., IOA, B & C) and that by 30 min most other subdivisions of IO (i.e., IOD, IOM, IODM & IOPr) show FOS activity. Activity in the IO peaked by 2 hours with regard to numbers and intensity of positive FOS nuclei and had returned to control levels by 18 hours post-harmaline. Medial subdivisions of IO were found to contain FOS activity for protracted times after lateral IO subdivisions returned to control levels. The cerebellar cortex showed marked increase in FOS activity by 1 hour post-harmaline. At 1 hour the granule cell layer throughout the cerebellum and the Purkinje cell (PC) layer of the vermis and paravermis showed FOS nuclear staining. A subset of PC in the vermis and paravermis were found to display FOS activity at 1 hour and all later times tested. FOS positive nuclei in the molecular layer (ML) were numerous in the vermis but sparse in the lateral hemispheres. Labeling in the ML peaked by 2 hours and gradually returned to control levels by 12 hours post-harmaline. The deep cerebellar nuclei also showed spatial and temporal changes in FOS activity. A morphologically diverse group of neuronal nuclei were evident in the fastigial nucleus by 30 min, but changed to a single morphological group of small nuclei by 18 hours. The interposed and lateral cerebellar nuclei displayed intense FOS activity by 2 hours and returned to control levels by 24 hours post-harmaline. Taken together these results suggest that there are distinct spatial and temporal changes in the cortex, IO and deep cerebellar nuclei in response to harmaline activation of the IO. Supported by Grant # NS31318 and DC01086.

ALTERATION OF CEREBELLAR GLUTAMATE RECEPTOR SUBUNITS FOLLOWING INFERIOR OLIVE AND PONTocerebellar TRACT LESIONS. J.J. Sanderson, R.H. Price, Jr.* and A.J. Beitz, Department of Veterinary Pathobiology, University of Minnesota, St. Paul MN 55108

The major cerebellar afferent pathways, climbing and mossy fibers, are reported to use an excitatory amino acid as their neurotransmitter. Chemical lesions of the inferior olive and mechanical lesions of the pontocerebellar mossy fiber tract were made in an effort to elucidate the receptor subtypes responsible for mediating cerebellar afferent neurotransmission. Intraperitoneal (IP) injections of 50 to 60 mg/kg 3-acetyl pyridine (3-AP) were used to chemically lesion the inferior olivary nucleus of young (150 to 250 g), male SD rats. The right middle cerebellar peduncle (MCP) was lesioned with a short, horizontal sweep of a 28 g needle inserted through the occipital skull plate. *In situ* hybridization histochemistry was used to monitor postsynaptic changes in the levels of mRNA for subunits of the NMDA (NR1), AMPA (GluR1) and metabotropic (mGluR1) subtypes of glutamate receptors. In addition, immunocytochemistry with specific antisera for the NMDA and AMPA receptor subunits NR1, GluR1, GluR2/3, and GluR4 was used to detect differences between control, 3-AP-lesioned and MCP-lesioned rats. Preliminary results suggest that GluR2/3 immunostaining in subpopulations of Purkinje cells oriented along parasagittal zones becomes more intense in the 3-AP-lesioned animals. In non-lesioned controls, all Purkinje cells appear to be uniformly stained. These results suggest a selective glutamate receptor subunit upregulation after climbing fiber destruction. Supported by NS31318.

GLUTAMATE RECEPTOR SUBUNITS AT THE GIANT MOSSY FIBER-UNIPOLAR BRUSH CELL SYNAPSE. E. Mugnaini* and D. Jaarsma, Lab. of Neuromorphology, Univ. Connecticut, Storrs, CT 06269-4145, USA

The unipolar brush cell (UBC), a previously neglected small neuron of the cerebellar granular layer, is densely concentrated in the vestibulo-cerebellum and is characterized by its single brush-like dendritic arbor arising from a short stalk (Mugnaini and Floris, J. Comp. Neurol., 339: 174-180, 1994). The UBC is innervated by one or two mossy fibers (mf) via an extraordinarily extensive synaptic contact (Mugnaini et al., Synapse, 16: 284-311, 1994). White matter activation results in NMDA and non-NMDA glutamate receptor-mediated EPSCs in the UBC (Rossi et al., this meeting). Here we used previously characterized antibodies specific for AMPA, kainate and NMDA receptor subunits to immunohistochemically identify the receptor/s associated with the mf-UBC synapse. Frozen and Vibratome sections of rat and cat cerebella, perfused with buffered aldehydes, were incubated with polyclonal antisera to GluR1, GluR2/3, GluR4, GluR6/7, KA-2, NMDA-R1 and NMDA-R2A/B (kindly donated by R. Wenthold), diluted 1:50 to 1:200, and with monoclonal antibodies (mab) recognizing GluR5/6/7 (Clone 4F5, Pharmingen) and NMDA-R1 (clone 54.1) subunits, diluted 1:500 to 1:2000. The PAP or the ABC method were employed using DAB as the chromogen. UBCs were strongly immunostained with the GluR2/3 and GluR5/6/7 (4F5) antibodies. Weak staining was observed with antibodies against the NMDA-R1 subunits. Antisera against the GluR1, GluR4, GluR6/7, KA-2 and NMDA-R2A/B subunits did not substantially immunoreact with the UBCs. At the electron-microscopic level, GluR2/3 and GluR5/6/7 immunoreaction products were found throughout the UBC cytoplasm. The mab to G5/6/7 stained the post-synaptic densities at the mf-UBC contact more densely than the polyclonal GluR2/3 antiserum. Thus we were able to clearly identify both AMPA and kainate glutamate receptor subunits at the mf-UBC synapse. Supported by USA PHS grant NS 09904.

ETHANOL SUPPRESSION OF GLUTAMATE-INDUCED ENHANCEMENT OF CEREBELLAR PURKINJE CELL DISCHARGE IN RAT. R. Grigorian*, G. Zernova, A. Khorkov, Sechenov Institute, St. Petersburg, Russia.

It is commonly accepted that both ethanol (ET) and glutamate (GLU) have powerful actions on the activity of cerebellar Purkinje cells (PC). The effects of intravenous injections of 1.0 g/kg of ET on glutamate-induced enhancement of cerebellar PC discharge was studied. The mean change in PC discharge frequency produced by microiontophoretic application of GLU across a range of current intensities (30, 80, 120 and 180 nA) was evaluated before and after the injection of small doses of ET. The circulating level of ET was determined by gas chromatography. Before application of ET, the mean frequency of PC discharge activated by mossy fibers was 26.56 ± 0.33 imp/s, the standard deviation was 2.6%, and the time to return to baseline after GLU was 600-1600 ms, depending upon the current intensity used for GLU injection. In contrast, after ET injection, the mean frequency of PC discharge in response to GLU was always less than before ET, across all current intensities employed. The standard deviation of PC discharge frequency after ET injection was reduced to 0.6%, one-fourth as variable as before ET. Further, the restoring time of PC discharge frequency in response to GLU was as much as 1.5-2.0 times faster after ET injection. These results demonstrate that ET suppresses the GLU-induced enhancement of cerebellar PC discharge frequency.

EVOKED RESPONSE MODULATION IN INTRACELLULARLY RECORDED CEREBELLAR PURKINJE CELLS BY SEROTONIN. L.J. Larson-Prior* and R.M. Bushey, Dept. of Neuroscience and Anatomy, Penn State College of Medicine, M.S. Hershey Medical Center, Hershey PA 17033.

Distinct differences in the extent and distribution of serotonergic input to the cerebellar cortex have been reported for several mammalian species based upon immunocytochemical data. In addition, the physiologic responses of extracellularly recorded cerebellar Purkinje cells to exogenously applied serotonin have been reported to be variable; eliciting both increased and decreased spontaneous firing rates. Recently, the 5HT_{1A} receptor has been implicated in the reduction of Purkinje cell activity (Darrow et al., Eur. J. Pharmac. 175:145, 1990; Kerr and Bishop, Brain Res. 591:253, 1992). Utilizing an isolated cerebellar preparation from the brain of the freshwater diving turtle which maintains the three-dimensional architecture of this brain region (Larson-Prior et al., J. Neurophysiol. 62:293, 1990), we have tested the effects of exogenously applied serotonin on synaptic responses of intracellularly recorded cerebellar Purkinje cells.

Consistent with activation of the 5HT_{1A} receptor subtype, recorded Purkinje cells were hyperpolarized with application of bath applied serotonin (5-10 mM) and showed a consistent decrease in membrane resistance. Firing rate, as assessed by injection of depolarizing current, was slowed following application of serotonin. Evoked responses were obtained by electrical stimulation of either the cerebellar peduncle or the cerebellar granule cell layer. In both cases, unitary EPSPs were reduced by bath application of serotonin. Trains of stimuli (5 stimuli, 50 Hz) produced a late, slow EPSP which was also attenuated with the application of serotonin. Supported by NS 30759.

IDENTIFICATION OF PASSIVE AND REFLEX COMPONENTS OF HUMAN DYNAMIC ANKLE STIFFNESS. R.E. Kearney¹*, R.B. Stein² and L. Parmeswaran¹.
¹Dept. of Biomed. Eng. McGill University, Montréal, Canada, H3G 1Y6 and ²Div. of Neurosci., University of Alberta, Edmonton Canada T6G 2S2

The role of stretch reflexes in the control of movement and posture remains unclear since it is difficult to distinguish the relative contributions of passive and reflex mechanisms to the torques generated in response to a joint perturbation. System identification techniques, using random perturbations, have yielded good descriptions of overall joint stiffness and reflex EMG dynamics but have had little success in characterizing the reflex contribution to the stiffness. Recent evidence suggests that the reflex response is strongly nonlinear and that on-going movements inhibit reflex action in proportion to their average velocity. This motivated us to re-examine human ankle stiffness using experimental and analytic methods designed to overcome these problems. We have used position perturbations which were designed to provide a wide-bandwidth position input with low average velocity. Possible nonlinearities in stiffness dynamics were accounted for through the use of a parallel-cascade system technique for non-linear system identification. Experiments using these new methods consistently identify two distinct components in the overall stiffness dynamics. The first component is position-dependent, acts at short-latency (< 40 ms) and display high-pass dynamics; it seems certain to reflect the passive contribution to stiffness. The second component is velocity-dependent, acts at longer latency (> 40ms) and has dynamics which are described by a static non-linearity followed by low-pass dynamics; this component likely represents the reflex contribution to ankle stiffness. The reflex contribution to stiffness was most significant at low frequencies (below 10 Hz); its size relative to the passive contribution varied strongly with the parameters of the perturbation as well as joint position and level of activation. Thus, the role of stretch reflexes in motor control is likely to be very context sensitive. (Supported by the Medical Research Council of Canada)

MOTOR UNIT ACTIVITY DURING SPASTICITY. B. H. Ross, and C. K. Thomas*. The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL 33136.

Spasticity is a common phenomenon following human spinal cord injury. Most studies to date have examined changes in reflex pathways in individuals who experience spasticity but during the absence of actual spasms. These data therefore provide important clues about the baseline condition from which spasticity stems. However, they provide little information about the processes which occur during spasms per se. The aim of the present study was to examine the patterns of motor unit activity during induced spasms. Seven individuals with chronic (> 1 yr post injury) spinal cord injury between C3-C6 induced spasms by either gentle touch to the side of the knee or weak upper body movements. The evoked electromyogram (EMG) was recorded unilaterally from the surface of each of the triceps surae muscles and intramuscularly from the medial gastrocnemius muscle. None of the triceps surae muscles were under voluntary control. However, during spasms, there were usually short bursts of EMG in all three muscles. Occasionally, periods of rhythmic clonic activity or sustained activation of these and many other muscles were induced. During the brief and sustained spasms, motor units responded: 1) at slow tonic rates (< 10 Hz), 2) with repetitive doublets, and/or 3) with an increase then decrease in rate as the strength of the spasm rose and fell. The first two patterns of motor unit activity seem unique to involuntary contractions whereas the third pattern is typical of motor unit behavior during voluntary contractions. During clonus, motor unit activity also rose and fell rhythmically with the repetitive rise and fall in surface EMG. Peak rates for different motor units occurred in phase. These data suggest that the asynchronous versus synchronous activity of different motor units may explain the nature of the spasm (brief burst versus clonic form).

Interaction of Flexion- (FR) and Crossed Extension Reflexes (CER) with Tilt-Evoked Responses (TER) in Standing Humans. N. Paquet* and C.W.Y. Hui-Chan, School of Phys. and Occ. Therapy, McGill University, Montreal, Canada, H3G 1Y5.

With the use of ischemia, ankle and foot somatosensory inputs were found to contribute to the early component of the TER in lower limb muscles (Busse et al., *Prog. Clin. Neurophysiol.*, 8:310-322, 1980). The purpose of this study was to examine whether FR afferent inputs would modify the lower limb TER in a functionally meaningful manner.

Thirteen young healthy subjects were blindfolded and stood fixed to a tilting apparatus with straps and a neck collar. They underwent sudden forward head-body tilts of 15° with an axis of rotation co-linear with the ankle joint. The mean head acceleration was 0.7g, as measured with a linear accelerometer mounted on a dental bite. FR and CER were elicited with electrical stimulation (ES) of the right tibial nerve behind the medial malleolus during standing (ES alone, n=10 trials) and tilting (tilt+ES, n=20 trials), when the background contraction of the ipsilateral tibialis anterior (TA) muscle was maintained at 10-20% of maximum voluntary contraction. The ES was delivered as a train of 1 ms pulses at 200 Hz during 30 ms at a mean of 3.3 x sensory threshold. TERs with tilt alone (n=10 trials) were also elicited for comparison purpose. EMG responses were recorded in the TA, soleus (SO), biceps femoris (BF) and vastus lateralis (VL) muscles bilaterally.

The FR area in the ipsilateral TA was increased (p<0.05) during tilt in the majority (n=6/7) of subjects whose TA FR area was significantly modified by tilt, while it was decreased in only 1 subject. The remaining 6 subjects showed no effect of tilt on the ipsilateral TA FR area (n=3), or less than 30% of FR occurrence (n=3). Moreover, more subjects showed a response in the contralateral TA during tilt+ES (n=6) than during ES (n=2) or tilt alone (n=1). Finally, a majority of respondents had a tendency for a larger EMG area in the ipsilateral VL (n=8/10 respondents), and contralateral SO and/or VL (n=5/6) during tilt+ES than ES alone.

These results indicate that whole head-and-body tilt tended to increase the excitability of lower limb flexor (including FR) and extensor (including CER) muscles activated by the flexion reflex afferents. The resultant co-contraction of ankle muscles and increased knee extensor activation is consistent with the more difficult task of maintaining a stance against perturbation. This project was financed by Parkinson's Foundation of Canada and a MRC studentship for N.P.

NONLINEAR SHORT-LATENCY REFLEXES PREVENT INSTABILITY IN ELBOW POSITION. R.B. Stein*, J.W. Hunter², S.R. Lafontaine² and L.A. Jones³, Div. of Neuroscience¹, Univ. of Alberta, Edmonton, Canada T6G 2S2, Dept. of Biomed. Eng.² and School of Phys. and Occ. Therapy³, McGill Univ., Montreal Canada.

A motor and digital control system have been developed which allow rapid stretches to be applied to the human elbow joint. The forearm is returned to the initial position and the properties of the control system can be varied before the reflex contraction. Thus, short latency reflex responses can be cleanly separated from intrinsic muscle properties under a wide variety of loading conditions. The reflex force varies linearly with the velocity of stretch over nearly two orders of magnitude. The reflex force also varies linearly with the tonic level of force over the entire range of forces studied (0 - 100 N). This contrasts sharply with, for example, the human ankle joint which shows a very limited linear range. As the control system is made more compliant (less stiff) reflex shortening increases dramatically and becomes more prolonged, whereas the reflex force becomes somewhat smaller and shorter. With compliant loads the reflex shortening is on average equal to the stretch that generated it. Simulations the results show that the dependence of reflex shortening and force on the stiffness of the load is mainly determined by the mechanics of the limb and muscles. The gain of the reflex is as high as it can be without causing instability. The presence of a rectification nonlinearity (e.g., lengthening the muscle produces a reflex, but shortening the muscle does not) is mainly responsible for preserving the stability of the elbow system.

AFFERENT CONDITIONING PRODUCES DIFFERENT EFFECTS ON FLEXION AND H REFLEXES IN MAN. J. Liu and C.W.Y. Hui-Chan*. School of Physical and Occupational Therapy, McGill University, Montreal, Québec, Canada

The objective of this study was to determine whether human flexion reflex (FR) and H-reflex (HR) were modified in a similar or different manner by repeated daily transcutaneous electrical nerve stimulation (TENS).

Twenty young healthy subjects were randomly assigned to a TENS or a placebo group, with 10 in each group for the FR test and 4 in each group for the HR test. Ten daily 60 min TENS or placebo stimulation was applied to the lumbro-sacral region over a two-week period. The FR was elicited by electrically stimulating the sole of subject's right foot and recorded electromyographically from the tibialis anterior (TA) and biceps femoris (BF) muscles. The HR was elicited by electrically stimulating the right posterior tibial nerve in the popliteal fossa and recorded electromyographically from the soleus muscle. ANOVA and planned comparison tests were used to compare the data obtained on Day₁ and Day₁₀ of the treatment period and between the two groups.

For the TA FR area, the pre-stimulation control value obtained on Day₁ was significantly decreased to 68.6% on Day₁₀ in the TENS (p<0.01), but not placebo group (92.5%; p>0.05). For the BF FR area, the pre-stimulation control value was depressed by both TENS and placebo stimulation to 63.8% (p<0.01) and 84.8% (p<0.05) respectively on Day₁₀, with TENS producing greater inhibitory effects than placebo stimulation (p<0.01). For the HR, no significant effect was found on the pre-stimulation control value on Day₁₀ either in the TENS (= 96.7% of Day₁ value; p>0.05) or placebo group (= 107.3%; p>0.05), or between the two groups.

Our results indicated that repeated daily TENS applications over a two-week period produced significant inhibitory influence on the FR but not the HR. Such a differential effects produced by the same afferent conditioning are consistent with the FR and HR being mediated respectively by a polysynaptic and predominantly monosynaptic reflex pathway. (This study was financed by the Fonds de la Recherche en Santé du Québec)

H-REFLEX CHANGES INDUCED BY TRANSCRANIAL MAGNETIC STIMULATION DURING VOLUNTARY MOVEMENT. A.M. Sherwood*, W.B. McKay and M. R. Dimitrijević; Restorative Neurology, Baylor College of Medicine, Houston, TX 77030-3498

Voluntary dorsiflexion movement modified early and later responses to transcranial magnetic stimulation (TMS) with marked, phase-dependent changes in amplitude and latency. To explore movement-related modification of segmental excitability, we evaluated the effects of TMS on H-reflexes over conditioning to test (C-T) intervals ranging from -10 to 100 ms while 5 healthy subjects lay supine during relaxation and during voluntary ankle movement. Half-maximum amplitude H-reflexes were conditioned by TMS at 20% above EMG threshold in the soleus (typically 50-60% of the maximum TMS output). During relaxation there was a slight overall facilitation, but no dependence on C-T interval. In plantar flexion, there was a dependence on C-T interval (p < 0.01), with an enhancement of H at 0 ms compared to 30-100 ms (p < 0.01). During dorsiflexion movement, there was an early decrease followed by increased excitability at a 60 ms C-T interval compared to control reflexes obtained during movement alone (260% increase, p < 0.01), and compared to TMS-conditioned responses at -10 to 40 ms (p < 0.01). These findings support the polysynaptic excitation of soleus motoneurons acting as antagonist during voluntary dorsiflexion movement hypothesized to be responsible for generation of the late MEP responses.

715.7

THE EFFECTS OF LOW INTENSITY CUTANEOUS STIMULATION ON THE H REFLEX MODULATION DURING STATIC AND DYNAMIC CYCLING MOVEMENTS. C. Labrecque and M. Bélanger*. Dép. de Kinanthropologie, Univ. du Québec à Montréal, Montréal, Québec, Canada, H3C 3P8.

Numerous studies have shown modulations of the cutaneous reflex during rhythmic movements such as walking and cycling. Similarly, the H reflex has also been shown to be modulated and depressed during such movements. However, in real life situations, the nervous systems must consider these two sources of interacting feedback during the ongoing movement. The main objective of this study was to examine the effects of cutaneous stimulation on muscular inputs during stationary positions and active cycling movements. The cutaneous stimulation consisted of a 10 ms train of 5-1 ms pulses, at 2 times the sensory threshold, and applied to the dorsal surface of the foot. The H reflex stimulation consisted of a 1 ms pulse applied to the tibial nerve and it followed the cutaneous stimulation by 50 ms. The intensity of the H reflex stimulation was adjusted throughout the experiment and trials which had a M-wave between 10-20% of the maximal M-wave were selected for analysis. Four muscles ipsilateral to the stimulation (Tibialis Anterior, Soleus, Biceps Femoris and Vastus Lateralis) and 4 phases of cycling (0° = top pedal position, 90°, 180° and 270°) were examined for both the static and dynamic conditions (cycling rate of 1 Hz and workload of 1 kpm). During the static condition, the soleus H reflex varied in amplitude depending on the phase, the largest one being at 90° and the lowest at 0°. The low intensity cutaneous stimulation had a tendency to increase the H reflex response particularly at the 270° position. During the active cycling, the H reflex was also modulated, the greatest response being at 90° while the lowest amplitude was observed at 0° and 180°. The H reflex continued to be modulated in a similar fashion following the cutaneous stimulation, however, the responses tended to be slightly inhibited. (Supported by PAFACC, UQAM)

PARALLELS BETWEEN CHANGES IN EXCITABILITY OF THE H REFLEX AND RECOVERY OF MOTOR FUNCTION IN CATS AFTER CUTTING AFFERENT AND EFFERENT CONNECTIONS OF MOTOR CORTEX. J.A. McMillan*, M. Sinyaya, A. Shelyakin, and T. Tobias, Montana State Univ., Bozeman, MT, 59717 and Pavlov Inst. Physiol. and Inst. Exp. Med., St. Petersburg, Russia

Earlier work has demonstrated compensatory plasticity of sensory projections to the cortex in cats following unilateral isolation of the cerebral cortex from its afferent and efferent connections with the spinal cord. (Sinyaya et al., 1991, *Sechenov Physiol. J. of Russia*, 77(8):24-31). The goal of the present study was to examine changes in excitability of the H reflex in cats after brain damage and to determine if such changes correlate with reported changes in asymmetry of reflex function in children undergoing functional biofeedback therapy for cerebral palsy (Bogdanov et al., 1991, *Sechenov Physiol. J. of Russia*, 77(10):24-28).

The H reflex was recorded from medial gastrocnemius in intact cats and in cats in which the corona radiata supplying left motor cortex was cut while leaving the cortex itself intact (cf. Sinyaya et al. above). Threshold for the reflex was lower in the right leg immediately after the lesion. Presynaptic inhibition of the reflex, monitored by comparing amplitude of control and test reflexes evoked by paired stimuli 100 msec apart, was less pronounced following the lesion. These changes were less evident 1-3 months after the lesion. We propose that the long-term changes in excitability of the H reflex reflect a compensatory process which affects motor as well as sensory function following brain damage. (Supported by NSF EPSCoR RII-8921978 and NIH 5S06GM08218-09).

PREPULSE FACILITATION OF THE ACOUSTIC STARTLE REFLEX IN THE RAT: STIMULUS PARAMETERS AND DRUG EFFECTS. M.K. Taylor, J.R. Ison* & S.B. Schwarzkopf, Depts. of Psychology and Psychiatry, University of Rochester, Rochester, NY, 14627.

Noise prepulses (PP) presented in a masking noise (N) just prior to a startle stimulus can either facilitate (PPF) or inhibit (PPI) the acoustic startle reflex (ASR). There are many studies of the psychophysical and pharmacological characteristics of PPI, but little is known about PPF. Here we report that a 20 msec PP ending with the startle pulse facilitates the startle in inverse linear proportion to its signal to noise ratio (PP/N). Accordingly, our weakest PP/N (a +3 dB ratio) approximately doubled the ASR to a 115 dB stimulus, whereas ratios greater than +9 dB resulted in increasing amounts of PPI. The PPF for a constant PP/N ratio (a +3dB difference) increased with noise levels from 30 to 40 dB, but then remained constant for higher intensities (tested to 73/70 dB). As PP lead time increased, PPF was enhanced up to 20 ms and changed to PPI beyond 60 - 80 ms. Both effects increased with experience. Diazepam enhanced PPF (revealing that PPF is different from other forms of ASR potentiation) but reduced PPI. In contrast, preliminary data show that PPF is reduced by apomorphine. Because these drugs affect PPF as well as PPI, their effects may not be restricted to inhibitory processes, as is generally thought. These drug effects on PPF and PPI may result from their disruption of attentional processes involved in stimulus discrimination and reflex control; and that PPF is altered at lead times as short as 5 ms indicates that these mechanisms have a peripheral site of action.

SPASTICITY IN THE CONSCIOUS RAT? QUANTITATIVE EXAMINATION OF STRETCH AND VELOCITY SENSITIVE REFLEX COMPONENTS. W.J. Thoman & J.S. Taylor*. Dept. Neurosci., U of FL Gainesville.

Although the rat has often been used as a model of spinal cord injury (SCI), no study has yet identified spasticity, defined as enhanced stretch activity and velocity-sensitive (VS) reflex components. Here we present preliminary data of a SCI model using the conditioned rat, with recording of long-latency triceps surae stretch reflex activity following subtotal lesions at the upper lumbar level. Background forces were closely matched before and after SCI to obtain more direct measures of test reflex activity. Injury-induced stretch reflex deficits were similar to those obtained previously from the conscious cat, with increases in both dynamic and static torque amplitude and no change in either the VS or dynamic index components. However, and in contrast with the cat, hyper-reflexia was not observed in the first week post lesion, but developed to a maximum over the first month. We conclude that with appropriate reflex testing conditions rats can also be defined as spastic following selective spinal lesions, but that increased VS of long-latency stretch reflexes as a hallmark of SCI should be re-examined using other testing procedures. Supported by Grant NS27511 and IDSTF.

IDENTIFYING THE INTERNEURONS INVOLVED IN THE REFLEX RESPONSE TO ELECTRICAL STIMULATION OF THE INTERNAL BRANCH OF THE FELINE SUPERIOR LARYNGEAL NERVE. Y. Tanaka, C.L. Ludlow*, and W.S. Selbie. VSS, NIDCD, NIH, Bethesda, MD 20892.

Electrical stimulation of the internal branch of the superior laryngeal nerve (ISLN) produces a bilateral adductor response in the feline larynx. The purpose of this study was to identify interneurons in the medulla oblongata that comprise this reflex pathway using the retrograde tracer cholera toxin B to label the nucleus ambiguus (NA) and the stimulus induced expression of the proto-oncogene, c-fos. Cholera toxin B was injected into the thyroarytenoid, lateral cricoarytenoid, cricothyroid and the posterior cricoarytenoid muscle to identify the efferent neurons in the (NA). After 72 hours, the cats were anesthetized with alpha chloralose and the right ISLN was placed in a bipolar cuff electrode. Following 4 hours rest the ISLN was stimulated at 0.5 Hz at supra maximal levels for 20 minutes immediately before euthanasia. Serial 50 µm transverse frozen sections were made through the medulla oblongata. Odd numbered sections were processed for immunohistochemistry by means of anti-c-fos protein. Even numbered sections were incubated with anti-cholera toxin B. As expected, cholera toxin B labeled neurons and dendrites in the NA and terminals in the NTS. C-fos-like immunoreactive neurons were identified bilaterally in the NTS from the level of the most rostral portion of the dorsal motor nucleus of the vagus to the most caudal portion of the inferior olivary nucleus (IO), and in the NA from the rostral end of the hypoglossal nucleus to the caudal end of the IO. Bilateral c-fos like reactions were also observed in the reticular formation around the NA. Neurons expressing c-fos that lay outside the anatomically defined NA and NTS are candidates as interneurons.

SYNAPSES IN ROSTROLATERAL MIDBRAIN MEDIATE "FEAR" POTENTIATION OF ACOUSTIC STARTLE AND ELECTRICALLY EVOKED STARTLE. J.S. Yeomans* and P.W. Frankland, Dept. Psychology, University of Toronto, Toronto Ont. M5S 1A1.

Electrical stimulation of the caudal ventral amygdalofugal (VAF) pathway from the amygdala to the brain stem evokes startle-like responses, or at lower currents enhances acoustic startle. Electrolytic lesions of these sites block fear potentiation of acoustic startle. Collision tests show that startle-like responses are due to short axons from the amygdala to the diencephalon-midbrain border, which synaptically activate long axons from the rostral midbrain to the medulla (Yeomans & Pollard 1993). The short axons that link the amygdala with the midbrain have moderate conduction velocities of about 10 m/s and 0.4-0.8 ms refractory periods, while the long axons that link the midbrain and medulla have fast conduction velocities of about 60 m/s and 0.2-0.5 ms refractory periods. The functional synapses were located in a small region of the rostralateral midbrain in two ways: 1) The transition zone from axonal to transsynaptic collision for electrically evoked startle was located by placing a series of electrodes near the midbrain-diencephalon border and testing for collision with medulla and diencephalon sites; 2) Bilateral ibotenate lesions (3 µg) of this same zone, dorsal to the substantia nigra, blocked fear potentiation of acoustic startle.

LESIONS OF THE CENTRAL GRAY BLOCK SENSITIZATION AND FEAR POTENTIATION OF THE ACOUSTIC STARTLE RESPONSE IN RATS. M. Fendt, M. Koch and H.-U. Schnitzler. (SPON: European Neuroscience Association). Tierphysiologie, Universität Tübingen, Auf der Morgenstelle 28, 72076 Tübingen, Germany.

The acoustic startle response (ASR) can be enhanced by conditioned or unconditioned fear. It has been shown that the central nucleus of the amygdala (cA) and its efferent pathway to the caudal pontine reticular nucleus (PnC), an essential part of the primary startle circuit, is important for the enhancement of the ASR. It was unclear, however, whether these modulations were directly mediated by the amygdaloreticular pathway or whether there exists a relay nucleus within this pathway. We tested the hypothesis that the midbrain central gray (CG) is important for the effects of fear on the ASR. Neuroanatomical tracing studies described a descending projection from the cA to that part of the CG where a descending projection to the PnC takes its origin. We lesioned this part of the CG with the neurotoxin quinolinic acid and then measured the effects of conditioned and unconditioned fear on the ASR. Lesions of the dorsal and lateral parts of the CG totally blocked the sensitization of the ASR by footshocks (unconditioned fear) and blocked the enhancement of the ASR by conditioned fear without affecting the ASR amplitude in the absence of the conditioned or unconditioned stimuli. This finding suggests a crucial role of the CG for the enhancement of the ASR by conditioned and unconditioned fear. The pathway from the cA via the CG to the PnC represents one part of a complex circuitry mediating the effects of conditioned and unconditioned fear to the ASR.

MUSCULAR REFLEXES ELICITED BY GENITAL STIMULATION IN THE FEMALE RABBIT. M. Martínez-Gómez*, M. Carro, P. Ordinala, H. Distel, R. Hudson and P. Pacheco. Centro de Investigaciones Fisiológicas-UAT, Mexico; Inst. Med. Psychol., Univ. Munich, Germany; Instituto de Investigaciones Biomedicas-UNAM, Mexico.

The present findings represent part of a larger study investigating the contribution of pelvic innervation to reproductive processes in the rabbit. In adult chinchilla-breed females, reflex EMGs of the Musculi constrictores vulvae and vestibuli, ischiocavernosus, bulbospongiosus, obturatorius internus, pubococcygeus, and rectus abdominis, were recorded in response to stimulation of the clitoral sheath, vagina, cervix, perineal, and perianal skin, and the flanks. Strong EMG activity was elicited by clitoral stimulation in all muscles except the rectus abdominis, and to a slightly lesser degree by stimulating the first and second thirds of the vagina using a glass rod. Both kinds of stimulation resulted in prolonged afterdischarges- up to 50 sec for the pubococcygeus and the obturatorius muscles. Stimulating the cervix produced a response only in the rectus abdominis with an afterdischarge of about 18 sec. Brushing or pressing the clitoral sheath, perineal or perianal skin resulted in EMG activity only in the pubococcygeus and, possibly, the constrictor vestibuli. Stimulating the flanks failed to elicit any response.

In summary: Clitoral and vaginal stimulation provoked strong EMG activity in almost all the muscles studied which was blocked by cervical stimulation. Withdrawal of cervical stimulation resulted in the reappearance of EMG activity which, however, was somewhat attenuated if clitoral stimulation was avoided.

715.14

STRIATED MUSCLE ACTIVITY DURING THE MICTURITION REFLEX IN THE RAT AND MICTURITION PATTERNS IN A SEXUAL CONTEXT. J. Manzo*, A. Esquivel, M.I. Vázquez, Y. Cruz and P. Pacheco. INE, Univ. Veracruzana, Xalapa, Ver; CIF, Univ. Autón. Tlax., Tlaxcala, Tlax; Inst. de Invest. Biomédicas, UNAM, México, D.F. México.

In rats, EMG activity of the external urethral sphincter (EUS) has been recorded during voiding, that is, during the high frequency oscillation phase (HFO) of the micturition reflex. Here we investigated if the EUS is the only striated muscle activated during HFO. The cystometrogram technique was combined with simultaneous EMG recordings of several muscles in the pelvic region. Results indicated that in addition to the EUS, the bulbospongiosus, levator ani, and pubococcygeus muscles show phasic EMG activity during HFO. The EMG frequency of all these muscles was 8 Hz, similar to the frequency of HFO. The duration of HFO and phasic EMG was also similar (6.5±0.25s). HFO phase and EMGs were reliably correlated with voiding.

Also we explored the existence of a behavioral pattern occurring during micturition in rats. An arena with two compartments (30x30 cm each) separated by a mesh was used. A receptive female was placed in one compartment and a sexually experienced male in the other. 40 such pairs were tested four times. Only males urinate consistently (62.5%) in this condition. Urine was expelled in a burst pattern, and placed in a line parallel to the dividing mesh at a mean distance of 12.65cm. These results are correlated with the data obtained from a group of n=10 males and n=10 females in which residual urine was measured after stress-induced micturition. It was showed that males retain significantly more urine than females (F(1,19)=15.63 p<0.05).

It is suggested that the somatic motor control of micturition in the rat is complex and serves not only elimination *per se*, but also other behavioral patterns associated with micturition and possibly having a communicatory function. SEP/IFI and CONACYT and PADEP-UNAM/JM

SPINAL CORD AND BRAINSTEM: PATTERN GENERATION

716.1

SPINAL CORD CONTROL OF BILATERAL HINDLIMB COORDINATION IN THE TURTLE. Field E*, Stein PSG; Biology Department and Movement Science Program, Washington University, St. Louis MO 63130.

The spinal turtle (*Trachemys scripta elegans*) produces three different forms of scratching behavior in location-specific responses to gentle mechanical stimulation of the lateral body surface (J. Neurophysiol. 53:1501, 1985). In such behaviors, activity is rhythmic with the force against the stimulated site generated by the limb ipsilateral to the stimulus.

Bilateral stimulation applied simultaneously to mirror-image locations, one on the left and one on right lateral body surface, elicits bilateral scratch behaviors. The most usual kinematic characteristic observed, in response to bilateral stimulation of rostral/rostral or pocket/pocket receptive field sites, is an out-of-phase relationship between the left and the right hip angles. The distal limb elements maintain their form-specific kinematic and electromyographic (EMG) intralimb relationships. When bilaterally asymmetric (i.e., rostral/pocket) sites are stimulated, the hip angles maintain an out-of-phase relationship while the distal limb segments perform disparate movements consistent with the site of stimulation on that side. The animal thereby produces, simultaneously, each of two different forms of scratching behavior, while maintaining an out-of-phase relationship between hip angles.

The pattern of hindlimb coordination observed during bilateral scratch in spinal turtles is similar to that of swimming behaviors in intact turtles. In forward swimming, the hindlimb movements are out-of-phase with each other. In the performance of turning behaviors, the intact turtle maintains the out-of-phase relationship between hip angles while the limb movements and the intralimb EMG relationships differ between the right and left sides. One limb displays forward swim kinematics; the other displays backward swim kinematics. The results in both intact and spinal turtles are consistent with the hypothesis that neural signals, related to control of the hips, play a major role in left/right interlimb coordination. BILATERAL MOTOR RHYTHMS DURING FICTIVE ROSTRAL SCRATCHING IN THE TURTLE. Paul S.G. Stein*, John C. Victor¹, Edelle C. Field¹, and Scott N. Currie². ¹Dept. Biology and Movement Science Program, Washington Univ., St. Louis, MO 63130, and ²Dept. Neuroscience, Univ. of California, Riverside, CA 92521.

Fictive rostral scratching is produced in a spinal, immobilized turtle by gentle mechanical stimulation of the ipsilateral (ipsi) midbody shell bridge (J. Neurophysiol. 53: 1517, 1985). Most previous work has focused on ipsi motor output. This output includes bursts of hip flexor (VP-HP) motor activity that rhythmically alternate with bursts of hip extensor (HR-KF) motor activity. Knee extensor (FT-KE) motor activity occurs during the latter portion of each burst of hip flexor activity.

Berkowitz and Stein (J. Neurosci. 14: in press, 1994) demonstrated rhythmic bursts of contralateral (contra) hip flexor activity that alternate with bursts of ipsi hip flexor activity during fictive rostral scratching.

We add to these previous findings. Stimulation of the ipsi shell bridge also produces a fictive motor pattern of contra hip extensor bursts that alternate with contra hip flexor bursts. Contra hip extensor activity occurs during the early part of ipsi hip flexor activity. Contra hip flexor activity begins during the latter part of the ipsi hip flexor activity and continues during ipsi hip extensor activity.

Simultaneous bilateral stimulation of mirror-image locations, one in the left rostral scratch receptive field and the other in the right rostral scratch receptive field, elicits bilateral fictive rostral scratching motor patterns. At the onset of stimulation, there is in-phase activation of left and right hip flexor nerves. After the first cycle of response and for the remainder of the response, the activity of each left motor pool alternates with the activity of its mirror-image motor pool on the right.

The patterns of activity seen during bilaterally activated fictive rostral scratching are similar to the patterns observed during bilaterally activated actual rostral scratching in spinal turtles as well as during actual forward swimming in intact turtles (Field and Stein, this volume). Thus, bilaterally activated fictive rostral scratching is an excellent model system to examine spinal mechanisms for the coordination of left and right rhythmic motor behavior. 716.3

DEPRESSION OF MONOSYNAPTIC GROUP II AND OTHER FIELD POTENTIALS DURING MLR-EVOKED FICTIVE LOCOMOTION SUGGESTS A REDUCTION OF TRANSMISSION IN SENSORY AFFERENT PATHWAYS. M.C. Perreault¹, J. Jiménez¹, S.J. Shefchyk and D. McCrea. Dept. Physiol., Univ. of Manitoba, Winnipeg, Canada, R3E 0W3, and CIEA-IPN¹, Mexico.

The possibility that transmission from sensory afferents might be affected during MLR-evoked fictive locomotion was examined in decerebrate cats. Monosynaptic field potentials were evoked by stimulation of extensor (Q, GS), flexor (Sart, PBSt) and cutaneous nerves and recorded in lumbar and sacral spinal segments. During MLR-evoked fictive locomotion monosynaptic components of group II field potentials were reduced up to 70%. In those trials where locomotion appeared several seconds after the onset of MLR stimulation, group II field potentials were maximally depressed only when the locomotor pattern was fully developed. Group I and cutaneous field potentials were also depressed but to a lesser degree. All monosynaptic field potentials were tonically depressed with the onset of fictive locomotion and for several seconds after its cessation. A smaller phasic depression during extension was often superimposed on the tonic depression. We suggest that both descending pathways and spinal locomotor networks contribute to the depression of transmission from group II, group I and cutaneous afferents during MLR-evoked fictive locomotion. Although the mechanisms have not yet been determined, presynaptic inhibition of the terminals of segmental afferents is likely. *Supported by the MRC and the Rick Hansen Legacy Fund.*

716.5

THE INFLUENCE OF N-TYPE CALCIUM CHANNEL BLOCKERS ON THE RESPIRATORY NETWORK OF ADULT CATS. J.M. Ramirez*, O. Pierrefiche, S.W. Schwarzer, F. Filloux, J.M. McIntosh, B.M. Olivera and D.W. Richter. Departments of Physiology and Anatomy, University of Göttingen, D-37073 Göttingen, FRG, Departments of Biology, Neurology and Psychiatry, University of Utah, Salt Lake City, USA.

The N-type calcium channel regulates the release of certain neurotransmitters and is specifically blocked by the ω -conotoxin GVIA. We used this ω -conotoxin to investigate the functional role of the medullary Pre-Bötzinger complex in the generation of respiratory rhythmic activity in adult mammals. Lesion experiments have demonstrated that the Pre-Bötzinger Complex is critical for rhythm generation in neonatal rats. In adult animals it has been demonstrated that all types of respiratory neurons are present within this medullary area but their importance for rhythm generation remains uncertain. In this study we pressure injected ω -conotoxin GVIA into the Pre-Bötzinger Complex of adult cats. Male and female cats were anaesthetized (Pentobarbital 40mg/kg i.p.), paralyzed, vagotomized and artificially ventilated. Respiratory activity was monitored from ipsi- and contralateral phrenic nerves while simultaneously recording intracellular respiratory neurons. When injected into the Pre-Bötzinger Complex, ω -conotoxin GVIA had profound effects on respiratory activity. In this limited area blockade of the N-type calcium channel decreased the amplitude and the slope of phrenic nerve activity and increased significantly the cycle length. Prolonged injection induced central apnea. Although ω -conotoxin GVIA was injected into the Pre-Bötzinger Complex on one side, the induced respiratory effects were bilateral. All effects lead to a decrease of synaptically induced drive potentials to late-inspiratory, post-inspiratory and expiratory neurons. We conclude that ω -conotoxin GVIA blocks tonic excitatory drive to a specific area in the respiratory network, the Pre-Bötzinger Complex. The data also demonstrate that in adult cats the Pre-Bötzinger Complex is essential for respiratory rhythm generation.

