We describe a novel method with unique advantages for the Golgi-like labeling of single neurons identified and recorded extracellularly. This procedure involves the use of fine glass micro-pipettes (tip diameter about 1 µm), which contain biocytin, Neurobiotin or biotin dextran dissolved in a salt solution (1.5% in 0.5 M NaCl or K-acetate), for the simultaneous juxtacellular recording and tracer iontophoresis. Low intensity positive current pulses (< 5 nA, 200 ms on/200 ms off, 5 to 30 mn), injected through the bridge circuit, modulate cell firing such as to keep it alive. Survival periods of 3-24 h (for biocytin or Neurobiotin) and of up to 4 days (for biotin dextran) yielded the best dendritic and axonal stainings. Rat thalamocortical cells, for instance, which were juxtacellularly labeled, could be traced to their most distal axonal processes in the cortex. Electrophysiological and histochemical data show that neuronal filling occurs during a cellular micro-puncture, electrically-induced at a somatic or dendritic membrane patch. Control experiments consisting in the selective killing of previously injected cells provide convincing evidence it is the stained unit that was recorded extracellularly and "tickled" by the juxtacellular iontophoretic pulses. This single-cell staining method has been used to label several types of rat brain neurons, including interneurons. Its success rate (85-100 %) far exceeds that obtained by direct intracellular injections of tracers as shown by the labeling of a large sample of 98 individual cells (from 113 attempts) in the thalamic reticular nucleus of 32 rats.

Provide care is taken to avoid the possible drawbacks and pitfalls that are illustrated and discussed, this novel juxtacellular staining method represents an ideal directed Golgi-like labeling tool for studying relationships between the structure and function of individual central nervous system neurons. *Supported by a grant from MRC of Canada to M. Deschênes.*

A NOVEL NEURAL TRACER USING THE PIG PARAMYXOVIRUS OF THE BLUE EYE DISEASE. M.A. Ramírez-Herrera, M.L., Mendoza-Magaña and S.H. Dueñas*.CUCS, Dept. of Physiology. Universidad de Guadalajara, Guadalajara, Jal. México. 44340.

This study analyzed weather the pig paramyxovirus of the blue eye disease (PPBED) was retrogradely transported from peripheral nerves to the CNS. In five suckling pigs (3-8 days old) and four cats (300-2500 g) a dose of 1 ml of paramyxovirus with 256 hemagglutinating units was injected in left medial gastrocnemius (MG) muscle or intradermal in the skin of the area innervated by the left sural (SU) nerve, or, it was also inoculated *per nasum*. After 11 - 40 days of injection or 5 -12 days of inoculation the animals were anesthetized with sodium pentobarbital (30 mg/kg) and fixed by intracardial perfusion with paraformaldehyde (6%) and glutaraldehyde (3%). Several distal to proximal segments (5 mm) of left and right (control) GM, SU, sciatic (SC) and nasal (NA) nerves as well as proximal and distal segments of L_5- and L_6 ventral and dorsal roots were cut and processed for paraffin embedding. Transversal sections of spinal cord, brain cortex, hippocampus and cerebellum were also processed for embedding. The presence of the virus was detected by an immunohistochemical method using mouse policlonal antibodies against the whole inactivated virus, which was revealed with rabbit anti-mouse IgG labeled with peroxidase. In pigs, the virus was detected in distal and proximal MG, SU, SC and NA nerves as well as in ventral and dorsal roots. It was not revealed in the control contralateral side. It also appeared in motoneurons of the infected side. In Purkinge and pyramidal neurons of hippocampus and brain cortex only appeared when, it was inoculated *per nasum*. In cats, the virus was only detected in distal portions of the peripheral nerves. It seems possible that PPBED penetrates to the CNS by the neural retrograde transport occurring in peripheral nerves.

COMPARISON OF THE UPTAKE AND TRANSPORT OF SOME COMMONLY USED RETROGRADE TRACING SUBSTANCES. J. Li* and P.N. Izzo. Dept. of Physiology, Royal Free Hospital School of Medicine, Rowland Hill St, London, NW3 2PF, U.K.

A variety of retrograde tracers have been used over the past two decades to study the projections of central and peripheral neurones. Although many of these substances are well established some of the more recent additions have not been critically examined. The purpose of the present study was to assess the properties of a number of classical and contemporary retrograde tracers and to compare their sensitivity.

Experiments were performed on anaesthetized male Sprague-Dawley rats (250-350 g). Individual tracers (HRP, cholera-toxin (CT) conjugated to HRP, fluorescent latex microspheres (30nm), WGA conjugated to colloidal gold particles (1 and 5nm) and Fluoro-Gold) were pressure injected (10-15 µl) into the tongue or hypoglossal nerve. After a suitable survival period (2-7 days) rats were perfused fixed and serial coronal sections (50 µm) of the medulla (at the level of hypoglossal nuclei) were cut on a vibrating microtome. The retrogradely transported substances were then detected and visualized using the appropriate method. Following tongue injections extensive labelling of hypoglossal motoneurones was observed with CT-HRP and Fluoro-Gold and to a lesser extent with HRP. However, following the injection of either WGA-gold or latex microspheres very little retrograde labelling was observed. In contrast, injection of all the tracers into the hypoglossal nerve resulted in labelling of hypoglossal motoneurones.

This study demonstrates that some of the more recently reported tracers employed in neuronal retrograde tracing studies are indeed retrogradely transported but are not readily taken up by axon terminals. Thus, previously reported retrograde transport achieved with these tracers must be attributed primarily to uptake and transport by damaged fibres at the site of injection. The results from this study suggest that the most specific and sensitive retrograde tracers are cholera-toxin and Fluoro-Gold, both of which are taken up by axon terminals and produce more numerous and extensive labelling of neurones.

ANTIGEN RETRIEVAL FOR PARAFFIN SECTION IMMUNOCYTOCHEMISTRY WITH ANTIBODIES COMMONLY USED IN STUDIES OF DEGENERATIVE DISEASES. J.C. Hedreen* and L.A. Mucci. Depts. of Psychiatry and Pathology, New England Medical Center and Tufts University School of Medicine, Boston, MA 02111

Paraffin section immunocytochemistry using human brain tissue obtained at autopsy and fixed for several weeks has presented difficulties with sensitivity. Recent methods of pretreatment using wet heat ("antigen retrieval") allow more reliable demonstration of many antigens at higher antibody dilution. The most convenient and effective methods in our hands include 10 min. autoclave or 20-30 min. at 90-95°C. (heating bath) in 0.01M citrate pH 6.0. Background staining is reduced by these pretreatments. A streptavidin-peroxidase kit (Biogenex) and DAB or DAB plus nickel as chromogen is used. With these methods, the following dilutions of commonly used antibodies produce optimal staining in paraffin sections from autopsy brain tissue of patients with Huntington's disease, Alzheimer's disease or controls, fixed in room temperature buffered formalin for at least 2 weeks:

Antibody	Type	Antigen	Source	Dilution
SMI-31	mono	phosph. NF	Sternberger-Monocl	1:100,000
10-D5	poly	Aß	Athena Neurosci	1:10,000
MAB1510	mono	ubiquitin	Chemicon	1:30,000
AB748	poly	collagen IV	Chemicon	1:100,000
N1506	poly	GFAP	Dako	1:300

Supplier's recommendations for dilution include: SMI-31 1:1000, AB748 1:320, N1506 1:1. Wet heat pretreatment for Aß substitutes for formic acid pretreatment. These methods promise to allow a wider research use of routinely prepared paraffin-embedded brain tissue.

APPLICATION OF FLOW CYTOMETRIC TECHNIQUES FOR PURIFICATION OF HUMAN FETAL BRAIN NEURAL POPULATIONS. A. Hassankhani*, R. Rozental, F.-C. Chiu, M. Urban, C. Bassallo and D.C. Spray. Depts. Neurosci. and Neurol., A. Einstein Coll. Med., Bronx, NY 10461, I. Biophysics, Fed. Univ. of Rio de Janeiro, Brazil.

We have established high density primary cultures of neuronal cells from second trimester human fetal brains (*J. Neurosci. Res.*, 1994). Here, we report that these neural cultures can be dissociated to single-cell suspensions, sorted (PS) by size using flow cytometry (low angle forward and side light scattering) and re-seeded to yield cultures selectively enriched for neuronal and glial populations. Neural cell analysis was initially performed on a FACScan and cell sorting was performed using the FACSstar Plus cell sorter. With our methods, two different regions (REG1 and REG2) could be simultaneously defined by electrostatic deflection on the FACStar Plus. Sorted neurons under REG1 were highly homogeneous and viable. As early as 3 hrs-PS, 10% of the cells evaluated proceeded to elaborate processes. Somatal area was ~ 30 μm^2 and lengths of the processes measured were ~ 15 μm. By 1 DIV-PS, numerous long processes were elaborated. By 3 DIV-PS, most of the small cells were process-bearing and all were glutamic acid decarboxylase (GAD)+, neurofilament protein-66 (NF-66)+ and glial fibrillary acid protein (GFAP)-negative. It appeared that these small neurons did not proliferate. By 6 DIV-PS, analyzed somatal area revealed a single component of about 50 μm^2 and lengths of the longest processes were ~ 46 μm. These cells expressed inward currents by 3-6 DIV-PS and spontaneous electrical activity after 10 DIV-PS. In parallel, larger cells with somatal area > 100 μ^2 were recovered under REG 2 (FACS chart). These cells were GFAP+, NF-66 negative and were not excitable. Homogeneous cell populations form human brain are particular interesting for the evaluation of neural dysfunctions that can not be studied in animal models.

709.3

DEVELOPMENT AND CHARACTERIZATION OF TWO HISTOCHEMICAL TECHNIQUES FOR THE RESPECTIVE DETECTION OF NEURONAL AND MYELIN DEGENERATION. L.C. Schmued*, A.C. Scallet, S. Ali, Z. Binienda, J. Bowyer, and W. Slikker Jr. Div. of Neurotoxicology, National Center for Toxicological Research /FDA, Jefferson AR, 72079.

Two techniques have been developed which allow for the rapid and sensitive localization of either neuronal or myelin degeneration following insults by a variety of neurotoxicants. Different classes of neurotoxicants used include excitotoxins (domoic or kainic acid), oxidative free-radical generators (iron or manganese salts), inhibitors of mitochondrial respiration (3-nitropropionic acid), and pyridoxal phosphate/GABA depleting agents (isoniazid). Neuronal degeneration was demonstrated by the use of fluorescent dyes which labeled the cell bodies and proximal dendrites of degenerating neurons. This labeling pattern was generally comparable to that seen using conventional suppressed silver methodologies. To facilitate multiple labeling studies, green (Fluoro-Jade) and red (Fluoro-Ruby II) fluorochromes were developed. These probes can be combined with fluorescent antibodies, apoptosis markers, axonally transported tracers, or counterstains of complimentary emission color to simultaneously reveal the degeneration status along with the anatomy, cytochemical content, chromosome fragmentation, or the connectivity of identified neurons. Degeneration of the myelin sheath was demonstrated by incubating the tissue in a heated, buffered, gold chloride solution. Depending on the nature and duration of toxicant exposure, myelin degeneration could be characterized by a swelling or fragmentation of the myelin sheath, the presence of myelin containing macrophages, or the absence of normal myelin staining. The aforementioned two methods provide a simple, reliable, rapid and sensitive means for detection of neuronal or myelin degeneration following exposure to different classes of neurotoxicants.

CONVENTIONAL AND FIELD EMISSION HIGH RESOLUTION SCANNING ELECTRON MICROSCOPY OF CEREBELLAR SYNAPTIC JUNCTIONS. O.J.Castejón*. Instituto de Investigaciones Biológicas. Facultad de Medicina. Universidad del Zulia. Maracaibo, Venezuela.

Teleost fishes, primate and human cerebelli were processed for conventional (CSEM) and field emission high resolution scanning electron microscopy (FEHRSEM) to study the outer and inner surfaces of axodendritic, glomerular and axosomatic synapses. Axodendritic junctions of climbing fibers and Golgi axonal ramifications were studied in gold-palladium and chromium coated samples. CSEM of cryofractured glomerular synapses exhibited the outer surface view of "en passant" mossy fiber glomeruli and the inner view of transversally and sagitally fractured glomeruli. The cryofracture method exposed the axosomatic contacts of basket axonal collaterals upon the Purkinje cell and the climbing fiber bulbous endings upon the Golgi cell. FEHRSEM of parallel fiber-Purkinje spines showed the three-dimensional structure of the synaptic membrane complex. The spheroidal synaptic vesicles appeared embedded in a homogeneous axoplasmic substance. Round subunits, 15-20 nm in diameter, were observed at the postsynaptic membrane and the postsynaptic density, presumably related to neurotransmitter receptors.

MEASUREMENT PROBLEMS ASSOCIATED WITH THE RECONSTRUCTION OF SYNAPTIC STRUCTURES AT THE ELECTRON MICROSCOPIC LEVEL. **R.L. Cooper*, A. Feuerverger[1], M. Menzinger[2], L. Marin and H.L. Atwood. Depts. of Physiology, Statistics[1], and Chemistry[2], Univ. of Toronto, Toronto, Canada**

Quantitative structural information on synaptic components, including synaptic vesicle diameters, synaptic area, and dimensions of the presynaptic dense bodies of 'active zones', is commonly obtained from ultrathin sections visualized with transmission electron microscopy. Consideration of the loss of structural information resulting from projection of a section of a three-dimensional structure onto a two-dimensional photographic plate is necessary. The relation between the true size distribution and the theoretical and actually observed size distributions of projected images is discussed for the case of a population of spherical synaptic vesicles. The observed distribution is demonstrably degraded due to the non-observation of optically thin sections of small radius. Consideration of the degradation of the observed projected images is used to devise a method for interpretating the observed distribution in terms of the true distribution. This approach provides a more rational measure of the population mean and coefficient of variation. For other, non-spherical, synaptic structures (dense bodies and synaptic area), available information on the uncertainties of the observations is used to determine methods for best estimates of the true structural dimensions. HOMOLOGUE OF *DROSOPHILA* NEURAL PROTEIN FREQUENIN SELECTIVELY EXPRESSED IN CRUSTACEAN PHASIC MOTOR TERMINALS. **H. L. Atwood[1]*, M Msghina[1], H. Lindemeier[2], and O. Pongs[2]. [1]Department of Physiology, University of Toronto, Toronto, Ontario, CA M5S 1A8, and [2]Zentrum für Molekulare Neurobiologie, Institut für Neurale Signalverarbeitung, D-20246 Hamburg 20, FRG**

Two types of nerve terminal with markedly differing release characteristics, classified as phasic and tonic, have been described in excitatory motor axons of crustaceans. Phasic terminals have high initial quantal output, but show less facilitation and more depression than tonic terminals (Atwood and Wojtowicz, 1986, Int. Rev. Neurobiol. **28**, 275-362). Individual crayfish muscles may be innervated solely by phasic or tonic motor axons, or by both types. Advantage was taken of this to study the expression of the Ca^{2+}-binding protein frequenin (frq; 21 KD), which has been implicated in modulation of synaptic facilitation (Pongs et al., 1993, Neuron **11**, 15-28). Affinity purified monospecific polyclonal anti-frq antibody (1:50), raised against *Drosophila* frequenin, was used in conjunction with FITC conjugated secondary antibody (1:200). Terminals were visualized with a Bio-Rad scanning confocal laser microscope and a Nikon 40x water immersion lens. For comparison, preparations were stained with the vital dye 4-Di-2-Asp, which strongly labels both types of terminal.

In all preparations tested, antibody reaction was strongest in phasic terminals, and absent or much weaker in tonic ones. Thus, there was a staining reaction in terminals innervating the superficial abdominal extensor muscle (purely phasic), weak reaction in the leg opener muscle (purely tonic), and selective staining of phasic terminals in the dually innervated leg extensor muscle. In the superficial abdominal flexor muscle (believed to be purely tonic) there was selective reaction in the terminals of one of the six axons. In all preparations, the main axon and preterminal axon branches showed only faint reaction. Our results indicate that frequenin, or a closely related protein, is enriched in crayfish phasic nerve endings that have high initial quantal output. (Supported by MRC Canada and Faculty of Medicine, Univ. of Toronto)

COMPARISON OF THE FM1-43 AND SV2 STAINING PATTERNS OF AMPHIBIAN NEUROMUSCULAR JUNCTIONS. A. W. Everett, S. J. Packard and L. Beazley*. Department of Physiology, University of Western Australia, Nedlands 6907, Australia.

The styryl dye FM1-43 labels nerve terminals in an activity dependent manner, purportedly by becoming trapped in recycled synaptic vesicle membranes at transmitter release sites in the terminal. We therefore compared the distribution FM1-43 labelled terminals with those labelled with an antibody to the SV2 antigen of synaptic vesicle membranes. Toads (*Bufo marinus*) were sacrificed by pithing and the iliofibularis was pinned-out *in vitro*. FM1-43 at 2 μM in Ringer containing 60 mM KCl was added to the muscle for 5 minutes. The muscle was then washed briefly and fixed. Other muscles were fixed for staining with the SV2 antibody. Terminals on teased muscle fibres were imaged by fluorescence confocal microscopy. FM1-43 staining appeared as spots or more often as bands along the length of terminal branches at a frequency of not less than 59/100 μm; some larger spots probably consisted of several bands that could not be clearly resolved. SV2 staining was similarly punctate with spots occurring at a frequency of not less than 40/100 μm of terminal branch; individual spots were generally larger than FM1-43 stained spots and less clearly defined. Furthermore, both staining procedures revealed very large differences in the intensity of staining of spots within single branches. The results support the notion that FM1-43 labels synaptic vesicles concentrated at release sites in a nerve terminal and that variation in the uptake of the dye at these sites may reflect differences in the number of vesicles or the composition of their membranes.

A 3D CONFOCAL STUDY OF TYPE-IDENTIFIED NEUROMUSCULAR JUNCTIONS. Y.S. Prakash*, S.M. Miller and G.C. Sieck. Depts. of Anesthesiology, Physiology and Biophysics. Mayo Foundation, Rochester, MN 55905.

We used a novel three-color fluorescence immunocytochemical technique to simultaneously visualize innervating axons and nerve terminals, motor endplates, and muscle fiber type in the rat diaphragm. Nerve terminals and axons were labelled with an antibody to protein gene product 9.5 (PGP), endplates with a-bungarotoxin, and muscle fibers with an antibody to fast (type II) skeletal myosin. Fluorescein (nerve terminal), tetramethylrhodamine (endplate) and Cy5 (type II muscle fibers) were used as fluorescent dyes to distinguish the three structures. The triple-labelled neuromuscular junctions (NMJs) were optically sectioned using a confocal microscope, and 3D views of the NMJs were created. Both 2D and 3D morphological parameters such as axonal diameter, terminal and endplate planar and surface areas, endplate gutter depth, and extent of overlap of terminal and endplate, were extracted from these images. The results indicate that 1) in general, larger axons innervate larger muscle fibers; 2) when normalized for fiber diameter, planar and surface areas of both terminals and endplates are larger on type I fibers; 3) NMJs on type II fibers generally appear more complex; and 4) the extent of overlap is greater in type I fibers. These morphological differences may underlie fiber type differences in neuromuscular transmission. Supported by NIH grants HL34817 and HL37680.

IMMUNODETECTION OF BOTULINUM TOXIN A (Bot A) ON ITS TARGET MEMBRANE TO SHOW BINDING SITES AT THE LIGHT MICROSCOPIC LEVEL. G.A. Canziani and R.D. Crosland*. Toxinology Div., U.S. Army Med. Res. Inst. Infec. Diseases, Frederick, MD 21702.

The most potent toxins known are produced by strains of *Clostridium botulinum*. To paralyze the vertebrate neuromuscular junction the toxin must attach to the nerve endings, be translocated into the terminal, and after activation of its enzymatic activity, hydrolyze proteins of the exocytotic apparatus. Our goal was to develop a convenient, reliable technique to detect specific binding of Bot A to its targets. Our technique utilized fluorescently labeled latex spheres, which are capable of detecting a single receptor.

Non-specific binding sites on 7 μm thick sections of unfixed, cryosectioned mouse diaphragm were first blocked with 20% goat serum in PBS (GS/PBS). We incubated the diaphragm for 1 h at RT with various concentrations of Bot A in GS/PBS, followed by incubation with rabbit anti-Bot A antibody, biotin-labeled goat anti-rabbit antibody, and finally avidin-labeled, 0.03 μm diameter, fluorescent latex spheres. As expected, binding was limited to the presynaptic membrane. The technique allowed us to visualize with light microscopy a minimum of 6 Bot A binding sites per μm^2 of nerve ending surface. In addition, we could detect binding on diaphragms that were exposed to as little as 10 pM Bot A, which is in the low range of effective *in vitro* doses that block twitch tension. This a convenient technique for detecting Bot A receptors and may be applicable to other receptors as well.

709.10

ASSESSMENT OF DIABETIC NEUROPATHY BY QUANTITATION OF NERVES IN HUMAN SKIN BIOPSY. W.R. Kennedy,, G. Wendelschafer-Crabb, U of MN, Minneapolis, MN 55455, and C. K. Knox,*, Minnesota Datametrics Corporation, St. Paul, MN 55126

Evaluation of nerves in skin biopsy yields valuable information about peripheral nerve endings. Comparison of nerves in skin from normal vs. diabetic donors reveals striking differences in the pattern of innervation as well as the amount of nerve present in various structures of the skin.

Biopsies obtained from normal and diabetic donors (with informed consent), were fixed, sectioned and processed for double-stain immunohistochemistry using antibodies to PGP 9.5 to localize nerves and type IV collagen to localize basement membrane. Digitized image files were obtained using a laser scanning confocal microscope. Lengthes and volume of nerve as a function of the volume of epidermis or sweat gland were determined by computer analysis and quantification of three dimensional reconstructions.

Nerves in skin can be clearly visualized using antibody to PGP 9.5. The relationship of nerve to other structures can be correlated by double staining with type IV collagen. The amount of nerve was greatly reduced or absent in the biopsies from diabetic donors as compared with controls. A similar decrease in numbers was seen in the sudomotor nerves of sweat glands in biopsies of diabetic subjects. The data clearly indicate that skin biopsy evaluation is useful in the clinical assessment of neuropathy. Staging of neuropathies from skin biopsy data will be useful in assessing the effects of treatments such as drug therapy and pancreas transplantation.

STABILITY OF TAU mRNA IN PC12 CELLS IS MEDIATED BY *cis*-ACTING SIGNALS, LOCATED IN THE 3'UTR OF THE MESSAGE. I. Ginzburg*, E. Sadot, R. Marx-Rattner and J. Barg. Dept. of Neurobiology, Weizmann Institute of Science (WIS), 76100 Rehovot, Israel

Induction of neurite outgrowth in PC12 cells is transcription-dependent and is associated with the accumulation of tau proteins. The increase in tau proteins levels, results from an increase of tau mRNA levels which reflects increased transcription and/or stability of the message.The latter possibility was tested in NGF induced PC12 cells. We found that the half life of tau-mRNA is elevated to 18 hours in induced cells as compared to 7 hours in uninduced cells.To identify tau sequences involved in mRNA stabilization, selected fragments of the 3'UTR were subcloned to the 3' end of the coding region of human c-fos, used as a reporter gene. The transfected cell lines overexpressing c-fos constructs did not show any morphological differences following NGF induction. Stable PC12 line containing construct B (about 1400 nucleotides of the 3'UTR), show a significant increase of 6 folds in the steady state c-fos mRNA levels following NGF induction. The results demonstrated that the half-life of fos-B mRNA increases to 2.1 hrs as compared with 1 hr in cells transfected with c-fos alone. The half-life of fos-B mRNA is even longer when transfected cells are treated with NGF>5.8 hrs. The effect is neuronal specific, as it is not observed in 3T3 cells transfected with the same constructs. By using a uv-cross linking assay a specific binding of proteins prepared from neuronal cells was observed while no binding activity was detected when extracts were prepared from 3T3 cells. Thus we conclude that tau mRNA stabilization is contributed by cis-signals located at the 3'UTR of the message in conjunction with trans-acting neuronal proteins. *[Supported by the Israel Academy of Sciences and Humanities, the GIF Foundation and the Forschheimer Center for Molecular Genetics (WIS)].*

CHARACTERIZATION OF IMMORTALIZED PINEAL CELL LINES DERIVED FROM TRANSGENIC MICE BY TARGETED TUMORIGENESIS AND ITS USE FOR THE STUDY OF TRYPTOPHAN HYDROXYLASE (TPH) GENE REGULATION. J.H.Chung*, S.O.Huh, Y.I.Chung, D.H.Park, T.H.Joh AND J.H.Son. Cornell University Medical College at The W.M.Burke Medical Research Institute, White Plains NY, 10605.

The lack of immortalized serotonergic cell lines has been a major obstacle to the study of the tissue-specific differential regulation of tryptophan hydroxylase (TPH) gene expression in the pineal gland during circadian rhythm. TPH is the first step enzyme in serotonin and melatonin biosynthesis in neuroendocrine cells of the pineal gland. Previously, we demonstrated that a 6.1 kb 5' upstream region of the mouse TPH gene directs the restricted expression of lacZ reporter gene expression to the pineal gland and the median and dorsal raphe nuclei in transgenic mice. Therefore, to develop TPH-expressing pineal cell lines we first established transgenic mice carrying a construct consisting of 6.1 kb of 5' flanking region fused to the SV40 T-antigen. These animals developed highly invasive pineal tumors and died at 12 to 15 weeks of age. The pineal tumors obtained from the transgenic mice were utilized to establish the immortalized pinealocyte-derived cell lines, PGT-811 and PGT-β, which exhibit characteristic properties of the pinealocyte, such as TPH and N-Acetyltransferase activities. Using PGT-β cells transient transfection analysis revealed cAMP responsive, tissue-specific enhancing and repressing elements in the 5' upstream region of the mouse TPH gene.

710.3

DNA Mismatch Repair and DNA Methylation in the Adult Rat Brain P.J. Brooks*, Cheryl Marietta, and David Goldman, Sect. on Mol Neurobiology, Laboratory of Neurogenetics, NIAAA/NIH

DNA repair is essential to maintaining the integrity of the nucleotide sequence of cellular DNA over time. While much data has accumulated recently on the mechanisms of DNA repair, little is known about the DNA repair capacity of cells in the adult brain. Such knowledge is important in view of the neurological deficits seen in individuals with DNA repair diseases such as Cockayne's Syndrome and Xeroderma Pigmentosum. In the present study, we have investigated the capacity of nuclear extracts from adult rodent brain neurons to carry out DNA mismatch repair. We focused on the repair of G:T and G:U mismatches, which arise from the spontaneous deamination of 5-methyl cytosine (5-MeC) to thymine, or cytosine (C) to uracil, respectively, as these are the only types of DNA mismatches that can arise in nondividing cells. Deamination of both 5-MeC and C occur spontaneously at an estimated rate of 1-10 (5-MeC) or 100-500 (C) times per day per human genome. We found that nuclear extracts from adult brain neurons can correct G:T and G:U mismatches back to GC base pairs. Several other types of DNA mismatches could not be processed. In brain nuclear extracts, the G:U repair system was much more active than the G:T repair system. These data provide the first direct demonstration that neurons in the adult mammalian brain have the capability to carry out specific types of DNA mismatch repair.

We previously reported (Nsci. Abst 20: 100.6) that the adult brain contains high levels of DNA methyltransferase activity. We propose that one function of DNA methyltransferase in the adult brain is to remethylate newly incorporated cytosine residues from G:T mismatch repair following deamination of 5-methyl cytosine, thereby maintaining the original pattern of DNA methylation.

710.4

TRIPLET - REPEAT DNA: UNSTABLE REGULATORY GENES COULD BE EVOLUTIONARY "TUNING-KNOBS". D. G. King*, Department of Anatomy and Department of Zoology, Southern Illinois University at Carbondale, Carbondale, IL 62901.

Excessive expansion of triplet repeat DNA sequences causes several neurological diseases (Martin, *Science* 262:674). But the length of these mutationally unstable sequences also modulates normal gene transcription activity (Gerber et al., *Science* 263:808), as predicted from the basic principle that site-specific mutation can offer significant evolutionary benefits (King, *Science* 263:595). The concept that highly mutable genes can be adaptively advantageous has not yet been widely applied in genetic neurobiology, presumably because it contradicts the common opinion that mutation in any form is almost always deleterious. In computer simulations, however, deterministic selection at a single locus can favor unstable alleles, if the quantitative phenotypic effects of individual mutations are small and if competing Mendelian alleles are not optimally fit, especially if the adaptive peak fluctuates over time. Natural selection might similarly favor mutation-prone genes if the usual consequences of mutation were suitably constrained. Regulatory genes based on unstable triplet-repeat length could thus function as evolutionary "tuning-knobs", efficiently establishing adaptive genotypes in a shifting environment. This idea may offer a useful paradigm for studying patterns of genomic organization underlying innate but evolutionarily flexible patterns of behavior.

710.5

IDENTIFICATION OF A REGION IMPORTANT FOR MAO-B SUBSTRATE AND INHIBITOR SELECTIVITY J. Grimsby*, M. Zentner and J.C. Shih. Dept. of Mol. Pharmacol. and Toxicol. Sch. of Pharmacy, Univ. of So. Calif., 1985 Zonal Ave., Los Angeles, CA 90033.

Monoamine oxidase (MAO) A and B are flavoenzymes that catalyze the oxidative deamination of biogenic and xenobiotic amines. The MAO isoenzymes are defined by their substrate and inhibitor selectivity. MAO-A preferentially oxidizes serotonin (5-HT), whereas MAO-B preferentially oxidizes phenylethylamine (PEA). To search for domains that confer substrate and inhibitor selectivities two chimeric proteins were constructed and expressed in yeast. Replacement of a MAO-A segment (residues 161-375) with the corresponding region of MAO-B, termed $AB_{161-375}A$, converted typical MAO-A catalytic properties to MAO-B like ones. Similar to wild-type MAO-B, $AB_{161-375}A$ oxidizes PEA (V_{max} 32±5 nmol/20 min/mg protein, Km 23±4 μM) but not 5-HT. The IC50 value for deprenyl is 20 fold less than the IC50 for clorgyline. However, the reciprocal chimera in which a MAO-B segment was replaced by the corresponding region of MAO-A, termed $BA_{152-366}B$, lacked catalytic activity. The lack of catalytic activity was not due to aberrant expression but rather an inactive protein as demonstrated by Western blot analysis. These results demonstrate that the MAO-B amino acids 152-366 contains a domain(s) that confers substrate and inhibitor selectivity. (Supported by NIMH grants R37 MH39085 (MERIT Award), K05 MH00796 (Research Scientist Award), R01 MH37020 and Welin Professorship).

710.6

SEQUENCE PREFERENCE OF MOUSE HISTONE H1° PROTEIN EXPRESSED IN E. *COLI* CELLS Duan Su, Philip G Rhodes* and Susan E. Wellman. Dept. Pharmacol.& Toxicol., Univ. MS Med. Ctr., Jackson, MS 39216

Histones are involved in packaging DNA in chromatin and maintaining the supernucleosome structure. When histones bind DNA, they may make DNA less accessible. The histone H1° exists mainly in quiescent or terminally differentiated tissue. To discover if histone has a DNA sequence preference will help to understand its cellular function.

The cloned mouse histone H1° protein expressed in E. *coli* cells has a sequence preference when it binds to a 214mer DNA fragment. This 214mer DNA is a fragment of plasmid vector pBR322. Structurally this 214mer DNA can be divided into two region: a GC-rich sequence and a AT-rich sequence. The results of thermal denaturation experiments show that histone H1° protein bound preferentially to the GC-rich region of 214mer DNA. This experiment indicates that the histone H1° protein is not totally non-specific, but rather binds with some sequence preference to DNA.

PARTIAL CHARACTERIZATION OF A BRAIN SPECIFIC ssDNA-BINDING PROTEIN. *Raghunathan, A., Poornima, T., Mohan C. Vemuri, School of Life Sciences, University of Hyderabad, Hyderabad 500134, India, Dept. of Biology, Wesleyan University, Middletown, CT 06459, USA.

Tissue- or cell-specific gene expression involves an interplay of DNA-protein interactions and DNA binding proteins play a pivotal role, in terms of regulation. This study involves the purification and characterization of a single strand DNA binding protein which is possibly involved in the developmental regulation of rat brain. The protein was purified using DNA-cellulose chromatography and DNA binding properties were confirmed using filter binding and mobility-shift assays. The protein has a molecular weight of 56 kDa with a pI of 5.2 and is denoted as 56 ssDBP. Intrinsic fluoroscence spectral studies suggest the presence of tryptophan in a buried condition and the amino acid analysis shows an abundance of glycine and serine residues. 56 ssDBP has no significant influence on conformation and melting profiles of calf thymus DNA. It showed no influence on DNA polymerase activity suggesting that the protein may not be involved in DNA replication, repair and/or structural organization, leaving scope to its likely involvement in transcriptional regulation. Immunological studies on Western blots indicated its distribution specific to the brain. (Supported by a SRF grant to AR from ICMR, India, and UGC-Research scientist-'B' grant from UGC, India, to MCV).

710.8

SOMATIC GENE DELIVERY TO GENERATE GAIN OF FUNCTION NGF MOSAICISM. B. Mukherjee, A. Brooks, R. Starr, and H.J. Federoff*, Departments of Microbiology, Immunology and Neurology, University of Rochester School of Medicine, Rochester, NY 14642.

To investigate NGF action in specific regions of the adult mammalian nervous system we are developing a somatic gene transfer approach to create genetic mosaics in mice. In this approach we use a binary system that involves an inactive germline-transmitted transgene that is activated by the somatic delivery and expression of cre recombinase. We have constructed an excision activated transgene (XAT) that is composed of the rat NSE promoter, an inactivating cassette, a bicistronic transcription unit consisting of a NGF minigene and IRES initiated reporter gene (NSEprNGFXAT). Introduction of the NSEprNGFXAT into *E. coli* that constitutively express cre recombinase resulted in removal of the inactivating cassette in 100% of clones. By constrast, no excisional process occurred in bacteria that did not express the recombinase gene. The NSEprNGFXAT has also been introduced into cell lines and transgenic mice. Several cell lines and transgenic lines of mice express the inactive NGF transcript. A defective herpes amplicon vector transducing the cre recombinase gene (HSVcre) has been constructed as the somatic gene delivery vehicle. Infection of cell lines, primary neurons isolated from transgenic animals, and transgenic mice is being used to produce activation of the NSEprNGFXAT. Studies are examining the efficiency of gene activation, levels of NGF and reporter gene produced, and the biological effects produced by patches of mosaic tissue.

AAV-VECTOR MEDIATED HUMAN HSP72 GENE TRANSFER INTO CULTURED CELLS. C. Lippman*, F. Welsh, M. Kaplitt, W. O'Connor, M. During, C. Mobbs, M. O'Connor, A. Freese. Div. Neurosurg. Univ. PA., Phila., PA 19104; Graduate Hosp., Phila., PA 19146; Lab. Neurosci. Rockefeller Univ., New York, NY 10021 .

Heat shock protein 72 (hsp72) expression is associated with increased neuronal survival after a variety of stresses. A causal relationship between this expression and neuronal protection has not been demonstrated. Introduction into the CNS of the gene encoding hsp72 resulting in expression may permit the assessment of such a relationship.

We have developed an adeno-associated viral (AAV) vector with the human hsp72 gene under control of a cytomegalovirus promoter (AAV-hsp72). When introduced into rat cortical or striatal mixed neuronal-glial cultures, the vector directed both short- and long-term hsp72 expression.

At three days, cultures were exposed to AAV-hsp72, AAV-LacZ (a control vector containing the LacZ marker gene), or PBS. Hsp72 expression was qualitatively measured after two or seven days of viral vector incubation. Using a monoclonal antibody against human hsp72, immunocytochemistry was performed. Only those cultures transfected with AAV-hsp72 demonstrated staining for hsp72, while staining for ß-galactosidase was observed in cultures transfected with AAV-LacZ, but not in cultures transfected with AAV-hsp72 or PBS. Western blot analysis showed similar results, with inducible hsp72 protein only present in those cultures transfected with AAV-hsp72. Absence of cytotoxicity was confirmed by a number of techniques.

These results demonstrate that this vector may be used to introduce the human hsp72 gene into CNS neurons with subsequent transgene expression. We are evaluating the neuroprotective effect of this vector and implications for therapy in stroke and trauma.

DEVELOPMENT OF VIRUS VECTORS FOR GENE TRANSFER INTO NEURONS: ANALYSES OF PROMOTER FUNCTION. S. J. Davis, J. Schaack, R. L. Smith and C. L. Wilcox* Depts. of Anatomy and Microbiology, Colo. State Univ., Ft. Collins, CO 80523, and Depts. of Microbiology and Neurology, Univ. of Colo. Health Sci. Ctr., Denver, CO 80262.

The ability to transfer genes into neurons has important utility in the study of neuronal physiology and gene regulation, and for gene therapy in the treatment of diseases of the nervous system. Replication-defective, recombinant adenovirus vectors have been used to infect neurons without evidence of pathogenicity. Development of virus vectors to provide cell-type-specific promoter regulation is important for many applications. We have constructed replication-defective recombinant adenovirus vectors to investigate the regulation of several promoters using the reporter *lacZ* gene to express ß-galactosidase. Initial studies have utilized rat dorsal root ganglia neurons in tissue culture to examine expression from several promoters. An adenovirus vector containing the cytomeglovirus immediate early gene promoter produced expression of ß-galactosidase in greater than 90% of the neurons 24 hr postinfection, with continued ß-galactosidase expression for 30 days without evidence of cytotoxicity. Infection with an adenovirus vector containing the adenovirus early E1A promoter driving *lacZ* resulted in ß-galactosidase expression in neurons. Use of the E1A promoter provides an expression system that is not active in the cell line required to package the adenovirus vector, thus allowing construction of vectors containing toxic genes.

EXPRESSION OF LACZ GENE USING A HERPES SIMPLEX VIRAL VECTOR RETROGRADELY TRANSPORTED INTO HIPPOCAMPAL GRANULE CELLS IN VIVO. P.A. Serrano*, R.L. Neve[1] & A. Routtenberg. Cresap Neuroscience Laboratory, Northwestern Univ., Evanston, IL 60208; [1]Harvard Medical School and Mclean Hospital, Belmont, MA 02178.

The herpes simplex virus (HSV-1) is used here to introduce foreign genes into postmitotic neurons. The HSV-1 mutant is replication incompetent not entering the lytic cycle (TINS, 1991, 14:428), spreads minimally through brain parenchyma, and is taken up by terminals in the region of the injection site. We determined the extent to which the IE 4/5 promoter of HSV-1 would activate the lacZ gene when introduced into rat hippocampal granule cells.

Injection targeted for mossy fiber terminals in the dentate hilus were guided by a laminar profile of the dentate gyrus constructed from single pulses to perforant path. The population spike and EPSP evoked by stimulation of the perforant path were recorded by an HSV-1-filled micropipette electrophysiologically guided to the dentate hilus. Ejection volumes of 0.1-1.0µl were delivered over a 45-60 min period by directly monitoring the movement of the solution meniscus in the micropipette. HSVlacZ injected into the hilus was retrogradely transported to granule cell bodies. We observed robust expression of ß-galactosidase in granule cell bodies on both the dorsal and ventral leaf 24-72h after a single injection. Dendritic trees of granule cells were filled with ß-galactosidase and mossy fiber axons could be traced to their terminal zone in stratum lucidum. Axons of mossy fibers showed the characteristic rosettes of mossy fiber terminals. CA3c pyramidal cells in the hilus did not translate lacZ. HSV-1 is a highly effective vector for introducing foreign genes into hippocampal granule cells in vivo and in combination with electrophysiological guidance can restrict expression to a particular cell type. RECOMBINANT VACCINIA VIRUS AS A TOOL TO OVER-EXPRESS PROTEINS IN CULTURED HIPPOCAMPAL NEURONS. T. Koothan*, M. Maletic-Savatic and R. Malinow. Jones Bldg, Cold Spring Harbor Lab., Cold Spring Harbor, NY.

Recombinant vaccinia viruses have been successfully used to over-express genes of interest in several mammalian cell lines and in rat hippocampal slices. Here we describe a method to over-express proteins of interest in cultured rat hippocampal neurons using the vaccinia virus system. Neurons cultured separately, as described by Banker, did not express the recombinant protein of interest following vaccinia virus infection. In contrast, co-cultures of hippocampal neurons and astrocytes survive and express beta-galactosidase protein following infection with recombinant vaccinia virus. The percentage of infected neurons depends upon the density of the astrocytes co-cultured along with neurons. Recombinant vaccinia virus carrying rat alpha-CamK II have been used to infect cultured hippocampal neurons. We discuss the localization of CamK II in the neurons following infection.

EXPRESSION OF HEAT SHOCK PROTEINS (HSP70 AND HSC70) AND NUCLEAR TRANSLOCATION IN THE RABBIT BRAIN FOLLOWING HYPERTHERMIA. P. Manzerra* and I. R. Brown. Dept. of Zoology, Univ. of Toronto, Scarborough Campus, West Hill, Ont., Canada M1C 1A4.

The heat shock response is characterized by i) an overall decrease in ongoing mRNA and protein synthesis, ii) an induction of heat shock mRNAs and proteins (hsps), iii) nuclear translocation of hsps and iv) collapse of elements of the cytoskeleton in some cell types. We have carried out Western blot and immunocytochemical studies using antibodies which are specific in recognizing constitutive hsc70 protein or stress-inducible hsp70 protein. Large neurons, such as Purkinje neurons and motor neurons of the spinal cord, express high levels of constitutive hsc70 protein, however their induction of hsp70 protein in response to hyperthermia is attenuated compared to the rapid and robust induction which is seen in adjacent glial cells. In the present study we have investigated whether neuronal cell populations exhibit other features of the heat shock response. Following hyperthermia a transient induction of hsp70 protein was observed primarily in non-neuronal cell populations in the rabbit brain (ependymal cells, oligodendrocytes and astrocytes). At 1 hr post-hyperthermia, a redistribution of both hsp70 and hsc70 protein from the cytoplasm into the nucleus occurs in ependymal cells of the choroid plexus with a return to the cytoplasm by 5 hr. Glial cells exhibit nuclear localization of stress-inducible hsp70 followed by a later appearance of the protein in cellular processes. Nuclear translocation of hsc70 protein was not observed in several neuronal cell populations in response to hyperthermia (Purkinje, hippocampal and thalamic neurons), however it was observed in motor neurons of the spinal cord. These neurons showed a translocation of hsc70 protein into the nucleus, followed by exit to the cytoplasm, with a temporal profile similar to that observed for ependymal cells.

710.14

CELLULAR LOCALIZATION OF HEAT SHOCK mRNAS (HSC70 AND HSP70) IN THE RABBIT BRAIN. J.A. Foster* and I.R. Brown. Dept. of Zoology, Univ. of Toronto, Scarborough Campus, West Hill, Ont. Canada, M1C 1A4.

The hsp70 multigene family is comprised of constitutive and hyperthermia-inducible members. Using radioactive *in situ* hybridization we have shown high constitutive expression of hsc70 mRNA in certain neurons. Here we employ non-radioactive *in situ* hybridization to examine cellular distribution of heat shock mRNAs. At high resolution, we observed hsc70 mRNA in the cell bodies of neurons. In cortical neurons (layer 2 and 5), deep cerebellar neurons (DCN), and brain stem neurons (BSN), we also detected hsc70 mRNA in apical dendritic processes. This dendritic distribution of hsc70 mRNA was not detected in hippocampal, some cortical neurons, and most cerebellar neurons. Following heat shock, neurons with the highest levels of constitutive hsc70 mRNA, i.e. BSN and DCN, showed more distal transport of hsc70 mRNA in dendritic processes. By radioactive and non-radioactive methods we do not detect hsc70 mRNA in glial cells. We have shown a strong glial induction of hsp70 mRNA after hyperthermia. For example, oligodendrocytes showed intense signal in cytoplasmic cap regions following 1 hour of hyperthermia. Later time points following heat shock showed this distribution to be more spindle-like but the extent of mRNA in oligodendrocyte processes was not comparable to that observed for hsc70 mRNA in dendritic processes of BSN and DCN. We detected basal levels of hsp70 mRNA in control neurons, particularly when tissue was fixed after freezing; this signal was localized to cell bodies. Following heat shock, an immediate glial induction and a delayed accumulation of hsp70 mRNA in cell bodies of neurons was observed. These data demonstrate that neurons with high constitutive levels of hsc70 mRNA increased dendritic transport of this message following hyperthermia, while the distribution of hsp70 mRNA was localized to cell bodies.

710.15

HETEROGENEITY OF TRANSCRIPTS ENCODING ISCHEMIA-INDUCED HSP70 IN BRAINS OF INDIVIDUAL WISTAR RATS.
Y. Yaida, W. Valentine, K.-S. Kim*, W. A. Pulsinelli and T. S. Nowak, Jr. Dept. of Neurology, University of Tennessee, Memphis, TN 38163.

Phosphorothioate oligonucleotides are more stable than normal phosphodiester oligos in brain, and should therefore be better antisense reagents to modify the postischemic stress response in brain. However, we have had limited success in reducing expression of the inducible 70 kDa stress protein, hsp72, perhaps in part due to heterogeneity of the transcripts encoding this subset of the hsp70 protein family. We have therefore employed a 5' amplification (RACE) method to sequence potential antisense targets in ischemia-induced hsp70 mRNAs. Male Wistar rats were subjected to 10 min 4-vessel occlusion ischemia. After 3 h brains were removed for mRNA preparation or in situ hybridization. The primer for cDNA synthesis consisted of a 30mer previously shown to detect inducible hsp70 mRNAs, which was then ligated to a 23mer from the rat somatostatin promoter, amplified, cloned and sequenced. We obtained the same sequence published for a 2.5 kb transcript from Wistar rats (1), that differs from Sprague-Dawley (SD) sequences (2,3) at positions 6, 9 and 10 bases 5' to the translation start site. However, a 21mer spanning this region of the SD sequence detected an induced mRNA in 30% of Wistar rats, suggesting that the sequences, rather than reflecting strain variation, may be differentially expressed in individual animals. Ongoing studies continue to characterize rat hsp70 mRNAs with the aim of developing suitable antisense reagents.

CONCOMITANT EXPRESSION OF INDUCIBLE HSP-70 WITH PROTEIN SYNTHESIS INHIBITION FOLLOWING ISCHEMIA, KAINIC ACID AND HYPERTHERMIA.
A.M. Planas [1*], M.A. Soriano [1,2], E. Rodríguez-Farré[1] and I. Ferrer[2]. [1]Dep. Pharmacol. & Toxicol., CID, CSIC, 08034 Barcelona, and [2]Unitat de Neuropatologia, Hospital Princeps d'Espanya, Universitat de Barcelona, Spain.

Inducible heat shock protein-70 (HSP-70) is expressed in certain regions of the rat brain following hyperthermia, ischemia and kainic acid-induced seizures. These conditions are also known to cause inhibition of protein synthesis. Here we examined induction of hsp-70 mRNA with *in situ* hybridization using a ^{32}P-labelled oligonucleotide probe, and cerebral protein synthesis following *in vivo* i.v. administration of a ^{14}C-labelled neutral amino acid. For each rat, hsp-70 mRNA induction and incorporation of labelled amino acid into proteins were studied in consecutive brain sections. Focal ischemia, hyperthermia and kainic acid caused selective hsp-70 mRNA expression in those brain regions showing decreases in labelled amino acid incorporation into proteins. The level of hsp-70 mRNA expression correlated with the percentage of decrease in labelled amino acid incorporation into proteins in relation to controls. Neither cycloheximide nor anisomycin induced any detectable hsp-70 mRNA expression, despite producing marked protein synthesis inhibition. These observations suggest that hsp-70 mRNA induction and protein synthesis inhibition are two simultaneous events of the cerebral stress response following a variety of insults.

MOLECULAR INTERACTION OF NMDA AND DOPAMINE D2L RECEPTORS IN HUMAN NEUROBLASTOMA SH-SY5Y CELLS.
V. D. Nair, H. B. Niznik[1] and R. K. Mishra*. Depts of Psychiatry and Biomedical Sciences, McMaster University, Hamilton, Ontario L8N 3Z5; and Laboratory of Molecular Neurobiology[1] ,The Clark Institute of Psychiatry, Toronto, Ontario, Canada.

The N-methyl D-aspartate (NMDA) receptor, a subtype of glutamate receptor, plays a key role in synaptic plasticity in the central nervous system and dopamine receptors are involved in regulating motor and cognitive behaviours. In the medium-sized spiny neurons of the neostriatum, dopamine modulates neuronal responses mediated by activation of excitatory amino acid receptors. A deficiency in glutamatergic neurotransmission resulting in a disturbed balance between glutamatergic and dopaminergic systems within the neostriatum may play a key role in the pathophysiology of schizophrenia. However the molecular mechanisms underlying this interaction are poorly understood. Using a human neuroblastoma cell line, SH-SY5Y cells, expressing clonal specific human dopamine $D2L_{Long}$ (D2L) receptor, we now demonstrate that transient expression of D2L receptors can be regulated by the inactivation of NMDA receptors. Protein tyrosine kinase inhibitor enhanced the D2L receptor gene activation, whereas inhibition of protein phosphatase 1 or 2A decreased receptor activation induced by NMDA blockade. The study support the possible interaction between NMDA and dopamine D2L receptor. Improved therapy may be obtained by developing drugs that target the molecules which regulate both NMDA and/or dopamine receptors.

CELLULAR EXPRESSION OF PIGMENT-DISPERSING HORMONES IN THE BLUE CRAB *CALLINECTES SAPIDUS*.
N. Jaenecke, J. M. Klein, J. Phillips, J. P. Riehm and K. R. Rao*. Dept. of Cellular and Molecular Biology, Univ. of West Florida, Pensacola, FL 32514.

Klein et al. (Biochem. Biophys. Res. Commun. 205, 410-416 (1994)) reported finding two different cDNAs which encoded the precursors of the pigment-dispersing hormones, PDH I and PDH II, in the blue crab *Callinectes sapidus*. In the present studies, these cDNAs have been used to design specific cRNA probes which hybridized selectively with the PDH I- and II-precursor encoding mRNAs.

Northern blot experiments showed that PDH I and II were expressed in eyestalk ganglia; no hybridization products were observed using heart, muscle or hepatopancreas preparations. In situ hybridization experiments showed expression patterns for PDH I and II in the eyestalk of a single animal. Staining of adjacent sections revealed that both PDH isoforms are probably expressed in different cells in the eyestalk. These results suggest different physiological functions of both peptides, as also indicated by the results of assays for melanophorotropic activity in fiddler crabs in which PDH II displayed a 400-fold less potency relative to PDH I.

710.19

EXPRESSION OF ZIF268 IN THE TEMPORAL CORTEX OF MONKEYS RELATED TO LEARNING OF VISUAL STIMULUS-STIMULUS ASSOCIATION.
H. OKUNO*, S. KANOU, W. TOKUYAMA and Y. MIYASHITA. Dept. Physiology, Sch. Medicine, Univ. Tokyo, Hongo, Tokyo 113, Japan.

To investigate the molecular basis of cognitive memory in the primate, we examined expression of immediate early genes in the temporal cortex of monkeys during visual learning. Three Macaque monkeys were trained to perform a pair-association task (PA) that required them to memorize the visual stimulus-stimulus association between computer-generated pictures. Another three monkeys were trained to perform a visual discrimination task (VD) which required them to memorize the stimulus-reward association by using the same set of stimulus pictures as that for the PA task. After training with 12 pairs of stimulus pictures, both PA and VD monkeys were trained using a new set of pictures. Before the monkeys' performance reached a plateau phase (PA, 8-10th session with the new set; VD, 5-6th session), they were perfused immediately after the completion of that day's training session. Serial coronal sections (0.5 mm intervals) of the temporal cortex were stained immunohistochemically. The specificity of the immunoreactivity of each antibody was confirmed by western blotting and by antigen-absorption experiments. We found that Zif268, a transcription factor encoded by an immediate early gene, was expressed in a different manner during PA and VD learning. *Zif268-immunopositive neurons were found to be distributed as patches in the inferior* temporal gyrus in PA monkeys, but not in VD monkeys. The patches included Zif268-immunopositive neurons in the superficial and deep layers as well as in layer IV. Quantification of the immunoreactivity revealed that the Zif268 expression levels in PA monkeys were higher than those in VD monkeys in area 36 ($P = 0.01$, t-test), but not in area 35 and TE. These results suggest that the PA learning activates different gene cascades in the inferior temporal gyrus, particularly in area 36, compared with VD learning, and that Zif268 may play a role in the formation of the visual associative long-term memory in the primate.

710.20

EXPRESSION OF CYTOSKELETAL mRNAs IS ALTERED AFTER AXOTOMY IN MATURE AND AGED F334 RATS.
J.M. Jacob*, B. Srinivasan and A.R. Whitetree. Dept. of Anatomical Sciences, OUHSC, OKC, OK 73190.

Axotomy results in a series of morphologic, biochemical and physiological changes in neuronal cell body. Axotomy also alters structural protein mRNA expression. In this study, the expression of several isoforms of β-tubulin (classes I, II, and IV) as well as the neurofilament triplet protein (NF-L, NF-M, NF-H) was examined in mature (6 mo) and aged (24 mo) F334 rats after axotomy. Fluorogold, a retrograde tracer, was used to locate the motor columns supplying the right sciatic nerve. Rats were killed by decapitation at 12hr, 1d, 3d, 7d or 14d after sciatic nerve transection; spinal cords were removed rapidly and frozen on dry ice. Longitudinal 20 µm sections were made through the lumbar spinal cord region containing the axotomized motor neurons. Using digoxigenin-labeled oligonucleotide or cDNA probes specific for each cytoskeletal protein, levels of mRNA expression were determined. These data suggest that message expression is down-regulated with advancing age, but that expression of cytoskeletal proteins after axotomy in the aging rat follows patterns similar to those seen in the young rat.

710.21

EXPRESSION OF THE PRION PROTEIN (PrP) GENE IN CULTURED NORMAL HUMAN MUSCLE. E. Sarkozi, V. Askanas, J. McFerrin, and W.K. Engel*. USC Neuromuscular Center, Los Angeles, CA 90017-1969.

Even though abnormal accumulation of PrP has been considered unique to the brain, we have recently demonstrated abnormal accumulation of PrP and increased PrP-mRNA in vacuolated muscle fibers in inclusion-body myositis (reviewed by Askanas et al, 1994). PrP and its mRNA are also increased in human muscle fibers regenerating in vivo, but PrP-mRNA is virtually undetectable in the mature muscle fibers (except focally at the neuromuscular junctions). We have now studied the expression of PrP gene in cultured normal human muscle.

Adult human muscle was cultured aneurally in monolayer from the satellite cells of portions of 5 normal muscle biopsies. PrP-mRNA abundance, relative to 28S ribosomal RNA, was measured at 10, 20 and 40 days of growth by Northern blots, using ^{32}P-labelled cRNA transcribed from a human PrP-cDNA (gift from S.B. Prusiner). To monitor muscle development, creatine kinase (CK) activity was measured in sister cultures. At each stage of growth, cultured human muscle expressed strong PrP-mRNA. Its expression was lowest in 10-day-old cultures, and increased 144% ($p < 0.02$) in 20-day-old cultures. Between days 20 and 40, PrP-mRNA increased only 37% ($p < 0.03$). Between days 10 and 20, increase of CK activity was 166% ($p < 0.04$), similar to the increase of PrP-mRNA; but in contrast to PrP-mRNA, between days 20 and 40 CK activity continued to increase significantly 138% ($p < 0.03$) and linearly. Our study demonstrates for the first time that: 1) the PrP gene is expressed in cultured normal human muscle; and 2) the highest level of its expression occurs during early muscle development. Thus, cultured normal and diseased human muscle should provide an excellent model to study factors influencing synthesis of PrP and its role therein.

LONG-TERM POTENTIATION: PHYSIOLOGY V

711.1

INHIBITION OF LONG-TERM POTENTIATION, BUT NOT LONG-TERM DEPRESSION, BY RYANODINE IN THE RAT DENTATE GYRUS Y Wang, MJ Rowan and R Anwyl* Department of Physiology, Trinity College, Dublin, Ireland

Regulation of Ca release from the intracellular Ca stores of the endoplasmic reticulum (ER) is known to occur in part via the ryanodine receptor, a Ca-activated Ca channel located on the ER. The role of intracellular Ca stores in synaptic plasticity has been studied by investigating the effects of ryanodine on the induction of long-term potentiation (LTP) and long-term depression (LTD). Intracellular patch clamp and field recordings of excitatory postsynaptic potentials and currents (epsps/epscs) were made from the dentate gyrus of hippocamapal slices in response to stimulation of the associational/commissural pathway of rats (~100g). In control recordings, LTP of epscs measuring 180±6%, n=9,(20 min post-stimulation) was induced in response to high frequency stimulation (8 trains each of 8 pulses at 200 Hz, intertrain interval 2 sec). LTD of field epsps and epscs measuring 40±8%, n=5, and 32±5%, n=9 respectively was induced by low frequency stimulation (900 pulses at 1Hz or 2 Hz). In experimental recordings, ryanodine (20 uM) was either perfused extracellularly in experiments recording field epsps, or put in the patch clamp electrode for recording epscs. Ryanodine was found to block LTP, but not LTD. Thus the amplitude of epscs at 20 min post-high frequency stimulation in the presence of ryanodine measured 99±5%,a significant inhibition of LTP. Low frequency stimulation induced LTD of field epsps and epscs measuring 34±6% and 40±8% respectively, values not significantly different from controls.

711.2

CORRELATING DENDRITIC SPINE STRUCTURE WITH FUNCTION BY COMBINED ELECTRON MICROSCOPY AND Ca^{2+} IMAGING. T.H. Murphy*, P.J. Mackenzie, M. Umemiya, and G.S. Kenner, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1Z3

By imaging Ca^{2+} entry associated with miniature excitatory synaptic currents (MESCs) under conditions that favor NMDA receptors (0 Mg^{++}, 5 mM $CaCl_2$, and 1 µM TTX), we have been able to monitor the activation of a single synaptic site. Using this approach we concluded that the amplitude of repeated MESCs at a single synapse (attributed to NMDA receptors) are variable, furthermore some synaptic sites show a higher frequency of MESCs than others. Using cultured cortical neurons that were injected with fura-2 and biocytin, we evaluated the ultrastructural characteristics of dendritic regions that show these miniature synaptic Ca^{2+} transients (MSCTs) by peroxidase staining and serial sectioning. In evaluating the $[Ca^{2+}]_i$ images we identifed a presumed high probability region that exhibited 12 MSCTs from a single ~1 µm^2 dendritic site. Neighboring sites were either inactive or showed only 1 MSCT. Transmission EM revealed that a single large spine synapse (~ 1 µm^2) was centered at the site of MSCT initiation at the presumed high probability synapse. Other synapses were several µm away, making it unlikely that they contributed to the MSCTs. Our results suggest that a high frequency of synaptic responses of varying amplitude can be attributed to a single large synapse.

711.3

Ca^{2+} Signals Associated With The Induction Of Long-Term Potentiation And Long-Term Depression In Pyramidal Cells Of The Rat Visual Cortex. C.Hansel, A.Artola[1] and W.Singer. (SPON: European Neuroscience Association) . Max-Planck-Inst. for Brain Research, Deutschordenstr.46, 60496 Frankfurt, FRG. [1]Present address: Dept. of Neurobiology, ETH-Hoenggerberg, CH-8093 Zürich.

We characterized Ca^{2+} signals evoked by tetanization patterns suitable for the induction of LTP and LTD in layer II/III pyramidal cells of the rat visual cortex using the fluorescent Ca^{2+} indicator fura-2. Neocortical slices (200-250 µm thick) were obtained from rats aged 5-7 weeks. Sharp microelectrode recordings were used to measure responses to stimulation in either layer IV (conditioning pathway) or lateral layer II (control pathway). Three different plasticity patterns were established in cells not filled with the indicator dye. LTD was reliably induced by 5x repeated 50Hz stimulation in layer IV (8 / 9 cells). Application of only one 50Hz burst reduced the success rate in LTD induction to 50% (3 / 6 cells). Pairing of the repetitive 50Hz stimulation with a postsynaptic 20mV-depolarization and lowering of $[Mg^{2+}]_o$ led to reliable induction of LTP (6 / 7 cells). For characterization of evoked Ca^{2+} dynamics, these tetanization patterns were applied to cells filled with fura-2 and changes of dendritic $[Ca^{2+}]_i$ were assessed with single-wavelength excitation at 380nm using an intensified CCD camera. Repetition of 50Hz bursts (LTD pattern) increased burst-induced Ca^{2+} elevations, although Ca^{2+} levels nearly completely recovered to baseline during the 10sec long interburst-intervals (1x50Hz burst: n=12; 5x: n=7). In contrast,Ca^{2+} levels accumulated during application of the LTP inducing tetanization pattern (n=5) to levels higher than those measured during LTD induction. These observations indicate that the induction of LTD and LTP is associated with differences in evoked Ca^{2+} dynamics that are reflected by differences in both amplitude and duration of Ca^{2+} elevations. These results support the assumption that the different thresholds for the induction of LTD and LTP are related to the amplitude and the kinetics of the postsynaptic increase of $[Ca^{2+}]_i$.

711.4

THE INTERPLAY OF DENDRITIC SPINE MORPHOLOGY WITH DEVELOPMENT OF GLUTAMATE RECEPTORS AND VOLTAGE GATED CALCIUM CHANNELS AND ITS IMPLICATION FOR CALCIUM DYNAMICS. S.S. Dalal* and C.E. Niesen. Dept. of Biomedical Engineering, University of Southern California, Los Angeles, CA 90089-1451; and Div. of Neurology, Childrens Hospital of Los Angeles and USC School of Medicine, Los Angeles, CA 90027.

A detailed biophysical computer model that simulates calcium dynamics in dendritic spines in rat hippocampal pyramidal neurons was created. Two features distinguish this model. Whereas previous models have only taken into account calcium efflux from the AMPA and NMDA glutamate receptors (GluRs), the present model accounts for calcium influx into dendritic spines from both GluRs and voltage-gated calcium channels (VGCCs). The existence of N-type VGCCs, within a subset of hippocampal spines, has been confirmed by confocal microscopy (Mills, et al., 1994). The distribution of VGCCs and GluRs on dendritic spines was varied with age from the first postnatal day (PN1) to adulthood as was dendritic spine morphology. Mechanisms that simulate diffusion, pumping, and buffering of calcium were taken from the methods described by Holmes and Levy (Holmes and Levy, 1990). Results from the simulations are in very good agreement with calcium imaging studies in the hippocampal slice (Guthrie, et al., 1991; Jaffe, et al., and Conner, et al., 1994) and other modeling studies (Gold and Bear, 1994; Koch and Zador, 1993), i.e. presynaptic stimulation elevates calcium levels in the spine head to tens of micromoles while, in the dendritic shaft, calcium concentration increases to less than 1 µM. In the adult, both the N-type and the T-type VGCC as well as the NMDA GluR are major contributors to this calcium boost which resulted in LTP. Neither the L-type VGCC nor the AMPA GluR alone could induce LTP. In modeling dendrites less than PN7, the lack of N-type VGCCs and the predominance of headless spines resulted in an absence of LTP. Both NMDA-dependent and NMDA-independent LTP can be induced in the model.

INDUCTION OF LTP AND LTD OBSERVED SIMULTANEOUSLY WITH A RISE OF POSTSYNAPTIC CALCIUM IN RAT VISUAL CORTEX.

H. Yasuda and T. Tsumoto* Department of Neurophysiology, Biomedical Research Center, Osaka University Medical School, Suita 565, Japan

An input-associated increase in calcium at postsynaptic sites is suggested to trigger processes for the induction of long-term changes in synaptic efficacy. Furthermore, the extent of this increase is hypothesized to determine the direction of the changes, i.e., a large increase beyond a certain threshold leads to long-term potentiation (LTP) while a small increase below the threshold to long-term depression (LTD). This hypothesis seems testable with microfluorometry using calcium-indicators, such as fura-2 or fluo-3, but so far was not successfully proofed at least in neocortex, probably because these dyes have a strong calcium-chelating action. So, we used another indicator, rhod-2, which has a much weaker chelating action. With this dye, we measured changes in calcium concentration in visual cortical neurons during tetanic synaptic inputs simultaneously with whole-cell current clamp recordings of synaptic activity.

In visual cortical slices of young rats at 9-18 postnatal days, rhod-2 was injected directly into pyramidal cell-like neurons of layer II/III through a patch pipette from which we simultaneously recorded excitatory postsynaptic potentials (EPSPs) of the neuron under observation. Tetanic stimulation of θ-burst type given to layer IV induced a clear increase in fluorescent signal. Usually, this increase was stronger in dendrites than in soma. Also, the decay time of the increased signal was much faster in dendrites than in soma. There was a tendency that tetanic stimulation which led to the induction of LTP of EPSPs induced a higher rise of calcium signal in dendrites than that which led to the induction of LTD.

DISRUPTION OF A CYCLIC-ADP-RIBOSE SIGNALING PATHWAY INTERFERES WITH LONG TERM POTENTIATION IN AREA CA1 OF THE RAT HIPPOCAMPUS. N.K. Mahanty*, M.E. Gurnack+, T. Walseth+, E.M. Schuman. Division of Biology 216-76, California Institute of Technology, Pasadena CA 91125, +Department of Pharmacology, University of Minnesota, Minneapolis MN 55455.

A recently identified endogenous ligand for the ryanodine-sensitive Ca^{2+} store is cyclic ADP-ribose (cADPr). The enzyme responsible for cADPr synthesis, an ADP ribosyl-cyclase, is stimulated by cGMP. Biochemical assays indicate that the hippocampus has ADP-ribosyl cyclase activity localized in the particulate fraction. The diffusible signal nitric oxide, NO, can stimulate cGMP production by activating a soluble guanlyl cyclase, raising the possibility that the NO generated during the onset of LTP induction may initiate a signal transduction cascade that eventually includes cADPr activation of ryanodine-sensitive Ca^{2+} stores. We have tested this idea by utilizing a competitive antagonist, 8-NH_2-cADPr, of the cADPr binding site on the ryanodine sensitive store. The inhibitor was introduced postsynaptically in a patch electrode into an individual CA1 cell in the acute hippocampal slice. Two independent Schaffer Collateral afferent pathways were alternately stimulated (0.03 Hz) and the evoked excitatory postsynaptic currents, (EPSCs) were recorded. After a 20 minute period of baseline stimulation, during which time the inhibitor was allowed to diffuse into the cell, LTP was induced by pairing depolarization with low frequency (1 Hz) stimulation of one pathway. Following the pairing of depolarization and 1 Hz stimulation a slowly decaying potentiation was observed which typically returned to baseline values within 20 min [mean % of baseline = 99.1 +/- 1.3]. This short-term potentiation was followed by a slow onset depression of approximately 50% which reached asymptote 40 minutes after LTP induction [mean % of baseline = 45.5 +/- 0.5]. Control slices or slices injected with boiled 8NH_2-cADPr exhibited normal LTP [mean % of baseline = 169.4 +/-2.1 and 157.3 +/-1.4]. These data suggest that a cADPr signaling pathway maybe involved hippocampal synaptic plasticity and may participate in determining whether synapses become potentiated or depressed during induction. MODELS OF CALCIUM BINDING TO KINETICALLY DISTINCT SITES ON CALMODULIN: IMPLICATIONS FOR LTP. O. V. Yousukhno*[1], W. R. Holmes[2] & W. B Levy[1]. [1]Univ. of Virginia Health Sciences Ctr., Dept. of Neurosurgery, Charlottesville, VA 22908 and [2]Dept. of Biological Sciences, Ohio University, Athens, OH 45701

We have revisited the Holmes & Levy (1990) biophysical model of associative LTP. Again we consider a morphologically correct granule cell of the dentate gyrus and the effects of brief, high-frequency synaptic activation (8 firings at 400 Hz), which causes Ca^{2+} influx through NMDA channels into a modeled spine. Here we update our model of calcium's interaction with calmodulin to include the currently accepted kinetics of this interaction. The calmodulin concentration used in the simulations was 20 μM. The four Ca^{2+} binding sites on a calmodulin molecule were modeled using the different kinetic constants summarized in Cox et al. (In *Calcium and Calcium Binding Proteins*, 1988) for the situation in which binding proteins are present. In these conditions, binding of the third Ca^{2+} to a calmodulin molecule exhibits a very high cooperativity (ibid). Brief, high-frequency activation of a single synapse produces 2-5 μM of calmodulin saturated with four bound calcium ions. This concentration (according to the data of Meyer et al., *Science* 256:1199, 1992, and assuming that there is more calmodulin than CaMKinase II) is enough Ca_4Calmodulin to fully activate CaMKinase II. This may even be enough Ca_4Calmodulin to lock the CamKinase II holoenzyme in a permanent autophosphorylation mode. Thus, these data indicate that CaMKinase II activation alone will not be sufficient to produce associative LTP because, in vivo, single synapses are not sufficient for homosynaptic LTP.

INVOLVEMENT OF Ni^{2+}-SENSITIVE CALCIUM CHANNELS IN HOMOSYNAPTIC LTD IN HIPPOCAMPUS L. K. Schexnayder*, B. R. Christie, and D. Johnston, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Recently we have shown that voltage-gated Ca^{2+} channels that are sensitive to Ni^{2+} (R- and T-type) are a major source of Ca^{2+}influx in the apical dendrites of CA1 pyramidal neurons (Christie et al., 1995, *J. Neurophysiol.*; Magee and Johnston, 1995, *Science*). In the present experiments we examined the role of these channels in homosynaptic LTD. Hippocampal slices were prepared from 2–4 week old rats using standard techniques and maintained in a submerged chamber. To assess basal synaptic strength, afferent fibers in the stratum radiatum were stimulated at 0.1 Hz. Initially we examined whether LTD could be induced at temperatures at which Ca^{2+} channel activity in dendrites has been examined. Slices maintained at 23°C exhibited a 19.9±7.4% (n=6) reduction in response size that lasted for at least 30 min following 1 Hz stimulation (900 pulses) and a 22.2±2.2% (n=5) reduction when 3 Hz was administered. No greater LTD was produced at 32°C, where the 1 and the 3 Hz produced −20.7±7.5% (n=7) and −21.7±12% (n=4) LTD, respectively. To evaluate the contribution of Ni^{2+}-sensitive channels to LTD induction, $NiCl_2$ was first added to the bathing medium for 25 min at one of three concentrations (25, 50 and 100 μM), and its effects on synaptic transmission were monitored for 30 min following washout. Both the 50 and the 100 μM concentrations produced a depression of synaptic strength when administered alone (50 μM: −21±4%, n=3; 100 μM: −20.1±5.2%, n=5). The 25 μM concentration, however, did not produce any discernable changes in synaptic strength (6.7±2.9%, n=5). Thus, in separate slices, we applied the 25 μM concentration during the administration of either the 1 or the 3 Hz stimuli and found that while a short-term depression was produced, Ni^{2+} blocked the expression of LTD (1Hz: 1.6±11.9%, n=6; 3Hz: 7.9±9.7%, n=6). FLUORESCENCE IMAGING OF INTRACELLULAR CALCIUM DURING THE INDUCTION AND EXPRESSION OF HOMOSYNAPTIC LTD IN HIPPOCAMPAL CA1 PYRAMIDAL NEURONS. B. R. Christie*, J. Magee, and D. Johnston Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Hippocampal neurons exhibit various forms of synaptic plasticity, including long-term potentiation and long-term depression (LTD). The induction of LTD depends, among other things, upon a rise in postsynaptic $[Ca^{2+}]_i$. To investigate the changes in $[Ca^{2+}]_i$ during LTD, we have combined fura-2 imaging with whole-cell recordings of visually identified CA1 neurons.

Hippocampal slices (400 μm) were obtained from 2–4 week old rats using standard procedures and maintained at 32°C in a submerged chamber. To measure fluorescence changes in intracellular Ca^{2+}, fura-2 (125 μM) was included in the pipette solution, and relative changes in ΔF/F were measured using a cooled CCD camera in sequential frame transfer mode (25 ms frame interval). Whole-cell recordings were made from CA1 neurons located within 50 μm of the slice surface. Following a 10 min baseline period, cells were synaptically activated at 3 Hz and evoked EPSPs and changes in fluoresence were monitored. LTD, which lasted at least 30 min, only occured in those neurons in which sufficient stimulation was given to elicit postsynaptic action potentials during the 3 Hz stimuli (subthreshold: −7.1 ± 5.8%, n=3; suprathreshold: −30.5 ± 15%, n=4). During the application of the 3 Hz stimulation, only neurons in the suprathreshold group exhibited detectable changes in postsynaptic calcium levels (ΔF/F, soma: 7.4 ± 1.1%; 0–75 μm: 6.9 ± 1.5%; 75–150 μm 6.8 ± 4.1%; > 150 μm: 4.3 ± 2.9%). These data suggest that the Ca^{2+} entry during suprathreshold synaptic stimulation is involved in the induction and maintenance of LTD (MH44754, MH48437, NS11535, NSERC103103).

DYNAMICS OF CALCIUM AND CALCIUM-BINDING PROTEIN IN A SPINE : AN ANALYSIS BY MODELING AND SIMULATION K.Ichikawa*, H.Okamoto and I.Yamaguchi. Foundation Research Lab. Fuji Xerox Co., Ltd., 430 Sakai Nakaimachi Ashigarakamigun Kanagawa, 259-01 Japan

Increase in the intracellular calcium concentration($[Ca^{2+}]_i$) triggers both long-term potentiation(LTP) and depression(LTD) depending on stimulus intensity. Although mechanisms which underlie long-term synaptic modification are not yet elucidated, Ca^{2+} was found to play a key role. In the present study, we constructed a model for $[Ca^{2+}]_i$ and Ca^{2+}-binding proteins in a spine, and analyzed their dynamics.

The present model includes N-methyl-D-Aspartate(NMDA) and α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid(AMPA) receptor channels with desensitization, Ca^{2+} flux through NMDA receptor channels, Ca^{2+}-buffers, Ca^{2+}-binding protein, Ca^{2+} extrusion, and Ca^{2+} diffusion. Dynamics of intracellular $Ca^{2+}$and Ca^{2+}-binding protein for tetanic stimulation(100Hz-1s), low frequency stimulation(1Hz), and theta-burst stimulation were compared.

The increase in $[Ca^{2+}]_i$ was transient even synaptic stimulation continued. This is because AMPA and NMDA receptor channels are desensitized, and the inward flow of Ca^{2+} is reduced. Furthermore, the peak level of $[Ca^{2+}]_i$ was much higher in theta-burst stimulation than in tetanic (continuous) stimulation because of the slow recovery from desensitization. This result explains why theta-burst stimulation is effective for inducing LTP. In contrast, low frequency stimulation resulted in much smaller increase in $[Ca^{2+}]_i$ which would lead to LTD. The concentration of activated form of calmodulin increased far more drastically than the increase in $[Ca^{2+}]_i$ as stimulating intensity was increased. Therefore, the role of calmodulin is to amplify the Ca^{2+} signal and stabilize the differentiation between LTP and LTD.

A PARALLEL INCREASE OF NMDA AND NON-NMDA RECEPTOR-MEDIATED CURRENTS IN CALCIUM-INDUCED LTP IN CA1 PYRAMIDAL CELLS OF HAMSTER HIPPOCAMPAL SLICES. S.-N. Yang*, D. W. Robinson and J. M. Horowitz. Sec. of Neurobiol., Physiol., and Behav., Univ. of Calif., Davis, CA 95616

Previously we reported the establishment of Ca^{2+}-induced LTP in area CA1 of the hamster hippocampal slice (Soc. Neurosci. Abs., 20: 119.3, 119.4, 1994). Here, we further study the involvement of NMDA and non-NMDA receptor-mediated currents in Ca^{2+}-induced LTP. Whole-cell patch-clamp recording of excitatory postsynaptic currents (EPSCs) evoked by single shocks to Schaffer fibers, and action potentials induced by depolarizing current injections were made from CA1 pyramidal cells of hamster hippocampal slices (350μm). The average resting membrane potential was - 61.4 ± 0.8 mV (n= 19). In current clamp mode (Vm= - 65 mV), application of high Ca^{2+} (without stimulating Schaffer fibers) only evoked a short-term increase of the firing rate of action potentials (n= 4). In contrast, a long-term increase of the firing rate was seen if sufficient single shocks were applied during a high Ca^{2+} pulse (n= 2). In voltage clamp mode (Vm= - 60 mV), a high Ca^{2+} pulse induced a *parallel*, long-term increase of both NMDA and non-NMDA receptor-mediated currents of the dual component EPSC (n= 8). Both the scaled EPSCs (n= 3) and normalized amplitudes of the decay times of EPSCs prior to, and following Ca^{2+}-induced LTP showed a similar pattern (n= 3). In addition, following a stable Ca^{2+}-induced LTP, tetanization of Schaffer fibers does not provide any additional enhancement of either NMDA or non-NMDA receptor components (n= 5). These results suggest that Ca^{2+}-induced LTP shares basic common mechanisms with tetanically-induced LTP. Moreover, the maintenance of Ca^{2+}-induced LTP involves a similar increase in NMDA and non-NMDA receptor components and no change in decay times of EPSCs. [NASA Grant #NAG-2-788]

NITRIC OXIDE SYNTHASE INHIBITORS SELECTIVELY BLOCK LTP OF MINIMAL AMPLITUDE SYNAPTIC RESPONSES. P. F. Chapman*, Psychology Department, Neuroscience Program, University of Minnesota, Minneapolis, MN 55455

The hypothesis that nitric oxide (NO) contributes to LTP has received a considerable amount of experimental support. At the same time, many laboratories have presented evidence that inhibitors of nitric oxide synthase (NOS) fail to block LTP, or block only under restricted conditions. These results suggest that NO might regulate the threshold for LTP induction at CA1 synapses. I have tested an alternative hypothesis; that NO might be required for LTP induction only at a relatively small subset of CA1 afferent synapses. According to the hypothesis, these synapses would be the most readily excitable of a heterogeneous group of CA1 afferents, and thus the most likely to be activated by weak stimulation. Therefore, LTP at the low end of the input/output curve should be blocked by NOS inhibitors, even following strong tetanus.

I have used an experimental protocol in which I alternated "weak" stimulation (40 μsec pulses) with "strong" stimulation (100 μsec pulses). Experiments were conducted at 31.5°C, in slices taken from rats 15-150 days old. Stimulus intensities were adjusted so that strong stimulation elicited a response about 30% of the maximum evoked field EPSP slope; weak baseline stimulation evoked an EPSP with a slope between 0.05 and 0.09 mV/msec. In normal ACSF, ten theta bursts, given at "strong" intensity, produced LTP of responses evoked by both strong (133±6%) and weak stimuli (150±28%) measured 60 minutes after tetanus. In contrast, the same stimuli given in the presence of 100 μM NOArg produced normal LTP as measured with 100 μsec pulses (172±24%), but no LTP when measured with 40 μsec pulses (103±6%). Bath application of 100 μM NOArg had no effect on baseline responses measured with 40 μsec pulses (99±1% of pre-drug baseline), or on LTP induced before drug application (150±28% at 60 min, 144±14% at 120 min). The results indicate a role for NO in LTP induced under physiological conditions, and suggest the presence of important heterogeneities in SC/C afferents to CA1. Supported by NSF grant IBN-9410131

711.13

DIFFERENTIAL EFFECTS OF NITRIC OXIDE SYNTHASE INHIBITORS ON LTP AT BASAL AND APICAL SYNAPSES OF HIPPOCAMPAL CA1 NEURONS. J.E. Haley and D.V. Madison* Dept. of Molecular and Cellular Physiology. Stanford University School of Medicine, Stanford, CA 94305-5426.

Diffusible messengers such as nitric oxide have been proposed to act as intercellular signals in the production of long-term potentiation. Recent reports (O'Dell, et al. [1994], Science 265, 542-6; Wendland, et al.[1994], PNAS 91, 2151-5) illustrate that different forms of NOS are localized to the somata and apical dendrites, but appear to be absent from the basal dendrites of these neurons. Thus, LTP elicited in synapses terminating in the basal dendrites of CA1 pyramidal cells may not depend on NO, in contrast to apical synapses. We have tested this theory by comparing the effects of the NOS inhibitors on LTP elicited by electrical stimulation in stratum radiatum (s.r.; apical) and s.oriens (s.o.; basal). In control, tetanization (100 Hz/1 sec) in s.r. caused LTP of 140.3 +/- 6.8% of basal transmission; s. o. tetanization resulted in LTP of 156.9 +/- 13.3%. After application of L-NO-Arg (100 uM), identical tetanization in s.o. still produced normal LTP (156.4 +/1 17.9%) but following tetanization in s.r., LTP did not occur (111.1 +/- 9.3%). Utilizing intracellular recording, we attempted to see if we could detect this differential effect of NOS inhibitors when they were injected into single postsynaptic cells. In these experiments, LTP was induced by pairing postsynaptic depolarization (by current injection) with 1Hz stimulation delivered simultaneously to s.o. and s.r. In control , this resulted in LTP of 155.7 +/- 14.3% in s.r. and 138.1 +/- 13.6 % in s.o. After injection of L-NMMA (100 mM) into postsynaptic cells LTP was prevented in both pathways (s.r.: 113 +/- 9.06%; s.o.: 100.1 +/1 7.7%). Thus a differential effect on LTP was not seen when using intracellularly injected NOS inhibitor with pairing-induced LTP. Present results suggest that there may be a differential role for nitric oxide in apical vs basal dendritic synapses in area CA1 of hippocampus. However, not all experimental results are consistent with this hypothesis. This discrepancy is being investigated.

711.14

A POTENTIAL ROLE FOR PROTEIN MYRISTOYLATION AND AN ENDOTHELIAL NITRIC OXIDE SYNTHASE (eNOS) IN LONG-TERM POTENTIATION (LTP). D. B. Kantor, G. R. Sandoval and E.M. Schuman*. Division of Biology. California Institute of Technology 216-76, Pasadena, CA 91125.

Previous studies utilizing broad spectrum NOS inhibitors (which inhibit both eNOS and neuronal NOS, nNOS) have suggested that NO may participate in LTP. Physiological and immunohistochemical studies from nNOS and wild-type mice have suggested that eNOS, rather than nNOS, activity may produce NO during LTP. To test this suggestion we have utilized a putative nNOS specific inhibitor, 7-nitroindazole (7-NI). In two pathway experiments, we found that 7-NI-treated slices (100 μM) exhibited significant LTP that was of a similar magnitude to control slices [mean % of baseline: control: 131.8 +/- 4.3 (n = 8) 7-NI: 119.7 +/- 6.5 (n = 10)]. The most striking difference between eNOS and nNOS isoforms is the co-translational N-terminal myristoylation and consequent membrane localization of eNOS. Accordingly, we have begun to examine whether myristoylation of proteins is important for LTP production by utilizing hydroxy-myristic acid (HMA), an inhibitor of protein myristoylation. Slices pre-incubated in HMA for 18-24 hrs. in HMA (200 μM-1mM) failed to exhibit LTP wheras control slices incubated in solvent alone for the same time period exhibited significant potentiation [mean % of baseline: HMA: 109.7 +/- 7.8 (n = 10), control: 182.3 +/- 14.4 (n = 9)]. Post-hoc *in vitro* assays of myristoylation indicate that the HMA pre-treated slices (that failed to exhibit LTP) exhibited significantly reduced myristoylation of an exogenous myristoylation peptide when compared to controls [^{3}H-myristic acid incorporation (cpm) control: 4142.0 +/- 516.0, HMA: 271.0 +/- 28.0 (n = 5)]. We are currently developing an adenovirus construct to deliver recombinant cDNA encoding eNOS mutants which lack catalytic activity yet retain the N-terminal glycine required for myristoylation. In preliminary experiments we have infected slices with an Ad-*lacZ* construct and obtained β-gal expression within 4 - 18 hrs; these same slices exhibit normal LTP.

711.15

PHOTOLYTIC RELEASE OF NITRIC OXIDE BLOCKS INDUCTION OF LTP BY DEPRESSION OF NMDA RECEPTOR-MEDIATED TRANSMISSION IN THE CA1 REGION OF RAT HIPPOCAMPUS K.P.S.J. Murphy and T.V.P. Bliss* National Institute for Medical Research, Mill Hill, London NW7 1AA, U. K.

We have used flash photolysis of a caged form of nitric oxide ($K_2Ru(NO)Cl_5$) to rapidly deliver known concentrations of nitric oxide (NO) to area CA1 of hippocampal slices prepared from young Sprague-Dawley rats (70-100g) maintained in an interface chamber at 24°C. In previous experiments designed to test the retrograde messenger hypothesis for NO we were unable to detect NO-induced potentiation of synaptic efficacy (Murphy *et al*, (1994) *Neuropharmacology* **33**, 1375-85). We report here evidence that NO may instead serve a role in setting the threshold for the induction of LTP (cf. Izumi *et al*, (1992) *Science* **257**, 1273-76). Prior exposure of slices to photolytically released NO (1-4.5μM), ten minutes before application of a conditioning tetanus, blocked the induction of LTP in a concentration-dependent manner; a control pathway potentiated before application of NO was unaffected. The magnitude of LTP observed after exposure to NO, expressed as a percentage of LTP in the control pathway, was (mean±sem) 101.0±15.0, 41.0±9.9, 30.3±4.1 and -14.8±17.9 for 0μM, 1μM, 3μM and 4.5μM NO respectively (n=3 for each concentration). The mechanism by which NO regulates the induction of LTP is possibly by modulation of NMDA receptors. We have shown previously that photolytically released NO selectively depresses NMDA receptor-mediated transmission in a persistent and concentration-dependent manner. NO-induced reduction in the efficacy of the NMDA receptor could be sufficient to raise the threshold and/or block the induction of LTP.

NO may modulate NMDA receptors by redox modification. Such a reaction would be expected to produce a rapid alteration in NMDA receptor function. However, the time-course of NO-induced depression, following photolytic release of NO, is surprisingly slow. Exposure to 2.7μM NO induced a 63.6±12% (n=6 slices) depression of the initial slope, taking 104.3±14.3s to reach half-maximum depression, suggesting that redox modification is not the primary mechanism of NO-dependent depression.

711.16

MODULATION OF LONG-TERM POTENTIATION BY REACTIVE OXYGEN SPECIES. E. Klann*, E.D Roberson, and R.M. Mack. Dept. of Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260 and Div. of Neuroscience, Baylor College of Medicine, Houston, TX, 77030.

The induction of long-term potentiation (LTP) in hippocampal area CA1 is associated with an increase in cofactor-dependent protein kinase C (PKC) activity which is mediated by both nitric oxide (NO) and superoxide ($\bullet O_2^-$) (Soc. Neurosci. Abstr. 20:446). To test the hypothesis that PKC is directly activated by reactive oxygen species, we incubated purified PKC with SIN-1, a compound which produces NO and $\bullet O_2^-$. Incubation of PKC with 1 mM SIN-1 increased cofactor-dependent PKC activity (196 ± 14% of control, n=12). This increase was attenuated by superoxide dismutase (SOD, 25 μg/ml; 131 ± 13% of control, n=4) and 10 μM hemoglobin (132 ± 22% of control, n=4), suggesting that both NO and $\bullet O_2^-$ are necessary for the activation of PKC. Because NO reacts with $\bullet O_2^-$, ultimately forming hydroxyl radical ($\bullet$OH), we hypothesized PKC could be activated by $\bullet$OH. PKC was incubated with SIN-1 and 10 mM mannitol, an $\bullet$OH scavenger. Mannitol inhibited the SIN-1-induced increase in PKC activity (108 ± 9% of control, n=4), suggesting that $\bullet$OH directly activates PKC. Given these findings, we hypothesized that reactive oxygen species such as $\bullet O_2^-$ and $\bullet$OH could modulate induction of LTP. LTP-inducing stimuli was delivered to the Schaffer collateral input into area CA1 of rat hippocampal slices either in the presence or absence of SOD (121 U/ml). In control slices, LTP was observed in 8 of 9 experiments (initial slope of EPSP = 159 ± 9% of control). In contrast, slices incubated with SOD exhibited LTP in 1 of 9 experiments (initial slope of EPSP = 101 ± 8% of control). However, SOD converts $\bullet O_2^-$ to H_2O_2, which has been shown to inhibit LTP. Therefore, in addition to SOD, catalase (260 U/ml) was incubated with slices in order to remove H_2O_2. LTP was observed in only 5 of 15 slices incubated with SOD and catalase (initial slope of EPSP = 115 ± 6% of control), whereas LTP was observed in 12 of 13 control slices (initial slope of EPSP = 150 ± 4% of control). These data suggest that $\bullet O_2^-$ can modulate the induction of LTP. Further experiments are necessary to determine if $\bullet$OH can also modulate LTP and if PKC is a target for reactive oxygen species after LTP-inducing stimuli.

INDUCTION OF LONG-TERM POTENTIATION IN THE PRESENCE OF INHIBITORS OF NITRIC OXIDE IN RAT MOTOR CORTEX.

L.Yi* and W.T. Greenough. Neuroscience Program, Depts of Psych. and Cell Struct. Biol. Beckman Inst., University of Illinois, Urbana, IL 61801.

Several studies have indicated that the induction of long-term potentiation (LTP) in the hippocampus may be dependent on the production of nitric oxide (NO). More recent studies have indicated that NO synthase inhibitors do not block LTP induction in all cases. To investigate whether NO is involved in the generation of activity-dependent synaptic plasticity in neocortex, we examined the role of NO in the production of LTP in rat motor cortex by administering extracellular NO synthase inhibitors. The results indicated that iontophoretic application of 50 mM N^G-nitro-L-arginine (NOARG) had no significant effects on the amplitudes of the population spike (PS) and EPSP. A similar result was observed when 40 mM hemoglobin was applied. Even at high concentrations of NOARG (80 mM) and hemoglobin (60 mM), the amplitudes of the PS and EPSP did not change significantly. LTP was induced by tetanic stimulation (50 Hz) in the presence of NOARG (50 to 80 mM) and hemoglobin (40 to 60 mM). Neither of these treatment significantly affected the induction of LTP.

The results presented here indicate that, in contrast to the hippocampus, NO does not play a major role in induction or maintenance of LTP in motor cortex. NO synthase inhibitors in the motor cortex have failed to reveal any significant effect on both evoked responses and the induction of LTP. These results suggest that NO is not necessary for LTP induction in motor cortex.

β-AMYLOID ENHANCEMENT OF LTP AND NMDAR-MEDIATED TRANSMISSION IN RAT HIPPOCAMPUS

Michael Rowan*, Jianqun Wu and [1]Roger Anwyl Depts. Pharmacology and Therapeutics and Physiology[1], Trinity College, Dublin 2, Ireland

β-Amyloid is released at central synapses and may have a role in modulating glutamatergic synaptic function. We have investigated this possibility in the rat dentate gyrus in vitro. Hippocampal slices were isolated and superfused using conventional techniques. Excitatory postsynaptic potentials and currents (epsps and epscs) evoked by electrical stimulation of the associational/commissural inputs to the dentate granule cells were recorded with extracellular and intracellular (whole cell patch clamp) electrodes respectively. β-Amyloid (1-40) was bath-applied (200nM) or applied intracellularly (100nM). NMDA receptor-mediated transmission was pharmacologically isolated using the AMPA receptor antagonist NBQX. Bath or intracellular application of β-amyloid resulted in a gradual enhancement of the NMDA receptor-mediated epsc which plateaued approx. 15 min later at a level averaging 140-160% of baseline ($P<0.05$). In those experiments where β-amyloid was washed off there was no reversal of the effect. Although there was no effect on basal AMPA receptor-mediated transmission after bath application of β-amyloid, high frequency stimulation-induced long-term potentiation (LTP) of the field epsp was enhanced by 30% ($P<0.05$). The enhancement of LTP of AMPA receptor-mediated transmission indicates that β-amyloid can facilitate synaptic plasticity. The long-lasting increase in basal NMDA receptor-mediated transmission is direct evidence that β-amyloid selectively interacts with this potentially neurotoxic target via a postsynaptic site.

LONG-TERM POTENTIATION: PHYSIOLOGY VI

712.1

LONG TERM POTENTIATION OF THE SPINAL CORD MOTONEURON DEMONSTRATED IN-VITRO IN THE SPINAL CORD OF NEONATAL RAT

R.A. Maselli,* and Mary Chao Univ. of California, Davis, CA 95616

Long term potentiation (LTP) is a used dependent form of synaptic plasticity characterized by a long lasting enhanced of synaptic strength. In the hippocampus LTP appears to be the physiologic substrate of memory. The existence and possible role of LTP at the spinal motoneuron have not been fully demonstrated. We have used the immature spinal cord of rats (1-6 days old) in-vitro with recordings of ventral root field potentials (VRFPs) and simultaneous electrical stimulation of the dorsal nerve roots or corticospinal tract. Sequential short trains of tetanic stimulation at 100-150 Hz during 5 seconds induced long-lasting potentiation of VRFP amplitudes. This phenomenon was partially and reversibly abolished by perfusion of the preparation with 2-amino-5-phosphonovaleric acid (APV). Exposure of the spinal cord to the non-N-methyl-D-aspartate (non-NMDA) receptor blocker 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) completely and irreversibly abolished VRFPs. These findings suggest that LTP is present at the spinal motoneuron of neonatal rats. The partial obliteration of this phenomenon with APV suggest that LTP at the spinal motoneuron may involve the

712.2

SUSTAINED POSTSYNAPTIC POTENTIATION OF MINIATURE POSTSYNAPTIC POTENTIALS IN CULTURED RAT SYMPATHETIC NEURONS.

K.Kuba*, C.Liu and T.Shirasaki. Dept. of Physiology, Saga Medical School, Saga 849, Japan.

Nicotinic synapses formed between cultured neurons of rat superior cervical ganglia were studied with whole cell patch clamp and fura-2 fluorescence recording techniques. A rapid rise in extracellular K^+ to 20-40 mM by the jump of a laminar flow increased the frequency of miniature excitatory postsynaptic potentials (MEPSCs). The amplitude of MEPSC gradually increased to 120-200% during the course of a high K^+ treatment. On the other hand, the frequency fluctuated around a constant value occasionally with oscillation at a rate of several minutes. Furthermore, an accompanied rise in the intracellular Ca^{2+} of putative presynaptic neurons was unchanged or gradually reduced under the same condition. The inward current induced by acetylcholine after the end of a high K^+ application was also augmented, indicating the postsynaptic mechanism of MEPSC. The potentiation was seen for more than 20 min after the end of a high K^+ treatment and reversibly inhibited by phorbol ester (20 nM). Since the cytoplasm of the ganglion cell body was dialyzed through a patch pipette, the mechanism of potentiation may take place in the localized region of the subsynaptic membrane or may not involve a diffusible messenger.

712.3

SHORT- AND LONG-TERM PLASTICITY OF EXCITATORY SYNAPSES BETWEEN PAIRS OF CELLS IN HIPPOCAMPAL SLICE CULTURES.

D. DEBANNE, N.C GUÉRINEAU*, B.H. GÄHWILER and S.M. THOMPSON.
Brain Research Institute, University of Zurich, 8029 Zurich Switzerland

Pairs of monosynaptically coupled neurons were recorded in rat hippocampal slice cultures. When two action potentials were elicited in a single microelectrode impaled CA3 pyramidal cell, the amplitude of the first postsynaptic current (EPSC) in a whole-cell voltage-clamped CA3 or CA1 cell varied, and the amplitude of the second EPSC was inversely related to the amplitude of the first. Paired-pulse facilitation (PPF) was observed when the first EPSC was small and paired-pulse depression (PPD) when the first EPSC was large. The number of trials displaying PPD was greater when release probability was increased experimentally, and smaller when release probability was decreased. PPD was not affected by decreasing postsynaptic ion flux or receptor desensitization. We conclude that PPD results from a decrease in quantal content, perhaps due to short-term depletion of readily releasable vesicles.

Long-term potentiation (LTP) and depression (LTD) in the hippocampus may be induced alternatively with synaptic responses resulting from the activation of many axons with extracellular stimulation. It is, however, still unknown whether unitary synapses may undergo both LTP and LTD. Pairs of pyramidal neurons in areas CA3 and CA1 of rat hippocampal slice cultures were recorded with sharp microelectrodes. Presynaptic high frequency tetani induced with 2-5 bursts of action potentials at 50 Hz in the presynaptic cell, were ineffective in inducing LTP. LTP could, however, be induced with synchronous pairing of single presynaptic action potentials and postsynaptic depolarizing pulses. This potentiation was reversed by induction of LTD using either low frequency tetani (3 Hz) or asynchronous pairing. These results demonstrate that the same unitary synapses may undergo mutually reversible long-term potentiation and depression.

712.4

THE DEVELOPMENT OF DENDRITIC SPINES IN HIPPOCAMPAL ORGANOTYPIC CULTURES.

N.J. Emptage*, T. Hosokawa and T.V.P. Bliss. National Institute for Medical Research, Mill Hill, London NW7 1AA, U.K.

We have investigated developmental changes in the size and density of dendritic spines on CA1 pyramidal cells in organotypic cultures using confocal microscopy.

Cultures were prepared from three day old Wistar rats using a method adapted from Stoppini *et al. (J. Neurosci. Meth. 37, 173, 1991)*. At 5-7, or 21-26 days, CA1 pyramidal neurones were iontophoretically injected with lucifer yellow dye, and imaged with a Biorad MRC 1000 confocal microscope. The architecture of CA1 cells from a mature organotypic culture (> 3wks) is comparable to that seen in CA1 neurones in acute slices from 3-4 week old rats. The stereologically uncorrected mean interval between spines on secondary apical dendrites was 1.4 ± 0.17 μm (n=40), and on basal dendrites was 1.7 ± 0.13 μm (n=128); the mean observed spine length was 1.12 ± 0.04 μm (n=46) for apical dendrites and 0.80 ± 0.02 μm (n=146) for basal dendrites. These values are similar to those reported in acute slices for Golgi stained CA1 cells. In contrast, spine density from immature cultures (< 1wk) was significantly less (mean density: 2.07 ± 0.26 μm (n=33) for apical dendrites, ($p < 0.01$), and 2.35 ± 0.37 μm (n=39) for basal dendrites, ($p < 0.001$). The length of spines however, was not significantly different from that observed in mature slices (mean length = 1.01 ± 0.06 μM, (n=37) for apical spines (N.S.), and 1.10 ± 0.07 μM (n=48) for basal spines (N.S.)).

These results indicate that CA1 neurones in organotypic hippocampal cultures systematically add spines during development, so that after three weeks a density is achieved which is comparable to that observed in acute slices, despite the fact that there are fewer CA3 projection cells in organotypic cultures than in the intact animal from which acute slices are cut. This implies either that the number of CA3 cells projecting to a given CA1 cell is greater in organotypic cultures than in acutely prepared hippocampal slices, or that each CA3 cell makes a greater number of contacts per target cell. The physiological observations of Debanne *et al. (J. Neurophys. 73, 1282, 1995)* indicate that the former is primarily the case.

712.5

DENDRITIC SPINES IN HIPPOCAMPAL NEURONS: CORRELATING STRUCTURE AND FUNCTION. C. Collin*[1], K. Miyaguchi[2], and M. Segal[3]. [1]LAS, [2]LN, NINDS, NIH, Bethesda MD, 20892 Dept. of Neurobiology, The Weizmann Institute, Rehovot 76100, Israel.

Dendritic spines have been proposed to constitute the locus of long-term memory storage in central neurons, yet little is known about the biophysical and morphological mechanisms underlying their role in memory. We studied the effects of chronic exposure to drugs which affect synaptic transmission on spine morphology and ability of slices to express long term potentiation (LTP) of population responses to afferent stimulation in area CA1 of rat hippocampal slices maintained in culture conditions for 1-5 weeks. Blockers of excitatory or inhibitory neurotransmission were added to some cultures. Extracellular field EPSP's (fEPSP) were recorded in field CA1 in response to stimulation of CA3 neurons. Individual cells were labelled with lucifer yellow, and were subsequently visualized in a confocal laser scanning microscope. Within 10 days in culture, CA1 dendrites had large filopodia-like structures and almost no spines. fEPSP amplitude was 3.5±1.1mV and tetanic stimulation (100Hz, 1 sec) caused no LTP. At 3 weeks, spines were present in large heterogeneity (mean density=0.81 spines/μm of dendrite), fEPSP amplitude was 5.6 ± 0.9 mV, and tetanic stimulation caused LTP in 63% of the slices. At 5 weeks, spine density was higher, but no significant increase in the fEPSP amplitude or ability to produce LTP was observed. Slices grown in the presence of picrotoxin did not show changes in spine density at 3 weeks, but the fEPSP amplitude was significantly smaller than controls (1.9 ± 0.6 mV). Tetanic stimulation failed to induce LTP. Spine density was reduced in slices grown in the presence of the NMDA antagonist APV, fEPSP amplitude was same as controls, but LTP was induced in 100% of the slices. The data suggest that the maturation of dendritic spines in hippocampal neurons is age-and activity-dependent. The ability to express LTP is correlated with the appearance of spines, but not with variations in spine morphologies.

712.6

QUANTIFICATION OF DENDRITIC SPINES AND SYNAPSES IN RAT HIPPOCAMPAL SLICES MAINTAINED FOR VARIABLE TIMES *IN VITRO*. K.E. Sorra*, B.A. Allwardt, and K.M. Harris. Dept. Neurol. & Prog. Neurosci., Children's Hospital and Harvard Medical School, Boston, MA 02115.

Hippocampal slices are widely used as a model system in which to study the cellular mechanisms of synaptic transmission and plasticity. As part of an ongoing study of the structural basis of synaptic plasticity (LTP), slices were evaluated electrophysiologically and the number and structure of dendritic spines were compared among slices that were maintained for short (1.75-2.5 hrs) or long (6-13 hrs) time periods *in vitro* and with previous *in vivo* values (Harris et al., 1992, J. Neurosci. 12:2685-2705). The unbiased series sample analysis was used to compute synapse densities and identify dendritic spine shapes. In the *in vivo* adult hippocampus, thin spines predominate whereas in the immature hippocampus stubby, mushroom and thin spines occur in roughly equal numbers. In adult slices overall synapse densities were equal at both *in vitro* time periods, but greater than those observed *in vivo*. This apparent increase occurred among the stubby and mushroom spines and did not affect the frequency of thin spines which still predominated across all conditions. These observations suggest that the *in vitro* condition *per se* could induce or alter dendritic spines; however the structural modifications appeared by 2 hrs and were relatively stable for up to 13 hrs *in vitro*. This stability suggests that the slice system is appropriate for ascertaining whether changes in synaptic efficacy, such as LTP, specifically alter spine and synapse structure. Preliminary observations from immature hippocampal slices suggest that all classes of spines are present and quantitative analysis will determine whether stable modifications also occur in immature spines maintained *in vitro*. 712.7

LONG-LASTING POTENTIATION IN CULTURED HIPPOCAMPAL PYRAMIDAL CELLS REQUIRES NMDA RECEPTOR ACTIVATION, Ca^{2+} AND NO SYNTHASE IN THE POSTSYNAPTIC CELL, AND G-KINASE. O. Arancio* and R. D. Hawkins. Ctr. Neurobiol. & Behav., Columbia Univ., NY, NY 10032.

We have begun to compare the properties of long-lasting potentiation in dissociated hippocampal cell culture with LTP in slices. Pairs of pyramidal-shaped neurons were maintained throughout the experiment under whole-cell voltage clamp. Three high-frequency trains of depolarization (50 Hz, 2 sec) of the presynaptic neuron in O Mg^{2+} saline produced immediate potentiation of the EPSC that lasted until the end of the experiment (average = 35% increase, $p < .01$, $n = 11$). There was no potentiation in experiments in which the bath solution contained the NMDA receptor blocker APV (50 μM) or in which the tetanic stimulation was delivered in normal Mg^{2+} saline ($n = 12$). We were able to produce long-lasting potentiation in normal Mg^{2+}, however, by pairing low-frequency stimulation of the presynaptic neuron (1 Hz for 30 sec) with depolarization of the postsynaptic neuron to O mV (average = 48% increase, $p < .01$, $n = 8$). Potentiation by tetanic stimulation was blocked by injection of the Ca^{2+} chelator BAPTA (20 mM) into the postsynaptic neuron ($n = 7$). Potentiation was also blocked by injection of the NO synthase inhibitor N^{ω}-methyl-L-arginine (0.5 μM) into the postsynaptic ($n = 9$) but not the presynaptic ($n = 8$) neuron. Conversely, long-lasting potentiation could be produced by bath application of NO (10 nM) paired with weak tetanic stimulation (50 Hz, 0.5 sec) of the presynaptic neuron (average = 37% increase, $p < .02$, $n = 10$). Finally, potentiation by either tetanic stimulation ($n = 7$) or low-frequency stimulation paired with postsynaptic depolarization ($n = 8$) was blocked by bath application of the G-kinase inhibitor Rp-8-Br-cGMPS (100 μM).

712.8

PRESYNAPTIC INDUCTION OF MOSSY FIBER LONG-TERM POTENTIATION IN DISSOCIATED CELL CULTURE. J. C. López-Garcia* and D. Baranes. HHMI, Ctr. Neurobiol. & Behav., Columbia Univ., NY, NY 10032.

It is widely accepted that long-term potentiation (LTP) in the Schaffer collaterals of the hippocampus requires postsynaptic activation of the NMDA subtype of glutamate receptors. In contrast, LTP in the mossy fiber pathway (MF) is NMDA receptor-independent. Attempts to identify its loci of induction and expression have yielded contradictory results due in part to the complex circuitry of the hippocampal slice. In the present work, we addressed this question using a simplified MF system composed of individual dentate gyrus granule cells and CA3 pyramidal neurons in dissociated cell culture. After 12-14 days *in vitro*, the two cell types present in the culture established glutamatergic synaptic connections that showed striking similarities with the intact MF: they had both non-NMDA and NMDA receptors and were modulated by the opioid peptide dynorphin A. Furthermore, this connections displayed NMDA-independent LTP. High-frequency stimulation of a single granule cell in the presence of NMDA receptor blockers produced a long-lasting increase in the amplitude of the excitatory postsynaptic currents recorded from a pyramidal neuron. This effect was not seen when the presynaptic cell was also pyramidal. A coefficient of variation analysis of the responses before and after the induction of LTP showed that their variance increased in direct proportion to the change of their mean amplitude, indicating a presynaptic mechanism for the induction of this form of synaptic plasticity. These experiments constitute the first demonstration of NMDA-independent LTP in cell culture and provide strong evidence of the presynaptic nature of mossy fiber LTP.

712.9

FORSKOLIN INDUCES THE EXPRESSION OF TISSUE-PLASMINOGEN ACTIVATOR (tPA) mRNA AND THE RELEASE OF ITS PRODUCT FROM PRESYNAPTIC SITES OF DISSOCIATED HIPPOCAMPAL CELLS IN CULTURE. D. Baranes*, K. Martin, D. Lederfein. HHMI, Ctr. Neurobiol. & Behav., Columbia Univ., NY, NY 10032.

Tissue plasminogen activator (tPA) has been implicated in a number of cellular processes in the nervous system such as axonal elongation and cell migration. Qian et al. (Nature 361:453, 1993) have demonstrated that long-term potentiation (LTP) increases tPA mRNA expression in the dentate gyrus. We have found that forskolin, an adenylyl cyclase activator, which produces LTP in the mossy fiber pathway connecting hippocampal granule cells to CA3 pyramidal cells (Huang et al., Cell 79:69, 1994), induces a five-fold increase in tPA mRNA levels in cultured neurons of the hippocampal mossy fiber pathway. Forskolin also induces a Ca^{2+}-dependent release of tPA beginning more than 1 min after application and reaching a peak 5 min after application.

Immunocytochemical analysis revealed that tPA is enriched at points where axons contact dendrites and is extensively colocalized with synaptophysin, a marker of presynaptic terminals. Of the positive sites, 73.5 ± 9.9% colocalized with synaptophysin, 26.5 ± 9.9% included tPA but no synaptophysin immunoreactivity, and 36.4 ± 11.3% of synaptophysin positive sites did not contain tPA immunoreactivity. In addition, western blot analysis of rat brain extracts revealed that tPA is present in synaptosomal fractions. Thus, these results suggest that tPA is present in presynaptic terminals and that its activity is increased during synaptic plasticity, both by transcriptional induction and by release of its product.

712.10

TISSUE-PLASMINOGEN ACTIVATOR PLAYS A CRITICAL ROLE IN THE LATE STAGE OF HIPPOCAMPAL LTP. Y.-Y.Huang*, T. Abel, and E. R. Kandel. Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, NY, NY 10032.

Long-term synaptic potentiation in the hippocampus can be divided into an early phase (E-LTP) and a late phase (L-LTP). L-LTP requires new protein and RNA synthesis. However, little is known about the identity of the proteins involved. Tissue-plasminogen activator (tPA) is an extracellular serine protease that is induced by neural activity and is correlated with morphological differentiation of neurons. We found that the brief application of tPA to hippocampal slices induces a slowly-developing and long-lasting (> 5 hr) synaptic potentiation in both the Schaffer collateral-CA1 pathway and mossy fiber-CA3 pathways. In each of these pathways, the tPA-induced potentiation is occluded by potentiation induced by a cAMP analog. In addition, a tPA inhibitor selectively blocks the late phase of LTP induced by three trains of tetanus but not the early phase of LTP induced by one train in both the CA1 and mossy fiber pathways. Moreover, the tPA inhibitor also blocks the cAMP analog-induced potentiation. These results indicate that tPA may play an important role in the late phase of LTP in both the NMDA-dependent Schaffer collateral-CA1 and the NMDA-independent mossy fiber-CA3 pathways. tPA appears to be one of the proteins by which cAMP mediates the late phase of LTP.

712.11

Mechanism of LTP at parallel fiber synapses of the cerebellum.
Salin P.* Malenka R.C. and Nicoll R.A. *Depts. of Cellular & Molecular Pharmacol, Physiol. & Psychiatry; UCSF, San Francisco, CA, 94143.*

It has recently been shown in hippocampus that LTP at mossy fiber (MF) synapses is induced and expressed presynaptically and may be mediated by cyclic AMP (Weisskopf et al, 1994). The Ca entry during a tetanus is proposed to activate a Ca sensitive adenylyl cyclase (ACI), leading to an increase in cAMP. This increase, via PKA causes a persistent enhancement in evoked glutamate release. Because ACI is highly expressed in parallel fibers (PF) we examined whether a similar form of LTP occurs at parallel fiber-Purkinje cell synapses in rat cerebellar slices. Extracellular recording techniques enabled us to monitor simultaneously both the fiber volley and postsynaptic response. Low frequency stimulation (LFS, 4Hz for 20 sec) caused an increase in the field amplitude of 30% that lasted at least 1 hour. In most cases the fiber volley was only modified transiently after LFS, but in some cases was enhanced over a prolonged period of time. PF LTP was associated with a decrease in paired pulse facilitation (PPF) and application of the glutamate receptor antagonist kynurenate (10mM) during LFS of PF did not prevent the induction of LTP. These results indicate that PF LTP is presynaptic in induction and expression, as previously suggested in cultured cerebellar neurons. Furthermore, a short term application of the adenylyl cyclase activator forskolin caused an enhancement of PF synaptic responses that lasted at least 1 hour and induced a decrease in PPF. These experiments strongly suggest that common mechanisms are involved in PF and MF LTP. *Supported by the NIH.*

712.12

LONG-TERM POTENTIATION OF NMDA-MEDIATED RESPONSES AT THE PRIMARY OLFACTORY SYNAPSE.
M. Ennis*, L.A. Zimmer, & M.T. Shipley. Dept. Anat., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Mitral cells (MCs) of the main olfactory bulb receive direct excitatory synapses from primary olfactory nerve (ON) terminals. Our recent studies demonstrated that glutamate released from rat ON terminals activates MCs via non-NMDA (i.e., AMPA/kainate) and NMDA receptors; AMPA/kainate receptors mediate rapid, brief excitation of MCs while NMDA receptors mediate a delayed excitation lasting several hundred msec. In cortical circuits, brief epochs of high frequency stimulation potentiate responses at NMDA and non-NMDA receptors, i.e., LTP. The goal of this study was to determine if excitatory responses at the ON->MC synapse undergo frequency dependent LTP.

Extracellular recordings were obtained from rat MCs in 400 μm-thick horizontal sections and a stimulation electrode was placed on the ON layer (ONL). A brief, low intensity (4-40 μA) train of impulses (10 sets of 4 pulses @ 100 Hz; each set separated by 200 msec) was applied to the ONL. This stimulation pattern corresponds to 2 sec of investigative sniffing typical for rats responding to novel odors or exploring the environment.

A single 2 sec train produced immediate, dramatic increases in NMDA excitatory responses in 13/15 cells, ranging from 126% - 345% of control (mean = 189 ± 17%; $p < 0.001$). By contrast, AMPA/KA responses were not altered (mean = 94 ± 4%; $p > 0.5$). Potentiation was long-lasting (50 min), comparable to LTP in hippocampus and piriform cortex. The NMDA receptor antagonist AP5 (50-100 μM) prevented the induction of LTP; LTP was obtained after AP5 washout. AP5 also reversed LTP following its induction.

These results demonstrate that ON—>MC synaptic transmission exhibits use-dependent plasticity *in vitro*. A two sec burst (corresponding to 10 sniffs) of ON activity induces specific LTP of NMDA mediated excitation of MCs. LTP at the ON—>MC synapse discloses a novel mechanism for rapid amplification of MC responses to sensory inputs that may function in rapid memory formation for specific odors. Our results suggest that stimuli evoking bursts of ON activity may potently modify the synaptic excitability of MCs *in vivo*. Future experiments will test this prediction. *Support: NIH DC00347, NS29218 and NS29635.*

712.13

SPATIAL LOCALIZATION OF CURRENT SINKS IN THE SUPERFICIAL LAYERS OF THE ENTORHINAL CORTEX FOLLOWING PYRIFORM CORTEX STIMULATION IN THE RAT.
C.A.Chapman* and R.J.Racine. Department of Psychology, McMaster University, Hamilton, Ontario, Canada L8S-4K1.

Field potentials in rat entorhinal cortex are potentiated for very long periods following strong stimulation of the pyriform cortex (SN Abstr 20:585.2), but the synaptic populations underlying these effects have not been spatially localized. Biphasic test pulses (225 to 650μA) were delivered to the pyriform cortex (AP-3.6, L6.5, V8.5-10mm) of urethane anesthetized (1.5g/kg) rats. A stainless steel (50μm tip) or tungsten recording electrode was advanced on the sagittal plane, 40° off horizontal and perpendicular to entorhinal cortex lamina, and aimed at a point 5.2mm lateral to the midline, and 2.6mm dorsal and 0.2mm anterior to the interaural line. Averages of 10 evoked field potentials were recorded at 50μm intervals at depths between 0.0 and 2.0mm, and electrode positions were verified using the Prussian Blue reaction, or with small lesions. The 2nd spatial derivative of smoothed depth profiles quantified the current source density in relative units. The major field potential component was spatially diffuse and approximately -0.55mV in amplitude at depths near 250μm with a ≈10ms onset latency and ≈18ms latency to peak. It corresponded to a current sink in layers II and III which peaked at depths between 250 and 350μm. A smaller, more prolonged sink with a ≈33ms onset latency was also observed in the deep layers. These results indicate that pyriform cortex efferents which support LTP terminate in the superficial layers of the rat entorhinal cortex.

712.14

LOW-FREQUENCY STIMULATION DEPOTENTIATES LTP IN RAT PIRIFORM CORTEX.
M. Fejtl* and D. O. Carpenter Wadsworth Laboratories, NYS Dept. of Health, and School of Public Health, Albany, NY 12201, USA.

Long-term potentiation (LTP) is a form of synaptic plasticity which is thought to be a mechanism underlying memory formation at mammalian central synapses. Recently, LTP has been under intense scrutiny with regard to a modulatory action of low-frequency stimulation, which itself can lead to long-term depression (LTD), a decrease in synaptic efficacy observed in the cerebellum and hippocampus. Here we report that in the rat piriform cortex low-frequency stimulation delivered to an already potentiated pathway depotentiates the test response to the control level.