FDL AND SOLEUS MOTONEURON ACTIVITY DURING SCRATCHING. S.H. Dueñas* and L. Castillo. CUCS, Universidad de Guadalajara and C.B., Universidad de Aguascalientes, México

This study analyzed whether the normal patterns of scratching activity of FDL and Sol motoneurons prevail during fictive scratching (FS). In four normal cats, six hindlimb muscles were chronically implanted with patch electrodes for EMG recordings. In thalamic and later on, spinal cats, several hindlimb nerves were used for ENG recordings. The changes in resting potential (RP) in four FDL and five Sol motoneurons were also analyzed. In normal scratching cats, FDL-EMG exhibited tonic or phasic or intermingled activity, in contrast, Sol-EMG remain silent almost the entire episode of scratching. Occasionally occurred phasic Sol-EMG activity. In thalamic cats, FDL-ENG exhibited tonic, or phasic or intermingled activity. In 36% of the episodes of scratching occurred a sustained decrease in RP of FDL motoneurons. In 64% of the episodes, sustained RP decrease was followed by phasic changes. At the onsets of the phasic bursts of activity occurred high frequency firing (doublets). Sol-ENG exhibited absence of motoneuron activity. Four out five Sol motoneurons were hyperpolarized during the episodes of fictive scratching. In spinal cats, FDL motoneurons only exhibit phasic activity but, without doublets. Sol motoneurons were phasically activated. Spinal scratch generator produces phasic activity in FDL and Sol motoneurons, and supraspinal nuclei elicited sustained facilitation and inhibition in FDL and Sol motoneurons respectively.

716.4

PROLONGED MODIFICATION OF THE MECHANICS OF THE STEP CYCLE BY SINGLE AND REPETITIVE MECHANICAL STIMULI IN CHRONIC SPINAL CATS. K. Nakada, J.A. Hodgson, R. de Leon, R.R. Roy and V.R. Edgerton¹. Physiological Science Dept and BRI, UCLA, LA, CA 90024

After step training, the hindlimbs of the spinal cat transected at T12-T13 can regain the ability for full weight-bearing locomotion on a treadmill. When an obstacle is placed in front of the foot during the swing phase of a step cycle, the limb can be lifted above the obstacle after contact and the swing phase completed. In this study, a plexiglass rod instrumented with a strain gauge was introduced during the swing phase to perturb the hindlimb step cycle. The swing phase of the first step following contact of the foot with the obstacle was elevated relative to pre-contact steps. With repetitive obstruction, the step height increased in succeeding steps thus minimizing contact with the obstacle. In some instances, contact with the rod led to complete avoidance in the subsequent step. Impact force records demonstrated that the stimulus strength necessary to elicit the response gradually decreased with successive perturbations. Several steps after the perturbation was removed, the step height usually returned to pre-contact levels. When many consecutive steps were disrupted, the step height returned to pre-contact levels more slowly and sometimes remained slightly elevated. Similar kinematic modifications were elicited when air puffs were used to displace the hairs on the dorsal surface of the paw during the middle of the swing phase. Thus, it appears that the spinal cord, in the absence of supraspinal input, can "learn" of the presence and absence of an obstacle and modify the hindlimb kinematics in a manner that improves the probability of continuing successful locomotion. (Supported by NIH Grant NS16333)

716.6

ANTIDROMIC ACTIVITY OF DORSAL ROOT FILAMENTS DURING TREADMILL LOCOMOTION IN THALAMIC CATS. I. Beloozerova and S. Rossignol*. Cntr. Res. Neuro. Sci., Université de Montréal, Montréal, Québec, Canada H3C 3J7.

Previous work has shown that the proximal stump of cut dorsal roots (DR) are cyclically depolarized twice per cycle during fictive locomotion in paralysed thalamic cats, with a greatest maximum during the activity of flexors and a second maximum during activity in the extensors. Single DR units discharging antidromically (AD) and rhythmically are often recorded in these cut rootlets. Since DR depolarizations can also be readily evoked by activation of peripheral afferents such as stimulation of the foot pads, we investigated whether the natural peripheral inputs during real locomotion could also play a role in the AD firing of DR units. Nine cats were decerebrated under Halothane anesthesia. Locomotion was either spontaneous or triggered by MLR stimulation. Units were recorded from the proximal ends of the cut rootlets with Ag/AgCl electrodes in an oil pool. Representative EMGs of ipsilateral limb were recorded and the movements videotaped. The Table shows the distribution and characteristics of 73 modulated units out of a total of 92 recorded units. Their peak discharge may occur during swing or stance; they may start (ON) or end (OFF)

	swing	stance	total
PEAK	39	34	73
ON & OFF	15	7	22
ON	27	24	51
OFF	17	12	29

their firing in stance or swing or be entirely confined within one phase (ON & OFF). It is concluded that not only central mechanisms but also peripheral events, such as foot contact during stance, may exert important presynaptic influences as revealed by the large proportion of units firing during stance. (Supported by MRC and FCAR).

IMMUNOHISTOCHEMICAL CHARACTERIZATION OF CAT SPINAL NEURONS ACTIVATED DURING FICTIVE LOCOMOTION. P.A. Carr*, B. Noga, A. Huang, X. Dai, D.M. Nance and L.M. Jordan. Depts. of Physiology and Pathology, University of Manitoba, Winnipeg, MB, CANADA, R3E 0W3.

Anti-c-fos immunohistochemistry or intracellular injection of a 3000 MW tetramethylrhodamine-dextran conjugate (TMR-D) was used to localize spinal neurons activated during fictive locomotion in paralysed, decerebrate cats. The neurochemical characteristics of c-fos-immunoreactive or TMR-D labelled cells were subsequently investigated using a variety of cytochemical markers. Locomotor-related spinal neurons were injected with TMR-D and tissue containing the intracellularly-labelled cells subsequently processed using anti-choline acetyltransferase (ChAT)-, aspartate- or c-fos-immunohistochemistry. Subpopulations of TMR-D labelled lamina VII neurons were seen to contain either ChAT- or aspartate-immunoreactivity. Simultaneous double labelling for c-fos and ChAT, aspartate, calcitonin gene-related peptide (CGRP) or NADPH-diaphorase was carried out on non-TMR-D labelled spinal cord tissue obtained from animals that displayed at least six hours of robust, MLR stimulus-evoked fictive locomotion. The majority of c-fos-immunoreactive cells were located in lamina VII and VIII of the lumbar spinal cord. Subpopulations of c-fos-immunoreactive neurons were seen to contain either NADPH-diaphorase reaction product, ChAT-immunoreactivity (-IR), aspartate-IR or to have close contacts with CGRP-immunoreactive fibres. These preliminary results reveal certain neurochemical characteristics of subpopulations of locomotor-related cat spinal neurons. They show that a subpopulation of c-fos-immunoreactive cells are first-order interneurons and some may utilize acetylcholine, aspartate and/or nitric oxide as neurotransmitters/modulators. LOCOMOTOR-RELATED PRESYNAPTIC MODULATION IN DORSAL CELL AXONS IN THE LAMPREY. A. El Manira*, J. Tegnér and S. Grillner. Nobel Institute for Neurophysiology, Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden.

Using the lamprey spinal cord *in vitro* preparation, we investigated the presynaptic control in the glutamatergic skin sensory neurons (dorsal cells) during fictive locomotion. The membrane potential of dorsal cells showed phasic depolarizations that occurred in phase with the ipsilateral ventral root burst. Negative current injections increased the amplitude of the depolarizations indicating that the depolarization is chemically mediated. In cells where no depolarization could be recorded, simultaneous intracellular recordings from their axons showed large depolarizations suggesting that the input synapses underlying these depolarizations are located on the axons. These depolarizations were insensitive to specific GABA_A (bicuculline) or GABA_B (phaclofen and saclofen) antagonists. On the other hand, GABA receptors are present on dorsal cells. GABA, muscimol and baclofen induced depolarizations in the dorsal cells which persisted after blockade of synaptic transmission with tetrodotoxin. Specific GABA antagonists had no effect on the amplitude of the induced depolarizations, suggesting that the GABAergic effects on dorsal cells are not mediated by conventional GABA_A and GABA_B receptors. Small bipolar neurons containing GABA-ir and NPY-ir have close apposition on dorsal cell axons. Our evidence show that the synaptic transmission from sensory cells is physically modulated by the neuronal network generating locomotion, as previously shown for network interneurons (Alford and Grillner, J. Neurosci. 1991).

716.11

EARLY APPEARANCE OF THE SYNCHRONIZED OSCILLATORY DISCHARGE OF THE CRANIAL NERVES IN THE IN VITRO ISOLATED BRAINSTEM OF NEWBORN CATS. F. Kato, R. T. Kado*, M.-P. Morin-Surun and M. Denavit-Saubié. Institut A. Fessard, CNRS, 91198, Gif-sur-Yvette, France.

To clarify the mechanism for the generation of high-frequency oscillatory discharges (HFO) correlated among the inspiratory nerves, we have applied the *in vitro* preparation of perfused isolated brainstem developed by Morin-Surun et al. (1992) to the newborn cats. One to 15 days-old cats were decapitated under pentobarbital anesthesia and the vascular system was perfused caudo-rostrally from the basilar artery with Krebs solution kept at 28°C. The efferent discharges of facial (VII), vagus (X) glossopharyngeal (IX) and hypoglossal (XII) nerves were recorded simultaneously. By the spectral analyses, the following results were obtained: i) In the power spectra of the inspiratory nerve discharges, a clear peak with a modal frequency of 30.1±1.7 Hz (mean±sd, n=19) was consistently observed. ii) In the coherence spectra for any pair of these nerves recorded, a peak with high values of coherence (0.91±0.09, n=9) was consistently observed, demonstrating the synchronization of this oscillatory discharge between nerves. iii) A rise in the temperature of Krebs solution of the superfusion chamber significantly augmented the modal frequency of the oscillation. iv) Perfusion with a high CO₂ Krebs solution accelerated the respiratory rhythm but did not give any significant influence on the oscillation frequency. v) This synchronized oscillatory activity was observed unchanged in X, IX and XII even after ponto-medullary transection. Based on these observations, we conclude that this synchronized oscillatory activity in the isolated brainstem of the newborn cats is identical to the HFO in mature animals and that the HFO could be generated in the medulla without any connection between other neural structures at least as early as ~12 hours after birth.

716.10

TTX-RESISTANT, NMDA RECEPTOR-MEDIATED MEMBRANE POTENTIAL OSCILLATIONS IN SPINAL NEURONS OF *XENOPUS LAEVIS* LARVAE ARE 5HT-DEPENDENT. J. F. S-Wedderburn & K. T. Sillar*. School of Biological and Medical Sciences, University of St. Andrews, St. Andrews, Fife, KY16 8LB, Scotland.

The spinal network controlling swimming in *Xenopus laevis* embryos (stage 37/38) is one of the best understood locomotor central pattern generators (CPG's) in vertebrates (see Roberts, 1990, *Sci. Prog. Oxf.* 74, 31-35). Unlike more adult systems, however, the activity is stereotyped and inflexible, with motoneurons normally firing only once in each cycle. During a brief period of post-embryonic development (24hrs), the progressive rostro-caudal invasion of the spinal cord by axons of developing serotonergic brainstem interneurons is implicated in the ontogeny of a more adult-like locomotor pattern, involving bursts of motoneuronal discharge in each cycle. Here we have begun to examine the cellular mechanisms that might underlie the developmental modulation of an embryonic motor circuit.

In the lamprey, spinal motoneurons express intrinsic NMDA receptor-mediated membrane potential oscillations which may play a role in swimming rhythm generation (Wallén & Grillner, 1987, *J. Neurosci.*, 7, 2747-2755). In *Xenopus* tadpoles (stages 37/38-42), in the presence of 1µM TTX, the bath application of 100µM NMDA depolarises motoneurons by about 20mV, but unlike the lamprey, does not lead to oscillations in membrane potential. However, the addition of 2-5µM 5HT induces sustained oscillations, whose amplitude (but not frequency) is voltage-dependent. Our results suggest that 5HT acts via receptors on spinal neurons to modulate the activity of the NMDA ionophore, thereby enabling expression of intrinsic membrane potential oscillations.

FAST OSCILLATORY ACTIVITY IN MESENCEPHALIC TRIGEMINAL NEURONS. C. Pedroarena, I. Pose, J. Yamuy, F.R. Morales*, and M.H. Chase. Depto. de Fisiología, Facultad de Medicina, Montevideo, Uruguay, and Dept. of Physiology and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

In contrast to all other muscle afferents, primary afferent fibers that innervate the jaw musculature have their cell bodies located within the central nervous system, in the mesencephalic trigeminal nucleus (MES-V). During experiments designed to study neurons within the reticular formation we found a remarkable oscillatory activity of the membrane potential of MES-V neurons, which is the object of the present report.

Intracellular recordings from MES-V neurons were obtained in the standard tissue slice preparation from adult rats; neurons were labeled by intracellular biocytin injection. The membrane potential of MES-V cells exhibited epochs of sinusoidal-like oscillatory activity within the frequency range of 80 to 125 Hz; its amplitude ranged between 1 and 5 mV. Large oscillatory waves often triggered bursts of action potentials. The oscillatory activity was not observed at resting membrane potentials levels more negative than -65mV, but it could be evoked by the injection of depolarizing currents. Tetrodotoxin abolished the oscillatory activity.

This is the first report of an oscillatory activity in the cell bodies of primary afferents. Consequently, we can only speculate on their functional significance. It is possible that this high frequency activity plays a role in the transmission of information from the jaw musculature to central neural structures. Because this activity originates in cell bodies, it is also possible that it may be synaptically modulated during different behaviors. Supported by USPHS Grant NS 09999.

SPINAL CORD AND BRAINSTEM: NEONATES

717.1

INTRACELLULAR PATCH ELECTRODE RECORDINGS FROM NEURONS IN THE ISOLATED SPINAL CORD FROM NEONATAL RATS.

M. Raastad* and O. Kiehn.

Sect. of Neurophysiology, Dept. of Medical Physiology, Copenhagen 2200, Denmark

The use of patch electrodes for intracellular recordings has several advantages compared to the use of traditional microelectrodes, particularly a better signal to noise ratio and the possibility for recording from small cells. We wanted to utilize these advantages in an intact spinal cord preparation, which has the benefit of intact large neurons and functional neuronal networks.

Neonatal rats (0-3 days old) were decapitated and the spinal cords dissected out with the preparation in ice-cold extracellular medium containing 0 mM Ca²⁺. For the experiments, the cord was submerged in extracellular medium at room temperature, containing 2 mM Ca²⁺. Pia mater could not be penetrated by the patch electrodes. Therefore, either a shallow cut was made from the ventral side immediately medial to the ventral root, or a hemisection preparation was used. The patch pipette, with positive pressure, could then be lowered 100 to 500 µm into the spinal cord, and GΩ seal formed by slight suction. This approaches gave a high (>50%) success rate for stable (20 to 60 minutes) whole cell recordings, often with access resistance around 5 to 10 MΩ.

Recordings from a variety of cell types, visualized with biocytin, were made in the intermediate and ventral areas of the cord. Typical resting membrane potentials were -45 to -55 mV, spikes were 2 to 3 ms wide with 70 to 90 mV amplitude. Cells could be recorded from during fictive locomotor activity, and the good signal to noise ratio made spontaneous and stimulated potentials from individual synapses clearly detectable.

717.2

NON INACTIVATING CHLORIDE AND POTASSIUM CHANNELS OF INSPIRATORY NEURONS IN THE IN VITRO BRAINSTEM-SPINAL CORD PREPARATION OF NEWBORN RAT. T.D. Jacquin, J. Champagnat, M. Denavit-Saubié*. Laboratoire de biologie fonctionnelle du neurone, Institut Alfred Fessard, CNRS, 91198 Gif sur Yvette Cx, France

Single channel activity was studied in inspiratory neurons identified by their pattern of firing related to phrenic motor output and located in the ventrolateral region (VLR) of the isolated *in vitro* brainstem-spinal cord preparation of a newborn rat. In outside-out recording under physiological condition, three channel types were identified by reversal potential, single-channel conductance, voltage sensitivity, pattern of activity and tetraethylammonium sensitivity. Two non inactivating potassium channels of 38 and 70 pS were found. Both channels showed voltage dependency, becoming more active at moderate depolarized potentials. The 70 pS channel showed tetraethylammonium sensitivity at 0.1-0.4 mM. Also, a chloride channel of 25 pS was seen. These channel types may be involved in the control of the resting membrane potential and bursting activity of the inspiratory neurons and contribute to their functions in the mammalian brainstem.

717.3

L-DOPA AND QUIPAZINE ELICIT AIR-STEPPING IN NEONATAL RATS WITH SPINAL CORD TRANSECTIONS. D.J. Stehouwer*, M.L. McEwen and C. Van Hartesveldt. Dept. Psychology, Univ. Florida, Gainesville, FL 32611-2065

Decerebrate neonatal rats respond to systemic injections of L-DOPA with coordinated locomotor activity on the ground, in water, or suspended in air (air-stepping). However, L-DOPA fails to elicit stepping in the hindlimbs of rats with mid-thoracic transections of the spinal cord, suggesting that the critical locus of action of L-DOPA is in the brainstem. Alternatively, it is possible that L-DOPA acts on spinal circuits, but that locomotor activation requires input from an additional descending system that originates in the brainstem. In the present study we examined the possibility that L-DOPA can elicit air-stepping in the hindlimbs of spinally-transected neonatal rats in the presence of the serotonergic receptor agonist, quipazine. Intact neonatal rats and those that had received complete mid-thoracic (T5) transections of the spinal cord were injected subcutaneously with L-DOPA (100mg/kg), quipazine (1.6 mg/kg), L-DOPA and quipazine in combination, or the vehicle solution. Results showed that neither L-DOPA nor quipazine alone elicited locomotor activity in the hindlimbs of rats with spinal cord transections. However, the combination of the two drugs elicited well-coordinated stepping in both the forelimbs and the hindlimbs, although the forelimbs and hindlimbs stepped independently of each other. In comparison to stepping of intact rats given L-DOPA alone, the forelimbs of spinal rats receiving the drug combination stepped faster, and the hindlimbs slower. The rate and topography of stepping were more variable in intact rats given the L-DOPA/quipazine combination than in intact rats receiving L-DOPA alone or in the hindlimbs of spinally-transected rats given the drug combination. These results show that quipazine and L-DOPA must both act on spinal targets to produce locomotion.

LOCALIZATION OF THE CENTRAL PATTERN GENERATOR FOR HINDLIMB LOCOMOTION IN THE NEONATAL RAT *IN VITRO*. A LESION STUDY. O. Kjaerulff and O. Kiehn (SPON: European Neuroscience Association). Sect. of Neurophysiology, Dept. of Medical Physiology, Univ. of Copenhagen, Copenhagen 2200, Denmark.

Our previous studies with sulforhodamine 101 as a marker of neuronal activity have shown that laminae VII and X in the lower thoracic and lumbar regions of the spinal cord may be of possible importance for the generation of locomotion in the neonatal rat (Kjaerulff, Barajon and Kiehn, *J. Physiol.*, in press, 1994). To test this conclusion we have monitored the rhythm-generating ability in surgically isolated subregions of thoracolumbar spinal cord (Th12-L6).

Rhythmic activity (RA) recorded from the ventral roots was induced with a combination of 5-HT and NMDA in spinal cords prepared from rats 0-2 days of age. RA was seen in isolated preparations consisting of segments Th12-L1 or L1-L3, while in preparations consisting of L4-L6 or L5-L6 either no RA or only slow, low-amplitude RA was found.

Preparations consisting of all segments from Th12 to L6 were sectioned in various planes. A midsagittal section did not prevent RA. Similarly, RA - alternating between the two sides - persisted after removal of the dorsal half of the spinal cord with a horizontal section. In contrast, preparations left from a paramedian section and comprising the lateral motoneuron pool, the lateral intermediate area and the dorsal horn showed no RA.

We infer that the neuronal networks important for spinal hindlimb locomotor activity predominate medially and ventrally in the thoracolumbar transition zone.

LARGE AMPLITUDE EXCITATORY SYNAPTIC CURRENTS MEDIATE STRYCHNINE-DEPENDENT SYNCHRONOUS MOTOR RHYTHMS IN THE NEONATAL RAT SPINAL CORD. K.C. Cowley*, S. Hochman, L.M. Jordan and B.J. Schmidt. Depts. Medicine and Physiology, University of Manitoba, Winnipeg, Canada, R3E 0W3.

Application of the glycine receptor antagonist strychnine to the bilaterally intact *in vitro* rat spinal cord transforms locomotor-like and other alternating patterns of hindlimb motor activity into synchronous rhythms (Harder & Schmidt, *Soc. for Neurosci. abstr.* 1992). We have now applied whole-cell recording methods to examine intracellular events in lumbar motoneurons and interneurons during strychnine-induced synchronization. NMDA, serotonin and acetylcholine were used alone or in combination to induce baseline rhythmic activity. Following strychnine (1 μ M), large amplitude rhythmic excitatory synaptic actions, in-phase with synchronous rhythmic ventral root activity, were recorded in all neurons examined. Rhythmic EPSCs (E_{rev} = 0 mV) as large as 200 pA resulted in synaptic drive potentials measuring over 50 mV in some neurons. An interneuron which previously received exclusively inhibitory synaptic input (E_{rev} = -50 mV) in response to dorsal root stimulation and during acetylcholine (10 μ M)-induced rhythmic activity, displayed only rhythmic EPSCs following strychnine. The maximal EPSC amplitude in this cell occurred at -40 mV suggesting involvement of NMDA receptor activation. In one interneuron rhythmic synaptic activity was not observed, despite the induction of phasic ventral root activity by serotonin (10 μ M) and NMDA (2.5 μ M); however, the cell developed rhythmic 10 mV depolarizing potentials after addition of strychnine. Thus blockade of glycine receptors may result in the phasic recruitment of neurons not previously associated with the production of motor rhythm. Finally, although rhythmic inhibitory synaptic currents (E_{rev} = -50 mV) re-appeared in interneurons following removal of strychnine from the bath, ventral root activity remained synchronized. LOCOMOTOR RESETTING PATTERN FOLLOWING MUSCLE AFFERENT STIMULATION IN AN ISOLATED SPINAL CORD-HINDLIMB PREPARATION OF THE NEWBORN RAT. M. Iizuka¹, O. Kiehn², O. Kjaerulff² and N. Kudo¹. ¹Dept. Physiol., Inst. Basic Med. Sci., Univ. of Tsukuba, Tsukuba 305, Japan and ²Dept. Neurophysiol., Univ. of Copenhagen, Denmark.

Effects of muscle afferents stimulation on the central pattern generator (CPG) for locomotion were examined using an isolated spinal cord-hindlimb preparation of newborn rats (P0-6). Locomotor activities were evoked by bath application of a combination of NMDA and 5-HT and recorded from flexor and extensor muscles. The locomotor rhythm was reset by a train of stimuli (20Hz, 10-20 pulses) to the quadriceps nerve (Qn). At P0-1, resetting was characterized by the generation of a new flexor burst when stimuli were applied during flexor phase in all of the 8 preparations tested. This resetting pattern was observed at all stimulation intensities (1.8-50 times threshold, T). At P2-6, however, different resetting patterns were observed depending on the stimulus intensity. Below 3xT Qn stimulation delivered during flexor phase truncated the flexor burst and reset the rhythm by initiating a new extensor burst in 4 of 6 cases at P2-3 and in 5 of 5 at P4-6. Higher intensity stimuli (>5xT) initiated a new flexor phase in all of the preparations tested. These results suggest that the pathway conveying suppressive effects from low threshold muscle afferents to the flexor CPG develops later than the pathway mediating excitatory effects from muscle afferents.

DURING LOCOMOTOR-LIKE ACTIVITY *in vitro*, NEONATAL RAT INTERMEDIATE LAMINAE SPINAL CORD NEURONS DISPLAY DRIVE POTENTIALS. Jason N. MacLean and David S. K. Magnuson*. Spinal Cord Research Centre, U. of Manitoba, Winnipeg, MB, Canada.

Studies using activity dependent¹ and retrograde labelling² suggest that neurons in lamina X and medial lamina VII of the lumbar spinal cord may participate in hindlimb locomotor activity. An *in vitro* spinal cord preparation which involved a midsagittal lumbar hemisection while keeping the thoracic cord intact, was used to examine these neurons. This reduced preparation exhibits drug-induced locomotor-like activity and provides unobstructed access to the lumbar intermediate grey matter. Locomotor-like activity recorded in ventral roots L3 and L5 was elicited by superfusion of the cord with N-methyl-D-aspartate (NMDA) and serotonin. During this activity, neurons in the medial grey matter were recorded from and labelled intracellularly. Thirteen of 15 cells displayed locomotor-like drive potentials (LDPs) up to 7mV peak to peak. These LDPs were either in or out of phase with the recorded ventral root rhythmic activity. The LDPs appeared to result from the summation of post-synaptic potentials. Dorsal root stimulation resulted in excitatory post-synaptic potentials (latency 0.2 - 3.6msec longer than monosynaptic VR latency) in 10 of these neurons. Five neurons received excitatory and 1 received inhibitory synaptic input from ventrolateral funiculus stimulation. Labelled neurons were located lateral and slightly ventral to the central canal, and had dorsoventrally oriented processes. These observations lend support to the hypothesis that neurons in this region of the lumbar spinal cord participate in the production of locomotor output. Supported by the Medical Research Council of Canada. J.N.M. is a Trainee of the Network of Centres of Excellence in Neural Regeneration and Functional Recovery.

NMDA RECEPTOR-MEDIATED VOLTAGE OSCILLATIONS IN MAMMALIAN MOTONEURONS. S. Hochman*, L.M. Jordan and B.J. Schmidt. Depts. of Medicine and Physiology, University of Manitoba, Winnipeg, Canada, R3E 0W3.

Whole-cell current clamp recordings were obtained from motoneurons in the bilaterally intact *in vitro* neonatal rat spinal cord in order to examine the effects of NMDA receptor activation. In one motoneuron, bath application of serotonin (30 μ M) and NMDA (10 μ M) produced a progressive membrane depolarization accompanied by repetitive firing (6 Hz). Re-adjustment of the membrane potential to -60 mV, via intracellular current injection, resulted in the emergence of prolonged post-spike after-depolarizations (ADPs) measuring 30 mV as well as an associated slowing of firing frequency (2 Hz). Following hyperpolarization of the membrane to -85 mV, Na⁺ spikes and ADPs were no longer present but rhythmic 10-15 mV slow-rising membrane potential oscillations (1-2 Hz) persisted. After blocking Na⁺ spikes and synaptic transmission with TTX (1 μ M), 10-15 mV oscillations and occasional superimposed faster-rising high amplitude (30 mV) potentials remained. In another motoneuron, NMDA (20 μ M) in the presence of TTX induced sustained rhythmic membrane oscillations between -55 and -25 mV (2 Hz). Hyperpolarization of the membrane to -60 mV had no effect on frequency but the oscillations were reduced in amplitude (10-15 mV). These voltage oscillations lasted 4 minutes after which the cell remained depolarized at -25 mV. Repolarization of the membrane to -60 mV and injection of a current ramp waveform revealed step changes motoneuron membrane potential compatible with the presence of a bistable property. In other motoneurons the frequency of NMDA-induced, TTX-resistant membrane potential oscillations was also insensitive to adjustments in membrane voltage between -90 and -40 mV. However, the frequency of oscillation was sensitive to the concentration of NMDA in the bath. These observations suggest that mammalian hindlimb motoneurons are capable of endogenous oscillatory behavior in the presence of NMDA receptor activation. (Supported by HSCF and MRC Canada)

VOLTAGE-DEPENDENT OSCILLATIONS OF MOTONEURON MEMBRANE POTENTIAL DURING RHYTHMIC MOTOR ACTIVITY IN THE *IN VITRO* NEONATAL RAT SPINAL CORD. B.J. Schmidt*, S. Hochman and L.M. Jordan. Depts. of Medicine and Physiology, University of Manitoba, Winnipeg, Canada, R3E 0W3.

The role of voltage-dependent properties in the generation of the rhythmic depolarizations in motoneurons during neurochemically-induced activity was examined using whole-cell recording methods. QX-314 (5 mM) was included in the pipette to block Na^+ currents. Serotonin and NMDA alone or in combination were used to induce activity. In voltage clamp mode, phasic inward currents (e.g. 50 pA at $V_h = -80$ mV) coincided with rhythmic ventral root discharge. In current clamp mode, NMDA (12 μM) induced fast rhythmic motor activity (4-6 Hz) associated with 5-10 mV voltage oscillations at hyperpolarized membrane potentials (e.g. -80 mV) and larger amplitude oscillations (20 mV) at resting potential (-60 mV). In one motoneuron, slowly depolarizing current ramp injections (15s) demonstrated a voltage-dependent 9 mV step increase (from 6 to 15 mV) in the amplitude of the NMDA (5 μM)-induced 1.8 Hz membrane oscillations. In another motoneuron, slow frequency (0.4 Hz) 5 mV oscillations with superimposed long-duration EPSPs (40-100 ms) were observed during rhythmic ventral root discharge induced by serotonin (60 μM) and NMDA (20 μM). Short-duration current ramps (250 ms) were delivered between -60 and -20 mV during the depolarized phase of the slow oscillations. An abrupt increase of superimposed EPSP amplitude, from 4 mV at -60 mV to 10 mV at ramp voltages of -40 mV, was observed.

These observations suggest that membrane depolarization can enhance the amplitude of excitatory events underlying motor rhythms and may reflect the voltage-dependent removal of Mg^{2+} blockade at NMDA receptor-activated synapses. (Supported by HSCF and MRC Canada).

CIRCUITRY AND PATTERN GENERATION V

EVIDENCE FOR FUNCTIONAL PARTITIONING WITHIN THE MASTICATORY PATTERN GENERATOR NETWORK. K.-G. Westberg, P. Clavelou, C. Valiquette, S. Lepage, J.P. Lund and H.H. Jasper*. Centre de Recherches en Sciences Neurologiques et Fac. Méd., Université de Montréal, Montréal, Québec, H3C 3J7, Canada.

During mastication, jaw muscle activity is adapted to the size and the texture of food. It has already been shown that last-order interneurons of subnucleus oralis- γ of the spinal trigeminal tract (NVspo) form part of the pattern generating circuits. The present study was performed to determine how these neurones behave during different forms of mastication.

Rabbits were anaesthetized with urethane. Different jaw movement patterns were elicited by repetitive electrical stimulation of four sites within the masticatory areas of the right and left hemispheres of the cerebral cortex. The animals were paralyzed and the fictive patterns of rhythmic activity were recorded in the trigeminal motor nucleus. The firing properties of trigeminal interneurons were analyzed during mastication induced from each cortical stimulation site. Changes in their responsiveness to low-threshold peripheral afferents were quantified by measuring the latency and frequency of axon potentials caused by stimulation of the inferior alveolar nerve.

Eighty-five neurones were recorded within NVspo- γ and 56 were rhythmically active during fictive movements. Thirty % of these showed rhythmic bursts only during one pattern. The other 70 % altered both their burst duration and frequency when the movement program changed. It was also observed that the response to the afferent input was specific to the type of motor pattern.

Our results suggests that last-order NVspo- γ interneurons form functional subpopulations to produce different patterns. In addition, the gain of reflex connections is specifically modulated according to the pattern of movement.

ACTIVITY OF SPINDLE AFFERENTS RECORDED AT THE LEVEL OF TRIGEMINAL SUBNUCLEUS ORALIS OF RABBIT DURING FICTIVE MASTICATION. P. Clavelou, K.-G. Westberg, S. Lepage, C. Valiquette and J.P. Lund*. Centre de Recherches en Sciences Neurologiques et Fac. Méd. Dent., Université de Montréal, Montréal, Québec, H3C 3J7, Canada.

Muscle spindle afferents from the jaw closing muscles have their cell bodies in the mesencephalic trigeminal nucleus (NVmes). Axon collaterals are sent to the trigeminal motor nucleus (NVmt), its border areas, and to the medial part of the oral nucleus of the spinal trigeminal tract (NVspo). We report here on the firing properties of slowly adapting masseteric spindle afferents recorded near the NVspo during fictive mastication in urethane-anaesthetized rabbits. Afferents were identified by their response to stretching of the jaw and to probing the muscle, and by short latency (<1ms) action potentials evoked by single pulse or repetitive (>300Hz) electrical stimulation of the motor nerve. Repetitive stimulation of the sensory motor cortex was used to evoke fictive movements that were monitored by recording the rhythmic activity in NVmt. The results show that the tonic firing of these afferents to a constant stretch is phasically inhibited during the opening phase, while an increase in frequency occurred during the closing phase of the cycle. Blocking of peripheral inputs with anaesthetic injected into the muscle or around the nerve supports the concept of a central origin for the observed modulation.

Kolta et al. (J. Neurophysiol. 1990, 64:1067-1076) recorded from the same type of spindle afferents at the level of NVmes. In agreement with us, they observed a phasic inhibition of all units during the opening phase of the chewing cycle, but only 2 of 33 fired bursts during closure. We conclude that the centrally-induced blocking of orthodromic invasion during the opening phase affects cell body, stem and central axons, while the burst of activity during the closing phase are probably generated at terminals of the central axonal branches.

THE THALAMIC VPL IN RATS PROMOTES BEHAVIORAL RECOVERY AFTER SOMATOSENSORY LESIONS. J. Wells¹, S. M. Henry^{1,2} and J. M. Held². Department of Anatomy and Neurobiology¹ and Department of Physical Therapy², University of Vermont, Burlington, VT 05405.

The transfer of information through VPL was found to be critical for the successful completion of a motor task and for the normal trajectory of the hindlimb. Bilateral VPL lesions resulted in a significant increase in the time to traverse a narrow bar for a reward and a significant modification of the swing phase of the gait cycle. The rats gradually recovered the rapid traverse of the bar, but the deficit in the swing cycle did not recover within 46 days. The cerebellar, basal ganglia and other motor areas did not serve as alternatives to the VPL, at least during the first 2 weeks for the locomotor task or the first 46 days for the hindlimb movement pattern. After unilateral lesions of only the gracile nucleus, there was no deficit in the task at the behavioral level, but recovery occurred in the movement pattern of the hindlimb over 3 weeks. VPL itself may promote the recovery in two ways. Structural recovery of the number of synapses begins at about the time that the movement pattern returns to normal. In addition, when there is a decrease in the somatosensory input to VPL, there may be a widespread disinhibition in VPL that would unmask normally ineffective synapses which may act as alternative inputs. HIGH FREQUENCY OSCILLATIONS IN MEMBRANE POTENTIALS (MP) OF MEDULLARY INSPIRATORY (I) AND EXPIRATORY (E) NEURONS. W.-X. Huang*, M.I. Cohen, Q.P. Yu and Q. He. Dept. of Physiol., Albert Einstein Col. Med., Bronx, NY 10461.

In 32 decerebrate, unanesthetized and paralyzed cats, we studied the characteristics of high frequency oscillations (HFOs) in MPs of medullary I and E cells. Simultaneous recordings were taken from bilateral phrenic (Phr) and recurrent laryngeal (RL) nerves and from cells (0 - 1.5 mm caudal to obex, 3.2 - 4.2 mm lateral). HFOs during I were found in MPs of 24 E and 15 I cells. Fourteen of these were identified as RL cells (7 I, 7 E) by a sharp peak in the spike-RL nerve discharge cross-correlogram. The HFO in MP during I, superimposed on depolarization in I cells or hyperpolarization in E cells, developed gradually after I onset, reached maximum amplitude around mid-I, then gradually decreased. The MP-Phr coherence peaks had a frequency range of 39.1 - 66.4 Hz (mean 55.6 \pm 8.3 SD Hz), with a mean coherence value of 0.55 \pm 0.18 (range 0.38 - 0.80). The MP-Phr cross-correlogram lags (peak MP depolarization to Phr) were: a) for E cells, mean of 5.6 \pm 1.8 ms (range 0 to 0.46 of an HFO cycle); and b) for I cells, 6.5 \pm 4.7 ms (range -0.06 to 0.93 of an HFO cycle). The results confirm that there are widespread short-term network interactions among I cells as well as between I and E cells; and the dispersion of lags suggests the existence of distributed connections between cells of the generating networks. (Supported by N.I.H. Grant HL-27300.)

NEUROMUSCULAR PARTITIONING OF THE HUMAN BICEPS BRACHII LONG HEAD. M.H. Mann, S.L. Wolf, R.L. Segal, Div. Phys. Ther., Dept. of Rehab. Med., Emory Univ. Sch. of Med., Atlanta, GA 30322.

Previous studies (ter Haar Romeny et al., 1984; Segal 1992) have suggested three functionally discrete longitudinally oriented partitions within the biceps brachii long head (BLH). A recent pilot study from our lab (see English et al., 1993) suggested the organization of BLH may be different than proposed by ter Haar Romeny et al. (1984).

In an attempt to clarify the organization of BLH, fine-wire electrodes were inserted into 3 strips of BLH running from medial to lateral in 6 subjects as determined from dissections. The activation order of motor units was determined for 3 tasks: elbow flexion, forearm supination, and combined flexion and supination. In addition, recordings were made during elbow extension, forearm pronation, and shoulder extension, flexion and abduction. Spike-triggered averages (STA) between motor units from the different recording sites were used to determine the level of correlated activity. During both elbow flexion and forearm supination medial motor units were usually recruited first while motor units from the lateral recording site were usually recruited last. Motor units from the central recording site were recruited more easily than the lateral site, especially when elbow flexion and supination were combined. However, motor units from the lateral recording site were most easily recruited during shoulder movements. Activity of motor units from the lateral site were not correlated with the motor units from the other sites, but motor units from the medial and central recording sites showed some correlated activity. This study supports partitioning of BLH, but possibly not as previously proposed. Future studies should study the activity of BLH during shoulder movements in more detail.

719.3

MOTOR UNIT FIRING DURING SHORTENING AND LENGTHENING CONTRACTIONS. J.N. Howell*, A.J. Fuglevand, M.L. Walsh and B. Bigland-Ritchie, J.B. Pierce Laboratory, 290 Congress, New Haven, CT 06519.

In order to examine motor unit firing patterns during movement, fine wire (25 μ) electrodes were inserted into the first dorsal interosseus (FDI). Unit activity was recorded as the FDI shortened and lengthened under constant loads and was compared to activity during isometric ramps. Single units, identified by wave shape analysis, could be followed reproducibly over many cycles of movement and in repeated isometric contractions. In most cases the first units to be recruited during shortening (concentric) were the last to be derecruited during lengthening (eccentric). An exception is shown, in which unit A turned off as B was recruited. B had a higher torque threshold during isometric activation than A. Unit B activity was simultaneously detected by a second electrode pair (not shown), making it unlikely that the appearance of B in the trace shown represented an artifact of electrode movement rather than unit recruitment.

ELECTROPHYSIOLOGICAL PROPERTIES OF DISSOCIATED PARAPODIAL MUSCLE FIBERS FROM *APLYSIA BRASILIANA*. Paul J. Laurienti* and James E. Blankenship, Marine Biomedical Inst., Univ. Tx. Med. Br., Galveston, TX 77555-0843.

The marine mollusc *A. brasiliana* swims by rhythmic flapping of its bilaterally symmetric wing-like parapodia. Motor neurons (MNs) and serotonergic modulatory neurons (POP cells) which innervate peripheral parapodial muscle are located in each pedal ganglion. POP cells and exogenous serotonin (5-HT) have been shown to modulate the activity of the cholinergic neuromuscular junction. The modulatory effect of 5-HT may be mediated through either pre- or postsynaptic mechanisms. We have recently demonstrated that 5-HT acts, at least in part, through a presynaptic mechanism. However, the possibility of postsynaptic modulation has not been investigated. To test the direct effect of 5-HT on parapodial muscle fibers, we have developed a dissociated muscle preparation in order to characterize the properties of these cells. We have successfully dissociated viable muscle fibers and have performed current clamp experiments using standard intracellular recordings. The resting membrane potential (RMP) of the dissociated fibers is approximately -70 mV, which is consistent with reports of the RMP in muscles in the intact parapodium. Muscle fibers are able to contract when depolarized by injecting intracellular current or in response to high K^+ . I-V curves from single fibers are non-linear, showing a decrease in cell resistance with depolarization and an increase in resistance with hyperpolarization. Preliminary experiments investigating the effect of exogenously applied acetylcholine (ACh) has revealed a Cl⁻-dependent hyperpolarization; other components of the ACh response are currently under investigation. Future experiments are planned to analyze the effect of 5-HT on both the intrinsic and ACh-induced currents in these muscle cells.

NONHOMOGENEOUS AND TASK DEPENDENT ACTIVATION OF THE FIRST DORSAL INTEROSSEOUS MUSCLE. D.H. Laidlaw†, G.H. Yue†, A.L. Alexander‡, A.F. Gmitro‡, E.C. Unger‡, and R.M. Enoka†*. †Dept. Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, OH 44195, and ‡Dept. Radiology, University of Arizona, Tucson, AZ 85724

Spin-spin relaxation time (T2) measured from the magnetic resonance image of skeletal muscle varies linearly with activation intensity of the muscle. T2 was used to investigate functional compartmentalization of the first dorsal interosseous (FDI) muscle of four healthy human subjects. Spin-echo images of two cross sections from the proximal half of the muscle were analyzed to determine regional differences in activation immediately following flexion and abduction exercises of the left index finger. The exercise was performed against an elastic load that was 20% of the maximum work capacity. Each cross section of the muscle was divided into eight regions about the major axes of the muscle. In each cross section, the signal intensity at four echo times (25, 50, 75, 100 ms) was measured and T2 relaxation time was calculated. Only areas showing homogeneous signals (i.e., no apparent high connective tissue or fat content) were measured. Percent change of T2 from initial resting measurements was used to quantify relative activation. The two major findings were: (1) during abduction, the dorsomedial portion was more active (10.8% increase) than the ventrolateral portion (3.7%); and (2) during flexion, the middorsal and ventrolateral portions were more active (11.0% and 12.6% increases respectively) than the other portions (4-9%). These findings suggest that the relative activation of the FDI muscle is nonhomogeneous and varies with the task performed.

ADAPTATION OF MOTOR UNIT DISCHARGE RATE AND VARIABILITY DURING SUSTAINED MAXIMUM VOLUNTARY CONTRACTIONS. A.J. Fuglevand*, V.G. Macefield, J.N. Howell and B. Bigland-Ritchie, John B. Pierce Laboratory, 290 Congress Ave., New Haven, CT 06519.