Brain slices (450 μm thick) of the piriform cortex were prepared from young adult male rats (150 - 200 g) in Na-free Krebs-Ringer solution (in mM: NaCl 125.5; KCl 3.5; $CaCl_2$ 2.4; $MgSO_4$ 1.3; KH_2PO_4 1.2; $NaHCO_3$ 26; glucose 10; NaCl was replaced by 213.3 mM sucrose) and allowed to recover in standard Ringer solution (pH 7.4 after equilibration with 95% O_2/ 5% CO_2) for 1 1/2 h. Slices were transferred to the recording chamber (submerged type) and continuously perfused at a rate of 3 ml/min. Test stimuli (50 μs; 10-40 V; 0.1 Hz) were delivered to the lateral olfactory tract (LOT) and the dendritic field EPSP's were recorded with a large (30 μm) extracellular electrode. LTP was induced by either a single tetanus (1 s at 100 Hz) or a θ-burst paradigm (10 bursts consisting of 5 pulses at 100 Hz at an interval of 200 ms). After the potentiated response was monitored for 30 min (114.2 ± 2 %, mean ± S.E.; n=4) low frequency stimulation (900 pulses delivered at 2 Hz) caused a significant reduction of the EPSP's to the control level (98.5 ± 3%; $p < 0.05$). The depotentiation lasted for the remainder of the recording (usually 30 min) and in one attempt could be reversed to the initial LTP level by an additional θ- burst.

This suggests that a potentiated synapse may still undergo plastic changes contingent upon subsequent synaptic activity. Hence, a switch may exist between the potentiated and the depotentiated state, giving a synapse additional bandwith to respond to a particular stimulus. Supported by NS 23807-10 (DOC).

LONG-TERM MODIFICATIONS OF SYNAPTIC TRANSMISSION IN RAT VISUAL CORTEX INDUCED BY INTRACELLULAR TETANIZATION
M.Volgushev, L.L.Voronin, M.Chistiakova, C.Hansel, W.Singer*
Max-Planck-Institute for Brain Research, 60528 Frankfurt/M, Germany.

We examined the possibility to induce long-term changes in synaptic transmission in the visual cortex by applying bursts of intracellular pulses (intracellular tetanization, IT) to the postsynaptic cell, without concomitant presynaptic stimulation. Postsynaptic potentials evoked from two stimulation sites in layers II and IV were recorded from layer II-III cells with sharp or whole cell electrodes. IT led to marked changes in synaptic transmission in the majority of cells. Fura-2 based Ca^{2+} measurements showed that IT produced a substantial increase in intracellular $[Ca^{2+}]$, comparable in magnitude to increases evoked by strong afferent tetanization. Inputs from layer IV were more often potentiated while layer II inputs were more often depressed. This difference is probably due to the different localization of the respective afferents at the dendritic tree. Ca^{2+} imaging showed that stimulation in layer IV activates inputs to the proximal parts of the apical dendrites, while stimulation in layer II activates more distally located inputs. To evaluate the involvement of presynaptic mechanisms in the lasting changes of synaptic transmission induced by IT, we analysed paired-pulse interactions before and after potentiation. Paired-pulse facilitation (PPF) usually decreased after induction of long-term potentiation (LTP) and the magnitude of the decrease correlated positively with LTP magnitude and with the pretetanic PPF ratio.

Our data show that manipulations of the postsynaptic cell, which lead to a significant rise of intracellular $[Ca^{2+}]$ are capable to produce long-term changes in synaptic transmission in the visual cortex. Changes in PPF ratio after LTP induction suggest that presynaptic mechanisms are involved in the maintenance of synaptic modifications induced by IT.

712.16

TRANSCALLOSAL INDUCTION OF LONG-TERM POTENTIATION AND DEPRESSION IN THE SOMATOSENSORY AND VISUAL CORTICES IN THE AWAKE RAT.
D.J. Froc and R.J. Racine*. Dept. of Psychology, McMaster University, Hamilton, Ontario., L8S 4K1.

We have recently found that long-term potentiation can be induced in the neocortex of chronically prepared rats, but only if the stimulation is applied over multiple sessions. These experiments were done with both stimulation and recording electrodes in the same hemisphere. The present experiments were designed to determine whether neocortical LTP could be induced if the stimulation and recording electrodes were in homologous sites in opposing hemispheres. We also tested the effects of low frequency stimulation trains. These have been reported to produce *depression* effects in the hippocampus and visual cortex. Thirty, 24 msec, 300 Hz trains were applied to the neocortex each day for 10 days. Stimulation intensity was set at 1259 μA. In one group, the trains were applied to the somatomotor cortex and in another group, the trains were applied to the visual cortex. Control groups were also run for each site. Before and after the application of the potentiating trains, pulses were applied to the stimulation site and the responses evoked in the contralateral cortex were recorded and analyzed. One week following the induction of LTP, 1 Hz trains were applied to the stimulation site for 15 min after which the test pulse runs were resumed. We found that the baseline response amplitudes were larger in anterior sites, but the LTP effects were similar in both sites. The potentiation had shown little decay 1 week following the completion of the train stimulation. At that point, the low frequency trains were applied in half the animals from each group. A transient depression effect was found following low frequency stimulation of the anterior site. These responses had returned to their potentiated levels by 24 hours. The depression effect following stimulation of visual cortex was still expressed 7 days post-treatment. The control animals showed only minor depression effects in their baseline responses.

NEOCORTICAL LONG-TERM POTENTIATION IN THE CHRONIC PREPARATION: INDUCTION AND DECAY PARAMETERS. C. Trepel* and R. J. Racine. Dept. of Psychology, McMaster Univ., Hamilton, Ontario, Canada, L8S-4K1.

The belief that long-term memories are stored in the neocortex suffers from the fact that neocortical LTP (the leading physiological memory model) has, until recently, been successfully induced only in acute and slice preparations. We have found, however, that LTP can be induced in the neocortex of chronically prepared rats if multiple stimulation sessions are used. Here we report the results of experiments designed to provide a more complete description of the induction requirements and the time course for neocortical LTP. Stimulating and recording electrodes were implanted into the corpus callosum and anterior neocortex (frontal area 1), respectively. Daily stimulation consisted of varying numbers of 8-pulse, 24 ms trains (pulse frequency: 300 Hz; train frequency: 0.01 Hz). Four groups of animals received one of either 10 trains/day for 10 days (Group 1), 60 trains/day for 10 days (Group 2), 10 trains/day for 25 days (Group 3) or 60 trains/day for 25 days (Group 4). Compared to baseline measures, all animals showed developing potentiation after three sets of trains. This was evidenced as an initial increase and subsequent decrease in the amplitude of the early component (latency-to peak range: 4.5-6.8 ms) of the EPSP, an increase in the amplitude and number of population spikes, and an increase in the amplitude of the late component (latency-to-peak range: 15.9-29.5 ms). In many animals this late component is clearly seen only following potentiation. These potentiation measures increased over the course of trains in all animals. Animals receiving 60 trains/day required fewer trains to reach asymptotic levels of potentiation of the late component and displayed both a larger increase and subsequent decrease of the early component. LTP persistence data are currently being collected and preliminary observations indicate that the groups receiving 60 trains/day have the longest LTP decay time constants. These chronic data provide much needed evidence that a presupposed center of long-term memory is capable of supporting LTP effects that can last for weeks or months.

712.18

ANALYSIS OF LONG TERM POTENTIATION IN THE CHICK IMHV REGION. E. Shimabayashi, K. Kiyosue, M. Kasai*, T. Taguchi†. Dept. of Biophys. Engineer., Fac., of Engineer. Sci., Osaka Univ., Toyonaka 560, Japan, †Osaka Nat'l. Res. Inst., Ikeda 563, Japan

The intermediate and medial part of hyperstriatum ventral (IMHV) is critical part of chick forebrain to establsh imprinting and many types of learning. Although many electrophysiological studies have been performed by Bradley et al., analysis with whole cell recording has not been carried out, which is necessary to understand precise mechanizms of synaptic plasticity in this area. Using conventional patch clamp technique, we have analyzed long term potentiation (LTP) in IMHV region, where E.P.S.C.s were evoked by local stimulus near the postsynaptic cell. The stimulus of 5 Hz for 1 min paired with postsynaptic depolarization was used to induce the potentiation. The potentiations were sustained for 80 min at most. The coefficient of variation of peak amplitude of E.P.S.C. did not change so much after the induction of potentiation. If the probabilistic transmitter release is governed by binomial process, this dose not indicate increase of transmitter release probability but increase of postsynaptic efficacy. Further, the ratio of AMPA/kinate type glutamate receptor-mediated currents to NMDA type glutamate receptor-mediated currents changed after conditioning stimuli. These results indicate that postsynaptic change is included in the mechanism for LTP expression in this area.

712.19

SYNAPTIC PLASTICITY IN THE DIRECT FEEDBACK PATHWAY TO THE ELECTROSENSORY LATERAL LINE LOBE OF *A. LEPTORRHYN-CHUS*. D. Wang, L. Maler and P. Fortier*, Dept.of Anatomy and Neurobiology, University of Ottawa. Ottawa, Ontario Canada. K1H 8M5

Electroreceptor afferents terminate in a laminated rhombencephalic structure: the electrosensory lateral line lobe (ELL). In addition to its peripheral input, the ELL also receives feedback input: feedback reaches the molecular layer of the ELL via a direct feedback projection, the stratum fibrosum (SF) which terminates in the ventral molecular layer (VML). Earlier studies have revealed that the feedback projections were glutaminergic and associated with NMDA receptors; further the input to VML has been hypothesized to be involved in attentional processes. We therefore used an *in vitro* preparation of the ELL (brain slice) to investigate possible synaptic plasticity in the VML.

We stimulated the SF at frequencies mimicking those which occur during natural activation of this pathway in vivo (20-300 Hz); optimal tetanic stimulation (100 Hz for 100 ms repeated 3 times at 1 Hz) produced a 30-40% posttetanic potentiation (PTP) of the field EPSP at 5 s; this PTP decayed to baseline after 1-2 minutes. Intracellular recording confirmed the potentiation of the EPSP and demonstrated that it was maximal (about 80%) 1 s post-tetannus. Stimulation in the presence of manganese prevented PTP, suggesting that it represents synaptic potentiation and not a lowered threshold of the SF. We did not find any evidence of LTP, even when tetanus was delivered in the presence of bicuculline.

We conclude that transient memories of sensory input may be important in attentional modulation of sensory input, and that NMDA receptors need not always be involved in traditional LTP.

712.20

HUMAN CORTEX SHOWS ROBUST NMDA DEPENDENT LONG TERM POTENTIATION. S.H. Lee*, W. Chen, , K. Kato, D.D. Spencer, G.M. Shepherd, and A. Williamson. Sections of Neurosurgery and Neurobiology, Yale University School of Medicine, New Haven, CT 06520

LTP has been extensively studied in animal models but not in the human cortex. Here we report the induction of LTP in human neocortex, and its dependence on NMDA receptors. The tissue was obtained from temporal lobectomies for control of intractable epilepsy. We harvested pathologically and electrographically normal cortical specimens from four patients. 500 µm slices were prepared and maintained in an interface chamber. EPSPs were measured in layer II/III following stimulation in layer IV. LTP was induced by giving five trains of tetanic stimulation (100 Hz for 1 sec each) at 30 sec intervals. The EPSP amplitudes were monitored for 20 min pre-tetanus and for 60 min following the stimuli.

In total, we performed 28 trials using these parameters in 17 slices. LTP was produced in 11 of 18 trials performed in normal ACSF. Averaged data from these 11 trials showed a 23.6 ± 8.59% potentiation from pre-tetanus EPSP amplitude 10 min. after the tetanus, and a 34.5 ± 6.64% potentiation 55 min after the tetanus. The remaining 7 of 18 trials showed no potentiation of the EPSP amplitude. Activity-dependent synaptic plasticity was modulated but not eliminated by NMDA antagonist, APV. In 10 trials following the bath application of 50 µM APV, LTP was only seen in 2 of 10 trials. Chi Square analysis showed a highly significant effect of APV in decreasing LTP induction ($P<0.0001$).

Our study shows that LTP can be induced in adult human neocortical slices without the application of bicuculline. The incidence of LTP (61%) is comparable to that seen in the sensory cortex of young rats. We found that the incidence of LTP is significantly decreased by the application of NMDA receptor antagonist APV, suggesting that NMDA receptors are also involved in the plasticity seen in human neocortex.

PROTEIN KINASE A OR PROTEIN KINASE C DOES NOT APPEAR TO BE INVOLVED IN THE INHIBITION OF ATP-ACTIVATED CURRENT BY ETHANOL IN SENSORY NEURONS. Chaoying Li*, Jin Zhai and Forrest F. Weight. Laboratory of Molecular and Cellular Neurobiology, National Institute on Alcohol Abuse & Alcoholism, National Institutes of Health, Bethesda, MD 20892-8205.

We have previously demonstrated that ethanol, in pharmacological concentrations, produced concentration-dependent inhibition of ATP-activated inward current in freshly isolated bullfrog dorsal root ganglion neurons by interacting with a small hydrophobic pocket on the receptor protein, rather than with membrane lipids (*Proc. Natl. Acad. Sci. USA* **91:** 8200, 1994). Using the perforated-patch recording technique (nystatin 150 mg ml^{-1} in the recording pipette), we found that the amplitude of the current activated by 2.5 µM ATP was decreased by the extracellular application of 100 mM ethanol by 40 ± 5% (n = 8 cells). This degree of inhibition was similar to that observed in experiments using whole-cell patch-clamp recording. The inhibition was not significantly altered by the extracellular preapplication of 100 nM phorbol 12-myristate 13-acetate (PMA) for 8 - 10 min (n = 4 cells), 1 µM staurosporin for 4 - 8 min (n = 4 cells), or 5 - 50 µM forskolin for 4 - 8 min (n = 5 cells), respectively ($P > 0.05$). These results suggest that protein kinase A or protein kinase C is not involved in the inhibition of ATP-activated current by ethanol in these neurons.

713.2

Reduced Ethanol Sensitivity of Recombinant NMDA Receptors Under Divalent Cation-Free Conditions. Toorai Mirshahi* and John J. Woodward. Department of Pharmacology and Toxicology, Box 980524 Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Although ethanol has been shown to inhibit recombinant NMDA receptors, no specific site of action has been defined. We have previously shown that mutant NMDA receptors with absent or decreased Ca^{++} permeability [NR1(N616R, N616Q)] display a reduced ethanol sensitivity. To further investigate the possible interaction of ethanol and the Ca^{++} permeation site of the NMDA receptor, wild type and Ca^{++} impermeable mutant NR1 subunits (N616R) were tested for their ethanol sensitivity under different ionic conditions. The wild type and mutant NR1 subunits were expressed along with the NR2A or the NR2C in *Xenopus* oocytes. NMDA-induced currents were measured using conventional two-electrode voltage-clamp methods. Recordings were performed in Mg^{++}-free normal frog ringers with 1.8 mM Ba^{++} (Ba-NFR) or divalent cation-free ringers supplemented with 2 mM polyvinylpyrrolidone (PVP-NFR). Cells were clamped at -80 mV and currents were recorded in the presence of 100 µM NMDA and 10 µM glycine with varying concentrations of ethanol. Mutant NR1/2A receptors in Ba-NFR as well as wild type NR1-2A in PVP-NFR showed significantly reduced inhibition by ethanol compared to the wild type NR1/2A in Ba-NFR. Wild type and mutant NR1/2C in Ba-NFR or PVP-NFR displayed similar sensitivity to inhibition by ethanol when compared to the mutant NR1/2A receptors. Together, these results suggest that Ca^{++} permeability of NMDA receptors may influence the sensitivity of this receptor to inhibition by ethanol. Supported by NIAAA 08089 and NIDA 07027.

713.3

FUNCTIONAL PROPERTIES AND ETHANOL SENSITIVITY OF ε_4/ζ_1 NMDA RECEPTOR SUBUNITS EXPRESSED IN *XENOPUS* OOCYTES.

C. Wu*, F. F. Weight and K. Masood. Lab. Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

The ε4 subunit of the NMDA receptor is expressed in the embryonic brain, but its expression diminishes two weeks after birth, suggesting that it may play a role in early neural development. To study the properties of the subunit combination ε4/ζ1, we used two-electrode voltage-clamp recording in the *Xenopus* oocyte expression system. The ε4/ζ1 subunits were found to have a high affinity for NMDA, with an EC_{50} of 3.3 μM. The affinity for NMDA was about ten times lower than that for glutamate. The NMDA-activated current in ε4/ζ1 subunits was blocked by Mg^{2+} in a voltage- and concentration-dependent manner with an IC_{50} of 156 μM. These results indicate that the ε4/ζ1 subunits, like the ε3/ζ1 subunits, have a high resistance to Mg^{2+} block. The ε4/ζ1 subunits were sensitive to Zn^{2+} inhibition with an IC_{50} of 47 μM. No potentiation by low concentrations of Zn^{2+} was observed. Ethanol at 100 mM decreased the E_{max} of the concentration-response curve for NMDA-activated current without significantly affecting the EC_{50}. An increase in the inhibition of NMDA-activated current was observed when the concentration of ethanol was increased from 10 to 250 mM. The percentage inhibition of NMDA-activated current by 10, 25, 50, 100 and 250 mM ethanol was 2.8, 9.5, 16.5, 28.4 and 56.8%, respectively. However, compared with the ε1/ζ1 subunits, the ε4/ζ1 subunits were found to be less sensitive to ethanol inhibition. The observations indicate that the ε4/ζ1 subunit combination is similar to the ε3/ζ1 subunit combination in ethanol sensitivity and several functional properties.

713.4

ETHANOL AUGMENTS GABA-INDUCED CHLORIDE CURRENTS IN CULTURED HIPPOCAMPAL NEURONS. N. T. Rodgers-Neame*, K. E. Isenberg, and C.F.Zorumski, Dept. of Psych., Washington Univ. Sch. of Med., St. Louis, MO 63110 and Dept. of Neurol., Univ. of S. Florida Col. of Med., Tampa, FL 33612

Apparently similar neurons are affected differentially by ethanol. The role of GABAergic mechanisms in the action of ethanol in the brain is particularly interesting because of the wide variations in effects. Our study shows that ethanol has a rapid effect on some hippocampal neurons, while other hippocampal neurons remain resistant.

Electrophysiologic potentiation of the $GABA_A$ choride channel by ethanol was studied using whole cell patch clamp methods in primary neuronal cultures of neonatal hippocampus. Activation of the chloride current by ethanol requires the presence of GABA, and can be detected at a GABA concentration of 0.1 to 0.5 μM. The concentration of ethanol required for measureable augmentation of the GABA induced current was 5 mM and maximum augmentation was observed to occur at approximately 60 mM. In addition, only 21% of neurons responding to GABA also responded to ethanol and GABA, independent of concention of either compound, the diameter of the neuron or the age of the animal.

The implications of these results are that 1) the effect on the chloride current by ethanol in hippocampal neurons is GABA dependent 2) the effects are dependent upon specific qualities of the individual neuron - most likely subunit dependent and 3) these concentrations are well within the range noted to induce a physiologic effect in whole animals, indicating that chloride induced hyperpolarization of hippocampal neurons may be an important factor in the physiologic effects of ethanol.

713.5

DIFFERENTIAL SENSITIVITY TO ETHANOL OF GLYCINE-ACTIVATED CURRENTS IN HYPOTHALAMIC AND CORTICAL NEURONS. D. Schiller*, J.-H. Ye, & J.J. McArdle. Departments of Pharmacol. & Anesthesiol., New Jersey Med. Sch. (UMDNJ) & Grad. Sch. Biomed. Sci., Newark, NJ 07103-2714.

We examined the effect of ethanol on glycine-activated currents (I-Gly) of hypothalamic (VMH) and cortical neurons freshly isolated from young mice. I-Gly of 18 VMH and 29 cortical neurons was recorded with the nystatin perforated patch technique. Holding potential was -60mV and a fast superfusion system delivered varying concentrations of glycine (Gly) alone or in combination with 21.6, 43.2, or 64.8mM ethanol. Peak I-Gly was -227.04±71.06 pA (mean±SEM) for 5 VMH neurons exposed to 100μM Gly. When 64.8 mM ethanol was co-applied to these neurons, I-Gly increased to -471.06±134.84 pA. In contrast, for two other VMH neurons exposed to 100μM Gly and 64.8mM ethanol I-Gly decreased. Likewise, two populations of VMH neurons were detected following exposure to 43.2 mM ethanol; peak I-Gly increased and decreased for 2 neurons out of 4 examined. Similar results were obtained from VMH neurons exposed to 200μM Gly and 21.6, 43.2, 64.8 mM ethanol. For 8 cortical neurons 100μM Gly produced a peak I-Gly of -243.65±61.7 pA. When 64.8 mM ethanol was co-applied to these neurons, I-Gly increased ($p<0.05$) to -352.4±80.99 pA. Likewise, 21.6, 43.2, or 64.8mM ethanol consistently enhanced I-Gly of all other cortical neurons exposed to 100, 200 or 300μM Gly. These differential responses of I-Gly to relevant concentrations of ethanol suggest that while two populations of Gly receptor exist in the VMH, the cortex is homogeneous in this regard. 713.6

ETHANOL INHIBITS RECOMBINANT α7 NICOTINIC ACETYLCHOLINE RECEPTOR-MEDIATED CURRENT IN *XENOPUS* OOCYTES. Dahong Yu, Li Zhang and Forrest F. Weight*, Lab. of Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

The α7 nicotinic acetylcholine receptor (nAChR) subunit has been cloned and characterized; it has the ability to form functional homomeric channels when expressed in *Xenopus* oocytes (*Neuron* 5:35-48, 1990). In addition, it is found in the mammalian CNS. Because of its high permeability to Ca^{2+}, it has been suggested that this subunit may be involved in the phenomena of neuronal plasticity, neural development and learning. Previous studies have shown that ethanol can potentiate nAChR mediated responses at the neuromuscular junction (*J. Physiol.* 244:409-429, 1975). Little is known, however, about the effects of ethanol on neural nAChRs. We expressed homomeric α7 nAChR cRNA in *Xenopus* oocytes and studied the effect of ethanol on the function of these receptors using the two-electrode voltage-clamp technique. We found that ethanol concentrations from 10 mM to 100 mM could produce a concentration-dependent decrease in the amplitude of α7 nAChR-mediated current. Maximal inhibition was observed at an ethanol concentration of 100 mM; maximal inhibition was 63% of control current induced by 10 μM (-)-nicotinic acid. The IC_{50} was 50 mM and the apparent Hill coefficient was 1.6. The observations indicate that ethanol modulation of α7 nAChR-mediated current differs from the effect of ethanol reported previously for nAChR at the neuromuscular junction .

713.7

ALIPHATIC ALCOHOLS EXHIBIT A CUTOFF IN POTENCY FOR ENHANCEMENT OF GABA-ACTIVATED ION CURRENT. Robert W. Peoples* and Forrest F. Weight. Laboratory of Molecular and Cellular Neurobiology, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Bethesda, MD 20892.

Intoxicating potency of straight-chain aliphatic alcohols increases as the number of carbons are increased up to 6 - 8 (the "cutoff"), then decreases despite increasing lipid solubility and membrane disordering potency (J. Pharmacol. Exp. Ther. 218: 669, 1981; Neuropharmacol. 17: 451, 1978). We have previously demonstrated that *n*-alcohols also exhibit a cutoff for inhibition of ion current activated by *N*-methyl-D-aspartate (NMDA) at 6 - 8 carbon atoms (Proc. Natl. Acad. Sci. USA 92: 2825, 1995). In this study, we investigated whether a cutoff for potentiation of $GABA_A$ receptors by *n*-alcohols could be observed in mouse hippocampal neurons in primary culture using the whole-cell patch-clamp technique. We found that the potency of alcohols for enhancing GABA-activated current increased as the carbon chain length was increased up to 11 - 12 carbons, but that maximally-attainable concentrations of alcohols with more than 12 carbon atoms did not enhance GABA-activated current. This cutoff thus differs from those previously reported for behavioral measures of alcohol intoxication.

713.8

EFFECT OF PENTANOL ON RECOMBINANT ACETYLCHOLINE RECEPTOR CHANNELS EXPRESSED IN HEK-293 CELLS. A. Ravindran*, K. Masood and F. F. Weight. Laboratory of Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

The nicotinic acetylcholine receptor (AChR) of adult skeletal muscle is a channel-forming glycoprotein consisting of four homologous subunits assembled into a $\alpha_2\beta\delta\epsilon$ pentamer. The modulatory effects of 1-pentanol on acetylcholine (ACh)-induced current was studied in HEK-293 cells transiently transfected with mouse $\alpha\beta\delta\epsilon$ AChR subunit cDNAs. 30-40 hr after transfection whole-cell and outside-out patch-clamp techniques were used to record ACh-induced inward current from cells expressing AChR. ACh alone and in combination with different concentrations of 1-pentanol were applied to the recorded cell or outside-out patch using a rapid perfusion system that enabled complete exchange of solutions in 0.8-4 ms. ACh activated rapidly desensitizing inward currents with an EC_{50} of 13 μM. Co-application of 1-pentanol (0.5-16 mM) increased the amplitude of current activated by 2 μM ACh in a concentration-dependent manner. The potentiation was between 28-150% of the control response. The rate of AChR desensitization was also significantly increased (3-5 fold) by pentanol in a concentration-dependent manner. At agonist concentrations ≥ 5 μM, low concentrations of pentanol caused potentiation and high concentrations caused inhibition of the peak current. Further studies are underway to elucidate the mechanism of pentanol action on AChR channels.

713.9

INTERACTION OF GLYCINE AND ETHANOL ON RECOMBINANT HETEROMERIC NMDA RECEPTOR SUBUNITS.

K. Masood*, F. F. Weight and C. Wu. Lab. Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

Glycine, a co-agonist of NMDA receptor channels, has been shown to potentiate NMDA-activated ion currents in heteromeric combinations. There is controversy regarding whether glycine can reverse ethanol's inhibitory effects on NMDA receptor channels. To address this issue and to understand the mechanism of action of ethanol at a molecular level, we examined the interaction of glycine and ethanol on ε1ζ1, ε2ζ1, ε3ζ1 and ε4ζ1 subunit combinations expressed in *Xenopus* oocytes. Membrane current activated by NMDA was recorded using the two-electrode voltage-clamp technique at a holding potential of -70 mV. Ethanol (100 mM) decreased E_{max} of the glycine concentration-response curve for all four heteromeric combinations. The inhibition of E_{max} by 100 mM ethanol for ε1ζ1, ε2ζ1, ε3ζ1 and ε4ζ1 combinations was 43.8, 15.0, 19.1 and 26.9%, respectively. However, ethanol did not significantly affect either the EC_{50} or the apparent Hill coefficient of these curves (ANOVA, $p>0.05$). The results indicate that ethanol is not competitive with glycine for the ε1ζ1, ε2ζ1, ε3ζ1 and ε4ζ1 subunit combinations.

713.10

ALIPHATIC *N*-ALCOHOLS EXHIBIT A CUTOFF IN POTENCY FOR THE INHIBITION OF RECOMBINANT GLUR3 RECEPTOR SUBUNIT CURRENT IN *XENOPUS* OOCYTES.

B. Emmanuel Akinshola* and Forrest F. Weight. Lab.Molecular and Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

The potency of straight-chain aliphatic alcohols for affecting the function of ATP-, NMDA- and 5-HT3-receptor gated ion channels increases as the number of carbons are increased up to a point called the "cutoff", where the potency decreases despite increased hydrophobicity of the alcohol (*PNAS* 91: 8200, 1994; *PNAS* 92: 2825, 1995; *Soc. Neurosci .Abst.*. 20: 1127, 1994). Although non-NMDA excitatory amino acid receptor-mediated responses have been reported to be inhibited with increasing potency with short-chain aliphatic *n*-alcohols from methanol to pentanol (*JPET* 262: 487, 1992), it has not been determined whether non-NMDA receptors exhibit a cutoff phenomenon. To address this question, we used the two-electrode voltage-clamp technique to study the effect of a series of straight-chain aliphatic alcohols on recombinant AMPA-type GluR3 receptor subunits expressed in *Xenopus* oocytes. We found that for short-chain alcohols from methanol to hexanol, potency for inhibition of kainate-activated current increased in proportion to the chain-length or hydrophobicity of the alcohol . However, potency decreased with heptanol and octanol, and nonanol did not inhibit kainate-activated current. The observations indicate that straight-chain aliphatic alcohols exhibit a cutoff in their potency for inhibition of non-NMDA glutamate receptors.

SODIUM CHANNELS I

714.1

SODIUM CHANNEL DENSITY IS INCREASED IN RAT DORSAL ROOT GANGLIA FOLLOWING CHRONIC CONSTRICTION INJURY (CCI)

L.B. Jakeman*, J. Kwan, D.W. Bonhaus, and J.C. Hunter Departments of Neuropharmacology and Analgesia, Syntex Research, Palo Alto, CA 94303.

Neuropathic pain caused by peripheral nerve injury is associated with a persistent spontaneous discharge of injured fibers. This abnormal firing may be due to an accumulation of Na channels in peripheral sensory neurons. To test this hypothesis, we have used quantitative [^{3}H]saxitoxin ([^{3}H]STX) autoradiography to examine the distribution, density (B_{max}) and affinity (K_D) of Na channels in rats following CCI. Brains, spinal cords and dorsal root ganglia (DRG) were harvested from 6 normal rats and 6 rats 30 days after unilateral CCI. [^{3}H]STX autoradiography was performed on 20 µm sections through cortex, midbrain periaquaductal gray, lumbar spinal cord, and L_5-L_6 DRGs. Saturation isotherms were best fit to a model describing a single class of binding sites with K_Ds ranging from 0.7 - 3.9 nM and B_{max} from 157 - 720 fmol mg^{-1} tissue equivalent (t.e.). Na channel density was increased in the DRG ipsilateral to the nerve injury (B_{max}=248.1 ± 14.4 fmol mg^{-1} t.e.) compared with the sham side (205.7 ± 7.9) or normal DRG (190.1 ± 20.5) ($p < 0.05$). No differences were found in other regions. In summary, CCI caused an increase in [^{3}H]STX binding sites in DRG neurons that persisted for 30 days after the injury. This reflects an increase in the density of STX-sensitive Na channels, and suggests a mechanism for the effectiveness of sodium channel blockers in neuropathic pain.

714.2

REGULATION OF SODIUM CHANNEL mRNAs IN A NEUROPATHIC PAIN MODEL.

L. Sangameswaran*, S. G. Delgado and R. C. Herman Biotechnology Unit, Syntex Research, Palo Alto, CA 94304.

Injury to the sciatic nerve evokes spontaneous electrical activity at high frequency. We have used a rat model where the sciatic nerve is loosely ligated to investigate the regulation of sodium channel mRNAs. A neuropathic pain condition ensues the loose ligature of the sciatic nerve. This syndrome includes symptoms of thermal and mechanical hyperalgesia and cold allodynia. The lumbar 4 and 5 dorsal root ganglia (DRG) from the ligated (right) and sham sides (left) were collected at different times following the loose ligature surgery. In addition to the central sodium channels mRNAs, the peripheral tissue expresses transcripts encoding novel channels. The mRNA levels of sodium channels in the above tissues were analyzed by QRT-PCR (Quantitative Reverse Transcriptase-Polymerase Chain Reaction). A unique external standard cRNA comprising a part of the 3'-UTR was synthesized for each of the brain type I and III and peripheral sodium channels. The complex regulation of sodium channel mRNAs following injury and its possible physiological significance will be discussed.

714.3

PROLONGED O_2 DEPRIVATION ALTERS Na^+ CHANNEL mRNA LEVEL IN EXCITABLE TISSUES IN THE DEVELOPING RAT.

Y. Xia* and G.G. Haddad, Dept. of Pediatrics (Section of Resp. Med.), Yale Univ. Sch. Med., New Haven, CT 06520

We have previously observed an increase in saxitoxin (a specific Na^+ channel ligand) binding sites in immature rat brains after being subjected to chronic hypoxia, suggesting that prolonged O_2 lack can regulate Na^+ channels in excitable tissues. In the present study, we asked whether Na^+ channel mRNA is regulated by O_2 availability in excitable tissues of the developing rat. Newborn rats (postnatal 0-3 day) were exposed to low O_2 environment (9.5±0.5%) for 27-30 days and then the brain, skeletal muscle and diaphragm were quickly removed for RNA extraction (n=4-9). Control litters were maintained in room air and studied simultaneously with the experimental rats. For the Northern blots, 20 µg of RNA was loaded in each lane on 1% agarose/formaldehyde gel. For the slot blots, serial concentrations (0.5-10 µg) of RNA were separately loaded in each slot. The cDNA probe is a 307 bp piece of Na^+ channel II α-subunit cDNA (from 4836 to 5142 bp) and is common all Na^+ channels (I, II, IIa, III). Northern blots show a clear band with a size of ~9.4 kb. Quantitation of slot blots shows that Na^+ channel mRNA markedly increased in brain (+80%) and skeletal muscle (+100%) in experimental rats; in contrast, no increase in mRNA was found in diaphragm with hypoxia. We conclude that long term hypoxia modulates Na^+ channel mRNA differently in various excitable tissues of developing rats (Supported by NIH grant P01 HD32573, HL 39924, NS 32578, and a UCP grant).

714.4

AUTORADIOGRAPHIC LOCALIZATION OF RADIOIODINATED δ-CONOTOXIN TXVIA BINDING SITES IN RAT BRAIN.

B.A.Kurz and F.Filloux*. Depts. of Neurology, Pediatrics, and Biology, University of Utah, Salt Lake City, UT 84112.

Sodium channels are ubiquitously expressed in excitable cells within the nervous system. They are believed to exist as multiple subtypes which may exhibit select properties and unique neuroanatomic distributions. In order to better understand functional differences between these classes, defining their distribution and localization in the central nervous system is essential. We have employed a radioiodinated conotoxin with sodium channel specificity to pursue this question.

δ–conotoxin TxVIA, originally isolated from the molluscivorous cone snail Conus textile, slows sodium channel inactivation presumably by interacting with a distinct site on sodium channels. A radioiodinated analogue of this δ-conotoxin was applied in an autoradiographic assay. Sagittal sections of rat brain were labeled with [125I] δ–TxVIA and specific binding determined by competition with unlabelled δ-TxVIA. Autoradiograms were generated and intensities of binding were quantitated using computerized image analysis.

A reproducible pattern of [125I] δ-TxVIA binding sites was identified, with the highest density of labelling present in the choroid plexus. In declining order of abundance, sites were also seen in Purkinje and molecular cell layers of the cerebellum, pyramidal layer of hippocampus, granule cell layer of dentate gyrus, and with substantially lower levels in the outer layers of the cerebral cortex and striatum. Specific binding was displaceable by other delta (GmVIA, PVIA) and µO (MrVIA) conotoxins which are presumed to share a common site on the sodium channel. This displacement was not seen with other sodium channel ligands such as µ-conotoxin GIIIA.

These results indicate that the δ-conotoxin TxVIA identifies a unique neuroanatomic pattern of binding sites within the rat brain which suggest the existence of a unique set of functionally distinct sodium channel subtypes.

REGULATION OF Na CHANNEL mRNA IN NEUROBLASTOMA CELLS. Fred N. Quandt*. Dept. Molec. Biophys. and Physiol. Rush Univ., Chicago, IL 60612.

Little is known about the stimuli or mechanisms for regulation of Na channel mRNA in neurons. Physiological signaling pathways which may alter transcription of Na channel mRNA are being identified using cultured N1E-115 neuroblastoma cells as a model system. Messenger RNA is isolated and measured using an assay in which reverse transcription is followed by a competitive polymerase chain reaction. Previously we have reported that Na channel membrane current and mRNA are down-regulated in differentiated neuroblastoma cells grown in a Ca ionophore (A23187 or ionomycin, Quandt, Hirsh, and Sievert, Neurosci. Abs. 20:1506, 1994). This effect was selective since Kv 3.1 was not reduced under this condition. The result suggests that internal Ca alters transcription or lifetime of Na channel mRNA. The effects of other agents expected to alter internal Ca are being studied. Growth of cells in either nitrendipine, BAY K 8644, or depolarization with high K in the presence of valinomycin did not result in changes in Na channel mRNA abundance. Open Ca channels therefore appear to contribute little to regulation of mRNA under the normal growth condition. Addition of 40 μM veratridine to the culture medium for 3 days reduced Na channel mRNA by 80%. The action of veratridine on mRNA may be mediated by an increase internal Ca following activation of Ca channels after depolarization, or more likely following a decrease in Ca efflux through Na/Ca exchange. Supported by the National Multiple Sclerosis Society.

TRANSCRIPTIONAL REGULATION OF HUMAN BRAIN SODIUM CHANNEL GENES: PRESENCE OF β1 MESSAGE IN LA-N-5 HUMAN NEUROBLASTOMA CELLS. M.L. Beckman* and G.B. Brown. Psychiatry and Behavioral Neurobiology and The Department of Molecular Genetics and Biochemistry, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Sodium channels from central neurons consist of a heterotrimeric complex of α, β1 and β2 subunits. Both the rat and human genes for the β1 subunit have been cloned. The β1 subunit modifies the sodium channel by accelerating inactivation, shifting the voltage-dependence of inactivation to more negative membrane potentials and increasing the peak amplitude of sodium current.

Our interest is in understanding the transcriptional regulation of the human brain sodium channel genes. The human neuroblastoma cell line LA-N-5 has been shown to express sodium channels based on sodium flux and saxitoxin binding assays in this laboratory (Lombardo and Brown, 1992). In addition, data from ligase detection reaction assays in this laboratory confirm the presence of α subunit subtypes II and III in these cells, but not subtype I. Weiss and Sidell have also described sodium conductances in these cells using the patch clamp technique (Weiss and Sidell, 1991).

We have extended these observations to show that these cells also express message for the β1 subunit. PCR amplification of DNase treated reverse transcribed mRNA from LA-N-5 cells was carried out and revealed the expected sized product. Currently, primer extension and 5'-RACE experiments are being conducted to map the transcriptional start site. The LA-N-5 cell line will be useful in our studies of the β1 subunit of human brain sodium channel and factors that may regulate its expression. (Supported by USPHS grant DA07237)

IMMUNOCYTOCHEMICAL AND ELECTROPHYSIOLOGICAL MEASURMENTS OF SODIUM CHANNEL DISTRIBUTION ON UNINNERVATED SKELETAL MYOTUBES. B.D. Anson*, and W.M. Roberts. Institute of Neuroscience, University of Oregon, Eugene, OR. 97403.

Vertebrate neuromuscular transmission depends, in part, on high densities of acetyolcholine receptors (AChRs) and voltage-gated sodium (Na^+) channels at the endplate. Much is known about the localization of AChRs to the endplate, but much less is known about Na^+ channels. To begin to understand how the specialized distribution of Na^+ channels on a muscle cell develops and is maintained, we have used immunoflurescent and electrophysiological methods to study the distribution of Na^+ channels on uninnervated chick skeletal myotubes growing in cell culture.

We labelled chicken myotubes with an affinity purified polyclonal antibody directed against the putative inactivation loop of the Na^+ channel, and then visualized the primary antibody distribution with a biotinylated secondary antibody and an avidin-conjugated fluorophore. Control myotubes were processed in parallel with experimental myotubes but without addition of primary antibody. The distribution of antibody labelling was examined by comparing blindly chosen areas of experimental and control myotubes.

Most areas on experimental myotubes showed no significant label over control. However, 18% (20/112) experimental areas showed label intensity greater than 2 standard deviations above the control mean. Furthermore, only 18% (15/82) of the patches containing nuclei showed significant labelling.

By using a tight-seal whole cell electrode to record currents focally elicited by a loose-seal patch electrode, we were able to record currents from 23 patches of membrane separated by 10-100μm from six different myotubes. For all but one patch, peak Na^+ current for each patch on a cell was between 0.5 and 1.5 of the mean for all patches from that cell.

These results suggest that: 1). Na^+ channels are distributed non-uniformly over uninnervated myotubes but that the distribution does not have a sharp boundary, and 2). Nuclei within a single cell may differentially express unequal amounts of Na^+ channel.

APPEARANCE OF SODIUM CURRENTS IN *XENOPUS* EMBRYONIC MYOCYTES MAY BE INDEPENDENT OF INNERVATION. E. Prabhakar and A.E. Spruce* Dept. of Pharmacology, Univ. of Birmingham, Birmingham, B15 2TT. UK.

Embryonic *Xenopus* myocytes are functionally innervated and able to generate sodium-dependent action potentials *in vivo* within 12 hr from Stage 15 (when morphological and functional differentiation of muscle begins). In neonatal rat muscle, sodium current (I_{Na}) expression is regulated by innervation. Therefore, by comparing the expression of I_{Na} in myocytes isolated either at St. 15 ("aneural") or at St. 24 soon after they had been innervated ("neural"), we were able to assess the role of nerve in this aspect of electrical differentiation. The timing of the whole-cell patch clamp recordings (relative to St. 15) from "aneural" and "neural" myocytes was equivalent 24.8 ± 0.5 hr (n = 17) and 20.8 ± 2.0 hr (n = 18), respectively. Although a higher proportion of "neural" myocytes expressed I_{Na} (61% (11/18) vs 41% (7/17)), its density was not significantly different: 62.1 ± 23.3 pA/pF ("neural", n = 18); 25.1 ± 8.2 pA/pF ("aneural", n = 17; $p < 0.2$). The expression of I_{Na} was found to be dependent on extracellular Ca^{2+}, however. When "aneural" myocytes were cultured in 0 mM Ca^{2+} (the recording solution which was spritzed onto the cells still contained Ca^{2+}), I_{Na} density was significantly reduced (5.9 ± 3.2 pA/pF; n = 11; $p < 0.03$), although the proportion of cells containing I_{Na} was not altered (45%; 5/11).

Therefore, the early expression of I_{Na} in developing myocytes appears to be a cell autonomous mechanism, possibly triggered by "muscle-derived factors" and involving Ca^{2+} entry. Nerve, however, may play a role in maintaining an accentuated level of I_{Na} (Corfas & Fischbach, 1993. J.Neurosci. 13:2118).

EXPRESSION OF mRNA FOR A SODIUM CHANNEL IN SUBFAMILY 2 IN SPINAL SENSORY NEURONS. S.G. Waxman and J.A. Black*. Dept. of Neurology, Yale Univ. Sch. of Med., New Haven, CT and Neuroscience Res., VA Med. Ctr, West Haven, CT 06516

Spinal sensory neurons (dorsal root ganglion [DRG] neurons) display a variety of voltage-sensitive sodium currents that differ in terms of kinetics and voltage-dependence. The expression of these different currents suggests the presence of multiple types of Na^+ channels in these cells. Previously we have demonstrated that adult DRG neurons express mRNA for rat brain Na^+ channel α-subunits I and II/IIA. In the present study we have used RNA blot and non-radioactive *in situ* hybridization methods with probes generated from the sequence of NaG, a putative glial Na^+ channel that appears to belong to Na^+ channel subfamily 2, to examine the expression of Na^+ channel mRNA from this subfamily in spinal sensory neurons and Schwann cells within DRG.

RNA blots showed a major band at ~7.5 kb in postnatal day 2 (P-2) and adult DRG RNA with the NaG probe, while no hybridizable RNA was detected in P-2 or adult brain or kidney samples.

In situ hybridization detected mRNA hybridizing with the NaG riboprobe within DRG neurons and Schwann cells *in vivo*, with higher levels of expression in the former. In contrast, hybridization with the NaG probe was not detected in neurons within the hippocampus, cerebellum or spinal cord. The expression of the mRNA hybridizing with the NaG probe appears to be developmentally-regulated in both Schwann cells and DRG neurons, with levels increasing as development proceeds. Thus, in addition to the mRNAs for rat brain types I and II/IIA α-subunits, the mRNA for an additional Na^+ channel belonging to subfamily 2 is expressed in DRG neurons.

DIFFERENTIAL DISTRIBUTION OF HUMAN BRAIN SODIUM CHANNEL SUBTYPE III mRNA: ANALYSIS BY LIGASE DETECTION REACTION (LDR) C.N. Lin* and G.B. Brown. Psychiatry and Behavioral Neurobiology, Univ. of Alabama at Birmingham, Birmingham, 35294

In a previous study a reverse transcriptase-polymerase chain reaction (RT-PCR) coupled ligase detection reaction (LDR) assay was used to detect the differential distribution of human brain sodium channel (HBSC) subtype I and II mRNA by quantifying the relative amounts of subtype I to II radio-labeled LDR product (Lu et al., 1992). However, information concerning HBSC III has been lacking. The RT-PCR-LDR analysis has now been extended to examine the distribution of subtype III mRNA in human brain. First total RNAs were extracted from seven regions (frontal, temporal and occipital cortex, cerebellum, spinal cord, basal ganglia and hippocampus) of different individual normal human brains and targeted mRNA fragements were amplified by RT-PCR using a pair of primers that are common to both III and I subtypes. Then a common ^{32}P-labeled primer (20mer) along with two subtype specific primers (30mer for III and 25mer for I, both abutting the 5' end of the common primer) were used in LDR reactions carried out for 30 cycles of 94°C for 1.5 min followed by 45°C for 4 min. The expression of subtype-specific mRNA can be quantified by densitometric analysis of the different-sized radiolabeled LDR products on autoradiograms. The results reiterate that LDR can provide a sensitive, quantative assay for measurement of total RNA containing allele-specific transcripts differing only by a single nucleotide. The data showed that HBSC III mRNA is differentially distributed in human brain compared to subtypes I and II, suggesting that they are differentially regulated. The relative ratio of III to I mRNA varies markedly from a low value of 0.49±0.07 in occipital lobe to a high of 2.92± 0.39 in cerebellum.

714.11

Expression of Na channel 6 alpha subunit mRNA in the developing rat central nervous system. K.L. Schaller and J.H. Caldwell*
Dept. Cellular and Structural Biology, Univ. CO Health Sciences Center, Denver, CO 80262.

A novel sodium channel isoform (NaCh 6) has been isolated and characterized from rat brain (Schaller et al, J. Neurosci, 1995). Previous studies showed that transcripts for NaCh 6 are abundant in the adult rat brain and by *in situ* hybridization are expressed in both neurons annd glia. Here the regional distribution of NaCh 6 mRNA expression in the developing rat brain was investigated by *in situ* hybridization. At embryonic days 15 and 18 weak hybridization is detectable over developing neuroepithelium. Transcript levels increase during postnatal development throughout the brain and spinal cord. By P1 NaCh 6 mRNA is detected in the pyramidal cells and dentate gyrus of the hippocampus, the granule cells of the cerebellum, and throughout the olfactory bulb. In these regions the levels of expression become progressively greater with maturation. In other areas of the CNS, for example the cortex, NaCh 6 transcript expression is highest at P7-P14 and then falls with further maturation. Expression of NaCh 6 transcripts in glial cells is seen beginning at P21 in both the brain and spinal cord. Thus it appears that the expression of NaCh 6 is both temporally and regionally regulated in the developing CNS.

714.12

CNS MYELINATION IS NOT REQUIRED FOR ESTABLISHMENT OF THE ADULT EXPRESSION PATTERN OF SODIUM CHANNEL SUBUNITS. P.A. Felts*, J.A. Black and S.G. Waxman. Dept. of Neurol., Yale Univ., New Haven, CT 06510 & PVA/EPVA Neurosci. and Regen. Res. Ctr., VAMC, W. Haven, CT 06516.

Rat brain sodium channels consist of a β_1-subunit, a β_2-subunit and an α-subunit. Currently there are at least 4 different α-subunits (forms I, II (Noda et al., *Nature* 320:188), III (Kayano et al., *FEBS Let* 223:417) and a putative glial subunit (NaG; Gautron et al., *PNAS* 89:7272)). During late embryonic-early postnatal development of the rat nervous system, the expression pattern of sodium channel subunits is altered: expression of form I and the β_1-subunit increases, and form III decreases. The adult expression pattern is attained at approximately 3 weeks postnatal age. Thus the developmental progression of sodium channel subunit expression is coincident with the period of most active myelination in the CNS. It is not known, however, if this progression is dependent upon myelination. We have therefore compared sodium channel α- and β_1-subunit mRNA expression in *myelin deficient* (*md*) rats and unaffected male littermates (20-22 days postnatal age). *md* is a sex-linked mutant of Wistar rats characterized by a near total lack of myelin in the CNS. Subunit expression was examined in the hippocampus, cerebellum, spinal cord and dorsal root ganglia (DRG) using *in situ* hybridization with digoxigenin labeled riboprobes.

The expression pattern we observed in unaffected animals was generally in accord with previous studies on adult animals. In the 3 CNS regions, the intensity of subunit expression was: II>β_1>I>III with no detected expression of NaG. In DRG neurons, α-subunits I and II and the β_1-subunit were prominently expressed, with less expression of α-subunit III. DRG neurons did express NaG mRNA. In *md* rats, the pattern of expression of sodium channel α-subunits I, II, III and NaG, and the β_1-subunit, was indistinguishable from the pattern observed in unaffected littermates in all tissues studied. This similarity indicates that CNS myelination is not necessary for progression from the embryonic to the adult sodium channel subunit expression pattern.

714.13

LOCALIZATION OF SODIUM CHANNEL-ENCODING mRNAs IN THE RAT CENTRAL NERVOUS SYSTEM. G.D. Pratt* and D.R. Riddall. Molecular Pharmacology, The Wellcome Foundation Ltd., Beckenham, Kent, BR3 3BS, United Kingdom.

Molecular cloning has revealed at least three subtypes of the α subunit of voltage-sensitive sodium channels in the rat brain, designated as I, II and III. We have employed *in situ* hybridization histochemistry to examine the distribution of mRNA species that encode sodium channel types I, II and III in the rat CNS. Complementary, subtype-specific 50-oligomeric deoxyribonucleotide probes were radiolabelled with α-[^{35}S]dATP using terminal deoxynucleotidyl transferase. Following hybridization, sections were washed under suitable stringency conditions and the specific microscopic transcript localization was resolved by dipping in Hypercoat™ LM-1 emulsion.

Sodium channel encoding mRNAs are differentially located throughout the brain. Only a weak general expression of type III mRNA was apparent in the adult rat brain although more concentrated levels were evident in the inferior olivary nucleus, nucleus of the solitary tract, locus coeruleus, medial habenula and also granule cells of the dentate gyrus. In contrast, expression of type II mRNA predominated in the cerebral cortex, the granule cell layer of the cerebellum, pyramidal cells of the hippocampus and dentate gyrus granule cells. Comparatively lower levels were found in the caudate putamen and thalamus. Type I mRNA expression is generally more pronounced in rostral structures with particularly high transcript levels being observed in motor neurones of the spinal cord, the spinal trigeminal nucleus, pontine nucleus, deep cerebellar nuclei, thalamic nuclei and layer III-IV of the somatosensory cortex. The anatomical substrates associated with type I mRNA may implicate the specific involvement of type I sodium channels with sensory spinal neurotransmission and also corticothalamic processing.

MODELLING IMPLICATES A SPECIFIC SODIUM CHANNEL TRANSITION DEFECT IN EQUINE PERIODIC PARALYSIS. WJB Hanna[1,2]*, RG Tsushima[2,3] & PH Backx[2,3]. [1]Biophysics Group, Dept Physics, Univ Guelph, Guelph, ONT, N1G 2W1, Canada; [2]Cardiology, Dept Med., Univ Toronto School of Med. & [3]CCRW, The Toronto Hospital, 101 College St, Toronto, ONT, M5G 2C4, Canada.

Equine hyperkalemic periodic paralysis (HPP) is associated with a skeletal muscle sodium channel α-subunit mutation corresponding to Phe1412Leu in the rat μ1 sodium channel (Rudolph et al., Nature Genetics 2:144, 1992).

Current from μ1 channels containing this mutation differ from the wild-type in several ways: (1) whole-cell peak currents decay several-fold more slowly and decay incompletely, producing a pedestal of sodium current, (2) whole-cell peak currents recover from inactivation approx. one order of magnitude more rapidly, (3) the steady-state inactivation curve is shifted to the right with no change in slope, (4) single channels produce brief re-openings during maintained depolarizations, (5) mean single-channel open-time is increased by approx. 40-60%. Activation parameters are not affected.

The phenotypic differences between control and HPP sodium channels are predicted by moderate changes in rate constants (in the sodium channel gating model developed by Kuo and Bean [Neuron 12:819, 1994]) involving transitions between the open ("O") and open-inactivated ("I") states. Reductions of O_{ON} combined with increases of O_{OFF}, each of one order of magnitude or less, in the Kuo/Bean model reproduce precisely the whole-cell inactivation gating abnormalities observed with the equine HPP mutation. Monte-Carlo simulations also predict the single-channel experimental results. Alterations of rate constants representing other molecular transitions in this model do not predict the complete HPP phenotype. These results suggest that the cytoplasmic end of S3-DIV is critical for normal binding of the inactivation gate with its receptor.

Supported by MRC Canada (WJBH) and MDA Canada (PHB and RGT).

CYSTEINE MAPPING IN THE SELECTIVITY REGION OF THE SODIUM CHANNEL. S.-F. Chen*[1], H.A. Hartmann[1] and G.E. Kirsch[1,2]. Depts. of Molecular Physiology and Biophysics[1] and Anesthesiology[2], Baylor College of Medicine, Houston, TX 77030.

The pharmacology of brain and skeletal muscle sodium channels (NaChs) is different from that of the cardiac isoform, but the ionic selectivity is the same in these different types of NaChs. A conserved lysine residue in the SS2 segment of domain III is critical for selectivity in NaChs (Heinemann *et. al.*, 1992; *Nature 356:441-443*). A single point mutation from cysteine to tyrosine in the SS2 of the domain I of cardiac NaCh switches the pharmacology to the type of brain/skeletal muscle NaChs (Satin *et. al.*, 1992; *Science 256:1202-1205*). A combined approach by systematic cysteine substitution and application of cysteine-modifying compounds was carried out in the SS2 of domains III and IV of the switched NaCh to map the residues which may line the narrowest part of the pore.

The negatively charged (2-sulfonatoethyl)methanethiosulfonate (MTSES) increased the conductance of D1713C and decreased the conductance of W1712C, M1421C, and W1420C. These results indicate that the SS2 of domain III and IV are not symmetrically aligned. D1713 is at external vestibule while the other three are already inside the narrow region. MTSES cannot modify K1418C and A1710C. This suggests that these two residues are deep inside the pore where anions cannot reach. The positively charged (2-aminoethyl)methanethiosulfonate (MTSEA) can still modify K1418C and A1710C with very slow kinetics. This indicates that the large molecule cannot freely rotates in the vicinity of these two residues. Selectivity amongst alkali metal ions was drastically reduced in the K1418C mutant such that P_K / P_{Na} became 1.2, versus 0.1 in control. The sequence of selectivity for all the other mutants remained as the Eisenman sequence X or XI. These results suggest that the side group of K1418 contributes to much of the spatial restriction at NaCh selectivity filter.

715.3

TTX DIFFERENTIALLY MODULATES FAST INACTIVATION GATES IN ADRENAL CHROMAFFIN CELL NA^+ CHANNELS.
F. Horrigan & R. J. Bookman* Dept. of Mol. & Cell. Pharmacology, University of Miami, Miami, FL, 33101

Na^+ current inactivation in chromaffin cells can be described by a kinetic model that includes two parallel fast inactivation states (I_{rfast} & I_{rslow}) that differ primarily in their time course of recovery from inactivation ($\tau_{fast} \approx 8$ ms, $\tau_{slow} \approx 140$ ms @ -80 mV). I_{rslow} and I_{rfast} interact in a strictly competitive manner such that transitions between inactivated states do not occur unless channels first recover from inactivation. Repetitive depolarizations (5 ms @+20 mV) at 5 ms intervals increase the fraction of channels in I_{rslow} since many channels recover from I_{rfast} during a 5 ms interval while few recover from I_{rslow}. Measurements of cell membrane capacitance (C_m) can be used to monitor the number of channels in I_{rslow} (Horrigan & Bookman 1994 Neuron, 13). A 5ms depolarization (+20mV) produces a transient increase in C_m (ΔC_t) as Na channels inactivate and then recover from inactivation. The decay of ΔC_t matches the time course of recovery from I_{rslow}. Repetitive depolarization produces an increase in ΔC_t amplitude consistent with the observed increase in I_{rslow}. TTX (1μM) abolishes I_{Na} and slows the decay of ΔC_t by a factor of 8 but does not alter the ΔC_t amplitude after a 5 ms pulse. Thus TTX binding appears to retard recovery from I_{rslow} significantly without altering the number of channels that enter I_{rslow} during a 5ms depolarization. In contrast, recovery from I_{rfast} is not modulated by TTX since the repetitive pulsing paradigm still produces an increase in ΔC_t amplitude. Thus TTX and related toxins may provide important tools for distinguishing the molecular mechanisms underlying these two forms of fast inactivation.

715.4

ON THE ACTIVATION-INACTIVATION COUPLING IN SODIUM CHANNELS. C. Y. Lee*, Department of Physiology, National Yang-Ming University, Taipei, Taiwan, R.O.C. 11221

The fast sodium inactivation is known to couple with the charge movement leading to channel opening. However, the IFM cluster responsible for inactivation [1] contains no charged residues to interact with the gating charges. How could the gating charge movement cause the IFM cluster to plug the pore? We propose that D1487, located next to IFM, could be mediating the activation-inactivation coupling. In the resting state D1487 may make hodrogen bonding with the residues in a particular domain (called the inactivation-coupled domain). This hydrogen bonding prevents the IFM cluster from moving to plug the pore through hydrophobic forces. During channel activation, a tyrosine or tryptophan may become negatively charged, breaking the hydrogen bonding. The IFM cluster could then move to plug the pore. This model can also explain why batrachotoxin activates the sodium channel without causing the fast inactivation by assuming one of its oxygen triad binds near Y1497-Y1498 [2].