Although the average discharge rate of motor unit populations is known to decline during a sustained maximum voluntary contraction (MVC) (Bigland-Ritchie et al., *J. Physiol.* 340: 335, 1983), little is known about how individual motor units adapt during this fatigue task. To address this issue, motor unit action potential trains were recorded with intramuscular tungsten microelectrodes during an MVC (60 - 120 s) of the extensor hallucis longus muscle in 27 experiments on 7 human subjects. The analyses were restricted to discharge trains in which at least 100 spikes were recorded. Each train was divided into segments having equal number of spikes but with no less than 50 spikes/segment. Mean discharge rate and the coefficient of variation in interspike intervals (cvISI) were determined for each segment. Adaptation was estimated for each unit from the segment values as the average change in discharge rate ($\Delta\text{rate}/10\text{ s}$) or in variability ($\Delta\text{cvISI}/10\text{ s}$) that would occur for each 10 s of activity. 15 trains with a mean (\pm SD) duration of $10.8 \pm 4.8\text{ s}$ were included in the analyses. The discharge rate of all units but one recorded within the initial 30 s of the MVC decreased with time from an initial mean rate of $19.5 \pm 8.0\text{ imp/s}$ (mean $\Delta\text{rate} = -4.4\text{ imp/s}/10\text{ s}$). Units monitored after 30 s showed little adaptation (mean $\Delta\text{rate} = 0.7\text{ imp/s}/10\text{ s}$). Discharge variability (initial cvISI = 0.2 ± 0.07) altered little over time for trains recorded within and after the initial 30 s of the MVC (mean $\Delta\text{cvISI}/10\text{ s} = -0.03$ and -0.04 , respectively). These findings imply that discharge-rate adaptation is confined to the early stages of sustained activity and that discharge variability remains stable. Supported by USPHS NS 14576 & HL 30062.

THIXOTROPIC BEHAVIOR OF THE PLANTARFLEXOR MUSCLES IN NORMAL INDIVIDUALS. Lamontagne A., Malouin F., Richards CL*, Tardif D. Physiotherapy Dept., Faculty of Medicine, Laval University and Neurobiology Research Center, Hôpital de l'Enfant-Jésus, Quebec City, Canada.

The primary aim of this study was to develop a method of assessing the thixotropic behavior of normal muscles with torque measures. Stiffness variations that are dependent on the previous history of muscle contraction or length (thixotropy) are thought to reflect intrinsic muscle fiber properties. We thus compared the effect of brief (30 s) lengthening and shortening periods of the plantarflexors on the resistive torque obtained during passive dorsiflexion (DF) of the ankle. In seven healthy persons (23 to 40 yrs), passive ankle movements ($n=6$) ranging from -23° to -8° of DF were imposed at $20^\circ/\text{s}$ with an isokinetic dynamometer (Kin-Com). Passive DFs were made before (pre-test) and after (post-test) a 30 s pause in a lengthened (-8°) position (condition 1) or a shortened (-23°) position (condition 2) of the plantarflexors. The foot was maintained in the footplate between pre-tests and post-tests. Surface electrodes on the tibialis anterior and soleus muscles monitored unwanted muscle activations during the tests. The last five trials of each test were averaged and the differences in the area (dA) under the torque-angle curves (-18° to -10°) between the pre-test and post-test were computed for each condition. In condition 1, the resistive torque was decreased in all 7 subjects ($dA=1.94\text{ N.m.deg}^{-1} \pm 1.11$) while in condition 2, we observed only a slight decrease for 6 subjects ($dA=0.18\text{ N.m.deg}^{-1} \pm 0.12$), indicating that resistive torque responses are sensitive to the recent history of muscle lengthening. Wilcoxon signed rank tests computed between the dA for condition 1 and 2 indicated that the lengthened position induced a larger effect ($p=0.01$) on torque than the shortened position. These results indicate 1) that normal plantarflexor muscles exhibit a thixotropic behavior that can be detected by measuring resistive torque to passive movement and 2) that this method may be applicable to the evaluation of changes in intrinsic properties of spastic muscle. (Supported by MRC of Canada).

SPROUTED MOTOR UNITS SHOW TYPE-SPECIFIC RESPONSES TO CHRONIC ENLARGEMENT FOLLOWING PARTIAL DENERVATION OF RAT LATERAL GASTROCNEMIUS. K.L. Seburn and P.F. Gardiner^{*}. Physiological Activity Sciences, Univ. of Montréal, Montréal, Que., Canada H3C 3J7.

Motor units (MUs), enlarged subsequent to partial denervation may, with extended periods, diminish in their capacity for force production. We studied this issue by comparing normal lateral gastrocnemius (LG) MUs, isolated via splitting of the L5 ventral root, with MUs which had been sprouted (L4 section), for either 30 or 90 days. Compared to control, MU proportions were unchanged and overall mean MU tetanic forces doubled at both 30 and 90 days. This increased tetanic force varied according to MU type: mean forces for S, FR and FF MUs were 330%, 195%, and 267% respectively, of controls. After 90 days FR MU force was further increased (25%), S was unchanged and FF decreased (26%), compared to 30 days. Twitch/tetanic ratios also responded differently according to MU type. Our results indicate that after the initial sprouting response is complete, MU reorganization continues based on size and/or activity level. Supported by NSERC Canada.

A DYNAMIC, 3-D, 7 DEGREE-OF-FREEDOM UPPER EXTREMITY

MODEL. A. Kakavand, G.T. Yamaguchi, A.B. Schwartz^{*}. Barrow Neurological Inst., 350 W. Thomas Rd., Phoenix, AZ 85013 and Arizona State University, Tempe, AZ 85287-6006

A 7 degree-of-freedom (DOF) dynamic model of the rhesus monkey upper extremity has been developed for use in trajectory planning studies. Dynamic equations of motion were derived using Kane's method and coded on a computer-graphic workstation. Included are 36 musculotendon forces to actuate the 7 DOF. Musculotendon origin and insertion points were obtained by dissection and measurement to ± 0.1 mm in Cartesian space via an Optotrak digitizing probe and transformed to bone centered reference frames. Via points describing each musculotendon pathway were also computed where necessary to prevent the paths from penetrating bone surfaces during joint rotation, using the graphical display program SIMM.

The model can be used to explore the neuromuscular strategies employed by the monkey to select joint angles when (i) holding the finger at a specified point in free space, or (ii) creating a trajectory in free space. When the finger position (or trajectory) is well within the physiological workspace, an infinite number of possible arm configurations will deliver the same endpoint position (trajectory). Optimal control theory was therefore used to compute minimum cost solutions to the kinematic redundancy problem. Cost functions include minimizing gravitational potential energy (C_1) and the sum of muscle stresses squared (C_2), which relates to metabolic energy expenditure.

A pseudoinverse method was used to compute musculotendon stresses with minimum positional (trajectory) error. Preliminary results for the positional study indicate that cost function C_2 predicts the preferred shoulder angles, elbow flexion angle, and wrist flexion/extension angle, but cost function C_1 does not perform as well. Supported by the NIH (NS 26375).

PROPAGATION OF CALCIUM IONS IN CULTURED COLONIC SMOOTH MUSCLE CELLS. S.H. YOUNG^{*}, H.S. ENNES, AND E. MAYER. Dept. of Physiology, UCLA School of Medicine, Los Angeles, CA 90024.

Smooth muscle cells are isolated by collagenase digestion from rabbit distal colonic circular or longitudinal smooth muscle, and then suspended in medium with high glucose (12 mM), non-essential amino acids, and 10% fetal bovine serum, and plated onto coverslips. After 5 or more days in culture, cells are loaded with the calcium indicator FURA-2 (5uM, 1 Hr, 37°C), and cell calcium concentrations are measured with an imaging system (Attofluor Instruments).

Intracellular calcium increases in response to bath application of bethanecol (10-5 M), or caffeine (10 mM). Increases are usually apparent first in the subplasmalemmal space, followed by spread to other regions of the cell. The response is usually symmetric around the cell, and no oscillations of calcium are seen. In contrast, single cells mechanically stimulated with a smooth glass pipette show strong response local to the stimulus site, followed by propagated waves of calcium away from the stimulus site. In cultures of high cell density, where several cells are in contact, these calcium waves propagate into neighboring cells.

BRAIN METABOLISM AND BLOOD FLOW: DISEASE MECHANISMS

INDOMETHACIN PRETREATMENT ABOLISHES ATTENUATION BY N^G-NITRO-L-ARGININE (L-NNA) OF CORTICAL SPREADING DEPRESSION (CSD)-INDUCED CEREBRAL VASODILATION. D. Busija^{*}, D. Colonna, AND W. Meng. Dept. of Physiology & Pharmacology, Bowman Gray Sch. of Med., Winston-Salem, NC 27157-1083.

The role of nitric oxide in cerebrovascular dilation during CSD is controversial. The purpose of this study was to examine effects of inhibition of nitric oxide synthase on cerebrovascular dilation during CSD. Since indomethacin pretreatment potentiates cerebrovascular dilation during CSD (*Am. J. Physiol.*, 261: R828, 1991), we speculated that nitric oxide might play a larger role under these conditions. Urethane-anesthetized rabbits were equipped with a closed cranial window and pial arteriolar diameter was examined via intravital microscopy. Baseline arteriolar diameters ranged from 80-100 μ m. We examined arteriolar responses to CSD in the absence of other drugs, and after intravenous administration of L-NNA (15 mg/kg) and/or indomethacin (10 mg/kg). CSD was induced by microinjection of 5% KCl. L-NNA reduced nitric oxide synthase activity by 90% in cerebral cortex ($n=12$ for controls and $n=24$ for L-NNA-treated) and reduced pial arteriolar dilation in response to 10^{-6} M acetylcholine from $30 \pm 10\%$ to $9 \pm 3\%$ ($n=3$). In the absence of indomethacin, L-NNA reduced peak cerebral arteriolar diameter from $56 \pm 6\%$ to $23 \pm 3\%$ during CSD ($p<0.05$; $n=8$). In other animals, indomethacin pretreatment increased arteriolar dilation from $41 \pm 5\%$ to $76 \pm 6\%$ during CSD ($p<0.05$; $n=5$). However, administration of L-NNA in the presence of indomethacin failed to reduce arteriolar dilation. In conclusion, following administration of indomethacin, inhibition of nitric oxide production by L-NNA fails to attenuate CSD-induced arteriolar dilation. Supported by HL 30260 and HL 46558.

MECHANISMS FOR PRESERVED CEREBROVASCULAR AUTOREGULATION DURING HYPERTENSION IN RATS AFTER SINOARTIC DENERVATION (SAD). W.T. Talman^{*}, D. Nitschke-Dragon. Dept. of Neurology, VAMC and Univ. of Iowa, Iowa City, IA 52242.

We have shown that cerebral blood flow (CBF) and cerebral vascular resistance (CVR) autoregulate at higher levels of arterial blood pressure (AP) after SAD in rat. In this study we sought to assess potential mechanisms for this phenomenon. CBF was monitored by laser flowmetry in intact rats in whom AP was increased by phenylephrine (PE), vasopressin, or angiotensin. AP was increased by PE in additional rats after: 1) SAD; 2) SAD plus bilateral removal of superior cervical ganglia; 3) SAD plus bilateral ligation and transection of renal vessels and nerves (isolation); or 4) SAD plus sympathectomy and renal isolation. Body temperature, arterial pCO₂, and rate of rise of AP were controlled. CBF and CVR broke through autoregulation when mean AP's were raised to 155 ± 4 mmHg by PE in intact rats but did not breakthrough at even higher levels of AP in SAD rats with intact (185 ± 2 mmHg) or interrupted (181 ± 5 mmHg) sympathetic innervation of cerebral vessels. Breakthrough was seen in rats in which AP was increased with vasopressin but not in those treated with angiotensin, which blocked baroreflex-mediated bradycardia that occurred in intact rats in response to increased AP. Nonetheless, breakthrough did not occur in SAD rats even when increases in plasma renin activity were prevented by isolation of the kidneys before SAD. This study suggests that the arterial baroreflex may participate in breakthrough of autoregulation at hypertensive levels of AP independent of its effects on sympathetic innervation of cerebral vessels or on plasma angiotensin levels. We speculate that breakthrough of cerebral autoregulation in response to hypertension may result from release of an active vasodilator. Support: VA merit review and career award, AHA grant in aid, and NIH HL32205 and HL14388.

THROMBIN INDUCES BRAIN EDEMA AND CONSTRICTION IN CEREBRAL MICROVESSELS: POSSIBLE ROLE IN INTRACEREBRAL HEMORRHAGE. K.R. Lee, A.L. Betz, O. Sagher*, R.F. Keep, G.L. Heath, and J.T. Hoff. Section of Neurosurgery, University of Michigan, Ann Arbor, MI 48109

Thrombin is a naturally occurring protein involved in the clotting cascade. In addition to its role in thrombogenesis, it is thought to have vasoactive and inflammatory effects. While under normal conditions the level of thrombin in the brain is undetectable, during intracerebral hemorrhage (ICH) large quantities of prothrombin are converted to thrombin, exposing the brain to thrombin. The present series of studies investigated the possibility that the intracerebral injection of thrombin induces local brain edema and microvascular constriction.

Rats received a 10 µl stereotaxic injection of either saline, thrombin (1, 10, or 100 units), or thrombin (10 units) and a thrombin inhibitor (hirudin, 10 units; or Nα-(2-naphthalenesulfonyl)glycyl-L-4-amidino-DL-phenylalaninepiperide (αNAPAP), 0.2mM). Local brain water increased in rats injected with 10 or 100 units of thrombin (4.0% or 5.8% respectively; $p < 0.01$ vs. sham animals). Animals injected with thrombin and hirudin had less water accumulation (2.0%; $p < 0.05$ vs. thrombin alone). Similar results were obtained with the thrombin inhibitor, αNAPAP.

In order to investigate the possibility that thrombin may induce microvascular constriction, a second series of experiments was performed in which *in vitro* brain slices were obtained from rats and examined with computerized videomicroscopy. Microvessels (30-70 µm in diameter) within the slices were monitored while the slices were superfused with thrombin (1 unit/µl in artificial cerebrospinal fluid) or vehicle (0.8% albumin solution) for 30 minutes. Thrombin induced a 35.4% microvascular constriction after 30 minutes, whereas treatment with vehicle resulted in a 2.9% constriction ($p < 0.005$). These studies suggest that thrombin induces brain edema, and that this effect may be due in part to the microvascular effects of thrombin. Brain edema/toxicity seen in ICH may be mediated by the local effects of thrombin. The results also suggest that the neurosurgical use of thrombin to augment hemostasis may be accompanied by local edema and vasoconstriction.

720.5

CEREBROVASCULAR RESPONSES TO HYPERCAPNIA AND HYPERTENSION AFTER SUBARACHNOID HEMORRHAGE IN RATS. S. Yamamoto*, S. Nishizawa, and K. Uemura. Dept. of Neurosurg. Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan, 431-31.

We sought to determine whether chronic cerebral vasospasm following subarachnoid hemorrhage (SAH) would modify cerebrovascular responses. To do this we: (a) analyzed the effect of SAH upon vessel calibers on cerebral angiogram 48 hours later; (b) investigated cerebral blood flow (CBF) reactivities to increase in pCO_2 and mean arterial blood pressure (MABP). SAH was produced by intracisternal injection of 0.45 ml of autologous blood or saline (sham) in anesthetized Sprague-Dawley rats. Angiography was performed by injection of contrast material via carotid artery in control (n=15), SAH (n=6) and sham (n=6) groups. CBF was measured by laser-Doppler flowmetry over the parietal cortex 48 hours after SAH in sham (n=8) and SAH (n=6) animals. Graded hypertension was induced with phenylephrine. SAH reduced, by over 50%, the mean vessel caliber of internal carotid, anterior cerebral and middle cerebral arteries significantly ($p < 0.05$, ANOVA). In other rats, hypercapnia (36 to 54 mmHg) increased CBF to a similar degree (sham 2.61, SAH 2.11 %/mmHg) in both groups. SAH did not abolish CBF autoregulation but shifted the least squares curve toward higher MABP ($p < 0.01$, ANOVA with covariates). SAH also increased cerebrovascular resistance calculated by MABP/CBF at any levels of MABP. We conclude chronic vasospasm following SAH changed the cerebrovascular responses to hypertension but not to hypercapnia.

CYTOCHROME OXIDASE ENZYME ACTIVITY IS UP-REGULATED IN RAT NUCLEUS ACCUMBENS AND DOWN-REGULATED IN MEDIAL PREFRONTAL CORTEX DURING WITHDRAWAL FROM CHRONIC COCAINE. J.R. Walker* and K.A. Sevarino. Division of Molecular Psychiatry, Departments of Psychiatry and Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06508.

Cytochrome c oxidase (CO) subunit I mRNA was previously found to be up-regulated by chronic cocaine treatment (15 mg/kg, i.p., twice daily for 14 days) in rat nucleus accumbens (NAc) (Walker and Sevarino, Soc. Neurosci. Abs. 19, 1858). CO enzyme activity, measured spectrophotometrically, was examined in multiple brain regions, and was found to be regulated in the medial prefrontal cortex (mPFC), as well as in the NAc, each with a unique time dependence during withdrawal from chronic cocaine. The peak increase in enzyme activity in the NAc occurred 18 hours after the last cocaine injection, at a time when the peak decrease in CO activity was observed in the mPFC. CO activity was not regulated in any other brain region studied. CO activity up-regulation was not observed in the NAc 18 hours after acute cocaine, chronic desipramine, chronic fluoxetine, chronic lidocaine, or chronic morphine treatments. We suggest that CO enzyme activity may serve as a biochemical marker for cocaine withdrawal.

720.4

HEMOGLOBIN AND BLOOD OXYGEN METABOLISM DURING ACUTE CYANIDE TOXICITY OF MINIATURE SWINE. E.U. Maduh*, E.W. Nealley, and S.L. Baskin. Biochem. Pharmacol. Branch, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010-5425

Monitoring changes in blood hemoglobin (Hb) and the related oxygen (O_2) parameters provides a means for evaluating treatment progress in acute cyanide (CN) poisoning. In the present study, serial measurements/calculations of O_2 , vol. %, Hb and its derivatives were obtained before and at time points over a period of 60 min after i.v. injection of NaCN (2.5 or 4.2 mg/kg) in the male miniature pig. Animals were anesthetized by isoflurane inhalation and cannulated for arterial blood collections. Whole blood was analyzed with a hemoximeter, for O_2 , carboxyhemoglobin (COHb), oxyhemoglobin (HbO₂), and methemoglobin (metHb). NaCN injection significantly decreased metHb (Gram% \pm SE) from 1.5 ± 0.17 to 1.05 ± 0.15 at the 10 min time point whereas COHb concentrations increased (0.46 ± 0.2 to 1.15 ± 0.35) over the same period after the 2.5 mg/kg dose was administered. The 4.2 mg/kg dose decreased metHb (1.68 ± 0.26 to 0.80 ± 0.11) and increased COHb, 0.5 ± 0.05 to 1.1 ± 0.4 at the same time point. With either dose, the decrease (metHb) or increase (COHb), continued in the subsequent 20 min reaching a plateau between the 30 and 60 min time points. Levels of O_2 and HbO₂ tended to increase following NaCN exposure but did not attain statistical significance. Previously, pretreatment with 1-(5-isquinolinesulfonyl)-2-methylpiperazine (H7) a protein kinase C (PKC) inhibitor, was shown to blunt the loss of brain metabolic energy elicited by NaCN *in vivo* (Maduh et al., FASEB J. 8:A647, 1994), suggesting a possible role of PKC in CN toxicity. Results of the present study further support the PKC possibility as H7 (1 mg/kg) pretreatment administered 30 min before NaCN at the 4.2 mg/kg dose, also diminished but did not eliminate the changes in the arterial blood Hb and O_2 parameters analyzed. Since changes in arterial blood Hb factor very importantly in brain viability and metabolic status, it is concluded that monitoring these parameters may be useful in assessing the effectiveness of prophylactic treatment to counter cyanide effects in the intact organism.

THREE-DIMENSIONAL IMAGE ANALYSIS OF LOCAL METABOLISM - BLOOD FLOW UNCOUPLING IN PHOTOTHROMBOTIC MCA OCCLUSION IN RATS.

T. Back, M.D. Ginsberg*, W. Zhao, J.Y. Loor, I. Valdés, O.F. Alonso, B.D. Watson, and R. Busto. Cerebral Vasc. Disease Research Center, Univ. of Miami School of Medicine, Miami, FL, 33101.

We applied 3D autoradiography to characterize the relationship between local cerebral glucose utilization (ICMRgl, studied by ^{14}C -2-deoxyglucose) and blood flow (ICBF, studied by ^{14}C -iodoantipyrine) at 1.5 h following permanent distal middle cerebral artery (MCA) occlusion coupled with 1 h contralateral and permanent ipsilateral carotid occlusions in halothane-anesthetized, physiologically monitored normothermic Sprague-Dawley rats. The MCA was occluded by laser-driven photochemical thrombosis. Brains were coronally sectioned subserially and aligned by disparity analysis to yield average 3D data sets for both ICMRgl and ICBF (n=7 each). Computer division produced a 3D ratio image depicting the average metabolism/flow couple. ICMRgl images showed remarkable maintenance of metabolism despite the fact that a volume of 109 mm³ exhibited penumbral flow values of 0.15-0.30 ml/g/min. Metabolic suppression (ICMRgl < 50% of control) was present in a volume of only 60 mm³ and corresponded to the most ischemic cortical zone (CBF < 0.15 ml/g/min). The ratio image revealed marked uncoupling (ratio values > 100% + 4xSD) in 152 mm³ of the ipsilateral hemisphere. Thus, CMR>CBF uncoupling, even at low CBF, is a prominent feature of this stroke model.

Reversibility of Hyperammonemic Encephalopathy

P.A. Hawkins, M.R. DeJoseph and R.A. Hawkins*. Department of Physiology and Biophysics, Finch University of Health Sciences / The Chicago Medical School, North Chicago, IL 60064.

Liver failure or shunting of blood past the liver leads to hyperammonemia and encephalopathy. Metabolic changes associated with this condition include decreased brain glucose consumption, increased neutral amino acid transport into the brain, and an abnormal amino acid spectrum in plasma and brain. The question is open whether these changes, especially those that occur in brain, are completely reversible after a sustained period of liver deficiency. We developed an animal model whereby portacaval shunting, which produces pronounced liver atrophy, could be reversed by restoration of blood flow to the liver. Three experimental groups were studied: 1) sham operated rats, 2) portacaval shunted rats and, 3) portacaval shunted rats with full blood flow restored to the liver for one week. Three weeks after the first operation (shunt or sham) we measured the plasma and brain amino acid spectrum, the liver-to-body weight ratio, brain glucose consumption, phenylalanine transport across the blood-brain barrier and the circadian rhythm of activity. Shunted animals showed the characteristic metabolic and kinetic abnormalities and a disruption of the normal circadian rhythm. Shunted rats that had restored normal liver blood flow regained the normal liver size, and were indistinguishable from the control group in every respect.

INCREASE IN CORTICAL INTERSTITIAL PURINE METABOLITES AND DECREASE IN CEREBRAL BLOOD FLOW FOLLOWING ASPHYXIA IN NEWBORN PIGS: IMPLICATIONS FOR SUPEROXIDE FREE RADICAL FORMATION. E.R. Gonzales, C.O. Park, A.R. Shah, R.G. Dacey*, T.S. Park, J.M. Gidday. Department of Neurological Surgery, Washington University School of Medicine, St. Louis, MO 63010

Previous studies showing increases in cortical SOD-inhibitable NBT reduction and increases in cortical lipid peroxidation products following asphyxia in piglets indicate that superoxide anion is generated in response to asphyxia. To test the hypothesis that superoxide free radical production may derive, in part, from xanthine oxidase activity, we implanted cortical microdialysis probes in isoflurane anesthetized newborn piglets (n=7) and measured purine metabolites at 20 min intervals over an 80 min post-asphyxial reventilation period. Cortical cerebral blood flow (CBF) and pial arteriolar diameter were measured concomitantly by laser doppler flowmetry and cranial window videomicroscopy, respectively. Significant increases in hypoxanthine, xanthine, and uric acid concentrations were measured throughout the 80 min reventilation period; peak increases of 167±49 % (p<.002), 61±13 % (p<.001) and 1906±377 % (p<.042), respectively, occurred at 40 min post-asphyxia. Significant reductions in CBF and arteriolar diameter occurred at 40-80 min post-asphyxia; peak reductions of 23±5 % (p<.001) and 39±13 % (p<.033), respectively, occurred at 80 min post-asphyxia. These findings are indicative of significant xanthine oxidase activity in piglet cortex, and suggest that purine degradation may contribute importantly to free radical formation following asphyxia, which may, in turn, play a role in post-asphyxial hypoperfusion and neuronal injury. (Supported by NIH RO1 NS21045).

EPIFLUORESCENCE VIDEOMICROSCOPY REVEALS INCREASED LEUKOCYTE ADHERENCE IN PIGLET PIAL VENULES DURING REPERFUSION FOLLOWING GLOBAL CEREBRAL ISCHEMIA. T.S. Park*, E.R. Gonzales, C.O. Park, A.R. Shah, J.M. Gidday. Department of Neurological Surgery, Washington University, St. Louis, MO 63010

We developed an *in vivo* model of cerebral ischemia-reperfusion wherein on-line videoimages of fluorescently-labelled leukocytes flowing within pial venules of anesthetized newborn pigs can be obtained. A closed plexiglass cranial window was implanted over the parietal cortex, and pial venules were imaged with an epifluorescence microscope (Olympus BHMJ) outfitted with a 100 watt mercury lamp, rhodamine filter cube (535/35 nm excitation; 565 dichroic; 610/75 nm emission), 10x immersion lens (Olympus; 0.4NA), and newvicon tube camera with gain/contrast enhancement capabilities (Hamamatsu C2400). Final image magnification captured to Super VHS videotape was 470x. Rhodamine 6G was administered as a 0.5 mg/kg i.v. loading dose and a 0.5 mg/kg/h i.v. maintenance dose in saline to selectively label circulating leukocytes. Under baseline conditions in 6 pigs, few labelled leukocytes were observed adhering to the endothelium of 75-150 µm diameter venules. However, following 10 min of global cerebral ischemia induced by reversible subclavian and brachiocephalic occlusion, a dramatic increase in rolling and adherent leukocytes was observed at 30, 60, and 90 min of reperfusion. At these times, cortical blood flow, measured by both laser doppler flowmetry and hydrogen clearance, was decreased by 25-40 % (p<.05). These findings demonstrate the feasibility of continuous *in vivo* monitoring of leukocyte adherence in cerebral venules, and suggest that reperfusion-induced adherence to venular endothelium may contribute to hypoperfusion following global cerebral ischemia. (NIH RO1 NS21045)

LEARNING AND MEMORY: PHARMACOLOGY—OTHERS II

721.1

NITRIC OXIDE FORMATION IS ESSENTIAL FOR ADAPTIVE MODIFICATION OF THE VESTIBULO-OCULAR REFLEX, A MODEL FOR NEUROPLASTIC CHANGES IN THE GOLDFISH. Jun Li¹, Sheryl S. Smith¹, and James G. McElligott². ¹Dept. of Anatomy, Inst. of Neuroscience, MCP-Hahnemann University, Phila., PA 19102; ²Dept. of Pharmacology, Temple University School of Medicine, Phila., PA 19140.

The gaseous second messenger nitric oxide (NO), implicated in neuroplasticity using *in vitro* models (Schuman and Madison, 1991), was tested for its role in adaptive modification of the vestibulo-ocular reflex (VOR) in the goldfish, an *in vivo* model for neuroplastic changes. Two potential mechanisms for NO release in the cerebellum, activation of climbing fiber afferents (Southam and Garthwaite, 1991) and activation of non-NMDA excitatory amino acid receptors (Garthwaite et al, 1989), also occur during adaptation of the VOR. This reflex functions to maintain a stable visual image on the retina during head movement. Adaptive increases in VOR gain were produced by sinusoidal rotation of the head in the horizontal plane 180° out-of-phase with a visual stimulus. NO synthase (NOS) was first localized to goldfish cerebellum, as identified by NADPH-diaphorase staining. For the VOR study, NO production was prevented by L-N^G-monomethyl-arginine (L-NMMA), a specific blocker of NOS, injected bilaterally (12.5µg/0.5µl/site) into the vestibulo-cerebellum. Treatment with L-NMMA, but not D-NMMA (the inactive isomer) significantly inhibited the robust adaptive gain increase (P<0.01) normally observed in vehicle-injected controls trained over a 3-hr period, but did not alter the basal, pre-adapted VOR gain. L-arginine, the substrate of NOS, injected concomitantly with L-NMMA, prevented the observed L-NMMA-induced inhibition of VOR adaptation. The inhibitory effect of L-NMMA application on VOR gain adaptation was not due to a vasoactive action as assessed by laser Doppler blood flow measurements. Thus, these results suggest a role for NO, within the cerebellum, in adaptive modification of the VOR, a learned response. (Supported by NIH#DC01094 to JGM and USAF Gr AFOSR#93-0136 to SSS.)

721.2

A selective neuronal nitric oxide synthase inhibitor has amnesic effects in the chick
C Hölscher* and SPR Rose

The Open University, Brain and Behaviour Group, Milton Keynes, MK7 6AA, U.K. (Sponsor: BRA)

Nitric oxide (NO) is a putative retrograde messenger that is supposed to play a role in synaptic plastic processes and in learning and memory formation. Previous studies show that inhibitors of NO synthases cause amnesic effects in chicks or rats. However, NO also is a blood vessel relaxing factor which is produced by endothelial cells. It is not certain if the amnesic effects might be the result of blood vessel constriction rather than inhibition of synaptic transmission.

7-nitro indazole (7-NI) is an NO synthase inhibitor that is selective for the neuronal isoform¹. We tested this inhibitor in a one-trial passive avoidance task in day-old chicks, in which the birds peck at and subsequently avoid a bitter tasting bead, displaying a typical disgust reaction. Chicks injected with 50mg/kg 7-NI i.p. 1 h before training and tested 30 min or 24 h after training showed amnesia for the training and the birds pecked the test bead (75% avoidance of test group compared to 30% of control group with received saline injections). Injection 5 min after training and testing 2 h after training did not produce amnesia.

This result supports the theory that NO acts as a neuronal transmitter which is of importance in processes of learning and memory formation.

MICRODIALYSIS WITH NITRIC OXIDE IN THE SEPTUM IMPROVES SOCIAL MEMORY OF RATS. T.Horn*, R.Landgraf and M.Engelmann. The Scripps Research Institute, La Jolla, CA, U.S.A., *Max Planck Institute for Psychiatry, Munich, Germany.

Nitric oxide (NO) synthase immunoreactivity in limbic areas of the rat brain including the septum implicates an involvement of NO in learning and memory. The present study tested whether NO in the septum of adult male adult rats is potent to modulate their juvenile recognition capacities. Animals which received artificial cerebrospinal fluid (aCSF) pre-gassed with a mixture of 5% NO in nitrogen via microdialysis into the septum showed a significantly improved juvenile recognition ability (p<0.01, ANOVA, n=13) compared to control sessions in which the same animal received aCSF pre-gassed with 100% nitrogen. To quantitate the applied amount of NO, chemiluminescence detection was used to analyze the *in-vitro* release from the microdialysis probes showing that approximately 40 pmol NO per min were released from the probes into the surrounding medium. Blockade of endogenous NO-synthesis by intraperitoneal administration of L-NAME (36mg/kg b.wt.), however, failed to affect juvenile recognition in another group of rats (n=13). These results indicate, that neuronal substrate of olfactory memory located in the septum is sensitive to NO. However, the fact that blockade of endogenous NO synthesis did not affect the behavioral performance of rats suggests that other mechanisms may substitute for endogenous NO. Supported by the DAAD.

721.4

INHIBITION OF NITRIC OXIDE SYNTHASE AND LONG-TERM HABITUATION TO NOVELTY IN THE NAPLES HIGH AND LOW-EXCITABILITY RAT LINES. M.P.Pellicano, F.Siciliano and A.G.Sadile, (SPON: European Brain and Behaviour Society). Lab. Neurophysiol. Behav. & Neural Networks, Dept. Human Physiol. "F. Bottazzi", SUN, Naples, Italy.

The role of nitric oxide (NO) as a neuromodulator in the CNS was assessed by a behavioral study in a genetic model of hippocampus-dependent trait by inhibition of the NO-synthase (NOS) enzyme. Adult male rats of the Naples High (NHE) and Low-Excitability (NLE) lines, and of random-bred controls (NRB) were tested for 10 min in a Lâ-maze during which two theta-related activity components such as walking and rearings, and an emotionality index such as defecation score were measured. Immediately upon completion of the test, they were given an intraperitoneal injection of the NOS inhibitor N^G-nitro-L-arginine (L-NOARG) 1-10 mg/Kg or vehicle. Retention testing took place 7 days later. The results indicate that in NRB-rats 10 mg/Kg impaired long-term habituation (LTH) of the vertical component with prevailing emotional meaning, whereas both 1 and 10 mg/Kg inhibited LTH of the defecation score, i.e. emotional habituation. Conversely, both doses exerted no effect on LTH of the horizontal component in the NLE, but had an impairing effect in the NHE. In addition, while 1 mg/Kg had no effect on LTH of the vertical component, 10 mg/Kg exerted a small improvement in both strains. The disruptive effect of L-NOARG on long-term habituation of the vertical component in random-bred rats supports the hypothesized role NO may play in the coupling of spatial and emotional information. In addition, the genotype-dependent differential effect of NOS inhibition in NLE and NHE lines, compared to NRB-rats, strengthens their usefulness as a genetic model for altered spatial and non spatial processing and storage in the mammalian brain. (Supported by CNR 93.00408.CT04, and MURST 40% grants).

721.5

CHRONIC ADMINISTRATION OF L-NAME IN DRINKING WATER ALTERS WORKING MEMORY IN RATS. E.L. Cobbs*, K.L. Ryan*, M.R. Esfai*, V. Guel-Gomez* and G.A. Mickleyle*. Radiofrequency Radiation Division, Armstrong Laboratory, Brooks AFB, TX, 78234; *Dept. of Biology, Trinity University, TX 78212. In order to examine the role of nitric oxide (NO) in the maintenance of working memory of rats, the effects of chronic administration (in drinking water) of the NO synthase inhibitor, N-nitro-L-arginine methyl ester (L-NAME), on this behavior was examined with a simple test of remembering recently explored objects. Unlike other working memory tasks that require a subject to perform for a reward such as food or water or to avoid shock, our task measured spontaneous exploration of novel and familiar objects and has been described as a "pure" working memory task (Ennaceur, 1988). Normal subjects spend significantly more time in contact with new environmental components and less time with familiar objects. A subject that extensively reexplores a stimulus with which it has previous experience is presumed to exhibit some memory loss associated with the object. Memory changes were evaluated by measuring the relative time subjects explored familiar vs. new stimulus objects. Rats (n=15) that chronically drank for 14 days, a dose of ≈ 100 mg/kg/day L-NAME, spent significantly less time exploring a novel object than rats (n=13) that drank only tap water ($p < .05$). This effect of L-NAME was significantly attenuated by concurrent administration of L-Arginine (≈ 5 g/kg/day). Total object exploration was not affected by our drug treatments, suggesting that our object discrimination task is not activity dependent. These data are consistent with the hypothesis that NO is required for some forms of working memory.

INVOLVEMENT OF CYCLIC AMP IN THE ACOUSTIC STARTLE RESPONSE AT THE LEVEL OF THE NUCLEUS RETICULARIS PONTIS CAUDALIS. T.C.M. de Lima & M. Davis*. Dept. of Pharmacology, Univ. Fed. Santa Catarina, Fpolis, SC, Brazil. *Dept. of Psychiatry, Yale Univ. Sch. Med., New Haven, CT. The acoustic startle reflex has a well-described neural circuitry in which the nucleus reticularis pontis caudalis (RPC) plays an essential role. Nevertheless, the pharmacology of this reflex is not fully known. Local infusion into the RPC of excitatory amino acid (EAA) antagonists suggests that glutamate may actually mediate startle at this level. EAA release at other synapses has been shown to be enhanced by increases of the second messenger cAMP. Previous studies have demonstrated the involvement of the amygdala in the modulation of the startle response, perhaps via a cAMP-dependent process at the RPC. As an initial test of this hypothesis, the present experiments evaluated whether a cAMP analog, 8-bromo-cAMP (8BR), or a phosphodiesterase inhibitor, Rolipram, would increase startle when infused directly into the RPC.

Rats implanted with cannulae in the RPC ($AP = -12.0$, $ML = \pm 1.5$, $DV = -9.6$, at an angle of 78°) were tested, one week after surgery, with 20 startle stimuli (115 dB bursts of noise, 50 msec duration, at a 30 sec interval) as a pre-drug baseline, and then infused successively with artificial cerebral spinal fluid (ACSF) and increasing doses of 8BR (0.125, 0.25, 0.5, 0.75 and 1.0 μ g). Immediately after each infusion they were retested with 40 startle stimuli. Other groups of animals were tested as above, but received repeated infusions either of ACSF alone or of 8BR (0.25 μ g). 8BR produced a dose-dependent increase in startle amplitude. Repeated infusions of vehicle or 0.25 μ g of 8BR did not reliably affect startle amplitude. Another group of animals infused with Rolipram 10 μ g/ μ l showed a marked increase in startle amplitude (108.1 %). These results suggest that the cAMP second messenger system can modulate startle amplitude at the level of the RPC. To characterize more precisely the involvement of cAMP in startle modulation, we are currently examining the effect of other compounds known to alter cAMP activity. EFFECTS OF APAMIN ON TIME-DEPENDENT CHANGES OF REGIONAL BRAIN METABOLISM DURING MEMORY PROCESSING IN MICE. W. Belcadi-Abbassi, B. Bontempi and C. Destrade*. Lab. des Neurosciences Comportementales URA CNRS 339, Univ. Bordeaux I, 33405 Talence France.

We previously showed that apamin, a blocker of calcium-activated potassium channels, facilitated memory processes when injected at non-convulsant doses, immediately after partial acquisition of a bar-pressing task in a Skinner-box (MESSIER et al, 1991, Brain Research, 551, 322-). Using the same learning paradigm we also analysed the post-test kinetics of regional mapping of 14C 2-Deoxyglucose (2-DG) uptake (SIF et al, 1991, Behav. Neural Biol. 56, 43-). The results showed a U-shaped curve of 2-DG labelling intensity in hippocampal and cortical areas as a function of the post-learning period (increase in labelling 15min and 3hr after training; decrease at the 1hr time interval).

In an attempt to characterise the effects of the post-training injection of apamin (APA) on the post-test kinetics of 2-DG uptake, APA (0.2 mg/Kg i.p.) or saline (SAL) was injected either before or at various time intervals (0min, 1hr, or 3hr) after training. 5min later, 2-DG was injected into the jugular vein. 40min later brains were processed for autoradiography. Quantitative densitometric comparisons of the autoradiographs of APA and SAL animals show that the post-training injection of APA, 1) significantly alters the 2-DG labelling patterns in the medial septum, hippocampal formation, subiculum, mammillary bodies, entorhinal, cingulate and pyriform cortices, which exhibit the highest density of central A₂ receptors, and 2) accelerates the temporal evolution of the 2-DG patterns. The diminution in 2-DG labelling which normally occurs at 1h 45min post-training in controls appears significantly earlier (45min) in APA treated animals. This phenomenon could be a consequence of an early APA-induced increase in neuronal activity which results in an acceleration of the brain mechanisms implicated in memory processing. REGULATION OF SPONTANEOUS ALTERNATION IN THE RAT BY GLUCOSE: A ROLE FOR GLYCOLYSIS. M.R. Stefani, M.E. Ragozzino, P.K. Thompson, K.Hellems, R.C. Lennartz and P.E. Gold*. Dept. of Psychology, University of Virginia, Charlottesville, VA 22903.

D-glucose administered peripherally has previously been shown to enhance memory on a variety of tasks and to attenuate the effects of certain memory-impairing drugs such as the opioid agonist morphine. The present studies show that morphine (3.95 nmols) injected centrally into the rat medial septum 30 minutes prior to behavioral testing produced memory deficits as measured in spontaneous alternation and inhibitory avoidance tasks. Glucose (18.3 nmols) administered concurrently with the morphine reversed the amnesic effects of morphine. To test whether the glucose effects were due to metabolites of glucose, pyruvate (18.3 nmols), the end product of the glycolytic metabolism of glucose, was injected intraseptally together with morphine. Pyruvate reversed the spontaneous alternation performance deficits induced by morphine administered alone. Furthermore, blockade of the glycolytic pathway with intraseptally administered iodoacetic acid (0.5 nmols), an inhibitor of glyceraldehyde-3-phosphate dehydrogenase, produced deficits in spontaneous alternation which were reversed by concurrent intraseptal injections of pyruvate (25 nmols), but not glucose (10 nmols). These results suggest that the memory-enhancing properties of D-glucose may be mediated by glucose metabolism. Glucose may act via the citric acid cycle to increase the availability of ATP and/or neurotransmitter precursors. [Supported by NSF (BNS 90-12239), NIA (AG07648) and ONR (N0001489-J-1216)]

EFFECTS OF ADENOSINE A₁ AND A₂ AGONISTS AND ANTAGONISTS ON CONFLICT LEARNING AND MEMORY IN THE MOUSE. M.E. Judge*. Pharmaceuticals Division, Novo Nordisk A/S, DK-2760 Måløv, DENMARK.

Adenosine is an inhibitory neuromodulator, exerting both activation-dependant and tonic effects on central neurotransmission, mediated in part by A₁ and A₂ receptors. Since drugs influencing these receptors have been shown to affect memory in several animal models, the effects of agonists and antagonists of these receptors were evaluated in a conflict memory test in mice. Thirsty mice were trained 30 min after an i.p. injection. They were given 5 min to drink for 5 sec. Side effects at high doses inhibited drinking, but not the next phase, delivery of mild shocks until drinking ceased. Memory was tested the next day. Anterograde amnesia was produced by treatment with the A₁/A₂ antagonist aminophylline, the A₂ antagonist DMPX, and the A₁ agonist R-PIA at doses below those suppressing responding during training. In contrast, the A₁ antagonist CPT and the A₂ agonist CGS 21680 only impaired memory at doses which also impaired responding during training. None of these compounds affected memory processes when injected after training or before testing. These results indicate that the formation of an associative memory can be impaired by either activation of A₁ receptors or blockade of A₂ receptors.