COMPARISON OF SLOW INACTIVATION IN WILD TYPE AND HYPP-T698M RAT SKELETAL MUSCLE Na^+ CHANNELS. T.R. Cummins*, W.S. Agnew+ and F.J. Sigworth. Interdept. Neurosci. Prog. and Dept. of Physiol., Yale Univ. Sch. of Med., New Haven, CT 06510 and +Depts. of Physiol. and Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

It has been hypothesized that slow inactivation must be compromised by mutations causing hyperkalemic periodic paralysis (HYPP) to account for the duration of the paralysis observed in patients with HYPP (R. Ruff, Biophys. J., 66:542-545, 1994). We are studying a mutation (T698M) in the rat skeletal muscle sodium channel that corresponds to one of the human HYPP mutations (T704M) and have compared slow inactivation of wild type and T698M channels stably expressed in HEK293 cells.

Wild type channels exhibit slow inactivation in HEK293 cells. Slow inactivation develops with a similar time course to that observed for sodium currents in rat skeletal muscle. As has been observed with other preparations, slow inactivation in HEK293 cells remains intact when fast inactivation is removed by chemical modification and coincides with a negative shift in the voltage dependence of gating currents. However, while in native rat muscle tissue slow inactivation occurs at more negative voltages than fast inactivation, in HEK293 cells the opposite is true.

T698M channels also exhibit slow inactivation in HEK293 cells. At negative potentials slow inactivation and recovery form slow inactivation occur with a similar time course to that of wild type channels. At depolarized potentials, slow inactivation develops more slowly and is much less complete for HYPP-T698M than for wild type channels. This indicates that slow inactivation is indeed defective in HYPP mutant sodium channels and may contribute to the maintenance of paralysis in patients with HYPP.

715.6

CHARACTERIZATION OF SODIUM-DEPENDENT PLATEAU POTENTIALS IN LEECH RETZIUS CELLS ISOLATED IN CELL CULTURE. J.D. Angstadt* and J.J. Choo. Department of Biology, Siena College, Loudonville, NY 12211.

Retzius cells, identified by their characteristic size and location, were removed from isolated ganglia of *Hirudo medicinalis*. Cells were plated in separate 35 mm petri dishes pretreated with concanavalin A or poly-L-lysine and containing L-15 medium with gentamicin. Most experiments were performed on neurons maintained in culture for 7-11 days. The isolated neuron was superfused with a variety of saline solutions and microelectrodes usually contained tetraethylammonium (TEA) to suppress K^+ currents. Isolated Retzius cells had resting membrane potentials (RMP) of -50 to -60 mV and were quiescent or fired impulses at a low rate. Prolonged plateau potentials (PP) were evoked by brief (1 s) depolarizing current pulses. The plateau depolarization stabilized near 0 mV and persisted for several minutes in some cells. The membrane potential repolarized to the normal RMP spontaneously or in response to a brief hyperpolarizing current pulse. PPs were associated with a conductance increase, persisted in salines containing 200 μM Cd^{2+} or where Ca^{2+} was replaced with Ca^{2+} channel blockers such as Co^{2+}, Ni^{2+}, or Mn^{2+}. In contrast, PP were rapidly and reversibly eliminated when Na^+ was replaced with an equimolar concentration of N-methyl-D-glucamine. In some cells, repetitive bursting activity occurred spontaneously or in response to injected current. These membrane potential oscillations were similar in many respects to those evoked in intact ganglia by salines containing calcium channel blockers.

715.7

CHARGE SENSITIVE LIGHT INDUCED SODIUM CHANNEL IN *HERMISSENDA* PHOTORECEPTOR M. Sakakibara*, T. Yoshioka, H. Inoue Lab. Neurobiol. Engr., Tokai Univ., Sch. of Hightech., Numazu 410-03, JAPAN, Lab. Mollec. Neurobiol., Waseda Univ., Sch. of Human Sci., Tokorozawa 359, JAPAN

Our previous study explained the two contradictory evidences on the mechanisms of invertebrate phototransduction; the process of PIP_2 hydrolytic breakdown into IP_3 and diacylgrycerol(DG) is necessary for the generation of photoresponse whereas the product, IP_3, is not requisite. We hypothesized that the local charge movement caused by PIP_2 hydrolysis near the inner surface of rhabdomeric membrane controls the gating of non-voltage dependent, light sensitive sodium channel. The hydrolytic charge liberation was confirmed on the suppression of photoresponse not only by the injection of charge chelators such as neomycin, spermine but stoppage of PI turnover by IBMX, LiCl and R59022. We postulated that the light sensitive sodium channel is activated in the charge sensitive manner. The indirect increase of pH inside the type B photoreceptor by perfusing NH_4Cl containing ASW augmented the initial component of photoresponse by 20 % increase in amplitude. On the other hand pH decrease by injection of acetate buffer(pH 4.6) maximally suppressed the photoresponse by 70% then returned to the original one within 20 min. The size of photoresponse was found to be proportional to the dissociation of phosphorus which was obtained by ^{31}P-NMR experiment. Here we assume that phospholipase C, hydrolysing PIP2, may be activated rapidly by membrane depolarization as observed in rat brain synaptosome. Since the voltage-dependent sodium channel in the squid axon has been known to be inactivated to the internal pH change, acidic/basic, it is likely that the B photoreceptor is activated by light in the membrane charge dependent fashion.

715.8

A NOVEL OUABAIN-SENSITIVE SODIUM ACTIVATED CATIONIC CURRENT OF FROG TECTAL NEURONES IN VITRO. A. Zaykin*, A.Nistri. Biophys. Lab, Int Sch Adv Studies (S.I.S.S.A.), 34013, Trieste, Italy.

Voltage clamp techniques based on whole cell patch recording were used to study transient voltage-activated currents of frog tectal neurones in a slice preparation at room temperature. The external solution contained oxygenated and buffered saline solution (100 mM NaCl). The pipette solution usually contained Cs sulfate (sometimes replaced by K gluconate) plus ATP, EGTA and 5-10 mM Na . In forty neurones held at -50 mV depolarizing voltage steps evoked a fast inward sodium current with threshold at about -40 mV and peak after 1 ms. Under these conditions sodium currents were always followed by a large transient outward current carried out in approximately equal degree by Cs or K ions with peak at about 3-5 ms. The same type of fast inward sodium current was also activated by command potentials more negative than -90 mV but in this case it was not followed by any outward component corresponding to the Cs current observed at depolarized potentials. Externally applied TTX (1 μM), ouabain (50 μM) or Cs (10 mM) simultaneusly blocked inward and outward current components induced by depolarizing command steps and also blocked the isolated sodium current evoked by voltage steps more negative than -90 mV. The present data suggest that frog tectal neurones possess a novel type of sodium activated transient cationic current probably characterized by a rapid change in the selectivity of the same channel from sodium to potassium/cesium following the initial entry of sodium into the channel itself. This current possesses some simillarity to the sodium/potassium pump current of peripheral cells but it seems to present the unusual properties of rapid kinetics and voltage-dependent activation.

DIFFERENTIAL PROPERTIES OF VOLTAGE-DEPENDENT Na^+ CHANNELS FOLLOWING AXOTOMY IN CUTANEOUS AFFERENT DRG NEURONS OF ADULT RAT. M.A. Rizzo, S.G. Waxman*, J.D. Kocsis. Dept. of Neurology, Yale School of Medicine, New Haven, CT 06510 and Neuroscience Research Center, VAMC, West Haven, CT 06516.

Studies of the behavior of Na^+ currents particular to cutaneous afferent dorsal root ganglion (DRG) neurons following chronic axonal injury should increase our understanding of hyperexcitability of these neurons following chronic axonal injury. Cutaneous afferent DRG neurons in short-term cultures were identified by retrograde fluorescence labelling of the sciatic nerve with Fluoro-gold. Using the whole-cell and bleb-patch-clamp recording techniques, Na^+ currents were recorded from these neurons pre (controls)- and 18 days post-axotomy and tested for sensitivity to 1 μM TTX and 100-400 μM lidocaine. Na^+ currents in neurons post-axotomy, in contrast to controls, tended to be blocked by TTX, and by relatively higher concentrations of lidocaine. Kinetically slow, TTX-resistant Na^+ currents predominated in control neurons. Predominantly kinetically fast, TTX-sensitive Na^+ currents emerge post-axotomy. Steady-state activation and inactivation curves constructed from Na^+ current recordings of somatic membrane blebs (fragments of membrane 3-8 μm diameter corresponding to 0.3-2 pF) excised from cutaneous afferent DRG neurons pre- and post-axotomy revealed that conductances post-axotomy had a decreased slope factor, broader window currents, and splay of steady-state inactivation in comparison either to slow Na^+ conductances in control neurons, or to kinetically equivalent (fast) counterparts in non-axotomized, non-cutaneous afferent DRG neurons. The results are consistent with the hypothesis that, following axotomy, new subpopulations of Na^+ channels occur on cutaneous afferent DRG neurons. This may confer altered neuronal excitability, contribute to ectopic impulse generation, and underly pain and paresthesias following chronic axonal injury.

SODIUM CHANNELS IN B104 CELL LINE: ELECTROPHYSIOLOGICAL PROPERTIES AND mRNA PROFILE. X. Q. Gu*, S. D. Dib-Hajj, J. A. Black and S. G. Waxman. Department of Neurology, Yale University School of Medicine, New Haven, CT. and Neuroscience & Regeneration Research Center, VA Medical Center, West Haven, CT. 06516.

B104 is an established neuroblastoma cell line which was reported to exhibit electrical excitability, but previous studies have not elucidated the Na current characteristics of these cells. We used whole-cell patch clamp, reverse transcription-PCR (RT-PCR) and *in situ* hybridization to examine the properties of Na current and the mRNA profile of the Na channel α and β1 subunits.

Whole-cell patch clamp studies of B104 cells maintained in DMEM media supplemented with 20% fetal calf serum showed Na currents in about 30% of pyramid-like or spherical cells but not in bipolar cells. Na current ranged up to 4.0 nA in amplitude. Voltage steps more positive than -60mV activated transient inward currents, and currents were largest at potentials close to -30mV. Ten nM TTX reduced sodium current amplitude by 20-60%.

RT-PCR followed by restriction enzyme analysis of the amplified products confirmed our published results that B104 cells express αIII subunit mRNA; αI and αII mRNAs were not detected. We now show that β1 subunit mRNA is also expressed in the B104 cells. *In situ* hybridization using antisense riboprobes specific for the various Na channel α and the β1 subunits demonstrated moderate-to-high levels of αIII and β1 mRNA expression in some B104 cells. The expression of Na channel αIII and the β1 subunits appears to provide the molecular basis for the TTX-sensitive, voltage-dependent Na current that is present in B104 cells.

This work is supported in part by the Medical Research Service, VA and NMSS.

MUSCARINIC MODULATION OF SODIUM CURRENT BY ACTIVATION OF PKC IN RAT HIPPOCAMPAL NEURONS. A.R. Cantrell*, T. Scheuer, and W.A. Catterall, Department of Pharmacology, University of Washington, Seattle, WA 98195.

Voltage -gated sodium channels play an important role in neuronal excitability in the hippocampus but are infrequently recognized as targets for neuromodulation. Phosphorylation of brain sodium channels by protein kinase C (PKC) decreases peak current and slows macroscopic inactivation. Hippocampal muscarinic receptors activate PKC. Therefore, we have tested whether sodium channels can be modulated by muscarinic receptor activation in acutely-isolated adult (3-5 wks postnatal) hippocampal neurons using whole-cell voltage clamp recording.

Application of the muscarinic agonist, carbachol (20μM), reduced peak sodium current an average of 29.8 ± 2.5% in 28 /33 cells tested and slowed macroscopic inactivation at all potentials. No change in the voltage dependence of activation or inactivation was observed. These effects were mediated via PKC as they were eliminated when a specific PKC inhibitor peptide (PKC19-31) was included in the pipette solution and mimicked by the extracellular application of the PKC activator, OAG.

These results demonstrate that muscarinic activation of endogenous receptors on hippocampal neurons strongly modulates sodium channel activity by activation of PKC. Such modulation is expected to have potent effects on overall neuronal activity.

FRACTAL KINETICS OF IONIC CURRENTS IN BIOLOGICAL MEMBRANES. K.-D. Kniffki* and C. BRAUN. Physiologisches Institut, Universität Würzburg, Röntgenring 9, D-97070 Würzburg.

Fractal geometry has provided a mathematical formalism for describing complex spatial and dynamical structures in nature (B.B. Mandelbrot, The Fractal Geometry of Nature, 1983). It seems natural to apply a fractal analysis to protein kinetics involved in the gating mechanism of ionic channels in excitable membranes. In the classical papers of Hodgkin and Huxley the rate constants k are treated as textbook descriptions of macroscopic kinetics, i.e. as time-independent entities. Recently, T.G. Dewey, Proc. Natl. Acad. Sci. 91: 12101-12104, 1994, described the exchange of protons in tritiated lysozyme in a restricted (fractal) geometry including concentration fluctuations by using $k(t) = k't^{-\lambda}$. Here k' is a time-independent constant and the scaling exponent λ is restricted to values between 0 and 1. By using this particular approach for the Hodgkin and Huxley gating "particles" $\mu = m, h, n, \ldots$ between their 'closed' and 'open' states, i.e. $k_\alpha(t) = k'_\alpha t^{-\lambda_\alpha}, k_\beta(t) = k'_\beta t^{-\lambda_\beta}$, and assuming just for simplicity $\lambda_\alpha = \lambda_\beta = \lambda_\mu$, the resulting differential equation with time-dependent coefficients is

$$\frac{d\mu}{dt} = -(k'_\alpha + k'_\beta)t^{-\lambda_\mu}\mu + k'_\alpha t^{\lambda_\mu}.$$

The general solution for rectangular voltage-clamp pulses is given by

$$\mu(t) = \mu_\infty + (\mu_0 - \mu_\infty)exp(-(t/\tau_\mu)^{1-\lambda_\mu})$$

with $\tau_\mu = (\frac{1-\lambda_\mu}{k'_\alpha + k'_\beta})^{\frac{1}{1-\lambda_\mu}}$ for all $0 < \lambda_\mu < 1$ and the classical Hodgkin-Huxley type solution is revealed by the limit $\lambda_\mu \to 0$. This fractal model provides an excellent fit for the decaying (inactivating) part of the Na-current in node of Ranvier of myelinated axons, without assuming more than one closed state for the k-system.

716.1

MODULATION OF Na CURRENT DENSITY IN CLONAL PITUITARY CELLS BY CHRONIC TREATMENT WITH DIHYDROPYRIDINES. E. Monjaraz, U. Meza, A. Navarrete, and G. Cota*. Dept. of Physiology, Biophysics and Neurosciences, Cinvestav, Mexico, DF 07000.

Several previous observations from our laboratory in anterior pituitary cells raise the possibility that high threshold Ca channels may contribute to regulate the expression and/or function of Na channels. To test this possibility, pituitary GH3 cells were grown 4-5 days either under standard conditions or in the presence of 0.5 μM nimodipine or 0.5 μM BAY K 8644. After a recovery period of 60-90 min in the absence of dihydropyridines, whole-cell sodium currents were recorded by using the patch clamp technique. Sodium current density decreased to 50% of its control value in nimodipine-treated cells, and increased by a factor of 2.5 in cells exposed to BAY K 8644. Chronic treatment with these drugs did not modify the time course of the sodium current nor the voltage dependence of Na channel activation or inactivation. Furthermore, the stimulatory effect of BAK K 8644 on sodium current density was blocked by simultaneous incubation with cycloheximide or actinomycin D. The results indicate that calcium influx through L-type Ca channels has a positive influence on the long-term activity of Na channels.

716.2

ROLE OF PROTEIN KINASE C ISOFORMS IN THE REGULATION OF THE VOLTAGE-DEPENDENT SODIUM CHANNELS IN ADRENAL CHROMAFFIN CELLS. T. Yanagita, H. Kobayashi, R. Yamamoto, T. Yuhi, M. Urabe, H. Yokoo and A. Wada*. Miyazaki Medical College, Miyazaki 889-16, Japan.

We examined whether protein kinase C (PKC) is involved in the regulation of Na channels in cultured bovine adrenal chromaffin cells. The chromaffin cells contained PKC α, ε and ζ isoforms, but not β, γ and δ isoforms. The immunoreactive PKC α and ε but not ζ were translocated from cytosol to membrane by a 15 h treatment of the cells with 12-O-tetradecanoylphorbol-13-acetate (TPA; 100 nM) and phorbol 12, 13-dibutyrate (PDBu; 100 nM), activators of PKC. The treatment decreased the B_{max} of [^{3}H]saxitoxin binding to the cells without altering the K_d value, and also reduced the veratridine-induced ^{22}Na influx, while 4 α-TPA, an inactive analogue, had no effect. The effect of TPA was abolished by H-7, an inhibitor of PKC. Even a 2 h pulse-treatment with PDBu followed by a 13 h incubation without PDBu caused the comparable decrease in [^{3}H]saxitoxin binding with the continuous 15 h treatment.

These results suggest that functional Na channels are down-regulated by a delayed-effect of short-term activation of PKC α and/or ε isoforms.

716.3

MODULATION BY INTRACELLULAR FATTY ACIDS OF HUMAN MUSCLE SODIUM CHANNELS EXPRESSED IN HEK293 CELLS IS DEPENDENT ON α SUBUNIT ISOFORM AND PATH OF DELIVERY. S. J. Wieland*[1], O-h. Gong[1], H. Poblete[1], J. E. Fletcher[2], L.-Q. Chen[3] and R. G. Kallen[3] 1. Dept. of Anat. & Neurobiology, 2. Dept of Anesthesiology, Med. Coll. of Penn. & Hahnemann Univ.; 3. Dept. of Biochem. & Biophysics, Univ. of Penn. School of Medicine

Free fatty acids (FFA) participate in signalling pathways, including the arachidonic acid (AA) cascades and activation of protein kinase C. These lipids are implicated in the direct and indirect modulation of a spectrum of voltage-gated ion channels. Skeletal muscle Na channels can be either activated or inhibited by FFA exposure; the response is dependent on both FA structure and site of exposure. Cytoplasmic delivery of 5 μM AA augmented the voltage-activated Na current of recombinant SkM1 skeletal muscle Na channels expressed in HEK293 cells by 190% (±54 SE, n=7) over a 20 min period. Similar results were seen with 5 μM oleic acid (OA). Na currents in cells expressing H1 cardiac muscle Na channels were insensitive to AA treatment (Figure 1), and exposure to OA inhibited the H1 currents over a 20 min period by 29% (±13 SE n=5). Increase in SkM1 current was not accompanied by shifts in voltage dependence of activation, steady-state inactivation or markedly altered kinetics of inactivation of the macroscopic current. Fatty-acid induced increase in Na currents was not dependent on protein kinase activity. In contrast, both isoforms were reversibly inhibited by external application of unsaturated FFA. Thus the differential effects of FFA on skeletal muscle Na channels first noted in cultured muscle cells can be reproduced by expressing recombinant Na channels in epithelial cells. We conclude that 1. SkM1 has 2 sites of response to FFA, one which produces augmentation of macroscopic currents with intracellular FFA, and a second which produces inhibition with extracellular FFA; 2. H1 has only one site, which produces inhibition with extracellular FFA. Supported by the MDA.

MECHANISM OF MODULATION OF THE ADULT SKELETAL MUSCLE SODIUM CHANNEL BY FATTY ACIDS. S. Bendahhou, T.R. Cummins‡, F.J. Sigworth‡ and W.S.Agnew*. Depts. of Physiology and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD, 21205 and ‡Interdepartmental Neuroscience Program, Yale University School of Medicine, New Haven, CT, 06510.

Unsaturated fatty acids, such as arachidonic acid, have been shown to affect the functional properties of Na channels from neuroblastoma cells (J. Physiol. Lond. 419:95-119, 1989), squid giant axons (J. Membrane Biol. 95:113-120, 1987), cultured human skeletal muscle cells (Am. J. Physiol. 263:C308-C312, 1992) and striatal neurons (Neuron 11:633-644, 1993).

We have investigated the effect of arachidonic (AA) and oleic (OA) acids on the adult rat skeletal muscle Na channel (μ1) stably expressed in HEK293 cells using both whole-cell and cell-attached configurations. External applications of 1-10 μM AA or OA produced 1) a decrease in peak current 2) a hyperpolarizing shift in the inactivation curve and 3) a substantial enhancement of the rate of the fast inactivation without alteration of slow inactivation. These effects were not prevented by inhibitors of protein kinase C, cyclooxygenase or lipoxygenase. Palmitic acid, a saturated fatty acid, had no effect on μ1 sodium currents.

In order to investigate the mechanism by which cis-unsaturated fatty acids affect the sodium channel, mutant channels with defective inactivation (F1304Q) were tested. The peak current was still inhibited and the hyperpolarizing shift was observed in the presence of AA. AA also decreased the current in cells where fast inactivation was removed with 100 μM chloramine-T. Preliminary results indicate that the gating current is also decreased by AA.

These data together suggest that the cis-unsaturated fatty acids may block the sodium channels directly from the extracellular side and/or through perturbations of the lipid environment. The mechanism underlying the effect of cis-unsaturated fatty acids may not involve the inactivation particle, at least not in the decrease of the peak amplitude. Because we have observed a decrease in both peak ionic and gating currents, we postulate that unsaturated fatty acids regulate electrical activity in the membrane by inducing the internalization of Na channels.

716.5

MODULATION OF SODIUM CHANNELS BY INSECT-SELECTIVE SCORPION AND SPIDER TOXINS.

T. M. Norris, D. Lee and M. E. Adams*. Depts. of Entomology and Neuroscience, University of California, Riverside, CA 92521.

A subset of arthropod Na^+ channel toxins are known to be selective for insect neurons. Two insect-selective toxins which show different types of Na^+ channel modulation are LqhαIT and μ-Aga-IV. Both toxins cause repetitive activity in insect motoneurons. LqhαIT increases both the amplitude and duration of evoked synaptic currents at the neuromuscular junction. In contrast, μ-Aga-IV produces a dramatic increase in spontaneous transmitter release.

Whole cell patch clamp recordings were performed to examine the effects of these toxins directly on sodium currents in insect neurons (*Heliothis virescens*). LqhαIT (200 nM) slows the rate of Na^+ channel inactivation and more than doubles peak current, effects which are consistent with an α-scorpion toxin-like action. Mammalian neurons (rat DRG) were markedly less sensitive to this toxin. μ-Aga-IV dramatically shifts the voltage dependence of Na^+ channel activation in insect neurons to more negative potentials and slows the rate of channel inactivation. These effects resemble in some respects the action of mammalian β-scorpion toxins. μ-Aga-IV showed no toxicity upon intracranial injection into mice and had no significant effect on rat DRG neuronal sodium currents. These data demonstrate that LqhαIT and μ-Aga-IV selectively modulate insect sodium channels in ways that explain their paralytic neuromuscular actions, and that the modulatory actions of these toxins resemble those of the mammalian α- and β-scorpion toxins, respectively.

AMINE-MODIFIED DERIVATIVES OF PD85639 AS SODIUM CHANNEL BLOCKERS. Sheryl J. Hays*, Ioannis Roufos and Roy D. Schwarz, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Co., Ann Arbor, MI. 48105.

Voltage-dependent sodium channels have been proposed as the site of action for anticonvulsant, antiarrhythmic, and local anesthetic agents. A structure-activity relationship study of a series of novel Na^+ channel blockers, structurally related to N-[3-(2,6-dimethyl-1-piperidyl)propyl]-α-benzene acetamide (PD85639), will be presented. The diphenylacetic acid portion of PD85639 was unchanged throughout the study, while structural features in the amine and amide portions of the molecule were altered. The compounds were tested for inhibition of veratridine-stimulated Na^+ influx in CHO cells expressing the alpha subunit of type IIA Na^+ channels. Our studies show that a three carbon spacer between the amine and the amide groups was optimal and a secondary amide linkage is preferred. Additionally, the presence of an aromatic ring in the vicinity of the amine group greatly enhanced the inhibitory activity of these derivatives.

716.7

EXTRACELLULAR APPLICATION OF QX-314 BLOCKS SODIUM CHANNELS AND CAUSES LOCAL ANESTHESIA. K.R. Bley*, M. Khabbaz, D.D. Blissard, C. Lee and J.C. Hunter, Depart. Analgesia, Roche Biosciences, Palo Alto, CA 94305.

QX-314, the quaternary derivative of lidocaine, is widely regarded to block Na^+ channels only following intracellular application, as its permanent positive charge is thought to restrict lipid bilayer permeation. Consequently, QX-314 and other permanently charged Na^+ channel blockers are not believed to be local anesthetics (see Hille, 1992, p. 405). In order to test these assumptions, we have examined the ability of QX-314 to block action potential propagation and cause local anesthesia. Reduction of nerve impulse conduction is proportional to the degree of Na^+ channel blockade. Accordingly, extracellular recordings were made of C-fiber compound action potentials in rat vagus nerves *in vitro*. Cumulative concentration-inhibition curves to superfused lidocaine or QX-314 were constructed using 10 min exposures to 1, 10, 100 and 1000 μM compound. Tonic block was measured with a slow rate of nerve stimulation (0.03 Hz), and phasic block with a 30 Hz burst of nerve stimulation at the end of each 10 min period. High frequency nerve stimulation shifted the IC_{50} for lidocaine only marginally, from 220 μM (tonic) to 210 μM (phasic). In contrast, the QX-314 IC_{50}s were >1000 μM (tonic) and 380 μM (phasic). Frequency-inhibition curves (0.1-30 Hz) were measured in the presence of ~IC_{50}s for tonic block. Lidocaine, a kinetically fast Na^+ channel blocker (τ_{rec} ~ 0.2 s in the heart), produced appreciable phasic block only at 30 Hz, whereas QX-314 (τ_{rec} ~ 300 s) caused significant phasic block even at 0.1 Hz. To measure local anesthesia, four intradermal injections of varying concentrations of lidocaine or QX-314 were made on the lower back of guinea-pigs. At 5, 10, 20 and 30 min after dosing, skin sensitivities were tested by pricking the skin with a needle. The number of negative responses (no skin twitch) out of five yielded EC_{50} values (expressed in %) of 0.116 for lidocaine and 0.235 for QX-314. The onset and duration of local anesthetic effects produced by QX-314 were slower and longer, respectively, compared to lidocaine. These studies suggest that QX-314 can penetrate cell membranes to block Na^+ channels. Penetration is slower than for lidocaine, but is still sufficiently fast to cause acute effects like local anesthesia.

CHICK EMBRYO SYMPATHETIC NEURONS: A MODEL TO STUDY SODIUM CHANNEL NEUROTOXINS. A.L. Rivera Rentas*, J.A. Mercado, [1]R. Rosa, [1]A. Rodríguez, [2]T.R. Tosteson, [2]I. González, [3]W. Silva, [4]L. Beress, G. Escalona de Motta. Inst. Neurobiology, Depts. of Biology, [1]Chemistry and [2]Marine Sciences, University of Puerto Rico, San Juan, P.R., [3]Pharmacology Dept., UCC, Bayamón, P.R., and [4]Toxicology Inst., Kiel University, Germany.

In this work we used primary cultures of chick embryo sympathetic neurons as a model system to study the mechanisms underlying the actions of known and new toxins on voltage sensitive sodium channels. Pharmacologically isolated inward sodium currents (I_{Na}) elicited by depolarizing stimuli were examined using the whole-cell technique in cultures after 48 hrs incubation. I_{Na} was described in terms of ionic nature, voltage dependence of activation and inactivation, and sensitivity to specific toxins. Tetrodotoxin and μ-conotoxin GIIIA blocked I_{Na} amplitude by nearly 80% and 20%, respectively. Venom samples of the scorpion *L. q. haebreus* inhibited inactivation at the μg/ml range and caused a delay in this proccess seen tail currents blockade at fg/ml. The site 5 toxin, brevetoxin type 1 (PbTx-1) from *P. brevis* shifted toward more negative potentials the voltage dependent processes and delayed I_{Na} reactivation. In other experiments the actions two novel agents were examined. An alkaloid from the sponge *A. oroides*, Dibromosceptrin, displaced ^{3}H-saxitoxin in rat brain synaptosomes, and as expected for a site 1 toxin, decreased by nearly 40% I_{Na} amplitude. It also shifted toward more negative potentials the voltage dependence of inactivation. A toxic extract from the dinoflagellate *O. lenticularis*, did not affect ^{3}H-PbTx3 binding, decreased I_{Na} amplitude by 20% and shifted by 30 mV to more negative potentials the voltage dependence of inactivation. Different from the brevetoxins reactivation were not altered by this dinoflagellate extract. (Supported by GM08102 & NIH48190)

716.9

INTERACTION OF BESIPIRDINE WITH THE VOLTAGE DEPENDENT SODIUM CHANNEL. L. Tang*, C.P. Smith, F.P. Huger and S. Kongsamut
Neuroscience Product Group Unit, Hoechst Roussel Pharmaceuticals, Inc., P.O. Box 2500, Somerville, NJ 08876.

The alkaloid toxins veratridine and batrachotoxin bind to a site (so-called site II) on the voltage dependent sodium channel where they cause persistent activation of the channel and depolarize the cell. Tetrodotoxin and saxitoxin bind to a different site on the sodium channel and can block the effects of veratridine and batrachotoxin. Other known modulators of sodium channels include anticonvulsants and local anesthetics which inhibit sodium currents and displace [^{3}H]batrachotoxin binding. Besipirdine (HP 749) is a compound undergoing clinical trials for efficacy in treating Alzheimer's Disease. Among other pharmacological effects, besipirdine inhibits voltage dependent sodium and potassium channels. We present here a more detailed study on the interaction of besipirdine with voltage dependent sodium channels. Besipirdin displaced [^{3}H]batrachotoxin binding with an IC_{50} of 5.5±0.2 μM in a rat brain vesicular preparation and inhibited veratridine-stimulated increases in intracellular free sodium ($[Na^+]_i$) and calcium ($[Ca^{2+}]_i$) in primary cultured rat cortical neurons in a concentration dependent manner. Furthermore, besipirdine dose-dependently inhibited veratridine-stimulated release of [^{3}H]norepinephrine (NE) from rat cortical slices. When examined in greater detail, besipirdine was found to inhibit [^{3}H]batrachotoxin binding in vesicular membranes competitively. However, when examined in rat brain synaptosomes, the antagonism by besipirdine was found to be non-competitive; that is, the maximal stimulation of $[Ca^{2+}]_i$ induced by veratridine decreased with increasing concentration of besipirdine. These results are discussed in relation to possible anticonvulsant activity of besipirdine.

716.10

ACTIONS OF PYRETHROID INSECTICIDES ON SODIUM CHANNELS EXPRESSED IN *XENOPUS* OOCYTES. Timothy J. Smith* and David M. Soderlund. Field of Environmental Toxicology and Dept. of Entomology, New York State Agric. Expt. Station, Cornell Univ., Geneva, NY 14456.

Pyrethroids make up a large class of potent neurotoxic insecticides whose principal target is the voltage-gated sodium channel. In intact nerves, pyrethroids induce prolonged sodium currents and afterpotentials which lead to uncontrolled repetitive firing or use-dependent nerve block. To further explore the molecular basis of pyrethroid action on sodium channels we employed the heterologous expression of sodium channel subunits in *Xenopus* oocytes. The rat brain IIa sodium channel α subunit and the rat brain β_1 subunit mRNAs were synthesized *in vitro* from cloned cDNAs. The α subunit mRNA was injected into oocytes either alone or in combination with the β_1 subunit mRNA and the actions of the pyrethroid deltamethrin on expressed sodium currents were assessed by two-electrode voltage clamp. Deltamethrin prolonged the time course of sodium channel inactivation and produced tail currents following repolarization that were qualitatively similar to the effects produced on sodium channels in intact nerves. The presence of the β_1 subunit enhanced rapid inactivation, as anticipated, but did not modify the effects of deltamethrin. These findings imply that the binding domain involved in the neurotoxic action of pyrethroids is associated with the sodium channel α subunit. Other pyrethroids also prolonged sodium channel inactivation and produced sodium tail currents in this assay system. The rate of tail current decay in this system was found to be compound-dependent.

716.11

VOLTAGE-DEPENDENT ACTIVATION AND LIDOCAINE (LI) SENSITIVITY OF BRAIN VOLTAGE-DEPENDENT SODIUM CHANNELS (VDSC) DURING DEVELOPMENT. C. Castillo, M.E. Díaz, B.C. Salazar, Villegas,G.M.*, E. Recio-Pinto. Instituto Internacional de Estudios Avanzados (IDEA) Apartado 17606 Caracas 1015-A, Venezuela. Anesthesiology Dept. Cornell University Medical College. New York, NY 10021.

In the brain, the number and types of VDSC change[1,2] and their TTX/STX affinity increase during development[2]. We are investigating whether other properties of VDSC undergo changes during forebrain development. Sodium channel activity from newborn (P0) and postnatal day 15 (P15) rat brains were studied in planar lipid bilayers in the presence of BTX and in symmetrical 200 mM NaCl. The steady state activation curve showed a hyperpolarization shift during development: the midpoint potential values were -54mV and -74mV for channels derived from P0 and P15 forebrains respectively. The maximal fractional open time was lower in channels derived from P0 than P15, due to a higher proportion of short- and long-lived channel closures in channels from P0. The level of LI-induced open channel block did not change during development. LI blocked the open state of brain channels with about ten times higher potency than that of muscle derived channels[3]. The higher LI affinity of brain channels was mainly due to a lower k_{off} value, indicating that the conformation of the channel structures defining the LI binding site is not identical in brain and muscle-derived sodium channels; while they appear to be the same in the various brain sodium channels. [1]Sheinman et al.,1989;[2]Villegas et al., 1994; [3]Zamponi et al., 1993.

716.12

SELECTIVE BLOCK OF TETRAMETHRIN-MODIFIED SODIUM CURRENT BY VITAMIN E. J-H. Song* and T. Narahashi. Dept. of Mol. Pharmacol. & Biol. Chem., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Pyrethroids are neurotoxic insecticides, which exert their effects by prolonging the open time of individual neuronal sodium channels. Occupational exposure to pyrethroids frequently leads to abnormal skin sensation or paresthesia. Vitamin E, (±)-α-tocopherol, has been known to reduce the cutaneous paresthesia, but the mechanism of action remains to be seen. Since the sodium channel is the major target site of pyrethroids, it is possible that vitamin E interacts with pyrethroids at their receptor site on the sodium channel. In present patch clamp study, we found the selective block of tetramethrin (a type I pyrethroid)-modified sodium current by vitamin E. Vitamin E 10 μM and 30 μM blocked 10 μM tetramethrin-modified tetrodotoxin-sensitive (TTX-S) sodium currents in rat cerebellar Purkinje cells by 31 % and 77 %, respectively, and in rat dorsal root ganglion cells by 34 % and 76 %, respectively, with no effect on the tetramethrin-unmodified current. The concentration-response curve for tetramethrin effects was shifted to higher concentrations by vitamin E in a competitive manner. Repetitive discharges and elevated depolarizing after-potential caused by tetramethrin were effectively blocked by vitamin E. Tetramethrin-unmodified tetrodotoxin-resistant (TTX-R) sodium current in dorsal root ganglion cell was blocked by vitamin E. Vitamin E block of tetramethrin-modified TTX-S sodium current was not dependent on voltage or depolarizing duration. Vitamin E could not reverse the tetramethrin-induced shift in the current-voltage curve, but partially reversed the shift in the steady-state sodium channel inactivation curve of TTX-S sodium channels. Vitamin A and its metabolic derivative, retinoic acid, slightly reduced the tetramethrin-modified sodium current accompanied by the block of normal sodium current. The selective block of tetramethrin-modified sodium current by vitamin E seems to be responsible for vitamin E alleviation of paresthesia.

716.13

δ-CONOTOXINS, A FAMILY OF SUBTYPE-SPECIFIC *CONUS* PEPTIDES WHICH INHIBIT INACTIVATION OF VOLTAGE-SENSITIVE SODIUM CHANNELS. K. Shon[1], M.M. Grilley[1], H. Terlau[2], W. Stühmer[2], W.R. Gray[1], J.S. Imperial[1]* and B.M. Olivera[1]. Dept. of Biology[1], Univ. of Utah, Salt Lake City, UT 84112; Max-Planck-Institut für experimentelle Medizin[2], D-37075 Göttingen, Germany.

A vertebrate-specific δ-conotoxin, δ-PVIA (the "lock-jaw peptide") was purified and characterized from the venom of *Conus purpurascens*, a fish-hunting cone snail (Shon et al., 1995, *Biochemistry* 34, 4913). The two δ-conotoxins previously characterized, δ-TXVIA (the King-Kong peptide") and δ-GMVIA (Hillyard et al., 1989, *Biochemistry* 28, 358; Shon et al. *Biochemistry*, 1994, 33, 11420) were from mollusc-hunting cone snail venoms, and exhibited potent activity on molluscan voltage-sensitive sodium channels. Like the other δ-conotoxins, δ-PVIA is a very hydrophobic peptide, with 29 amino acids and 3 disulfide bridges. Although the disulfide bridge framework is conserved in all three δ-conotoxins, the non-cysteine amino acids are not conserved in the three family members. δ-Conotoxin PVIA elicits excitatory symptoms in mice and fish, but is inactive in molluscs even at doses 100-fold higher. The peptide inhibits sodium channel inactivation in both cloned mammalian sodium channels expressed in *Xenopus* oocytes, as well as in cultured mammalian neurons. The δ-conotoxins are a promising group of *Conus* peptides for discriminating between various vertebrate subtypes of voltage-sensitive sodium channels. δ-Conotoxin TXVIA is generally inactive in vertebrate systems; δ-conotoxin GMVIA causes excitatory symptoms but only in immature mammals. In contrast, δ-conotoxin PVIA exhibits broad activity in a wide range of vertebrate systems tested. cDNA clones for all three δ-conotoxin sequences have been characterized; this makes it possible to systematically identify additional δ-conotoxins from *Conus* species using molecular biological techniques.

NEW CONOTOXINS WHICH BLOCK NEURONAL SODIUM CHANNELS. J.M. McIntosh[1,3], A. Hasson[4], M.E. Spira[4], W.R. Gray[1], W. Li[1], M. Marsh[2], D.R. Hillyard[2], H. Terlau[5], W. Stühmer[5] and B.M. Olivera.[1]* Depts. of Biology[1], Pathology[2] and Psychiatry[3], Univ. of Utah, Salt Lake City, Utah, 84112; Dept. of Neurobiology[4], Inst. of Life Sciences, Hebrew Univ. of Jerusalem, Jerusalem, 91904 Israel; Max-Planck-Institut für experimentelle Medizin[5], D-37075 Göttingen, Germany.

We previously characterized ω-conotoxins, μ-conotoxins and δ-conotoxins, which target voltage-sensitive calcium channels, voltage-sensitive sodium channels and inhibit sodium channel inactivation, respectively. We report a new family of peptides, the μO-conotoxins. The 31-residue peptides, μO-conotoxins MRVIA/B, were purified from the venom of *C. marmoreus*. Their structures were confirmed by mass spectrometry, molecular cloning, and chemical synthesis. The peptides were isolated by electrophysiologically screening venom fractions in cultured *Aplysia* neurons, where these ligands potently and selectively block sodium conductance. μO-Conotoxins are also active in vertebrate systems; unlike the μ-conotoxins which are specific for muscle Na channels in adult rats, μO-conotoxins potently inhibit neuronal subtypes. Although the μO-conotoxins block voltage-sensitive sodium channels like the μ-conotoxins, the disulfide framework of the μO-conotoxins is that of the ω- and δ-conotoxins but not of the μ-conotoxins. Thus, together the ω-, δ- and μO-conotoxins define a superfamily of *Conus* peptides.

716.15

BRAIN VOLTAGE-DEPENDENT SODIUM CHANNELS SHOW TEMPORAL CHANGES IN THEIR LIDOCAINE APPARENT BINDING AFFINITY. B.C. Salazar, C. Castillo, M.E. Díaz, E. Recio-Pinto*. Anesthesiology Dept, Cornell University Medical College, New York, NY 10021. Instituto Internacional de Estudios Avanzados (IDEA), Apartado 17606, Caracas 1015-A, Venezuela.

Local anesthetics block the open state of various voltage-dependent sodium channels. In muscle-derived channels, lidocaine (LI) and the permanently charged lidocaine analog QX-314 produce a constant level of open channel block. In brain-derived channels, however, we found that when studied under identical conditions, the level of open channel block induced by LI and QX-314 showed periods in which it was highly reduced. Therefore, in brain channels, the level of open channel block shows two dominant modes, a high- and a low-affinity mode. The amount of time the channel expends in the low-affinity mode was larger in the presence of QX-314 than of LI. With QX-314 it was possible to detect the presence of more than one high-affinity mode in brain sodium channels. The various affinity modes suggest the presence of various open channel conformations. The level of the LI/QX-314-induced open channel block increased with depolarization. The magnitude of this voltage dependence was the same in the various LI/QX-314 affinity modes. This indicates that the distance between the lidocaine binding site and the intracellular channel aspect does not change with changes in the open channel conformation. Noise analysis showed that the various anesthetic affinity modes display the same k_{off} but different k_{on} rates, indicating that the channel open conformational changes most likely involve changes in the hydrophilic pathway leading to the binding site, rather than changes at the binding site itself.

716.16

INHIBITION OF VERATRIDINE-INDUCED [14C]-GUANIDINE FLUX IN CNAIIA-1 CELLS. S. Connaughton, T. Wolcott, L.D. Margolin & J.B. Fischer*, Cambridge Neuroscience, Inc., Cambridge, MA 02139.

Experiments were performed in a Chinese hamster ovary cell line that stably expresses the alpha-1 subunit of the mammalian type IIA neuronal sodium channel (CNAIIA-1). Electrophysiological studies demonstrate that CNAIIA-1 cells generate a rapidly inactivating, inward sodium current with normal time course and voltage dependence (Scheuer et al., 1990; Knapp et al., 1993).

The neurotoxin,veratridine, causes persistent activation of sodium channels at resting membrane potential by blocking inactivation and this effect is enhanced by scorpion venom. Veratridine-induced [^{14}C]-guanidine flux in CNAIIA-1 cells in a dose dependent manner with maximal flux occuring at 125-300 µM. Scorpion toxin (6 µg/ml) potentiated this flux up to 14-fold. Veratridine-induced flux in the absence and presence of scorpion toxin (6 µg/ml) was linear with time up to at least 60 min and 45 min, respectively. TTX inhibited the veratridine (90 µM)-induced flux in the absence and presence of Scorpion toxin (6 µg/ml) with an IC_{50} of 6.8 and 33.8 nM, respectively. Several anticonvulsants, the sodium channel blocker, BW 1003C87 and a number of our putative sodium channel blockers inhibited veratridine induced [^{14}C]-guanidine flux as shown below:

COMPOUND	IC50 ± S.E.M.(µM)	COMPOUND	IC50 ± S.E.M.(µM)
LAMOTRIGINE	44.4 ± 14.4, n=5	PHENYTOIN	32.6 ± 0.96, n=2
BW 1003C87	2.21 ± 0.38, n=2	CNS 1237	1.64 ± 0.04, n=5
RILUZOLE	2.15 ± 0.96, n=4	CNS 1145	2.03 ± 0.33 n=7

In conclusion, this flux assay in CNAIIA-1 cells is a useful high throughput screen for compounds with putative type IIA sodium channel blocking activity.

SODIUM CHANNELS IV

717.1

STABLE COEXPRESSION OF α and β1 SODIUM CHANNEL SUBUNITS IN CHO-K1 CELLS: EFFECT OF THE β1 SUBUNIT ON THE DENSITY AND NEUROTOXIN BINDING PROPERTIES OF THE EXPRESSED CHANNELS. D.W. Bonhaus*, R.C. Herman, C.M. Brown, Z. Cao, L.-F. Chang, D.N. Loury, P. Sze, L. Zhang and J. C. Hunter Syntex Research, Palo Alto, CA 94034 and Edinburgh Scotland.

Mammalian brain sodium channels consist of a principal α subunit and two smaller β subunits. The α subunit, by itself, forms a functional channel, whereas the β1 subunit may modify the stability and inactivation kinetics of α subunit. To examine the effect of the β1 subunit on the functional expression of α subunit sodium channels, a Chinese hamster ovary (CHO) cell line stably coexpressing the rat IIA α and human β1 subunits was generated. Cells expressing both the α and β1 subunits had a five fold higher density of [^{3}H]Saxitoxin binding sites and a 2 fold greater maximum rate of veratridine-stimulated [^{14}C]guanidinium influx than did cells expressing only the α subunit. Brevetoxin, α Scorpion toxin, and the pyrethroid RU39568 increased (5-20 fold) veratridine-stimulated [^{14}C]guanidinium ion influx in both cell lines with similar EC_{50} values. However, these neurotoxins stimulated [^{3}H]Batrachotoxinin ([^{3}H]BTX) binding only in membranes of cells expressing both α and β1 subunits; brevetoxin, α scorpion toxin and RU39568 had no effect on [^{3}H]BTX binding to membranes of cells expressing only the α subunit. These findings indicate that coexpression of the β1 subunit increased the number of functional sodium channels and enabled the neurotoxins to evoke conformational changes in the α subunit associated with an increase in [^{3}H]BTX binding. These findings are consistent with a role for the β1 subunit in maintaining the α subunit in the membrane in a functional, neurotoxin-sensitive, conformation.

717.2

PRIMARY STRUCTURE AND FUNCTIONAL EXPRESSION OF THE β2 SUBUNIT OF THE RAT BRAIN NA^+ CHANNEL. L.L. Isom*[1], D.S. Ragsdale[2], K.S. DeJongh[3], B.F.X. Reber[4], and W.A. Catterall[2]. [1]Dept. of Pharmacology, The Univ. of MI, Ann Arbor, MI 48109, [2]Dept. of Pharmacology, Univ. of WA, Seattle, WA 98195, [3]CTI Seattle, WA 98119, [4]Dept. of Pharmacology, Univ. of Berne, Switzerland.

Voltage-sensitive Na^+ channels are the membrane proteins responsible for the rising phase of the action potential observed in excitable cells. Na^+ channels isolated from rat brain are a heterotrimeric complex composed of an α subunit and two auxiliary β subunits, β1 and β2. β1 has been shown to be non-covalently associated with α while β2 is covalently linked to α by disulfide bonds. The β1 subunit has been cloned, sequenced and expressed and shown to play a modulatory role in sodium channel kinetics and expression levels. We now describe the primary structure of the rat brain Na^+ channel β2 subunit. The deduced primary structure of β2 shows that it is a 20,902-dalton protein that contains a cleaved signal peptide, a single putative transmembrane domain, and 4 potential N-linked glycosylation sites. β1 and β2 subunits share topological similarities, yet are not homologous at the nucleotide or amino acid levels. Comparison of the β2 peptide sequence with other known sequences in the peptide databases shows that β2 contains a domain that is homologous to a neuronal cell adhesion protein that has been implicated to play a role in the formation of the developing nervous system. Northern blot analysis of mRNA expression suggets that β2 is limited to the central nervous system. Coexpression of Type IIa α and β2 subunits in *Xenopus* oocytes results in a β2 concentration-dependent increase in peak current amplitude, an increase in the rate of macroscopic inactivation, and a small hyperpolarizing shift in the voltage-dependence of inactivation. These functional effects of β2 appear to be additive with β1. Thus, β2 subunits may function as important regulators of Na^+ channel expression, modulating electrical excitability in the embryonic and adult central nervous systems.

717.3

Functional effects of neuronal Na^+ channel β1-subunit heterologously co-expressed with µ1 Na^+ channel in Xenopus oocytes I.F. Potts* & W.S. Agnew Dept. of Physiology, Johns Hopkins School of Medicine, Baltimore, MD 21205.

The mammalian adult skeletal muscle voltage-sensitive Na^+ channel underlies the action potentials observed in the sarcolemma. Functional µ1 channels can be heterologously expressed in *Xenopus* oocytes using RNA encoding the α-subunit alone but display anomalously slow inactivation kinetics (gating mode 2) unless co-expressed with neuronal β_1-subunit RNA, suggesting a modulatory role for that auxiliary subunit (which is closely related or identical to the skeletal muscle Na^+ channel β-subunit). To test whether the β_1-subunit might also enhance the surface expression of functional µ1 channels, peak I_{Na} was observed over time in *Xenopus* oocytes heterologously expressing µ1 alone or with the β_1-subunit. Maximal peak expression of Na^+ current occurred at least two times faster in the presence of the β_1-subunit than when µ1 was expressed alone. To test whether the β_1-induced stabilization of mode 1 gating conformation requires co-translation of the two subunits in *Xenopus* oocytes, RNA injections were delayed by 24 or 48 hours. Regardless of subunit RNA injection order or the length of delay between injections (≤48 hours) all cells receiving β_1-subunit RNA exhibited significantly greater I_{fast}/I_{slow} ratios than cells injected only with RNA encoding µ1 α-subunit. "post-injected" β_1 induced a significant decrease in slow-inactivating (mode 2) whole cell I_{Na} with no net change in channel density (as estimated from weighted whole cell peak I_{Na}) it seems likely that the observed shift in gating mode prevalence represents a conversion of channels already in the plasma membrane from mode 2 to mode 1 conformation.

717.4

GENES ENCODING THE β1 SUBUNIT OF VOLTAGE-DEPENDENT BRAIN SODIUM CHANNEL IN RAT, MOUSE AND HUMAN CONTAIN AN INTRON. Sulayman D. Dib-Haji* and Stephen G. Waxman. Department of Neurology, Yale University School of Medicine, New Haven, CT and Neuroscience & Regeneration Research Center, PVA/EPVA, VA Medical Center, West Haven, CT 06516.

In an effort to understand the fuctional role of the different subunits of voltage-dependent sodium channels, we recently described a transcript (β1.2) that is closely related to the voltage-dependent brain sodium channel β1 transcript (β1.1). cDNAs of the β1.2 transcript were analyzed and revealed two major differences between β1.1 and β1.2. First, an 86 bp insert in β1.2 is present in the 3' untranslated sequence, 6 bp downstream of the translation termination codon. Second, a single nucleotide substitution changes the Aspargine at position 110 to Serine; this change eliminates a putative N-linked glycosylation site that is present in the β1.1 proteins of rat and human channels. These observations suggested that this new transcript could represent an isoform (β1.2) of the previously described β1.1 species.

We now report that the 86 bp insertion has the hallmarks of an intron. The 5' and 3' termini of the insert are the invariant dinucleotides GT and AG, respectively. A polypyrimidine-rich sequence precedes the AG dinucleotide and the sequence C T A A G, located 26 bp upstream of the 3' end is a good match to branch point motif C/T T A/G A C/T (the highlighted A is the branch nucleotide) of higher eukaryotic introns. Using PCR, we have amplified segments of rat, mouse and human genomic DNAs that contain this intron. Preliminary evidence suggests that the intron is conserved in the three species. We will utilize this intron to determine whether a single β1 gene is present in the three genomes.

Ths work is supported by funds from the VA and NMSS.

717.5

SODIUM CHANNEL β1 SUBUNIT mRNA IN OLFACTORY SYSTEM DURING POSTNATAL DEVELOPMENT AND FOLLOWING DENERVATION. S.Sashihara*, C.A.Greer, Y.Oh and S.G.Waxman. Depts. of Neurol. and Neurosurg. Yale Univ., New Haven, CT 06510 & PVA/EPVA Neurosci. and Regen. Cnt., VAMC, W. Haven, CT 06516.

We investigated the developmental and denervation-induced regulation of the β1 subunit (Naβ1) of the Na^+ channel in rat olfactory system. *In situ* hybridization at postnatal days 4, 7, 14, 28 and 47 shows that Naβ1 mRNA expression is upregulated with increasing age, but with different time courses in mitral, tufted, and pyramidal cells. In mitral cells, label was detected at postnatal day 4 (P4) and gradually increased to peak at P14. Tufted cells were devoid of Naβ1 mRNA at P4 and P7, but at P14 through adult, most tufted cells expressed Naβ1 mRNA. In pyramidal cells of pyriform cortex (PC), Naβ1 expression is further delayed, and is not clearly detectable until P14, with peak expression at P28.

We surgically deafferentated the olfactory bulb (OB) at P30, and compared effects of such deafferentation on Naβ1 with those for Na^+ channel α subunit (Naα) mRNAs. Within 5 days of surgery, the signals for Naβ1 and NaαII expression in mitral cells were decreased to low-to-moderate levels. In pyramidal cells, Naβ1 mRNA expression was moderately decreased without significant change in NaαII mRNA. The deafferentation had no apparent effects on expression of mRNAs αI and αIII in these cells of the OB and PC. These data indicate that Naβ1 mRNA is differentially expressed in various cell types in the olfactory system during normal development. Moreover, deafferentation data suggest that the expression of Naβ1 is regulated independently of Naα mRNAs via cell-specific and pathway-specific mechanisms. Supported in part by the VA, NMSS and NIH.

717.6

DIFFERENTIAL Na^+ CHANNEL β1 SUBUNIT mRNA EXPRESSION IN DRG NEURONS IN VITRO AND IN VIVO. Y. Oh*, S. Sashihara+, K. McNabola+, J.A. Black+, S.G. Waxman+. *Department of Medicine, Division of Nephrology, and Neurobiology Research Center, University of Alabama, Birmingham, AL 35294; and +Department of Neurology, Yale University School of Medicine, New Haven, CT 06510.

The voltage-sensitive Na^+ channel β1 subunit (Naβ1) mRNA has recently been localized within the developing and adult CNS, where its expression is regulated temporally and spatially. In the present study, we have examined the expression of Naβ1 mRNA in adult rat dorsal root ganglion (DRG) neurons *in vitro* and *in vivo* using non-radioactive *in situ* hybridization cytochemistry. At 3-4 days in vitro, Naβ1 mRNA was prominent in DRG neurons. The level of Naβ1 expression appeared to be greater in medium-to-large (>25 μm in diameter) DRG neurons than in small (<25 μm) DRG neurons. The Naβ1 mRNA was localized to the somata of the DRG neurons and was not detectable in the neurities. In intact DRGs, results were consistent with those of *in vitro* studies. The level of Naβ1 mRNA expression was higher in intermediate-to-large (>25 μm) DRG neurons compared to that in small (<25 μm) DRG neurons. This cell body size-related Naβ1 mRNA expression is consistently observed beginning at postnatal day 4 and continues throughout development to adulthood. These results demonstrate that Naβ1 mRNA is expressed in PNS neurons *in vitro* and *in vivo*, and suggest that Naβ1 gene expression in DRG neurons is differentially regulated in relation to their cell body size. [Supported in part by the VA and NMSS]

717.7

THE *tipE* GENE OF *DROSOPHILA MELANOGASTER* ENCODES A NOVEL MEMBRANE PROTEIN REQUIRED FOR EXPRESSION OF *para* SODIUM CHANNELS IN XENOPUS OOCYTES. Linda M. Hall*, Guoping Feng, and Maninder Chopra. Department of Biochemical Pharmacology, SUNY at Buffalo, Buffalo, NY 14260.

Mutations in the *tipE* gene cause a temperature-induced paralysis and reduction in sodium channels as measured electrophysiologically (O'Dowd and Aldrich, *J. Neurosci.* **8**:3633, 1988) and by saxitoxin binding. Cloning by chromosome walking and transformation rescue has shown that the *tipE* gene encodes a novel 50,000 dalton protein. *In vitro* translation in the presence of microsomes shows that *tipE* is a glycosylated, integral membrane protein with two transmembrane domains. Both the amino and carboxy termini are on the cytoplasmic side of the membrane. The *tipE* protein is required in mid to late pupal development when the nervous system is undergoing final maturation in order to rescue paralysis in adults. In addition, expression is also required in adults to prevent a heat-induced lethality which is independent of the paralysis phenotype. Coexpression in Xenopus oocytes with the sodium channel α subunit encoded by the *para* locus shows that *tipE* is required for functional expression of this sodium channel. A dendrogram comparing previously cloned sodium channel α subunits from a variety of species suggests that many of those which have been difficult to express may require a *tipE* homologue. Site directed mutagenesis coupled with expression in Xenopus oocytes is being used to define functionally important domains on the *tipE* protein. [*para* clone provided by J. Warmke, P. Wang, L. Van der Ploeg (Merck) & R. Reenan, B. Ganetzky (U. Wisconsin)]

717.8

THREE NEW PUTATIVE VOLTAGE GATED SODIUM CHANNELS (VGSC) FROM HUMAN NEUROBLASTOMA (SH-SY5Y) CELLS: A PCR BASED CLONING STRATEGY. **J.L. Walewski*, J. Ziauddin, and E. Recio-Pinto** Depts. of Anesthesiology and Physiology, Cornell University Medical College, New York, N. Y. 10021

When exposed to retinoic acid, SH-SY5Y cells undergo neuronal differentiation, i.e., neurite outgrowth and the induction of electrical excitability (increased expression of voltage gated Na^+ and Ca^{2+} channels). To identify VGSC expressed by the undifferentiated or differentiated cells, total RNA from each treatment was transcribed into first strand cDNA, then subjected to two rounds of PCR (2nd nested), using degenerate primers specific to segments of the highly conserved third and fourth transmembrane regions of the alpha subunit. Cloning, restriction analysis, and sequencing revealed three distinct sub-clones (one from undifferentiated and two from differentiated cells) which are unique, yet highly homologous to other members of the VGSC family. Amino acid (AA) translation of the amplified cDNA demonstrated the expected high homology (Table 1) at the transmembrane regions, the presence of the IFM fast inactivation motif, and otherwise considerable AA variation in the III-IV cytoplasmic loop.

Table1

	HuVGSC	Hu Card	Rat II	Eel	Drosph	Jellyfish
CLONE	% Iden	% Iden	% Iden	% Iden	% Iden	% Iden
3	89	82	89	64	50	35
5	96	83	96	68	51	35
6	75	68	75	59	75	35

Identification of a partial cDNA encoding a putative voltage-gated sodium channel from the parasitic flatworm *Bdelloura candida*. **Michael C. Jeziorski*, Robert M. Greenberg and Peter A.V. Anderson. The Whitney Laboratory, University of Florida, St. Augustine, FL.**

Alterations in the fast inward sodium current responsible for the initiation of action potentials in human muscle and heart have been implicated in the pathology of several disorders, such as paramyotonia congenita (PC) and long QT syndrome. The specific defect in these diseases, supported by identification of several mutations, is thought to be a decrease in the efficiency of transition from the open state to the inactivated state of the voltage-gated sodium channel (VGSC), resulting in a sustained inward current, depolarization of the membrane and loss of membrane excitability. The fast inward sodium current expressed by neurons of the platyhelminth *B. candida* also exhibits a non-inactivating, tetrodotoxin-sensitive component. We have used RT-PCR with degenerate primers to isolate a cDNA fragment from *Bdelloura* RNA that displays homology to known VGSCs. This fragment, which hybridizes to an RNA of approximately 5.5 kb, includes a sequence encoding the III-IV interdomain cytoplasmic loop, a region known to be one of several components essential to inactivation of VGSCs. This region of the *Bdelloura* channel contains an alanine in place of a threonine that is conserved in every other identified VGSC cDNA (T1491 in the rat brain II channel), and that is mutated in one manifestation of PC. Additional residues within the III-IV loop vary from other known sequences and may also underlie incomplete inactivation of the sodium current. Further work will be directed toward identification of the complete cDNA sequence, heterologous expression of the channel, and characterization of its sensitivity to tetrodotoxin. (Supported by NSF grant IBN-9410565 to PAVA and NRSA grant MH 10625 to MJ.)

717.10

EXPRESSION AND FUNCTION OF SPECIFIC SODIUM CHANNEL ISOFORMS IN EMBRYONIC NEURONS. D.D.Hodges[1], S. Takamatsu, B. McNevin, and D.K. O'Dowd*[1,2]. Dept. of Anat. & Neurobiol.[1] and Dev. & Cell Biol. [1,2] U. C. Irvine, CA 92717.

Voltage gated sodium channels play a key role in electrical excitability of cells in vertebrate and invertebrate nervous systems. The *para* gene encodes functional voltage-gated Na^+ channels in cultured *Drosophila* embryonic neurons. Using a combination of electrophysiology and single cell RT-PCR, we have previously shown that *para* transcripts containing alternative exons i and /or a are positively correlated with large I_{Na} density. We have initiated experiments to test the hypothesis that phosphorylation at a PKA site in exon a regulates I_{Na} density. Treatment of cultured neurons with forskolin, an activator of PKA, results in a 10-30% decrease in peak I_{Na}. The ability of other phosphorylation activators and inhibitors to modulate sodium currents is currently under investigation. We have also generated transgenic flies which express heat shock inducible ribozymes designed to eliminate all *para* transcripts or specifically those containing exon a. A preliminary hatching assay on one of these lines indicates that heat shock prior to *para* expression results in a small decrease in hatching and larvae that hatch display a sluggish phenotype similar to that described for *para* nulls. Other paralytic assays and RT-PCR analysis of total *para* mRNA from different developmental stages, as well as electrophysiological and single cell RT-PCR analysis of cultured embryonic neurons from these transgenic lines are in progress. These studies are supported by NIH grants NS27501 to DOD and NS07351 to DDH.

717.11

CHARACTERIZATION OF SODIUM CHANNEL GENES FROM INSECTICIDE-SUSCEPTIBLE AND INSECTICIDE-RESISTANT HOUSE FLIES. Patricia J. Ingles, Pamela M. Adams, Douglas C. Knipple and David M. Soderlund*. Dept. of Entomology, New York State Agric. Expt. Station, Cornell Univ., Geneva, NY 14456.

The *kdr* insecticide resistance trait of the house fly (*Musca domestica*), which confers reduced neuronal sensitivity to DDT and pyrethroid insecticides, exhibits tight genetic linkage to RFLP markers lying within a sodium channel gene that is homologous to the *para* gene of *Drosophila melanogaster*. The coding sequence of the house fly *para* gene was determined by direct automated DNA sequencing of PCR fragments obtained by amplification on first strand cDNA from adult heads. The predicted house fly amino acid sequence was >90% identical to that of the *D. melanogaster para* gene product. In contrast to the multiplicity of sodium channel isoforms that result from alternative exon usage in *D. melanogaster*, there was no evidence for the existence of multiple splice variants among the cDNAs obtained from adult house fly head preparations. The house fly *para* sequence identified in this study was most similar to the [$a^+b^-c^-d^+e^-f^-$] splice variant of *D. melanogaster*, which occurs as a minor variant in adults but not embryos. However, the house fly sequence also contained segments located within the region of anticipated alternative splicing that do not correspond to any of the identified alternative exons from *D. melanogaster*. Comparison of *para* coding sequences for the NAIDM (susceptible) and 538ge (*kdr*-resistant) house fly strains revealed several nucleotide substitutions that result in changes in amino acid sequence. The role of these sequence polymorphisms in conferring the *kdr* insecticide resistance phenotype remains to be determined.

717.12

CLONING OF A SODIUM CHANNEL α-SUBUNIT (PN1) FROM RAT DORSAL ROOT GANGLIA. L.M. Fish, L. Sangameswaran, S.G. Delgado, B.D. Koch, L.B. Jakeman, J.Kwan, and R.C.Herman*. Biotechnology Unit and Center for Peripheral Nervous System Res.,Syntex, Palo Alto, CA 94304.

We have isolated a full-length sodium channel α-subunit clone, designated peripheral sodium channel 1 (PN1), from a rat dorsal root ganglia (DRG) cDNA library. The cDNA encodes an open reading frame of 1984 amino acids. Northern blot analysis shows that the 11 KB PN1 transcript is abundant in DRG. Amplification of the PN1 sequence by RT-PCR indicates that PN1 is expressed in the CNS, as well as in sympathetic ganglia of the peripheral nervous system. Specifically, it is detected in brain, spinal cord, DRG, nodose ganglia, superior cervical ganglia, sciatic nerve, and heart, but not in skeletal muscle. The functional expression of PN1 in *Xenopus oocytes* and its cell distribution in DRG by *in situ* hybridization studies will be discussed.

POTASSIUM CHANNEL PHYSIOLOGY, PHARMACOLOGY AND MODULATION II

718.1

ACETYLCHOLINE ACTIVATES APAMIN-SENSITIVE K^+ CHANNELS IN CHICK COCHLEAR HAIR CELLS. W.A. Yuhas* and P.A. Fuchs, Dept. Physiol., U. Colorado Sch. Med., Denver, CO 80262.

Acetylcholine (ACh) hyperpolarizes cochlear hair cells by activating calcium-dependent potassium channels. It has been suggested that this mechanism employs the large conductance calcium-activated K^+ channels (maxi-K^+s) that support electrical tuning in hair cells of some nonmammalian vertebrates. We show here that this suggestion is unlikely to be correct since the K^+ current elicited by ACh ($I_{K(ACh)}$) differs both physiologically and pharmacologically from that flowing through maxi-K^+ channels ($I_{K(Ca)}$) in the same hair cells. The I-V relation for $I_{K(ACh)}$ is approximately linear through its reversal potential near E_K and has an "N-shape" that peaks near 0 mV. In contrast, the I-V relation for $I_{K(Ca)}$, flowing through maxi-K^+ channels, is sharply outwardly rectifying about the reversal potential at E_K and reaches its maximal value near +30 mV, suggesting different permeation and activation mechanisms. Substitution of internal K^+ with Cs^+ ions prevents $I_{K(Ca)}$ but not $I_{K(ACh)}$. The scorpion venom peptide charybdotoxin blocks half of $I_{K(Ca)}$ at 3 nM but has no effect on $I_{K(ACh)}$ at 65 nM. In contrast, the bee venom peptide apamin blocks half of $I_{K(ACh)}$ at 10 nM but leaves $I_{K(Ca)}$ unaffected at 1 μM. These data show that ACh activates K^+ channels that are distinct from maxi-K^+ channels, and are likely to be members of the small conductance class of calcium-activated K^+ channels. Supported by NIDCD DC 01508 and the National Organization for Hearing Research.

718.2

DEVELOPMENT OF Kv3.1-LIKE CURRENTS IN ACOUSTICO-VESTIBULAR NEURONS OF THE CHICKEN EMBRYO BRAIN IN VITRO R.Hendriks, W.Amin Hossain, D.K.Morest, L.K. Kaczmarek, R.M. Davidson and E-M. Ostapoff* Dept. Anat., Univ. of Connecticut Health Ctr., Farmington, CT 06030 & Dept. Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06520.

The *Shaw*-like, mammalian Kv3.1 channel is a voltage-dependent potassium channel, highly expressed in mature auditory brainstem nuclei. Associated currents have a high activation threshold, are slow to inactivate and are very sensitive to 4-AP and TEA. We have characterized these currents in the acoustico-vestibular anlage, containing the presumptive nuc. magnocellularis (NM, putative homologue to the mammalian anteroventral cochlear nucleus) at several developmental stages. Whole-cell patch recordings were made from normotypic cell cultures that were highly enriched with NM neuroblasts. Since these neuroblasts normally start to migrate at E5.5, explants were made on E4 and E7 and cultured for 2 days (E4/2D and E7/2D, respectively). They were identifiable microscopically as large, phase-bright, spherical cell bodies with neuritic processes. Sodium-like current transients, characteristic of neurons, were absent at E4/2D but pronounced at E7/2D for these cells. Subsequent recordings were performed in defined external saline solutions containing 1μM TTX (for E7/2D only) and zero-added calcium, to block voltage-dependent sodium conductances and calcium and/or calcium-dependent conductances, respectively. At E4/2D and E7/2D, step depolarizations revealed macroscopic outward currents that were a composite of two components: a fast initial transient current and a slowly inactivating current. The initial transient current could be fully revealed by pre-conditioning pulses to -100mV (Vh=-70mV) and eliminated with pre-conditioning pulses to -40mV. This A-like current was smaller at E4/2D than at E7/2D. The second component had Kv3.1-like properties, based on criteria for this current, including an activation threshold of about -10 mV. *In summary*, Kv3.1-mediated currents appear to occur very early in neuronal development, well before synaptic activity in ascending auditory pathways. Supported by T32DC00025, NS29613.

MICE LACKING THE DELAYED RECTIFIER POTASSIUM CHANNEL MKV1.1. S.L. Smart*, A. Messing, S.Y. Chiu, P. Schwartzkroin, B. Tempel. Depts. of Pharmacology, Otolaryngology, and Neurological Surgery, U. of Washington, Seattle, WA 98195; Depts. of Neurophysiology and Vet. Medicine, U. of Wisconsin, Madison, WI 53706.

The mouse delayed rectifier potassium channel mKv1.1 is widely expressed in the CNS and elsewhere, and is thought to be important in normal neuronal functions such as axonal conduction. In order to assess the consequences of the absence of this channel, the mKv1.1 gene open reading frame (ORF) was removed through targeted homologous recombination. A targeting construct was built containing 129Sv genomic DNA sequences flanking the mKv1.1 gene ORF, a neomycin resistance cassette, and a thymidine kinase gene. The construct was electroporated into cultured embryonic stem cells, which were then subjected to both positive and negative selection. Three of the surviving ES cell clones which screened positively by Southern blot for having undergone homologous recombination were injected into blastocysts for production of chimaeras. Chimaeric mice from two clones proved capable of germline transmission. The chimaeric founders have been mated with Black Swiss, 129Sv and C57/B6 mice, and homozygotes have been obtained from heterozygote intercrosses. Use of an mKv1.1 ORF probe on a Southern blot has confirmed the absence of the mKv1.1 gene ORF in homozygous animals. The homozygotes show increased mortality and a phenotype with possible motor and/or neurological components. Studies are underway to elucidate the physiological basis of the apparent phenotype.

TWO DISTINCT, OVERLAPPING "DELAYED-RECTIFIERS" DETERMINE THE VOLTAGE-DEPENDENT POTASSIUM CURRENT PHENOTYPES IN ST. LACUNOSUM-MOLECULARE INTERNEURONS IN PRIMARY CULTURE. A. Chikwendu* and C.J. McBain. NICHD-LCMN , NIH, Bethesda, MD 20892.

Whole cell, voltage-clamp recordings were made from primary cultures of dissociated st. L-M interneurons from rats P5-P10. In cells with a bipolar morphology, "delayed rectifier" outward K^+ currents were activated at test potentials positive to -40mV (V_h = -60mV). One of two current phenotypes was usually observed which we termed "sustained" and "slowly-inactivating". The voltage-dependence of activation of either current phenotype, however, was fit by the sum of at least two boltzmann equations suggesting that the total outward current resulted from the temporal overlap of multiple components. The total outward current showed minimal (~20%) voltage-dependent inactivation (Vhalf = -65 ± 3.8mV, n=14). In cells possessing predominantly "slowly-inactivating" outward currents, 4-AP dose-dependently (10μM - 30mM) blocked a fraction of the total outward current with an IC_{50} of 312 ± 101μM. At a maximal concentration of 30mM, 4-AP selectively blocked 41% of the total current. Isolation of the 4-AP sensitive component yielded a "slowly-inactivating" current with a positive voltage dependence of activation (Vhalf = 11.9 ± 1.4mV, n=4). The current remaining in 30mM 4-AP was "sustained" and also possessed a positive Vhalf of 6.2 ± 2mV (n=4). In cells where a "sustained" outward current dominated, 4-AP (30 mM) again removed a "slowly-inactivating" component which represented only 23% (n = 5) of the total outward current. TEA dose-dependently (10μM - 30mM) blocked the total outward currents with an IC_{50} of 142 ± 47μM. In 30mM TEA, 85% of the total outward current was blocked regardless of whether the current phenotype was predominantly "sustained" or "slowly inactivating". However, low concentrations of TEA (10 - 100μM) selectively removed the "slowly-inactivating" current component (Vhalf = 10.1 ± 1.3mV, n=5).

In conclusion, bipolar st. L-M interneurons have at least two "delayed rectifier" currents with similar activation profiles which can be differentiated based on their sensitivity to 4-AP and TEA. The differing proportions of either current component usually determines the overall current phenotype in any given cell.

718.5

DO CHANNELS FORMED BY Kv1.4 CONTRIBUTE TO THE TRANSIENT CURRENT IN ST. PYRAMIDALE INTERNEURONS ? L. Zhang* and C.J. McBain NICHD-LCMN, NIH, Bethesda, MD 20892-4495.

Homomeric channels formed by the voltage-dependent K^+ channel subunit Kv1.4 exhibit a transient current which is inhibited by decreasing external K^+ concentrations ($[K^+]_o$). Immunohistochemical studies have shown the Kv1.4 protein to be localized to cells tentatively identified as interneurons of the CA1 hippocampus. Here we have examined the effects of $[K^+]_o$ on the transient current of cells from subfield CA1 and correlated these effects with cell morphology in slices from neonatal rats (11-15 days). With whole-cell and outside-out patch voltage clamp techniques, transient currents were elicited by depolarization to potentials positive to -60mV (Vhold -90mV) and were isolated from sustained currents by use of different prepulse paradigms. Isolated whole-cell transient K^+ currents in various $[K^+]_o$ were compared with control transient current recorded in 3.5 mM $[K^+]_o$. 38% of all the cells recorded (n = 78) and whose morphology was subsequently identified by biocytin labeling showed a selective reduction (36%) or increase (62%) in the amplitude of the transient current measured at 0mV when perfused with a K^+-free or a 10 mM $[K^+]_o$ solution, respectively. Analysis of the voltage-dependence of this transient current revealed a Vhalf of -20 ± 2.1 mV (n = 11). Of these cells, 60% were identified as inhibitory interneurons located close to the border of st. pyramidale, 17% were observed in st. radiatum proper, and 10% were CA1 pyramidal neurons. In all other cells the transient current was increased in K^+-free conditions as would be expected. Current-clamp recordings from cells exhibiting a decrease in transient current in K^+-free solution in voltage-clamp studies (n = 3) demonstrated an increase in their action potential duration (18%) concomitant with an augmentation of the afterhyperpolarization amplitude (52%) in K^+-free solution. In addition K^+-free solution also caused a membrane hyperpolarization of ~3 mV. Our data suggest that external K^+ can modulate a transient K^+ current presumably arising from Kv1.4 subunit expression in hippocampal CA1 neurons. This current contributes to the total transient current and participates in the action potential repolarization in inhibitory neurons of st. pyramidale.

PERMEATION PROPERTIES OF THE M-CURRENT IN RAT SUPERIOR CERVICAL GANGLION NEURONS.

R. Cloues*, J.P. Adelman, and N.V. Marrion. Vollum Institute, OHSU, Portland, OR 97201.

The M-current is a voltage-dependent potassium (K^+) current which is inhibited by muscarinic acetylcholine receptor activation. We have examined aspects of M-channel permeation including the relative permeabilities of various monovalent cations and whether the M-channel displays anomalous mole fraction behavior. Whole-cell M-currents were recorded from cultured rat superior cervical ganglion (SCG) neurons using the nystatin perforated-patch technique. To determine relative permeabilities, cells were bathed in a solution containing 135 mM NMG (a non-permeant cation) and 15 mM of the cation of interest (acetate salt), as well as 5 mM MgAc, 0.1 mM CaAc, 0.2 mM CdAc, and 10 mM 4-AP (to block other voltage-dependent K^+ channels). Shifts in M-current reversal potential were measured and the permeability of different cations relative to K^+ determined. The permeation sequence of the M-current is: $Tl^+ > K^+ > Rb^+ > NH_4^+ >> Na^+$. For example, Rb^+ is less permeable than K^+ ($P_{Rb}/P_K = .78$), blocks conduction through the channel ($g_{Rb}/g_K = .40$), and slows the deactivation tail currents at -50 mV from 107 ± 15 ms to 136 ± 18 ms (sem; n=4; $P < 0.1$). The M-current displays anomalous mole fraction behavior, a property suggestive of a multi-ion pore. In these experiments, M-currents were recorded in isotonic K^+ (150 mM) and then titrated with increasing amounts of Rb^+. M-current conductance goes through a minimum as the mole fraction of Rb^+ varies from 0 to 1.0. The M-channel thus displays many of the properties of other voltage-dependent K^+ channels.

CHARACTERIZATION OF THREE DISTINCT K^+ CURRENTS MODULATED BY ATP IN HUMAN NEOCORTICAL NEURONS.

C. Jiang* & G. G. Haddad, Department of Pediatrics, Section of Respiratory Medicine, Yale University, New Haven, CT 06510

ATP-modulated K^+ channels play an important role in regulating membrane excitability and neuronal responses to metabolic stress. In order to study the presence and modulation of these K^+ channels in *human* neocortical neurons, single channel K^+ currents were recorded in the excised patch configuration from dissociated human neocortical neurons. Three outward currents sensitive to ATP were characterized. All channels were selectively permeable to K^+. One of them had an unitary conductance of ~45pS and showed a strong inward rectification with symmetric K^+ across the membrane. This K^+ current was inhibited by ATP with IC_{50} of ~150μM, and channel activity was suppressed by non-hydrolyzable ATP analogue AMP-PNP and glibenclamide. The second K^+ current had a conductance of ~170pS, but no rectification was seen. This current was also inhibited by ATP, AMP-PNP and glibenclamide. Unlike the 45pS current, however, activation of this current required the presence of μM Ca^{++} on the cytosolic side. The third K^+ current was Ca^{++} dependent, had a conductance of ~260pS and was inhibited by charybdotoxin. Unlike the other 2 channels, ATP (0.03-1.0mM) *enhanced* channel open probability and increased the unitary conductance. These results indicate that a number of K^+ channels are regulated by physiologic concentrations of ATP in human neocortical neurons. (Supported by NIH P20 NS32578, HD15736)

HIERARCHY OF GLUTAMATE AND NORADRENERGIC RECEPTOR FUNCTION IN HIPPOCAMPAL CA1 NEURONS. R. Nouranifar*, T. Wong, R.D. Blitzer and E.M. Landau. Dept. of Psychiatry, Mt. Sinai School of Medicine and Bronx VAMC, New York NY 10029

Intracellular recording techniques were used to investigate the interaction between the metabotropic glutamate and β-adrenergic signaling pathways in pyramidal cells from the CA1 region of adult rat hippocampal slices. Both trans-1-aminocyclopentane-1S,3R-dicarboxylic acid (ACPD) and isoproterenol (ISO) blocked the slow afterhyperpolarization (sAHP) which followed membrane depolarization when applied individually. However, their effects were less than additive when applied in combination. The effect of the combined agonists became additive when protein kinase C (PKC) was inhibited by PKC_{19-31} in the recording electrode. The involvement of PKC confirmed by the bath application of chelerythrine, a specific inhibitor of PKC, which also rendered the combined effect of ISO/ACPD additive. Interestingly, the inhibitory effect of ACPD on AHP was not blocked by chelerythrine, which did prevent the blockade of the AHP by phorbol-12,13-dibutyrate (PDBu). The ISO-ACPD interaction could be mimicked by the combination of ISO and PDBu, and most importantly, by 8-bromo-cAMP and PDBu. The results indicate that the metabotropic glutamate pathway coupled to PKC prohibits the β-adrenergic inhibition of the AHP.

The demonstration that PKC can prevent an effect of the PKA pathway reveals a potentially important motif of interaction between these two pathways, expressed as an assignment of rank to different neurotransmitters. Thus, a neurotransmitter of a higher rank (glutamate, coupled to PKC) can override the effect of a lower-ranking transmitter (norepinephrine, coupled to cAMP), enabling the neuron to discriminate among neurotransmitters released in temporal proximity. Such interacting effects on the AHP might function as a protective mechanism, preventing over-stimulation of pyramidal neurons upon release of multiple excitatory neurotransmitters. Supported by NARSAD and a VA Merit Grant.

Properties of Ca^{2+}-dependent, large conductance K (BK) channels in cultured rat melanotrophs. S.J. Kehl*, K. Kheirani, M. Mitton, and K. Wong, Department of Physiology, UBC, Vancouver, B.C., Canada, V6T 1Z3

The biophysical and pharmacological properties of BK channels were studied by using the patch clamp technique. In excised patches the open probability (P_o) was increased by depolarization and/or by increasing $[Ca^{2+}]_i$. The current/voltage relationship in symmetrical K^+ (150 mM) was linear between -60 and 60 mV and had a slope of 267 pS (95% C.L. 258-275 pS). Relative permeabilities, estimated from the reversal potential obtained either directly or by extrapolation in biionic conditions in which the test cation completely replaced internal K^+, gave a permeability sequence of K^+ (1) > Rb^+ (.87) > NH_4^+ (.17) > Cs^+ > Na^+ (<.02). Outward Rb^+ currents had a slope conductance of 30-40 pS suggesting a long mean dwell time for Rb in the pore. Outward currents were not seen with either Cs^+ or Na^+. External TEA^+ caused a weakly voltage-dependent open channel block. The K_D for the block at 0 mV was 260 μM and the slope of the Hill plot was 0.82 implying that the block was produced by the binding of a single molecule of TEA^+. Internal TEA^+ (80 mM) had no effect. External charybdotoxin (10-40 μM) caused a slow block of BK channels. Difficulty in obtaining a stationary P_o with outside-out patches precluded a systematic study of the binding kinetics of charybdotoxin.

CALCIUM-ACTIVATED POTASSIUM CHANNELS IN FERRET RETINAL GANGLION CELLS. G-Y Wang, D.W. Robinson, J.M. Horowitz* and L.M. Chalupa. Neurobiology, Physiology and Behavior and Center for Neuroscience, University of California, Davis, CA95616.

Patch-clamp techniques were used to study the calcium-activated potassium currents in retinal ganglion cells (RGCs) retrogradely labeled by prior injection of rhodamine latex beads. In the cell-attached configuration, with 140mM K^+ in the electrode and 5.9mM K^+ in the bathing solution, two types of calcium-activated potassium channel were identified. These channels had conductances of 118pS (BK) and 22pS (SK) and were sensitive to increases in intracellular calcium concentration resulting from the addition of Bay-K8644 to the bathing solution. In the inside-out configuration the open probability of both channels increased as intracellular patch calcium concentration was increased. In the current-clamp mode, bath application of charybdotoxin, a selective blocker of BK channels, significantly increased the firing frequency of RGCs which responded in sustained manner to maintained depolarization. In contrast, charybdotoxin had little or no effect on the discharge patterns of RGCs which responded to such current injections in a transient fashion. These results demonstrate that the BK channel of the calcium-activated potassium conductance regulates the firing frequency of sustained RGCs. Supported by NIH grant EY-03991 to LMC

ATP-SENSITIVE K^+ CHANNELS OF HUMAN SKELETAL MUSCLE FIBERS: AGE-DEPENDENT CHANGES OF CHANNEL PROPERTIES. D. Tricarico*, R. Petruzzi and D. Conte Camerino. Unit of Pharmacology, Dept. of Pharmacobiology, Univ of BARI, via Orabona n° 4, I-70125 BARI, ITALY.

ATP sensitive K^+ channels (K_{ATP}) are the most abundant K^+ channels in skeletal muscle were may differently respond to various metabolic insults. An abnormal functionality of K_{ATP} channels has been proposed to contribute to the pathogenesis of hypokalemic periodic paralysis (HOPP), in which the primary cause involve a mutation of DHP receptor. However, at present, the link between the channel mutation, that results in an increase of inactivation of Ca^{2+} channels (Sipos et al., *Biophysical J.* 68/2: A209, 1995), the muscle paralysis and the lowering of the serum K^+ concentration is still obscure. In the present work, a preliminary screening of human K_{ATP} channels of skeletal muscle fibers has been performed by patch clamp technique. The experiments were carried out on biopsies of human skeletal muscle removed, under general anaesthesia, from vastus lateralis of patients who required a orthopedic surgery. Single channel recording were performed in inside-out configuration at constant voltage (-60 mV), at 20 °C, in symmetrical KCl 150 mM or during voltage step going from -70 mV to + 70 mV (Vm). The biopsy from a 17 year old man, showed an high K_{ATP} channel activity (mean patch current, $I_{\cdot}$: 37 pA) due to a 64 pS channel. The channel density ($N/_{area}$) was 12 and the open probability (P_{open}) was 0.313. The IC_{50} for ATP was about 50 μM. The patient did not show abnormality in the level of the serum metabolites nor in the concentration of K^+ ion being 5.4 meq/L. In contrast, the biopsy from a 67 year old woman showed a lower K_{ATP} channel activity (I : 14,4 pA) due to a decrease of $N/_{3\,\mu m^2}$ that was 3.5, and P_{open} that was 0.0312. The single channel conductance did not change with aging being 61 pS. Moreover, the sensitivity of the channel for ATP was about 50 times higher. The patient did not show abnormality in the levels of the serum metabolites while the plasma concentration of K^+ ion was lower being 4.7 meq/L. Our data suggest that, as observed in aged rat skeletal muscle in which a decrease of $N/_{3\,\mu m^2}$ and P_{open} was found (D. Tricarico and D. Conte Camerino, *Mol. Pharmacol.* 46:754, 1994), the aging process alter also the K_{ATP} channels of human skeletal muscle. We also observed that the decrease of K_{ATP} channel activity found in aged human skeletal muscle is paralleled to a decrease of plasma K^+ level. The financial support of Telethon-Italy (Grant no. 579) is gratefully acknowledged.

DEPRESSION OF POTASSIUM CURRENT BY 5-HT7 RECEPTOR STIMULATION IN CULTURED RAT SUPRACHIASMATIC NEURONS. Y. Edagawa*, H. Saito and H. Katsuki. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Bunkyo-ku, Tokyo113, Japan

The suprachiasmatic nucleus (SCN) receives a serotonergic projection from the mesencephalic raphe nuclei and this input is thought to be important in circadian rhythms regulation. We performed the whole-cell recordings from the cultured postnatal rat SCN neurons to investigate the possible modulation of delayed rectifier potassium current (IK) by serotonin (5-HT). Sustained outward current induced by depolarization to 0mV by pulse stimulus for 500ms was identified as IK, since it was greatly inhibited by tetraethylammonium treatment. Administration of 5-HT depressed IK in a dose-dependent manner (10^{-7} to 10^{-5}M). 8-OH-DPAT (5-HT1A,7 agonist, 10^{-7} to 10^{-5}M) and 5-CT (5-HT1A,1B,7 agonist, 10^{-7} to 10^{-5}M) had similar effects of depression by 5-HT, but DOI (5-HT2 agonist, 10^{-5}M) had no significant effect. Ritanserin (5-HT2,7 antagonist,10^{-6}M) inhibited the suppressive effect by 8-OH-DPAT (10^{-6}M), whereas pindolol (5-HT1A,1B antagonist, 10^{-5}M) did not. The effect of 5-HT (10^{-6}M) was also inhibited by ritanserin (10^{-6}M), but not by pindolol (10^{-5}M) or MDL72222 (5-HT3,4 antagonist, 10^{-5}M). Forskolin, adenylyl cyclase stimulator, and 8-Br-cAMP, membrane-permeable cAMP analog, also reduced the IK.The effect of 5-HT and forskolin were not additive. Moreover, the inhibitory effect by 5-HT was attenuated by H-8, potent inhibitor of protein kinase A. These results indicate that the depression of IK is induced by the stimulation of 5-HT7 receptors, which is linked to intracellular cAMP-coupled mechanisms.

718.13

DIFFERENTIAL DEPLOYMENT OF FAST POTASSIUM CHANNELS ON CELL BODIES AND AXONS OF ADULT RAT DORSAL ROOT GANGLION NEURONS. B. Everill, D. Donnelly*[1] and J. D. Kocsis. Depts. of Neurology & Pediatrics[1], Yale Univ. Med. Sch., New Haven, CT. 06510, and Neuroscience Res. Ctr., VAMC, West Haven, CT. 06516.

Myelinated rat peripheral nerve fibers have a variety of kinetically fast and slow potassium channels (Roper, J. and Schwartz, J.R. 1989), but little is known about the K^+ channel organization of the cell bodies of these axons. Recently, several workers have indicated that Na^+ channel and GABA receptor organization of dorsal root ganglia (DRG) neurons change in response to axotomy. The present study was undertaken to characterize K^+ currents on the cell bodies of DRG neurons as a precursive examination of injury-induced plasticity of these currents. DRG neurons were dissociated from adult female Wistar rats and prepared for short-term (10-24 hrs.) examination. Whole cell patch clamp recordings were obtained from medium-sized neurons which give rise to myelinated peripheral axons. K^+ currents were isolated by blocking Na^+ and Ca^{2+} currents with appropriate ion replacement and channel blockers. The neurons were held at -80 mV and depolarized in 10 mV step (100 ms duration) increments to +20 mV. A prominent TEA-sensitive noninactivating delayed outward current was observed, and an outward leak conductance remained after application of 40 mM TEA inside and outside of the neurons. Little evidence for a fast 4-aminopyridine-sensitive K^+ current was observed using the voltage clamp protocol or those designed specifically to identify A-currents. Intra-axonal recordings from myelinated sensory axons in the root revealed a prominent 4-AP sensitive after-hyperpolarization suggesting the presence of fast K^+ currents on these axons. The presence of prominent transient 4-AP-sensitive currents on axons of these neurons and their absence or paucity on the cell body suggests that adult DRG neurons primarily deploy fast K^+ currents on their axons and not their cell bodies. Supported in part by the VA and the NIH.

CORTICOSTERONE EFFECTS LEAK BUT NOT Q CURRENT IN RAT HIPPOCAMPAL CA1 NEURONS. S.Purnyn, S. Beck.* Dept. of Pharmacology, Loyola University Medical School, Maywood, IL 60153.

Basal leak (I_{leak}) and Q currents (I_Q) were studied in CA1 neurons from rat hippocampal slices using patch-clamp technique in whole cell configuration. These currents were compared in cells from rats that were naive, sham operated (Sham), adrenalectomized (ADX) or ADX with corticosterone (CT) replacement by subcutaneous pellet implantation (ADX+CT).

I_Q was defined as a Cs^+ (EC_{50} = 0.33 mM) sensitive inward current induced by hyperpolarizing voltage steps from a holding potential of -65 mV. Delay in activation, but not in inactivation of this current was apparent. I_Q activation at -100 mV was best fit to second order kinetics. The time constant of I_Q activation was highly temperature dependent (Q_{10}=5) and it lost it's voltage dependence at 32°C. Cs^+ inside the cells was not able to block I_Q in concentrations sufficient to block the delayed rectifier. Substitution of intracellular K^+ with Na^+ did not change the amplitude of I_Q. No significant difference in the amplitude of I_Q was found between Sham, ADX and ADX+CT animals.

I_{leak} was isolated by subtracting I_Q from the current responses evoked by hyperpolarizing voltage steps used to study I_Q. In -65 to -110 mV voltage region I_{leak} V-I characteristic appeared to be linear with a reversal potential (Er) equal to the membrane resting potential of -63.2 mV and had a slope of 21.6 nS in cells from the Sham treated animals. I_{leak} showed temperature dependence with Q_{10} of 1.85 and no sensitivity to Cs^+ at 2mM concentration. Replacing intracellular K^+ with Cs^+ dramatically decreased I_{leak} conductivity. Replacing intracellular K^+ with Na^+ had no effect on conductivity but slowly shifted Er in a positive direction. I_{leak} conductivity was significantly lower in ADX+CT treated animals (14.8 nS). The reversal potential did not change. Decreasing I_{leak} might be responsible for increasing excitability of the cells by CT. Supported by USPHS NS28512 and KO2MH00880 to SGB.

AN INACTIVATING INWARD-RECTIFYING K CURRENT IN RAT LACTOTROPH CELLS IN PRIMARY CULTURE. J.R. Schwarz , B.J. Corrette, C.K. Bauer (SPON: European Neuroscience Association), Inst. Physiol., UKE, D-20246 Hamburg, Germany

Whole-cell patch-clamp experiments were performed in lactotroph cells from primary cultures of pituitaries from lactating rats. Cells were identified as lactotrophs by staining using a prolactin antibody (NIDDK, Baltimore, MD). Cells were kept in culture for up to 5 weeks. Throughout this period, an inward-rectifying K current (K_{IR}) was recorded in lactotrophs using isotonic KCl as external solution. This current differed from cell to cell with respect to current density and rate of inactivation. Inactivation starts at about -70mV and becomes faster and more complete with more negative potentials. This inactivation is independent of external Na^+. The fast-inactivating current type in lactotrophs strongly resembles the inward-rectifying K current of GH_3B_6 rat somato-mammotrophic tumor cells (Bauer et al., J. Physiol. 429:169, 1990). Changing the external K^+ concentration from 150 to 15 mM (K^+ exchanged by Na^+) produced a mean shift in the reversal potential of -55.2 mV, demonstrating a high selectivity of the recorded current for K^+ over Na^+. K_{IR} is effectively blocked by 5 mM Ba^{++}, but 0.5 mM Ba^{++} reduced the peak current by only 10-20%. 10 mM TEA partially (<50%) blocks K_{IR}.

A physiological role of K_{IR} in the control of prolactin secretion is suggested by the fact that the secretagogue TRH inhibited K_{IR} in about half of the lactotrophs tested. This inhibition might underlie membrane depolarization resulting in a TRH-induced enhanced Ca^{++} influx into the cell, as has been observed in a proportion of lactotrophs (Reid et al., in prep.).

Ca^{2+}-ACTIVATED POTASSIUM CHANNELS UNDERLYING AFTERHYPERPOLARIZATION IN NEOCORTICAL PYRAMIDAL NEURONS. Jian Kang*, John Huguenard and David A Prince, Department of Neurology and neurological sciences, Stanford University, Stanford, CA 95304

To investigate the ion channels underlying afterhyperpolarizations (AHPs) we utilized dual patch clamp recordings with two electrodes , a whole-cell current clamp and a cell-attached patch, on single rat neocortical neurons in visualized slices. The large conductance Ca^{2+}-activated K^+ channel (BK) has been hypothesized to contribute to repolarization and fast afterhyperpolarization in neurons because it opens after a single spike in GH_3 cells and dissociated hippocampal neurons (Lang & Ritchie, Pflüger Arch 1987; Yoshida, Jap. J. Physiol. 1991). We found that the BK channel was not triggered by depolarization induced spikes in pyramidal neurons in slices. Instead, an intermediate conductance Ca^{2+}-activated K^+ channel (IK) with a conductance of 64 pS was seen immediately following the AP transient and with mean post-spike channel activity lasting 9.0±0.9 ms. A small conductance Ca^{2+}-activated K^+ channel with a conductance of 29 pS (SK) was also observed immediately following the AP transient or IK openings, and the activity of SK lasted 94.5±6.3 ms. The same results were also obtained by synaptically evoked spikes and at different temperatures. Spike-related openings of IK and SK were markedly reduced by superfusion of 0.3 mM Cd^{2+}. In contrast, the BK channel only opened as neuronal responses deteriorated eg. smaller or absent spikes and in a spike-independent manner. The membrane potential became hyperpolarized (>-10 mV) during BK channel activity. Inside-out patches excised from slices or dissociated neocortical pyramidal neurons also contained three types of Ca^{2+}-activated K^+ channels. IK and SK are more sensitive to Ca^{2+} than BK. Similar to BK, IK was also voltage-dependent and blocked by 1 mM TEA or 100 nM Charybdotoxin (ChTX) in the pipette solution. SK was voltage-independent and insensitive to TEA, ChTX or apamin. We conclude that IK and SK respond to the transient intracellular Ca^{2+} elevation elicited by the action potential and contribute to the two components of AHPs. BK does not contribute to the AHP during short periods of stimulation.

TWO CLASSES OF BK CHANNELS IN RAT NEURO-EPITHELIAL CELLS. J.-M. Mienville* and J.L. Barker. Lab of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

In situ patch-clamp recordings from E12-14 rat telencephalon reveal two classes of large-conductance Ca-activated K (BK) channels: the first one represents only a very small percent (~1%) of occurrences and displays properties of classical BK channels, i.e., normal gating mode, sensitivity to charybdotoxin (CTX), absolute requirement of Ca for activation, and voltage dependence of 10-15 mV per e-fold increase in Po. In the second class, channels exhibit a *buzz* gating mode and, as described previously (J. Physiol. **481**: 293-298), switch to normal mode upon exposure to intracellular trypsin. These channels appear to be insensitive to CTX, are capable of activation in the absence of cytoplasmic Ca, and display voltage dependences >40 mV per e-fold increase in Po. An interesting feature is that their Po can be "titrated" with intracellular trypsin, longer enzyme applications yielding lower Po's. Following treatment, these channels are stimulated by increases in cytoplasmic Ca. Because of its overwhelming presence in embryonic tissue, this channel subclass may encompass immature forms of BK channels.

THE HYPERPOLARIZED SHIFT OF I_A INACTIVATION IN HYPERTENSIVE RATS IS NOT SECONDARY TO ELEVATED BLOOD PRESSURE. Walter P. Robertson and Geoffrey G. Schofield*. Department of Physiology, Tulane University School of Medicine, New Orleans, LA 70112.

Increased sympathetic nerve activity has been implicated in the development and maintenance of hypertension. Consistent with this hypothesis, I_A in superior cervical ganglion neurons from adult spontaneously hypertensive rats (SHR) inactivates at more hyperpolarized potentials than in normotensive WKY rats. In neurons from young, pre-hypertensive SHR rats the mean I_A half inactivation potential (V_h) was not different than that recorded from neurons of young WKY (-76.4 ± 2.4 and -78.5 ± 2.1, respectively). These data suggest that alterations in I_A gating are not causative of hypertension in the SHR. However, new preliminary data shows that the V_h for I_A inactivation does shift in adult SHR rats prevented from developing hypertension by prolonged treatment with the anti-hypertensive drug enalapril. Thus the hyperpolarizing shift of I_A inactivation is not a secondary adaptation to the elevated blood pressure.

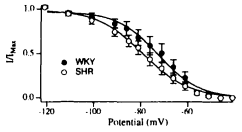

Figure. H infinity plots of peak A-current. I_A was recovered for 1.0 sec prior to a step to -30 mV. Rats received 25 mg/L enalapril in drinking water from 3-4 weeks of age until use. Mean V_h for SHR neurons was -79 ±3 mV and -72 ± 4 mV for WKY neurons. Solid lines are a least-squares fit of the data to a Boltzmann function.

POTASSIUM CONDUCTANCES PLAY IMPORTANT ROLES IN PRODUCING MAGNETIC FIELDS IN THE GUINEA PIG HIPPOCAMPAL LONGITUDINAL CA3 SLICE. J. Wu* and Y. C. Okada. Depts. Neurol. & Physiol., Univ. New Mexico Sch. Med., Albuquerque, NM 87131

We analyzed the influence of K^+-conductances on size and shape of the magnetic evoked fields (MEFs) in the guinea pig longitudinal CA3 slice. Evoked potentials (EPs) were recorded simultaneously with the MEFs to compare their similarities in timing and temporal waveforms. Intracellular recordings were carried out to gain further insight into the cellular currents generating the MEFs. The stratum lucidum of rectangular CA3 slice was stimulated by single pulses (1.0 mA, 50 μs, 0.1 - 0.5 Hz) with six pairs of bipolar electrodes in Ringer solution (concentrations in mM: NaCl 124, KCl 5, $NaHCO_3$ 26, NaH_2PO_4 1.2, $MgCl_2$ 0.6, $CaCl_2$ 2.5, glucose 10, 36-37°C) containing 0.1 mM picrotoxin. The MEF consisted of an initial component with 5 ms peak latency followed by a biphasic slower component lasting 100 ms. 0.1 mM 4-aminopyridine (4-AP), which selectively blocks $g_{K(A)}$, reversibly enhanced the slower component of both the MEF and EP. 1 mM tetraethylammonium (TEA), which blocks $g_{K(C)}$, reduced the initial MEF component, but increased the amplitude of the slower component of both the MEF and EP. Blocking of $g_{K(AHP)}$ with 1 μM cabachol was demonstrated in our preparation with intracellular recording. The same concentration prolonged the latency of the slower biphasic MEF component with some increase in amplitude. The latency of EP response was also prolonged and its amplitude was clearly enhanced. These results indicate that: (1) the blockade of $g_{K(A)}$ increases the duration of depolarization after the opening of g_{Na}, thereby increasing the probability of opening g_{Ca} and consequently increasing the MEF amplitude; (2) the blocking of $g_{K(C)}$ may lead to an increase in the duration of the Ca^{2+}-activated action currents, enhancing the magnitude of the slower MEF component; (3) the blockade of the long-lasting afterhyperpolarization may prolong the voltage-dependent Ca^{2+} channel open time, thereby broadening the slower component of MEFs. We conclude that active conductances are important in interpreting MEFs.

HODGIN-HUXLEY REDUX: EXCITABILITY OF THE SQUID GIANT AXON REVISITED. J.R. Clay*. NINDS, NIH, Bethesda, MD 20892 and MBL, Woods Hole, MA 02543.

The Hodgkin and Huxley model (J. Physiol. 117:500, 1952) is generally believed to provide a good description of the excitability properties of the squid giant axon. This view is incorrect. Specifically, the model predicts a steady train of action potentials (AP's) in response to a sustained current pulse of sufficient amplitude, whereas the axon itself generates only a single AP for these conditions regardless of pulse amplitude or duration. The underlying mechanism for this result concerns, primarily, I_K, which requires significant revision in the model. Specifically, the I_K current-voltage relation is a non-linear function of $(V-E_K)$, which is well described by the GHK equation (Clay, J. Physiol. 444:499, 1991). This result, in turn, gives a much steeper activation curve for I_K than in the HH model, in particular a steep rising phase at -45 mV. Consequently, I_K acts, effectively, as an impedance shunt during a sustained current pulse as the membrane potential is depolarized from the foot of the initial spike. I_{Na} is thereby shortcircuited, and the membrane quiescently rests in the -55 to -45 mV range, depending upon pulse amplitude. The squid giant axon is, therefore, a good model system for rapid accommodation, rather than bursting, or tonic firing behavior.

POTASSIUM CHANNEL PHYSIOLOGY, PHARMACOLOGY AND MODULATION III

719.1

ARE K^+ CHANNEL β-SUBUNITS NAD(P)H-DEPENDENT OXIDOREDUCTASE PROTEINS ? T. McCormack[1], K. McCormack[2]*, H. Moreno[1,3], and B. Rudy[1]. 1) Dept of Physiology and Neurosciences and Dept. of Biochemistry, New York University Medical Center, NY NY 10016 2) Dept. Genetics, University of Wisconsin, Madison , WI. 3) Dept Fisiologia Universidad Nacional de Colombia-CIF.

We have observed that Shaker K channel β-subunits (β1, β2 and β3) show homology to members of an NAD(P)H -dependent oxidoreductase superfamily. We have also identified EST sequences from rice and Arabidopsis to which β-subunits show 40-55% identity over the 96 amino acids encoded by these partial cDNA's. We are interested in determining whether K^+ channel β-subunits are functional enzymes and whether pyridine-nucleotide cofactors play a role in modulating K^+ channels through β-subunits. In order to pursue these studies we have cloned human homologs of the rat β-subunits. The β1 gene is complex and generates alternatively spliced products with different amino termini and tissue-specific expression. The β1 product is expressed mainly in brain, while β3 is most abundant in heart. Additional studies will focus on the physiological roles of β-subunits and on the interactions of specific α- and β- subunits.

THE MODULATION OF HUMAN (*hslo*) CA^{2+}-ACTIVATED K^+ CHANNELS BY PROTEIN KINASES AND ATP ANALOGS. T.J. DiChiara* & P.H. Reinhart, Dept. of Neurobiology, Duke University Medical Center, Durham, NC 27710 USA.

We have investigated the modulation of human Ca^{2+}-activated K^+ channels (the hbr5 splice variant of hslo) in a stably transfected HEK293 (human embryonic kidney) cell line. Using inside-out patch clamp analysis we have shown that these channels can be up-modulated to a similar extent by either protein kinase A (PKA) or protein kinase C (PKC). Both of these kinases increase the steady-state Ca^{2+}-dependence of these channels, and also have profound effects on the channel activation kinetics (n=4). When added in the absence of protein kinases, ATP does not up-modulate hslo channels, however, it slows channel 'run-down' measured as a right-shift in macroscopic g/g_{max} curves (28 of 31 experiments). As soon as ATP is washed out, 'run-down' continues. ATPγS has a similar, although less robust, effect which is resistant to wash-out (n=12). Three other non-hydrolyzable ATP analogs AMP-PNP (n=11), AMP-PCP (n=3), and AMP-CPP (n=3) have no effect on the rate of run-down nor on peak currents. These data indicate that human Ca^{2+}-activated K^+ channels can be targeted by numerous signal transduction cascades. Furthermore the data show that ATP itself also modulates hslo channels, and that this effect is distinct from modulation by PKA and PKC. The mechanism of ATP modulation appears to involve protein phosphorylation rather than a direct effect of nucleotide binding. Supported by NIH grant NS31253 to PHR.

719.3

REGULATION OF rKv 1.6 AND rKv 3.1 EXPRESSED IN *XENOPUS* OOCYTES BY PROTEIN KINASE C. A.C.S. Costa*, L.C. Starke and P.J. Pfaffinger, Baylor College of Medicine, Houston, TX 77030.

The regulatory actions of PKC on cloned rKv 1.6 and rKv 3.1 were studied here with both electrophysiological and biochemical approaches. By using conventional two electrodes voltage-clamp, we showed a 40-50% reduction in peak amplitude of currents recorded from oocytes expressing either rat K^+ channel clones after 15-20 minutes incubation in external solution containing phorbol-12-myristate, 13-acetate ester (50 nM). In contrast, rKv2.1 was not suppressed under these conditions. However, to avoid possible artifacts due to PKC stimulated membrane internalization, we switched to studying regulation in inside-out excised macropatchs. Patches were excised from oocytes expressing either rKv 1.6 or rKv 3.1 and then tested with internal solutions containing a partially purified preparation of PKC in an optimized low Ca^{2+} buffer. The kinase activity in this solution was 25% of the Ca^{2+} stimulatable activity. Where patches could be held long enough, the current could be reversed upon kinase removal. The reversible nature of the regulation, and recording in excised, low Ca^{2+} solutions, demonstrates that the effect is not due to internalization. To begin to characterize the PKC sites on the channels, we have performed *in vitro* phosphorylation assays of a purified N-terminus fragment of rKv1.6. This protein only shows a slight ability to be phosphorylated, around 1% phosphorylated. We are further refining this biochemical strategy, along with mutagenesis, to better characterize the mechanism of regulation by PKC.

PHOSPHATASE 2B (CALCINEURIN) PROMOTES LOW OPEN PROBABILITY BEHAVIOUR IN LARGE CONDUCTANCE CALCIUM-ACTIVATED POTASSIUM CHANNELS IN CULTURED HIPPOCAMPAL NEURONS. G.A.Hicks, B.A.Perrino, and N.V. Marrion*. Vollum Institute, O.H.S.U., Portland, Oregon 97201.

Phosphorylation and dephosphorylation can modulate the activity of large conductance calcium-activated potassium (BK) channels. We are investigating the potential role of the calcium/calmodulin dependent phosphatase, calcineurin, in modulation of BK channels in rat hippocampal neurons. BK channel activity was recorded from 'inside-out' patches in isotonic potassium with Ca^{2+} buffered with EGTA. Channel open probability (Po) was dependent upon membrane potential and the [Ca^{2+}] in the bathing solution. For example, in 3 patches held at +20mV, the mean Po was 0.25 in the presence of 1μM Ca^{2+} and 0.92 in 10μM Ca^{2+}. Channel activity was, however, observed to vary significantly between patches under the same conditions of membrane potential and [Ca^{2+}]. With a [Ca^{2+}] of 1μM, channel Po ranged from 0.02 to 0.66 at a membrane potential of +20mV. This variability suggests that channel activity may be under the control of factors other than voltage and [Ca^{2+}].

A calcium-calmodulin independent form of calcineurin (92 or 120nM) was applied to patches in the presence of either 1 or 10μM [Ca^{2+}] in which Po was >0.3. In 6 out of 8 patches a reduction in Po was observed. The reduction was either sustained (n=4) for the duration of the calcineurin application, or transient (n=2), channel activity returning to control levels before application was ceased. The vehicle alone had no effect (n=4). The sustained response consisted of a 50-100% reduction in Po and was fully reversed in 3 of the 4 patches when calcineurin application was ceased. The transient response consisted of one or more transient reductions (30-90%) in Po over the first minute of calcineurin application followed by a return to control levels. Preliminary evidence suggests that the reduction in Po is due to an increase in closed duration with no change in mean open time. Both the reversal of the sustained response and the transient nature of other responses suggests that an active kinase and ATP may be present in the excised patch. Inhibitors of protein kinases will be used to investigate this possibility. (This work was supported by The Wellcome Trust.)

PHOSPHORYLATION OF CB-1 BY PROTEIN KINASE C. K. Mackie*, D.E. Garcia, A. Perdichizzi, P. Hill+, and B.J. Murphy, Departments of Anesthesiology, Physiology and Biophysics, and Pharmacology, Univ. of Wash., Seattle, WA 98195-6540. +Panlabs, Bothell, Wa 98011-8805.

Neurotransmitters that stimulate protein kinase C (PKC) in neurons disrupt activation of inwardly-rectifying potassium currents (K_{ir} current). In AtT-20 cells transfected with rat brain cannabinoid receptor (CB-1), stimulation of PKC by pretreatment with 100 nM PMA blunted the activation of K_{ir} current: In cells treated with the inactive phorbol ester, 100 nM 4α-phorbol, the cannabimimetic, 100 nM WIN 55,212-2, increased K_{ir} current (5.2± 0.9 pA/pF, n=23) while in cells treated with the active analog, 100 nM PMA, WIN 55,212-2 stimulation was blunted (2.2±0.5 pA/pF, n=16). This may be a consequence of CB-1 phosphorylation by PKC. To address this issue we studied phosphorylation of CB-1-glutathione-S-transferase (GST) fusion proteins corresponding to the intracellular domains of CB-1. GST was not a substrate for PKC. The fusion protein corresponding to the third intracellular loop was heavily labeled by PKC. The first and second loops were phosphorylated to a lesser extent and the carboxy terminus was poorly phosphorylated. Phosphoserine was the only phosphoamino acid detected. Hence, PKC stimulation blunts cannabinoid activation of K_{ir} current, and CB-1 intracellular domains potentially involved in G protein coupling are PKC substrates.

TYROSINE PHOSPHORYLATION DOWN-REGULATES A CLONED VOLTAGE-GATED K^+ CHANNEL. D.A. Fadool*, K.S. Berman, T.C. Holmes, and I.B. Levitan. Dept. of Biochem. and Center for Complex Systems, Brandeis University, Waltham, MA 02254.

We are studying the regulation of ion channels by protein tyrosine kinases (TKs) using a cloned voltage-dependent potassium channel, Kv1.3, as a model. Kv1.3 channels are studied by transient expression of their cDNAs in human embryonic kidney (HEK 293) cells using lipofectamine transfection. We have demonstrated previously that Kv1.3 tyrosine phosphorylation increases following co-expression with the constitutively active cellular TK, v-src. The functional correlate of such tyrosine phosphorylation was examined by patch-clamping HEK 293 cells in the cell-attached configuration. Kv1.3 transfected cells exhibit a characteristic slowly inactivating macroscopic current in response to a depolarization from -80 to +40 mV; this current is absent in cells co-transfected with Kv1.3 and v-src. However, the Kv1.3 current is observed when co-transfected cells are treated for 7 min to 24 h with either of three different TK inhibitors: 50 μM genestein, 50 μM ST638, or 1.7 μM herbimycin A. Diadzein (59 μM), the inactive structural analog of genestein, does not produce this effect. We have constructed single point mutants (Y to F) of Kv1.3 at putative tyrosine phosphorylation consensus sequences. Mutation of residue 449 near the C-terminus (Y449F) generates a mutant channel that has similar kinetic properties to the wild-type Kv1.3. However, the Y449F mutant channel is not down-regulated by co-transfection with v-src. This suggests that tyrosine phosphorylation down-regulates the Kv1.3 channel, and that residue Y449 is a specific target for TKs.

719.7

EXPRESSION OF THE VOLTAGE-DEPENDENT POTASSIUM CHANNEL Kv1.3 DECREASES CELLULAR TYROSINE PHOSPHORYLATION. T.C. Holmes*, K.S. Berman, M.R. Bowlby and I.B. Levitan. Dept. of Biochemistry and Center for Complex Systems, Brandeis University, Waltham, MA 02254.

Tyrosine phosphorylation modulates the properties of the Kv1.3 K^+ channel. To determine whether Kv1.3 activity in turn alters tyrosine phosphorylation, human embryonic kidney (HEK 293) cells were transfected by lipofection with cDNAs coding for control-vector, Kv1.3 and/or the constitutively active v-src tyrosine kinase. The expression of these proteins was verified in cell lysates by western blot analysis using specific antibodies. Protein tyrosine phosphorylation (PYP) in cell lysates was detected by western blot analysis using phosphotyrosine specific monoclonal antibodies. Treatment with the membrane permeant tyrosine phosphatase inhibitor pervanadate (250 μM, 5-60 min) results in robust increases in PYP in control-vector transfected cells. Kv1.3 transfected cells exhibit 40-50% lower PYP following pervanadate treatment as compared to control cells, without any change in the protein levels of cellular kinases. Thus, Kv1.3 expression inhibits the activity of endogenous tyrosine kinases. Similar Kv1.3 induced decreases in PYP are observed in cells co-transfected to express the channel together with v-src. Transfection with a non-conducting mutant (W386F) Kv1.3 channel does not cause a decrease in PYP. Thus potassium channel activity can modulate tyrosine kinase signal transduction pathways.

719.8

THE EGF RECEPTOR TYROSINE KINASE INHIBITS THE VOLTAGE-DEPENDENT POTASSIUM CHANNEL Kv1.3. M.R. Bowlby*, T.C. Holmes and I.B. Levitan. Dept. of Biochem. and Center for Complex Systems, Brandeis University, Waltham, MA 02254.

The epidermal growth factor receptor (EGFr) tyrosine kinase is known to directly tyrosine phosphorylate a variety of targets within cells, as well as couple to several downstream serine/threonine kinase signaling pathways. We have been examining modulation of the voltage-dependent potassium channel, Kv1.3, by the EGFr. cDNA's for the human EGFr and Kv1.3 were expressed in HEK 293 cells using lipofectamine reagent. Expression and tyrosine phosphorylation levels of Kv1.3 and other EGFr substrates were detected using biochemical techniques, while Kv1.3 activity was measured by patch clamp recording. Co-expression of the EGFr and Kv1.3 results in a large increase in the tyrosine phosphorylation of Kv1.3, without affecting its expression. Physiologically, co-expression of the EGFr and Kv1.3 produces a decrease in peak current levels as compared with co-expression of Kv1.3 and vector control. Treatment of EGFr and Kv1.3 co-transfected cells, with an inhibitory EGFr ligand binding domain antibody, blocks the EGFr-induced downregulation of Kv1.3. In addition, acute EGF treatment of co-transfected cells produces a decrease in peak current and some speeding of inactivation kinetics. The physiological modulation may be due to direct tyrosine phosphorylation of the channel, or may occur via downstream signaling events.

719.9

THE *DROSOPHILA SLOWPOKE* (*dSlo*) CALCIUM-DEPENDENT POTASSIUM CHANNEL IS A SUBSTRATE FOR PROTEIN KINASES. J. Wang* and I. B. Levitan. Dept. of Biochem. and Center for Complex Systems, Brandeis University, Waltham, MA 02254.

The activity of the cloned calcium-dependent potassium channel *dSlo* can be modulated by protein phosphorylation (Esguerra *et al*, 1994). To determine whether *dSlo* is a substrate for protein kinases, partial *dSlo* sequences were expressed in *E. coli* as glutathione-S-transferase fusion proteins. Purified fusion proteins were examined for their ability to be phosphorylated *in vitro* by protein kinases. One fusion protein containing *dSlo* residues 821-993 is readily phosphorylated by both protein kinase A catalytic subunit (PKA) and protein kinase C (PKC). In contrast, a corresponding mutant fusion protein in which the serine residue at position 942 (S942), within a consensus PKA site, is replaced by alanine (S942A), cannot be phosphorylated by either kinase under the same assay conditions. These results indicate that S942 can be phosphorylated by both kinases *in vitro*. Another fusion protein containing the last 828 residues (337-1164) of *dSlo*, a proposed cytoplasmic domain of the channel protein, can also be phosphorylated by both kinases. An S942A mutation abolishes the phosphorylation by PKA, suggesting that S942 is the only target for PKA in this long stretch of protein sequence. However, the same mutant protein can still be phosphorylated by PKC, indicating the presence of other serine or threonine residues accesible to PKC.