THE TYROSINE PHOSPHORYLATION OF A SET OF PROTEINS IN THE RAT GUSTATORY CORTEX, THAT IS MODULATED BY GUSTATORY EXPERIENCE, IS ALSO MODULATED BY *IN VIVO* ADMINISTRATION OF CARBAMYLCHOLINE. K. Rosenblum, S. Hazvi, D. E. Berman, C. Naor and Y. Dudai*. Weizmann Institute of Science, Rehovot, Israel.

We have previously reported that gustatory experience alters tyrosine phosphorylation in the rat insular cortex (Rosenblum et al., Soc. Neurosci. Abst. 18: 743, and *submitted*). Thus, conditioned taste aversion (CTA) training, and to a lesser extent exposure to a novel taste (saccharin or NaCl), increased tyrosine phosphorylation of several polypeptides, the major ones being of MW 100, 115 and 180kD. The effect was specific to the insular cortex, peaked within minutes and vanished within hours. The 100 and 180kD proteins are synaptic membrane glycoproteins. We have set out to identify neurotransmitters that mediate the effect *in vivo* and hence might molecularly encode sensory input in the cortex. Toward that end, we have microinjected transmitter agonists and antagonists into the insular cortex and quantified their effect on tyrosine phosphorylation by immunoblotting the cortical tissue with anti-phosphotyrosine antibodies. We found that carbamylcholine increased tyrosine phosphorylation of the same proteins that were affected by the gustatory experience. The effect was dose dependent at the range of 1-100 mM carbamylcholine and time dependent, peaking at ca. 1 hr. Choline chloride had no effect, while atropine abolished the effect of carbamylcholine. In parallel experiments we found that injection of scopolamine into the insular cortex prior to the exposure to saccharin in CTA training blocked CTA memory, thus corroborating the role of acetylcholine in mediating sensory input to the cortex in CTA training. (Supported by the Whitehall Foundation.)

MICE RECEIVING CHRONIC TREATMENT WITH ERYTHROPOIETIN SHOW INCREASED HEMATOCRIT AND IMPROVED PERFORMANCE IN A SWIM MAZE. J. Hengemihle, O. Abugo, J. Rifkind, E. Spangler, D. Danon, and D. Ingram*, Lab. of Cellular and Molecular Biology, Gerontol. Res. Ctr., Natl. Inst. Aging, NIH, Baltimore, MD 21224

Erythropoietin is a glycoprotein produced endogenously in the kidney, which stimulates red blood cell production. We evaluated the effects of chronic treatment with recombinant human erythropoietin (EpoGen®:Epo) on the performance of 8-mo old male C57BL/6J mice in a complex spatial task, the Morris water maze. Mice were treated with either Epo (1.5 units injected s.c. every other day) or vehicle (PBS also injected s.c. every other day). Results indicated that the treatment had no effect on maze performance after 9 wks, but after 20 wks the Epo-treated mice learned the task significantly faster than controls over 4 days of training as measured by mean distance (cm) to reach the goal platform. The results suggested that the improved performance in mice resulted from an increase in hematocrit which was not achieved until after 20 weeks of Epo treatment. Evaluation of several hematological parameters indicated that the only significant effect of Epo treatment was to raise hematocrit values at 20 wks. This rise was found to be significantly correlated with swim maze performance.

721.13

ETHANOL IMPAIRS PLACE LEARNING BUT NOT RESPONSE LEARNING IN THE RAT. W.T. Kendrick, J.L. Vandergriff, D.B. Matthews, P.J. Best, and P.E. Simson*. Lab. of Neuropsychopharmacology, Dept. of Psychology, Miami University, Oxford, OH 45056.

Ethanol blocks long-term potentiation *in vitro* (Sinclair and Lo, 1986) and inhibits NMDA-evoked activity of hippocampal neurons both *in vitro* (Lovinger *et al.*, 1989) and *in vivo* (Simson *et al.*, 1993). In behavioral studies, acutely administered ethanol impairs the use of spatial memory (Matthews *et al.*, RSA Meeting, 1994), and chronically administered ethanol impairs learning of a spatial task (Arendt *et al.*, 1988) that has been shown to be sensitive to hippocampal damage (Olton and Papas, 1979). More recently, Matthews *et al.* (RSA Meeting, 1994) report that ethanol, but not diazepam or MK-801, markedly alters the spatial properties of hippocampal neurons recorded electrophysiologically in awake behaving rats. In contrast to these results, however, Devenport *et al.* (1989) conclude that ethanol is virtually without influence on spatial localization.

In the present study, we investigated the effect of ethanol on spatial and non-spatial tasks that Matthews and Best (1993) demonstrated to be differentially sensitive to fimbria/fornix lesions. Results show that animals injected with ethanol prior to each training session learned significantly slower than saline-injected animals on the spatial task ($p < .01$). In contrast, ethanol-injected and control animals performed similarly on the non-spatial task ($p > .1$). These results suggest that ethanol produces an impairment in spatial learning similar to that produced by fimbria/fornix lesions.

721.15

HIPPOCAMPUS: POSSIBLE SITE OF AMELIORATION OF EYEBLINK CLASSICAL CONDITIONING BY NEFIRACETAM D.S. Woodruff-Pak* & Y.-T. Li. Lab. of Cognitive Neuroscience, Phila. Geriatric Cntr, Phila., PA & Temple Univ., Phila., PA 19122.

We demonstrated that Nefiracetam (NEF) ameliorates eyeblink classical conditioning (EBCC) in older rabbits in the 750 msec delay paradigm. The present study is an attempt to identify the brain site of action. If NEF affects EBCC via the hippocampus, injection of NEF in rabbits with intact hippocampus should ameliorate EBCC whereas injection in hippocampectomized rabbits should not. Five groups of older rabbits were run in 750 msec delay EBCC: 1) hippocamp-ectomy, 10 mg/kg NEF (N=8); 2) partial cortical removal, 10 mg/kg NEF (N=9); 3) sham surgery, 10 mg/kg NEF (N=9); 4) no surgery, 10 mg/kg NEF (N=8); 5) no surgery, vehicle (N=8). Among groups treated with NEF, trials to learning criterion (T/C) was significantly greater in hippocampectomized rabbits (1,038) than in rabbits with intact hippocampus (cortical = 738; sham surgery = 445; no surgery = 473). Rabbits with vehicle had significantly more T/C than those with NEF (845 vs. 445 and 473). Analyses of percentage of conditioned responses supported the results with T/C. Hippocampectomized rabbits with NEF learned more slowly than cortical surgery and controls with intact hippocampus. NEF may act to ameliorate EBCC in older rabbits via the hippocampus. EFFECT OF AIT-082 ON ETHANOL-INDUCED AMNESIA AND BEHAVIOR. R.F. Ritzmann*, J. Priscaru, C.L. Melchior, F. DeLeon-Jones and A.J. Glasky. Olive View UCLA Medical Center, Sylmar, CA 91342 and Advanced ImmunoTherapeutics, Tustin, CA 92680

AIT-082, a derivative of the purine hypoxanthine, has been shown to improve memory in the win-shift test of working memory. This test consists of placing a mouse in a T-maze with a reward in both goal boxes; the mouse is allowed to choose one of the goal boxes. On the next trial, if the mouse remembers which box it entered on the previous trial, it will enter the other box. By increasing the delay between trials, the length of time a mouse can remember can be determined. In C57BL/6 mice, the longest delay that these mice can remember is 120 seconds. Mice receiving AIT-082 (30 mg/kg) were able to remember at delays over 180 seconds. Ethanol (0.5 mg/kg), 10 minutes prior to testing, at 120 second delay, reduced the correct responses to 65%, without altering the time to leave the start box or the time to traverse the maze, indicating that ability to perform was not impaired. AIT-082, given 20 minutes prior to ethanol, blocked the amnesic effect of ethanol.

A behavioral analysis of the effects of AIT-082 was performed at doses from 0.005-60 mg/kg. The tests included: locomotor activity, exploratory activity, plus maze test of anxiety, hot plate analgesia and roto-rod test of motor coordination. The only significant effects of AIT-082 were improved performance on the roto-rod test at doses from 0.05 to 60 mg/kg and a decrease in locomotor activity only at the highest dose (60 mg/kg). The decrease in locomotor activity along with the lack of any effect on exploratory activity may be an increase in the rate of habituation, which would be consistent with the effects of AIT-082 on memory in other tests. Supported by grants from NIAAA and NIA (AG09911)

721.14

ACUTE ETHANOL IMPAIRS SPATIAL MEMORY BUT NOT NON-SPATIAL MEMORY IN RATS: COMPARISONS WITH DIAZEPAM AND MK-801. P.J. Best*, D.B. Matthews, J.L. Vandergriff, W.T. Kendrick & P.E. Simson. Cognitive Neurosci. Lab. Dept. Psych. Miami Univ. Oxford, OH 45056.

Ethanol blocks LTP in hippocampal slices (Sinclair & Lo, 1986) and inhibits NMDA-evoked activity of hippocampal neurons *in vivo* (Simson *et al.*, 1993). Chronic ethanol also impairs learning a spatial task (Arendt *et al.*, 1988) that has been shown to be sensitive to hippocampal damage (Olton & Papas, 1979). In addition, Matthews *et al.* (see accompanying abstract) report that ethanol alters the spatial properties of hippocampal neurons.

We investigated the effects of acute ethanol on two tasks requiring spatial memory and one requiring non-spatial memory. Ethanol significantly reduced the ability to use spatial memory but not non-spatial memory. Also, MK-801 (only at doses that produce ataxia) but not diazepam impaired spatial memory. Neither drug affected non-spatial memory.

Therefore, ethanol's contribution to auto accidents, may not be limited to impairment of judgment and reflexes but may include diminished cognitive capacities necessary for the use of spatial memory.

721.16

BENEFICIAL EFFECTS OF PRE-084, A SELECTIVE σ LIGAND, ON PHARMACOLOGICAL MODELS OF LEARNING IMPAIRMENT IN MICE. T. Maurice¹, T.-P. Su², D.W. Parish³ and A. Privat¹.

¹ INSERM U 336, ENSCM, 8 rue de l'Ecole Normale, 34053 Montpellier cedex 1, France; ² NIDA-Addiction Research Center, NIH, POB 5180, Baltimore, MD 21224; ³ Bio-CAD Corporation, 545 Oakmead Parkway, Sunnyvale, CA 94086.

We investigated the effects of PRE-084, a selective sigma ligand derived from phencyclidine, on several pharmacological models of learning impairments in young adult mice. Tests included spontaneous alternation in a Y-maze, for immediate spatial working memory, and the step-down type passive avoidance, elevated (+)-maze, and place learning in a water maze, for long-term memory. (1) PRE-084, at doses about 1 mg/kg sc, significantly attenuated the impairment of alternation, decrease in step-down latency, and increase in transfer latency induced by MK-801 (0.2 mg/kg ip). These effects were antagonized by the simultaneous administration of BMY-14802 (10 mg/kg ip), and suppressed in mice chronically treated with haloperidol (4 mg/kg/day sc for 7 days). (2) At the same dose range, PRE-084 significantly attenuated the impairments induced by mecamylamine (10 mg/kg ip), but not by scopolamine (1 mg/kg ip). (3) PRE-084, at 0.3 - 1 mg/kg, also prevented the impairment of alternation, decrease in step-down latency, and impairment of place learning induced by the calcium antagonist nimodipine (0.3 mg/kg ip). These results confirm previous studies showing that sigma ligands may modulate the learning processes, mediated via the NMDA receptor or the nicotinic cholinergic activation, and the resulting calcium mobilization. Thus, PRE-084, by acting selectively at sigma sites, may be useful in improving the cognitive impairments due to aging or Alzheimer's disease.

THE NOVEL COGNITION ENHANCING AGENT S 12024-2 FACILITATES OBJECT AND SOCIAL RECOGNITION MEMORY AFTER ACUTE OR CHRONIC TREATMENT IN RATS. W. Raaijmakers, J. Prickaerts, A. Schoffeleers¹, and J. Jolles, Dept. of Psychiatry and Neuropsychology, Univ. of Limburg, Maastricht, NL-6200 MD, and ¹Dept of Pharmacol., Univ. of Amsterdam, The Netherlands.

Preliminary experiments suggested that S 12024-2, a novel compound [Servier], might enhance memory. We used two different tests to establish whether S 12024-2 facilitates recognition memory. Twenty adult male Wistar rats were tested in the object exploration test [Ennaceur & Delacour, *Behav Brain Res*, 1988]. In the first trial (3 min) exploration times were scored for two identical objects. After 24 h the rats did no longer discriminate between an identical, familiar object and a novel object. When they had received S 12024-2 (3.4 mg/kg ip) immediately after the first trial, they discriminated between the two objects indicating that the treatment had facilitated recognition memory. This effect of S 12024-2 was replicated. Subsequently, two groups were formed that received either distilled water (n=8) or a solution of S 12024-2 (16 mg/kg/day; n=12) to drink. After 10 days the S 12024-2-treated, but not the control, rats showed significant recognition of the familiar object. This effect was replicated after 17 days of treatment.

Another group of 20 rats was used for the social memory test [Dantzer et al., *Psychopharmacol.*, 1987]. A similar design was used: all animals were tested after post-training ip injection of saline or 3.4 mg/kg S 12024-2. After 24 hours a decrease in exploration of a juvenile rat was found only when treated with S 12024-2. This effect was replicated. In the chronic treatment condition S 12024-2 facilitated social recognition after 6, 10 and 12 days of treatment. From these results it can be firmly concluded that S 12024-2 is effective as a cognition enhancing agent with respect to recognition memory.

WHY DOESN'T DRUG DISCRIMINATION TRAINING LOWER THE DOSAGE AT WHICH DRUG STATES CONTROL RESPONSE OCCURRENCE. D.A. Overton*, G.D. Stanwood, S.R. Pragada, B. Patel, N.M. Bormann and H. Chai, Psychiatry Dept., Temple Medical School, Philadelphia, PA 19140.

Two studies were conducted to determine the lowest dosage of phenobarbital that could (1) maintain discriminative control in a drug discrimination (DD) task, and (2) produce appreciable state dependent learning (SDL). Both studies progressed through successive cycles of training in a 2-lever operant task with a different dosage used in each cycle. Both used Long Evans male rats and injection of phenobarbital (D) or saline (N). The SDL study used the following procedure: (1) Train for 5 sessions while D (or N) to press lever 1; (2) Give one D and one N test session (either lever reinforced); (3) Train for 5 sessions to lever 2 while N (or D); (4) Give two D and two N test sessions; (5) Untrain the rats by reinforcing responses on the drug-inappropriate lever. SDL was noted after D->N transitions with doses as low as 3 mg/kg. The DD study used conventional D vs N training with FR10 vs extinction schedules of reinforcement on the correct and incorrect levers. Dosage during successive cycles of 18 sessions was selected by a dosage titration paradigm to determine the lowest dosage that could support above-criterion discriminative control. The threshold regularly-discriminated dosage was 3 mg/kg and extrapolation from the accuracy vs. dosage plots indicated an absolute threshold dosage of about 2 mg/kg. Hence SDL generalization failures occur with dosages almost as low as the lowest dosage that can be discriminated after prolonged DD training. The results suggest that "drug cues" may not be processed via mechanisms that allow the rats to "pay attention" to drug effects.

721.18

ACUTE ADMINISTRATION OF ESTRADIOL ENHANCES SPATIAL MEMORY IN INTACT MALE RATS. G.M. Alexander, M.G. Packard, W.L. Nores, & R.D. Olson* Dept. Psychology, Univ. New Orleans, N.O., LA 70148.

We examined the effects of acute post-training injections of Estradiol-Hydroxypropyl-B-Cyclodextrin Inclusion Complex on memory of intact male rats trained in a single-platform spatial water maze task. Unlike traditional forms of sex hormone administration, injection of estradiol inclusion complex results in a rapid rise of hormone in blood plasma, similar to that induced by normal hormone release.

Rats received a single 8 trial (30 second inter-trial-interval) training session with a submerged escape platform located in the same quadrant of the maze on all trials. Following trial 8, rats received a post-training subcutaneous injection of estradiol (0.25, 0.5, or 0.75 mg/kg) or saline. On a retention test session 24 hours later, latency to mount the escape platform was used as a measure of memory. The retention test escape latencies of the animals given 0.75 mg/kg of estradiol were significantly lower than those of saline treated rats, indicating an enhancement of spatial memory. Estradiol at doses of 0.25 and 0.5 mg/kg had no effect on retention test latencies. The findings indicate that acute post-training administration of estradiol can enhance spatial memory in male rats.

CIRCADIAN CLOCK REGULATES ROD AND CONE INPUT TO GOLDFISH CONE HORIZONTAL CELLS. S.C. Mangel* and Y. Wang, Dept. of Ophthalmology, University of Alabama School of Medicine, Birmingham, AL.

To determine whether a circadian clock regulates the effects of dark adaptation in the retina, goldfish L-type cone horizontal cells (HCs) were studied. Fish were maintained in constant darkness. Surgery was performed under dim red or infrared light. Retinas were superfused in darkness for 90 min ("prolonged darkness"), following which a HC was impaled without the aid of any light flashes. Following prolonged darkness during subjective day, light responses were fast and response amplitudes averaged 17 mV to the brightest stimuli. Spectral sensitivity was similar to that of red (625 nm) cones. During subjective night, light responses were very slow, response amplitudes averaged 5 mV to the brightest stimuli and response duration was 5-6 times longer than stimulus duration. Spectral sensitivity was similar to that of rod HCs. Reversing the light-dark cycle for 10 days reversed the rhythm of dark adaptation. These results indicate that a circadian clock regulates HC light responses such that following dark adaptation, red cone input predominates during the subjective day and rod input predominates during the subjective night.

722.2

LIGHTING CONDITION AS AN ENVIRONMENTAL VARIABLE AFFECTING ETHANOL SELF-SELECTION IN LABORATORY RATS. F. L. W. Goodwin and Z. Amit* Ctr. Stud. Behav. Neurobiology, Concordia Univ., Montreal, Quebec, Canada H3G 1M8.

Wistar rats were exposed to two lighting conditions, constant light or a standard 12/12 hr light/dark cycle. The animals were acclimated to lighting conditions for 2 wks prior to ethanol (EtOH) acquisition with water and food available ad lib. EtOH was presented in increasing concentrations from 2% (v/v; 95% EtOH with water) to 10% on alternate days in free choice with water. Immediately following the acquisition phase, a maintenance period was initiated which began with everyday presentations of 10% EtOH solution in free choice with water. After 10 days maintenance, lighting conditions were switched such that rats in constant light were exposed to 12/12 light/dark cycle and vice versa. EtOH and water intake were recorded for an additional 10 days. Rats exposed to constant light conditions during EtOH acquisition and maintenance consumed significantly less EtOH during the maintenance period than rats exposed to normal lighting conditions. There were no differences between the two groups in water consumption reflecting some specificity for EtOH intake. When lighting conditions were switched, rats previously exposed to constant light increased their water consumption. In addition, EtOH intake between the two groups was no longer different. Although fluid consumption patterns differed among the groups, both demonstrated undifferentiated weight gain throughout. The present study showed that the environmental variable of lighting can exert a selective influence on EtOH self-selection in rats.

722.3

THE HAMSTER POSTERIOR LIMITANS NUCLEUS (PLI) RECEIVES AFFERENTS FROM RETINA AND INTERGENICULATE LEAFLET (IGL). J. Blanchard* and L.P. Morin. Dept. Psychiatry, Stony Brook Univ., NY 11794.

Hamster NPY- or ENK-IR neurons in the IGL project to the suprachiasmatic nucleus (SCN) by a geniculohypothalamic tract (GHT). Cells also project to the contralateral IGL, but few contain NPY- or ENK-IR. A third major IGL-efferent path is now identifiable.

NPY- and ENK-IR fibers extend dorsally from the IGL into the superior thalamic radiation. A thin, vertically oriented terminal field is evident in the PLI along the lateral border of the anterior pretectal nucleus, extending ventrally and laterally along the medial geniculate nucleus. Retrograde studies (cholera toxin β -IR) show IGL cells projecting to the dorsal thalamic and pretectal nuclei. Anterograde transport of Phaseolus vulgaris leuco-agglutinin reveals a strong ipsi- and a weaker contralateral, projection to the PLI from the IGL. Anterograde transport of cholera toxin from the eye indicates that the dense NPY-/ENK-IR plexus in the PLI also receives retinal input. The results suggest that the circadian system communicates with an area integrating visual, acoustic and somesthetic stimuli.

PHASE SHIFTS TO LIGHT AT CT18 ARE INCREASED BY PRETREATMENT WITH ANTISERUM TO NEUROPEPTIDE Y. S.M. Biello, N. Mrosovsky and M. Ralph*. Depts. of Zoology and Psychology, University of Toronto, Toronto, Ont., Canada M5S 2L8

Previous work has indicated that antiserum to neuropeptide Y (aNPY) blocks phase shifts to certain non photic stimuli at CT 4. To insure this effect was specific to non photic phase shifts, and not a general interference with the ability of the clock to phase shift, we administered aNPY just prior to a light pulse at CT 18. Hamsters housed in constant darkness (DD) were implanted with a guide cannula aimed at the suprachiasmatic nucleus. Animals were injected with 200nl of aNPY or 200nl of normal serum (NS) at CT 18 under a dim red safe light. They were then either exposed to light (approximately 200 lux) for 15 minutes or returned to DD. Hamsters shifted significantly more to the light pulse when pretreated with aNPY (mean NS + light = 1.18 minutes; mean aNPY + light = 1.92 minutes; $p < 0.01$ on both two-tailed paired t test and Wilcoxon test). Therefore, antiserum to NPY did not block photic advances and in fact potentiated them. This indicates that the low levels of NPY found in the SCN at this time may be involved in photic phase shifting.

722.7

EFFECTS OF PROTEIN SYNTHESIS INHIBITION ON PRESUMPTIVE OSCILLATOR PROTEINS AND CIRCADIAN PHASE OF THE OCULAR CIRCADIAN PACEMAKER OF *BULLA GOULDIANA*. Michael H. Roberts* and Nancy A. Krucher. Dept. of Biology, Clarkson University, Potsdam, NY, 13699-5806

The eye of the marine snail, *Bulla gouldiana* contains a circadian pacemaker. In previous work we have proposed that members of two protein families, some of whom regulate the eukaryotic cell division cycle, are involved in circadian rhythm generation. Using Western blotting techniques we have identified a protein (p40) possibly related to the cell division kinase, p34cdc2, in the *B. gouldiana* eye. We have also identified a presumptive 66kDa homolog (p66) of the regulatory protein cyclin.

In the current work we have characterized the phase dependent effects of the protein synthesis inhibitor cycloheximide (CHX 10mM) on both the phase of the circadian rhythm and the levels of p40 and p66. CHX had no effect on the rhythm when given from CT 2-6, while phase delays appeared at CT 6-10 (1.6 ± 0.75 hrs) and increased gradually to 3.0 ± 1.17 hrs from CT 22-2. In preliminary studies, p40 levels are increased by CHX during the day and are decreased at night. In contrast, CHX increases p66 when given from CT 18-22 and decreases p66 at other phases. The effects of CHX on circadian phase as well as on the level of these proteins are consistent with our hypothesis that p40 and p66 may be involved in circadian rhythm generation.

EFFECTS OF LESIONS OF THE PARAVENTRICULAR NUCLEUS OF THE THALAMUS ON PHOTOPERIODIC PARAMETERS. C.C. Purvis*, M.J. Duncan. Dept. of Anatomy & Neurobiology, Univ. of Kentucky Med. Center, Lexington, KY 40536-0084.

This study of Siberian hamsters, investigated whether lesions of the paraventricular thalamic nucleus (PVT), which contains melatonin binding sites, affect pineal-dependent short photoperiod (SD)-induced responses: testicular regression, loss of body weight, winter molt, and torpor. Adult male hamsters received stereotaxic injections of ibotenic acid (LES, N=11) or saline (CON, N=10) into the anterior PVT. One week later, animals were transferred to SD (10L:14D); after 12 weeks, they were transferred to a cold room (7°C) and were observed daily for the display of torpor. After 60 days, the animals were perfused transcardially with fixative to histologically verify the location of the lesion. Although PVT lesions did not affect molting, they inhibited the expression of the other three photoperiodic responses. Testes weight (mg) was greater in the LES than in the CON hamsters (LES: 139 ± 43 vs CON: 42 ± 3 , $p < 0.05$); body weight (g) was also higher (LES: 42.1 ± 1.8 vs CON: 32.2 ± 1.9 , $p < 0.005$). A reduction was seen in the incidence of torpor (LES: 19.3 ± 2.6 vs CON: 43.3 ± 7.0 , $p < 0.005$). The results also showed that the incidence of torpor was correlated with body weight ($p < 0.001$). Current studies are further investigating the role of midline thalamic nuclei and body weight in the expression of photoperiodic responses.

INTRAVENTRICULAR APPLICATION OF C-FOS AND JUN B ANTISENSE-OLIGONUCLEOTIDES BLOCKS LIGHT-INDUCED PHASE SHIFTS OF THE MAMMALIAN CIRCADIAN SYSTEM F. Wollnik*¹, F. Gillardon², R. Bravo³, M. Zimmermann², W. Brysch⁴, K.H. Schlingensiepen⁴, T. Herdegen². ¹ University of Konstanz, Germany, ² University of Heidelberg, Germany, ³ Bristol-Myers Squibb Institute, Princeton, USA, ⁴ Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany

Light-induced phase shifts of the mammalian circadian system result in the expression of c-Jun, JunB, JunD, c-Fos, FosB and Krox-24 transcription factor gene proteins in the ventrolateral subdivision of the suprachiasmatic nucleus (SCN) lasting up to 8 hrs. In order to assess the role of these transcription factors in the control of the circadian system we blocked the expression of c-Fos and JunB proteins by intraventricular application of antisense phosphorothioate oligodeoxynucleotides (ASO; 4mM in 2 μ l).

While a light pulse (300 lux, 1 hr) at circadian time (CT) 15 induced a phase shift (-125 ± 15 min) of the circadian rhythm, application of ASO 6 hours before the light pulse blocked the phase shift (-10 ± 16 min). Application of nonsense (control)-ASO (NSO; 4mM in 2 μ l) did not prevent the effect of the light pulse, resulting in a phase shift (-127 ± 20 min) not significantly different from the one induced by light alone. These results demonstrate that transcription factors of the *jun* and *fos* gene families are an essential part of the cellular signal transduction pathway mediating light-induced phase shifts of the circadian pacemaker.

722.8

AFFERENT COMPONENTS IN THE PROTOCEREAL (pc) CIRCADIAN SYSTEM OF CRAYFISH. B. Barrera-Mera* and E. Barrera-Calva. Depto de Fisiología Fac. Medicina UNAM. A. Postal 70-250 México 04510 D.F.

The pc system of crayfish (Fig 1) has been studied in isolated preparations "in vivo". Under these conditions a robust circadian (c) rhythm of sustaining response neurons (s), retina (r) and distal (d) retinal shielding pigments (RSP) show its endogenous character. While this activity can occur spontaneously, presumably, in the normal animal, the pc c pacemaker (pm) is modulated by interneurone input from the rest of the nervous system, as shown by the variety of elements in the optic tract. In the pc c system we found that only the c response of r, s and the jittery fibers remain unchanged. They apparently are the afferent input of both left and right pc c pm, which are expressed throughout the synchronous release of neurohemal neurosecretions as light-adapting hormone (LAH) from the sinus gland (sg).

LYMNAEA STAGNALIS LACKS CIRCADIAN PERIODICITY IN THE SPONTANEOUS ACTIVITY OF ITS OPTIC NERVE. P.M. Casey and T.J. Mueller*. Department of Biology, Harvey Mudd College, Claremont, CA 91711.

The circadian clock of the gastropods *Aplysia* (Jacklett, 1969), *Bulla* (Block & Wallace, 1982), *Bursatella* (Block & Robert, 1981), and *Navanax* (Eskin & Harcombe, 1977) has been found to be located in the eye. Recordings made in complete darkness from each of these organisms' optic nerves showed a marked increase in the rate of spontaneous firing during their preferred activity period.

Like these other gastropods, the freshwater snail *Lymnaea* displays a locomotive circadian rhythm (Tobin & Mueller, SNS 1993). However, recordings made from its optic nerve with a suction electrode showed no evidence of circadian periodicity in over twenty individuals tested.

This is an unusual finding since it differs from the classic *Aplysia* circadian model. However, there is evidence from *Aplysia* (Lickey & Wozniak, 1979) which indicates the presence of secondary circadian clocks outside of the eye. Since *Lymnaea*'s visual system appears to behave differently from *Aplysia* and *Bulla*, and its circadian behavior is weaker, it is possible that *Lymnaea*'s circadian system may be based on the use of these other clocks.

722.10

CHANGES ON THE CIRCADIAN LOCOMOTOR ACTIVITY IN CRAYFISH PROCAMBARUS UPON RED LIGHT STIMULUS. V. Inclán-Rubio*, R. Valladares-Bejar and A. Merlín-Pérez. Departamento de Fisiología. Facultad de Medicina, UNAM. AP. 70250, CP. 04510, México, D.F. México. The crayfish *Procambarus* has a circadian rhythm in locomotor activity that shows a free running period (t) in darkness (23.4h) and lightness (26.2h) constant conditions, a shifting phase response to white light pulses and t modifications by photo-periodic changes. In other circadian rhythms, the application of red light promotes important changes in acrophase and amplitude. The present study pursues to know the effect evoked by red light (623 nm) on the locomotor activity. We used adult *Procambarus bouvieri*. Each crayfish was placed within an automatic monitor locomotor activity, and exposed to (LD:12:12) cycle, with white, red or white and red light illumination, during at least 24 days. The temperature was always the same (19°C). The results obtained by radiogram analysis of the animals activity show: 1) A clear 24h period in LD cycle. 2) An important reduction in total amplitude when red light is present in the photoperiod. 3) The red light effect disappears between the 4th or 5th day when the amplitude of locomotor activity increases again. 4) No difference in the acrophase value between white and red light stimulus was noted.

BIOLOGICAL RHYTHMS: MODELS

723.1

USE OF LED TECHNOLOGY IN PROVIDING CONTROLLED LIGHTING FOR ANIMAL RESEARCH. M. Drews, I-H. Tang, T. Tandon, and C.A. Fuller*. Section of Neurobiology, Physiology & Behavior, University of California, Davis, California 95616-8519.

The light environment is critical for animal research, including both basic husbandry and experimentation. In order to study how animals respond to different aspects of light, we utilized the characteristics of light emitting diodes (LED). The LED technology offers several advantages, including: 1) they are solid state devices, 2) they provide narrow spectral band output near their peak wavelength, 3) they are available in several discrete wavelengths, 4) they demonstrate negligible shift in spectral distribution at different intensities, 5) they have a high degree of stability and longevity, 6) they produce virtually no heat, 7) they are small and have minimal power requirements, and 8) their output intensity can be controlled linearly and dynamically. We have developed an autonomous computer based controller to provide variable profile light cycles, including: 1) rate of light intensity change, 2) range of minimal and maximal intensity, and 3) duration. The output intensity profile can be monitored in real time. We have examined the photic entrainment of hamsters in a simulated natural light-dark cycle using this device. This device can also be applied to study the photic entrainment thresholds of a defined spectrum. We have also studied the entrainment behavior of a small primate, the squirrel monkey, using the narrow spectral qualities of the LED light source. (Supported by NASA Grant NAG2-792.)

723.2

PHOTIC ENTRAINMENT BY SIMULATED NATURAL LIGHT-DARK CYCLES. I-H. Tang, D.M. Murakami*, C.A. Fuller. Section of Neurobiology, Physiology & Behavior, University of California, Davis, California 95616-8519.

This study compared the entrainment characteristics of simulated natural light-dark (LD) cycles and square wave LD cycles (14:10) in golden hamsters. The simulated natural LD cycle was composed of a 4 hr linearly ramped dawn-mimicking period, a 6 hr full light intensity day period and a 4 hr linearly ramped dusk-mimicking period. Animals were implanted with biotelemetry transmitters to record body temperature and activity at 10 min intervals via microcomputer. The phase angle at which animals entrained was determined by onset times of the animals' ambulatory activity. Animals under simulated natural LD cycles exhibited advanced phases relative to square wave LD cycles. An additional study was performed to examine the role of bilateral vs. unilateral vision on the entrainment responses. Animals that received unilateral optic nerve transection exhibited a further advance of activity onset. In all conditions, there was a stable phase angle between body temperature and ambulatory activity under simulated natural LD cycles, suggesting anticipatory behavior. Preliminary data also demonstrated that animals with a unilateral optic nerve transection showed different c-Fos expression compared to intact animals in response to identical night time light pulses.

723.3

A MONTE CARLO TECHNIQUE FOR CHARACTERIZING EPOCHS OF ELECTROCORTICAL ACTIVITY IN THE FETAL SHEEP. S.R. Robinson¹*, W. P. Smotherman¹, C. H. Wong¹, S. S. Robertson², and P. W. Nathanielsz³. ¹Laboratory of Perinatal Neuroethology, Dept. Psychology, Binghamton Univ., Binghamton, NY 13902; ²Dept. Human Development and Family Studies, Cornell Univ.; ³Laboratory of Pregnancy and Newborn Research, College of Veterinary Medicine, Cornell Univ., Ithaca NY 14853.

Electrocortical activity (ECOG) recorded from fetal sheep is a measure of sleep-wake state that differentiates into epochs of low voltage and high voltage late in gestation (term = 145 days). Five fetal sheep were surgically prepared at 113-114 days of gestation with an array of chronic instrumentation, including stainless steel electrodes overlying the dura of the parietal lobes to measure fetal electrocortical activity. ECOG signals were sampled at 32 Hz, amplified, full-wave rectified, averaged over 1-s intervals, and recorded continuously over days 121-133. Brief epochs of low- and high-voltage ECOG were distinguished on day 121, with durations that persisted significantly longer than predicted by Monte Carlo reordering of ECOG time series. Average ECOG voltage increased with age, and duration of low- and high-voltage ECOG epochs also increased, with the most rapid development evident about days 129-131. The developmental increase in duration appeared to be due to the selective elimination of brief (< 5-s) transitions in ECOG activity that interrupted epochs of longer duration. These results suggest an objective, quantitative strategy for characterizing epochs of low- and high-voltage electrocortical activity that may be relevant for understanding the prenatal ontogeny of behavioral states.

This research was supported by a subcontract with Cornell University to WPS and SRR under NIH Grant HD 28014.

723.4

EVIDENCE THAT MAMMALIAN CIRCADIAN RHYTHM IS COMPOSED OF ULTRADIAN SUBCYCLES: SIMILARITIES BETWEEN CALCIUM OSCILLATION IN SUPRACHIASMATIC NUCLEUS CELLS TO THE MAMMALIAN CIRCADIAN PACEMAKER. Shin Yamazaki¹*, Shin-Ichi T. Inouye² and Yoichiro Kuroda¹

¹Department of Molecular and Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, 2-6 Musashidai, Fuchu-shi, Tokyo 183, Japan; ²Laboratory of Integrative Brain Function, Mitsubishi Kasei Institute of Life Sciences, 11 Minami-Ooya, Machida-shi, Tokyo 194, Japan.

A central question in the elucidation of the mechanism of circadian rhythm generation in the suprachiasmatic nucleus (SCN) is whether individual cells have an intrinsic capacity to generate circadian rhythms or the rhythmicity requires the interaction of cells. Like cortical neurons in culture (Kuroda et al. Neurosci. Lett. 135, 255, 1992), dissociated cultures of rat SCN show spontaneous oscillations of intra-cellular Ca²⁺ with 5-8 second period (ultradian rhythm). Replacement of H₂O by deuterium oxide (D₂O) in the culture medium lengthened the period of this oscillation, while tetrodotoxin did not inhibit the deuterium oxide sensitive Ca²⁺ oscillation. Since these characteristics resemble those of the mammalian circadian pacemaker, the ultradian Ca²⁺ rhythm may be involved in the circadian rhythm or have a similar rhythm generation mechanism. The gap junction inhibitor, halothane, stopped this oscillation. Gap junctions may be necessary in order to generate rhythmic oscillations.

723.5

THETA EEG GENERATOR IN RAT NEOCORTICAL BRAIN SLICES. H. S. Lukatch* and M. B. MacIver. Dept. of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

The present study describes a novel neocortical EEG theta generator in rat brain slices. Theta EEG frequencies ($7.31 \pm .94$; $n=19$) were evoked and maintained *in vitro* by mimicking ascending cholinergic and GABAergic tone with carbachol (100 μ M) and bicuculline (10 μ M). Mapping studies revealed that this theta activity was limited to a strip of medial cortex running rostral caudally (partially overlapping cortical areas Oc2MM, RSA, Fr1, and Fr2). The presence of a theta generator intrinsic to cortical areas Oc2MM and RSA was confirmed by isolating mini-slices of these areas and inducing theta EEG activity in these mini-slices. Two electrode differential recordings were used to determine that theta generating cells were localized to layer 5. This theta activity was blocked by the muscarinic receptor antagonist atropine sulfate (0.5 μ M), similar to *in vivo* cholinergically driven theta. Preliminary loose patch single unit recordings revealed two cell types which exhibited different firing patterns in relation to the theta oscillations. One cell type fired only at the beginning of each theta burst and remained silent during the theta train. The other cell type was quiet at the beginning of each theta train, and attained its highest rate of discharge during periods of sustained theta activity. Supported by USAF OSR/SCEEE Graduate Fellowship.

PREDICTABILITY OF BIOLOGICAL RHYTHMS? K.-D. Kniffki*, C. Braun, A. Klusch and P. Tran-Gia*. Physiologisches Institut und Institut für Informatik, Universität Würzburg, Röntgenring 9 and am Hubland¹, D-97070 Würzburg.

Temporal fluctuations which cannot be explained as consequences of statistically independent random events are found in a variety of physical and biological systems. The fluctuations of these systems can be characterized by the power spectrum density $S(f)$ decaying as f^{-b} at low frequencies with an exponent $0.5 \leq b \leq 1.5$. We present a new approach to describe the individual biological rhythms of humans using data from a colleague who has kept daily records for four years of his state of general well-being applying a fifty-point magnitude category rating scale. This time series $\{R(t_i)\}$ was described as a point process by introducing discriminating rating levels r and s for the occurrence of $R(t_i) \geq r$ ('ups') and $R(t_i) \leq s$ ('downs'). $\{R(t_i)\}$ after introducing a certain r or s is described as $y(t) = \sum \delta(t - t_i)$, whereby $\delta(t - t_i)$ represents Dirac's delta function, and t_{ij} the time of a particular value $R(t_i) \geq r$ or $R(t_i) \leq s$. Applying counting statistics (Kniffki et al., Fractals 1:380, 1993) to evaluate $S(f)$ two scaling regions were found: first scaling region $1d \leq \Delta t \leq 15d$ for the 'ups' and 'downs' where $S(f) \propto f^{-b}$ with $b \approx 0.7$; second scaling region $\Delta t \geq 15d$ exhibiting an almost random behavior with $b \approx 0.0$.

We speculate that the basic mechanisms of the neuronal/humoral systems responsible for biological rhythms are expressions of a 'self-organized critical state' as introduced by Bak, Tang and Wiesenfeld (Phys. Rev. Lett. 59:381, 1987) for physical systems. Because of the first scaling region and based on one's own monitored biological rhythm it should be possible to predict future episodes ($\Delta t \leq 15d$) with a certain probability by using methods of nonlinear time series analysis or modified feed-forward neural networks learning with backpropagation algorithm.

NEONATAL ISOLATION ENHANCES LTP AND RESPONSES TO AMPHETAMINE CHALLENGE IN JUVENILE RATS. J. Hoffman, A. Arabshahi, R.J. Austin-LaFrance, J.D. Bronzino and P. Kehoe*. Neuroscience Program, Trinity College, Hartford, CT 06106.

Using a within-litter design, pups were isolated from mother and littermates for 1 hr. per day over PN days 2-9. At 30 days of age, the response of the dentate granule cell population to tetanization of the perforant pathway was examined in previously isolated and non-isolated littermates. Measures of population spike amplitude (PSA) and population EPSP slope obtained at several times following tetanization were used to assess the magnitude and duration of LTP obtained from each group. Preliminary results indicate that the degree of enhancement to both EPSP slope and PSA measures obtained from neonatally isolated animals was markedly greater than that of controls across the 24 hr. recording period. In a separate group of littermates, striatal dopamine response to amphetamine (7.5mg/kg) challenge was assessed on PN day 27 by *in vivo* microdialysis. In comparison to controls, previously isolated animals showed significantly higher dopamine levels over the first 1hr. following amphetamine administration. Behaviorally, these animals demonstrated a significantly enhanced amphetamine hyperactivity. In summary, neonatal isolation significantly enhances LTP and amphetamine-induced behavioral and dopaminergic responsivity. The results suggest that the impact of neonatal isolation on response properties of both the hippocampus and striatum endures into the juvenile period of development and can be revealed by both electrophysiological and pharmacological challenges administered well after cessation of the stress paradigm.

724.2

EFFECT OF CHRONIC STRESS AND ANTIDEPRESSANT TREATMENT ON PHOSPHORYLATION OF MICROTUBULE-ASSOCIATED PROTEIN IN RAT BRAIN

Y. Sasuga, T. Higuchi*, M. Asakura, S. Miyamoto, J. Imafuku, K. Osada, T. Tsukamoto, Y. Gamo and A. Aoba. Dept. of Neuropsychiatry, St. Marianna Univ. Sch. of Med., Kawasaki, 216 Japan

We examined the effect of long-term treatment with antidepressant drugs on the tubulin polymerization in rat cerebral cortex, and also compared effects of acute and chronic stress (single and variable) on tubulin assembly. The tubulin was prepared in buffer containing protein phosphatase inhibitors, calyculin A and sodium orthovanadate. The polymerization of microtubule was monitored in turbidity at 345 nm by a spectrophotometer. Treatment with desipramine, mianserin or citalopram for 7 days decreased the initial rate of tubulin assembly while a single injection of desipramine increased the rate. However, the tubulin preparation without phosphatase inhibitors nullified the inhibition of tubulin assembly following long-term desipramine treatment, suggesting that the inhibition of tubulin assembly is attributed to the phosphorylated microtubule-associated proteins (MAPs: MAP2 and/or tau factor). On the other hand, A single restraint stress increased the assembly rate, and the increase in the rate was recovered after chronic restraint stress for 7 days. In contrast, after chronic variable stress (cold-swimming, restraint, tail-pinch, shaking) for 7 days the increase in the rate was not recovered. It is thus proposed that the inhibition of tubulin assembly by the phosphorylation of MAPs may be an adaptive change to a novel stressor and this mechanism might be enhanced by long-term antidepressant treatment.

724.3

EFFECTS OF NEONATAL ISOLATION ON BEHAVIOR FOLLOWING AMPHETAMINE. C. Arons*¹, P. Kehoe² and W. Shoemaker¹. ¹Dept. of Psychiatry, UCONN Health Center, Farmington, CT 06030, ²Dept. of Psychology, Trinity College, Hartford, CT 06106.

As part of a study on the ontogeny of stress-induced behavioral sensitization we examined the proximal effects of neonatal isolation on locomotor activity and vocalizations following administration of amphetamine. One half of each litter was marked weighed and subjected to a daily one hour isolation from postnatal days (PND) 2-9. The other half of the litter was marked weighed and immediately returned to the nest and dam. Additional litters served as non-handled controls. Pups from these litters remained with their dams undisturbed through PND 9. On PND 10 all pups were tested. Pups from each group were randomly divided into one of three challenge groups, saline 0.5 mg/kg amphetamine (AMPH) and 2.0 mg/kg AMPH. Activity measures were recorded for a five minute period beginning 15 minutes after drug administration. Ultrasonic vocalizations were recorded during this time with a bat detector. Females that were isolated and received 0.5 mg/kg AMPH showed higher levels of activity than the two control groups, significantly so in the case of patterned movements. These effects of isolation were not apparent in females tested with saline or 2.0mg/kg AMPH. Males that were isolated and tested with 0.5 mg/kg AMPH showed an opposite trend, they had lower activity scores than control males. Both doses of AMPH reduced vocalizations compared to saline. Among saline animals there was a clear effect of handling on the pattern of vocalizations over the five minute test period. There was a slight but insignificant trend for isolated animals to vocalize less than non-isolates, particularly with 0.5 mg/kg AMPH. These results suggest that neonatal isolation alters behavior following the administration of a low dose of amphetamine, at least when pups are tested 24 hour after the final isolation period. In addition, females seem to be effected to a greater degree than males, with regards to activity measures.

Stimulation of macrophages reduces cholesterol levels in stressed and unstressed rats. F. X. Brennan*, M. Flesher, L. R. Watkins, & S. F. Maier. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Stress can increase levels of cholesterol in plasma. Cholesterol is cleared from plasma primarily by high affinity cell-surface receptors. However, there is a secondary mechanism involving macrophages, a phagocytic immune cell. Thus, the effect of macrophage stimulation was examined as a potential mechanism for attenuating stress-induced increases in cholesterol. Rats (12 per group) were exposed to three sessions of inescapable tailshock (100 1.6 mA shocks, one session per day for three successive days), or remained in their home cage. Half of each group were injected with zymosan (30 mg/kg, s.c.), a drug known to stimulate macrophage function *in vivo*. Animals received one zymosan injection for each of the three days prior to, as well as 15 min prior to each stress session. Control animals received vehicle injections. Results indicated that both stressed and control animals receiving zymosan had lower total plasma cholesterol levels than their saline-treated controls. Zymosan also blocked stress-induced decreases in spleen weight, and exacerbated stress-induced decreases in thymus weight. These data suggest that macrophage suppression is not the primary mechanism for stress-induced increases in cholesterol. However, stimulation of macrophages may prove to be a prophylactic manipulation in attenuating the cholesterol increases seen after stressor exposure. NIH-MH45045

STRAIN-SPECIFIC DEFICITS OF MORRIS WATER-MAZE PERFORMANCE: EFFECTS OF NEONATAL HANDLING. M.D. Zaharia¹, N. Shanks², M. J. Meaney³, and H. Anisman^{1*}.

¹Dept. of Psychology, Carleton Univ., Ottawa, Ontario, K1S 5B6, ²Clinical Immunopathology, Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA. 15213, ³Douglas Hosp. Res. Ctr., Montreal, Que.

BALB/cByJ mice are highly reactive to stressors relative to other strains (e.g., C57BL/6ByJ), exhibiting hyper-corticosterone secretion in response to stressors, as well as particularly marked brain catecholamine alterations. Behaviorally, BALB/cByJ mice exhibit a wide variety of behavioral disturbances after stressors that are more pronounced than in other strains. Interestingly, BALB/cByJ mice fail to acquire a spatial learning response in a Morris water-maze paradigm. In view of the particularly marked stress reactivity of the BALB/cByJ mouse, it was of interest to determine if the spatial learning deficit in this strain could be modified by neonatal stimulation, just as such a manipulation has been found to dampen stress responses in mature animals. We observed that the performance deficit, which is not evident when visual intramaze cues are present, is apparent as early as 30 days of age. Moreover, using a cross fostering paradigm it was determined that the deficits were not related to maternal factors. If pups were handled (i.e., separated from the Dam for brief periods over the course of the initial 21 days postpartum) the behavioral deficits were prevented. The data were related to central neurochemical and endocrine changes induced by stressors and the modification of such effects by neonatal handling.

724.7

BEHAVIORAL STRESS ENHANCES LTD IN RAT HIPPOCAMPUS. J. J. Kim¹, M. R. Foy² and R. F. Thompson¹.

¹Neurosciences Program, Univ. of Southern Calif., Los Angeles, CA 90089-2520 and ²Psychology Dept., Loyola Marymount Univ., Los Angeles, CA 90045-2669.

Uncontrollable and unpredictable stress is known to impair certain learning tasks, and also to impair hippocampal long-term potentiation (LTP). In the present study, we examined the effect of stress on another form of hippocampal synaptic plasticity, long-term depression (LTD). Hippocampal slices were prepared from adult Long-Evans male rats immediately following exposure to behavioral stress (60 tailshocks: 1 mA, 1-s, 30-90 s apart; animals immobilized). Field EPSP recordings (amplitude and slope) from dendrites in area CA1 following Schaffer/commissural stimulation (900 pulses at 1 Hz) indicate that LTD was significantly greater in stressed animals than that recorded from control animals. These results argue that an additional form of hippocampal plasticity can be modified by behavioral stress.

724.9

CHANGES IN BOMBESIN (BN) LEVELS AND ITS RECEPTORS IN THE RAT BRAIN FOLLOWING ACUTE IMMOBILIZATION STRESS. P. Kent^{1*}, Z. Merali^{1,2}, and H. Anisman², ¹Psychol & ²Pharmacol, Univ. of Ottawa, ³Carleton University, Ottawa, Ontario, Canada.

The neurochemical mechanisms underlying the coincident activation of the pituitary-adrenal axis and the sympathetic nervous system in response to stress remain unclear. Central injection of the neuropeptide bombesin (BN), potently releases epinephrine from the adrenal medulla and adrenocorticotrophic hormone (ACTH) from the pituitary, and elicits behaviors typically associated with increased emotionality and arousal. The objective of the current study was to determine whether stress is associated with changes in the endogenous levels of BN-like peptides and/or their receptors. Male Sprague-Dawley rats were subjected to acute immobilization stress for 0 (control), 30 min or 120 min. Plasma ACTH levels increased in response to stress, peaking at 30 min. BN-like immunoreactivity increased significantly at the hypothalamus and medulla, within 30 min, and declined to control levels by 120 min. The peptide levels in several other regions, including the hippocampus, striatum, midbrain, pituitary, and pons, failed to change significantly. Autoradiographic analysis of BN/GRP receptor densities for 8 regions examined are listed in ascending order: hippocampus, nucleus tractus solitarius (NTS), paraventricular (PVN), arcuate (Arc) and periventricular hypothalamic nuclei, paraventricular thalamic nucleus, central amygdala and nucleus accumbens. Significant increases in binding were found after 30 and 120 min of stress in the NTS, and after 120 min in the PVN and Arc. These data indicate that BN-like peptides may serve to mediate and/or integrate responses to stress.

724.6

SPECIFIC CHANGES IN AMPA RECEPTORS ASSOCIATED WITH BEHAVIORAL STRESS. S. Standley, J.J. Kim, G.I. Wong, M. Baudry*, and R. F. Thompson. Neurosciences Program, Univ. of Southern Calif., Los Angeles, CA 90089-2520.

Behavioral stress has effects on LTP and learning and memory. Autoradiographic studies of ligand binding to the AMPA/GluR receptor have also shown that the binding characteristics of the receptors are rapidly altered in the hippocampus and other brain structures following stress. While these studies reported a general increase in ³H-AMPA binding in stressed animals, the nature (B_{max}, or K_d), and type (high affinity or low affinity) of receptor change have not been reported in detail. To evaluate the nature of the changes in AMPA receptors, we performed equilibrium saturation kinetic studies with ³H-AMPA on synaptic fractions (P2) prepared from telencephalon obtained from both acutely stressed (60 tail shocks: 1 mA, 30-90 s interval) and control Long Evans rats. As previously reported, saturation kinetic data were better fitted to a two site than a one site model, indicating the existence of a small population of high affinity sites (K_d ≈ 20 nM) and a large number of low affinity sites (K_d ≈ 600 nM). Stressed animals exhibited a significant increase in the maximal number of low affinity binding sites without significant changes in high affinity sites. As the low affinity receptors have been postulated to be synaptic receptors, whereas the high affinity receptors are enriched in nonsynaptic subcellular fractions, the results suggest that stress might alter some steps involved in receptor insertion or internalization. The results might also account for the impairment of LTP associated with stress, inasmuch as LTP shares the same cellular mechanisms of expression via AMPA receptor regulation. Supported by grants from NRSA 1F32MN10521-01 BNR to JJK, NSF 91103787 to MB, and NSF BNS-8718300 & NIH (NIA) AG05142 to RFT.

RECURRENT BRAIN POLYAMINE RESPONSE AFTER REPEATED STRESS AND ITS ENHANCEMENT AFTER AN ADDITIONAL DELAYED STRESS EPISODE. V.H. Gilad* and G.M. Gilad. Faculty of Med., Technion-Israel Inst. of Technology., Haifa, Israel.

Rapid changes in brain polyamine (PA) metabolism, termed the PA response, are generally induced with a magnitude proportional to the stressor intensity. The effects of repeated stress episodes on the PA response are unknown. Therefore, we examined effects of repeated restraint, a relatively mild stressor, on ornithine decarboxylase (ODC) and S-adenosylmethionine decarboxylase (SAM-DC), two key PA synthesizing enzymes. Rats were subjected to 2 h restraint once daily for 5 days, and enzyme activities assayed in the hippocampus 6 h after the beginning of each stress episode. We found that ODC activity was increased repeatedly after each stress episode to about 130% of control. In contrast, SAM-DC activity was reduced after the first episode (86% of control), but remained unchanged thereafter. Additional stress application, 7 days after the last (5th) episode, resulted in a much larger ODC increase (180% of control), without a change in SAM-DC activity. We conclude that: 1) even mild stress can induce a characteristic PA response in the brain; 2) the ODC response is induced after each episode of stress, and 3) additional stress episode applied days after cessation of the initial stressful stimuli, results in a much greater increase in ODC activity. The study implicates an overactive PA response in the (mal)adaptive response to stressful events.

THE PROTECTIVE EFFECTS OF STRESS CONTROL MAY BE MEDIATED BY INCREASED BRAIN LEVELS OF BENZODIAZEPINE RECEPTOR AGONISTS.

R.C. Drugan*, A.S. Basile, J.H. Ha and R.J. Ferland. Department of Psychology, Brown University, Providence, RI 02912 and Laboratory of Neuroscience, NIDDK, NIH, Bethesda, MD 20862.

Control over stress protects against many of the deleterious effects of stress exposure, but the endogenous mediators responsible for these prophylactic effects have remained elusive. Using behavioral pharmacology, *in vitro* radioligand binding and neurochemical analyses, we demonstrate that exposure to escapable stress results in brain and behavior changes reminiscent of benzodiazepine administration. The stress control group shows significant protection against picrotoxinin-induced seizures, reductions in [35S] t-butylbicyclophosphorothionate binding at or near the chloride channel and a 3-fold increase of benzodiazepine-like agonists in brain compared to both yoked-inescapable shock and non-shock controls. These observations suggest that active coping behavior leads to the release of endogenous benzodiazepine-like agonists that protect the organism from stress pathology. ALCOHOL AVAILABILITY AND AGGRESSION LEVEL AFFECT BEHAVIOR IN THE OPEN FIELD AND PLUS MAZE, AND 5-HT RECEPTORS IN TRIAD-HOUSED RATS. L.A. Pohorecky*, X. Huang, S. Larson, C. Quinn, D. Benjamin. Center of Alcohol Studies, Rutgers University, Piscataway, NJ 08855.

Individually- and triad-housed male Long Evans rats were tested in the open field and elevated plus maze. Subjects were 18 triads and 14 single caged rats, half of which had a choice of drinking a 6% solution of ethanol (ET) or water. Dominance status was determined by monitoring behavior during the initial 30 minutes of colony formation. Initially, the number of attacks by the Alpha (α) on the Beta (β) and Gamma (γ) was observed daily to classify triads by aggression level. Body weight loss 1 day after group housing was similar for β and γ but minimal for α , and singles gained. Less weight gain was observed in high aggression (HT) than in middle aggression (MT) or low aggression triads (LT). Weight gain of α was not affected by aggression level. Only the β were affected by ET availability, with lower weight gain overall. Headpokes were affected by level of aggression; in LT headpokes were less frequent, and of shortest total duration, but in MT, α showed the lowest duration and frequency. In the LT, ET increased headpoke duration and frequency. In triads with ET available, α had significantly lower headpoke frequency. In the MT, ET decreased grooming, but had no effect in LT. In triads with ET available, the MT showed significantly less grooming than MT or LT. In the β , availability of ET increased center time significantly. The availability of ET produced anxiolytic effects in singly housed, but not in triad-housed rats. 5-HT_{2A} receptor binding was significantly affected by aggression level; whereas HT showed rank-related increases above control levels in β and γ , LT showed rank-related decreases in β and γ . Effects on 5-HT_{2C} binding were also observed. These results demonstrate that aggression levels vary between triads and interact with rank and ET to produce complex effects on 5-HT receptor binding and behavior (Supported by NIAAA 05306).

HORMONAL CONTROL OF REPRODUCTIVE BEHAVIOR: OTHER II

725.1

TEMPORAL REGULATION OF PREPROENKEPHALIN-A (PPE-A) mRNA EXPRESSION BY ESTROGEN IN THE POSTERIOR DORSAL MEDIAL AMYGDALA (MeApd) OF THE FEMALE RAT. C.B. Eckersell*, C.A. Priest and P.E. Micevych. Dept. Anatomy and Cell Biology, Laboratory of Neuroendocrinology, UCLA School of Medicine, Los Angeles, CA 90024.

Gonadal steroids modulate reproductive behavior through their effects on intercellular signaling in the limbic-hypothalamic neural circuit. Within this circuit, the up-regulation of PPE-A mRNA (encoding met-enkephalin) by estrogen, in the ventromedial nucleus of the hypothalamus, has been correlated with reproductive behavior in the female rat. The MeApd also is an integral part of the limbic-hypothalamic neural circuit that plays an important role in opioid regulation of female reproductive behavior. To examine the temporal effects of acute estrogen exposure on PPE-A mRNA levels in the MeApd, adult ovariectomized Long-Evans rats were injected with 50 μ g estradiol benzoate (EB), perfused at one of nine successive time points from 0 to 72 hours after injection and used for quantitative *in situ* hybridization histochemistry of PPE-A mRNA. PPE-A mRNA was localized to neurons within the MeApd using an ³⁵S-labelled, single-stranded, cRNA probe complementary to the entire coding sequence of the PPE-A mRNA (gift from Drs. Yoshikawa and Sabol, NIH, Bethesda, MD). EB treatment induced a biphasic increase in the number of PPE-A mRNA expressing cells in the MeApd with maximal levels occurring at 1 and 24 hours post treatment. These peaks were interrupted by a dramatic decrease in the number of PPE-A mRNA expressing cells at 4 hours after EB injection. By 72 hours post-EB, PPE-A expressing cell numbers returned to basal levels. The biphasic increase in PPE-A mRNA expressing cell numbers with acute estrogen treatment supports the idea that there are two temporal and perhaps mechanistic regulatory events for PPE-A transcription within the MeApd. PROGESTERONE DECREASES EXTRACELLULAR SEROTONIN IN THE VENTROMEDIAL HYPOTHALAMUS AND MIDBRAIN CENTRAL GREY IN ESTROGEN-PRIMED OVARECTOMIZED RATS. C.J. Farmer, T.R. Isakson and K.J. Renner*. Dept. Biomedical Sciences, Southwest Missouri State Univ., Springfield MO 65804.

Progesterone (P) effects on extracellular (EC) 5HT were monitored in the ventromedial hypothalamus (VMH), midbrain central grey (MCG) or medial preoptic area (mPOA) using microdialysis. Rats primed with estradiol benzoate (5 μ g) were anesthetized with chloral hydrate (400 mg/kg, i.p.). Samples were collected at 20 min intervals. Once a stable 5HT baseline was obtained, rats were injected (s.c.) with 0.5 mg P or vehicle (V). In the mPOA, EC 5HT levels were not affected by P. Significant decreases in EC 5HT levels were present in the MCG and VMH 40 and 60 min after P, respectively. In the VMH, EC 5HT decreased to $57 \pm 5.9\%$ of pretreatment values 100 min after P. 5HT levels in the MCG decreased to $56 \pm 5.1\%$ of pretreatment values 80 min after P. The decreases in EC 5HT in the VMH and MCG persisted during the remainder of the sampling period. 5HT baseline levels were stable in the respective V-treated groups. These results demonstrate that P-influenced decreases in 5HT release in the MCG and VMH occur *in vivo* and support previous studies which suggest that decreases in 5HT activity in the VMH and MCG contribute to the facilitation of female receptivity. (supported by IBN-9309451)

725.2

PROGESTERONE ENHANCES AN ESTRADIOL-INDUCED INCREASE OF FOS-IMMUNOREACTIVITY IN LOCALIZED REGIONS OF FEMALE RAT FOREBRAIN. A.P. Auger and J.D. Blaustein*. Neurosci. & Behav. Program, Univ. of Massachusetts, Amherst, MA 01003.

In female rats, the onset of reproductive behavior depends on the sequential presence of estradiol followed by progesterone. Although treatment with high doses of estradiol has been shown to increase immunostaining for the Fos protein, an immediate early gene product that is expressed upon cellular activation, another report conflicts with this finding. However, the previous reports agree that subsequent treatment with progesterone has no apparent effect on Fos expression. In order to resolve this discrepancy and investigate possible effects of progesterone, we used Fos-immunocytochemistry combined with computer-aided image analysis. In experiment one, we found that treatment with 5 μ g of estradiol increased Fos-immunoreactivity (Fos-IR) within the medial preoptic area and the dorsal medial hypothalamus. Subsequent treatment with 500 μ g of progesterone one hour before perfusion increased the intensity of the immunostaining within the medial preoptic area and the dorsal medial hypothalamus, although it had no significant effect on Fos-IR cell number. In experiment two, a lower concentration of Fos antiserum was used in order to diminish the immunostaining sensitivity to a level in which no increase of Fos-IR cell number was observed after treatment with estradiol. Under these immunocytochemical conditions, subsequent treatment with progesterone increased the number of Fos-IR cells in the medial preoptic area, the dorsal medial hypothalamus and the steroid receptor-rich area lateral to the ventromedial hypothalamus. Thus, treatment with behaviorally-effective doses of both estradiol and progesterone induces Fos expression in localized regions of female rat brain.

SUBCELLULAR LOCALIZATION AND KINETIC PROPERTIES OF AROMATASE IN THE RAT BRAIN. C.E. Roselli*. Department of Physiology, Oregon Health Sciences University, Portland, OR. 97201.

The conversion of testosterone (T) to estradiol is catalyzed by cytochrome P450 aromatase. *In situ* aromatization is required for the full expression of the effects of T in the brain. This study examined the subcellular distribution and reaction kinetics of aromatase in the adult rat brain. Preoptic area (POA), hypothalamus (HYP) and amygdala (AMYG) were homogenized in isotonic sucrose buffered with potassium phosphate. Homogenates were fractionated by a sequential series of centrifugations to obtain: 800 x g pellet (nuclei); 11,000 x g pellet (mitochondria and synaptosomes); 100,000 x g pellet (microsomes); and 100,000 x g supernatant (cytosol). Aromatase activity (AA) was measured using a previously validated ³H₂O assay. Marker enzymes were measured to identify organelles in the different subcellular fractions. We found that AA in all 3 tissues was enriched 8-14 fold in microsomes, but not in other cell subfractions. The addition of either a NADPH-generating system or 1 mM NADPH to the reaction mixture stimulated AA in all subfractions, whereas NADH was only minimally effective. Affinity constants were equivalent in all subfractions (~10 nM) suggesting that only one form of the enzyme is present in the rat brain. One week after castration, AA was significantly reduced in all cell subfractions of POA and in the homogenate and microsomes of HYP. Castration did not significantly alter AA in any subfraction of AMYG. To more critically evaluate its subcellular localization, AA was measured in purified synaptosomes. AA was not enriched in these preparations suggesting that aromatase is not substantially associated with nerve terminals in rat brain.

HYPOTHALAMIC δ OPIOID RECEPTORS IN MALE JAPANESE QUAIL (*Coturnix c. japonica*) P. Deviche⁽¹⁾, C.C. Gullledge⁽¹⁾, N. Thompson⁽²⁾, and M.A. Ottinger⁽²⁾. ⁽¹⁾Inst. Arctic Biology, Univ. Alaska Fairbanks, Fairbanks, AK 99775; ⁽²⁾Dept. Poult. Sci., Univ. Maryland, College Pk, MD 20742.

Central opioids regulate mammalian reproductive behavior and physiology, but little information on this is available for nonmammalian species. In Japanese quail (*Coturnix c. japonica*), administration of the preferential δ receptor agonist enkephalin (ENK) dose-relatedly decreases the *in vitro* hypothalamic release of gonadotropin-releasing hormone (GnRH), and hypothalamic regions of the avian brain (dark-eyed junco, *Junco hyemalis*; pigeon, *Columba livia*) contain δ receptors. The present study used quantitative *in vitro* autoradiography to measure specific pCI-DPDPE binding site densities in hypothalamic (paraventricular n.; medial preoptic area) and extrahypothalamic (medial and lateral septum; neostriatum) regions of sexually active and inactive young, middle-aged, and old male quail. High densities of δ opioid receptors were found in hypothalamic regions, suggesting a local action of endogenous opioid peptides. Receptor densities did not differ as a function of sexual activity level or age. These receptors are localized in areas important in GnRH regulation and are likely to be involved in ENK modulation of GnRH release. GALANIN - IS IT A REPRODUCTIVELY RELEVANT PEPTIDE IN THE TELEOST FISH, *HAPLOCHROMIS BURTONI*. T. Bushnik* and R.D. Femald. Department of Psychology, Stanford University, Stanford, CA.

Galanin, a 29 amino acid peptide present in both the gut and the brain, has been called a hypothalamic-hypophysiotropic hormone because it can effect the release of pituitary hormones such as growth hormone, prolactin, and gonadotropins. Galanin and its mRNA can be co-localized in gonadotropin releasing hormone (GnRH) cells in the hypothalamus/preoptic area (POA) although it is labile. We decided to investigate the role of galanin in regulating GnRH release in the teleost fish, *H. burtoni*. Males of this species exhibit size changes in the POA GnRH cell population that are correlated with changes in social status and reproductive maturity. These changes in cell size are plastic; that is, up-grading or down-grading the social status of an adult *H. burtoni* male results in a corresponding increase or decrease in the size of the GnRH cells in the POA. We addressed three questions: 1) is there galanin-like immunoreactivity (GAL-LI) present in the POA of *H. burtoni* males?, 2) do these GAL-LI cells project to the pituitary?, and 3) do these GAL-LI exhibit a correlation between cell size and social/reproductive status similar to that which has been reported for GnRH cells in the POA? *H. burtoni* males were observed behaviorally for 4 weeks to establish social status, then sacrificed, and crystals of fast DII were applied to the transected pituitary stalks of the paraformaldehyde fixed brains. After 35-38 days, the brains were sectioned on a vibratome and immunostained for galanin using a fluorescein label. It was observed that 1) GAL-LI cells were present in the POA of all males, 2) the majority of these GAL-LI cells did not contain fast DII suggesting that only a very small minority of these cells may project to the pituitary, and 3) the GAL-LI cells showed a tendency towards a correlation between social status and cell size with socially dominant males having larger GAL-LI cells although the size differential was small. AQUEOUS EXTRACT ACTION OF RUTA CHALEPENSIS ON SPERM MOTILITY. E. Gijón*, L. Cartas, M. Lorenzana-Jiménez and X. García. Dept. of Physiol. and Dept. of Pharmacol. Sch. Med. UNAM México D. F. 04510. México.

Muccitelli and Ferguson (1) point out flaws in the experimental design of a recent study by Kupitz and Atlas (2), where the experimental condition do not guarantee that the applied concentration of each compound was present at the membrane surface of the mature egg, and that a more likely target for the compounds is the sperm if any of the applied compounds interfered with sperm activation or motility. This prompted us to try aqueous extract of *Ruta chalepensis* on rat sperm motility, as it has been suggested that *Ruta chalepensis* extract has an anticonceptive action, and it is used in traditional medicine as vaginal wash before sexual intercourse. Exposing sperm recently obtained from rat testicle to *Ruta chalepensis* extract, we found under light microscope: a reduction in motility, decomposition of tail motility, until complete immobilization of spermatozoa without determining the involvement of ion channels. This *Ruta chalepensis* effect may play a role in its postulated anticonceptive action. 1. Science 263:98, 1994; 2. Science 261:484, 1993.

725.6

EVOLUTION OF THE GNRH FAMILY OF PEPTIDES INFERRED FROM CDNA SEQUENCES. R.C. Francis* and R.D. Femald. Department of Psychology, Stanford University, Stanford, CA.

The decapeptide GnRH is an important regulator of vertebrate reproductive function and has been highly conserved during the course of vertebrate evolution. Most, and perhaps all, vertebrates express at least two forms of GnRH. Chicken-II GnRH (cGnRH-II) is the most ubiquitous form, and has been identified in every major vertebrate taxon. Previously it was thought that eutherian mammals do not express cGnRH-II but the gene encoding this form has now been cloned and sequenced in members of this taxon as well. While it has potent gonadotropin releasing action *in vitro*, cGnRH-II neurons are generally confined to midbrain regions, and with the possible exception of elasmobranchs, are not thought to function in gonadotropin release *in vivo*. In this study we used a variety of evolutionary distance measures and tree-building techniques to analyze amino acid and cDNA sequences, both to explore the evolutionary history of this family of peptides and their functional divergence across vertebrates. Our results suggest that there are two distinct GnRH lineages, which we call GnRH-I and GnRH-II, which resulted from a single gene duplication event early in the course of vertebrate evolution. The GnRH-I lineage includes mammal GnRH (mGnRH), chicken-I GnRH (cGnRH-I) and salmon GnRH (sGnRH) and all other forms of placodal origin. The GnRH-II lineage includes cGnRH-II and other forms expressed in the midbrain. All forms of GnRH exhibit, at both the cDNA and amino acid levels, a high degree of sequence identity in the GnRH region, somewhat less so in the signal sequence, and markedly less so in the associated peptide coding region. All GnRH-I forms have a single associated peptide (GAP), while GnRH-II forms have two associated peptides. The low degree of conservation of these associated peptides implies that whatever function they serve, if any, requires little in the way of sequence specificity.

725.8

THE POSSIBLE ROLE OF NPY Y1 RECEPTORS IN THE CONTROL OF LORDOSIS. Jan Thornton* and Laurie Holcomb. Neuroscience Program and Dept Biology, Oberlin College, Oberlin OH 44074.

Previously we have shown that NPY plays a facilitatory role in the control of lordosis. These studies examined if NPY acts at Y1 receptors to affect lordosis. Adult guinea pigs were ovx and implanted with a cannula into the lateral ventricle. In Exp 1, females were injected with 20ug Estradiol Benzoate (EB) followed 40h later by .5mg Progesterone (P). Females which displayed lordosis after P were injected ICV with either 0.5 or 5 ug of the NPY Y1 agonist leu31, pro34 NPY, or were used as controls. The 5 ug dose of the Y1 agonist significantly increased lordosis responding. In Exp 2, ovx cannulated females were injected with 20ug EB and tested for lordosis 40h later. They were then injected ICV with NPY Y1 agonist (5ug) or were used as controls. The Y1 agonist did not facilitate lordosis in these females. These data suggest that 1) NPY acts at Y1 receptors to facilitate lordosis and 2) NPY may affect some progesterone mediated component of lordosis since only EB+P but not EB induced lordosis was facilitated.

REGULATION OF GLUTAMATE RECEPTOR BINDING FOLLOWING CHRONIC NEUROLEPTIC TREATMENT. Ian Creese*, F.I. Tarazi and W.J. Florijn. Center for Molecular & Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

Glutamate receptors may play an important role in the pathophysiology of schizophrenia and the motor side effects of chronic neuroleptic drug treatment. We examined changes in the binding of three glutamate receptor subtypes using ^3H -MK801 (NMDA-R antagonist), ^3H -CNQX (AMPA-R antagonist) and ^3H -Kainic acid (kainate-R agonist) *in vitro* receptor autoradiography following one month's treatment of rats with SCH23390 (SCH) (0.5 mg/kg/day), clozapine (CLZ) (25 mg/kg/day), haloperidol (HAL) (1.5 mg/kg/day), or raclopride (RAC) (10 mg/kg/day). Chronic SCH treatment elevated ^3H -MK801 binding in the hippocampal formation with significant increases in CA2 and dentate gyrus. This result suggests a specific role for dopamine D1 receptors in the regulation of hippocampal NMDA receptor function. In contrast, chronic HAL or RAC treatment did not alter ^3H -MK801 binding in any of the brain regions analyzed. However, chronic CLZ treatment caused a significant decrease in ^3H -MK801 binding in caudate putamen (medial: -34%, lateral: -22%) without affecting the hippocampal formation, nucleus accumbens or the cortex. This might explain why it produces minimal extrapyramidal side effects. Results for AMPA and kainate receptors will also be reported.

726.3

AKATHISIA-LIKE RESPONSE TO HALOPERIDOL IN RATS TRAINED TO PERFORM A SUSTAINED ATTENTION TASK. B.J. Brockel* and S.C. Fowler. Univ. of Mississippi, University, MS 38677.

Rats were trained to remain immobile with their heads in observation tunnels where brief (0.12-s) visual stimuli were presented. The rats learned to react to 1 of 3 visual stimuli by executing a nose-poke response within 3 s of stimulus presentation. Exits from the tunnel were penalized by a 7.5-s time out, a contingency that made the rats refrain from locomotion for most of the 900-s session. Forty animals were equally divided into 5 separate groups with each group receiving its own dose (0.0 to 0.12 mg/kg) of haloperidol (Hal) daily for 23 days. Hal decreased reinforcers and dose-dependently increased proportion of errors of omission, suggesting that Hal not only reduces responding but also produces attention deficits. Number of head exits from the observation tunnel was dose-dependently increased by Hal. This effect showed gradual tolerance across the chronic dosing. Head exits in this paradigm may serve as an animal model of akathisia. Supported by MH43429.

NITRIC OXIDE SYNTHESIS INHIBITION ATTENUATES HALOPERIDOL-INDUCED SUPERSENSITIVITY. C.M. Pudiak*, & M.A. Bozarth. Department of Psychology, University at Buffalo, Buffalo, NY 14260-4110.

Previous work has shown that nitric oxide is involved in sensitization to the locomotor-stimulating effect of repeated cocaine injections (Pudiak & Bozarth, *Life Sci.* 53: 1517-1524, 1993). Increased responsiveness to stimulants can also be produced by chronic dopamine-receptor blockade. This study examined the effectiveness of nitric oxide synthesis inhibition in blocking the supersensitivity following chronic neuroleptic treatment (i.e., dopamine-receptor blockade). N ω -nitro-L-arginine (L-NAME) was used to inhibit nitric oxide synthesis, while haloperidol was used to produce supersensitivity by chronically blocking dopamine receptors.

Male, Long-Evans rats were tested in locomotor activity chambers for 30 min following an injection of normal saline (1 ml/kg, i.p.). On the next day, they were retested following an injection of cocaine hydrochloride (10 mg/kg, i.p.). All rats then received daily injections of haloperidol (0.2 mg/kg, i.p.) for 14 days. Half of the rats were pretreated with normal saline (1 ml/kg, i.p.) and half were pretreated with L-NAME (30 mg/kg, i.p.) 30-min before their haloperidol injections. Seventy-two hours after their last injections, all rats received an injection of cocaine (10 mg/kg, i.p.) and were tested for 30 min in locomotor activity boxes.

Rats treated with saline plus haloperidol showed greater stimulation of locomotor activity than during their first cocaine test, while rats treated with L-NAME plus haloperidol showed no change between the two tests. This finding suggests that inhibition of nitric oxide synthesis attenuated the haloperidol-induced supersensitivity to cocaine. Similar mechanisms may be involved in neuroleptic-induced supersensitivity and stimulant-induced sensitization.

726.2

REGULATION OF DOPAMINE RECEPTOR BINDING FOLLOWING CHRONIC NEUROLEPTIC TREATMENT. F.I. Tarazi*, W.J. Florijn and Ian Creese. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

We examined changes in dopamine receptor binding in various brain regions following one month's treatment of rats with SCH23390 (0.5 mg/kg/day), haloperidol (HAL) (1.5 mg/kg/day), raclopride (RAC) (10 mg/kg/day) or clozapine (CLZ) (25 mg/kg/day) using *in vitro* receptor autoradiography. Chronic SCH23390 treatment significantly increased ^3H -SCH23390 binding in nucleus accumbens (NA) [+55%] and caudate putamen (CP) [+28%]. ^3H -7OH-DPAT binding to dopamine D3 receptors was not changed by any of the neuroleptic drugs. In HAL-treated rats ^3H -YM-09151-2 and ^3H -spiperone binding was increased in CP [+50% and +45%] and in NA [+89% and 45%]. RAC treatment also elevated ^3H -YM-09151-2 and ^3H -spiperone binding in CP [+20% and +28%] and in NA [+28% and +25%]. ^3H -raclopride binding was only increased in the lateral CP [+17%] of HAL-treated rats. Since ^3H -YM-09151-2 and ^3H -spiperone have similar affinities for D2, D3 and D4 receptors but ^3H -raclopride has low affinity for D4 receptors, these results suggest that D4 receptors are majorly upregulated by the HAL treatment. Thus, ^3H -YM-09151-2 and ^3H -spiperone binding in the presence of a D2 and D3 receptor saturating concentration of raclopride (300 nM) to quantify selectively putative D4 receptors was significantly increased in both the CP and NA (+70%) of HAL-treated rats. Interestingly, the binding of both radioligands in the presence of 300 nM raclopride was significantly increased in CP (+26%) but not in NA of CLZ-treated rats.

Supported by MH44211 and Sigma Xi grant (F.I.T.)

HALOPERIDOL-INDUCED MONOAMINE DEPLETION: TYROSINE HYDROXYLASE-NEGATIVE SUBSETS OF DOPAMINE NEURONS ARE AFFECTED IN GASTROPOD CNS

D. Sakharov*, E. Voronezhskaya, L. Nezlil, K. Elekes, M. Baker, R. Croll¹, ¹Inst. Devel. Biol., 117808 Moscow, Russia, ²Bal. Inst. Limnol., H-8237 Tihany, Hungary, ³Dept. Physiol. & Biophys., Dalhousie Univ., Halifax, Canada B3H 4H7

Long-term treatment of leeches with haloperidol (HAL) was shown to result in depletion of specific subsets of putative dopamine (DA) neurons (NeuroReport 1994, 5:667). With the aim of further investigating what appears to be a novel action of HAL, the present study was performed on adult and juvenile specimens of the pond snail *Lymnaea stagnalis* kept for up to 20 days in 0.5-2.0 μM Hal solutions. HPLC-EC analysis of the CNS revealed a concentration-dependent DA depletion which reached 20-50% over the first 4-8 days and thereafter remained stable. (A comparable DA depletion was observed in the land snail *Achatina fulica* as a result of daily HAL injection, 1 $\mu\text{mol/kg}$, for 4 days.) In *L. stagnalis* a transient, dose-dependent, serotonin depletion was also observed which, by day 12, reached its 60 to 80% maximum followed by a complete (for 0.5 μM HAL) or partial recovery by day 20 of treatment. Glyoxylate-induced fluorescence was found depressed or undetectable in some, but not all, identifiable clusters of DA neurons in the CNS of animals treated with HAL for 3-4 days or more. A peculiar feature of HAL-sensitive DA neurons was that they were non-reactive to antibodies raised against tyrosine hydroxylase, whereas HAL-resistant DA neurons showed such reactivity. Thus the previous and present reports suggest that the depleting action of low doses of chronic HAL observed in specific subsets of DA neurons may be a phylogenetically conserved characteristic which, if generalized to vertebrates, may account for therapeutic effects of this and related drugs.

EFFECTS OF ANTIPSYCHOTICS ON THE PENTYLENETETRAZOLE (PTZ) SEIZURE THRESHOLD RELATIVE TO *IN VIVO* POTENCY MAY BE PREDICTIVE OF CLINICAL SEIZURE LIABILITY. S.G. McInerney, D.C. Hoffman, H. Donovan, L.J. Cornfield, R.J. Meade, J.V. Cassella* and D.W. Gallager. Neurogen Corp. Branford, CT 06405.

Antipsychotic drugs are known to cause a variety of neuropsychiatric side effects including the precipitation of seizures. However, as yet there is no animal model which is predictive of seizure liability. In the present studies, several clinically used antipsychotic drugs were evaluated for their ability to affect the onset of seizures induced by IV infusion of the chemical convulsant PTZ in rats. When administered IV prior to threshold determination, all of the reference antipsychotics reduced the PTZ seizure threshold at some dose when tested across a wide range of doses. In order to determine a behaviorally relevant dose range, the potency of each antipsychotic agent was assessed for its ability to antagonize *d*-amphetamine-induced hyperactivity, one measure of *in vivo* potency. The minimum efficacious dose (MED) for decreasing the PTZ seizure threshold was determined and compared to the ED50 (dose calculated to produce 50% reduction in hyperactivity) for antagonizing amphetamine-induced hyperactivity by the ratio of MED/ED50. In our studies, clozapine produced the lowest ratio of MED/ED50 of 0.67, with proconvulsant activity occurring well within the behaviorally relevant dose range. Haloperidol, trifluoperazine and chlorpromazine produced the highest ratios (25, 16.7 and 14.7, respectively). The ratio of proconvulsant activity to *in vivo* potency for these and additional drugs was found to correlate with available reports of clinical seizure incidence. This ratio may therefore serve as a predictor for proconvulsant liability among antipsychotic agents.

EFFECTS OF SOCIAL ISOLATION ON LOCOMOTOR ACTIVITY AND PREPULSE INHIBITION IN WISTAR RATS AND INTERACTIONS WITH ANTIPSYCHOTICS. T.C. McCloskey*, H.J. Ketteler, G.M. Fadavel, C.J. Schmidt and J.H. Kehne, Marion Merrell Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, Ohio 45215.

Social isolation of postweaning rats results in a syndrome of behaviors and a pattern of biochemical alterations that are, at least in part, indicative of enhanced dopaminergic sensitivity. Given the postulated role of dopaminergic overactivity in schizophrenia, and the need to develop new, non-pharmacological therapeutic models, the present study began investigating the behavioral effects of social isolation in rats, and interactions with antipsychotics. Male Wistar rats were housed either singly ("isolated" condition) or in groups of 4 ("grouped" condition) beginning at 25 days of age. When tested 5 weeks later, isolated rats placed in a novel test environment showed a significant locomotor hyperactivity relative to grouped rats. This hyperactivity was particularly notable during the first 10 min of testing when initial exploratory levels of activity are high. Isolated rats also tended to show disrupted prepulse inhibition of acoustic startle using either an auditory prepulse (weak white noise burst) or a visual prepulse (lightflash). Dose-response studies indicate that the locomotor hyperactivity can be reduced by the DA antagonist haloperidol at doses that did not significantly reduce baseline levels of activity. Preliminary findings of increased dopamine concentrations in the striatum and n. accumbens are also consistent with enhanced dopaminergic activity in the isolates. These data support the conclusion that the locomotor hyperactivity produced by social isolation is attributable, at least in part, to dopamine hyperactivity.

726.9

S 17828 AND S 14956, NOVEL BENZISOXAZOLES DISPLAYING ANTIPSYCHOTIC PROPERTIES AND A LOW SIDE-EFFECT PROFILE IN ANIMAL MODELS: A COMPARISON TO RISPERIDONE. J.-L. Peglion, V. Audinot, M. Brocco, K. Bervoets*, C. Daquet, A. Newman-Tancredi, H. Canton and M.J. Millan, Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, France.