719.10

REGULATION OF POTASSIUM CHANNEL EXPRESSION IN DEVELOPING GnRH NEURONS BY FIBROBLAST CONTACT. Martha M. Bosma*. Dept. Pharmacology, Univ. Washington, Seattle WA 98195.

GnRH neurons in the adult animal are situated in the hypothalamus, but are embryonically derived from the peripheral olfactory placode, making them a unique system in which to study CNS neurons during migration and development. GnRH neurons were enzymatically dissociated from olfactory placodes isolated from E11.5 mouse embryos, currents recorded using whole cell patch clamp, and cells identified by immunocytochemistry. Isolated GnRH cells were compared with those in contact with fibroblasts. Isolated GnRH cells increased in size (measured by cell capacitance) with time in culture from 2.8±0.2 pF (n=18) on day 1 to 11.8±2.7 pF (n=4) on day 5. From days 1-5 peak outward current increased, but current density remained low due to the increase in cell size (day 1, 10.6±1.8 pA/pF; day 5, 6.3±1.8 pA/pF). 50% of these isolated cells expressed a small transient inward current. In contacted cells, outward currents were larger on day 2 (15.8±2.7 pA/pF, capacitance 6.6±1.3 pF, n=5), and increased on days 3-5 (day 5, 35.5±9.1 pA/pF, capacitance 6.5±0.6, n=4). In addition, these cells expressed a large transient inward current. Immunocytochemistry with an antibody specific to the Shaker subfamily potassium channel mKv1.1 demonstrated expression of this protein in the isolated GnRH neurons. Supported by the Andrew W. Mellon Foundation.

EFFECT OF DOCOSAHEXAENOIC ACID ON $mK_V1.1$ AND $mK_V1.2$ K^+ CHANNELS. Jennifer C. Garratt, Matthew P. M^c Evoy and David G. Owen* Molecular Pharmacology, Wyeth Research, Taplow, Berkshire, SL6 0PH, UK.

Docosahexaenoic acid (DOHA) is a long chain polyunsaturated fatty acid which is abundant in fish oil. External administration of DOHA caused a time dependent block of the cardiac channel, $K_V1.5$ (Honoré *et al*, 1994). Using whole-cell patch clamp, the potassium channel-blocking effects of DOHA were examined on two cloned mouse brain potassium channels, $mK_V1.1$ and $mK_V1.2$ stably expressed in Chinese hamster ovary cells. Transfected cells expressed a non-inactivating, "delayed rectifier"-type potassium channel; $mK_V1.2$ has a slower activation rate. For purposes of quantifying dose-dependent block of these currents overall charge transferred during the voltage step (Q_{step}) was measured. External administration of DOHA produced a dose-dependent, reversible block of $mK_V1.1$ (EC_{50}=7.7μM) and $mK_V1.2$ (EC_{50}=2.1μM). Blockade of these channels is time-dependent *eg* at +70 mV for $mK_V1.1$ DOHA (15μM) the time constant of deactivation (τ_D) was 52.5±4.5ms and for $mK_V1.2$ DOHA (10μM) was 11.6± 0.34ms. The time constants of the DOHA induced decay of $mK_V1.1$ and $mK_V1.2$ decreased in a concentration-dependent fashion. Interestingly DOHA was found to increase the rate of activation of $mK_V1.2$ (0.86±0.02ms compared with control value 1.78±0.14ms). Internal administration of DOHA (300μM) did not alter either $mK_V1.1$ or $mK_V1.2$ current. These findings suggest that DOHA blocks both $mK_V1.1$ and $mK_V1.2$ channels at a site which is only accessible via the external mouth of the channel and only once the channel is open.

719.12

THE EFFECTS OF THREE DENDROTOXINS AND 4-AMINOPYRIDINE ON AN ENDOGENOUS OUTWARD CURRENT AND A HETEROLOGOUSLY-EXPRESSED POTASSIUM CHANNEL(rKv1.1) IN HEK-293 CELLS. F. Heblich, M. Minchin* and D. G. Owen. Electrophysiology Laboratory, Molecular Pharmacology Department, Wyeth Research (UK), Huntercombe Lane South, Taplow, Berks, SL6 0PH.

Using the whole cell patch clamp technique we have examined the electrophysiological characteristics of the cloned potassium channel, rKv1.1 (RCK1), stably-expressed in HEK-293 cells. The steady-state conductance-voltage relationship for rKv1.1-expressing cells was best fitted with a two component Boltzmann function, consistent with the presence of an endogenous current in the HEK-293 cells. Examination of untransfected cells revealed in many cases, an endogenous outward current, activated by depolarization with amplitudes of up to ca. 600pA (measured at +45mV; V_H = -90mV). The conductance-voltage relationship of the endogenous current was fitted by a single component Boltzmann function, with a slope equivalent to that of the second component of the conductance curve obtained in transfected cells. 4-aminopyridine (4-AP) and three dendrotoxin (Dtx) homologues, toxin K, α- and δ-Dtx blocked rKv1.1 currents in a dose-dependent manner. IC_{50}s were 195μM, 241pM, 23nM and 130pM, respectively, compared to IC_{50}s of 2.5nM for toxin K (Robertson *et al*, 1994. *J. Physiol.*, **481**(P), 41P) and 5nM for α- and 1nM for δ-Dtx (Wittka & Pongs personal communication) *vs* rKv1.1 when expressed in oocytes. Whereas, high concentrations of 4-AP and toxin K blocked all voltage-activated current α and δ-Dtx blocked ca. 80% max. All of the blockers caused a two-fold slowing of the activation time constant (τ_n) of rKv1.1 (e.g. 10nM δ-Dtx lengthened τ_n from 0.95±0.15ms to 2.5±0.35ms at +45mV ,n=4). It could therefore be suggested that toxin K, α-Dtx, δ-Dtx and 4-AP hinder the allosteric changes which occur as the channel opens. Thanks to Prof. O. Pongs for the rKv1.1 cell-line and Dr. B. Robertson for helpful discussions.

719.13

STUDIES ON THE N-TYPE INACTIVATION OF THE MOUSE Kv1.1 CHANNEL INDUCED BY THE Kv3.4 BALL PEPTIDE. G. J. Stephens, D. G. Owen, A. Opalko, M. R. Pisano, W. H. McGregor & B. Robertson*. Wyeth Research (U.K), Taplow, Berkshire SL6 0PH, U.K. and Wyeth-Ayerst, Radnor, PA 19101, U.S.A.

A 28-mer peptide based on part of the N-terminal of the human Kv3.4 K^+ channel (NleISSVCVSSYRGRKSGNKPPSKTCLKEE) transforms the mouse brain cloned K^+ channel, mKv1.1, from a non inactivating to a rapidly inactivating current. Using the whole cell patch clamp technique to examine this 'ball and receptor' model system in Chinese hamster ovary cells, we have probed some of the residues important for N-type inactivation by introducing various mutations and deletions to the hKv3.4 peptide. The sensitivity of hKv3.4 peptide to redox modulation is critically dependent on the cysteine at position 6 (Stephens & Robertson; *J. Physiol.* 484, 1-13). Cysteine to serine substitutions destabilised the inactivated state of the mKv1.1/3.4 peptide channel, but did not abolish inactivation. Control time constant of recovery from inactivation ($\tau_{rec.}$) at -90 mV was 1.3 ± 0.1 s (n=9); this was faster in the mutants C6S (0.2 ± 0.04 s; n=3), C24S (0.6 ± 0.1 s; n=4) and C6S, C24S (0.3 ± 0.02 s; n=7). The apparent K_d (control = 8 ± 2 μM; n=7) was most drastically reduced by the double mutant C6S, C24S (44 ± 9 μM; n=5) and C24S (22 ± 8 μM; n=6), but not by C6S (12 ± 5 μM; n=4). Deletion of the five residues preceding C6 (Δ1–5) reduced the apparent affinity of the peptide (K_d = 33 ± 12 μM; n=7); this deletion most noticeably affected association rate (K_{on}), with the control value of 0.31 ± 0.05 $x10^6M^{-1}s^{-1}$ (n=7) being reduced to 0.05 ± 0.01 $x10^6M^{-1}s^{-1}$ (n=4) for Δ1–5. In contrast, deletion of the four residues after C24 (Δ25–28) caused an increase in K_{on} to 0.78 ± 0.16 $x10^6M^{-1}s^{-1}$ (n=8); Δ25–28 had a K_d of 6 ± 2 μM (n=8). The results indicate that neither cysteine residue is essential for N-type inactivation, but that their presence does stabilise the inactivated state and that residues closest to the N-terminal may be important for occupation of the ball receptor. It is hoped that such studies will reveal more about the processes of inactivation, and possibly its potential for modulation.

ACCESS OF SUBSTANCES TO POTASSIUM CHANNELS IN XENOPUS OOCYTES: INFLUENCE OF FOLLICULAR TISSUES. M. Madeja*, U. Mußhoff and E.-J. Speckmann. Institut für Physiologie, Robert-Koch-Str. 27a, D-48149 Münster, Germany

Oocytes of Xenopus laevis are a widespread model system to express and characterise neuronal ion channels and receptors. Concerning the investigations of these molecules, however, it is unclear, if the oocytes' follicular tissues reduce the access of substances to the molecules expressed. In order to shed some light on this, the effects of various blocking agents on currents of voltage-operated Kv1.1 potassium channels were studied in oocytes with and without follicular tissues.

The experiments revealed the following: (i) Each tested blocking agent was more effective when applied to oocytes without follicular tissues. This was found true for ions (lead, barium), smaller molecules (TEA, 4-AP, diltiazem, nifedipine, verapamil, pentylenetetrazol) and large molecules (DTX, MCDP; n = 9 to 21 each). (ii) The concentration-response curves were shifted to the left in oocytes without follicular tissues. The IC_{50} values in oocytes with and without tissues were 4.1 and 1.0 mmol/l for TEA and 30.0 and 1.2 μmol/l for lead, respectively. (iii) The times needed to reach the half-maximal blocking effect (t_{50}) were reduced in oocytes without follicular tissues. The t_{50} values in oocytes with and without tissues were 0.33 and 0.07 s for TEA, 8.8 and 2.4 s for DTX and 4.2 and 0.2 s for lead, respectively.

On a whole, the follicular tissues appear to reduce the sensitivity of the potassium channels to blocking agents. This 'barrier effect' has to be considered in pharmacological work on oocytes.

BK_{CA}-CHANNEL PHARMACOLOGY: A COMPARISON BETWEEN CLONAL AND RECOMBINANT CELL LINES

R. Wittka* and T. Glaser. Institute for Neurobiology, Troponwerke GmbH & Co.KG, Berlinerstr. 156, D-51063 Koeln, F.R.G.

Ca^{2+}-regulated potassium (K)-channels of large conductance (BK_{Ca}-channels) are widely distributed in peripheral tissues as well as in the central nervous system (CNS) and are also expressed in a variety of neural cell lines including PC-12, NG108-15, C6-BU1 and GH3 cells. The BK_{Ca}-channels from drosophila (dslo), mouse (mslo, 1) and human brain (2) have recently been cloned and stably expressed in CHO cells. The aim of the present study was to compare the pharmacological profiles of BK_{Ca}-channels expressed in rat glioma C6-BU1 and pituitary GH3 cells with those in recombinant CHO cells transfected with dslo (PTS2, from O. Pongs) or mslo (from L. Salkoff) by means of rubidium (Rb) efflux. For a number of BK_{Ca}-channel blockers including charybdotoxin, iberiotoxin, tetrandrine, quinine and the dihydropyridines nitrendipine, nicardipine and nimodipine good and signifincant correlations of IC_{50}-values from inhibition of ionomycin-stimulated Rb-efflux from C6-BU1, PTS2 and mslo cells were obtained. However, the potencies of the compounds were generally somewhat lower in the recombinant cells, especially the toxins were up to 30-fold less active. The indole alkaloid paspalicine, reported to block BK_{Ca}-channels (3) did not inhibit the Rb-efflux from either cells. Moreover, in patch clamp recordings from GH3-cells using either outside-out or inside-out patches this compound did not significantly block single BK_{Ca}-channels. The present data reveal very similar, if not identical, pharmacological profiles of BK_{Ca}-channels of C6-BU1, GH3 and recombinant cells.

POTASSIUM CHANNEL PHYSIOLOGY, PHARMACOLOGY AND MODULATION IV

720.1

CHARACTERIZATION OF [^{125}I]-α-DENDROTOXIN BINDING TO A STABLE CELL LINE EXPRESSING THE RAT VOLTAGE-DEPENDENT POTASSIUM CHANNEL Kv1.2

D.M. Pearsall*, S.P. Nawoschik, K.J. Rhodes and L.E. Schechter. Wyeth-Ayerst Research, CNS Disorders, Pearl River, NY 10965.

Alpha-Dendrotoxin (α-DTX) is a potent blocker of potassium (K+) currents associated with Kv1.1, Kv1.2 and Kv1.6 voltage-gated K+ channels. The rank order of potency determined by electrophysiological technique in clonal cell lines or oocytes for α-DTX is : Kv1.2 > Kv1.1 > Kv1.6. Furthermore, biochemical studies have revealed that Kv1.2 is the major component of the DTX-sensitive receptors in brain. The present study characterized the radioligand binding profile of [^{125}I]-α-DTX to the rat Kv1.2 subunit stably expressed as a homomeric channel. The cDNA for Kv1.2 (RAK) was subcloned into a mammalian expression vector (pREP9) containing a neomycin resistance gene. Subsequently, the plasmid was transfected using lipofectamine into LMTK$^-$ cells which were grown in the presence of neomycin to select for cells expressing the Kv1.2 subunit. Individual clones were initially screened for expression of Kv1.2 by immunocytochemistry using an affinity-purified polyclonal antibody to the rat Kv1.2 subunit and later confirmed by [^{125}I]-α-DTX radioligand binding. [^{125}I]-α-DTX binding to whole cells expressing the rat Kv1.2 channel was saturable and of high affinity with a calculated Kd and Bmax of 128 ± 17 pM and 33 ± 9.9 fmol/mg protein, respectively. The rank order of potencies for K+ channel blockers was Margatoxin (0.66 ± 0.12 pM) > Stichodactyla Toxin (30 ± 11 pM) > α-DTX (24 ± 8 pM) ≈ Charybdotoxin (CTX;23 ± 3 pM) > Mast Cell Degranulating Peptide (588 ± 86 pM). Interestingly, the Hill coefficient for CTX was significantly closer to unity in the Kv1.2 cell line as compared to previous results in rat brain. Although Kv1.2 plays an important role as a DTX-sensitive subunit in brain, the pharmacological profile of [^{125}I]-α-DTX binding differs significantly between brain and the clonal Kv1.2 cell line.

720.2

BEHAVIORAL EFFECTS OF THE POTASSIUM CHANNEL BLOCKER 4-AMINOPYRIDINE AND ITS STRUCTURAL ANALOGS

R. Brandsgaard*, J.E. Barrett, S. Thomas and S. Rosenzweig-Lipson. Wyeth-Ayerst Research, CNS-Biology, Pearl River, NY 10965.

Biochemical and electrophysiological studies have demonstrated that 4-aminopyridine (4-AP) and its structural analogs are blockers of voltage-dependent potassium (K) channels. However, few studies have evaluated the behavioral effects of this group of compounds and several studies have suggested that many of the analogs have limited CNS penetrability. In the present study, rats (N=6) were trained to discriminate 4-AP (1 mg/kg s.c) from saline in a two-lever drug discrimination procedure. 4-AP (0.3-1.7 mg/kg) produced dose dependent increases in responding on the drug appropriate lever with moderate rate decreasing effects at the highest dose. After the discrimination was established, substitution tests were conducted with the structurally related analogs 2-AP, 3-AP, 3,4-diaminopyridine (3,4-DAP), 2,6-DAP, and pyridine HCl. Like 4-AP, 3-AP (1-10 mg/kg) and 2,6-DAP (0.3-17.8 mg/kg) substituted fully in all animals tested. 2-AP (1-30 mg/kg) substituted fully in 4 of 5 rats and 3,4-DAP (3-17.8 mg/kg) substituted fully in 3 of 6 rats. Pyridine (3-100 mg/kg) only substituted fully in 1 of 5 rats. In general, doses of the aminopyridines that substituted for 4-AP had little effect on response rates. The rank order of potency and efficacy for substitution was 4-AP>3-AP>3,4-DAP≥2-AP>>pyridine. 4-AP and its analogs including 2,3-DAP and 4-dimethylaminopyridine (4-DMAP) were also evaluated for their convulsant effects in mice. With the exception of pyridine, all compounds produced dose-dependent increases in the percentage of mice exhibiting clonic convulsions. The rank order of potency for producing convulsions was 4-AP>2,3-DAP=3,4-DAP>3-AP≥4-DMAP>2-AP>2,6-DAP>>pyridine. The present results demonstrate that 4-AP and its analogs have similar behavioral effects in rodents that are likely due to their actions at CNS K-channels.

720.3

ANTIDEPRESSANT-LIKE EFFECTS OF POTASSIUM CHANNEL BLOCKERS

T.M.K. Trella*, S. Thomas, A. Thurman, J.E. Barrett and S. Rosenzweig-Lipson. Wyeth-Ayerst Research, CNS Biology, Pearl River, NY 10965.

The antidepressant-like effects of the potassium channel blockers 4-aminopyridine (4-AP) and quinine were compared with those of imipramine in three animal models (tail suspension test, forced swim test, DRL-72 sec schedule) that are sensitive to clinically effective antidepressants. For the tail suspension test, mice were suspended upside down by their tails and the duration of immobility was scored during a 6-min test session. For the forced swim test, rats were placed in a cylinder of water for a 15-min swim pretest. A subchronic dosing procedure was used, with injections occuring 30 min, 19 hours and 23 hours following the swim pretest. At the 24th hour, rats were placed in a cylinder of water and the duration of immobility was scored during a 5-min swim test session. For the DRL 72-sec schedule, rats were trained to lever press for a food pellet reinforcer. A response was reinforced only if it occurred 72-sec after the previous response or the start of the session. Both 4-AP and imipramine produced antidepressant-like effects in all three animal models. 4-AP, like imipramine, produced dose-dependent decreases in immobility time in the forced swim and tail suspension tests. In addition, both 4-AP and imipramine dose-dependently increased the number of reinforcers earned and produced modest decreases in response rate in rats responding under a DRL 72-sec schedule. Quinine produced antidepressant-like effects in two of three animal models. Quinine produced dose-dependent decreases in immobility time in the forced swim test, but did not affect immobility time in the tail suspension test. Quinine also produced dose-dependent increases in the number of reinforcers earned and produced modest decreases in response rate in rats responding under a DRL 72-sec schedule. The present results suggest that K-channel blockers may have therapeutic potential as antidepressant drugs.

720.4

5-HT_{2A} RECEPTOR INVOLVEMENT IN THE EFFECTS OF THE POTASSIUM CHANNEL BLOCKER 4-AMINOPYRIDINE.

A.L. Gorman*, S. Rosenzweig-Lipson and L.E. Schechter. Wyeth-Ayerst Research, CNS Disorders, Pearl River, NY 10965.

Previous studies have shown that the potassium (K^+) channel blocker 4-aminopyridine (4-AP) induces wet dog shakes, forelimb and head movements, and tremors in rats. Since these behaviors resemble those produced by 5-HT_{2A} agonists, the present studies were conducted to determine whether 4-AP-induced behavioral changes were mediated by 5-HT_{2A} receptors. In the first study, rats were pretreated with the 5-HT_{2A} receptor antagonist ketanserin (3 mg/kg ip) 30 min prior to administration of 4-AP (1 or 3 mg/kg sc) or saline (S). During the 30 min post-injection period, 4-AP increased the number of wet dog shakes (Mean±SEM: S=0, 1 mg/kg=19±6, 3 mg/kg=14±5) and the number of rapid repetitive forelimb movements (S=0, 1 mg/kg=19±8, 3 mg/kg=14±8). Ketanserin pretreatment attenuated both 4-AP-induced effects (Wet dog shakes:S=0, 1 mg/kg=4±3, 3 mg/kg=6±2; Repetitive forelimb movements:S=0, 1 mg/kg=2±1, 3 mg/kg=6±4), suggesting 5-HT_{2A} receptor modulation of these behavioral responses. To characterize further the pharmacological properties of 4-AP, rats were injected with either 4-AP (1 mg/kg sc) or saline once daily for 3 weeks, and sacrificed 24 hours after the last injection for tissue collection. In whole cortical membrane preparations, 5-HT_{2A} receptors were labeled with [^{3}H]ketanserin (0.15-5 nM), and non-specific binding was defined by 1 μM cinanserin. A significant decrease in Bmax was detected in the cortex of rats chronically treated with 4-AP (Mean±SEM (fmol/mg): saline=306±57; 4-AP=157±30), with no significant changes in K_d noted. Therefore, chronic 4-AP treatment resulted in a down-regulation of 5-HT_{2A} receptors, an effect associated with antidepressants (see Trella, this meeting). The results indicate that 4-AP-induced effects may be partially mediated by 5-HT_{2A} receptors. These data are consistent with the *in vitro* results of Schechter (this meeting) who found that 4-AP stimulates [^{3}H]5-HT release. Taken together, the results suggest that K+ channel blockade modulates serotonergic neurotransmission.

720.5

A Novel Neuroselective Agent Producing Glibenclamide-insensitive, K+-dependent Hyperpolarization. J.C. Chisholm*, J.N. Davis and E.J. Hunnicutt, Jr., Institute for Dementia Research, Bayer Corp., West Haven, CT 06516

Although the widespread presence and diversity of K+ channels make them a potential site of selectivity for pharmacologic intervention, there are far more classes of K^+ channel characterized than there are pharmacological agents known to interact with them. We reported a novel hyperpolarizing activity found in BAY x 9227, an enantiomer of a K^+_{ATP} channel activator, which differed from the latter in important ways: it is remarkably potent (EC_{50} 3 picomolar), with greater than 1000-fold selectivity for neurotypic over vascular smooth muscle cells, and is not blocked by the K^+_{ATP} channel blocker, glibenclamide [Eur. J. Pharm. 261:R1 (1994)]. We now report that one strain of N1E-115 neuroblastoma cells, which was unresponsive to K^+_{ATP} agents and showed no hyperpolarization in response to ATP depletion (produced by application of oligimycin and 2-deoxy-D-glucose), responded with hyperpolarization to 30 pM BAY x 9227. Hyperpolarizing activity is eliminated by removing the electrochemical driving force for K^+ out of the cell. Finally, functional correlates to the hyperpolarization produced by BAY x 9227 include inhibition of depolarization-induced elevations in neuronal $[Ca^{2+}]_i$, protection from glycine(Mg^{2+}-free)-induced neurotoxicity and inhibition of depolarization-induced insulin release from RINm5F cells, all produced by concentrations of BAY x 9227 less than 30 pM. In combination, these data implicate a site other than classic K^+_{ATP} channels for mediation of the potent effects of this compound, and suggest a novel site for therapeutic intervention.

720.6

A BASELINE CHANNEL IN *APLYSIA* NEURONS IS INHIBITED BY FMRFAMIDE AND HALOTHANE. Bruce D. Winegar*, John R. Forsayeth, and C. Spencer Yost. Department of Anesthesia, University of California, San Francisco, San Francisco, CA 94143-0648.

We have studied volatile anesthetic actions on single noninactivating ion channels in the nervous system of the marine mollusk, *Aplysia californica*. Outward single-channel currents were recorded from pleural ganglion neurons with artificial seawater in the recording pipette. Several distinct baseline channels were observed, including a voltage-insensitive, noninactivating channel with a linear slope conductance of ~40 pS that reversed at ~-40 mV. The channel was active in cell-attached and excised patches and was insensitive to external 10 mM TEA. Channel activity was completely inhibited in the presence of 3 μM FMRFamide (Phe-Met-Arg-Phe-NH_2). A reversible decrease in the channel mean open probability was produced by perfusion with 400 μM (0.008 atm) halothane, which shortened the open times but did not affect the current amplitudes. Our results demonstrate that a distinct baseline channel is inhibited by clinical concentrations of volatile anesthetics. Baseline channels contribute to the resting membrane potential and may be possible target sites that mediate volatile anesthetic actions.

720.7

ORGANIC AMINE BLOCKADE OF DOPAMINE-MODULATED K^+ CHANNELS ON RAT CAUDATE-PUTAMEN NEURONS. Yong-Jian Lin* and Jonathan E. Freedman. Dept. Pharmaceutical Sciences, Northeastern Univ., Boston, MA 02115.

Using cell-attached patch-clamp recording from freshly dissociated rat corpus striatum neurons, we are studying the blockade properties of an inwardly-rectifying 85 pS K^+ channel, which is activated by D_2-like dopamine receptors. Previous studies showed that this channel was sensitive to sulfonylurea drugs, and was blocked by nanomolar concentrations of quinine and related quinuclidine amines. Here, we found that both tetraethylammonium (TEA, 5 mM) and 4-aminopyridine (4-AP, 1 mM) partially blocked this channel when applied to the external surface of the membrane via the patch pipette. Block was relatively voltage-insensitive, and was accompanied by a reduction of open time and an increase of closed time. These cells also express other inwardly-rectifying K^+-permeable channels with conductances ≤35 pS, which are dopamine-insensitive. In contrast to the 85 pS channel, these channels were largely insensitive to block by 10 mM TEA or 5 mM 4-AP. Our results indicate that the dopamine-modulated K^+ channel is blocked by various organic amines with differing potencies, and that inwardly rectifying ion channels of the striatum are heterogeneous in their sensitivities to blockade by these compounds.

MECHANISMS OF DIHYDROPYRIDINE BLOCK OF SHAKER POTASSIUM CHANNELS. A. Kamath, K. Larson, E.F. Shibata*, and T. Hoshi, Dept. of Physiology and Biophysics, Univ. of Iowa, Iowa City, Iowa 52242.

Dihydropyridines (DHPs) are well known as Ca^{2+} channel agonists and antagonists. Recent evidence indicates that DHPs also affect voltage-dependent K^+ channels. Thus, we examined how DHPs affect *Shaker* K^+ channels expressed in Xenopus oocytes using the patch-clamp method.

Nifedipine, nicardipine, nimodipine, and Bay K 8644 at 10 to 100 μM induced a time-dependent reduction of the K^+ currents of mutant Shaker channels with disrupted N- and C-type inactivation (ShBΔ6-46 T449V). The time course of the current decline induced by the DHPs was approximated by one exponential. When applied intracellularly, the onset of the current reduction was rapid and the effect was reversible. Single channel analysis showed that the DHPs reduced the mean open time in a concentration-dependent manner without affecting unitary conductance.

Efficacy of the DHPs was dependent on residue 463 located in the S6 segment. This residue has been shown to influence C-type inactivation. The estimated DHP off rate was much slower with isoleucine at this position than with alanine. Since the DHPs induced an apparent inactivation, we investigated whether they compete with N- or C-type inactivation. The results suggest that the DHPs do not compete with either inactivation and that they may work to accelerate the intrinsic inactivation rates.

Structural groups on different DHPs crucial in reducing K^+ channel currents were also examined. The estimated off rate was greater for nifedipine and Bay K 8644 than for nicardipine, suggesting that the side group at C3 may be important in determining the DHP efficacy. (Supported by American Heart Association Iowa Affiliate, and Klingenstein Fellowship to T.H. and an Established Investigatorship award from the AHA to E.F.S.)

720.9

PROSTACYCLIN ANALOG CARBACYCLIN INHIBITS CA^{2+}-ACTIVATED K^+ CURRENT IN CULTURED BARORECEPTOR NEURONS. Z. Li, H. Lee, K. Bielefeldt, M.W. Chapleau,* and F.M. Abboud. Depts. of Physiol. & Biophys. and Internal Med., Univ. of Iowa Coll. of Med. and DVA Med. Ctr., Iowa City, IA 52242.

In the isolated carotid sinus prostacyclin enhances arterial baroreceptor (BR) sensitivity. We tested the hypothesis that the mechanism involves inhibition of K^+ currents. BR neurons from rat nodose ganglia were dissociated and identified using retrograde label with fluorescent dye (DiI) applied to the aortic arch two weeks earlier. Whole-cell outward K^+ current was recorded with standard patch-clamp techniques and measured at 200 ms after depolarization from -40 to +40 mV. Drugs were delivered by exchanging the bath solution. The stable prostacyclin analog carbacyclin (CC; 100μM) reversibly inhibited the current to 65±6% of control (n=8). CC failed to inhibit the current in the absence of Ca^{2+} in pipette and bath solutions (n=4). Charybdotoxin (CTX; 100nM), a specific blocker of Ca^{2+}-activated K^+ current ($I_{K\text{-}Ca}$), inhibited the outward current (73±3% of control). CC did not cause any further inhibition after CTX (n=6). Including $PKI_{(5\text{-}24)}$, a specific inhibitor of protein kinase A, in the pipette solution abolished the inhibitory effect of CC (n=6). We conclude that prostacyclin inhibits the CTX-sensitive $I_{K\text{-}Ca}$ in BR neurons through a protein kinase A-dependent pathway. This mechanism may contribute to the sensitization of BR by prostacyclin.

720.10

NITRIC OXIDE ACTIVATES CALCIUM-DEPENDENT POTASSIUM CHANNELS IN CEREBROVASCULAR SMOOTH MUSCLE CELLS. C. Chen, D.A. Mathers*. Dept. of Physiology, Faculty of Medicine, Univ. of B.C., Vancouver, B.C., Canada, V6T 1Z3

Nitric oxide is probably the major endothelium-derived relaxing factor (EDRF). It is thought to relax smooth muscle cells by stimulation of guanylate cyclase, accumulation of its product cyclic GMP, and cGMP-dependent modification of several intracellular processes, including activation of potassium channels through cGMP-dependent protein kinase. Here we present evidence that sodium nitroprusside (SNP), a vasodilator that decomposes into nitric oxide, can directly activate large conductance calcium-dependent potassium channels (K_{Ca} channels) in cell-free, inside-out membrane patches excised from cerebrovascular smooth muscle cells of adult rats.

The K_{Ca} channels studied here showed the conductance of 203±8.3pS (mean ±s.e, n=15) between -80 and +80 mV in symmetrical 140 mM KCl solutions. Bath solution contained (in mM): 140 KCl; 2.86 $CaCl_2$; 10 HEPES; 3 EGTA (free calcium concentration 1μM). Patch pipettes solution contained (in mM): 140 KCl; 1.48 $CaCl_2$; 10 HEPES; 3 EGTA. Application of SNP (100 μM) to the bath solution enhanced the K_{Ca} channel open probability by 1.6±0.12 times (mean±s.e., n=15), particularly the mean closed time of the channels was 0.6±0.05-fold (mean ±s.e., n=15) that seen in control solution. However, no difference was found between the conductances of SNP activated and control K_{Ca} channels.

720.11

REDOX AND NITRIC OXIDE (NO)-DEPENDENT MODULATION OF POTASSIUM CHANNELS OF SQUID STELLATE GANGLION NEURONS. [1]W.F. Gilly, L.L. Moroz and R. Gillette*. [1]Hopkins Marine Station, Stanford University, Pacific Grove, CA 93950; Dept. Physiology, University of Illinois, Urbana/Champaign, IL 61801.

Stellate ganglia (SG) are the main peripheral centers controlling coordinated mantle contractions and jet propulsion in cephalopod molluscs. In many species the SG giant fibre lobe (GFL) neurons fuse to form giant motor axons. We have screened for distribution of putative NO synthase containing cells in SG of cuttlefish (*Sepia officinalis, Rossia pacifica*) and squid (*Loligo opalescens*) NADPH-diaphorase (NADPH-d) histochemistry. Both *Sepia* and *Rossia* had either no or very low levels of NADPH-d activity in SG. In contrast, intense NADPH-d labelling was detected in *Loligo* around neuronal somata, mainly in the medial part of SG and in the sheath of the stellate nerve axons (including giant axons). This suggests that NO might modulate neuronal activity in squid SG. In experiments on isolated, cultured GFL neurons we found that NO-donors (SNAP, DEA) increase the rate and extent of inactivation of K-current in whole cell patch recordings. The reducing agent DTT potentiated these effects when applied extracellulary with the NO-donors. These effects were also seen in insect Sf-9 cells in which the major K-channel gene expressed by GFL neurons, squid Kv1.1 (previously called KZ4, Perry et al., 1995 Biophys. J., 66,:A105), was expressed via baculovirus infection. The action of NO-donors was not mimicked by 8-Br-cGMP and may arise from direct modulation of K-channel proteins.

720.12

LINOPIRDINE, A NEUROTRANSMITTER RELEASE ENHANCER, BLOCKS VOLTAGE-ACTIVATED POTASSIUM CURRENTS IN HIPPOCAMPAL NEURONS. M.E. Schnee and B.S. Brown*, Preclinical Pharmacology, The DuPont Merck Pharmaceutical Co., Wilmington, DE 19880.

Linopirdine [3,3-bis(4-pyridinylmethyl)-1-phenylindolin-2-one] enhances the potassium-stimulated release of a number of neurotransmitters from rat neocortex, hippocampus and striatum *in vitro* without affecting basal release. Recently linopirdine was found to block M-current in hippocampal CA1 neurons with an IC_{50} of 8.5 μM, a value closely paralleling it's IC_{50} for enhancement of acetylcholine release (3.2 μM). To determine whether linopirdine selectively blocks M-current, whole cell and outside-out patch clamp techniques were used to examine its effects on other voltage-activated potassium currents of CA1 neurons in rat hippocampal slices.

In whole cell experiments, the peak amplitude of the transient (I_A) and sustained (I_K) outward currents were reduced by bath application of linopirdine in a dose dependent manner with an IC_{50} of approximately 100 and >300 μM, respectively. Linopirdine also markedly increased the rate of I_A inactivation. The mixed Na/K inward rectifier, I_Q, and I_{AHP} were unaffected by up to 100 μM linopirdine. In outside-out patch experiments on I_A, the IC_{50} was approximately 30 μM for enhancing the rate of current inactivation and >30 μM for reducing peak current amplitude.

These results support the hypothesis that linopirdine is selective for M-current at concentrations <10 μM. At 10 μM and above the increased rate of I_A inactivation could also contribute to enhanced neurotransmitter release.

720.13

SR141716A BLOCKS CANNABINOID MODULATION OF POTASSIUM A-CURRENT IN CULTURED RAT HIPPOCAMPAL NEURONS

Jian Mu, Robert E. Hampson, Shouyuan Zhuang, Virginia C. King and Sam A. Deadwyler*, Dept. of Physiology & Pharmacology, and Center for the Neurobiological Investigation of Drug Abuse, Bowman Gray School of Medicine, Wake Forest Univ., Winston-Salem, NC 27157.

The potent cannabinoid agonist, WIN 55,212-2, modulates the voltage-dependence of potassium A-current (I_A) in rat hippocampal neurons via a cAMP dependent process (Deadwyler *et al.* 1995, JPET v.275 in press). An antagonist to the CB1 cannabinoid receptor, SR141716A (Sanofi) has been shown to be effective in blocking the reduction in cAMP produced by cannabinoid receptor agonists.

Whole-cell currents were recorded from cultured E-18 fetal rat hippocampal neurons, 7-15 days in culture, with TTX 1μM, 4-AP 500μM and TEA 30mM in the bathing medium to block sodium and non-A-type potassium currents. WIN 55,212-2 (Research Biochemicals) was diluted from 1mM stock in ethanol (which was later evaporated under a nitrogen stream) and delivered via pressure pipette in bathing medium at 1-2μM concentrations. SR141716A was prepared from 1mM stock (in ethanol), diluted to 100-500nM in bathing medium, and applied via bath perfusion.

Pressure pipette application of 1μM WIN 55,212-2 produced a 10-15 mV positive shift in voltage dependence of steady state inactivation that was completely blocked by bath perfusion of 300nM SR141716A. The 15-20 mV positive shift in steady-state inactivation of I_A produced by 2μM WIN 55,212-2 was partially blocked (50%) following 5 min bath perfusion with 300nM SR141716A. Dose effect curves revealed that the EC_{50} for the WIN modulation of I_A was shifted from 0.8μM to 2.0μM via competitive antagonism with SR141716A. Higher concentrations (500nM) of SR141716A antagonist alone precipitated decreases in I_A suggesting the possible presence of an endogenous cannabinoid ligand in the hippocampal cultures.

[Supported by NIDA grants DA07625, DA03502 and DA00119 to S.A.D., and a gift of SR141716A from Sanofi Recherche, Montpellier, France]

720.14

A NEW ASPECT OF AN APOVINCAMIC ACID DERIVATIVE, VA-045, AS A K^+ CHANNEL OPENER IN CNS NEURONS. N. Harata*, M. Munakta, H. Araki** and N. Akaike. *Dept. of Physiology, Kyushu Univ. Fac. of Med., Fukuoka 812-82, Japan, **Research Center, Taisho Pharmaceutical Co. Ltd., Ohmiya 330, Japan.

VA-045 ((+) - Eburnamenine - 14 carboxylic acid (2-nitroxyethyl) ester) is a novel apovincamic acid derivative, which has multiple activities on the central nervous system (CNS). This compound improves neurological disturbances evoked by head injury *in vivo*. However, the mechanism of the action has been largely unknown. We investigated, therefore, the effects of VA-045 on the neurons acutely dissociated from the rat cortex, using nystatin perforated-patch clamp technique. Under the current-clamp mode, VA-045 hyperpolarized the membrane, decreasing the firing activities. Under the voltage-clamp mode (V_H=-40 mV), it evoked an outward current in a concentration-dependent manner (EC_{50}=0.5 μM). The VA-045-induced current resulted from an increased K^+ conductance and had an outward rectification. This current showed distinct pharmacological properties to K^+ channel blockers. Glybenclamide (10μM), an ATP-sensitive K^+ channel blocker, had no effect. Apamin (1μM), charybdotoxin (1μM) or Ba^{2+} (3mM) also failed to block the current, while TEA decreased it (IC_{50}=2mM). VA-045 could repetitively activate the K^+ current in the absence of external Ca^{2+}. Both ryanodine and thapsigargin had no effect on this current. The current was not significantly affected by staurosporine (0.1μM), quinacrine (10μM), wortmannin (1μM) and genistein (10μM). These results indicate that VA-045 may directly activate K^+ channels, not by any of Ca^{2+} or other second messengers. The hyperpolarizing action of VA-045 may protect CNS neurons from overexcitation and extensive Ca^{2+} influx through voltage dependent Ca^{2+} channels in the pathological conditions such as hypoxia and injury.

TOLBUTAMIDE SUPPRESSES SEVERAL VOLTAGE-DEPENDENT K CURRENTS OF CA1 HIPPOCAMPAL NEURONS **B. Esplin*, G. Erdemli & K. Krnjević, Anaesthesia Research & Pharmacology Departments, McGill University, H3G 1Y6 Montréal, Québec, Canada.**

Though consistently effective as ATP-sensitive K-channel (K_{ATP}) antagonist (Ashcroft & Ashcroft, 1992 Biochim. Biophys. Acta 1175:45), tolbutamide (TOLB) is not wholly selective: it inhibits protein kinases (Kanamori et al 1976 Biochim. Biophys. Acta 429:147) and D-type K channels (Crépel et al 1993 J. Physiol. 466:39). We tested TOLB on voltage-activated outward currents (I_{out}'s) in slices kept at 33° (from Sprague-Dawley rats). Recordings were by whole-cell patch clamp with $KMeSO_4$-containing electrodes. TOLB (0.05-1 mM) depressed afterhyperpolarizations (AHPs) seen after bursts of spikes evoked with depolarizing pulses: the initial peak (medium or mAHP) by 60.3 ± 8.6 % and the slow AHP (sAHP) by 61.3 ± 10.6 % (n=11). The EC_{50} was ≈0.18 mM for the mAHP and 0.34 mM for the sAHP. In 5 cells clamped at ≈ -50 mV, TOLB reduced I_{out} by 65.3 ± 5.3 % and tail currents by 57.2 ± 14.1 %. The TOLB-sensitive I_{out} is Ca-dependent as TOLB (1 mM, 15 min) had no significant effect on I_{out} in Mn^{2+} /low Ca^{2+} medium (-10.5 ± 6.4 %, n=5). TOLB probably acts independently of any changes in Ca-currents because TOLB induced only minor (non-significant) depressions of sustained HVA Ca-currents (by -19.5 ± 9.6 %, n=5). TOLB also depressed M-current (I_M) by 40.9 ± 12.9 % (obtained from inward relaxations evoked by hyperpolarizing pulses from V_H=-30 mV, n=7). Judging by these results, TOLB is not a selective K_{ATP} antagonist in CA1 neurons, since it also depresses voltage- and Ca-dependent I_{out}'s (I_M, $I_{K(Ca)}$). The suppression of several I_{out}'s explains why TOLB enhances excitability and ongoing firing in hippocampal slices.

BLOCK BY LOCAL ANESTHETIC OF TRH EFFECTS ON K^+ CURRENTS IN NEUROENDOCRINEL CELLS. Z.-L. XIONG, F. POPITZ-BERGEZ* AND G. STRICHARTZ. ANES. RES. LAB., BWH, HARVARD MED. SCH., BOSTON, MA 02115.

In rat anterior pituitary tumor (GH_3) cells two types of voltage dependent potassium currents (I_K), a slow-inactivating I_s and a fast-inactivating I_{To}, were observed using whole-cell voltage clamp. Under physiological conditions, thyrotropine-releasing hormone (TRH: 0.01 - 1 μM) evoked a dose-dependent, biphasic response of both types of I_K: a transient increase, with peak effect (120 - 360 % of control) at 1 min, followed by a sustained inhibition (60 - 92% of control). This response was repeatable after washout of TRH for 6 min or longer. When a high concentration (4 mM) of EGTA was present intracellularly and 0.2 mM cadmium was added to the bath to block Ca^{2+} entry to the cell, the stimulatory phase from TRH disappeared whereas the inhibitory phase remained unchanged, indicating that the transient stimulatory phase is a Ca^{2+} dependent response (i.e., $I_{K(Ca)}$). On the other hand, when GDP-β-S (0.5 mM) was applied intracellularly, both responses of I_K to TRH were almost abolished, implying a G-protein mediated effect. Lidocaine could inhibit I_K completely (IC_{50} of 1.9 mM) and also inhibit I_{Ca} (IC_{50} of 2.6 mM). In addition, pretreatment (5 - 8 min) of cells with much lower doses of lidocaine (10 - 100 μM, at which I_K was unaffected), largely blocked the effect of TRH. Simultaneous application of lidocaine (100 μM) with TRH (1 μM) failed to block the hormone-induced response. Thus, local anesthetics inhibit the G-protein mediated response in excitable cells at concentrations that do not block ion channels directly. Lidocaine at such concentrations is known to have substantial effect as a systemic analgesic. (Supported by NIGMS 15904).

CAPSAICIN BLOCKS K^+ AND Ca^{++} CURRENTS AND SELECTIVELY ACTIVATES SENSORY CELLS IN SPINAL NEURONS OF *XENOPUS* EMBRYOS. F. M. Kuenzi* and N. Dale. School of Biological and Medical Sciences, University of St Andrews, KY16 9TS, UK

Besides its selective activation of the slow-conducting pain fibres in mammals, capsaicin also potently blocks voltage-gated ion channels, showing selectivity in some preparations. To test whether this compound could be used to separate fast and slow components of the voltage-gated K^+ currents in *Xenopus*, whole-cell patch-clamp recordings were made from neurons that had been dissociated from spinal cords of stage 37/38 embryos and maintained in culture for up to six hours. In all cells 100 μM capsaicin reduced the potassium current by 88±3.6% (mean ± sem, n=5), 95% maximally, suggesting that both conductance components are affected. The blocking reaction had a K_D = 21 μM and a Hill coefficient of 1.72, suggesting that two molecules of capsaicin may be required. The block was time dependent, having little effect on the time course of activation, but causing an increase in apparent inactivation. The rate of inactivation increased with the concentration of capsaicin. This suggests that capsaicin may act to block the open channel.

Ca^{++} currents were also sensitive to capsaicin, being reduced at 10 μM by 11.4± 1.8% (n=12). Although the voltage-dependence of activation was not affected, capsaicin caused a marked increase in the rate of inactivation of the current in some cells during a 70 ms step.

A proportion of cells that had the appearance of Rohon-Beard sensory neurons in culture (Dale, 1991, *Europ. J Neurosci.* 3, 1025-1035), also responded to low doses of capsaicin with an inward current that was slow to activate and dose-dependent. This response may be analgous to the effects of capsaicin on mammalian C fibres and cultured DRG neurons.

ZINC MODULATES EXTRACELLULAR FATTY ACID BLOCK OF RECOMBINANT VOLTAGE-GATED POTASSIUM CHANNELS EXPRESSED IN MAMMALIAN CELLS J.S. Poling*[1,3], S. Vicini[1], M.A. Rogawski[2], and N. Salem, Jr.[3] [1]Dept. of Physiology and Biophysics, Georgetown Univ., Wash., DC 20007;[2]NINDS/NIH, Bethesda, MD 20892;[3]NIAAA/NIH, Rockville, M.D. 20852.

Docosahexaenoic acid (DHA), an omega-3 fatty acid, is the major polyunsaturated fatty acid (PUFA) found in mammalian brain and is selectively incorporated into the membrane phospholipid pool of retina and synapses. We have previously reported that certain PUFAs potently blocked native voltage-gated K^+ channels (K_d = 2.5 μM, DHA) and exert their action directly from the extracellular side of the membrane by an open-channel blocking mechanism (Poling et al., Mol. Pharm. 47(2), 1995). In CL1023 fibroblasts stably expressing Kv1.2 or Kv3.1 channels, DHA also blocked whole-cell K^+ currents and accelerated the current decay in a concentration-dependent manner (Kv1.2, K_d = 1.8 μM; Kv3.1, K_d = 690 nM). Block was observed in the whole-cell or outside-out patch configuration indicating that the interaction between DHA and the K^+ channel occurred at an extracellular site. Divalent zinc (10^{-4} M) non-competitively inhibited block of Kv1.2 to a greater extent than Kv3.1. Zinc is present within some neurotransmitter containing vesicles and can be co-released into the synaptic cleft suggesting a novel role for 22:6n3 and zinc as modulators of K^+ channels.

A ROLE FOR ARACHIDONIC ACID IN GENERAL ANESTHETIC ACTION D. D. Denson and D. C. Eaton*. Depts of Anesthesiology and Physiology and The Center for Cellular and Molecular Signaling, Emory Univ. Sch. of Med., Atlanta, GA 30322.

General anesthetic block of BK channels in GH3 cells is mimicked by PLA_2 inhibitors and attenuated by exogenous arachidonic acid (AA). Untreated GH3 cells continuously produce measurable levels of AA implying tonic PLA_2 activity. PLA_2 activity in GH3 cells can be blocked by concentrations of the intravenous general anesthetic, ketamine, that are comparable to those used clinically (100μM). If general anesthetic block of BK channels is mediated by an inhibition of PLA_2, then addition of exogenous AA should attenuate the anesthetic block and reduce the slope of the ketamine dose response curve. To test this hypothesis, we examined the dose response curve for ketamine in the presence and absence of AA. Single channel recording techniques in excised patches were used to examine the effect of racemic ketamine (10, 50, 100, 500 and 1000μM) on the BK channel activity in GH3 cells. Solutions containing 150 mM KCl were used in both the pipette and bath. Ca_i^{+2} in the bath was buffered to 0.1 μM with 5mM K_2EGTA. AA by itself increased the open probability of BK channels. Ketamine reduced the open probability of channels in the presence and absence of AA, but the ketamine block was significantly different for channels activated by AA (1 μM) compared to channels in absence of AA. Exposure of BK channels to AA caused not only a shift in the ketamine dose response curve to the right as evidenced by a significant ($p<0.001$) increase in EC_{50} from 3.4 ± 0.4 to 693 ± 379 μM but a significant ($p<0.001$) decrease in slope from 1.40 ± 0.21 to 0.59 ± 0.05. These data suggest that exogenous AA is activating BK channels and attenuating general anesthetic block by increasing the membrane concentration of AA that is reduced by general anesthetic inhibition of PLA_2. Since PLA_2 is inhibited by all of the general anesthetics we have examined, disruption of AA production may be an important mechanism for the action of general anesthetics on ion channels within the central nervous system.

720.20

THE POTASSIUM CHANNEL BLOCKERS, 4-AMINOPYRIDINE AND TETRAETHYLAMMONIUM, INCREASE THE SPONTANEOUS BASAL RELEASE OF [3H]5-HYDROXYTRYPTAMINE IN RAT HIPPOCAMPAL SLICES. L.E. Schechter*. Wyeth-Ayerst Research, CNS Disorders, Pearl River, NY 10965.

Previous investigations have demonstrated that compounds capable of blocking presynaptic K+ channels can stimulate neurotransmitter release at both peripheral and central synapses. This study examined the *in vitro* effects of the "classical" K+ channel blockers, 4-aminopyridine (4-AP) and tetraethylammonium (TEA), on the spontaneous basal release of [3H]5-hydroxytryptamine ([3H]5-HT) from rat hippocampal slices using an automated superfusion apparatus. 4-AP and structural analogs increased the spontaneous basal release of [3H]5-HT in a concentration-related manner. The rank order of potencies from the estimated EC50 values indicated that 3,4-DAP(0.88 mM) ≈ 4-AP(1.2 mM) > 2-AP(89 mM) > 3-AP(100 mM) > pyridine(256 mM). TEA stimulated [3H]5-HT release with an estimated EC50 value of 63 mM and was less efficacious than the pyridine congeners. The release induced by 4-AP (0.3, 1 and 10 mM) and TEA (30, 100 and 300 mM) was significantly attenuated in a Ca^{+2}-free buffer containing 1 mM EGTA. Tetrodotoxin (TTX; 1 μM), a Na^+ channel blocker, was unable to block the response of 4-AP (1 mM) and TEA (100 mM). Notably, this concentration of TTX reduced the stimulation of [3H]5-HT release produced by the Na^+ channel opener veratridine (5 μM). The enhancement of release induced by 1 mM 4-AP was additive with 100 mM TEA and 5 μM veratridine but not with 25 or 50 mM KCl. Taken together, the results demonstrate that K+ channel blockade can enhance the spontaneous basal release of [3H]5-HT in rat hippocampal slices. These effects are at least partly dependent on extracellular Ca^{+2} and do not appear to be mediated by modulating Na^+ channel function. In conclusion, this is the first direct demonstration that presynaptic K+ channels can regulate 5-HT neurotransmission.

ACETYLCHOLINE RECEPTOR: NICOTINIC—PHARMACOLOGY

721.1

Functional Pharmacology of Neuronal Nicotinic Acetylcholine Receptors (AChRs) from the Human Cell Line IMR-32
Nelson, M.E., Gerzanich, V., Criswell, L., and Lindstrom, J.M.* Dept. of Neuroscience, Univ. of Pennsylvania Medical School, Philadelphia, PA 19104.

The IMR-32 cell line is a human neural crest derived cell-type that has been shown to express neuronal-type AChRs including α3, α5, α7, β2, and β4 subunits (Neurosci. 32: 759-767; FEBS Lett. 312: 67-70). Here we report the pharmacological characteristics of functional AChRs expressed in these cells using patch-clamp electrophysiology in order to identify the subunit composition of native human AChRs by comparisons to recombinant human AChRs expressed in *Xenopus* oocytes. IMR-32 cells responded with relatively robust currents (averaging about 350 pA of maximal current) when exposed to the nicotinic agonists dimethyl-phenylpiperazinium (DMPP), nicotine, cytisine, acetylcholine (ACh) and tertramethylammonium (TMA). All agonists had similar efficacies and their respective EC_{50} values were approximately 7.6, 22.5, 31.2, 59.0, and 1030 μM. Currents activated by ACh (100 μM) were completely antagonized by d-tubocurarine, mecamylamine, and hexamethonium with IC_{50} values of 0.4, 3.2, and 8.5 μM, respectively, while methyllycaconitine (up to 1 μM) was virtually ineffective. Single-channel currents activated in outside-out patches from IMR-32 cells had a chord conductance of 46 pS and distributions of channel open times that were best fit by double exponential functions with time constants of 1.7 and 6.0 ms. Comparisons between IMR-32 nicotinic responses and human neuronal AChRs functionally expressed in *Xenopus* oocytes suggest that the predominant AChR expressed in IMR-32 cells is one including α3 and β4 receptor subunits, although participation of other receptor subunits cannot be excluded based on the present data. (Supported by grants from NINDS, STRC, CTR, and MDA.)

721.2

GALANTHAMINE IS A POSITIVE MODULATOR OF THE α-BUNGAROTOXIN-SENSITIVE HIPPOCAMPAL NICOTINIC RECEPTOR ACTIVITY. E.X. Albuquerque[1,2*], E.F.R. Pereira[1], A. Schrattenholz[3], A. Maelicke[3] [1]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201, USA; [2] Lab. Mol. Pharmacol., Inst. Bioph. "Carlos Chagas Filho", UFRJ, Rio de Janeiro, RJ 21944, Brazil; [3] Inst. Physiol. Chem. Pathobiochem., Johannes-Gutenberg Univ. Med. Sch., Mainz D-6500, Germany.

A new binding site has been identified on neuronal and muscle nicotinic receptors (nAChRs) through which the ion-channel can be activated (*J. Pharmacol. Exp. Ther.* 265: 1474, 1993). This site is referred to as the physostigmine (PHY) site, is insensitive to classical nicotinic agonists such as ACh and anatoxin-a (AnTX), and recognizes as agonists the anticholinesterases PHY and galanthamine (GAL). To determine whether the nAChR activity induced by classical nicotinic agonists can be modulated via this novel site, we used the whole-cell mode of the patch-clamp technique to investigate the effects of GAL on α-bungarotoxin (α-BGT)-sensitive currents elicited by 500-ms pulses of AnTX to cultured hippocampal neurons. When applied to the neurons as an admixture with AnTX (10 μM), GAL (0.1-100 μM) changed neither the peak amplitude nor the decay time constant of AnTX-induced currents. However, following the recording of the AnTX-induced current, perfusion of the neurons for 5 min with GAL (1 μM)-containing external solution prior to their subsequent exposure to the admixture of GAL (1 μM) and AnTX (10 μM) caused an increase of the peak amplitude and a prolongation of the fast decay phase of the AnTX-induced current; the peak amplitude was increased by about 30 % and the decay time constant was prolonged from 23.6 ± 1.9 ms to 30.2 ± 2.1 ms (mean ± SEM, n = 4). These results suggest that a ligand capable of binding to the PHY site may play an important role in regulating the desensitization of the α-BGT-sensitive, presumably an α7-bearing, hippocampal nAChR. (USPHS Grant NS25296).

721.3

α-CONOTOXIN-ImI: A POTENT ANTAGONIST AT THE α-BUNGAROTOXIN (α-BGT)-SENSITIVE HIPPOCAMPAL NICOTINIC RECEPTOR (nAChR). E.F.R. Pereira [1*], M. Alkondon[1], J.M. McIntosh [2] and E.X. Albuquerque [1,3]. [1]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201, USA; [2]Depts. of Psychiatry and Biology, Univ. Utah, Salt Lake City, Utah 84112, USA; [3]Lab. Mol. Pharmacol., IBCCF, UFRJ, RJ 21944, Brazil.

α-Conotoxin-ImI (α-CTX-ImI), a neurotoxin isolated from the venom of the snail *Conus imperialis*, has been characterized as a disulfide-rich dodecapeptide that (i) acts as a nicotinic antagonist at the frog neuromuscular junction, (ii) does not cause paralysis when injected intraperitoneally in mice, and (iii) causes seizures when injected into the intracerebroventricular space of rats or mice (*J. Biol. Chem.* 269: 16733, 1994). Whereas α-CTX-ImI seems to be a poor antagonist at mammalian muscle nAChRs, it may act as a potent antagonist at mammalian neuronal nAChRs. The fact that α-BGT also causes seizures when injected intracranially in rats and mice led us to test whether α-CTX-ImI interacts with the α-BGT-sensitive, presumably α7-bearing, hippocampal nAChR. Nicotinic whole-cell currents elicited by 500-ms pulses of ACh (1 mM) were recorded from cultured hippocampal neurons using the patch-clamp technique. In this study, α-BGT-sensitive currents (referred to as type IA currents) were characterized by their fast decay and by their reversible inhibition by methyllycaconitine (1 nM) (*J. Pharmacol. Exp. Ther.* 265:1455, 1993). The effect of α-CTX-ImI on type IA currents was evaluated after superfusing the neurons with α-CTX-ImI-containing external solution for 5 min. At 100 nM, α-CTX-ImI decreased the peak current amplitude to 45 ± 2.5% of control (mean ± SEM, n =3). The relationship between the normalized peak current amplitude and the concentration of α-CTX-ImI revealed that the IC_{50} for this toxin in inhibiting type IA current is about 95 nM. The α-CTX-ImI-induced inhibition of type IA currents was reversed by washing. Our results indicate that α-CTX-ImI potently and reversibly inhibits the activation of α-BGT-sensitive hippocampal nAChRs. (USPHS Grants NS25296, ES05730).

721.4

POTENCIES OF MUSCLE RELAXANTS PANCURONIUM AND (+)-TUBOCURARINE AT MUSCLE NICOTINIC RECEPTORS (nAChR). C.M. Garland, L. Holden-Dye, J. Chad, S.D. Jane, R.C. Foreman, R.J. Walker*. Dept. of Physiol. & Pharmacol., University of Southampton, Southampton SO16 7PX, UK.

Clinically, pancuronium is more effective than (+)-tubocurarine (tc) (Kreig *et al.*, 1980, Br. J. Anaesth. 52, 783-787) as a muscle relaxant. We are investigating the molecular basis for their action at nAChRs.

In oocytes expressing nAChRs (mouse muscle, αβγδ) pancuronium (IC_{50} 5.0 ± 1.9 pM; n=4) was more potent at blocking currents induced by 1 μM ACh than tc (IC_{50} 7.4 ± 0.8 nM; n=4). In the rat phrenic nerve diaphragm pancuronium and tc were less potent (IC_{50} 2.5 μM, n=2 and 5.0 μM, n=2, respectively). The possibility that the potency of pancuronium is partly determined by the expression system/tissue is being investigated by comparison with effects on mouse muscle myoblasts (which also express αβγδ subunits). Confocal microscopy of Indo-1-AM loaded myoblasts is used to detect increases in intracellular Ca^{++} activity ($aCa^{++}i$) an indirect measure of nAChR activation. 10 μM ACh increased $Ca^{++}i$ from 100-200nM to 400-600nM and this was blocked by 1 μM pancuronium. We are currently quantifying the potency of tc and pancuronium in this system.

cDNA clones were kindly donated by Professor S. Heinemann, Salk Institute, California. CMG is supported by Organon Teknica, Belgium. We thank Dr R.J Marshall and Dr A. Muir for helpful discussions.

721.5

A NOVEL NON-COMPETITIVE *CONUS* PEPTIDE INHIBITOR OF THE NICOTINIC ACETYLCHOLINE RECEPTOR. M. M. Grilley*, K.-J. Shon, C. Hopkins, D. Yoshikami, and B. M. Olivera. Department of Biology, University of Utah, Salt Lake City, UT 84112.

Venomous snails of the genus *Conus* produce a variety of peptide toxins which individually target a range of receptors and ion channels. Venom milked from the fish hunting *C. purpurascens* has been fractionated and found to contain, among others, a peptide unique both structurally and mechanistically among previously characterized conotoxins. The 24 amino acid peptide was chemically synthesized and, like the native material, caused paralysis and death following injection into goldfish. Binding and photoaffinity labeling of the peptide to *Torpedo* electric organ membrane indicate it targets the nicotinic acetylcholine receptor, but that it does not compete with α-bungarotoxin or the α-conotoxins, competitive inhibitors of α-bungarotoxin binding on the muscle subtype of the acetylcholine receptor. Electrophysiology studies suggest the peptide acts as a non-competitive inhibitor of the acetylcholine receptor by physically blocking the pore. Further analysis of analogs of this peptide will allow determination of functional groups important for the peptide-channel interaction. (Supported by NIDA grant #DA05485.)

721.6

INHIBITORY EFFECTS OF THE ANTIVIRAL AGENT AMANTADINE ON NICOTINIC ACETYLCHOLINE RESPONSES IN RAT HIPPOCAMPAL CULTURED NEURONS. H. Matsubayashi* and E.X. Albuquerque. Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201, USA.

Amantadine is used for the treatment of influenza and Parkinson's disease. On frog sartorius muscle, this drug decreases the amplitude of the endplate current and reverses the slope of the relation between half-decay time and membrane potential, suggesting an alteration of the nicotinic acetylcholine receptor/ion channel (nAChR) (*Science* 199:788, 1978). In the present study the effects of amantadine on hippocampal nAChRs were investigated. At least three distinct current types, IA, II and III, have been recorded from hippocampal neurons (*J. Pharmacol. Exp. Ther.*, 265:1455, 1993), and they are subserved by nAChRs with different subunit compositions. In this study, whole-cell currents were recorded from cultured hippocampal neurons according to standard patch-clamp technique. The external perfusing solution contained atropine (1 μM) and tetrodotoxin (300 nM). The results showed that amantadine (500 μM) decreased the peak amplitude of all three types of currents elicited by pulse application (0.5-2 s) of ACh (1 mM) to the cultured neurons. When amantadine was simultaneously applied via the background perfusion and as an admixture with ACh via the U-tube, and ATP-regenerating solution was used to prevent rundown of type IA current, the IC_{50} for amantadine in inhibiting ACh (0.3 mM)-induced type IA current was 6.21 μM. Amantadine was more potent in inhibiting the activation of nicotinic currents in hippocampal neurons than in inhibiting endplate currents (*Mol. Pharmacol.* 22:82, 1982). It is concluded that amantadine is a more potent antagonist of neuronal nAChRs than of muscle nAChRs. (*Support*: USPHS Grants NS25296 and ES05730)

721.7

DEVELOPMENT OF A NOVEL CLASS OF NICOTINIC RECEPTOR ANTAGONISTS: INHIBITION OF NICOTINE-EVOKED STRIATAL DOPAMINE RELEASE AND THE ELECTROPHYSIOLOGICAL RESPONSE OF A CLONED NICOTINIC RECEPTOR SUBTYPE IN *XENOPUS* OOCYTES. P.A. Crooks, L.H. Teng, A. Ravard, S.T. Buxton, B.N. Cohen, D.D. Allen* and L.P. Dwoskin. College of Pharmacy, Univ. of Kentucky, Lexington, KY 40536 and Div. of Biomedical Sciences, Univ. of California, Riverside, CA 92521.

We have undertaken the development of subtype selective antagonists of the neuronal nicotinic receptor site. A series of pyridyl N-substituted nicotine analogues were synthesized and evaluated for their ability to inhibit nicotine (10 μM)-evoked [^{3}H]dopamine ([^{3}H]DA) release from rat striatal slices. Antagonist potency increased with increasing carbon number. The N-octyl analogue NONI was the most efficacious and potent in the series, and afforded greater inhibitory efficacy than the competitive neuronal nicotinic receptor antagonist, dihydro-β-erythroidine (DHβE) and the nicotinic receptor channel blocker, mecamylamine (MEC). The N-allyl analogue NANI was less potent than NONI and had similar efficacy to DHβE. The order of potency in the release assay was NONI>DHβE>MEC>NANI, with IC50s of 1.3, 2.5, 3.0, 12 μM, respectively. In electrophysiological studies, NONI blocked the response of cloned α3β2 nicotinic receptors to 1 μM acetylcholine by 50% at 5 μM, and by 100% at 100 μM, and displayed no agonist activity. These data suggest that the antagonists may block the α3β2 receptor to inhibit nicotine-evoked [^{3}H]DA release from striatum. Molecular modeling data suggest that this new class of antagonist binds in a novel manner to the nicotinic receptor. (Supported by a grant from the Tobacco and Health Research Institute, Lexington, KY).

721.8

DEVELOPMENT OF A NOVEL CLASS OF NICOTINIC RECEPTOR ANTAGONISTS: DISPLACEMENT OF [^{3}H]NICOTINE BINDING FROM RAT STRIATAL MEMBRANES. L.H. Wilkins, P.A. Crooks, A. Ravard, R.A. Yokel* and L.P. Dwoskin. College of Pharmacy, University of Kentucky, Lexington, KY 40536.

To study the mechanism of action of nicotine in the CNS, we have undertaken the development of subtype selective antagonists of the neuronal nicotinic receptor site. A series of N-substituted nicotine analogues were synthesized and evaluated for their ability to displace [^{3}H]nicotine binding from rat striatal membranes. The effects of the analogues were compared to the competitive nicotinic receptor antagonist dihydro-β-erythroidine (DHβE). Scatchard analysis of [^{3}H]nicotine binding revealed a Kd = 1.46 ± 0.15 nM and Bmax = 117 ± 9.05 fmol/mg protein. In displacement studies, the Ki's for nicotine, DHβE, S(-)N-allylnicotinium iodide (NANI), S(-)N-methylnicotinium iodide (NMNI) and S(-)N-octylnicotinium iodide (NONI) were 0.38 ± 0.11 nM, 64.9 ± 10.4 nM, 2.38 ± 0.24 μM, 3.10 ± 0.40 μM and 20.1 ± 1.6 μM, respectively. Moreover, the order of potency for displacement of [^{3}H]nicotine binding does not correlate with the order of potency for inhibition of [^{3}H]dopamine release from rat striatal slices (Crooks et al, Soc. Neurosci., 1995). This poor correlation suggests that the receptor subtypes that control [^{3}H]dopamine release differ from the subtypes that are primarily responsible for high-affinity [^{3}H]nicotine binding. Thus, the analogues had marginal affinity for the [^{3}H]nicotine binding site in rat striatum compared with DHβE, suggesting that they do not have a significant affinity for the α4β2 neuronal nicotinic receptor subtype, but may be selective for the α3β2 subtype. (Supported by a grant from the Tobacco and Health Research Institute, Lexington, KY).

721.9

PHARMACOLOGICAL COMPARISON OF NICOTINE-EVOKED RELEASE OF STRIATAL DOPAMINE AND HIPPOCAMPAL NORADRENALINE FROM SUPERFUSED SYNAPTOSOMES
P.B.S. Clarke* and M. Reuben. Dept of Pharmacology and Therapeutics, McGill Univ., Montreal, Canada H3G 1Y6.

In situ hybridization studies suggest that rat nigrostriatal dopamine neurons express mainly α4, α5, and ß2 nicotinic receptor subunits, whereas dorsal bundle noradrenaline neurons express mainly α3, ß2 and ß4 subunits (Wada et al 1989, 1990; Dineley-Miller and Patrick 1992). In order to test for pharmacological differences, agonist-evoked release of striatal ^{3}H-DA and hippocampal ^{3}H-NA was measured from superfused synaptosomes prepared from rat. Nicotine, cytisine, DMPP and ACh (with esterase inhibitor and muscarinic antagonist) increased NA release in a concentration-dependent manner (EC50s of 3.7 µM, 6.0 µM, 8.9 µM and 13 µM, respectively). Maximal drug effects were similar for each agonist. DA was released more potently than NA by L-nicotine (EC50 0.16 µM vs. 6.4 µM) and anatoxin (EC50 0.035 µM vs 0.39 µM). Isoarecolone (1 – 320 µM) released DA more than NA at each concentration, but a maximal effect was not reached. Lobeline evoked DA release but not NA release. High K^+ (10 mM) released DA and NA to similar extents. The nicotinic antagonist mecamylamine (10 µM) virtually abolished NA and DA release evoked by high concentrations of all agonists tested except lobeline. The nicotinic antagonists DHBE and methyllycaconitine inhibited nicotine-evoked DA release more potently than NA release, each with a 45-fold DA:NA potency difference when tested against EC50 values for nicotine. Thus, nicotinic receptors associated with striatal DA and hippocampal NA afferents have different pharmacological profiles that may be attributable to their subunit composition.

EFFECTS OF A-85380 ON NICOTINIC RECEPTOR MEDIATED $^{86}Rb^+$ EFFLUX FROM MOUSE THALAMIC SYNAPTOSOMES.
M.J.Marks* and S.F.Robinson. University of Colorado, Boulder, CO.

A-85380 [3-(2(S)-azetidinylmethoxy)pyridine], a novel, potent nicotinic agonist that activates a variety of human nicotinic receptor subtypes, was evaluated for its ability to stimulate the efflux of $^{86}Rb^+$ from synaptosomes prepared from thalamus of C57BL/6 mice. The stimulation of $^{86}Rb^+$ efflux by A-85380 was concentration dependent, but apparently biphasic. One component had a very high affinity (EC_{50} = 4.2 nM) and a maximal response approximately equal to that measured for 10 µM nicotine. A second component, that did not saturate by 3 µM, was observed at concentrations above 300 nM. The $^{86}Rb^+$ efflux measured using either 30 nM or 3 µM A-85380 were each inhibited approximately 90% by 10 µM mecamylamine. Exposure to stimulating concentrations (0.3-10 nM) of A-85380 desensitized $^{86}Rb^+$ efflux. An EC_{50} value about 4 nM was calculated for both stimulation and desensitization of efflux. Desensitization of the efflux stimulated by 10 µM nicotine was also observed with concentrations of A-85380 that elicited little efflux (IC_{50} = 0.2 nM). The desensitization rate for 0.3 nM A-85380 (0.27 min^{-1}) was lower than the maximum rate observed for activating concentrations (2.4 min^{-1}). Synaptosomes that had been desensitized by exposure to either nonstimulating (0.3 nM) or stimulating (30 nM) concentrations of A-85380 partially recovered responsiveness after the termination of treatment (75% and 35%, respectively). The recovery from desensitization after treatment with 0.3 nM was faster ($k=0.34^{-1}$) than that after 30 nM ($k=0.19$ min^{-1}). The kinetics of desensitization observed after exposure to either stimulating or nonstimulating concentrations of A-85380 were comparable to those measured previously for the extremely potent nicotinic agonist, epibatidine. These studies indicate that A-85380 is among the most potent agonists yet tested at nicotinic receptors in the CNS. Supported by Abbott Laboratories.

CHOLINERGIC ACTIVATION OF THE ELECTROCORTICOGRAM: AN AMYGDALAR ACTIVATING SYSTEM.
H.C.Dringenberg, and C.H.Vanderwolf*. Neuroscience Program, University of Western Ontario, London, Ontario, Canada, N6G 2V4.

In urethane-anesthetized rats, 100 Hz electrical stimulation of the basal amygdala changed the slow wave activity of the neocortex from 2-6 Hz large irregular slow activity (LISA) to low voltage fast activity (LVFA) including frequencies of above 10 Hz. A similar activating effect was seen in the hippocampus where amygdala stimulation induced the appearance of rhythmical slow activity (RSA) in the 2-6 Hz range. This activation of neocortical and hippocampal slow wave activity by amygdala stimulation was blocked by the cholinergic-muscarinic receptor antagonist scopolamine (0.5-5.0 mg/kg, i.p.), but not by the peripheral antagonist methyl-scopolamine, in a concentration-dependent manner. In contrast, a blockade of ascending inputs from the midbrain to the neocortex by treatment with the serotonin-depletor *p*-chlorophenylalanine or cauterization of the rostral midbrain did not block neocortical LVFA to amygdala stimulation, even though the lesions abolished all LVFA to strong noxious stimuli such as tail pinches. Unilateral infusions of the local anesthetic lidocaine (1%) into the basal forebrain selectively blocked LVFA in the neocortex ipsilateral to the infusion. However, intracerebral or systemic administration of various excitatory amino acid antagonists (2-amino-5 - phosphonovaleric acid, kynurenic acid, NPC 12626) was not effective in blocking LVFA to amygdala stimulation. Extracellular single unit recordings in the basal forebrain showed that about 50% of cells that were more active during periods of neocortical LVFA relative to LISA were excited by single pulse stimulation of the basal amygdala. Cells that were more active during LISA often were inhibited by amygdala stimulation. The basal amygdala appears to provide an important excitatory input to the basal forebrain cholinergic system involved in activation of the electrocorticogram. (Supported by NSERC, Canada).

EXCITATORY AMINO ACID RECEPTORS: RECEPTOR LOCALIZATION

722.1

SELECTIVE VULNERABILITY OF NEURONS IN THE HUMAN NUCLEUS BASALIS OF MEYNERT: PUTATIVE ROLE OF AN AGE-RELATED DECREASE IN GLUR2/3 RECEPTOR SUBUNIT IMMUNOREACTIVITY.
M.D. Ikonomovic*, R. Sheffield, and D.M. Armstrong. Allegheny-Singer Research Institute, Medical College of Pennsylvania, Pittsburgh, PA 15212.

Polyclonal antibodies directed against the GluR1 and GluR2/3 subunits of the AMPA receptor complex were employed in order to examine in brains of elderly humans (average age = 75) the distribution and subunit composition of AMPA-selective receptors within magnocellular neurons comprising the nucleus basalis of Meynert (NBM). Within each case (n = 9) NBM neurons were intensely labeled for GluR1, yet displayed virtually no immunolabeling for GluR2/3. In contrast, GluR2/3, but not GluR1, labeled neurons were abundantly observed within adjacent brain regions of these same cases (*i.e.*, amygdala, hippocampus and entorhinal cortex). Collectively, these data suggest that within elderly subjects the molecular composition of AMPA receptors may differ between neurons in the NBM and surrounding regions. In addition, we examined three younger cases (ages 5, 33 and 50 y) in order to assess whether the paucity of GluR2/3 immunolabeling within the NBM of elderly subjects was a consequence of normal aging or consistent throughout life. Within the 5 and 33 year old cases we observed GluR2/3-labeled neurons within the NBM, although the intensity of immunolabeling was relatively modest within the younger case. In contrast, little if any GluR2/3-labeling was observed on NBM neurons in the 50 year old cases, although robustly labeled neurons were present within adjacent brain regions. Although preliminary these latter data suggest that with advancing age there is a selective decrease in GluR2/3 immunoreactivity within NBM neurons, we hypothesize that the loss of the GluR2/3 subunit may render these neurons functionally distinct with respect to their responsiveness to glutamate. Therefore, alterations in the molecular composition of the AMPA receptor may contribute to the selective vulnerability of these cells to excitotoxic insults and to their severe loss in a number of neurodegenerative diseases including Alzheimer's disease.

722.2

AMPA-SELECTIVE GLUTAMATE RECEPTOR SUBTYPE IMMUNOREACTIVITY IN THE HIPPOCAMPAL FORMATION OF PATIENTS WITH ALZHEIMER'S DISEASE: EVIDENCE FOR HIPPOCAMPAL PLASTICITY.
D.M. Armstrong*, R. Sheffield, and M.D. Ikonomovic. Allegheny-Singer Research Institute, Medical College of Pennsylvania and Hahnemann University, Allgheny Campus, Pittsburgh, PA 15212.

Immunocytochemical techniques were employed in order to examine the distribution and intensity of immunolabeling for AMPA receptor subunits GluR1 and GluR2/3 within the hippocampal formation of normal controls and Alzheimer's disease (AD) cases. Throughout our investigation we examined cases exhibiting a wide range of pathologic severity, thus allowing us to correlate our immunohistochemical data with extent of pathology. Specifically, we investigated the distribution of these receptor subunits in hippocampal sectors which are particularly vulnerable to AD pathology (*i.e.*, CA1 and subiculum) and compared these findings to those obtained following examination of sectors which are generally resistant to pathologic change (*i.e.*, CA2/3, dentate gyrus). Within vulnerable sectors we observed a variable loss of GluR1 and GluR2/3 immunolabeling. The degree to which these proteins were reduced correlated with the extent of neurofibrillary pathology and cell loss. Despite the loss of labeled cells the intensity of immunolabeling within remaining neurons was comparable to and in many instances even greater than that observed in control cases. Within resistant sectors, the distribution of immunoreactive elements was comparable in both case groups yet the intensity of immunolabeling was markedly increased in AD cases, particularly in the molecular layer of the dentate gyrus and in the stratum lucidum of CA3 (*i.e.*, termination zones of perforant pathway and mossy fibers). In addition, within AD cases dramatic increases were observed within the surpagranular and polymorphic layer of the dentate gyrus (*i.e.*, terminal zones of sprouting mossy fiber collaterals). The increase in GluR1 and GluR2/3 immunolabeling is hypothesized to occur in response to the deafferentation of selected glutamatergic pathways. Moreover, our data support the concept that hippocampal plasticity is preserved, even in severe AD cases, and suggest a critical role for AMPA receptor subunits in maintaining hippocampal functioning.

722.3

AMPA-SELECTIVE GLUTAMATE RECEPTOR SUBUNITS IN THE VISUAL AND PARIETAL CORTICES OF NORMAL CONTROLS AND PATIENTS WITH ALZHEIMER'S DISEASE. A. Oguntola, R. Sheffield*, M.D. Ikonomovic, and D.M. Armstrong. Medical College of Pennsylvania and Hahnemann University, Allegheny-Singer Research Institute, Pittsburgh PA 15212.

We employed immunocytochemical techniques and antibodies against the AMPA-receptor subunits GluR2/3 to examine the distribution of these receptor subunits within the visual (Areas 17 and 18) and parietal cortices of normal elderly subjects and patients with Alzheimer's disease (AD). These studies are part of a continuing effort to investigate the selective vulnerability of glutamatergic neurons in AD. These regions were selected for study because they represent areas of brain that express abundant (*i.e.*, parietal cortex) and modest (*i.e.*, visual cortex) AD neuropathology. Within the visual cortex, we observed GluR2/3-labeled pyramidal and non-pyramidal neurons, with the latter being the more predominant. In area 17, the majority of GluR2/3-positive neurons were distributed within layers V and VI. In contrast, within area 18 both cell types were observed within layers V and VI as well as within layers II and III. When these same regions were examined in AD cases no significant reduction in GluR2/3 labeled neurons was observed. Within the parietal cortex, GluR2/3 pyramidal and non-pyramidal neurons were observed, with pyramidal neurons being the more abundant cell type. As in Area 18, these cells were distributed throughout layers II and III as well as within layers V and VI. Labeled non-pyramidal neurons were not reduced in the parietal cortex in AD compared to controls. In contrast, GluR2/3-positive pyramidal neurons were reduced by 70% within layers II and III and 62% within layers V and VI of the parietal cortex of AD cases compared to controls. These latter data suggest that in the parietal cortex GluR2/3 pyramidal neurons are particularly vulnerable to pathologic insult. We are now examining the extent to which AMPA receptors contribute to the degeneration of these cells.

CHARACTERISATION AND LOCALISATION OF ALTERNATIVE SPLICED ISOFORMS OF THE NMDAR1 mRNA IN THE HUMAN HIPPOCAMPUS. X.F. Huang*, G. Dixon, S.V. Catts, P.B. Ward, N. Di Girolamo, D. Wakefield, G. Paxinos, and A. Lloyd. Schools of Pathology, Psychiatry, & Psychology. UNSW, Sydney 2052, Australia

The gene for human N-methyl-D-aspartate receptor 1 (NMDAR1) has recently been cloned and in the rat eight alternatively spliced, regionally distributed, and functionally unique isoforms have been identified. We sought to define the presence and distribution of alternatively spliced NMDAR1 mRNAs in adult human hippocampus. Human brains were obtained at autopsy from five individuals without neurological disease with postmortem delay of 4 to 24 hours. Total RNA was prepared from specific regions of human hippocampal tissue. Reverse transcriptase polymerase chain reactions was used to amplify across the two predicted splice junctions of the human NMDAR1 cDNA to identify possible isoforms in the human gene. The amplified cDNAs were characterised by Southern hybridisation using oligonucleotide splice junction probes specific for each of the unique splice sequences. In the amino terminal region, three apparent splice isoforms amplified from the rat brain RNA and four amplified products were seen in the human hippocampal RNA. In the carboxyl terminal region, there were five amplified products in both rats and human. Northern analysis with rat brain and human hippocampal RNA demonstrates a band at 4.4 Kb prolonged gel electrophoresis and in Northern hybridisation it allowed preliminary definition of regional quantitative differences in the NMDAR1 mRNA isoforms. The in situ hybridisation studies showed an heterogenous distribution of NMDAR1 isoforms in the human hippocampal formation. The dentate gyrus, CA4, and CA3 had a similar intensity of mRNA expression of all six splice isoforms, whereas NMDAR1-2 isoform appeared to have considerably lower expression in CA1 and was almost absent in the parasubiculum. These data may provide clues to the differential susceptibility to pathological processes including ischaemia, epilepsy, and schizophrenia. Supported by the NH&MRC of Australia.

IMMUNOLOCALIZATION OF GLUTAMATE AND GLUTAMATE RECEPTORS IN THALAMOCORTICAL, THALAMOSTRIATAL AND CORTICOSTRIATAL SYSTEMS IN TURTLES. M. Fowler* and A. Reiner. Dept. Anatomy & Neurobiology, University of Tennessee, Memphis, TN 38163.

Although thalamocortical, thalamostriatal and corticostriatal projection systems are present in turtles, it is uncertain if these systems utilize glutamate as a neurotransmitter, as has been shown to be the case in mammals. Immunohistochemical localization of glutamate and three of the AMPA type glutamate receptors subunits (GluR2/3 and GluR4) were used to address this issue. Glutamate immunolabeling was found to be intense in essentially all neurons of the dorsomedial and dorsolateral thalamic nuclei in turtle, which appear to correspond to the mammalian intralaminar thalamic nuclei. Intense glutamate immunolabeling was also observed in neurons of the nucleus reuniens, and less intense glutamate labeling was observed in neurons of the nucleus rotundus and dorsal lateral geniculate nucleus. These neurons relay auditory (reuniens), visual tectal (rotundus) and retinal (geniculate) information to the telencephalon. Within the telencephalon, the pallial cell groups receiving thalamic input (i.e. the dorsal cortex, pallial thickening and the dorsal ventricular ridge) were in rich in glutamatergic neurons. Additionally, these regions were pervasively rich in neurons possessing GluR2/3 subunits and a small subpopulation were rich in GluR4 subunits. A similar distribution of GluR2/3 and GluR4 subunits was found in the striatal part of the basal ganglia, and the pallidal region was specifically rich in large neurons possessing GluR4 subunits. These results indicate the thalamostriatal, thalamocortical and corticostriatal projections systems of turtles to be glutamatergic. Supported by NS-19620, EY-05298 (A.R.).

HUMAN NT2-N NEURONS EXPRESS THE NR1 and NR2B SUBUNITS OF THE NMDA RECEPTOR **P. McGonigle*, L. Lu, B.B. Wolfe and M. Munir Departments of Pharmacology, University of Pennsylvania and Georgetown University.**

In this study, we used modulation of glutamate excitotoxicity to characterize pharmacological properties and specific antibodies to detect individual subunits of NMDA receptors expressed by terminally differentiated NT2 neurons. The glycine site antagonist 7-chlorokynurenic acid completely blocked glutamate toxicity in a dose-dependent manner. The polyamine agonists spermine and spermidine enhanced glutamate toxicity in a dose-dependent manner consistent with expression of a NR1-NR2B combination of subunits. The polyamine antagonists putrescine and di-ethylene triamine had no effect on toxicity. Surprisingly, the putative inverse agonists diaminodecane and diaminododecane also enhanced toxicity in a dose-dependent manner. The atypical antagonist ifenprodil completely blocked glutamate toxicity with a uniformly high affinity characteristic of interaction with the NR1-NR2B combination of subunits. Approximately 300 fmol/mg protein of the NR1 subunit was detected with a specific antibody directed against a fusion protein containing a region common to all of the known splice variants of the NR1 subunit. Approximately 700 fmol/mg protein of the NR2B receptor was detected with a specific antibody directed against this subunit. Neither protein was detectable in undifferentiated cells. In contrast, only 12 fmol/mg of the NR2A subunit was detected in NT2-N cells and 7 fmol/mg protein was detected in undifferentiated cells. The pharmacological and immunological results indicate that a functional NR1-NR2B combination of subunits are expressed by these cells. There is no pharmacological evidence that these cells form a functional combination of NR1 and NR2A subunits. The effects of the inverse agonists may indicate the expression of a novel splice variant of the NR1 subunit in these cells. (Supported by NS-08803 and GM-34781)

N-METHYL-D-ASPARTATE RECEPTOR (NMDAR1) SPLICE VARIANTS DIFFER IN SELECTED REGIONS OF RAT CNS. M. Brodsky*, K. Elliott, B. Warwick and C. E. Inturrisi. Department of Pharmacology, Cornell University Medical College, New York, NY 10021.

The NMDA receptor plays an important role in excitatory neurotransmission and neuronal plastisity, and is thought to be involved in the mechanisms of chronic pain and in mu opioid tolerance. Pharmacologically distinct (homomeric) receptors are expressed from the eight cloned splice variants of the NMDAR1 subunit (1a,1b through 4a,4b) (Hollmann et al., Neuron 10:943, 1993). Thus, the pharmacological profile of a neuronal population may depend on the ratio of splice variants it expresses. We have used a ribonuclease protection assay followed by phosphorimager analysis to quantitatively define the NMDAR1 splice variant ratios for selected regions of rat CNS involved in nociceptive processing and opioid antinociception, and for the cerebellum (Cblm). ^{32}P-labelled riboprobes were directed against the N- and C-terminal splice sites, and tailored (by PCR) to yield different size protected fragments. The ratio of the -a to -b types of NMDAR1 splice variants is 1:2 in the spinal cord dorsal horn (SpC), 3:2 in nucleus raphe magnus (NRM), 1:1 in medial hypothalamus (Hyp), 5:1 in periaqueductal grey (PAG), 2:1 in midline thalamus (Thal), 5:2 in sensorimotor cortex (Ctx), and 1:1 in Cblm. The ratio of the NMDAR1 variants at the C-terminal splice site, i.e. -1 to -2 to -3 to -4, is (in %) 7:23:4:66 in SpC, 5:31:2:62 in NRM, 7:22:5:66 in PAG, 17:18:9:56 in Hyp, 15:26:8:51 in Thal, 41:17:15:27 in Ctx, and 13:31:5:51 in Cblm. Thus, while SpC, NRM and PAG appear to have similar % ratios of the splice variants at the C-terminal site, they differ markedly from the ratios in diencephalon, Ctx, and Cblm. Our results illustrate the differential distribution of the NMDAR1 splice variants in rat CNS, which may contribute to the regional variation in the pharmacological properties of the NMDA receptor. ***IN SITU* HYBRIDIZATION STUDIES OF THE DISTRIBUTION OF A CPP-BINDING PROTEIN IN RAT BRAIN.** R. Pal*, K.T. Eggeman, K.N. Kumar, A.E.Allen and E.K. Michaelis. Dept. of Pharmacol. & Toxicol., the Higuchi Biosciences Center, and the Mental Retardation Research Center, Univ. of Kansas, Lawrence, KS 66045.

A complex of proteins that has recognition sites for NMDA receptor ligands was isolated from rat brain synaptic membranes (Kumar et. al., *J. Biol. Chem.* **269,** 27384-27393, 1994). Antibodies to three of the proteins, a 70 kDa glutamate binding protein (GBP), a 54 kDa CPP-binding protein, and a 60 kDa glycine/TCP-binding protein were used to demonstrate the presence of these three proteins in the complex purified from synaptic membranes. The antibodies raised against the CPP-binding protein labeled an 80-83 kDa protein in synaptic membranes and were used to screen hippocampal cDNA libraries and to clone a 3.8 kb cDNA insert (Kumar et al., this meeting). A 1.4 kb PstI fragment of the original 3.8 kb clone was used to synthesize the antisense and sense cRNA probes used in the *in situ* hybridization studies. The probes were labeled with [^{35}S]CTP. The results of the *in situ* hybridization studies were indicative of high levels of expression of the mRNA for the CPP-binding protein in cerebellum, hippocampus, dentate gyrus, and olfactory tubercle. Intermediate levels of expression were detected in cerebral cortex, and relatively low levels in the inferior and superior colliculus. An almost identical pattern of labeling was observed when the antisense cRNA probes for the glutamate-binding protein were used. The anti-CPP-binding-protein antibodies labeled the same population of cells as that labeled by the cRNA probes structured on the basis of the 3.8 kb cDNA that was cloned. Based on the results of both the *in situ* hybridization studies and the immunohistochemical labeling it appeared that the CPP-binding protein of an NMDA receptor-like complex was widely distributed in the rat brain and was most highly expressed in areas of strong glutamatergic activity. MEMANTINE INDUCES HEAT SHOCK PROTEIN HSP-70 IN THE POSTERIOR CINGULATE AND RETROSPLENIAL CORTEX OF RAT BRAIN. S.Tomitaka*, K.Hashimoto, N.Narita, Y.Minabe and A.Tamura. Natl. Inst. Neurosci., NCNP, Tokyo and Dept. of Psychiatry, Tokyo Women's Medical College

NMDA antagonists, e.g. MK-801 have been investigated for their therapeutic potential in brain ischemia and other neuropathological disease. However, the clinical potential of these agents may be limited by the observations that these NMDA antagonists cause neuronal injury or reversible neuronal swelling. This damage is manifest as a vacuolization in neurons of the cingulate and retrosplenial cortices as well as induction of the 70 kDa heat shock protein (HSP-70) in neurons. Memantine (1-amino-3,5-dimethyladamantane) has been used clinically for the treatment of Parkinson's disease. It has been reported recently that memantine have antagonistic effect at the NMDA type of glutamate receptor. Although numerous studies have reported the NMDA antagonistic properties of memantine, there are no data on neurotoxic effects of memantine in vivo. To investigate the effect of memantine in the CNS, the experiments were designed to examine the neurotoxic potential of memantine using the induction of HSP-70 as a marker of neuronal damage. Memantine (10-75 mg/kg. i.p.) was injected into male SD rats. The immunochemistry of HSP-70 was studied 24 hr after administration of memantine. The administration of memantine produced the HSP-70 in the posterior cingulate and retrosplenial cortex of rat brain, similar with other NMDA antagonists. This result suggest that memantine have antagonistic effect at NMDA receptor in vivo and raise the possibility that memantine may cause neuronal injury.

CONFOCAL IMAGING OF A GLUTAMATE RECEPTOR SUBUNIT ON LIVING HIPPOCAMPAL NEURONS S.A. Richmond[1], A.J.Irving[2], F. Michaelangelli[3], E. Molnar[4], J. McIlhinney[4], W.W. Anderson[1]*, J.M. Henley[1] and G.L. Collingridge[1] [1]Dept. of Anatomy, Medical School, University of Bristol, Bristol BS8 1TD, U.K. Depts of Pharmacology [2] and Biochemistry [3], University of Birmingham, Birmingham B15 2TT, U.K. [4] MRC Anatomical Neuropharmacology Unit, University of Oxford, Oxford 0X1 3TH, U.K.

In order to observe glutamate receptor subunits in a living system, well-characterised polyclonal antibodies directed against the extracellular N-terminus of the AMPA receptor subunit GluR1 were applied to hippocampal neurons in culture. GluR1 immunoreactivity was visualised by the addition of fluorescent secondary antibody and by confocal laser-scanning microscopy (BioRad MRC 600 U/V). On the soma and dendrites of mature neurons puncta of immunoflourescence were observed. In contrast glial cells were immunonegative. In double-labelling experiments the majority of GluR1 immunoreactivity was associated with that of synaptophysin, although some extrasynaptic labelling was also apparent. Using a technique that enables discrimination between membrane-bound and intracellular immunoreactivity, cytosolic GluR1 immunofluorescence was present predominantly in the soma of hippocampal neurons, although some intracellular immunoreactivity was also present in primary dendritic regions. In addition, a few neurons that did not express GluR1 on the plasma-membrane displayed considerable cytosolic GluR1 immunoreactivity. These results demonstrate the viability of differentiating between populations of surface and intracellular receptor subunits.

SYNAPTIC AND SUBSYNAPTIC DISTRIBUTION OF GLUTAMATE RECEPTOR SUBUNITS IN CEREBRAL CORTEX. Weinberg R.J.,* Popratiloff A., Wenthold R.J.† and Kharazia V.N. Dept. Cell Biology, UNC, Chapel Hill, NC 27599; †Lab of Otolaryngology, NINDS 20892.

LM immunocytochemistry suggests that glutamate receptors concentrate at synapses. This conclusion is generally supported also by EM studies, though non-synaptic staining has also been reported. To determine more accurately the location of these receptors, a new postembedding gold technique was used to localize glutamate receptor subunits in rat S-1. Analysis of gold particles coding for AMPA receptor subunits GluR1, 2, 3 and NMDAR1 revealed that labeling concentrated over active zones, with maximal density over the synaptic cleft and postsynaptic membrane. Significant labeling was also found in presynaptic terminals, especially for NMDA receptors. Subunits were also found within dendritic cytoplasm, concentrating ~20 nm inside the postsynaptic membrane. Distribution of all four receptor subunits across the synaptic cleft was similar; however, subunits differed in their tangential distribution along the active zone: GluR1 and NMDAR1 concentrated in central parts of the active zone, whereas GluR2 was denser at its periphery.

These results demonstrate that Glu receptor subunits are mainly at synapses. Subsynaptic labeling may represent a reserve pool of receptor proteins. We hypothesize that rapid translocation of receptor from this pool into the synaptic membrane may be involved in certain types of synaptic plasticity. Supported by NIH # NS-29879 (to RJW)

722.12

SYNAPTIC LOCALIZATION OF AMPA AND NMDAR1 RECEPTOR SUBUNITS IN RAT CEREBRAL CORTEX. Kharazia V.N.*, Phend K., Wenthold R.J† and Weinberg R.J. Dept. of Cell Biology & Anatomy, UNC, Chapel Hill, NC 27599; †Laboratory of Otolaryngology, NINDS, NIH, Bethesda, MD 20892.

We used postembedding immunogold labeling to study synaptic localization of glutamate receptor subunits on dendrites of cortical neurons. In neuropil of layers II-III of S-1, AMPA-positive axospinous synapses were ten times more frequently encountered than were AMPA-positive axodendritic synapses, whereas NMDA-positive synapses were only 4 times more likely to be axospinous than axodendritic. At least 90% of synapses double-labeled for GluR1 and GluR2 were axospinous, whereas only 75% of synapses double-labeled for GluR2/3 and NMDAR1 were axospinous. Since the large majority of cortical synapses are axospinous, these data suggest that NMDA receptors are concentrated on dendritic shafts, whereas AMPA subunits are more uniformly distributed. Supporting a differential distribution of AMPA and NMDA subunits, NMDAR1 staining in layers I-IV was over smaller active zones than GluR1 or GluR2/3 staining ($p < 0.001$). Since most synapses onto GABAergic neurons are axo-dendritic, we examined material double-labeled for receptors and GABA. AMPA staining over axodendritic synapses onto GABA-positive profiles was common, but NMDA staining was rare. Thus, NMDA appears to concentrate at synapses onto dendritic shafts of pyramidal neurons. Supported by NIH # NS-29879 (to RJW)

AMPA AND NMDA RECEPTOR SUBUNITS UNDERLYING FINE CALIBER PRIMARY AFFERENTS. Popratiloff A*, Wenthold R.J.†, Weinberg R.J. and Rustioni A., Dept of Cell Biology & Anatomy, UNC, Chapel Hill, NC 27599; †Lab. of Otolaryngology, NIH, Bethesda, MD 20892.

Glutamate is the major neurotransmitter in primary afferents terminating in the dorsal horn of the spinal cord. Different classes of primary afferents may be presynaptic to different glutamate receptors. We report initial results of an EM study of the distribution of these receptors, using a new postembedding immunogold technique. Rats were perfused with mixed aldehydes; sections, postfixed in tannic acid (rather than osmic acid) and treated with iridium tetrabromide and phenylenediamine, were processed as described previously (Phend et al., 1995) using antibodies for the AMPA subunits GluR1, GluR2/3 and NMDAR1. The distribution of gold particles coding for these antigens over different types of terminals was studied. Counts from all terminals in lamina II identifiable on morphological grounds as primary afferent terminals showed that the large majority of particles were in a region between 30 nm outside, and 40 nm inside the postsynaptic membrane. Particles coding for GluR1 and GluR2/3 were almost exclusively associated with the postsynaptic membrane; particles for NMDAR1 were also present more than 30 nm presynaptic to the active zone. Preliminary results indicate that primary afferent terminals of different morphologies, likely to exhibit differing functional properties, contact the GluR1, GluR2/3, and NMDAR1 subunits in differing proportions. Terminals likely to release both glutamate and neuropeptides were more likely than others to be presynaptic to NMDA receptors.

EXPRESSION OF THE NMDAR1 GLUTAMATE RECEPTOR SUBUNIT IN COS-7 CELLS. J.E. Roth*, P.H. Franklin, T.F. Murray and M. Leid. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

COS-7 cells were transiently transfected with the rat NMDAR1 (NR1) subunit and the pharmacologic properties of homomeric NR1 recombinant receptors characterized using radioligand binding techniques. In addition, transient transfection of NR1 using electroporation and calcium phophate precipitation methods were compared. A 3.5 kb HindIII - StuI fragment containing the NR1-1a coding and flanking sequences was excised from pN60 (a gift from S.Nakanishi) and inserted into the HindIII - SmaI digested pTL1 (Leid et al., Cell. 68:377, 1992) to yield the eukaryotic expression vector NR1. COS cells were cultured in Dulbecco's modified Eagle's medium and plated to a density of 5×10^5 cells/10cm plate one day prior to transfection. Cells were transiently transfected with 10 µg NR1 using a BTX ECM600 electroporation system or by calcium phosphate precipitation. Inter-plate transfection efficiency was normalized by co-transfection with pSG5-LacZ (a gift from Ph. Kastner), a high copy number β-galactosidase expression vector. Membrane homogenates derived from transiently transfected COS cells showed specific binding of the glycine site antagonist [^{3}H]5,7-dichlorokynurenic acid (20 nM) 24 hours post-transfection. Expression of NR1, as demonstrated by specific binding of [^{3}H]5,7-dichlorokynurenic acid, was enhanced ten-fold (1.8 pmol/mg protein) in COS cells transiently transfected by electroporation relative to those transfected by calcium phosphate.

This work was supported by an NIH grant to TFM (DA 07218).

GLUTAMATE RECEPTOR SUBTYPES ON DISSOCIATED MAGNOCELLULAR BASAL FOREBRAIN NEURONS IN CULTURE D.J. Waters, T.G.J. Allen, J.A. Sim & D.A. Brown* Department of Pharmacology, University College London, Gower Street, London WC1E 6BT, UK.

Glutamate is the principal fast excitatory neurotransmitter in the mammalian CNS. We have attempted to identify subtypes of glutamate receptor present on magnocellular cholinergic cells from rat basal forebrain nuclei (BFN). BFN neurons were cultured from 12-14 day-old Sprague-Dawley rats (Allen, Sim & Brown (1993) J. Physiol. 460 91-116.) After 5 days to 3 weeks in culture, magnocellular cells were voltage-clamped using the whole-cell variant of the patch-clamp technique. Responses to glutamate receptor agonists were studied by pressure-ejection from a glass micropipette or by bath-application.

Pressure-ejection of N-methyl-D-aspartate (NMDA) elicited an inward current with two components; one rapidly desensitizing and one sustained. Both components were sensitive to 1mM magnesium and to 2-amino-5-phosphonopentanoate (AP5). Pressure-ejection of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) elicited an inward current with rapidly desensitizing and sustained components. Both components were antagonised by kynurenic acid and by 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). Bath-application of AMPA produced a large steady-state current with an EC_{50} of approximately 3μM. Bath-application of the benzothiodiazide cyclothiazide greatly potentiated AMPA-induced current whereas the lectin concanavalin A had little effect. Pressure-ejection of the non-NMDA agonists kainate and domoate elicited a sustained inward current, which was sensitive to both kynurenic acid and CNQX. Responses to pressure-ejection of domoate were reduced, but not eliminated, by bath-application of AMPA. These data indicate the presence of an NMDA-type, an AMPA-type and possibly a kainate-type receptor on these cells.

ONTOGENESIS OF STRIATAL AMPA RECEPTORS IN THE RAT. M.W. Jakowec*, V. Jackson-Lewis and S. Przedborski. Dept. Neurol., Columbia University, New York, NY, 10032.

Glutamate is a major component of the chemical neuroanatomy of the basal ganglia. Its neurotransmitter/neuromodulator and neurotoxic actions are mediated by a variety of receptors. Thus far, little is known about the ontogeny of these receptors in the striatum. Therefore, we have examined the distribution of the transcripts GluR1 and GluR2 which encode subunits of the non-NMDA α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor within the striatum of the developing rat brain using *in situ* hybridization histochemistry. We found that transcripts encoding the subunit GluR1 are expressed at high levels in the striatum at postnatal days 2 and 7. In contrast, they are expressed at low levels in the adult striatum. Transcripts encoding the AMPA subunit GluR2 seem to follow the same pattern in that they are expressed at a higher level in neonates than in adults. Nevertheless, the difference in the level of expression between the neonate and the adult striatum is less dramatic for GluR2 than for GluR1. These results indicate that there are fundamental phenotypic differences in the subunit composition of AMPA receptors of neonates and adults. This phenomena may play a significant role in the establishment of proper synaptic circuitry within the developing striatum as well as contribute to differences in susceptibility to injury and disease in the aging brain.

DEVELOPMENTAL STUDIES OF NMDA RECEPTOR SUBUNITS IN RAT BRAIN. **J.-H. Luo, Y.-H. Wang, T.Z. Bosy, R.P. Yasuda, B.B. Wolfe*. Dept Pharmacology Georgetown Univ. Sch. of Med., Washington,D.C. 20007**

Developmental profiles of NMDA R1, R2A, and R2B subunits were determined in rat CNS. Quantitative immunoblots were used to determine protein levels. In all brain areas measured, levels of NR1 subunit increased 2.5-4.5 fold during the first three weeks after birth. There were large differences in the amounts (pmol/mg) of NR1 subunit expressed (2.5, HP; 1.3, CX; 1.0, OB; 0.85, MB; 0.41, CB). For NR2A, low levels were expressed in newborns followed by a progressive increase of this subunit from P7 to P22 at which time adult levels were reached. The ontogenic profiles of NR1 and NR2A were similar to each other and correspond with mRNA expression studies. Furthermore, the absolute numbers obtained were close to those reported for [3H]MK-801 binding site densities. In contrast, ontogenic profiles of NR2B subunit were distinct in all brain regions. Typically, NR2B was expressed at relative high levels at early ages (P2~P4) which sometimes increased modestly over the next several days and then decreased. Peak densities of NR2B subunit in various brain regions were attained at different times (P4, CB; P7, CX; P11, MB; P16, HP). In OB, the levels of NR2B subunit were almost constant over the entire period tested. In CB, NR2B declined after P7 to undetectable levels at P22. These data provide a rationale to explain functional changes in NMDA receptor properties in different brain regions during development. (Supported by NS28130, AG09973, AG09884)

GABA RECEPTORS V

723.1

REGULATION OF $GABA_A$ α1 SUBUNITS, NEURONAL GROWTH AND SURVIVAL BY $GABA_A$ RECEPTOR LIGANDS IN EMBRYONIC RAT BRAINSTEM CULTURES. J. Liu*[1], A.L.Morrow[2] and J.M.Lauder[1]. [1]Dept. of Cell Biology and Anat., [2]Dept. of Psychiatry, Univ. of N. Carolina, Chapel Hill, NC 27599.

Previous studies have indicated the presence of functional α, β, γ and δ subunits of $GABA_A$ receptors in embryonic rat brainstem cultures. GABA or $GABA_A$ antagonist bicuculline differentially regulate the survival of brainstem monoamine and GABA neurons (Liu et al., 1994). In the current study, dissociated cultures were prepared from embryonic day 14 (E14) brainstem and cultured in BME + 10% NuSerum for 1 day *in vitro* (DIV) , then treated for 48 hrs with 10 μM GABA and /or 10 μM bicuculline or the organochlorine pesticide dieldrin in serum-free medium. Effects of GABAergic agents on relative levels of α1 protein were determined by quantitative immunobinding assays and absolute amount of α1 mRNA transcripts were quantified by competitive PCR. Results indicated that expression of α1 protein and mRNA were up-regulated by both bicuculline and dieldrin. Effects on survival of neurons were quantified by counts of immunoreactive cells. GABA promoted survival of 5-HT and TH neurons. Dieldrin blocked this effect, and by itself had inhibitory effects on survival of these cells and stimulatory effects on survival of GABA neurons. Cell size, shape and complexity of neurite outgrowth by 5-HT, TH and GABA neurons were analyzed by computer-assisted morphometry. GABA, bicuculline and dieldrin also had differential effects on neurite outgrowth by these neurons depending on their neurotransmitter phenotype. These results support the hypothesis that GABA is an important trophic signal for developing monoamine neurons and may regulate expression of its own receptors during brain development. $GABA_A$ antagonists, such as organochlorine pesticides may interfere with this regulation. Supported by NIEHS grant to JML. The authors thank Dennis Grayson for providing α1 internal standards for competitive PCR.

723.2

$GABA_A$ RECEPTOR SUBUNIT mRNA PROFILES IN SINGLE DEVELOPING CEREBELLAR GRANULE CELLS. E. V. Grigorenko*, T. Y. Rikhter and H. H. Yeh. Dept. Physiology & Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157

Although $GABA_A$ receptor ($GABA_AR$) subunits are differentially expressed during brain development, the changes in subunit profiles remain to be analyzed for individual neurons. We are examining the molecular profiles of $GABA_AR$ subunits in the postnatal cerebellum and in single cerebellar granular cells developing *in situ* and in culture.

In whole cerebellar tissue, prominent expression of the α1, β2 and γ2S subunits were detected by birth and remained relatively constant throughout the first two postnatal weeks. Other subunits tended to increase either progressively (γ2L) or abruptly (e.g. α6 and δ) around the time of formation of the granule cell layer. Granule cells derived from postnatal day 8 cerebellum were also maintained in long term cultures. Single cells maintained for 4, 9 and 13 days in culture (DIC) were harvested and profiled for representative messages normally expressed in mature granule cells, i.e., α1, α6, β2, β3, γ2S and δ. To date, the α1 and β2 messages have been detected by 4 DIC, and α6 by 9 DIC. The abrupt increase in the expression of the δ subunit message was observed around 7 DIC.

Our data indicate that $GABA_AR$ subunit genes are differentially and developmentally regulated. The demonstration at the single cell level carries the analysis to identified individual developing neurons, providing prerequisite information for a systematic developmental and functional analysis of $GABA_AR$ expression in the cerebellum.

723.3

GABA$_A$ CURRENTS IN DEVELOPING MEDIAL SEPTUM/DIAGONAL BAND (MS/DB) NEURONS. S.-H. Hsiao[1], J.R. West[2] & G.D. Frye[1]*. Dept. of Med. Pharmacol. & Toxicol.[1], Dept. of Med. Anat.[2], Texas A&M Univ. Col. of Med., College Station, TX 77843-1114

The GABA$_A$ receptor is a ligand-gated Cl^- channel which plays a prominent inhibitory role in the adult central nervous system. During postnatal development, the expression of GABA$_A$ receptor subunits undergoes major changes (Laurie et al., J. Neurosci. 12:4151, 1992) and receptor function may shift from mediating excitation to inhibition (Gaiarsa et al., J. Neurobiol. 26:339, 1995). The present study examined changes in GABA$_A$ currents in acutely dissociated neurons from MS/DB of postnatal male and female Sprague Dawley rats. Two age groups of rats were examined: pups (pn4-10) and juveniles (pn11-16). GABA (0.3-300 μM) response curves were concentration- and development-dependent. The maximum GABA response of the juvenile group (338.7±66.4 pA/pF, n=12) was significantly larger than that of pups (176.8±25.8 pA/pF, n=11; p>0.05). The Ka values changed as well (7.66±1.50 μM juveniles vs 3.64±0.71 μM pups; p<0.05). The Hill coefficient (1.71±0.11 vs 1.86±0.16; p>0.05) and capacitance (16.12±1.47 vs 12.95±1.26; p>0.05) did not change for juveniles vs pups, respectively. These data suggest that there are significant changes in GABA$_A$ receptor function in MS/DB neurons during early development in the rat. Supported in part by AA06322 (GDF).

DEVELOPMENTAL INDUCTION OF GABA$_A$ RECEPTOR α1-SUBUNIT POLYPEPTIDES IN CHICK EMBRYO CORTEX AND DERIVED NEURONS IN CULTURE. J.D. Miranda* and E.M. Barnes, Jr. Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

In order to produce high-titer antibodies which are capable of recognizing native GABA$_A$ receptor subunits, we have produced fusion proteins containing selective receptor sequences from the intracellular loop region. The chick GABA$_A$ receptor α1(331-381) subunit sequence was expressed as a fusion protein containing a hexahistidyl leader peptide, purified by Ni^{2+}-affinity chromatography, and used for rabbit immunizations. The resulting RP4 antiserum showed a high titer for immunoprecipitation of receptor ligand binding to cortical extracts from chick embryos 16 days in ovo. Representing the threshold for antibody saturation, 1 μl of crude antiserum was able to immunopreciptate 61% of ^{3}H-flunitrazepam binding. The antiserum is also selective because no cross reaction was detected on slot blots of β2S(317-428) or β4S(316-437) fusion proteins. Western blots utilizing a 1:1000 dilution of the RP4 immune serum showed a reaction with a single 50-51 kDa polypeptide from chick embryo cortex. This protein was not detected in heart, liver or skeletal muscle. Similar analysis on immunoblots revealed an increase in the expression of the GABA$_A$ receptor α1-polypeptide in chick cortical neurons from day 2 to day 6 in culture and in chick cerebral cortex from embryonic to adult stages. In both cases this pattern of developmental expression was similar to that found previously for induction of the major ligand binding sites of GABA$_A$ receptors.

723.5

A RHO-LIKE GABA RECEPTOR SUBUNIT IS TRANSIENTLY EXPRESSED IN NEONATAL RAT BRAIN. M.Mladinic,E.Cherubini*.Biophys.Lab.,Int.Sch. Adv. Studies (SISSA), 34013Trieste, Italy.

A novel bicuculline and baclofen insensitive chloride mediated response has been described in neonatal hippocampus (Strata&Cherubini, J.Physiol.480,493-503,1994).This response clearly resembles the one present in the retina and supposed to be mediated by GABA$_C$ receptors. It is conceivable that this new receptor channel is an heterooligomeric protein assembled from the rho1 subunit.To see whether a rho-like GABA receptor subunit is present in the rat brain, *in situ* hybridization on brain sections from neonatal and adult rats was performed. Rho1 and rho2 GABA receptor subunit specific antisense oligonucleotide probes as well as another probe that revealed both rho1 and rho2 subunits (rho1+rho2) have been used. The rho1 probe was homologous to the 1325-1372 nucleotide sequence of the rho1 gene (Cutting et al., Proc.Natl.Acad.Sci.USA, 88,2675,1991) and the rho2 probe to the 1249-1296 nucleotide sequence of the rho2 gene (Cutting et al.,Genomics,12,804,1992). The rho1+rho2 probe was homologous to the nucleotide sequence of the rho1 gene (1130-1174) and nucleotide sequence of the rho2 gene (1042-1086). As a positive control a beta3 subunit specific antisense probe was used. Negative control were sense oligonucleotide probes. The same probes were utilized to hybridize sections of the rat retina. The autoradiographic signals obtained with rho1 and rho2 probes were low in the neonatal as well as in the adult brain. However signal obtained with rho1+rho2 probe was suprisingly strong in the neonatal brain sections, expecially in the forebrain or in the hippocampus. In the retina high signals with all three rho probes were obtained.In the adult brain the signal obtained with rho1+rho2 probe was present only in the cerebellum but comparing to neonatal brain was lower.These results strongly suggest that a novel rho-like subunit is expressed in the neonatal brain during a critical period of postnatal development.

DIFFERENTIAL INTERACTION BETWEEN NEUROACTIVE STEROIDS AND DIAZEPAM AT THE GABA$_A$ RECEPTOR IN RAT FETAL VS ADULT BRAIN. C.K. Kellogg* and G.L. Pleger. Dept. of Psychology, Univ. of Rochester, Rochester, New York, 14627.

Specific neuroactive steroids elicit positive modulatory effects on the GABA$_A$ receptor. This observation, coupled with our observations that prenatal exposure to diazepam (DZ) alters neural and behavioral stress responses that emerge over adolescent development under the influence of gonadal steroids, led us to hypothesize that neuroactive steroids may exert organizational influences during development via the GABA$_A$ receptor. Early exposure to DZ could alter this influence. Measuring GABA-stimulated ^{36}chloride influx in synaptoneurosomes prepared from the cerebral cortex of adult males and fetal forebrain at 20 days gestation. we evaluated the interaction between DZ and neuroactive steroids that affect the GABA$_A$ receptor and that could be present in fetal tissue during gestation. The 3α,5β progesterone metabolite, pregnanolone (P, 500 nM), increased the potency (decreased the EC$_{50}$) of GABA in both adult male and mixed-sex fetal tissue by 38-48%. DZ also increased the potency a comparable amount in adults, but the effect was much more pronounced in fetal tissue (a 77% decrease). The in vitro addition of both DZ and P had an additive effect in the adult but in fetal tissue, the potent effect of DZ masked an effect of P. The testosterone metabolite, androsterone (2.5 μM), also decreased the EC$_{50}$ in adult and fetal tissue (separated by sex), but the effect was more pronounced in fetal tissue, particularly in female forebrain. Supported by Grant No. DA 07080.

723.7

PRENATAL DIAZEPAM EXPOSURE: INFLUENCE ON BASAL AND STRESSOR-INDUCED mRNA LEVELS FOR GABA$_A$ RECEPTOR SUBUNITS. A.A. Roberts*, M.H. McCollum, G.L. Pleger, and C.K. Kellogg Dept. of Psychology, Univ. of Rochester, Rochester, New York, 14627.

Developmental modulation of GABA$_A$ receptor function, via administration of diazepam (DZ) to the pregnant dam, alters behavioral and GABA$_A$ receptor responsiveness to stressors in the exposed adult rat. Recent studies have also shown that the molecular composition of the GABA$_A$ receptor is linked to pharmacologic responsiveness of the receptor. Furthermore, exposure to acute environmental challenges changes mRNA levels of specific receptor subunits. In this study, we evaluate the effect of exposure to DZ (2.5 mg/kg) over gestational days 14-20 on basal mRNA levels for α_1 and α_2 GABA$_A$ receptor subunits in the cerebral cortex, hippocampus, and hypothalamus of adult (60-70 days) male rats. The results are compared to those from animals exposed over the same period to vehicle (40% propylene glycol, 10% ethanol) or co-exposed to DZ and the antagonist flumazenil (10 mg/kg). Early exposure led to a significant 15% increase in the basal level of mRNA for α_1 in the cerebral cortex. This effect of DZ was prevented by co-exposure to flumazenil. There was no change in α_1 mRNA in any other region, and α_2 mRNA was unaffected in all regions examined. Because early DZ exposure interferes with environment-specific social behavior, we have examined the effect of this challenge on mRNA for the two subunits. In naive adult male rats, cortical mRNA for α1 is significantly increased by 10 min of testing in either a familiar or novel environment. The impact of early DZ exposure on this response is being evaluated. Supported by Grant No. DA 07080.

723.8

GABA$_A$-Cl RECEPTOR COMPLEX IS INVOLVED IN SEXUAL DIFFERENTIATION OF PARENTAL BEHAVIOR.