In addition to dopamine receptors, both serotonergic and adrenergic receptors are implicated in the pathogenesis and treatment of schizophrenia. Risperidone (RIS) is of interest in view of its high affinity at 5-HT_{2A}/α₁/α₂ vs D₂ receptors (pK_is = 9.2/8.9/8.3 vs 8.3) as compared to haloperidol (7.1/7.9/5.9 vs 8.7), and, also, as it elicits a less pronounced extrapyramidal (EPS) syndrome in man at antipsychotic doses. In this study, we show that the novel benzisoxazoles, S 17828 and S 14956, also manifest high affinity at 5-HT_{2A}/α₁/α₂ vs D₂ receptors; pK_is were 8.5/8.2/8.2 vs 8.7 and 8.5/9.1/8.2 vs 8.5, respectively. Interestingly, the affinity of S 17828 for cloned, human D₂ receptors was high (8.8) as compared to S 14956 (7.7) and RIS (8.0). Further, S 17828, S 14956 and RIS all showed low affinity at M₁ sites (< 6.0) and S 17828 (7.0) and S 14956 (7.1) showed only low affinity at H₁ sites as compared to RIS (8.9). *Ex vivo*, in (male) rats, S 17828 and S 14956 mimicked RIS in showing high occupancy of 5-HT_{2A} and α₁ vs D₂ sites: % occupation at 10.0 mg/kg, p.o.: S 17828 (71/33 vs 39), S 14956 (59/75 vs 13) and RIS (78/48 vs 18). RIS elicited catalepsy in rats only at doses (ED₅₀ = 2.1 mg/kg, p.o.) higher than those inhibiting amphetamine-induced locomotion in rats (ID₅₀ = 0.5 mg/kg, p.o.) and apomorphine-induced climbing in (male) mice (ID₅₀ = 0.02 mg/kg, p.o.), such dose-differences were likewise marked for S 17828 (1.7 vs 0.04 and 0.02) and S 14956 (16.7 vs 1.1 and 0.6). In a model reflecting putative hypotensive properties *in vivo*, RIS potentially elicited ptosis in rats (ED₅₀ = 0.1 mg/kg, p.o.) whereas S 17828 (5.3) and S 14956 (1.3) were only weakly active. In conclusion, these rodent models suggest that S 17828 and S 14956 may be effective antipsychotics with a low side-effect profile.

726.11

STRUCTURAL ANALOGUES OF THE ANTIPSYCHOTIC SERTINDOLE. STUDIES ON THE FIRING OF DOPAMINE NEURONES IN A10 AND A9 RAT BRAIN AREAS AFTER CHRONIC ADMINISTRATION. J. Perregaard*, T. Skarsfeldt, K. Andersen, K.P. Bagesø, K. Frederiksen, Research & Development, H. Lundbeck A/S, Ørttilavej 9, DK-2500 Copenhagen-Valby, Denmark.

The atypical antipsychotic sertindole, 1-[2-[4-(5-chloro-1-(4-fluorophenyl)-1H-indol-3-yl)-1-piperidinyl]ethyl]-2-imidazolidinone, has high affinity for serotonin 5-HT_{2A} (IC₅₀=0.39 nM), 5-HT_{2C} (IC₅₀=1.1 nM), and dopamine D₂ (IC₅₀=4.1 nM) receptors and for α₁ adrenoceptors (IC₅₀=3.4 nM). *In vivo* sertindole has a long lasting antiserotonergic effect in the rat (inhibition of quipazine-induced head twitches; ED₅₀=0.039 μmol/kg, 24 hours after po administration). Despite high affinity *in vitro* for dopamine D₂ receptors sertindole exerts no cataleptogenic effects. Within the group of close structural analogues of sertindole similar neurochemical binding profiles were found. Such analogues include variation in the 5-substituent of the indole, ^{1a} moving the 5-chlorine atom to the 6-position, ^{1b} isosteric interchange of the indole N-1 and C-3 atoms, ^{1c} and the corresponding (1*R*,3*S*)-trans-1-piperazino-3-phenylindan derivative. Sertindole potently and selectively decreases the number of firing dopamine neurones in A10 versus A9 in the rat after 3 weeks of treatment.² The receptor binding profiles will be presented and discussed in relation to the effects on A10/A9 dopamine neurones after chronic administration with the sertindole analogues. A partial and selective inhibition of A10 dopamine neurones was found for some compounds. Results for the antipsychotics haloperidol, clozapine, and remoxipride will be included for comparison.

A TEMPORAL SHIFT IN THE LOCOMOTOR RESPONSE TO APOMORPHINE MAY PREDICT EPS LIABILITY OF ANTIPSYCHOTICS. M.J. Maichrzak*, V. Guanowsky, P.A. Seymour, & S.H. Zorn, Dept. of Neuroscience, Central Research Division, Pfizer Inc., Groton, CT 06340

Apomorphine is a dopamine receptor agonist that produces hyperactivity and stereotypy in rats. In order to examine the effects of known typical and atypical antipsychotics on the pattern of the behavioral response to apomorphine, locomotor activity was measured in habituated rats using photocell chambers. Stereotypy was measured in separate experiments by an observer blind to treatment. A dose of 1.78 mg/kg, s.c., initially produces stereotypy without locomotor stimulation, followed by a period of hyperactivity that begins 75-90 min later and lasts approximately 30 minutes. Pretreatment with the typical antipsychotics haloperidol, raclopride and fluphenazine produce a "temporal shift" in the apomorphine locomotor response. This response is characterized by a dose dependent leftward shift in the time course of the hyperactivity without attenuation of its magnitude. The temporal shift observed with typical antipsychotics is not due to an attenuation of stereotypy, since doses that temporally shift locomotor activity are not sufficient to antagonize stereotypy. The atypical antipsychotic clozapine, produces a dose dependent antagonism of the apomorphine locomotor response without a temporal shift or antagonism of stereotypy. The D1 antagonist SCH-23390, and the mixed D2/5HT-2 antagonist risperidone, inhibited the hyperactivity with no temporal shift. They did, however, both antagonize stereotypy. Since agents that produce temporal shifts are known to produce EPS clinically, and those that do not produce temporal shifts have reduced EPS liability, it is hypothesized that the temporal shift may be predictive of antipsychotic efficacy associated with EPS liability. This behavioral assay may be useful for the identification of antipsychotics with a reduced propensity for EPS.

726.10

A PARAMETRIC CHARACTERIZATION OF THE LATENT INHIBITION-CONDITIONED EMOTIONAL RESPONSE (LI-CER) MODEL OF SCHIZOPHRENIA IN RATS. R. Schreiber, S. Monneyron and M.J. Millan*, Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, France.

Disruption of LI, that is, the inability to ignore irrelevant stimuli, has been proposed as a model of the attentional-cognitive deficits of schizophrenia. In the present study, we characterized this model by use of a three-step paradigm. After establishment of a stable baseline of licking behaviour, (male) rats were first pre-exposed (PE) or not pre-exposed (NPE) to a series of tones. One day later, during a conditioning session, they were exposed to two tone-shock pairings and 24h later, on the test-day, allowed to make 100 licks until the tone commenced. The time to complete licks 90-100 (t₁) and licks 100-110 (t₂) was measured and the suppression ratio (SR) was defined as: t₁/t₁+t₂. It was found that weight (200 vs. 300 g), pretest-criterion (completion of either 600 or 1000 licks within 10 min), duration of pre-exposure (40 tones/40 min vs. 40 tones/15 min) and the duration of shock (0.8 mA/1s vs. 0.8 mA/3s) were not critical for the establishment of LI. An inverted U-shaped shock-SR curve was obtained with maximal effects emerging at 0.5 mA (SR ± SEM: 0.09 ± 0.02 and 0.28 ± 0.03, for NPE and PE, respectively, P < 0.05). D,L-Amphetamine (2 x 1.5 mg/kg, i.p.) disrupted LI when injected 15 min before PE (40 tones) and conditioning using a 24h delay between sessions but failed to disrupt LI when PE and conditioning were performed on the same day. Under the former conditions, haloperidol, 2 x 0.1 and 2 x 0.16 mg/kg, i.p., evoked LI in rats pre-exposed to 10 tones. It is concluded that, in the LI-CER model, the intensity of the unconditioned stimulus is decisive for the induction of LI and that, based on the results obtained with d,l-amphetamine and haloperidol, this paradigm is an appropriate model for the characterization of antipsychotic drugs.

726.12

PHARMACOLOGICAL PROFILE OF SM-13496, A NOVEL ANTIPSYCHOTIC AGENT WITH MINIMAL EXTRAPYRAMIDAL AND CNS DEPRESSIVE SIDE EFFECTS. Y. Ohno*, K. Ishida, T. Ishibashi and M. Nakamura, Res. Cent., Sumitomo Pharmaceuticals Co., Ltd., Konohana-ku, Osaka 554, Japan.

SM-13496 is a newly discovered antipsychotic that preferentially acts on dopamine D₂ and 5-HT₂ receptors. SM-13496 showed high to moderate affinities for D₂ (K_i=14.4 nM) and 5-HT₂ (K_i=26.8 nM) receptors, but had negligible affinities for D₁, 5-HT₁, 5-HT₃, α₁, β, muscarinic, GABA_A, benzodiazepine, σ, or glutamate receptors. Oral administration of SM-13496 blocked dopaminergic behaviors (e.g., methamphetamine-induced hyperactivity in rats and apomorphine-induced climbing behavior in mice) and selectively suppressed the conditioned avoidance response in rats (ED₅₀=1.7-4.9 mg/kg). SM-13496 also inhibited 5-HT₂ receptor-mediated behaviors (e.g., tryptamine-induced clonic seizure and p-chloroamphetamine-induced hyperthermia in rats, ED₅₀=3.0-5.6 mg/kg) and had anticonflict activity in the Vogel's conflict test (MED=10 mg/kg). Despite its potent D₂ blocking activities, SM-13496 showed only negligible actions in inducing extrapyramidal side effects (i.e., catalepsy and bradykinesia, ED₅₀>1000 mg/kg), potentiation of anesthesia (ED₅₀>1000 mg/kg), muscle relaxation (ED₅₀>1000 mg/kg) and inhibition or potentiation of convulsion (ED₅₀>1000 mg/kg). In conclusion, SM-13496 is a novel atypical antipsychotic with minimal extrapyramidal and CNS depressive side effects.

726.13

5-HT₂ RECEPTOR BLOCKADE BY SM-9018, A NOVEL 5-HT₂ AND D₂ ANTAGONIST, COUNTERACTS ITS ACTIONS AT STRIATAL DOPAMINE D₂ RECEPTORS. T. Ishibashi, Y. Ohno, K. Ishida, K. Ikeda, T. Tatsuno* and M. Nakamura. Res. Cent., Sumitomo Pharmaceuticals Co., Ltd., Konohana-ku, Osaka 554, Japan.

SM-9018 is a potential atypical antipsychotic that has potent 5-HT₂ and D₂ blocking activities. To elucidate the role of its 5-HT₂ blocking activity in the striatum, we studied the effects of SM-9018 (5-HT₂/D₂ antagonist), haloperidol (D₂ antagonist) and 5-HT₂ antagonists on the induction of extrapyramidal side effects (i.e., bradykinesia), *ex vivo* c-fos mRNA expression in the striatum and *in vitro* acetylcholine (ACh) release from striatal slices. Antipsychotics (e.g., SM-9018 and haloperidol) dose-dependently induced bradykinesia in the pole-descending behavior of mice with relative potencies consistent with those for catalepsy induction. SM-9018 was about 70 times weaker than haloperidol in inducing bradykinesia and had a 13 times higher therapeutic index (anti-apomorphine/bradykinesia ratio). 5-HT₂ antagonists (e.g., ritanserin) had no effects by themselves, but significantly reduced the haloperidol-induced bradykinesia. Oral administration of haloperidol markedly enhanced c-fos mRNA expression in the rat striatum (about 7 fold at 30 mg/kg) whereas SM-9018 showed only a slight increase (about 1.8 fold) at doses of up to 30 mg/kg. 5-HT₂ antagonists failed to affect c-fos mRNA expression by themselves, but markedly attenuated the haloperidol-induced c-fos expression. Finally, SM-9018 was about 10 times weaker than haloperidol in enhancing the *in vitro* [³H]ACh release upon 3Hz electrical stimulation while it was as potent as haloperidol in binding to D₂ receptors and in antagonizing the inhibitory effects of exogenous quinpirole (a D₂ agonist) on [³H]ACh release. Simultaneous application of the 5-HT₂ antagonist significantly reduced the haloperidol-induced enhancement of [³H]ACh release. Our findings suggest that the 5-HT₂ blocking activity of SM-9018 counteracts its antagonistic actions at the striatal D₂ receptors, which seems to contribute to its low incidence of extrapyramidal side effects.

726.15

COMPARATIVE INTRINSIC ACTIVITIES OF DOPAMINE D₂ AGONISTS. L.M. Georgic, S.Z. Whetzel, L.W. Cooke, C.L. Christoffersen, K.A. Serpa, D.H. Van Leeuwen, R.G. MacKenzie, M.D. Davis, T.A. Pugsley, L.T. Meltzer* and T.G. Heffner. Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, MI 48105.

Intrinsic activity may be an important determinant of the clinical antipsychotic profile of partial dopamine (DA) D₂ agonists. In order to determine the utility of preclinical tests for estimating intrinsic activity we measured the maximal effects of a series of partial DA agonists in models commonly used to characterize dopamine D₂ agonists *in vivo* and compared the results to the maximal inhibition of forskolin-stimulated cyclic AMP accumulation in GH4C1 cells expressing the human D₂ receptor *in vitro* (cAMP). *In vivo* tests included substantia nigra dopamine neuron firing (DNF), gamma-butyrolactone-stimulated brain dopamine synthesis (GBL) and intrastriatal microdialysis (ISMD) in rats. Drugs were tested at 1 μM in cAMP, a level verified as supramaximal for selected agonists. Dose-effect curves were determined for DNF (i.v.) and high single doses were used for GBL (i.p.) and ISMD (i.p. or s.c.). Relative intrinsic activity in cAMP was: apomorphine > B-HT920 ≈ EMD38362 > CI-1007 = terguride ≈ (-)-3-PPP > SDZ 912 > haloperidol. Maximal effects in DNF and GBL revealed a similar order of intrinsic activity. However, maximal effects in DNF and GBL suggested: apomorphine = B-HT920 and CI-1007 > (-)-3-PPP. While apomorphine and B-HT 920 produced large decreases in striatal DA overflow in ISMD, SDZ 912, terguride, (-)-3-PPP and haloperidol caused increased DA overflow. The close agreement with results from the cAMP assay suggest that the GBL and DNF tests may be useful for estimation of DA agonist intrinsic activity, while the ISMD test does not discriminate between weak partial agonists.

726.14

STUDY OF THE STRUCTURE-METABOLISM RELATIONSHIPS OF ANALOGUES OF CI-1007 (PD 143188), A DOPAMINE AUTORECEPTOR AGONIST AND POTENTIAL ANTIPSYCHOTIC AGENT.

J. L. Wright, D. M. Downing, M. R. Feng, T. G. Heffner, T. A. Pugsley, L. D. Wise* and D. S. Wright. Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, MI 48105.

We have recently described CI-1007 (PD 143188) as a dopamine (DA) receptor agonist and potential antipsychotic agent. As part of studies directed at understanding the pharmacokinetics and metabolism of CI-1007, we have identified three phenyl-hydroxylated metabolites of CI-1007. One of these metabolites shows pharmacological activity similar to CI-1007 and could contribute to the activity of CI-1007 *in vivo*. Fluorinated analogues of CI-1007 were synthesized to block metabolism. One compound retained DA autoreceptor agonist properties and had a longer half-life in isolated rat hepatocytes than CI-1007. However its *in vivo* half-life was short and it showed no improvement over CI-1007 in oral activity in the monkey conditioned avoidance test. A 3-pyridyl analogue of CI-1007 was more potent *in vitro* but this did not translate into superior oral activity in the monkey. The half-life of this compound was extremely short in rat hepatocytes but the corresponding 4-methyl-3-pyridyl analogue was more stable. This compound showed improved activity versus the 3-pyridyl analogue in the monkey but none of these compounds had an overall profile as optimal as CI-1007. We have learned that simple blockade of metabolism does not necessarily improve oral activity of compounds.

726.16

ANTIPANIC-LIKE ACTIVITY OF S 21357-1 IN MICE

M.C. Reiton¹, D.H. Caionard¹, P. Renard¹, G. Griebel², R.J. Blanchard² and B. Guardiola-Lemaitre¹. ¹I.R.I. Servier, 6 pl des Pléiades, 92415 Courbevoie, France. ²Pacific Biomedical Res. Center, Békésy Lab. of Neurobiology, 1993 East-West Rd, Honolulu, Hawaii 96822, USA

S 21357-1 (1-naphthyl-1-piperazine-1-yl-1-n-butyl-1-benzothiazol-2-one) binds *in vitro* with high to moderate affinity to the 5HT_{2A} (K_i=2nM), 5HT_{1A} (K_i=7 nM), 5HT_{1D} (K_i=32 nM), 5HT_{1B} (K_i=35 nM) and 5HT_{2C} (K_i=240 nM) receptors and with low affinity (K_i>1000 nM) to the 5HT₃, α and β-adrenergic, D₁, D₂, sigma and opioid receptors.

S 21357-1 was evaluated in the anxiety/defense test battery which is able to measure escape and defensive reactions of a mouse after exposure to a predator (i.e. a rat). The animals were tested in the oval runway in two situations: after exposure to the predator (a stress mimicking generalized anxiety disorders) and in the presence of the predator reproducing a panic attack. In the first situation, S 21357-1 was able to prevent the increase of the jump escapes induced by the stress and the stress-induced decrease of wall rears at the doses of 0.125, 0.5 and 2 mg/kg i.p.; in addition, S 21357-1 prevented the increase of the wall climbs only at the lowest dose. In the second situation, S 21357-1 also reduced the escape behaviors: the number of avoidances was reduced at the doses of 0.125 and 0.5 mg/kg i.p. (respectively -29%, p<0.01 and -19%, p<0.05) as well as the avoidance distances (94% for the doses of 0.125, 0.5 and 2 mg/kg IP, p<0.01). During the forced contact, S 21357-1 significantly decreased the frequency of biting towards the rat at 0.125, 0.5 and 2 mg/kg i.p. (respectively -38%, -31%, -24%, p<0.01). S 21357-1 showed anxiolytic-like activity in the 2-compartment exploratory model in mice: it dose-dependently increased the number of transitions in the oral doses of 0.25, 1 and 4 mg/kg (respectively +195%, p<0.02, +438%, p<0.01 and +590%, p<0.005) and the time spent in the light compartment (respectively +141%, p<0.05, +300%, p<0.02 and +265%, p<0.01) without affecting locomotor activity or rearing.

These results suggest the interest of S 21357 as an antipanic-like and anxiolytic-like agent with minimal side effects.

727.1

THE DELAYED ANTICONFLICT EFFECT OF MK-801 IN RATS: SIGMA VERSUS NMDA (PCP SITE) RECEPTOR MECHANISMS. Z.C Xie* and R.L. Comisar, Dept. of Pharmaceutical Sciences, Wayne State Univ., Detroit, MI 48202 U.S.A

The present studies examined the receptor mechanism for the delayed anticonflict (i.e., anxiolytic-like) effect produced by dizocilpine (MK-801) in conditioned suppression of Drinking (CSD) conflict paradigm. Two questions were addressed: (1) do other agents which reduce NMDA neurotransmission mimic the delayed anticonflict effect? and (2) what treatment(s) can block the MK-801 effect? In Experiment 1, female rats were tested in the CSD conflict task using a multiple within-day test procedure (3 conflict sessions/day; 5 minutes/session). A thorough (0-60 hours in 6-hour increments) time course for the effects of MK-801 and a variety of agents which reduce NMDA neurotransmission was determined. As expected, MK-801 (0.1-0.4 mg/kg, IP) exerted a delayed anticonflict effect with a latency to onset of approximately 12 hours and a maximal effect at approximately 18-24 hours; no other NMDA antagonists exerted a delayed anticonflict effect, although CPP and AP-7 did produce modest anticonflict effects at a short (i.e., 40 minutes) pretreatment interval. In Experiment 2, the delayed anticonflict effect of 0.2 mg/kg MK-801 was selectively antagonized by the sigma site antagonist rimcazole (10 mg/kg, IP); in contrast, the PCP site antagonist metaphit (0.2 mg, ICV), the opiate antagonist naltrexone (1.0 mg/kg, IP) and the benzodiazepine antagonist Ro15-1788 (0.5 mg/kg, IP) did not antagonize MK-801. Together, these data indicate that the delayed anticonflict effect of NMDA antagonist MK-801 may be due to its actions at sigma, rather than NMDA, receptors. (Supported in part by MH 48171 to RLC).

727.2

CENTRAL INFUSION OF MK-801 DISRUPTS PREPULSE INHIBITION OF THE STARTLE RESPONSE. V.P. Bakshi* and M.A. Geyer. Dept. of Neuroscience, UCSD, La Jolla, CA 92093.

Intense auditory or tactile stimuli elicit an involuntary startle response. Presentation of a weak stimulus just prior to the primary stimulus attenuates the magnitude of the startle response. This phenomenon of "prepulse inhibition" (PPI) is thought to reflect sensorimotor gating mechanisms. Because deficits in sensorimotor gating are characteristic of several disorders including schizophrenia, it is of interest to determine the neural substrates underlying PPI. Systemic administrations of dizocilpine (MK-801) and other non-competitive NMDA antagonists such as phencyclidine markedly disrupt PPI in rats. In humans, administration of non-competitive NMDA antagonists can result in psychosis that closely resembles schizophrenic symptomatology. Relatively little work has focused on the effects on sensorimotor gating of central administration of these compounds. The purpose of the present investigation was to determine the effects on PPI of intracerebral microinfusions of MK-801. Male Sprague-Dawley rats received intracerebroventricular infusions of MK-801 (0, 10 or 30 μg/5 μl) in a counterbalanced order over three test days. Five min after drug administration, animals were tested in startle chambers. The test session consisted of presentations (in a counterbalanced order) of a 120 dB "pulse" (the primary startling stimulus) either alone or immediately preceded by non-startling "prepulses" that were 3, 6, or 12 dB above the background noise (65 dB). MK-801 markedly reduced PPI and increased startle amplitude following intracerebral administration. This result suggests that the PPI-disruptive effects of MK-801 are mediated by CNS receptors. Studies to identify the specific structures subserving this effect are in progress.

727.3

EFFECT OF CARBAMAZEPINE ON PREGNENOLONE SYNTHESIS IN C6 GLIOMA CELLS AND RAT BRAIN

B.S. Pan, K. Suyama*, H.K. Manji, and W.Z. Potter. Section of Clinical Pharmacology, NIMH, Bldg 10, Rm 2D46, Bethesda, MD, 20892

Although carbamazepine (CBZ) has proven effective in the treatment of both neurological and psychiatric disorders, its mechanisms of action remain unclear. We have begun to explore the hypothesis that CBZ may affect the brain levels of pregnenolone, a neurosteroid known to modulate GABA_A receptor in CNS. In the present study, cultured C6 glial cells were incubated with CBZ at concentrations of 1 to 100 μ M for 0 to 120 min. After incubation, samples were homogenized and extracted with ethyl acetate. Pregnenolone was separated by HPLC, and quantitated using a radioimmunoassay method. The pregnenolone content increased after incubation with CBZ for 30 min. with the maximal effect being apparent after 60 min. The synthesis of pregnenolone was stimulated by CBZ in a concentration-dependent manner with the maximal effect at 50 μ M. In rat brain slices, CBZ also produced a dose- and time-dependent increase in pregnenolone content. These results provide evidence that CBZ can increase steroid synthesis in rat brain tissue at concentrations used therapeutically in humans. This finding may provide novel insights into the mechanisms underlying one or more clinical effects of CBZ.

727.5

ANTAGONISM OF AMPHETAMINE-INDUCED BEHAVIORAL CHANGES IN SELECTED MEMBERS OF PRIMATE SOCIAL COLONIES BY LOW DOSE APOMORPHINE. R.F. Schlemmer*, L.V. Medina, J.E. Young, and J.M. Davis. Dept. of Pharmacology & Pharmacodynamics & Dept. of Psychiatry, Univ. of Illinois at Chicago, & Research Dept., Ill. State Psychiatric Inst., Chicago, IL 60612.

Low doses of the dopamine (DA) agonist apomorphine (APO) have been shown to lessen psychotic behavior in schizophrenic patients. This activity appears to be related to action on the pre-synaptic DA autoreceptor resulting in decreased DA release. Recently, there has been interest in developing agents with this property as antipsychotic candidates. In this study, we tested the effect of low dose APO on amphetamine (AMPH)-induced behavioral changes in monkeys that appear to have face validity or correlative validity to human psychotic behavior. The effect of APO was compared to the atypical antipsychotic clozapine (CLOZ). The subjects were 4 females of a stable social colony of 5 adult stump-tail macaques (*Macaca arctoides*). The study followed a cross-over design with 2 monkeys receiving drug per treatment day. Following observation of normal behavior (baseline), d-AMPH, 1.0 mg/kg, was given i.m. 15 min before observation for 2 days. Then, either APO, 0.1 mg/kg, was administered i.m. 15 min or CLOZ, 5 mg/kg, n.g. 2.5 hr before observation for 2 consecutive mornings and in the afternoon of day 1. AMPH was given as before. On each day, a "blind" observer quantitated and recorded the behavior of each animal using a checklist of over 40 social and solitary behaviors. Alone, AMPH significantly increased submissive gestures, checking (visual scanning), induced stereotypy, and eliminated initiated social grooming. APO antagonized AMPH-induced submissiveness, stereotypy, and restored social grooming, whereas, CLOZ blocked AMPH-induced submissiveness and checking. Neither APO or CLOZ induced movement abnormalities, but CLOZ-treated monkeys had a significant increase in resting. The results of this study suggest that this paradigm may be valuable in screening DA partial agonists as potential antipsychotic agents.

727.7

SEROTONERGIC OVERACTIVATION, LIKE DOPAMINERGIC OVERACTIVATION OR GLUTAMATE UNDERACTIVATION, DISRUPTS CROSS-MODAL SENSORY GATING AS MEASURED BY AUDITORY AND VISUAL PREPULSE INHIBITION IN RATS. J.H. Kehne*, T.C. McCloskey, R.A. Padich, V.L. Taylor, & C.J. Schmidt. Marion Merrell Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, Ohio 45215.

Dopamine (DA) and/or glutamate (GLU) imbalances are generally thought to contribute to schizophrenic symptomatology. Increasing evidence suggests a possible role for serotonin (5-HT) as well. Prepulse inhibition (PPI), a measure of sensory gating, is disrupted in schizophrenics, and by psychotomimetics in rats. In the present study, cross-modal PPI of acoustic startle in Wistar rats was produced by using either an auditory stimulus (sound) or a visual stimulus (light) as the prepulse. DA overactivity induced by d-amphetamine or apomorphine, or GLU underactivity produced by the cation channel blockers phencyclidine (PCP) or MK-801, disrupted auditory and visual PPI. MDL 100,453, a competitive NMDA antagonist, decreased baseline without markedly disrupting PPI. The 5-HT releaser fenfluramine (5.0 mg/kg) disrupted both auditory and visual PPI, and these effects were attenuated by the 5-HT uptake blocker MDL 28,618A, or by central 5-HT depletion produced by the 5-HT neurotoxin p-chloroamphetamine (PCA; 10 mg/kg) injected two weeks prior to testing. These findings indicate that excessive 5-HT overactivation, like DA overactivation or GLU underactivity, can disrupt auditory or visual sensory gating processes. The findings with PCA also suggest the utility of PPI as a tool to evaluate functional deficits accompanying CNS 5-HT neurotoxicity.

DESENSITIZATION AFTER A SINGLE DOSE OF THE 5-HT_{1A} RECEPTOR AGONIST FLESINOXAN UNDER BASAL AND DEFENSIVE-BURYING CONDITIONS.

J. van der Gugten, L. Groenink, B. Olivier*. Department of Psychopharmacology, Faculty of Pharmacy, Rudolf Magnus Institute for Neurosciences, Utrecht University, Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands.

A single injection of a 5-HT_{1A} receptor agonist has been shown to attenuate 8-OH-DPAT-induced corticosterone secretion in the rat (Kelder and Ross, N.-S. Arch. Pharmacol. (1992) 346: 121). In order to assess whether this also implies behavioral desensitization, we studied the effects of a single pretreatment with flesinoxan under basal conditions and in the shock-prod defensive-burying paradigm. Male rats received an anxiolytic dose of flesinoxan (3 mg kg⁻¹ s.c.), which suppresses defensive burying, or vehicle on day 1. Plasma corticosterone and glucose concentrations were determined on day 2 or day 8, 60 min after a second flesinoxan or vehicle treatment. On day 2 only, drug-induced increases in corticosterone and glucose under basal conditions were found to be diminished after flesinoxan pretreatment. No effect of pretreatment on lower lip retraction was observed. In the defensive-burying condition, flesinoxan pretreatment on the previous day also attenuated plasma corticosterone and glucose elevations. It is suggested that desensitization related to hormonal effects of 5-HT_{1A} receptor agonists involves a mechanism distinct from that underlying other symptoms of 5-HT_{1A} receptor activation.

In Vivo Electrophysiological Effects of ABT-418: A Novel Cholinergic Channel Activator (ChCA). R.J. Radek*, C.A. Briggs, S.P. Arneric. Neuroscience, Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, IL, 60064-3500

ABT-418[(S)-3-methyl-5-(1-methyl-2-pyrrolidinyl)isoxazole] has *in vitro* nicotinic-cholinergic functional and receptor binding properties (Arneric, et. al., *J Pharmacol Exp Ther*, in press), that, in conjunction with animal behavior studies (Decker, et. al., *J Pharmacol Exp Ther*, in press), suggests a more selective and less toxic action compared to nicotine. Nicotine itself desynchronizes neocortical EEG while also suppressing paroxysmal spike wave discharges. This study evaluated the effects of ABT-418 on these neocortical EEG parameters that are affected by nicotinic acetylcholine (nAChR) receptor activation.

Six and 12 month Wistar rats were surgically implanted with recording electrodes over the frontal and parietal cortices. ABT-418 (0.62, 1.9, & 6.2 μ mol/kg, i.p.) did not produce any significant change in FFT-analyzed EEG activity in unanesthetized 6 month rats. In contrast, all tested doses of (-)-nicotine (0.19, 0.62, 1.9 μ mol/kg, i.p.) significantly ($p < 0.05$) lowered 1-13 Hz total power values. ABT-418 (1.9 & 6.2 μ mol/kg, i.p.) significantly lowered the incidence of spontaneous 6-10 Hz neocortical spike wave discharges in awake 12 month rats. This effect was inhibited by the cholinergic channel blocker mecamylamine (5.0 μ mol/kg, i.p.) indicating that ABT-418 attenuation of spike wave activity is mediated by nAChRs.

The relative lack of ABT-418-induced neocortical desynchronization distinguishes this compound from nicotine. This study suggests that the attenuation of spike wave discharges and the reported behavioral effects of ABT-418 are not a simple consequence of the neocortical activation.

USE OF NON-PERMEABLE MICROCARRIER BEADS IN ALKALI METAL ION TRANSPORT NMR STUDIES OF PERFUSED NEUROBLASTOMA CELLS. C. Zachariah* and D. Freitas. Dept. of Chemistry, Loyola University of Chicago, Chicago, IL 60626.

In Nuclear Magnetic Resonance (NMR) studies of cells in suspension, it is possible to distinguish between the chemical shifts of the intracellular and extracellular ⁷Li, ²³Na, ³⁹K and ⁸⁵Rb NMR resonances by the use of anionic shift reagents (SR) in the extracellular medium. In NMR studies of cells anchored on microcarrier beads, which are permeable to alkali metal ions and/or SR, the intracellular resonance may overlap that of the internal bead volume.

Cell-free suspensions of four types of beads which differed in size, ion permeability, matrix composition, magnetic susceptibility and charge distribution were used in this study. Cytodex 1 and CultiSpher-G beads in buffered solutions gave rise to two separate ⁷Li and ²³Na resonances, while only one ⁷Li and ²³Na resonance was observed in suspensions containing Biosilon or glass beads. Hence the physical basis for the discrimination between the alkali metal NMR resonances in cell-free suspensions of Cytodex 1 and CultiSpher-G is the cation and anion permeabilities of these materials. ⁷Li NMR transport experiments of human neuroblastoma cells anchored on impermeable Biosilon beads will be presented. The relevance of these studies to understanding the mechanisms of lithium action in the treatment of manic depression will be discussed.

HYDROFLUORIC ACID ENHANCES RECOVERY FROM ISOFLURANE ANESTHESIA IN MICE: *BEHAVIORAL AND PHYSICO-CHEMICAL MEASURES. T.P. Jerussi, R.A. Del Vecchio, J. Bandekar, C.G. Huang and M.J. Benveniste. Dept. of Biological Research, Ohmeda, PPD, Murray Hill, NJ 07974.

When isoflurane (I) with trace amounts of hydrofluoric acid (HF) was tested for anesthesia in mice, the recovery appeared markedly faster than that of I alone. Therefore, a systematic investigation of the mixture was initiated. Mice were exposed to I or I containing 0.006-0.052% HF. LC_{50} s, EC_{50} s for loss of righting, and recoveries, the time for the return of righting, were determined for each concentration. Differences between I and I + HF, and the soda lime stability of I + HF were analyzed by FT-IR. I and HF interactions were also investigated by theoretical (*ab initio* quantum chemical) calculations using a model system of HF-dimethyl ether.

All of the EC_{50} s were significantly different from I alone whereas the LC_{50} s did not change. Moreover, recoveries of mice exposed to I + 0.023-0.130% HF were significantly faster than those of I. The main differences between the FT-IR spectra of I and I + 0.023% HF were shifts in peak positions and band-broadenings. The FT-IR spectra of the liquid and vapor phases of I + 0.023% HF exposed to soda lime were identical to that of an untreated sample. Quantum chemical calculations indicated that a strong (8.85 kcal/mole) hydrogen bond was formed between the oxygen of dimethyl ether and the H of HF.

The addition of small amounts of HF to I creates an I-HF adduct that has distinct physicochemical properties and produces a different pharmacological profile than I, resulting in greater potencies and faster recoveries from anesthesia.

BIOCHEMICAL STUDIES OF YM-35992 - A NOVEL ANTIDEPRESSANT.

T. Yamaguchi*, S. Yatsugi, H. Takeuchi, M. Fujii. Yamanouchi Institute for Drug Discovery, 21 Miyukigaoka, Japan 305.

YM-35992, (-)-(S)-2-[[[(7-fluoro-4-indanyl)oxy]methyl]morpholine monohydrochloride, showed biochemical characteristics of potent selective serotonin re-uptake inhibitor. In the ³H-citraplasm binding study, YM-35992 showed the same high affinity as fluoxetine ($K_i=21$ nM). 5HT selective uptake inhibition was also observed in the study using synaptosome preparation ($IC_{50}=140$ nM). YM-35992 did not inhibit both dopamine re-uptake and norepinephrine re-uptake ($IC_{50}>10\mu$ M and $=6.7\mu$ M respectively). These results show YM-35992 is a potent and selective 5HT re-uptake inhibitor as compared with amitriptyline and trazodone. However citraplasm and fluoxetine have no affinity against 5HT₂ receptor, YM-35992 showed the almost same affinity as trazodone in ³H-ketanserin binding study ($K_i=186$ nM). In another receptor binding studies, a relatively weak affinity for only α_1 receptor was observed. YM-35992 was also found to inhibit potently the aggregation of platelets ($IC_{50}=2.15\mu$ M), the results revealed an antagonistic activity of this compound for 5HT₂ receptor.

In contrast to the first generation of antidepressant (ex. tricyclic), several selective serotonin re-uptake inhibitors (SSRI) show relatively weak side-effects and fast onset of effectiveness. Up-regulation of 5HT₂ receptor is observed in the brain of patients with depression, and also clonic treatment of antidepressant down-regulate this receptor. Such down-regulation of 5HT₂ receptor possibly contribute to the clinical effectiveness. Thus YM-35992, SSRI with 5HT₂ antagonistic activity, might show the potent therapeutic action as a novel antidepressant in comparison with conventional SSRIs.

DEGENERATIVE DISEASE: ALZHEIMER'S—MODELS, ASSESSMENT, AND TREATMENT

728.1

DEATH OF SEPTAL CHOLINERGIC NEURONS PRODUCED BY CHRONIC EXPOSURE TO GLUTAMATE IS PREVENTED BY MK-801: ROLE OF NGF AND NITRIC OXIDE. Y. Agid* and P. P. Michel. INSERM U289, Hôpital de la Salpêtrière, 47, bld de l'hôpital, 75013 Paris, France.

To study the sequence of neurodegenerative events which could be associated with cholinergic cell death in Alzheimer's disease, rat septal cholinergic neurons in culture were exposed to chronic excitotoxic stress by glutamate. Counts of ChAT immunopositive cells and measurement of ChAT activity revealed that concentrations of glutamate on the order of 70 μ M killed 50% of cholinergic neurons after 24 h. of treatment. Neurotoxic effects were not aimed at cholinergic neurons specifically since other populations of cells present in these cultures were also affected. The non competitive NMDA receptor/channel antagonist, MK-801 (10 μ M), abolished acute neuronal swelling and rescued from late degeneration both cholinergic and non cholinergic cells when concentrations of glutamate did not exceed 500 μ M. The same degree of neuroprotection was afforded by the polyamine antagonist, Ifenprodil (20 μ M). On the other hand, the kainate/quisqualate receptor antagonist, CNQX lacked protective effects. NGF used in standard culture conditions to enhance expression of the cholinergic phenotype was shown not to influence excitotoxic processes. It should be noted that the presence of the NO synthase enzyme in most of the cholinergic neurons did not confer to these cells a particular resistance to glutamate intoxication. Furthermore despite the fact that the NO generating agent, sodium nitroprusside, was capable of mimicking some of the effects of glutamate, the lack of protection of various NO synthase inhibitors (L-NAME, L-NOARG; 30-100 μ M) against glutamate-induced septal cell death suggests that NO does not participate to the toxic process as an intercellular messenger.

727.10

PHARMACOLOGICAL STUDIES OF YM-35992 - A NOVEL SELECTIVE SEROTONIN RE-UP TAKE INHIBITOR WITH 5-HT₂ ANTAGONISTIC ACTIVITY - S. Yatsugi, H. Takeuchi, K. Nakato, H. Hattori, K. Koshiya, M. Fujii, E. Wanihuchi* and T. Yamaguchi. Yamanouchi Institute for Drug Discovery Research, 21 Miyukigaoka, Tsukuba, Ibaraki 305, Japan.

YM-35992 ((-)-(S)-2-[[[(7-fluoro-4-indanyl)oxy]methyl]morpholine monohydrochloride) possesses affinities for not only serotonin (5-HT) uptake sites ($K_i=21$ nM) but also 5-HT₂ receptors ($K_i=100$ nM), and has a relatively weak affinity for α_1 receptors ($K_i=247$ nM). YM-35992 induced symptoms of central serotonergic activation in mice when coadministered with l-5-HTP (90 mg/kg, iv), the 5-HT precursor. The ED_{50} values for the induction of these symptoms including tremors, head-twitches and hindlimb abductions were 6.3, 7.2 and 14.1 mg/kg ip, respectively. On the other hand, trazodone, which also has affinities for 5-HT uptake sites ($K_i=142$ nM) and 5-HT₂ receptors ($K_i=38$ nM), did not show any interactions with l-5-HTP even at a dose of 60 mg/kg ip. YM-35992 and trazodone significantly reduced the number of head-twitches in mice induced by DOI (2.5 mg/kg ip), a 5-HT₂ agonist, with the ED_{50} values of 7.1 and 7.8 mg/kg ip, respectively. YM-35992 (10 mg/kg ip) significantly reduced the immobility time in the mouse tail suspension test, but trazodone conversely prolonged the immobility time in a dose-dependent manner. Interestingly, both YM-35992 and trazodone ameliorated the learning impairment in olfactory bulbectomized rats after an acute administration, but citalopram did not. In this model, most antidepressants are known to ameliorate the learning impairment only after chronic but not acute administration. These results suggest that YM-35992 would be a novel type antidepressant with more potent effects than trazodone and earlier onset of action than conventional selective serotonin re-uptake inhibitors.

728.2

LACK OF EFFECT OF UNILATERAL NEUROTOXIC LESIONS OF THE BASAL FOREBRAIN (BF) CHOLINERGIC SYSTEM ON CEREBRAL GLUCOSE UTILIZATION (CMRglc): A POSITRON EMISSION TOMOGRAPHY (PET) STUDY IN BABOONS. C. Chavoix*, I. C. Le Mestriç, P. Rioux, I. C. Fallet-Bianco, I. P. Allain, L. A. R. Young, J. J. Epelbaum, F. Mézenge, E. T. MacKenzie and J. C. Baron. INSERM U320*, CEA DSV-DRIPP*, CNRS URA 1829*, Centre Cycéron, BP5229, 14074 Caen Cédex, and INSERM U159*, 2Ter rue d'Alésia, 75014 Paris, France.

Loss of BF cholinergic neurons and associative neocortex hypometabolism are two presumably inter-related features of Alzheimer's disease (AD). Unilateral lesions to the nucleus basalis of Meynert (nbM) in baboons were reported to induce a marked but transient neocortical, preferentially ipsilateral, hypometabolism (Kiyosawa et al., Brain, 1989; 112:435); however, the lesions were electrolytic and there was no control group. To re-evaluate this issue, we studied with PET the effects of ibotenic acid lesions of the entire BF cholinergic system on CMRglc in 4 baboons and 3 sham-operated controls. In each baboon, magnetic resonance imaging (MRI) was used to 1) pre-operatively locate the target sites (n=17), 2) post-operatively confirm damage to the BF area, 3) determine internal cerebral landmarks for PET positioning, and 4) identify brain structures for CMRglc measurements. High-resolution coronal PET coregistered with MRI was performed in baboons under phenylcyclidine-N2O, once before and 1-4 times after surgery (at days -7, 5, 12, 35, and 70; sacrifice was at day 75). CMRglc and choline acetyltransferase (ChAT) activity were measured in neocortical areas and hippocampus. Lesion accuracy was confirmed by post-mortem histology (e.g., 25-100% neuronal loss in the nbM) and significant reduction in ChAT activity (e.g., ~ 60% decrease in frontal cortex). Nevertheless, there was no statistically consistent metabolic effects of BF lesions as compared to sham-animals, and no positive correlation between CMRglc and ChAT activity values in both groups for any time post-surgery. These results suggest that cholinergic deafferentation does not contribute to the brain hypometabolism observed in AD.

728.3

Animal model of wandering in Alzheimer's disease: Neural changes in proximal and distal sites following colchicine lesions of the dorsal hippocampal formation. R.J. Donahue* and J.P. Ryan. Neurobehavioral Research Lab, Psychology Department, SUNY Plattsburgh, Plattsburgh, New York 12901.

The neuropathology and neurobehavioral effects of wandering in Alzheimer's disease (AD) have been virtually unexplored despite the problematic nature of the behavior. Ryan and colleagues (1990, 1993) have investigated the behavior in an animal model using intrahippocampal injections of the neurotoxin colchicine. Marked behavioral deficits have been observed implicating not only the hippocampus but associated regions of the hippocampal system. The present study investigated changes in the hippocampus and related structures following dorsal hippocampal formation lesions. Twenty-four Long Evans hooded rats received either bilateral injections of one of three colchicine doses (10 µg, 15 µg, 25 µg) or artificial CSF into the dentate gyrus and/or CA1 regions. Ten days following surgery the animals were tested in the T-maze for spontaneous alternating behavior. Neural changes were detected using two immunocytochemistry procedures for Glia Fibrillary Acidic Protein (GFAP) and for dopamine. Results indicate marked changes in the hippocampal formation as well as related brain regions supporting the hypothesis that behavioral alterations in the animal model of wandering in AD are the consequence of damage to the hippocampal system.

728.5

PREHENSION IN ELDERLY AND DAT SUBJECTS. V. Diggles-Buckles*, J.C. Morris, J. Duchek, L. Hunt, J. Zieleskiewicz. Alzheimer's Disease Research Center, Washington Univ. Sch. of Med., St. Louis, MO 63110

Dementia of the Alzheimer type (DAT) is associated with reduced functional abilities, e.g. driving. The effect of impaired motor control mechanisms for these functional abilities have been underemphasized relative to cognitive loss. To explore basic kinematic and coordination differences in elderly controls and DAT subjects, we examined phases of simple prehension. Prehension was chosen for comparison as a pure motor function to minimize skill, past experience, and cognitive load. DAT subjects were divided into 2 groups according to dementia severity: very mild (n=5) and mild (n=5). Controls and DAT subjects were asked to grasp a cylinder (5 cm wide) 20 cm from starting hand position, lift and place it on a target 20 cm from the cylinder's original location when they heard a tone. Subjects were instructed to "move as quickly and accurately as possible," e.g. the cylinder must be on the target (7 cm wide) and still standing after release. **Results:** DAT subjects were slower in reaction time and movement time (based on switches) but used larger peak velocities, accelerations and decelerations to achieve the task. The coordination of finger prehension and limb transport to the cylinder was more tightly coupled temporally in controls than in the mildly demented subjects. There are motor changes associated with DAT that go beyond simple slowing to include disruption of coordination. Supported by NIA AG10145

THE CASE FOR DIAGNOSTIC DICHOTOMY BETWEEN EARLY- AND LATE-ONSET ALZHEIMER'S DISEASE. A. Carta, D. Bravi, M. Calvani, S. Nibhuachalla, M. Raskind*. Scientific Affairs Dept., Sigma-Tau Pharmaceuticals, Gaithersburg, MD 20878. *Alzheimer's Disease Research Center, Univ. of Washington, Seattle, WA 98108.

The practice of diagnosing Alzheimer's disease (AD) without classification as to age of onset is under increasing challenge. Recent reports of genetic dissimilarity between early- and late-onset AD patients provide qualitative support for previously noted differences between the two groups. These observations span clinical, neurobiological, and neurohistological parameters. Even the classic pathology of AD has yielded to observations that the substantive histological similarities, once used to unify early- and late-onset patients, segregate the groups in terms of quantity and distribution. To assess the validity of an age-based dichotomy, published data supporting and refuting the argument were reviewed. Conclusive claims cannot be made from a review of small patient cohorts; yet, a substantial amount of data differentiate early- and late-onset AD. Among them, evidence for differences in disease course, language, cholinergic deficits, and metabolic function are strongly supportive of heterogeneity in AD identified by age of disease onset. These observations are reviewed in light of the recent genetic data, and their implications for continuing AD research are explored.

728.4

Colchicine lesions of the dorsal hippocampal formation induce psychomotor impairments and perseveration. J.P. Ryan*, Z. Israelian, and D. Wagoner. Neurobehavioral Research Lab, Psychology Department, SUNY Plattsburgh, Plattsburgh, New York 12901.

The animal model of wandering in Alzheimer's disease (AD) developed by Ryan and colleagues (1990, 1993) has identified two behavioral components which may contribute to wandering in patients with AD: spatial memory impairments and psychomotor dysfunction. The present study elaborated on the psychomotor aspects and further investigated contributions of attention, activity level and perseveration in the animal model. Forty-four Long-Evans hooded rats received either bilateral injections of one of three colchicine doses (10 µg, 15 µg, 25 µg) or artificial CSF into the dorsal hippocampal formation. Ten days following surgery the animals were behaviorally tested in the activity chamber for attention and exploration followed by four consecutive days of T-maze testing for spontaneous alternating behavior. Increased activity, decreased attention and perseveration were indicated in rats with marked cell loss in the dorsal dentate gyrus and CA1. The study supports the hypothesis that deficits in spatial memory characterized in the animal model of wandering in AD are exacerbated by perseverative behavior and hyperactivity.

728.6

CORPUS CALLOSUM PATHOLOGY IN ALZHEIMER SUBJECTS: DISRUPTION IN INTERHEMISPHERIC TRANSFER. Y. Lakmache*, F. Lepore*, S. Gauthier* and M. Lassonde¹. ¹ Groupe de Recherche en Neuropsychologie Expérimentale, Univ. de Montréal et ² Centre McGill pour Etudes sur le Vieillessement, Montreal, Qc., Canada.

The main feature of Alzheimer's disease (AD) concerns the neuropathological and physiopathological changes in the associative areas of the cortex. Recent studies have demonstrated that besides the grey matter, the white matter of the centrum semiovale, which includes the minor and major forceps of the corpus callosum (CC), is also severely affected in AD. This might be in part a result of the degeneration of the pyramidal cells within these areas which furnish most of the commissural fibers. Fibers of the CC link the two hemispheres following a rostro-caudal topographical distribution. Thus, the motor fibers of the CC are mainly found in the genu, the somesthetic fibers occupy the trunk, the auditory fibers cross in the isthmus and the visual fibers project through the splenium. The aim of this study was to evaluate interhemispheric transfer in AD subjects and hence to assess the integrity of the CC. Several tasks, including tactile denomination, tactile and visual discrimination, simple reaction time to lateralized flashes of light or to puffs of air, bimanual coordination, etc., which attempted to test interhemispheric transfer within these systems were administered to 10 AD and 10 matched controls. Results showed that inter- but not intrahemispheric performance was significantly impaired in AD relative to controls. This finding is interpreted as showing that AD affects not only the well established memory and cognitive functions but also interhemispheric integration.

728.8

ASSOCIATION BETWEEN MOTION SENSITIVITY DEFICITS AND DIFFERENTIAL LUMINANCE SENSITIVITY IN SENILE DEMENTIA OF THE ALZHEIMER'S TYPE. A. Bellefeuille¹, G. L. Trick^{1,3}, P. Morris², M. Wolf² and M. Pito^{1*}. ¹University of Montreal, Montreal, H3C 3J7, Canada, ²Washington University, St Louis, MO 63110 and ³Henry Ford Hospital, Detroit, MI 48202.

The visual abnormalities associated with senile dementia of the Alzheimer's type (SDAT) include both motion sensitivity deficits and reductions in differential luminance sensitivity (DLS). The principal objective of this study was to determine the relationship between these deficits in patients with early to mild SDAT. Random dot kinematograms (RDKs) were used to assess global motion sensitivity in 16 patients with diagnosed SDAT and 19 visually and cognitively normal control subjects of similar age. Motion sensitivity testing was conducted twice within a month on each participant and the results of the two tests were averaged. DLS was evaluated with automated static perimetry (Humphrey, 30-2). Only participants with reliable visual fields (by manufacturer's criteria) were included. The global sensitivity, indices of visual field sensitivity (i.e., mean deviation [MD], pattern standard deviation [PSD], and corrected PSD [CPSD]) were used to quantify differential luminance sensitivity. Motion sensitivity was reduced significantly in SDAT patients compared to the controls (p < 0.05). DLS was depressed significantly (i.e., significant visual field defects were detected) in 11/16 SDAT patients. MD, an index of generalized reduction in DLS, was significantly correlated with motion thresholds (r = -0.37, p < 0.05). PSD and CPSD, more representative of focal reduction of DLS, were not significantly correlated with motion thresholds (p > 0.10). These results support previous findings of significant motion and differential luminance sensitivity deficits in patients with SDAT. In addition, the correlation between motion and luminance sensitivity suggests a link between these two deficits. (Supported in part by NIH grant AG05681).

728.9

REDUCTION IN AREA 17 BLOOD FLOW TO HIGH BUT NOT LOW FREQUENCY FLASHING LIGHTS IN DEMENTIA OF THE ALZHEIMER TYPE (DAT). M.J. Mentis, J. Stoll*, C. Grady, P. Pietrini, W. Hong, D. Mangot, G.E. Alexander, J. Ma, Maisog, J.W. VanMeter, M. Kurkjian, U. Freg, S.I. Rapoport, M.B. Schapiro. Lab. Neurosci., Natl. Inst. on Aging, NIH, Bethesda, MD 20892.

To determine the functional integrity of area 17 in DAT across a parametric range of passive visual stimuli we compared regional cerebral blood flow (rCBF) in 8 patients with DAT (75±6yr, Mini Mental State 21±4) and 12 healthy controls (63±13yr) using positron emission tomography (PET), [15-O] water and arterial catheterization for rCBF calculation. The visual stimulus was administered by goggles which flashed red lights alternately into each eye. All subjects had 6 scans, one at each frequency (0, 2, 4, 8, 16, 32 Hz) in randomized order. The healthy controls showed a linear rCBF increase from 0 through 16 Hz and then a decline at 32 Hz which confirmed earlier reports of linear increase with maximal rCBF at ± 8 Hz (simultaneous flashing into both eyes). In area 17, compared to the healthy controls, the DAT group had a) significantly lower rCBF values for all frequencies ($p < 0.001$), b) maximum rCBF response at 8 not 16 Hz, and c) similar percentage rCBF increases at 2, 4, and 8 Hz but significantly lower increases at 16 and 32 Hz ($p = 0.001$). This suggests that in DAT patients the neural circuits responsible for generating the area 17 response to flashing lights are normal for low but fail at high flash frequencies, perhaps a differential failure of magno and parvocellular systems.

728.11

A META-ANALYSIS EVALUATION OF CLINICAL TRIALS IN ALZHEIMER'S PATIENTS TREATED WITH ACETYL-L-CARNITINE. D. Bravi*, G. Kochi, M. Calvani, A. Bacchieri, P. Pola, S. Nibhuachalla, A. Carta. Scientific Affairs Dept., Sigma-Tau Pharmaceuticals, Gaithersburg, MD 20878. *Univ. of North Carolina, Chapel Hill, NC 27599-7400.

Alzheimer's disease (AD) is divided according to DSM-III-R into presenile (onset before age 65) and senile groups. There are many genetic, neurobiological, and clinical data indicating that presenile AD patients may differ from their senile counterparts. Thus, different therapeutic approaches may be considered for early- and late-onset AD patients. Several clinical trials with acetyl-L-carnitine (ALCAR) have been conducted in AD patients in recent years. It seemed appropriate to look retrospectively at the effect of ALCAR in presenile AD patients. Eight placebo-controlled, double-blind, clinical studies with ALCAR in patients diagnosed with AD were pooled in a comprehensive meta-analysis. For each study, cognitive and functional outcome measures for efficacy were evaluated. By using standardized ranks for treatment comparison on cognitive tests, ALCAR-treated early-onset patients tended toward slower progression of symptoms ($p < 0.1$) than placebo-treated subjects, whereas using logrank scores the effect of ALCAR achieved significance ($p < 0.05$). Functional tests showed a treatment effect favoring ALCAR by using standardized ranks ($p < 0.006$). These data suggest that ALCAR may affect the clinical progression of presenile AD.

728.10

RELATIONSHIP BETWEEN NEUROIMAGING AND PATHOLOGY IN ALZHEIMER'S DISEASE.

N.Nakano¹, R.Fukatsu¹, M.Fuji¹, J.Miyazawa¹, S.Murakami¹, K.Utsumi¹, S.Hayashi¹, T.Saito¹, K.Tsuzuki², and N.Takahata¹. Dep. of Neuropsychiatry¹, and Microbiology², Sapporo Med. Univ., Sapporo, Japan 060.

Neuroimaging is very useful in establishing the clinical diagnosis, and has been widely available in clinical neuropsychiatry. But little is known about the significance of alterations in neuroimaging. In this paper, we present comparative study between alterations in neuroimaging and neuropathological findings in a case of Alzheimer's disease (AD).

case: 64 yro female, began to show memory disturbance, followed by difficulties in house keeping at 59 yro. showed disorientation and apraxia, language disability, and Balint's syndrome. was gradually deteriorated. **Neuroimaging:** Longitudinally examinations of 123I-IMP SPECT revealed that asymmetry of hypoactive regions (lt. side dominant) was observed in parietal and temporal lobes at early stage and expanded into surrounding areas in advanced stages. Asymmetrical atrophy was evident in the same regions.

Neuropathology: AD was confirmed pathologically. 16 cortical regions in each hemisphere, which were matched to ROI in SPECT, were selected for further quantitative analysis. Neuronal cell count (NCC) and B/A4 deposited area (BDA) were estimated using computer-assisted image processing. NCC reduced in number remarkably in lt. parietal, temporal, and frontal lobes. BDA in lt. hemisphere was significantly larger than that in rt. side.

Neuroimaging, especially hypoactive lesions in SPECT show good correlation with NCC and BDA. And functional decline in regions revealing hypoactive in SPECT could precede pathological changes in AD.

728.12

LIPOPHILIC VIP ANALOGUES: NOVEL DRUGS FOR TREATMENT OF NEURODEGENERATIVE DISEASES

I. Gozes*, A. Bardea, A. Reshef, R. Zamostiano, S. Zhukovsky, S. Rubinraut, M. Fridkin and D.E. Brenneman. Sackler Med. Sch., Tel Aviv Univ.; Weizmann Inst., Israel; SDMP, NICHD, Bethesda, MD.

Vasoactive intestinal peptide (VIP) has been shown to be involved in promotion of neuronal survival as well as in acquisition of learning and memory. We now demonstrate that a superactive lipophilic VIP agonist inhibited neuronal cell death in an Alzheimer's model *in vitro* and ameliorated cognitive functions in an *in vivo* Alzheimer's paradigm. Thus, addition of 25µM of a fragment of the beta-amyloid peptide to rat cerebral cortical cells *in vitro* resulted in 70% cell death which was attenuated by co-treatment with stearyl-Nle¹⁷-VIP. Furthermore, in an *in vivo* Alzheimer's model of rats treated with the cholinergic blocker AF64A, which induced an impairment in spatial learning, stearyl-Nle¹⁷-VIP injected i.c.v or inhaled intranasally alleviated the impairment characteristic of Alzheimer's disease. These data supports neuropeptide intervention as a therapeutic strategy for neurodegenerative diseases.

We thank Dr. H. Leder for the initial sample of AF64A. Supported by Fujimoto Corp. Japan.

DEGENERATIVE DISEASE: PARKINSON'S—HUMAN STUDIES

729.1

USE OF ADVANCED INFORMATION FOR PROGRAMMING A PREHENSION TASK IN PARKINSON'S DISEASE. P. Weiss*, G.E. Stelmach, A. Chaiken and C. Waterman. Motor Control Laboratory, Arizona State University, Tempe, AZ 85 287 -0404, USA

The influence of precuing on the generation and modification of motor programs in young and elderly control subjects and 9 PD patients was examined by giving advanced information about the target size before a prehension movement: Subjects were instructed to prepare the prehension movement for the first shown (precued) target and then actually grasp the second shown target, which was of either the same or a different size. While under the high probability condition (valid size precue), the preparation of a adequate motor program for the grasp was feasible, the motor program had to be restructured in the low probability condition (invalid size precue).

3D movement trajectories were recorded by an Optotrak®-system at 100 Hz. The kinematics of the wrist movement (transport time (TT), peak velocity (PV) and peak acceleration (PA) amplitudes) were used for the analysis of the reaching component, while the maximum grip aperture (MGA) between thumb and index was utilized for analysing the manipulation component.

Changes in target size led to a combined modification of the manipulation as well as the reaching component in both, the controls and in the patient group, indicating a preserved global motor programming in PD. But for the PD patients motor coordination was impaired indicated by the later occurrence of MGA during the reach. In addition, PD patients failed to use a safety grip margin in comparison to the elderly controls. An invalid target size precue forced the subjects to restructure their motor program reflected by longer reaction times (RT). While controls showed no additional modifications of the reach, PD patients failed to completely restructure the motor program in the prolonged RT under the invalid precue condition revealed by an additional changed reaching component.

PD patients are generally able to adjust their prehension program to the task demands, however, they are disadvantaged in high demanding task because of their reduced rate in restructuring a motor program.

WHEN ASKED TO SWING THEIR ARMS, PERSONS WITH PARKINSON'S DISEASE WALK BETTER WITH FASTER, LARGER STEPS. WHY?

A. Behrman, P. Teitelbaum*, J. Cauraugh, P. Moreno, J. Fryman, Q. Teitelbaum. Depts. of Psychology and Exercise & Sport Sciences, University of Florida, Gainesville, FL 32611

Persons with Parkinson's disease (PD) typically walk with small, shuffling steps and little or no arm swing. We hypothesized that persons with PD could improve the temporal and spatial aspects of their gait patterns if asked to walk in specific ways. Five community-dwelling subjects with PD (age 71.8 ± 4.8 years; 10.2 ± 6.4 years since diagnosis) and 5 age- and gender-matched subjects without PD (age 70.8 ± 3.9 years) participated. Subjects were videotaped while walking across a 23' path under various instructional cues. Trials of natural walking were interspersed between four randomized cued conditions: walk while deliberately swinging their arms, counting aloud, taking large steps, or taking fast steps. When asked to swing their arms, 4 of 5 subjects with PD did so. This markedly increased the size of steps and speed of walking. Conversely, when asked to walk with larger steps, arm swing increased substantially (2/5). When asked to walk fast, arm swing increased (2/5). All control subjects when: 1) asked to swing their arms, did so with concomitant increases in speed and in step size; 2) taking large or fast steps, increased arm swing excursion; 3) taking large steps increased the speed of walking; and 4) fast walking increased step size. For both PD and control subjects, counting aloud resulted in inconsistent patterns of change in speed and arm swing. Two theoretical models of motor control, reafferent allied reflexes and dynamical systems, can account for these findings. Variability between subjects with PD and level of disability may further explain these findings. Training with self-instructional cues may be a potential intervention technique to improve walking patterns in persons with PD.

IMPAIRMENTS IN PARALLEL PROCESSING OF MOTOR RESPONSES DURING SWITCHING TASKS IN ELDERLY SUBJECTS AND PARKINSON'S DISEASE (PD) PATIENTS. M. Plotnik^{1,3}, R. Inzelberg^{1,2}, E. Schechtman¹, T. Flash² & A. Korczyn^{2,3}. 1. Dept. of Applied Mathematics, Weizmann Institute of Science, Rehovot, Israel. 2. Dept. of Neurology, Tel Aviv Sourasky Medical Center. 3. Dept. of Physiology and Pharmacology, Tel Aviv University, Sackler School of Medicine, Israel.

The objective of the present study is to examine the switching abilities of PD patients and elderly subjects using the double-step target displacement paradigm. The subjects were instructed to move their hands toward a visual target presented on the surface of a horizontal table. This target could remain lit (a control trial) or, unexpectedly change after an inter stimulus interval - ISI within the reaction time - RT (a switching trial). In the switching trials two types of hand trajectories were observed: double segment movements in which the hand moved first toward the first target and then toward the second target, and movements that were initially directed toward the second target. The second response was more prevalent in PD patients than in control subjects. In both groups, almost no movements had intermediate values of initial movement direction (IMD) in between the first and second target locations. Both control subjects and patients, had prolonged RT to the second stimulus (RT2) compared to the RT to the first stimulus - RT1 ($p < 0.01$). The ratio RT2/RT1 was larger in PD ($p < 0.05$). The values of RT2 obtained in the switching trials were highly compatible with the values expected according to the single channel theory for preparing motor responses for two consecutive stimuli (Welford Q J Exp Psychol 1959; 11: 193-210).

Analyzed with reference to the modification time (definition: $D = RT - ISI$), the IMDs in the switching trials were directed toward the first target for small values of D, and toward the second target for large values of D. Hence, when grouping together all switching trials, the IMDs were correlated with the values of D (Spearman, $P < 0.01$). However this pattern was not observed when the two classes of responses were separately analyzed. Our results suggest that unlike in neurologically healthy young adults (Van Sooderen et al. Exp Brain Res 1988; 71: 139-146), in elderly subjects and PD patients a gradual shift in the direction of the movement to be initiated does not occur within the preparatory period of the movement. Instead, beyond a certain threshold of D, a sharp change in the IMD is observed. Taken together, our observations can be interpreted as expressing impairments in the abilities of elderly subjects and more prominently PD patients to parallelly prepare two motor responses in the arm trajectory modification task.

POSTURAL ADJUSTMENTS DURING WRIST AND ELBOW MOVEMENTS IN PARKINSON'S DISEASE. A.A. Aruin, M.L. Latash*, J. Neyman, J.J. Nicholas, M.B. Shapiro. Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612.

Patients with Parkinson's disease, age-matched controls, and young control subjects performed fast, discrete elbow or wrist flexion or extension movements in a sagittal plane under the instruction to move one of the joints "as fast as possible". Relative stability in the other, postural joint was comparable in the patients and in both control groups. Typically, EMG patterns in muscle pairs acting at both joints displayed a commonly observed tri-phasic pattern. During both elbow and wrist movements, in both flexion and extension, the elbow flexor and the wrist flexor demonstrated similar, synchronized EMG patterns, while the elbow extensor and the wrist extensor also showed similar patterns of activation. A cross-correlation analysis of the EMGs confirmed virtually simultaneous bursts in the wrist and elbow flexors and in the wrist and elbow extensors. In all three groups, there were no signs of anticipatory activation of postural muscles in about 90% of movements. The analysis of a simple biomechanical model has suggested that simultaneous EMG bursts may be used to minimize the displacement in the postural joint. We assume that postural anticipation is not a separate process, but a separate peripheral pattern of a single control process that may involve a number of joints and muscles. The observed relation between the EMG patterns is apparently a universal synergy which is preserved in elderly and in Parkinson's disease. We conclude that the postural deficits in Parkinson's disease are not related to a basic deficit in feedforward postural control but to other factors that may include the specificity of maintaining the vertical posture.

729.7

ALLEVIATION OF MOTOR SIGN OF PARKINSON DISEASE AFTER STIMULATION OF THE INTERNAL SEGMENT OF THE GLOBUS PALLIDUS: EXPERIMENTAL EVIDENCE IN HUMAN. Ch. Gross, A. Rougier, T. Boraud, B. Bioulac*, and J. Julien. Groupe Motricité URA CNRS 1200, Services de Neurologie et Neurochirurgie, Centre Hospitalier et Universitaire de Bordeaux, 33076 BORDEAUX Cedex France.

Parkinsonian rigidity and akinesia are associated to an hyperactivity of the internal Globus Pallidus (GPi). Leitinen & other teams have recently reactualised the old Leksell concept of Pallidotomy. Inhibitory effect of High Frequency Stimulation (HFS) of the Subthalamic nucleus has previously been shown in Monkey and Human. In the present work, we have studied the effect of HFS of GPi in five Parkinsonian Patients, with severe unilateral bradykinesia with associated rigidity. Patients between 40 and 60 years old, were at Hoehn and Yarn stage 1 to 3 and suffering from Pharmacological resistant form of the disease. Patients were tested with electrokinetic methods, "tapping" test and UPDRS before and after the electrode implantation in 6 different situations: one week before the operation 1) with and 2) without Dopatherapy, two weeks after the implantation with Dopatherapy, and 3) with and 4) without stimulation; and without Dopatherapy, and 5) with or 6) without Stimulation. Monopolar electrode was stereotactically implanted using ventriculographic Landmarks from stereotactic atlas and MRI. Results showed that for stimulation sites situated at the base of the GPi, the more medial and the more caudal as possible, HFS of GPi may reduce bradykinesia and rigidity. This indicates that HFS efficacy seems to act on similar territories as the Leitinen Pallidotomy without the irreversibility of a lesion.

729.4

RECRUITMENT OF MOTOR UNITS IN ANTAGONIST MUSCLES IN PARKINSON'S DISEASE. D.S. Glendinning*, E.B. Montgomery Jr., B.M. Enoka. Depts. of Exercise and Sport Sciences and Neurology, Univ. Arizona, Tucson, AZ 85721, and Dept. of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, OH 44195.

Several authors have reported that the surface electromyogram (SEMG) is diminished during attempted fast movements in persons with Parkinson's disease (PD). We examined MU recruitment in PD to determine if abnormalities could explain the reduced SEMG. Ten persons with PD (40-78 yrs), ten older (51-77 yrs), and ten younger (21-39 yrs) healthy persons volunteered for the study. We measured muscle activity and forces associated with contractions of the first dorsal interosseous (FDI) muscle of the left hand. We also used nerve stimulation to evoke a maximal twitch response in the FDI. Both forces and SEMG signals during maximal voluntary contractions were reduced in the PD group. However, the evoked maximal twitch and M-wave showed no reduction. In all three groups, MU recruitment followed the size principle such that progressively larger MUs, as measured with spike-triggered averaging, were sequentially recruited as the isometric force increased. Threshold derecruitment forces for single MUs were higher than recruitment forces, but a greater discrepancy between these forces was found in the PD group. For all tasks, antagonist activity was increased in the PD and elderly subjects, but was rarely present in the young group. These results suggest that the diminished SEMG signal is not caused by abnormal MU recruitment order in PD, but may be related to inadequate motor neuron activation, increased reciprocal inhibition from coactive muscles, or premature derecruitment of motor units.

Change in movement kinematics of the discrete arm movement by accuracy demand for the Parkinson's subjects. M.K. Rand, J.K. DeWitt, G.E. Stelmach*. Motor Control Lab., Arizona State Univ., Tempe, AZ 85287-0404.

Slowness of movement is one of the most common features of the movement disorder for the Parkinson's disease (PD). The purpose of this study was to investigate the reasons of movement slowness for PD by using tasks where the accuracy demand at the end of the movement varied. Ten Parkinson's and ten elderly subjects performed two types of discrete arm movements in the horizontal plane. All movements consisted of a two segment, shoulder horizontal adduction and elbow extension movement. In the accuracy condition (ACC) the subjects attempted to move from the home position to a 3cm x 3cm target 25cm away. In the non-accuracy (NO-ACC) condition the subjects were asked to move through the target, but not to stop when the target was reached. All subjects were instructed to make precise movements as fast and as straight as possible after an auditory go-signal. Ten trials/condition were recorded. Movement time (MT), peak velocity, time to the peak velocity, and deceleration time (DT) were evaluated. The movements in the ACC condition were analyzed from start to end and the movements in the NO-ACC condition were analyzed from start to the target position.

The Parkinson's subjects showed generally longer MTs compared to the elderly subjects. This feature was pronounced in the ACC condition. This was mainly caused by the prolongation of the DT. Slowness of the movement for PD appears to be caused by either the problem in braking the movement or by increased error correction modulation.

SPATIAL LEARNING DEFICITS IN PARKINSONISM

R. J. Arcement*, D. J. Ingle and L.J. Cote. Neurological Institute, Columbia-Presbyterian Medical Center, West 168th St., New York, N.Y. 10032.

Ingle and Thompson (1993) showed that Parkinson Disease (PD) patients of moderate severity performed poorly on a spatial memory task after walking 4 to 8 meters forwards. Recently Arcement, et. al. replicated the post walking deficit in a new group of PD patients. In the present study we measured localization memory linked to arm movement, rather than to locomotion. Here the blindfolded subjects (S) point to a remembered target (T) on the table before them using the tip of a bent wire held by one hand at the other end. All Ss had the opportunity to learn the location of the bent wire's tip in relation to the hand during a two minute period of touching the tip to various table locations. Testing was done with both the bent wire and the index finger. When 14 PD and 13 controls were tested, the PD Ss were not significantly worse than controls in localizing T (by memory) using their index finger, but were significantly worse in learning to point with an artificial extension of the hand. The control errors averaged 73 mm each while the PD patient errors averaged 96 mm each. We speculate that spatial memory linked to locomotion and to arm movement are mediated by the caudate nucleus and the putamen respectively.

729.9

REVERSAL OF CATALEPSY BY STRESS: INVOLVEMENT OF THE MESOCORTICAL BUT NOT THE MESOLIMBIC SYSTEM. L. Hernandez*, S. Tucci, E. Murzi and T. Baptista. Laboratory of Behavioral Physiology, Medical School, Los Andes University, Mérida 5101, Venezuela.

Stress reverses catalepsy in Parkinsonian patients presumably by releasing dopamine. In an experimental model, i.e. haloperidol induced catalepsy which was reversed by forced swimming (FS), DA activity was assessed by microdialysis of the prefrontal cortex (PFC) or the nucleus accumbens (NAC) in rats. For each region (PFC or NAC) one group (HAL+SWIM) received an ip haloperidol injection (5 mg/Kg) and was forced to swim, another group (HAL) received haloperidol but was not forced to swim and a third group (VEH+SWIM) received vehicle and was forced to swim (six groups total). After haloperidol the rats exhibited catalepsy and dopamine and its metabolites increased. FS increased DA activity in the PFC too. However, the increase was significantly greater in the PFC of the HAL+SWIM than in the HAL or the VEH+SWIM groups ($F(2/96)=28.78$, $p<0.001$). No difference of DA activity in the NAC was observed when the HAL+SWIM vs the HAL group were compared ($F(1/112)=3.01$, NS). Another three groups of rats received microinjections of DA in the PFC during haloperidol induced catalepsy. Intracortical DA injections abolished catalepsy ($F(1/11)=34.9$, $p<0.001$). These experiments suggest that DA release in the PFC contributes to the reversal of catalepsy by stress.

SPECT IMAGING WITH [I-123]β-CIT DEMONSTRATES STRIATAL DOPAMINE TRANSPORTER LOSS IN HEMI-PARKINSONISM. K.L. Marek*, J.P. Seibyl, B. Sandridge, B. Fussell, E.O. Smith, R.M. Baldwin, S. Zoghbi, P.B. Hoffer, R.B. Innis. Depts Neurology, Psychiatry, Diagnostic Radiology, Yale Univ/VA Med Ctr, New Haven CT

[I-123]β-CIT (2β-carboxymethoxy-3β-(4-iodophenyl)tropane) labels monoamine transporters located on the terminals of dopaminergic projections from the substantia nigra to the striatum providing a marker for neurons which degenerate in Parkinson's disease (PD). [I-123]β-CIT SPECT imaging was performed in 8 idiopathic PD patients with exclusively hemi-Parkinsonian symptoms and in 8 age and sex-matched healthy subjects. All patients had very mild symptoms in the effected side (Hoehn and Yahr stage 1) and had not received treatment with L-Dopa. Data was analyzed relative to two outcome measures: ratio of specific:non-specific striatal activity and striatal uptake expressed as percent of injected dose. Disease stage and severity was assessed by Hoehn and Yahr Staging and UPDRS scales. Specific:non-specific striatal binding ratios in PD patients contralateral (2.7 ± 0.9) to the symptomatic side were reduced to 47% and ipsilateral (3.9 ± 1.1) to the symptomatic side were reduced to 68% of HS ratios (5.7 ± 1.1). Striatal activity in PD patients expressed as percent injected dose was reduced to (55%) of HS (with no difference in occipital uptake). The reduction in striatal activity in the PD patients both in the symptomatic and the 'effectively pre-symptomatic' striatum suggests imaging of dopamine transporters with [I-123]β-CIT may be a useful *in vivo* marker for early diagnosis of PD and possibly for 'pre-symptomatic' mesencephalic dopaminergic degeneration.

ALTERED AMOUNT OF DA TRANSPORTER (DAT), TYROSINE HYDROXYLASE (TH), AND THEIR mRNAs IN MIDBRAIN OF PARKINSON, ALZHEIMER-PARKINSON AND ALZHEIMER'S G. Smutzer*, C. Whittey, A. Myers, M. Bannan and J.N. Joyce. ¹Dept. Psychiatry, Univ. Penn. Sch. Medicine, Philadelphia, PA and ²Dept. Psychiatry, Wayne State Univ., Detroit MI.

We have previously shown that Alzheimer's disease (AD) cases with a Parkinson-like syndrome (AD/Park) show significant (50-80%) losses of [³H]mazindol binding to DAT sites in striatum. However, the majority of cases show normal numbers of DAT sites over midbrain neurons. In contrast, with Parkinson's disease (PD) there are 90% losses in striatum and SNpc. We then examined levels of DA-related proteins and expression of their mRNAs in midbrain neurons of a subset of these same cases. The midbrain of six control (age = 66 ± 13 yrs; PMI = 13 ± 6 hr), AD (76 ± 11 yrs; 7 ± 4 hr); AD/Park (78 ± 5 yrs; 12 ± 5 hr) and PD (74 ± 8 yrs; 8 ± 6 hr) cases were sectioned at 16 μm and then processed for TH immunohistochemistry, *in situ* for DAT mRNA (Bannan et al, 1992, PNAS 89: 7095) and *in situ* for TH mRNA (O'Malley et al, 1987, Biochem 26:6910). In normals there is significantly higher TH protein, DAT binding sites, and TH/DAT mRNAs in the Paraganglionic region of the SN (PN) and the ventral tier of the SNpc than in the dorsal tier of the SNpc. In PD the amount of TH was reduced (-88%) in the ventral tier of SNpc, -62% in dorsal tier of SNpc and -35% in PN. TH was normal in the SNpc and PN of AD and was elevated by 25% in SNpc and 17% in PN of AD/Park cases. TH mRNA was significantly reduced in the SNpc of PD and AD/Park groups but normal in AD. DAT mRNA was significantly reduced in SNpc of PD (-92%) and nonsig in AD/Park (-39%) and AD (-35%). PN was normal in PD (-40%), AD (-14%) and AD/Park (-21%). Whether these markers in midbrain of AD/Park reflects compensatory events prior to cell death (as in PD) or largely independent processes (e.g., protein accumulation in cell bodies) needs to be determined. LEVODOPA-INDUCED BLOOD FLOW RESPONSES IN MIDBRAIN ARE GREATER IN NORMALS THAN IN PARKINSON'S DISEASE PATIENTS. L.W. Tempel*, T.O. Videen, A.S. Snyder, L. Minnich, J.S. Perlmuter. Departments of Neurology and Radiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

We measured regional cerebral blood flow (rCBF) with positron emission tomography (PET) and $H_2^{15}O$ before and after acute administration of levodopa (in combination with carbidopa) in 12 patients (5 females) with Parkinson's disease (PD), Hoehn and Yahr stages 1 and 2, and 5 age-matched normal women (NL). All subjects were pretreated with 200 mg of carbidopa about 2 hrs prior to PET. Regional CBF was measured prior to levodopa and 75 minutes after taking p.o. levodopa 150 mg with carbidopa 37.5 mg. Images were transformed into standard stereotactic space. We split both the PD and NL groups into 2 subgroups to permit response identification and subsequent confirmation in each group. Levodopa produced discrete foci of activation in the range of 5 to 15 % above normalized mean global flow. In the PD group, there were confirmed responses in bilateral midbrain, right frontal cortex and left putamen. Right putamen response only reached $p<0.1$. In the NLs, there were confirmed responses only in right midbrain and right frontal cortex. The relatively low n for NLs limited the power of response confirmation. The bilateral midbrain responses in the NLs were significantly greater than in the PD subjects ($p=0.04$ for MANOVA of bilateral midbrain, bilateral putamen and right frontal cortex responses for NL and PD; post hoc t-tests $p=0.05$ for right and left midbrain). There were no other statistically significant differences between NL and PD. We believe that levodopa-induced blood flow responses provide a powerful tool for investigation of functional changes in dopaminergic neurons and their connections.

A NOVEL METHOD FOR ASSESSING DOPAMINERGIC NEURONAL LOSS IN PARKINSON'S DISEASE

P. Damier^{1,2}, E.C. Hirsch², Y. Agid² and A.M. Graybiel¹. ¹Dept. Brain & Cogn. Sci., MIT, Cambridge, MA 02139; ²INSERM U289, Hôpital de la Salpêtrière, Paris, France.

Parkinson's disease (PD) is characterized by a massive degeneration of dopamine-containing neurons in the midbrain. However, the vulnerability of these neurons is heterogeneous both across different dopaminergic subgroups and within the substantia nigra pars compacta (SNpc), the most affected structure in this disease. To determine the exact pattern of cell loss, it is necessary to have landmarks independent of the degenerative process to subdivide the SNpc. We have developed a calbindin D_{28k} (CaBP) immunostaining protocol for this purpose.

Sets of closely spaced transverse sections (40 μm thick) from the midbrains of three controls and three parkinsonians were processed for CaBP immunohistochemistry. To permit distribution mapping of dopamine-containing neurons in relation to CaBP staining patterns, sets of adjacent sections were stained for tyrosine hydroxylase immunohistochemistry. We found a heterogeneous pattern of CaBP immunoreactivity in the ventral midbrain of the controls. CaBP staining was intense in the SNpc and the SN pars reticulata, and immunostaining appeared to be associated with the neuropil rather than with cell bodies in the SNpc. Within the SNpc, there were conspicuous CaBP-poor zones, which had variable shapes, some being long and thin, others being rounded or branched. Analyzed in serial sections, many of the pale zones seen in individual sections were continuous with one another, forming elements of a branched three-dimensional labyrinth. This organization was consistent from one control to another. Some dopaminergic neurons were located within the CaBP-rich zones, but most of them were densely packed together within the CaBP-poor zones. The CaBP-poor compartments thus can be used to delineate subgroups of dopamine-containing neurons within the SNpc.

The CaBP-positive neuropil staining in the ventral midbrain survived in the PD brains. Moreover, although the CaBP-poor zones were shrunken, their three-dimensional organization was similar to that seen in the control midbrains. We conclude that CaBP immunostaining patterns could be used to calculate very precisely the relative loss of dopamine-containing neurons in the different parts of the SNpc. PRESYNAPTIC SEROTONERGIC MARKERS IN THE DORSAL RAPHE IN PARKINSON'S DISEASE: RECEPTOR AUTORADIOGRAPHY AND *IN SITU* HYBRIDIZATION STUDIES. F. Valdeorriola, R. Cortés, G. Mengod, F. Cruz-Sánchez, J.M. Palacios and E. Tolosa¹. ¹Dept. Neurology, Hosp. Clínic i Provincial, Barcelona E-08036, ²Dept. Neurochemistry, CID-CSIC, Barcelona E-08034, ³Laboratorios Almirall, Barcelona E-08024, Spain.

There exists neuropathological and biochemical evidence indicating that the serotonergic system is affected in Parkinson's disease. The alterations observed include the presence of Lewy bodies in 5-HT cells in the dorsal raphe, a loss of more than 50% of large neurons in this nucleus, and a decrease in the levels of 5-HT and its metabolite 5-HIAA in the cortex and basal ganglia. In addition, in these structures, the binding of several ³H-ligands to the 5-HT transporter is also reduced. In contrast, recent autoradiographic studies have shown unaltered densities of ³H-citalopram binding in some raphe nuclei. In the present work we have examined the binding to the 5-HT transporter and the 5-HT_{1A} receptor in the dorsal raphe of control and Parkinsonian patients using ³H-citalopram and ³H-8-OH-DPAT, respectively. The binding of both ligands in the dorsal raphe in Parkinson's disease was not significantly different from control levels. This contrasts with the reported decreases in 5-HT transporter binding in forebrain regions and loss of 5-HT cells in the dorsal raphe in this disease. One explanation would be that the remaining neurons overexpress the 5-HT transporter in order to compensate for cell loss. We thus examined the mRNA encoding the 5-HT transporter by *in situ* hybridization using a ³²S-labeled oligonucleotide probe. A strong hybridization signal was observed overlaying cell bodies in the dorsal raphe. In the cases examined, the density of autoradiographic grains per cell was higher in Parkinsonian patients compared to normal subjects. These results might reflect an enhanced expression of 5-HT transporter mRNA. The type/s of cells expressing this mRNA remains to be determined.

CHOLINE ACETYLTRANSFERASE IMMUNOREACTIVITY IN THE BASAL FOREBRAIN: POSSIBLE RELATIONSHIP TO PARKINSON'S DISEASE ASSOCIATED DEMENTIA. C. Charlton, and J. Mack. Department of Pharmacology, Meharry Medical College, Nashville, TN 37208.

Excess brain methylation caused Parkinson's disease (PD)-like changes in rats. Alzheimer's type dementia (ATD) is often seen with PD, therefore, it is of interest to determine if methylation is involved in PD-associated-ATD (PDATD). Since the major pathology of ATD is the degeneration of acetylcholine (ACh) neurons in the basal forebrain (BF), experiments were designed to determine if the icv injection of S-adenosylmethionine (SAM), the methyl donor, affects choline acetyltransferase (ChAT) immunoreactive neurons in the BF. ChAT-immunoreactivity (I) was determined. Brightly labelled ChAT-I neurons, ipsilateral and contralateral to the injection side, were seen in the BF of control rats. The ipsilateral BF of the SAM injection rats showed no ChAT-I, but pale ChAT-I neurons were seen in the contralateral BF. SAM caused PD-like impairments. Methylation increases in aging and produces neurotoxins, thus methylation may serve an antitrophic role, depleting dopamine terminals and cholinergic neurons in the forebrain, which will precipitate PDATD in predisposed individuals. Supported by NIH RRO-3032, RO1-28432 and RO1-31177.

LACTOTRANSFERRIN AND LACTOTRANSFERRIN RECEPTOR IMMUNOHISTOCHEMISTRY IN THE MESENCEPHALON OF CONTROL SUBJECTS AND PATIENTS WITH PARKINSON'S DISEASE.

B.A. Faucheux¹*, N. Nillesse², G. Spik², B. Leveugle², J.J. Hauw³, Y. Agid¹, E.C. Hirsch¹. ¹Lab. Physiopathol. Pathogénèse Maladies Neurodégén., INSERM (U289), Hôpital Salpêtrière, Paris; ²Lab. Chimie Biol., CNRS (UMR111), Univ. Sci. Technol., Lille; ³Lab. Neuropathol., Hôpital Salpêtrière, Paris, F-75013, France.

Iron levels are increased in the substantia nigra (SN) of patients with Parkinson's disease (PD). Since this metal catalyzes the formation of highly reactive oxygen free radicals which damage biological molecules, its increase may contribute to the cascade of events involved in nigral neuronal death. A dysregulation of intracellular uptake of this metal by neurons and glial cells may lead to its accumulation in SN. Lactotransferrin (LTF), also called lactoferrin and first discovered in human milk, is supposed to play a role in binding and transport of iron, growth factor activity, antibacterial activity and in immunological processes. LTF and LTF receptor (LTFR) immunostaining have been observed using specific rabbit polyclonal antibodies directed either against LTF or LTFR. Fourty μ m thick sections of paraformaldehyde / picric acid fixed midbrains obtained at *post mortem* from control subjects and PD patients were studied. LTF- and LTFR-immunoreactivity were present on perikarya, apical dendrites and axons of neurons in periaqueductal gray substance, nuclei of the oculomotor nerve, ventral tegmental area, SN pars compacta (SNpc) and locus ceruleus. Astrocytes, oligodendrocytes and endothelial cells of microvessels were also immunoreactive. In the SNpc, some LTFR-positive neurons were melanized (dopaminergic) and some were not; some dopaminergic neurons of controls showed low immunoreactivity however. Quantitative computer-assisted image analysis is in progress to compare PD patients and control subjects. These results suggest that LTF and LTF receptors may be involved in iron accumulation occurring in the SN of PD patients. [Research supported by INSERM, CNRS, ACB, and FdF (grant No 91-5716)]

MENTAL ILLNESS: DEPRESSION, ANXIETY AND SCHIZOPHRENIA

730.1

OLFACTORY BULBECTOMY (OBX) MODEL OF DEPRESSION IN A PRIMATE: BEHAVIORAL EFFECTS IN VERVETS AND REVERSAL BY ELECTROCONVULSIVE TREATMENT (ECT). A. Sattin*, A.S. Kling, R.L. Lloyd, M.J. Balegh and M.T. McGuire. Psychiatry Service, Sepulveda VA & UCLA, Sepulveda, CA 91343.

OBX rats simulate aspects of chronic Major Depression in humans, eg. appetitive learning deficits, abnormal sleep, reduced weight gain and increased corticosterone in plasma. These are not caused by anosmia and are usually reversed by antidepressant treatments, including ECT. Vervets are old world monkeys, closely related to humans, that maintain complex social relationships. Individual and inter-individual social behaviors of four adult females, living in stable social groups, were quantified by trained observers, blind to hypothesis and treatments. Two subjects were OBX'd and two controls were craniotomized without additional surgery. Standardized behavioral measures selected to characterize patterns of social interactions with other group members were grooming, proximity to others, aggression, withdrawal, locomotion and eating. All ss's were assessed during four sequential epochs: 1) Pre-operative, 2) Post-operative, 3) Post-six treatments with anesthesia only: ketamine+I.V. nitroglycerine, to induce hypotension, 4) Post-nine ECT's (under ketamine). All treatments were given in early PM on Mon, Wed & Fri. OBX greatly reduced grooming and proximity and greatly increased withdrawal, all of which were normalized by ECT, but not by anesthesia alone. Aggression increased following OBX, decreased after anesthesia, then increased above pre-op levels after ECT, but aggression didn't change in the sham OBX ss's. Eating decreased after OBX, but ECT increased eating over initial levels in all ss's. Locomotion appeared unaffected by any treatment. If confirmed, these observations will increase the validity of the OBX model of depressive and antidepressant mechanisms. Supported by Research Service, US Dept. of Veterans Affairs.

MAGNETIC RESONANCE IMAGING AND BRAINSTEM EVOKED RESPONSE IN GERIATRIC DEPRESSION. B. Kalavam, R. Bajulaive, RC Young* and GS Alexopoulos. The New York Hospital - Cornell Medical Center, 21 Bloomingdale Road, White Plains, NY 10605.

Introduction Rate-dependent latency shift in brainstem auditory evoked response (BAER) is reportedly associated with occult brainstem pathology. Latency increases in BAER in elderly patients with late age of onset of major depression was previously reported by our group. Preliminary findings are now reported that corroborates the latency change with findings on brainstem magnetic resonance imaging (MRI) in nine elderly depressives (66 to 77 yrs age; mean \pm SD = 71.7 \pm 4.2 yrs) evaluated with MRI and BAER. Psychiatric diagnosis was established using a structured clinical interview. Proton density axial images of the brainstem were classified using criteria proposed by the Consortium for Establishment of a Registry in Alzheimer's Disease (CERAD) as normal, or with probable punctate, or confluent white matter changes. BAER was performed using stimulus rates of 11.4/sec and 80.4 clicks/second and the latency shift for wave V was examined. **Results** Two patients with confluent lesions and one patient with punctate lesions of the lower brainstem had latency shift > 0.4 milliseconds. In these cases depression was of the late-onset type. Among the remaining six patients, latency shift was < 0.4 ms; punctate lesions were detected in two and brainstem imaging was normal in four. Depression was of the early-onset type in five of these six cases. **Conclusion** The above findings need further investigation using a larger sample. In depressed geriatric patients poorer response to antidepressant drug treatment and relapse in the course of illness may be associated with brain morphologic changes. Brainstem imaging and BAER may prove useful prognostic tests in these patients.

A RAT MODEL FOR MANIA: RELATION TO BRAIN AMINES

R. S. El-Mallakh, R. Li, L. T. Harrison, D. G. Changaris, and R. S. Levy*. Dept. of Psychiatry, Biochemistry, Neurology, and Laboratory of Biological Psychiatry, University of Louisville School of Medicine, Louisville, KY 40292.

We previously have described an animal model for bipolar illness patterned after clinical observations of mood-state-related decreases of erythrocyte Na,K-ATPase pump activity in manic and depressed bipolar patients. We duplicated our initial findings by documenting an ouabain dose-related increase in open field locomotor activity over 30 min. following a 5 μ l left lateral intracerebroventricular (ICV) injection of ouabain or artificial cerebrospinal fluid in rats 3 days after ICV cannula placement. Open field activity was increased over controls by ouabain 10⁻⁴M, 0.5x10⁻³M, and reached statistical significance at 10⁻³M ($p < 0.05$). Since human mania is associated with cerebrospinal fluid changes in concentrations of amines and their metabolites, we examined amine concentrations in the hippocampi of the animals. The brains of the animals were harvested immediately following open field testing, which was 30 minutes after ICV injection. Animals were sacrificed with decapitation following halothane anesthesia. The hippocampi were dissected out over ice and frozen at -80°C until analysis. Following sonication, the tissues were extracted over perchloric acid 0.1N. Using an HPLC with a reversed phase column (C-18) and a dual electrochemical detector, the following amines were quantified: dopamine, dihydroxyphenylacetic acid (DOPAC), norepinephrine, homovanillic acid (HVA), serotonin (5HT), and 5-hydroxyindolacetic acid (5HIAA). There were no differences in any of the amines between any of the experimental groups, or between the right and left hippocampi. This finding is surprising given the tremendous increase of activity observed in the high dose animals, and that the injections were made exclusively into the left ICV. Other brain structures and neurochemicals need to be examined.

730.4

REDUCED STIMULATED MONONUCLEAR LEUKOCYTE (MNL) ADENYLYL CYCLASE (AC) ACTIVITY IS ASSOCIATED WITH ELEVATED G α AND G β LEVELS IN BIPOLAR DISORDER (BD). J. Warch*, L.T. Young, P.P. Li, A. Kamble and R.T. Joffe. Clarke Institute of Psychiatry, Toronto, Ontario, Canada, M5T 1R8.

We previously reported higher postmortem cerebral cortical levels of the stimulatory G protein α -subunit, α_s , in BD compared with control subjects (Young et al., J. Neurochem. 61:890, 1993). Levels of α_s and the inhibitory G protein α -subunit, α_i , were also increased in MNLS from BD but not major depressive disorder (MDD) subjects (Young et al., Am. J. Psychiat. 151:594, 1994). In the present study, the functional consequences of these G protein changes were assessed in MNL membranes from BD and MDD subjects by determining basal, GTP γ S- (10 μ M), NaF- (10 mM) and forskolin (100 μ M)-stimulated AC activity. Subjects included depressed BD (N=9; age=31.4 \pm 8.4 [mean \pm SD]; 4f,5m; HAM-D=22.7 \pm 1.93) and MDD (N=9; age=35.8 \pm 6.8; 7f,2m; HAM-D=18.4 \pm 0.77) patients compared with age-(35.2 \pm 9.5 and 35.5 \pm 7.8, respectively) and sex-matched healthy controls. In BD subjects, MNL membrane GTP γ S- and NaF-stimulated AC activity, expressed as a percent of basal values, were significantly reduced (GTP γ S=31.8%, paired t =2.36, p <0.05; and NaF=18.7%, t =2.4, p <0.05; respectively versus controls), whereas forskolin-stimulated AC activity showed a non-significant reduction (24.1%, t =2.17, 0.1 p >0.05) and basal AC activity was not different (t =0.8, p =0.4) from that in healthy subjects. In comparison, basal MNL membrane AC activity was significantly reduced in MDD subjects (-26%, t =2.7, p =0.027) compared with matched controls but GTP γ S-, NaF- and forskolin-stimulated AC activity did not differ. Thus, despite higher MNL α_s levels in BD compared with healthy subjects, G protein-coupled AC activation is reduced in these cells contrasting with the possible enhanced functional state of this signal transduction process found in postmortem BD cerebral cortex (Young et al. J Neurochem. *ibid*). This difference, however, may be attributed to more effective compensatory adaptations in inhibitory control of AC activity and/or AC levels in MNLS than in cortex of BD subjects. (Supported by grants from the NAMI Stanley Foundation and MRC Canada).

VOLUMETRIC STUDIES IN LATE LIFE DEPRESSION USING MRI. A. Kumar, D. Miller, L. Burke, W. Ball*, D. Ewbank, S. Samuels, G. Gottlieb. Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The purpose of the study was to examine the volumes of ventricular, sulcal and whole brain cerebrospinal fluid (CSF) spaces in subjects with late life depression and to compare these indices to healthy age-matched controls and subjects with probable Alzheimer's disease (DAT). Using a 1.5 tesla GE Signa scanner, we studied 24 subjects with late life depression (15 W, 9 M, Mean age 73.7 SD 7.45), 29 healthy controls (17 W, 12 M, Mean age 67.2 SD 8.45) and 34 subjects with DAT (17 W, 17 M, Mean age 66.4 SD 8.56). All depressed subjects met DSM-III-R criteria for major depressive disorder and had Hamilton depression scores of greater than 15 (Mean 19.7 SD 3.84). All subjects were medically stable and free of significant other neuropsychiatric disease. Proton density and T2 weighted images were used to maximize the contrast between brain and CSF. A semiautomated boundary program and segmentation algorithm were used to differentiate brain tissue from CSF. On normalized measures of ventricular and whole brain CSF, depressed subjects had larger volumes in both hemispheres when compared to the control subjects ($p < 0.01$), as did the DAT subjects. When depressed and DAT subjects were compared, subjects with DAT had larger whole brain and right hemisphere CSF volumes and total and right hemisphere sulcal CSF volumes ($p < 0.05$). These data suggest that widespread structural brain changes underlie late life depression and may be significant in the pathogenesis of mood disorders in late life.

730.7

EVIDENCE FOR INCREASED CONCENTRATIONS OF NEUROPEPTIDE Y IN PLASMA OF PATIENTS WITH PANIC DISORDER. S. Bouali*, J.P. Boulenger, I. Jerabec, R. Leduc, F. Jolicoeur and A. Cadieux. Departments of Psychiatry and Pharmacology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4

Recent experimental evidence suggests that neuropeptide Y (NPY) is involved in the modulation of anxiety-related behavior in rodents. Furthermore, NPY's physiological effects are strongly associated with those of noradrenaline, a neurotransmitter involved in the expression of anxiety symptoms in humans both at the central and at the peripheral levels. The aim of the present study was to assess the relationship between NPY plasma concentration and anxiety levels in both normal volunteers ($n=13$) and patients ($n=13$) fulfilling the DSM-III-R criteria for panic disorders with or without agoraphobia. Plasma levels of NPY-like immunoreactivity (NPY-Li) were measured in duplicate using a radioimmunoassay developed in our laboratory with detection limits being 7 pg/100 μ l. The first results of this study suggest that, compared to normal controls, the baseline NPY-Li levels of panic disorder patients is increased (75 ± 10 pg/ml vs. 130 ± 8 pg/ml respectively). This difference was statistically significant, $p < 0.05$.

730.9

CARDIOVASCULAR, RESPIRATORY AND PARASYMPATHETIC ACTIVITY IN PANIC DISORDER, POST-TRAUMATIC STRESS DISORDER AND NORMAL CONTROLS. G.N.M. Gurguis*, J.C. Choate, D. Anti-Otong, R. Andrews, F. Pettv, and A. J. Rush. Dallas VA Medical Center and Department of Psychiatry, UT Southwestern Medical School, Dallas, TX 75216.

Although increased autonomic activity is observed in panic disorder (PD) and post-traumatic stress disorder (PTSD), it is unclear if autonomic pathophysiology is similar or different in these disorders. Heart rate (HR), systolic (SBP), diastolic (DBP), mean arterial pressure (MAP), respiratory rate (RR), indices of respiratory sinus arrhythmia (heart period variance, HPV, heart range, HR, and vagal tone, VT) were monitored while supine and for 10 minutes after standing in 19 normal controls (NC), 18 PD and 16 PTSD patients. There were overall trends for higher resting cardiovascular measures in PD and PTSD. PD patients had higher RR (NC: 15.37 ± 2.5 vs PD: 18.52 ± 3.5 , $p < 0.02$) and a trend for a higher anion gap and lower potassium levels than NC or PTSD patients. In response to standing, 3-way repeated measures ANOVA showed: (1) significant elevations in cardiovascular measures and a drop by 15% in VT in all three groups. (2) PD patients had statistically significantly lower SBP, DBP, and MAP, but normal HR, responses than NC and PTSD patients. (3) PTSD had statistically significant group x time interaction in SBP only while other cardiovascular measures fell on a continuum between NC and PD. (4) PD patients, but not PTSD, had statistically significant group x time interactions in HPV and HR which showed a rebound increase 8 minutes into standing. These observations suggest that abnormal respiratory function may be specific to PD and that the profile of abnormal cardiovascular and parasympathetic responses may be different between PD and PTSD.

Calcium dependency of the release of DA and 5HT from CNS slices from animals subjected to models of depression. E.H. Jaffé*, V. DeFrías, C. Ibarra. Lab. Neurochemistry, IVIC, Apdo. 21827, Caracas 1020-A.

5HT and DA systems have been implicated in the physiopathology of depression. Previously (Neurosci. Lett. 162:157,1993) we showed an increased K stimulated release of 5HT from hippocampus (Hip) and inhibition of the basal release from Hip, n. accumbens (n. acc) and prefrontal cortex (PFC) of animals subjected to forced swim test and chronic isolation. Here we study the Ca dependency of the release of DA and 5HT from these 3 CNS structures. Slices were incubated in a static chamber system. DA and 5HT release measured by HPLC with electrochemical detection. K (30 mM) stimulated DA release was only significantly higher in n. acc of isolated animals and inhibited with Cd (150 μ M) a Ca channel blocker. 0Ca-10mM Mg inhibited at the same degree release of control and isolated animals. A similar pattern was seen with the K stimulated release of 5HT from n. acc and Hip which were significantly increased in isolated animals, showing a greater inhibition with Cd than controls. Basal DA release was similar in control or isolated animals from the 3 CNS structures with a strong and significant inhibition of the release in 0Ca/Mg Krebs from isolated animals but not from control. A greater sensitivity to Ca blockade of the Ca dependent DA and 5HT release from isolated animals is suggested.

SODIUM LACTATE INFUSIONS IN AN ANIMAL MODEL OF PANIC DISORDER: FURTHER STUDIES. A. Shekhar*, S.R. Keim, J.R. Simon and W.J. McBride. Dept. of Psychiatry, Indiana University Medical Center, Indianapolis, Indiana 46202.

GABA_A receptor blockade in the dorsomedial hypothalamus (DMH) of rats elicits a panic-like response. Our preliminary studies have shown that rats that have inhibition of GABA synthesis in the DMH are susceptible to physiological arousal by lactate infusion similar to patients with panic disorder. To characterize this response further, rats equipped with femoral arterial and venous catheters were chronically infused with L-alylglycine (L-AG, active isomer whose metabolite blocks glutamic acid decarboxylase, GAD) or D-alylglycine (D-AG, inactive isomer) via Alzet mini-pumps implanted unilaterally in the DMH. Infusion of 0.5N sodium lactate (10 ml/Kg, i.v.) elicited significant increases in heart rate and blood pressure after 4, 7 or 14 days only in rats with L-AG pumps and not D-AG pumps. Rats with L-AG pumps also showed increased "anxiety" in the plus-maze and social interaction tests as well as decreased GABA content in the DMH when compared to rats with D-AG pumps. These results further strengthen this animal model of panic disorder. (Supported by MH 45362)

PLASMA PROTEIN PATTERN VARIATIONS IN SCHIZOPHRENIA. A. Brett Larive, Dale M. VanderPutten, Carl R. Meril*, Laboratory of Biochemical Genetics, NIMH, Washington, DC 20032 and Monoclonetics International Inc., Houston, TX 77027.

Plasma protein patterns in 2-D gels from monozygotic twins discordant for schizophrenia were found to be significantly less alike than the protein patterns of normal monozygotic twins and monozygotic twins concordant for schizophrenia. The ELSIE 5 2-D gel analysis program found significantly ($p < 0.01$) fewer protein spot matches between discordant monozygotic schizophrenic twins than either normal monozygotic twins or concordant monozygotic schizophrenic twins. The relative silver stained intensity of matched plasma proteins was also found to vary to a greater extent between monozygotic twins discordant for schizophrenia. Several polypeptide spots were elevated only in the schizophrenic twin. One of these proteins was also found to be significantly ($p < 0.0001$) elevated in the plasma of unrelated schizophrenic individuals ($n = 75$). Additionally, we found differences in plasma haptoglobin levels between monozygotic twins discordant for schizophrenia suggesting variations in liver metabolism.

730.11

MITOGENIC RESPONSE TO BASIC FIBROBLAST GROWTH FACTOR (bFGF) TO EPIDERMAL GROWTH FACTOR (EGF) OF SKIN FIBROBLASTS FROM FIRST-EPISODE PSYCHOTIC PATIENTS. J. Mahadik, N. S. Shendarkar, R. Scheffer, E. E. Correnti, S. Mukherjee*, S. P. Mahadik. Dept. of Psychiatry & Health Behavior, MCG & VAMC, Augusta, GA 30912.

There is increasing evidence that abnormal brain development is involved in schizophrenia. Among several factors, growth factors play critical roles in brain developmental processes: neuronal proliferation, maintenance, survival and maturation. Since molecular mechanisms of their mitogenic actions are common across cell types, cultured skin fibroblasts were used to investigate such mechanisms. The mitogenic responses of bFGF and EGF was examined in fibroblasts from first-episode, drug-naïve psychotic patients (N=10) and normal controls (N=10). Known number of fibroblasts were first synchronized by serum starvation for 24 hr. and then growth factors were added in serum containing medium, and growth was continued. The final number of cells was counted on 7th day. Growth response was determined as % change in cell number. As expected, fibroblasts from normals showed increased mitogenic response (mean% \pm sem, bFGF=150.1 \pm 9.7, EGF=192.7 \pm 11.99). However, the mitogenic response was reduced in fibroblasts from patients (bFGF=90.8 \pm 4.64, $p<.0001$; EGF=144.4 \pm 17.74, $p<.04$). Further studies on underlying receptor-mediated processes will be presented.

730.13

EVALUATION OF NEURAL-IMMUNE ACTIVATION IN CSF OF PATIENTS WITH SCHIZOPHRENIA. G.R. Heninger*, P. Rao, L. Karper, M.P. Heyes and J. Krystal. Dept. of Psychiatry, Yale Univ. and West Haven Veterans Admin Hosp., New Haven, CT 06510 and Lab Clin. Science, NIMH, Bethesda, MD 20892

There is evidence that infectious and/or abnormal neural-immune mechanisms may be involved in schizophrenia. To evaluate this possibility, 6 measures sensitive to neural-immune activation were assessed in the CSF of 21 male patients (mean age: 41) with schizophrenia (SCH) in comparison to 16 healthy controls (HC) (mean age: 35). Quinolinic acid (QUIN), was measured by GC/MS, and interleukins (IL1B, IL2, and IL6), tumor necrosis factor alpha (TNF alpha) and beta 2 microglobulin (B2MG) by double antibody ELISA.

Mean QUIN levels in SCH were increased by 24% over those in HC (18.7 vs 15.0 nM/L respectively, $P<.04$ Chi square). Mean IL6 and B2MG levels did not differ between SCH and HC (2.4 vs. 2.2 pg/ml and 1.3 vs. 1.4 uE/ml respectively). Levels of IL1B, IL2, and TNF alpha did not differ between SCH and HC since 82vs88; 100vs100, and 71vs81% respectively, had levels below the lower detection limits of the assay.

The relatively small 25% increase in QUIN levels in SCH is less than the 200-500% increase seen in early stage HIV infected patients. The data suggest that a strongly active and abnormal neural-immune process is not occurring in the large majority of these chronic SCH patients. Supported by MH25642, the Stanley Foundation and WHVAMC Schizophrenia Center.

730.15

FIRST BREAK PSYCHOSIS AND PLASMA HOMOVANILIC ACID. R. Scheffer, B.L. Diamond*, R.L. Borison, E.E. Correnti, and S. Mukherjee. Dept. of Psychiatry, Eisenhower Army Hosp. and Med. Coll. of GA, Augusta, GA 30912.

Plasma homovanillic acid (pHVA) levels were examined in 17 patients during their first episode of psychosis before initiating neuroleptic treatment and in 8 normal controls. The effect of neuroleptic treatment was assessed after 3 weeks "doctor's choice" treatment. The mean age of patients was 22.88 yrs and the mean duration of psychosis at entry to protocol was 4.44 days (range 2-10). At six months follow-up, 14 patients met DSM-III-R criteria for schizophrenia. Baseline pHVA (8.68 \pm 2.4 ng/ml) and post-treatment pHVA (8.04 \pm 2.7 ng/ml) both were significantly lower in patients than in normal controls (14.5 \pm 3.6 ng/ml) ($P=.001$ for both comparisons). Change in pHVA levels was not correlated with change in clinical state after neuroleptic treatment. However, lower baseline pHVA levels were associated with less improvement of both positive ($r=-.54$, $P=.05$) and negative ($r=-.65$, $P=.02$) symptoms. These findings are consistent with low pHVA in early age of onset postmortem studies showing chronic presynaptic dopaminergic underactivity in early onset patients. In summary, our findings indicate that, in some patients, pHVA is low at the very onset of psychosis and this is associated with a suboptimal early response to neuroleptic treatment.

730.12

UPTAKE OF ESSENTIAL FATTY ACIDS IN SKIN FIBROBLASTS FROM SCHIZOPHRENIC PATIENTS. N. S. Shendarkar, S. Mukherjee, J. Mahadik and S. P. Mahadik*. Dept. of Psychiatry and Health Behavior, MCG&VAMC, Augusta, GA 30912.

A generalized abnormal plasma membrane phospholipid (PL) metabolism exists in schizophrenia. Abnormality is predominantly in the distribution of esterified polyunsaturated fatty acids (EPUFAs) of essential fatty acids (EFAs: linoleic, LA and linolenic, ALA). The underlying mechanisms are unclear. The cellular uptake of EFAs and conversion to PUFAs are critical for the quantity and quality of PLs. It is difficult to investigate these processes *in vivo* or using easily available tissues or blood cells *in vitro*. Cultured skin fibroblasts are well suited for this. The uptake of EFAs in fibroblasts was compared in three schizophrenic patients with normal controls matched for age, sex and race. Cultures were synchronized by serum starvation for 24 hr. and then grown in serum containing medium for next 24 hr., and fatty acid uptake was determined as pmoles/mg protein for 30 min. The uptake of both the fatty acids was normal in fibroblasts from patients with LA:ALA ratio of 1:1 (means \pm SEM for LA, $P=139.5\pm26.54$, $N=108.83\pm22.77$; for ALA, $P=73.4\pm8.07$, $N=54.57\pm8.39$) and 20:1 (LA, $P=504.37\pm192.33$, $N=317.47\pm119.49$ and for ALA, $P=31.3\pm11.11$, $N=15.83\pm5.81$). Data indicate that reported lower levels of membrane fatty acids may be a result of defective conversion into EPUFA and incorporation into functional lipids.

730.14

ALTERED CYCLIC AMP RESPONSE TO PROSTAGLANDIN E₁ AFTER PROTEIN KINASE C ACTIVATION IN EBV-TRANSFORMED B-LYMPHOCYTES FROM SCHIZOPHRENICS. N. Natsukari*, R. J. Wyatt, I. Baker, E. F. Torrey, H. Kulaga and J. M. Masserano. Neuropsychiatry Branch, NIMH Neuroscience Center, Washington, D.C. 20032.

Cyclic AMP (cAMP) accumulation was evaluated in EBV-transformed human B-lymphocyte cell lines from normal and schizophrenic individuals. Each cell line showed characteristic individual responses to PGE₁, a prostaglandin agonist, isoproterenol (Iso), a β -adrenergic agonist, phorbol 12-myristate-13 acetate (PMA), an activator of protein kinase C (PKC) and staurosporin (STP), an inhibitor of PKC. PGE₁ significantly elevated cAMP accumulation. Iso produced a slight but non-significant increase in cAMP accumulation. Pretreatment of the cells with PMA (10^{-8} M) significantly enhanced cAMP accumulation following treatment with Iso. STP reduced the potentiation of cAMP accumulation produced by PMA plus Iso (1μ M). In contrast, STP enhanced cAMP accumulation following treatment with PGE₁ (10μ M) plus PMA. Cell lines from controls showed a significantly greater cAMP response following treatment with PGE₁ plus PMA compared with the cell lines from schizophrenic patients. These data suggest that a deficit may exist in the PKC and/or PGE₁ response systems in schizophrenic patients.

730.16

QUANTITATION OF NEUROTENSIN AND METABOLITES IN CSF OF PATIENTS WITH SCHIZOPHRENIA. P.D. Butler*, D.J. Printz*, F. Issa*, J.M. Gorman*, R.E. Carraway*. Psychiatry Service, DVAMC, NY, NY 10010*, Dept. Clinical Psychobiology, NY State Psychiatric Instit. NY, NY 10032*, Neuropsychiatry Branch, NIMH, Washington, DC 20032*, U. Mass. Med. Center, Worcester, MA 01655*.

Neurotensin (NT), an endogenous neuroleptic tridecapeptide, and its metabolites were quantitated in CSF collected at 8 AM from patients diagnosed with schizophrenia. CSF was placed into enzyme inhibitors on ice and 8-12 ml was subjected to HPLC and RIA using N- and C-terminal antisera. NT added to CSF was recovered in good yield. Direct assay of CSF ($n=12$) gave more N-terminal (mean \pm SEM; 7.1 ± 1.0 fmol/ml) than C-terminal (< 2 fmol/ml) immunoreactivity. Quantitation after HPLC ($n=4$) gave the following constituents (fmol/ml corrected for 80% yield; mean \pm SEM): NT (0.8 ± 0.2); NT¹⁻¹¹ (6.8 ± 0.8); NT¹⁻¹¹ (1.6 ± 0.2); NT¹⁻¹² (0.7 ± 0.2). These results indicate that the levels of HPLC-identified NT in patient CSF are 50-200 fold lower than previously reported (Lindstrom et al. Schizophrenia Res. 1:55-59, 1988; Garver et al. Am J. Psychiatry, 148:484-488, 1991) and that the metabolite, NT¹⁻¹¹, is the predominant form present. Future studies aim to determine whether patients with schizophrenia metabolize NT differently from controls.

730.17

REGIONAL CEREBRAL GLUCOSE USE IN SCHIZOPHRENIC PATIENTS BEFORE AND AFTER HALOPERIDOL WITHDRAWAL. D.R. Medoff, H.H. Holcomb, G.K. Thaker, R.F. Dannals, C.A. Tamminga, M.P.R.C., University of Maryland, Baltimore, MD 21228.

Chronic use of antipsychotic drugs produces therapeutic effects on psychosis, concurrent side effects, and neurochemical changes in selected transmitter systems. Much is known about the chronic effect of these drugs on D₂ and GABA_A receptors, dopamine (DA) turnover, and DA neuronal activity. However, the integrated functional effect of chronic antipsychotic drug administration in human brain is less well studied, as are the consequences of its withdrawal. We report here results of a within-subject study of regional cerebral glucose metabolism (rCMRglu) with chronic haloperidol (HAL) in three different states: on HAL treatment, after a 5-day withdrawal, and after 30 days in a drug-free state. Differences between the on-HAL state and the drug-free (30 day) state were found in the caudate and putamen (8% and 7% increase respectively), the thalamus (9% increase), frontal cortex (4% decrease) and cingulate (8% decrease). At the five day withdrawal time, based on our previous studies of supersensitivity phenomena in patients, we had predicted rCMRglu findings consistent with supersensitivity. Examples from representative structures are presented in the Table. After five days of withdrawal, no significant changes from the on-HAL scan were apparent in rCMRglu in the brain areas analyzed. These data fail to provide functional metabolic evidence of withdrawal supersensitivity.

	on HAL	5 days off	30 days OFF
R caud	8.1 (2.9)	8.02 (3.19)	7.5 (1.8)
R thal	7.4 (3.2)	7.50 (3.1)	6.5 (2.4)
R STG	7.6 (3.5)	7.0 (2.7)	8.2 (3.4)

730.18

EFFECTS OF THE NMDA ANTAGONIST KETAMINE ON CEREBRAL BLOOD FLOW PATTERNS IN SCHIZOPHRENIC PATIENTS. A.C. Lahti, H.H. Holcomb, M. Zhao, D. Medoff, R.F. Dannals, C.A. Tamminga, MPRC, University of Maryland, Baltimore, MD 21228 and The Johns Hopkins University, Baltimore, MD 21205

To evaluate glutamatergic transmission in the pathophysiology of schizophrenia, we have studied the action of the NMDA antagonist ketamine in symptomatic inpatients. Research protocols were approved by the University of Maryland IRB. Three subanesthetic doses of ketamine (0.1, 0.3 and 0.5 mg/kg) and placebo were given to schizophrenic patients in a double blind injection study. Ketamine worsened mental status 20 minutes after injection in a dose sensitive fashion, selectively on positive psychotic symptoms. Now we have determined regional cerebral blood flow changes in medicated schizophrenic patients given acute ketamine (0.3 mg/kg). Three ¹⁵O water cerebral blood flow PET scans were completed prior to drug administration and seven scans, at timed intervals, after ketamine. Data were analyzed using Statistical Parametric Mapping (Friston, 1991). The three baseline scans were combined and compared with the two most proximal post infusion scans from three subjects. The brain regions significantly affected by ketamine were the cingulate cortex and dorsomedial thalamus. Hippocampal activity elevations were also evident in individuals. Ketamine-induced activity changes in the cingulate and thalamus may partially account for its psychotomimetic effects.

INTRACEREBRAL TRANSFECTION USING CATIONIC SYNTHETIC LIPID: AN ALTERNATIVE TO VIRAL VECTOR IN C6 GLIOMA "SUICIDE GENE" THERAPY. F. Berger, J.M. Vicat, M. Lainé, D. Crapari, H. Chen, G. Amalfitano, J.F. Brunet, L. Molin, M.F. Nissou, J.M. Verna, A.L. Benabid, INSERM U 318, BP 217X GRENOBLE 38043 Cedex 09 FRANCE.

Therapeutical trials have begun in human gliomas using retroviral transfection. It confronts us with the ethical problem of the use of vector obtained from infectious agents. For these reasons we investigate direct in vivo transfection using the synthetic vector DOTAP.

We used the "suicide gene" Herpes thymidine kinase (TK). It transforms the antiviral ganciclovir in toxic phosphorylated components and induces a bystander effect which explains that no more than 10 to 20 % of the cells need to be transfected.

DOTAP injected in normal rat brain did not induced any histological damages. In vitro killing of C6 cells transfected with TK and treated with GC was observed. A single stereotaxic TK transfection induced focal necrosis and no more than 50% volume reduction. Then, we used intratumoral cannula providing intratumoral targeting and repeated transfections. In these conditions we observed dramatic tumor regression. When TK was injected outside the tumor we did not observed histological damages in the brain itself conforting the absence of toxic effect of TK transfection in non dividing cells.

These results suggests that the DOTAP vector is as efficient as retroviral vector in a "suicide gene therapy" for experimental glioma. It confort a phase I study in humans using repeated transfections through a rickham intra-tumoral delivery.

COMPLETE REGRESSION OF EXPERIMENTAL BRAIN TUMORS TREATED WITH A HERPES SIMPLEX VIRUS (HSV) MUTANT AND GANCICLOVIR. M. Chasse, E.J. Boviatsis, Miguel Sena-Esteves, X.O. Breakefield, and E.A. Chiocca* Molecular Neurogenetics and Neurosurgery, Massachusetts General Hosp.-East, Charlestown, MA 02129.

Transfer of the HSV thymidine kinase (TK) gene into tumors has been shown to confer chemosensitivity to ganciclovir. Retrovirus or adenovirus vectors have been used to achieve TK gene transfer to tumors *in vivo*. These vectors cannot spread throughout a tumor mass due to their inability to replicate. To overcome this limitation, we have employed viral vectors, based on HSV, that selectively replicate in tumor cells in the brain based on complementation of the HSV defect by dividing mammalian cells. We stereotactically inoculated an HSV mutant (designated as hrR3, from Dr. S. Weller, U. Conn.), that possesses an intact TK gene, but has a defective ribonucleotide reductase (RR) gene, into 9L gliosarcomas, previously established into the frontal lobes of rats (n = 41). Control rats received an injection of: 1) an HSV mutant (designated as RH105, obtained from Drs. D. Ho and E. Mocarski, Stanford), that possesses a defective TK gene and an intact RR gene, (n = 21) and 2) medium alone (n = 20). Seven days later, half the animals from each group received intraperitoneal injections of saline or ganciclovir for seven days. Ten out of 21 rats from the hrR3 plus ganciclovir group and 4/20 from the hrR3 plus saline group survived more than 90 days after which they were sacrificed. Rats from the other groups did not survive more than 40 days (p < 0.001, Kruskal-Wallis one way ANOVA). Histological analysis revealed the occurrence of extensive tumor necrosis during ganciclovir treatment in the hrR3 group. Selective HSV-mediated gene expression could also be assayed in the tumor before and during ganciclovir treatment by staining for β -galactosidase (both hrR3 and RH105 contain a lacZ gene). These findings indicate that HSV mutant vectors that retain an intact TK gene can confer dramatic tumor sensitivity to ganciclovir.

A NOVEL HERPES SIMPLEX VIRUS "PIGGY BACK" PACKAGING SYSTEM FOR AMPLICON VECTORS. Peter Pechan, E. Antonio Chiocca, Maureen Chasse, Richard Thompson, David P. Corey* and Xandra O. Breakefield. Depts. Neurology and Neurosurgery, Massachusetts General Hospital, Harvard Medical School, Boston MA 02114; *Dept. Mol. Genetics, University of Cincinnati Medical Center, Cincinnati, OH 45267.

Herpes virus type 1 (HSV-1) vectors have proven to be efficient at transgene delivery to neurons and other cell types in culture and *in vivo*. In the recombinant virus system transgenes are incorporated directly into the HSV-1 genome. In the amplicon system a plasmid bearing the HSV-1 origin of DNA replication and a packaging signal, as well as a transgene, is packaged into virions through the aid of a helper virus. These two systems can be combined by making propagation of the vector and helper viruses mutually dependent on each other. In this study we are characterizing an amplicon "piggy-back" vector system that uses a viral promoter to express a gene essential for HSV-1 replication, propagated with a mutant virus deleted in the same replication-essential gene. We have constructed amplicon vectors bearing the immediate early ICP4 gene under the control of the SV40 and the glial specific JC virus promoter elements. These promoters can be used to regulate expression of both ICP4 and another gene in one amplicon using an IRES translational read-through element. As a helper virus we have used the ICP4 deletion mutant d120 from Dr. Neal DeLuca, Univ. Pittsburgh, propagated on Vero cells or U87 glioma. The presence of helper virus recombinants was analyzed by PCR and Southern blots of Vero plaque lysates. Current data indicate that this novel packaging system has markedly delayed cytopathic effects as compared to wild type virus, and should prove useful for transgene delivery to neurons. This system provides a basic model which can be modified to include cell-specificity of vector propagation and inclusion of multiple transgene elements.

Herpes virus mutants offer a potential therapeutic alternative to conventional treatment modalities for malignant brain tumors. The rationale for this approach is that these genetically mutant viruses replicate preferentially in tumor cells and not within cells of the nervous system, which are generally post-mitotic. Thus, they selectively lyse tumor cells within the CNS. We have used a neuro-attenuated Herpes Simplex Virus type I (strain 1716) for *in vitro* and *in vivo* studies. *In vitro*, HSV-1716 is efficient at lysing human NTERA-2 (a teratocarcinoma cell line) cells and two medulloblastoma lines DAOY and D283. *In vivo*, HSV-1716 regresses human NTERA-2 brain tumors in nude mice and prolongs their survival relative to mock treated, tumor bearing mice. We documented the pathology over time associated with tumor formation and HSV treatment using Magnetic Resonance Imaging and immunohistochemical localization of HSV and tumor cells. We have also observed that viral replication is limited to the tumor as predicted. Thus, our results suggest that this is a feasible approach for the treatment of malignant brain tumors.

Long-term Observations of Thymidine Kinase Deficient HSV-1 Infection in the Rat Brain

William W.-G. Jia*, Jiren Tan, Max Cynader, Frank Tufaro and James Goldie
Department of Microbiology, University of British Columbia and Medical Oncology, BC Cancer Agency, Vancouver, BC, Canada

We have been using Herpes simplex virus to deliver foreign genes into the nervous system and to treat brain tumors. As a human pathogenic virus, the HSV-1 in its wild type form has been well known to cause clinical symptoms, including severe encephalitis. We have recently demonstrated the effectiveness of the HSV-1 viral vectors in both gene expression and tumor-cell killing (Jia, McDermott, Goldie, Cynader, Tan, and Tufaro., J.Nat.Canc.Inst.,1994 in press) in the present study, we have investigated pathogenic effects of the viral vectors in animals that survived at least 18 months after treatment. Rats were intracerebrally injected with 1 µl (108 pfu) of KOS-SB, a thymidine kinase defective HSV-1 mutant (tk(-) HSV-1). Animals that survived at least 18 months without showing any sign of illness before sacrificed, and brain tissue was sectioned for histological and immunocytochemical observations. Nissl stains showed a significant enlargement of the lateral ventricles in both hemispheres. Otherwise, the histology of other brain regions appeared normal. Immunocytochemistry with a polyclonal antibody for the HSV-1 virus failed to detect any viral antigen in these long-term survived animals while positive immunoreaction could be seen in brains of animals 7 days after viral injection. In these "short-term" animals, cells in the paraventricular regions showed strong reaction to the antibody staining. Monoclonal antibodies against major histocompatibility complex (MHC) antigens were also used to detect possible immune and inflammatory responses to the viral invention. No immunopositive cells were found in brains of the long term rats. Our results suggest that, although intracerebrally injected tk(-) HSV-1 virus caused mild encephalitis, the damage was limited and long term effects were minor. The failure to detect antigens of both the virus and MHC in long term animals further suggests that any damage observed resulted from an acute response rather than a chronic effect.

ADENOVIRUS-MEDIATED GENE THERAPY FOR EXPERIMENTAL PRIMARY AND METASTATIC BRAIN TUMORS A. Colak, M.J. Perez-Cruet, T.W. Trask, S.H. Chen, J.C. Goodman, S.L.C. Woo, R.G. Grossman, and H.D. Shine Neurosurg., Cell Biol., Path., and Howard Hughes Inst., Baylor College of Medicine, Houston, TX 77030.

The therapeutic efficacy of adenovirus-mediated transduction and ganciclovir (GCV) administration was tested in models of primary and metastatic brain tumors. A replicative-defective recombinant adenovirus vector (ADV-tk) was created that contained the herpes simplex virus thymidine kinase (HSV-tk) gene controlled by the Rous sarcoma virus LTR. HSV-tk phosphorylates GCV which acts as a chain terminator of DNA synthesis and selectively kills dividing cells. Syngeneic tumors were generated by injection of cultured glioma (9L) or breast tumor cells (MAT-B) cells into the rat caudate. Eight days after tumor cell injection, ADV-tk or a control adenovirus carrying the β-gal gene was injected into the tumors. The animals then were treated twice daily for 6 days with GCV or saline. Twenty days after tumor cell injection, the brains were examined microscopically and tumors were measured. Control rats in both models had large tumors. Rats treated with ADV-tk and GCV had no tumors at the primary site. Necrosis with macrophage and lymphocyte infiltration was present. In survival tests, control rats lived only 22 days after 9L cell injection. Treated rats lived 125 days when they were examined and found to have no residual tumors. These results demonstrate that adenovirus-mediated transfer of the HSV-tk gene confers cytotoxic sensitivity to GCV to tumors *in vivo*.

KEY WORD INDEX

The *Abstracts* Volume 20 Key Word Index is printed on the following pages. This subject index uses a permutation process to create an index entry for every key word in the abstract title. Key words are placed at the beginning of the center column of the index and the program numbers in the right column. Text reading left and right of the key word is retained for understanding in context. A slash (/) shows the end and the beginning of the author's title. Space limitations do not permit the full abstract title to be printed. Words with limited search value are not listed as key words. The BioSciences Information Service Subject Index is used by many scientific organizations and has become the standard in computerized scientific indexes.