Del Cerro, M.C.R. (3); Pérez-Laso, C.; Rodríguez-Zafra, M.; Ortega, E. (2); Claro, F.; Ambrosio, E.; Izquierdo, M.A.P.; Guillamón, A. and Segovia, S. (1) . Departamento de Psicobiología, Ciudad Universitaria s/n, U.N.E.D. 28040 MADRID. SPAIN. (2) Departamento de Bioquímica y Biología Molecular, Facultad de Medicina. Universidad de Granada. GRANADA. SPAIN.*

In this work we study the effects of experimentally induced changes in the opening frequency of Cl^- channel of the GABA$_A$/BDZ receptor complex on the sexual differentiation of maternal behavior (MB) and its correlation with morphological and/or endocrine alterations. Our rationale is as follows: 1) MB is a sexually dimorphic behavior; 2) MB is under hormonal control and tonic vomeronasal inhibition; 3) The vomeronasal system (VNS) is a sexually dimorphic neural system; 4) GABA is present in about 90% of the accessory olfactory bulb (AOB) granular populations; 5) Diazepam (DZ) postnatal injections during neural sexual differentiation period induce a feminine morphological pattern of the AOB (volume and neuron numbers)in the male rat and facilitates the induction of MB in virgin females when adult; 6) DZ increases the the opening frequency of the Cl^- channel of the GABA$_A$/BDZ receptor, while Picrotoxin (PIC) reduces it.

We hypothesize that treatment during developmental periods with drugs acting in an opossite way on the GABA$_A$/BDZ Cl^- channel (DZ/PIC), would cause opossite behavioral, morphological and/or endocrine effects.

Fifty rat pups of the Wistar strain were randomly divided in the day of birth into four groups: a) untreated males (UT males N=15); b) 2.5 mg/Kg of DZ s.c. injected males (DZmales N=10); c) untreated females (UT females N=15) and d) .5 mg/Kg PIC s.c. injected females (PIC females N=10). MB test was initiated at 90 days of age, during 12 consecutive days. MBR Software was used to register MB. Blood samples were collected before transcardiac perfusion, AOB removed and histologically processed.

DZ treatment significantly increased the following MB patterns in relation to UT males and PIC females: Nest score, grooming, licking and physical contact to pups and percentage of animals reaching sensitization criteria (2 consec. days of complete retrieval). DZ males did not differ from UT females in any behavioral pattern, except in licking.

Our results indicate that Cl^- channel is involved in the sexual differentiation of the VNS.

LOSS OF Na,K-ATPase α3-ISOFORM mRNA EXPRESSION IN THE INTERNEURONS OF AGING RAT HIPPOCAMPUS. N. B. Chauhan* and G. J. Siegel. Cellular and Molecular Neuroscience, Department of Neurology, Hines VA/Loyola University Chicago, , Hines, IL 60141.

Age-related changes in the expression of Na,K-ATPase α1- and α-3 isoform mRNA in young (3 month, N=6) and old (24 month, N=6) Fischer-344 male rat brains were analyzed. *In situ* hybridization was performed on 5 µm-thick paraffin sections of paraformaldehyde-perfused brains with [^{35}S] labeled riboprobes. Sections were hybridized for 21 h at 42°C, treated with RNase A, washed and exposed to NTB-2 Kodak emulsion for 4 weeks at 4°C. After development and counterstaining with cresyl violet, grains were counted under dark-field illumination with the use of the BioQuant Image Analyzer. Sense controls showed no significant labeling. Total grains were counted in 10 squares of 250^2 µm^2 in each of stratum moleculare (SM), stratum radiatum (SR) and stratum oriens (SO), and over the single interneurons within each square. The results show: (1) Specific labeling of α3-mRNA in the young rat over medium- and large-sized interneurons within SM, SR and SO in the form of grain clusters. (2) In addition, fine grains related to α1- and α3-mRNA are distributed diffusely throughout SM, SR and SO. (3) Aging resulted in more than 95% loss of α3-mRNA clusters over the interneurons within SM, SR and SO, with no significant change in the cell density. (4) The diffuse fine grain density for α3-mRNA, excluding interneurons, in the old rat did not show any significant change relative to the young ($P>0.05$) (ANOVA, unpaired, two-tailed Student-*t* test). (5) The diffuse density of α1-mRNA grains in SM, SR and SO increased by 8 to 10 times in the old rats ($P<0.0001$). The increased α1-mRNA may be due to age-related glial hyperactivity. The loss of neuron specific α3-mRNA in the GABAergic interneurons may reflect an early change in GABA-mediated inhibition underlying age-related memory and cognitive deficits. Multiple Kinases differentially modulate GABAergic conductances in cultured retinal neurons E.Wexler*, P.K.Stanton, S.Nawy; Depts. Neuroscience, Neurology and Ophthalmology and Visual Sciences,

GABA gated chloride channels have been found to be present in all types of retinal neurons. The most thoroughly studied are those belonging to the classically defined "GABAa" subtype. The responses mediated by these receptors are characterized by a rapid, non-voltage dependent desensitization and competitive antagonism by bicuculline. Studies by other investigators have demonstrated the presence of multiple consensus sites for phosphorylation by a variety of protein kinases. The effects of these kinases upon GABAergic responses were investigated in cultures of retinal ganglion cells using fast flow perfusion and conventional whole-cell recording techniques. In agreement with (Veruki and Yeh 1994), we find that the application of Vasoactive Intestinal Peptide (1µM), which is to known activate adenylate cyclase, transiently potentiates GABA evoked responses in ganglion and bipolar cells. Either Phorbol-Diacetate (10µM) or Phorbol-DiButyrate (1µM), in the intracelluar pipette solution did not alter the rate at which GABA responses rundown. In order to examine the effect of PKG mediated phosphorylation we perfused extracellularly with a cell permeant cGMP analogue known to activate PKG. One minute application of either 8Br-cGMP 1 mM resulted in a 15% decline in the GABA evoked response as compared to 2.6% for controls. In sum, ganglion cells are able to fine tune their response to GABA by selective activation of different protein kinases. Supported by NIH grant EY-10254, and ALCON Laboratories.

POSSIBLE ALTERATIONS IN [^{35}S]t-BUTYLBICYCLOPHOSPHOROTHIONATE (TBPS) BINDING AFTER *IN VITRO* PHOSPHORYLATION OF $GABA_A$ RECEPTOR: AN AUTORADIOGRAPHIC STUDY T. Ito*, T. Suzuki, S. E. Wellman and I.K. Ho. Dept. of Pharmacol. & Toxicol., Univ.of Mississippi Med. Ctr., Jackson, MS 39216

Increasing reports on intracellular regulation of the $GABA_A$ receptor show possible involvement of phosphorylation/dephosphorylation of the receptor. Consensus sequences for protein kinase(s) are inferred from some subunit DNA sequences. Electrophysiological studies reveal that desensitization and/or "run-down" of $GABA_A$ receptors may be related to their state of phosphorylation. In this study, alterations in $GABA_A$ receptors caused by phosphorylation were visualized using receptor autoradiography. Frozen rat brain slices were treated with 50 µM Mg-ATP at physiologically relevant conditions after preincubation in 50 mM phosphate buffer with 200 mM NaCl and 1 mM EDTA. Treated slices were then incubated in the phosphate buffer with 3 nM [^{35}S]TBPS. Major alterations were observed in the cerebellum. Binding was decreased in the granule cell layer (-39% of control), while that in the molecular layer showed an increase(+26% of control). Because the α_6 subunit is localized to the granule cell layer, the observed increase maybe related to this subunit. Moreover, since the mean changes in binding were in either direction, the effect of phosphorylation might be region-specific. Although this is an indirect assay for receptor phosphorylation, our method detected region-specific alterations that biochemical studies can not detect. It may be a powerful and versatile tool for studies of receptor phosphorylation for other receptors as well as for $GABA_A$ receptors. (supported by NIDA-04480)

723.12

PHOSPHATASE INHIBITORS SHORTEN IPSC DECAY BY ALTERING $GABA_A$ CHANNEL KINETICS.

M.V. Jones* and G.L. Westbrook. The Vollum Institute, Portland, OR 97201.

Phosphorylation and dephosphorylation are potentially important mechanisms for regulating the shape of inhibitory postsynaptic currents (IPSCs), but have usually been studied with long applications of low GABA concentrations. The synaptic GABA transient, however, is thought to be quite high and brief. Therefore, we studied the effects of phosphatase inhibitors on the decay of IPSCs, and on chloride currents activated by brief (2-10 ms) pulses of saturating (1-10 mM) GABA to outside-out patches.

Cultured rat hippocampal neurons and patches were voltage clamped (-60 mV, 25°C) using Cs or KCl-based pipette solutions (5 mM ATP, ~50 nM free Ca^{2+} with BAPTA). We evoked autaptic IPSCs with 5 ms steps to +60 mV. A piezoelectric device was used to exchange control and GABA-containing solutions in patch experiments. Whole-cell recordings were held for >200 seconds before pulling patches when phosphatase inhibitors or ATPγS were present in the patch pipette. All current decays were best fit with two exponentials, but for simplicity are expressed as an average time constant: $\bar{\tau} = (Amp_1 \times \tau_1) + (Amp_2 \times \tau_2)$.

ATPγS (5 mM) significantly ($p < 0.05$) shortened *IPSC* decay from 89 ± 32 ms (n = 4, mean ± SD) to 39 ± 9 (n = 3), as did the serine/threonine phosphatase inhibitors calcineurin inhibitory peptide (CIP, 300 µM, 32 ± 8, n = 5) or okadaic acid (OA, 5 µM, 45 ± 12, n = 6). ATPγS, CIP and OA also significantly shortened the patch current decay from 122 ± 40 ms (n = 13) to 45 ± 11 (ATPγS, n = 9), 64 ± 20 (CIP, n = 4) and 52 ± 26 (OA, n = 4). These results suggest that under synaptically relevant stimulation, prolonged $GABA_A$ channel gating requires serine/threonine phosphatase activity. Dynamic regulation of endogenous phosphatase activity may thus produce >2-fold changes in the duration of IPSCs.

NOREPINPHRINE AND cAMP ENHANCE DENTATE GRANULE CELL $GABA_A$ RECEPTOR CURRENTS Jaideep Kapur* and Robert L Macdonald Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

There is an association of noradrenergic and GABAergic terminals on the perikarya and dendrites of dentate granule cells. The effect of noradrenergic stimulation on $GABA_A$ receptor (GABAR) currents in dentate granule cells is not known.

Dentate granule cells were acutely isolated and GABAR currents were recorded using conventional whole cell-patch clamp methods. Drugs were applied by rapid application system.

500 µM or 1 mM norepinephrine and the selective β-adrenergic agonist, isoproterenol enhanced GABAR currents elicited by 30 µM or 1 mM GABA in 12/19 granule cells. 1 mM 8-Bromo - cAMP also consistently enhanced dentate granule cell GABAR currents elicited by 30 µM or 1mM GABA. The effect of cAMP on GABA concentration response relationship was studied and the data were fitted to a sigmoid dose response curve. Maximal current was enhanced in all cells (42% +/-12% N = 4, p = 0.04) . The EC_{50} shifted to the left in 2 of 4 cells, from 99 µM to 20 µM (p = 0.28). We wished to test if norepinephrine and cAMP were acting by activating cAMP-dependent kinase (PKA). GABA concentration response curves were obtained in dentate granule cell populations with intracellular recording solution containing no ATP (Maximal I_{GABA} = 174 pA, EC_{50} = 84.2 µM, n = 7), ATP regeneration system (Maximal I_{GABA} = 531 pA, EC_{50} = 41.3 µM, n = 7) or catalytic subunit of PKA and ATP regeneration system (Maximal I_{GABA}= 712 pA, EC_{50} = 20 µM, n = 4).

Norepinephrine, Isoproterenol, cAMP, PKA and ATP consistently enhanced maximal dentate granule cell GABAR currents, and produced a left shift of GABAR concentration response curve.

GABA RECEPTOR FUNCTION IS MAINTAINED BY ADENINE NUCLEOTIDES IN ACUTELY DISSOCIATED COCKROACH NEURONS. G.B. Watson* and V.L. Salgado. Insect Management Biochemistry, DowElanco, Indianapolis, IN 46268.

While vertebrate GABA receptors have been shown to be regulated intracellularly by phosphorylation, little is known about the intracellular regulation of insect GABA receptor function. Toward this end, small diameter (< 25µ) neurons from the sixth abdominal ganglion of the American cockroach, *Periplaneta americana*, were enzymatically isolated and responses to exogenously applied GABA were recorded using the whole-cell patch clamp technique. With a minimal intracellular medium, responses to repeated applications of GABA decreased to zero within a few minutes. The rate of rundown of GABA responses was decreased by the phosphatase inhibitors microcystin and okadaic acid, and accelerated by the inclusion of protein kinase A inhibitor (PKI) in the intracellular solution, strongly suggesting that phosphorylation is necessary for the maintenance of cockroach GABA receptor function.

When added to the intracellular medium, 5 mM ATP completely blocked GABA response rundown. ADP also slowed GABA response rundown, but responses stabilized at a level about half that seen with ATP. In the presence of PKI, ATP was only as efficacious as ADP in slowing rundown. PKI had no effect on the ability of ADP to slow rundown, suggesting that the β-phosphate of ADP is not involved in PKA-dependent phosphorylation of the GABA receptor. Guanine nucleotides had no demonstrable effect on GABA responses. These results suggest that in cockroach neurons, GABA receptor function is maintained intracellularly by adenine nucleotides, not only by phosphorylation, but also by an interaction with a nucleotide recognition site unrelated to PKA-dependent phosphorylation.

cAMP-DEPENDENT PROTEIN KINASE MODULATES THE FUNCTION OF RECOMBINANT GABA$_A$ RECEPTORS IN MOUSE L929 FIBROBLASTS.

D.J. Hinkle*[1], K.F. Haas[1], and R.L. Macdonald[2,3]. Neuroscience Program[1] and Depts. of Neurology [2] and Physiology [3], Univ. of Michigan, Ann Arbor, MI 48109

Many studies have demonstrated that phosphorylation modulates the function of ligand-gated ion channels; however, the effects of phosphorylation on the γ-aminobutyric acid type A receptor (GABAR) remain controversial. In the present study, we examined the effects of cAMP-dependent protein kinase (PKA) on the function of recombinant rat $\alpha_1\beta_1\gamma_{2L}$ GABARs expressed in L929 mouse fibroblast cells. GABAR currents were recorded using conventional whole-cell patch-clamp methods with symmetrical chloride concentrations at holding potentials of -75 mV. Complete GABA concentration response curves (1 μM- 300 μM) were obtained for each condition examined. To reduce the variability often encountered when comparing populations of cells, a reimpalement protocol was used in which paired whole-cell recordings were obtained successively from individual cells. When a standard intrapipette solution was used for both the initial and reimpalement cell recordings, GABAR peak currents (100-3600 pA) uniformly decreased (-29%, n=5) with minimal change in EC_{50} (9.3 μM to 7.5 μM). In contrast, PKA catalytic subunit applied intracellularly on reimpalement enhanced peak current amplitudes when compared to the initial control impalement (+9% , n=13), with no significant shift in GABA EC_{50} (14.1 μM to 15.1 μM). This enhancement was not observed if protein kinase inhibitory peptide (PKIP), a specific PKA inhibitor, was coapplied with PKA in the recording pipette on reimpalement (-9%, n=5). A similar decline in peak current amplitudes was seen on reimpalement with PKA in cells expressing recombinant receptors containing the β_1 subunit mutation of serine 409 to alanine (-12%, n=6), a consensus site for PKA phosphorylation in the putative cytoplasmic domain. These data indicate that PKA phosphorylation of the β_1 subunit at a specific serine residue modulates GABAR responses. Support by R01-NS03300 (RLM), T32NS07222 (KFH).

PROTEIN KINASE C MODULATES GLYCINE-ACTIVATED CHLORIDE CURRENTS OF HYPOTHALAMIC NEURONS.

J.-H. Ye*, W.-H. Wu and J.J. McArdle. Depts. of Anesthesiol. & Pharmacol., New Jersey Med. Sch. (UMDNJ), Newark, NJ 07103.

Glycine (Gly) is an important inhibitory transmitter in the spinal cord and other regions of the CNS. While the modulatory influence of phosphorylation by protein kinase C (PKC) on the Gly receptor has been explored for oocytes injected with either poly(A)+ mRNA isolated from nervous tissue or synthetic mRNA, little is known about the influence of PKC on the native Gly receptor protein of intact cells. Therefore, we examined the effect of phorbol dibutyrate (PDBu), an activator of PKC, on Gly-activated current, IGly, of hypothalamic neurons freshly isolated from the brains of young mice. IGly was recorded with the nystatin perforated patch technique in order to minimize perturbation of the cytoplasmic milieu that occurs with conventional whole cell recording. Bath application of 1 μM PDBu consistently depressed IGly; for 7 separate neurons, peak IGly declined to 36.6 ± 15.5 % of control. Although the time course of this effect was variable, peak suppression occurred within 2-5 min after PDBu. For some neurons, the suppression of IGly persisted while for others it recovered even in the continued presence of PDBu. These results suggest that the Gly receptor can be phosphorylated *in vivo* by PKC. Thus, neurotransmitters affecting the activity of PKC could profoundly alter the efficacy of Gly as an inhibitory neuromediator in the CNS. NIAAA AA08025 and NIH NS31040.

THE ALPHA SUBUNIT OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II ENHANCES GABA$_A$ AND GLYCINE RECEPTORS-MEDIATED RESPONSES OF SPINAL NEURONS.

R.A. Wang*, G. Cheng, M. Kolaj and M. Randić. Dept. of Vet Physiol. and Pharmacol. and Neuroscience Program, Iowa State University, Ames, IA 50011.

Evidence exists for the regulation of γ-aminobutyric acid type A (GABA$_A$) and glycine receptors function by protein kinase A and protein kinase C. In addition, phosphorylation of GABA$_A$ receptor by calcium/calmodulin-dependent protein kinase II (CaM-KII) has been recently demonstrated (*J. Biol. Chem.* 269:18111, 1994), suggesting a role for this kinase in modulating GABA$_A$ receptor function *in vivo*. Here we report that in acutely isolated rat spinal dorsal horn (DH) neurons, intracellularly applied the α-subunit of CaM-KII increased GABA (5-20μM)- and muscimol (2-5μM)-activated currents (GABA: to 164.2% ± 10.3 of control; n=14; muscimol: to 150.6% ± 6.3, n=4) recorded with the whole-cell patch-clamp technique. This effect was associated with reduced desensitization of the GABA response. Heat-inactivated CaM-KII (n=12) did not alter the GABA responses. In addition, GABA$_A$-mediated inhibitory postsynaptic potentials in rat hippocampal CA1 neurons were enhanced by CaM-KII (to 204.4% ± 29.8, n=6). Since GABA and glycine coexist in the DH, we examined the possibility of modulation of glycine-activated current in DH neurons by CaM-KII. The α subunit of CaM-KII increased (to 180.7% ± 22.9, n=7) glycine-induced current, whereas heat-inactivated CaM-KII did not alter (to 109.3% ± 15.8, n=8) the glycine response. These results suggest that the function of GABA$_A$ and glycine receptors is enhanced by the α subunit of CaM-KII, either by direct CaM-KII phosphorylation of the GABA$_A$ and glycine receptors, or indirectly through phosphorylation of some membrane-bound regulatory proteins. This mechanism may contribute to long-term enhancement of inhibitory synaptic transmission. (Supported by NS-26352 and IBN-9209462).

REGULATION OF γ-AMINOBUTYRIC ACID TYPE A (GABA$_A$) RECEPTORS BY PROTEIN PHOSPHORYLATION.

B.J. McDonald*, G.H. Gorrie, B.J. Krishek[1], C.N. Connolly, A. Amato[1], T.G. Smart[1] and S.J. Moss.

MRC LMCB, University College London, WC1E 6BT and [1]School of Pharmacy, London WC1N 1AX.

We have investigated the role of a number of protein serine/threonine and tyrosine kinases in modulating the function of GABA$_A$ receptors.

All β receptor subunits are phosphorylated on a conserved serine residue by PKA, PKG, PKC and CamKII, the β1 and β 3 subunits also contain a second site that is phosphorylated by CamKII only. Both γ2 subunit types (γ2S and γ2L) are phosphorylated by PKC and CamKII,the γ2L subunit having an extra recognition site for both kinases. Receptor phosphorylation by protein serine/threonine kinases reduces the response to applied GABA, the magnitude of this effect being dependent on subunit composition.

Coexpression of protein tyrosine kinase vSRC with receptor subunits results in specific phosphorylation the β1, γ 2S and γ2L subunits. Receptor tyrosine phosphorylation by vSRC enhanced the response to applied GABA.

Our results suggest that GABA$_A$ receptors may be functionally up-regulated or down-regulated via a number of signal transduction pathways which may have profound effects on inhibitory transmission in the nervous system.

AMINO ACID RECEPTOR EXPRESSION IN DEVELOPING HYPOTHALAMUS: GABA EVOKES LARGE CURRENTS AT EARLY EMBRYONIC AGE.

G. Chen[1]*, P. Q. Trombley[2] and A. N. van den Pol[1]

Sect. Neurosurg.[1] and Neurobiol.[2], Yale Univ., New Haven, CT 06520.

Whole cell voltage and current clamp were employed to investigate the developmental changes of GABA, glutamate, and glycine responses in cultured embryonic neurons (N=140) from rat hypothalamus. Every neuron studied from a few hours after plating at E15 to two weeks later responded to GABA (30 μM). The currents evoked by GABA increased by 5-fold within two weeks in culture. The time constants of the desensitization of GABA currents did not change during this period. In younger cultures, GABA (5 μM) induced depolarization and action potentials rather than hyperpolarization in gramicidin perforated current clamp recordings. Glutamate and glycine mediated currents developed later than GABA mediated currents. Whereas all neurons expressed GABA receptors, some developing neurons did not express glutamate receptors or glycine receptors. The percentage of cells responding to glutamate (500 μM) or glycine (500 μM) was 20% at 0 days in vitro (DIV), and increased to 100% at 6 DIV. The glutamate and glycine mediated currents increased by 20- and 50-fold within two weeks in culture. Astrocyte substrates increased the amplitude of currents evoked by and the percentage of cells responding to both glutamate and glycine, but had no effect on GABA mediated currents. The currents and conductances elicited by GABA were much greater than those generated by glutamate or glycine throughout the period examined, particularly evident in younger cells. Each of the three amino acid evoked currents increased from E15 (1 DIV) to E20 (1 DIV), indicating an intrinsic development in the expression of the amino acid receptors in vivo. The similarity of the GABA and glutamate evoked currents between E15, 10 DIV and E20, 5 DIV (both 25 days after conception) suggests parallel developmental patterns for amino acid receptor expression in vitro and in vivo. These data suggest that GABA may play a dominant role, possibly an excitatory one, in early development and that glutamate and glycine receptors may be more sensitive to regulation by the cellular environment than GABA receptors.

723.20

OPTICAL RECORDING USING A VOLTAGE-SENSITIVE DYE PROVIDES EVIDENCE FOR A NOVEL TYPE OF GABA RESPONSE IN THE EARLY EMBRYONIC CHICK BRAINSTEM.

K. Sato, Y. Momose-Sato, T. Sakai, A. Hirota and K. Kamino*. Dept. of Physiol., Tokyo Med. and Dent. Univ. Sch. of Med., Tokyo 113, Japan.

Evidence for a novel γ -aminobutyric acid (GABA) response was found for glutaminergic excitatory postsynaptic potentials in the early embryonic chick nucleus tractus solitarius (NTS), using a multiple-site optical recording technique employing a fast voltage-sensitive dye. In various areas of the vertebrate central nervous system, it is known that release of GABA provides inhibitory modulation of excitatory postsynaptic potentials. Classically, two classes of GABA receptors, GABA$_A$ and GABA$_B$, have been identified. The GABA$_A$ receptors are blocked by the competitive antagonist bicuculline, and the non-competitive blocker picrotoxin. The GABA$_B$ receptors are specifically blocked by 2-hydroxysaclofen. In addition, bicuculline- and 2-hysroxysaclofen-insensitive GABA$_C$ receptors have been described. The GABA response found in the present experiment was insensitive to GABA$_A$ antagonists (picrotoxin, dieldrin, bicuculline, SR95531) and GABA$_B$ antagonists (2-hydroxysaclofen, phaclofen, CGP35348), but was stimulated by either muscimol or baclofen.

THE $GABA_A$ RECEPTOR β4 SUBUNIT IS AN EMBRYONIC ISOFORM IN THE CHICK CEREBRAL CORTEX. M.H. Jalilian Tehrani*, B.J. Baumgartner, and E.M. Barnes, Jr., Dept. of Biochemistry, Baylor College of Medicine, Houston, TX 77030.

Because of the great diversity of $GABA_A$ receptor subunits, selective antibodies are invaluable reagents for examining receptor polypeptide distribution and regulation. Since covalent labeling of these subunits is a useful adjunct to such studies, it is important that the antibodies have high titers for immunoprecipitation. Accordingly, polyclonal antibodies were produced from an intracellular loop region of the chick $GABA_A$ receptor β4 subunit. The β4S(316-437) sequence was expressed as a fusion protein containing a $(His)_6$ leader peptide, purified by Ni^{2+}-affinity chromatography, and used for rabbit immunizations. The resulting RK3-6 antiserum showed a high titer (EC_{50} = 0.1 µl) for immunoprecipitation of ^{3}H-flunitrazepam binding from extracts of chick embryo cortex and reacted with a single 56-57 kDa polypeptide on Western blots. After preabsorption of RK3-6 antiserum with a β2S(317-428) fusion protein, a $1:10^4$ dilution reacted strongly on slot blots with 10 ng of the β4S(316-437) and β4L(316-441) fusion proteins but not with those containing β2S(317-428), β2L(317-445), or α1(331-381) $GABA_A$ receptor subunit sequences. Saturating levels of the preabsorbed β4 antibody immunoprecipitated 66 ± 3% and 38 ± 4.5% of ^{3}H-flunitrazepam binding to extracts from 16-day-old chick embryo and adult chicken cerebrum, respectively. The results suggest that the β4 subunit of the $GABA_A$ receptor represents an embryonic isoform.

PEPTIDE RECEPTOR STRUCTURE AND FUNCTION IV

724.1

CLONING AND CHARACTERIZATION OF THE RAT GALR1 GALANIN RECEPTOR FROM RIN 14B INSULINOMA CELLS E.M. Parker*, D.G. Izzarelli, H.P. Nowak, C.D. Mahle, L.G. Iben, J. Wang and M.E. Goldstein, Dept. of Psychobiological Disorders, Bristol-Myers Squibb Co., Wallingford, CT

Galanin is a ubiquitous neuropeptide that regulates a wide array of physiological processes via interaction with specific G protein-coupled receptors. A rat galanin receptor cDNA was cloned from the Rin14B insulinoma cell line. The isolated cDNA encodes a 346 amino acid G protein-coupled receptor that is 92% identical to the recently reported human GALR1 galanin receptor. [^{125}I]Galanin binds to high and low affinity states of the rat GALR1 receptor in COS1 cell membranes ($K_{D\text{-}H}$=19 pM, $B_{max\text{-}H}$=0.47 pmol/mg protein, $K_{D\text{-}L}$=300 pM, $B_{max\text{-}L}$=1.63 pmol/mg protein). Galanin, N-terminal galanin fragments and the putative galanin receptor antagonists galantide, C7, M35 and M40 bind with high affinity to the rat GALR1 receptor. In contrast, C-terminal galanin fragments do not bind to this receptor. Galanin inhibits basal and forskolin-stimulated cAMP formation in CHO cells expressing the rat GALR1 receptor via a pertussis toxin-sensitive G protein. The GALR1 receptor is expressed in rat spinal cord, small intestine, Rin14B insulinoma cells and several brain regions, particularly ventral hippocampus, amygdala, supraoptic nucleus, hypothalamus, thalamus, lateral parabrachial nucleus and locus coeruleus. In the late stage rat embryo, the GALR1 receptor is expressed in brain, spinal cord, dorsal root ganglia and small intestine. Cloning of the rat GALR1 galanin receptor cDNA will permit many new experimental strategies to be applied to studies of the structure and function of galanin receptors.

724.2

IMMUNOCYTOCHEMICAL LOCALIZATION OF THE SOMATOSTATIN RECEPTOR SSTR2 IN RAT BRAIN USING A SPECIFIC ANTI-PEPTIDE ANTIBODY. P. Dournaud, Y.Z. Gu‡, A. Schonbrunn*‡, J. Mazella, G.S. Tannenbaum and A. Beaudet. Mc Gill University, Montreal., Québec, Canada, H3A 2B4 and ‡University of Texas, Houston, TX 77225.

In the present study, we have used a rabbit polyclonal antibody generated against a unique sequence in the SSTR2 receptor to visualize the regional and cellular distribution of this receptor subtype in rat brain. Specificity of the antiserum was demonstrated by immunoblot reactivity, and by its selective recognition of cultured COS-7 cells transfected with the cDNA encoding SSTR2, but neither SSTR1 nor SSTR2b receptor subtypes. In rat brain sections, SSTR2-like immunoreactivity was mainly evident within neuronal perikarya and dendrites distributed throughout layers II-III and V of the cerebral cortex, the lateral septum, caudate putamen, nucleus accumbens, central amygdaloid nucleus, medial habenula, locus coeruleus and the pyramidal cell layer of the CA1-CA2 fields of the hippocampus. Dense plexuses of SSTR2-immunoreactive axon-like fibers were also observed in the deep layers of the cortex, claustrum, basolateral nucleus of the amygdala, and superior colliculus. Only sparse, moderately labeled perikarya and fibers were apparent within the hypothalamus, namely in the preoptic area, periventricular nucleus and arcuate nucleus. The thalamus and cerebellum were both devoid of immunoreactivity. In the hippocampus, medial habenula and central amygdaloid nucleus, the immunoreactivity was found by electron microscopy to pervade the cytoplasm of perikarya, dendrites and dendritic spines. In the median eminence, a few axon terminals also displayed reaction product suggesting a presynaptic localization of SSTR2 in this area. The present results provide the first demonstration of the regional and cellular distribution of SSTR2 receptor in rat brain, and suggest that this receptor subtype is involved in the transduction of both pre- and postsynaptic effects of somatostatin in the central nervous system.

724.3

IMMUNOLOGICAL ANALYSIS OF ANGIOTENSIN TYPE 2 RECEPTORS IN THE BRAIN AND PERIPHERY OF DEVELOPING RAT. L.P. Reagan*, S.Y. Chow, L.Y. Ma, D.K. Yee, R.R. Sakai and S.J. Fluharty. Depts. of Animal Biology, Pharmacology, Psychology and the Institute of Neurological Sciences, University of Pennsylvania, PA 19104.

Angiotensin II (AngII) receptor levels are high in neonates and decrease to adult levels as the animal matures. A larger proportion of this reduction is due to decreases in Type 2 (AT_2) receptors rather than Type 1 (AT_1) receptors. In the present study, AT_2 antisera were used to study the distribution of AT_2 receptors in the developing rat brain and in peripheral tissues by immunohistochemical and immunoblot analysis.

Rat brains at 4, 9, and 12 days of age were examined via immunohistochemical techniques and compared with previous results from adult rat brain. As with the mature animal AT_2 receptor immunoreactivity was seen in the locus coeruleus, the supraoptic nucleus and the paraventricular hypothalamic nucleus. AT_2 receptor staining was also associated with the Purkinje cell layer of the cerebellum, as was seen in the adult rat. Dissimilar from the adult, AT_2 receptor immunoreactivity in the neonatal rat pup was less dense in the hippocampus.

Immunoblot analysis was performed to determine the expression of AT_2 receptors in both neonatal and adult rat peripheral tissues. Interestingly, AT_2-directed antisera did not immunodetect proteins in the neonate or adult adrenal, a tissue which is know to exhibit AT_2 binding activity. However, in the neonate a 66 kDa immunoreactive protein was detected in the aorta and the kidney. In neonatal atria, immunoreactive bands of 210, 66 and 50 kDa were observed, with the 66 kDa band being the most intense. In contrast, the major immunoreactive protein was approximately 50 kDa in adult aorta, atria and kidney.

Collectively, these results establish the localization of AT_2 receptors in the developing rat brain, in addition to examining AT_2 receptor expression in neonatal and adult peripheral tissues. These results further support the hypothesis of AT_2 receptor heterogeneity. (Supported by MH43787 and NS23986)

724.4

CLONING AND MUTATIONAL ANALYSIS OF AN ANGIOTENSIN TYPE 2 RECEPTOR FROM MURINE NEUROBLASTOMA N1E-115 CELLS. D.K. Yee*, P. He, X.-D. Yang, L. P. Reagan, L. A. Rogers, J. N. Heerding, J. Hines, and S. J. Fluharty. Depts of Animal Biology, Psychology, Pharmacology, and Institute of Neurological Sciences. Univ. of PA, Phila., PA 19104.

An angiotensin Type 2 (AT_2) receptor identical to other cloned AT_2 receptors has been isolated from a murine neuroblastoma N1E-115 cDNA library using homology-based polymerase chain reaction. When transfected into COS-1 cells, this clone displayed *(i)* AT_2 pharmacology, *(ii)* GTPγS-insensitive agonist binding, and *(iii)* augmentation of agonist binding by dithiothreitol. Previously, we had demonstrated that N1E-115 cells possess two distinct subpopulations of AT_2 receptors, defined as Peak I and Peak III receptors (Siemens et al. *J.Neurochem.* 52:1393, 1994). The pharmacological profile and distinctive ligand binding properties in the presence of GTPγS and dithiothreitol of the cloned AT_2 receptor are consistent with that of Peak III receptors. Moreover, antisera raised against Peak I receptors failed to immunoreact with either Peak III or cloned AT_2 receptors. Collectively, these data suggest that the cloned AT_2 receptor is identical to Peak III receptors and that an apparently novel AT_2 receptor (in Peak I) remains to be cloned.

It was previously shown for the AT_1 receptor that mutating a specific lysine (Lys^{199}) residue to glutamine diminished its affinity for peptidic ligands (Yamano et al., *BBRC* 187:1426, 1992). An analogously mutated AT_2 receptor (Lys^{215}), when expressed in COS-1 cells, possessed greatly reduced affinity for ^{125}I-angiotensin II compared to wild type receptor. More extensive pharmacological analysis of the mutated receptor to both peptidic and non-peptidic ligands is currently in progress. The effects of the lysine mutation on the AT_2 receptor suggests that despite the low homology between AT_1 and AT_2 receptors (only 34%), some commonalities in the binding mechanism for angiotensin II exists between the two receptor subtypes. (Supported by NS23986 and MH43787)

724.5

ANTISENSE OLIGONUCLEOTIDES REDUCE EXPRESSION OF ANGIOTENSIN TYPE 2 RECEPTORS IN DIFFERENTIATED MURINE NEUROBLASTOMA N1E-115 CELLS. L. A. Rogers, D. K. Yee, and S. J. Fluharty*. Depts. of Animal Biology, Pharmacology, Psychology, and Institute of Neurological Sciences. Univ of PA. Phila., PA 19026.

Previously, we have demonstrated that murine neuroblastoma N1E-115 cells possess both Type 1 (AT_1) and Type 2 (AT_2) angiotensin receptors. Inducing differentiation of these cells by the addition of dimethyl sulfoxide (DMSO) results in up to a ten-fold increase in the expression of AT_2 receptors. In order to evaluate the efficacy of antisense oligonucleotides in reducing expression of this angiotensin receptor subtype, either AT_2 antisense or scrambled 15-mer *S*-oligonucleotides were administered concurrently with DMSO treatments. Following three 24 hr treatments of the *S*-oligos, the cells were harvested and AT_2 receptor expression was determined by radioligand binding assays. At concentrations of either 50 *n*M or 500 *n*M, the AT_2 antisense oligoucleotide effectively attenuated the upregulation of these receptors during differentiation by approximately 40% compared to cell cultures treated with scrambled oligonucleotides. These studies are the first demonstration that antisense oligonucleotides decrease *in vitro* the expression of the AT_2 receptor subtype and therefore should prove to be an important new tool in studying function and regulation of this angiotensin receptor subtype. (Supported by NS23986 and MH43787)

724.6

HIGH EXPRESION OF VASOPRESSIN RECEPTORS (AVP-R) IN THE THALAMUS OF GENETICALLY OBESE RATS (fa/fa). Y. Arsenijevic[1], F. Rohner-Jeanrenaud[2], E. Tribollet[1], M. Muhlethaler*[1] and B. Jeanrenaud[2]. [1]Dept. of Physiology, Univ. Med. Center, [2]Lab. Metab. Res., Dept. of Medecine, 1211 Genève 4.

The rat Zucker strain has a recessive mutation responsible for obesity in homozygous animals. Obese fa/fa rats present numerous abnormalities, in particular hyperinsulinemia, hypogonadism and an altered response to stress. In normal rats, AVP-R and oxytocin receptors (OT-R) are present in brain regions implicated in the regulation of these parameters, i.e. the hypothalamus, the hippocampus and the dorsal motor nucleus of the vagus nerve. This suggests 1) that AVP and OT may participate to this regulation and 2) that the expression of AVP-R and OT-R may differ in obese rats. To test these hypothesis, brain slices of obese and lean rats were labelled using two iodinated ligands specific for V_{1a} AVP-R and for OT-R respectively. Autoradiogramms were quantified with an image analyser: the density of the receptors was measured and the number of receptors per labelled structure was estimated. No differences were detected in the hypothalamus, the hippocampus, and the brainstem between both groups, while in the thalamus, AVP-R were much more numerous in obese than in lean rats: the number of AVP-R was 40 % higher in the thalamic ventromedial nucleus, and 100% higher in the ventrolateral, the mediodorsolateral and the posterior thalamic nuclei. These four nuclei are essentially implicated in motor control. The physiopathological significance of these results is under investigation.

724.7

VASOPRESSIN-INDUCED CALCIUM SIGNALING IN CULTURED CORTICAL NEURONS. M.C. Son* and R.D. Brinton. Dept. Molecular Pharmacology & Toxicology, Univ. of Southern California, Pharmaceutical Sci. Ctr., 1985 Zonal Ave., Los Angeles, CA. 90033.

Our early evidence of recognition sites in the cerebral cortex for the neuropeptide vasopressin (Brinton et al. PNAS 1984, Chen et al. *Hippocampal*, 1993) suggested the existence of V1 vasopressin receptors. Based on these findings, we have pursued the signal transduction mechanism of V_1 receptors in cultured cortical neurons using a selective V_1 vasopressin receptor agonist. The dose-response of V_1 agonist-induced accumulation of $[^3H]IP_1$ was concentration dependent and showed a significant linear increase from 250nM (138%±16, $p<0.01$) to 1000nM (189%±16, $p<0.001$). A significant increase in the accumulation of $[^3H]IP_1$ was observed within 20min exposure to V_1 agonist. Peptide specificity indicated that the closely related vasopressin metabolite peptides AVP_{4-8} and AVP_{4-9} also induced significant increases in $[^3H]IP_1$ accumulation as did oxytocin. We further determined whether V1 receptor activation regulated the influx of calcium by conducting $^{45}Ca^{2+}$ uptake analyses. Results of these investigations demonstrated that V_1 agonist (250nM) induced a significant increase in $^{45}Ca^{2+}$ uptake from the extracellular medium within 5 sec. V_1 agonist-induced $^{45}Ca^{2+}$ uptake dose-response analysis exhibited a nonlinear profile. These results demonstrate that V1 vasopressin receptor activation leads to calcium signaling in cortical neurons through the PIP_2 pathway and calcium uptake from the extracellular medium. Future studies will investigate V1 agonist-induced increases in intracellular calcium using calcium fluorometry analysis.

Vasopressin-Induced Specific Gene Expression in the Cultured Cortical Neurons. Qi Chen*, S. Schreiber and R.D. Brinton. Depart. Molecular Pharmacology & Toxicology, Univ. of Southern California, Pharmaceutical Sciences Center, 1985 Zonal Ave., Los Angeles, CA 90033

Work from our laboratory has demonstrated the existence of V1a vasopressin receptors (V1aR) in cerebral cortex (Brinton et al, 1989, Yamazaki et al, 1995). In addition, we have found V1aR induces calcium signaling in cortical neurons and astrocytes (Son and Brinton, 1995). Downstream effects induced by V1aR activation are, however, still unknown. We have investigated specific gene expression induced by V1aR activation in cultured rat cortical neurons by using differential display PCR. Eighteen-day-old rat cortical neurons were cultured in serum-free media for 16 hours and treated with 250nM V1aR agonist for 15 min, 2 hours and 24 hours, respectively. Total RNAs were isolated and subjected to differential display PCR by using an anchor oligo(dT) primer and an arbitrary primer. Differential patterns were run on the polyacrylamide gels and visualized by silver staining or labelled by ^{35}S-dATP. Our preliminary results indicate V1aR-induced specific gene expression. Further identification by Northern blot analysis and sequencing will be conducted.

V1a VASOPRESSIN RECEPTOR GENE EXPRESSION IN CULTURED CORTICAL NEURONS, ASTROCYTES AND OLIGODENDROCYTES. R.S.Yamazaki[1]*, Q.Chen[1], S. Schreiber[2] and R.D. Brinton[1]. Dept of Molecular Pharmacology & Toxicology[1], Dept. of Neurology[2], Univ. of Southern California, Pharmaceutical Science Center, 1985 Zonal Ave., Los Angeles, CA 90033

Our early evidence of recognition sites in the cerebral cortex for the neuropeptide vasopressin (Brinton et al. *PNAS* 1984, Chen et al. *Hippocampus*, 1993) suggested the existence of V1 vasopressin receptors. To date there has been no direct evidence of the specific type of cells in cerebral cortex that express the V1 receptor. We pursued this question by using selectively enriched cultures of cortical neurons, astrocytes, and oligodendrocytes. Dissociated cortical cells derived from E18 rat pups were cultured in T-75 flasks in serum containing medium. Neurons were collected after 4 days in vitro (DIV). Oligodendrocytes and astrocytes were collected separately after 21 DIV. Total RNA from each fraction was extracted and purified. To convert mRNA to cDNA and amplify the signal, RT-PCR was performed on each sample using 2 sets of 20mer oligonucleotides targeted to a vasopressin V1a receptor (V1aR) sequence of ~350 bp and a vasopressin V1b receptor (V1bR) sequence of ~500bp. Samples were electrophoresed and immobilized on nylon membranes. Hybridizations of the samples with ^{32}P-labeled probes directed against V1aR and V1bR detected the presence of V1a cDNA, and the absence of V1bR cDNA, in all 3 cell types in the cerebral cortex. These data suggest that distinct vasopressin receptor types are localized in cortex and that within the cortex, the V1a receptor type is expressed in each of the 3 major cell types. Consequently, vasopressin may have pleiotropic effects in the cerebral cortex. In situ hybridization studies to determine the magnitude of expression and proportion of each cell type that expresses V1aR are in progress.

IDENTIFICATION OF OPIOID RECEPTOR-LIKE SEQUENCES AMONG DIFFERENT SPECIES. X. Li*, D.E. Keith Jr., C.J. Evans. Department of Psychiatry and Biobehavial Sciences, University of California at Los Angeles School of Medicine, Los Angeles CA 90024-1759

The DNA sequences of members of the opioid receptor family (mu,delta kappa and the orphan ORL-1) have regions highly conserved - a conservation that is retained in human, rat and murine sequences. Areas that are highly homologous within this family of G-protein coupled receptors include the intracellular loops and the transmembrane domains. In order to gain insights into the evolution of the opioid receptor family, degenerate primers were designed according to sequences highly conserved within the family and polymerase chain reaction (PCR) was used to screen genomic DNA from a number of different species. DNA was assayed both from the protostome and deuterostome branches of the metazoan phylogenetic tree. The specific products from PCR were subcloned into pCRII and sequenced. Opioid receptor-like sequences were obtained from beef, chicken, fish and frog. No specific opioid like sequences were obtained from *C-elegans* or *drosophila*. In frog, we obtained three different receptor sequences that were highly homologous but not identical to the mu, delta, and kappa opioid receptors previously isolated from mouse. Among the three receptors identified from frog, the kappa receptor was most divergent from the murine counterpart in the PCR sequence that was analysed. Lower species are presently being investigated to more fully understand the evolution of the opioid receptor family. Supported by NIDA DA05010 and W.M. Keck Foundation.

A NOVEL BOMBESIN-LIKE-PEPTIDE ISOLATED FROM THE FROG *RANA CATESBEIANA*. B.J. Barry, S.R. Nagalla, M.S. Smith*, E.R. Spindel. Div. Neuroscience, OR Rgl. Primate Research Ctr., Beaverton, OR 97006.

Bombesin was originally characterized in the skin of *Bombina bombina*. Many bombesin-like peptides (BLPs) have since been isolated from various amphibians and mammals. The BLPs are usually divided into three subfamilies; the GRP subfamily, the NMB subfamily, and the bombesin-related peptide (BRP) subfamily which contains bombesin, ranatensin, and phyllolitorin. Traditionally, the ranatensins have been distinguished from the bombesins by the presence of a Phe rather than a Leu as the penultimate C-terminal amino acid; however a Phe form of bombesin has recently been cloned. This discovery indicates that bombesin and ranatensin may be more closely related than thought, while also increasing the apparent complexity of BLPs. Previously Ranatensin C, which is highly homologous to ranatensin, was characterized in *Rana catesbeiana*. Using RT-PCR and degenerate oligos we have identified a new BLP, Ranatensin-V, in *R. catesbeiana* skin. Ranatensin-V has a valine in the penultimate position- the only BLP as yet to have this feature.

Bombesin	**Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met.NH2**
Ranatensin	**pGlu-Val-Pro-Gln-Trp-Ala-Val-Gly-His-Phe-Met.NH2**
Ranatensin-C	**pGlu-Thr-Pro-Gln-Trp-Ala-Thr-Gly-His-Phe-Met.NH2**
Ranatensin-V	**pGlu-Thr-Pro-Gln-Trp-Ala-Val-Gly-His-Val-Met.NH2**

Binding experiments have indicated that the penultimate amino acid is important for the binding of BLPs to potential receptors. Thus this new peptide may identify an entirely new class of BLPs characterized by a penultimate Val, or alternatively may derive from a conservative evolutionary amino acid switch from Leu to Val. Just as Phe and Leu forms of both bombesin and phyllolitorin have been isolated, this new ranatensin may actually be the Val/Leu form of ranatensin as a complement the previously characterized Phe form.

IDENTIFICATION OF NOVEL CHEMOKINE-LIKE RECEPTORS IN THE MAMMALIAN CNS BY PCR M.E. Charlton*, S.R. Marsh, A. M. Ciabarra and R.S. Duman. Laboratory of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06598

Over the past several years studies in our laboratory have focused on the function of several discrete brain regions implicated in the etiology and treatment of psychiatric disorders. In order to ultimately study the molecular actions of psychotropic drugs within these brain regions we have initiated studies to identify novel receptors belonging to the G-protein coupled receptor superfamily. Using a PCR based approach with degenerate primers corresponding to regions highly conserved among particular receptor subfamilies, our laboratory has identified several cDNA fragments encoding putative G-protein coupled receptors from discrete rat brain regions including the ventral tegmentum (VT) and locus coeruleus (LC). Sequence analysis of the novel clones VTR 15-20 and LCR 3-12 has revealed a homology at the amino acid levels to the IL-8 and Monocyte Chemoattractant Protein (MCP) receptors, respectively. The distribution pattern and relative expression levels of the mRNA encoding these clones was determined by RNase protection assay and northern blot analysis. The highest expression levels were detected in peripheral tissues (spleen, lung, heart, liver) and lower levels of mRNA expression were apparent in CNS regions (thalamus, pons, cortex, hippocampus, and cerebellum). We are currently isolating full length clones encompassing VTR 15-20 and LCR 3-12 from a rat spleen cDNA library. Further studies will include characterization of the ligand specificity, pharmacology, and the regulatory properties of these receptors. These studies demonstrate the existence of these novel chemokine-like receptors in brain and suggest a role for chemokines in the regulation of brain function.

Molecular Cloning of a Rat C-C Chemokine Receptor; Expression in Cultured Microglia. J.K. Harrison[1]*, Y. Jiang[1], M.N. Salafranca[1], N.A. Pennell[2], and W.J. Streit[2]. Departments of Pharmacology[1] and Neuroscience[2], University of Florida.

Chemoattractant cytokines (chemokines) are a class of pro-inflammatory peptides that are important mediators of leukocyte migration. While these agents have been well characterized in peripheral systems and models of peripheral inflammation, little is known about the role or function of these cytokines in normal and pathological states of the central nervous system (CNS). Receptors for some of the chemokine peptides have been identified by molecular cloning and are members of the large gene superfamily of G-protein coupled receptors (GCRs). Using degenerate oligonucleotide primers encoding highly conserved regions found in known chemokine receptors, we amplified (by the polymerase chain reaction) DNA fragments encoding several novel members of the GCR superfamily. These fragments were used subsequently to screen rat genomic DNA libraries. Sequence analysis of one of these genomic clones (gCrec13) revealed a translational open reading frame of 354 amino acids. The conceptualized amino acid sequence is 77% identical to the human monocyte chemoattractant protein-1 (MCP-1) receptor, with the greatest divergence in the N-terminus and second extracellular loop. Northern analysis of cultured rat microglia demonstrated the presence of mRNA hybridizing to Crec13 DNA. Treatment of the cultures with Interferon-γ resulted in a dramatic up-regulation of this mRNA. We are hypothesizing that the rat CNS (and specifically microglia) express functional MCP-1 receptors.

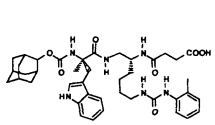
COMPARATIVE INTERNALIZATION PROFILE OF INSULIN-LIKE GROWTH FACTORS (IGF-I and IGF-II) IN A PRIMARY CULTURE MODEL OF RAT HIPPOCAMPAL NEURONS. R. Quirion*, S. Doré, and S. Kar. Douglas Hosp. Res. Ctr, Dept Psychiatry, McGill University, Montreal, Quebec, Canada, H4H 1R3.

IGF-I and IGF-II are structurally related peptides with distinct actions in the brain. Their physiological responses are mediated by specific receptors which are uniquely distributed throughout the brain, being especially concentrated in the hippocampus. We have shown using superfusion of hippocampal slices that concentrations of 10^{-14} to 10^{-8} M of IGF-I inhibit whereas IGF-II potentiates K^+ (25mM)-evoked acetylcholine release (Soc. Neurosc. Abst. 20:81, 1994). After establishing the optimal conditions for the culture of embryonic (E18) rat hippocampal neurons, binding properties of IGF receptors were characterized (Soc. Neurosc. Abst. 20:40, 1994). Competition with insulin revealed the presence of both the type I and type II IGF receptors on these neurons. In order to investigate the putative internalization profile of the IGF-I and IGF-II /receptor complexes in this model, a technique of acid stripping was used. Both total and internalized ^{125}I-IGF-I and ^{125}I IGF-II labelling reached a plateau after a 20 minute incubation at 37°C. The apparent speed of internalization profile was more pronounced for the IGF-II receptor complex than for the IGF-I receptor. The internalization of IGF-I and IGF-II was confirmed by using phenyl arsine oxide (10μM), a general inhibitor of endocytosis, which significantly blocked both internalization processes. In order to eliminate the possible recycling of receptors under our experimental conditions, an inhibitor of receptor-recycling mechanism, monensin (10μM) was used and shown to have no effect on the internalization of either ligands. As the type I IGF receptor is coupled to tyrosine kinase activity, tyrphostin 47 (0.1-10mM), a specific tyrosine kinase inhibitor, was used and showed to significantly decrease IGF-I/receptor internalization without affecting the IGF-II/receptor complex. Hence, the IGF-I is apparently mostly internalized via the type I receptor while IGF-II is not. Taken together, these results provide further evidence for the existence of at least two classes of IGF receptors in the hippocampal formation, the IGF-I ligand receptor complex being internalized via a tyrosine kinase sensitive pathway. In contrast, the IGF-II ligand receptor complex is likely internalized via a different pathway possibly related to a mannose-phosphorylated residues as the IGF-II/mannose-6-phosphate has been implicated in the intracellular targeting of lysosomal proteins containing mannose-6-phosphate residues. (Supported by the MRCC and The Alzheimer Society of Canada).

724.15

DIFFERENT OCCUPANCY OF AGONISTS AT THE CCK-A RECEPTOR R. Ray, K. Doring, H. Schmitthenner, R. Simmons and J. R. Bostwick*.
Dept. Biology, Fisons Pharmaceuticals, 755 Jefferson Rd., Rochester, NY 14623

A recent report that a CCK peptoid analog, Compound *I*, is an agonist prompted us to investigate the nature of its interaction with the CCK-A receptor. We compared the effect of Compound *I* on the binding of an agonist, [^{125}I]CCK8, and an antagonist, [^{3}H]MK329, in rat pancreas membranes. Scatchard analysis confirmed that CCK8 competitively blocked [^{3}H]MK329 binding in this preparation, with 10 nM CCK8 increasing the apparent K_d for [^{3}H]MK329 binding from 0.3 nM to 2 nM with no effect on B_{max}. Compound *I* competitively displaced [^{125}I]CCK8 binding. In the presence of 5 nM Compound *I*, the apparent K_d for [^{125}I]CCK8 shifted from 20 pM to 225 pM with no change in B_{max}. In contrast, 100 nM Compound *I* was a non-competitive inhibitor of [^{3}H]MK329 binding, decreasing B_{max} from 244 pmoles/gram tissue to 78 pmoles/gram tissue. These data show that two compounds, both of which compete with CCK8 for binding at the A receptor, are noncompetitive with each other. The finding that Compound *I* binding is noncompetitive with [^{3}H]MK329 whereas CCK8 binding is competitive with [^{3}H]MK329 indicates that the interaction of each agonist with the CCK-A receptor is different. We propose a model wherein Compound *I* and MK329 occupy separate but allosterically linked domains of the CCK8 binding region in the A receptor.



Compound *I*

CHARACTERISATION OF RADIOLIGAND BINDING BY SCINTILLATION PROXIMITY ASSAY TO ANGIOTENSIN II TYPE 1, DOPAMINE D_2 AND 5-HYDROXYTRYPTAMINE TYPE 1A RECEPTORS EXPRESSED IN INSECT CELLS USING THE BACULOVIRUS SYSTEM. G. O'Beirne[1], A.J. Harris[1], M. Dennis[2], A. Patel[1]* and N.D. Cook[1]. 1. Amersham International plc, Cardiff Labs., Whitchurch, Cardiff, Wales, U.K. CF4 7YT. 2. BioSignal Inc. 1744 rue William, Montréal, (Québec), Canada. H3J 1R4.

Scintillation Proximity Assay# (SPA) technology was used to characterise the binding of radioligands to various human recombinant receptors expressed in Sf 9 insect cells via the baculovirus system. It was possible to couple the Sf 9 cell membranes containing the baculovirus expressed receptors to both wheatgerm agglutinin (WGA) and polylysine coated SPA beads. The SPA beads contain scintillant which detects low energy emissions (ie: β-particles from ^{3}H or Auger electrons from ^{125}I) only when the radioisotope is in close proximity to the bead. Consequently, in SPA receptor binding assays it is not necessary to separate receptor-bound ligand from free, as only radioligand bound to receptors coupled to the beads causes light to be emitted.

In these experiments the binding characteristics of transfected receptors were determined by SPA using WGA SPA beads and compared to those determined using traditional filtration methods. Three different receptor/ligand systems were examined in detail; [^{125}I][Sar^{1}Ile^8]angiotensin II binding to angiotensin II type 1 receptors, [^{125}I]epidepride binding to dopamine D_2 receptors and 8-hydroxy-[^{3}H] dipropylaminotetralin (8-OH-[^{3}H]DPAT) binding to 5-hydroxytryptamine type 1A ($5HT_{1A}$) receptors. Comparable K_D values were found when saturation binding experiments were performed by both SPA and filtration methodologies. These studies demonstrate that it is possible to use SPA to characterise binding to recombinant receptors expressed using the baculovirus insect cell system.

Scintillation Proximity Assay technology is covered by US Patent No. 4568649, European Patent No. 0154734 and by Japanese Application No. 84/52452.

DESIGN OF NEW CRF ANALOGUES AND MOLECULAR CHARACTERIZATION OF FUNCTIONAL CRF RECEPTORS. Andreas Rühmann, Frank M. Dautzenberg, Andreas K. E. Köpke and J. Spiess*. Max-Planck-Institute for Exp. Med. Dept. Mol. Neuroendocrinology, Hermann-Rein-Str. 3, D-37075 Goettingen, Germany.

Corticotropin releasing factor (CRF) is an early signal in stress response. A functional CRF receptor which increases adenylate cyclase activity on stimulation by CRF has been demonstrated in the human Y79 retinoblastoma line [Olianas, M.C., Lampis, G., and Onali, P., 1995, J. Neurochem. 64, pp 402].

On these findings, newly designed lipophilic CRF agonists and antagonists have been developed which show similar binding affinities and biopotencies when compared to h/rCRF (1-41) and the antagonist [DPhe^{12}, Nle^{21,38}] h/rCRF (12-41), respectively.

In a PCR based approach we could demonstrate that CRF_1 receptor is expressed in Y79 cells. Furthermore, three different variants of this receptor type were found. The first variant encodes the previously cloned CRF_{1a} receptor polypeptide. The two additional variants are novel. Both have deletions of different lengths in the extracellular N-terminal domain. The presence of different receptors is consistent with our binding data performed on Y79 membrane homogenates, that favor the existence of high- and low-affinity binding sites.

For the identification of the ligand binding site with a potent photoactivatable CRF analogue, HEK 293 cells were transfected with the rat CRF_1 receptor. The CRF binding constant did not deviate significantly from the corresponding values of pituitary or Y79 cell receptors. However, the CRF receptor density was significantly increased in HEK cells when compared to the receptor density in Y79 cells. The ongoing production of stable cell lines expressing functional CRF receptors at higher level will facilitate the structure activity relationship (SAR) studies with CRF agonists and antagonists.

724.18

IRREVERSIBLE ANTAGONISM OF THE GONADOTROPIN-RELEASING HORMONE RECEPTOR TO EVALUATE " SPARE RECEPTORS" IN TRANSIENT TRANSFECTION SYSTEMS. S. Kitanovic*, S.C. Sealfon. Fishberg Center for Neurobiology and Dept. of Neurology, Mount Sinai Medical Center, New York, NY 10029

Transient transfection systems are frequently employed to study the coupling of wild type (WT) and mutant receptors. However, EC_{50} values obtained in functional studies may depend on the level of receptor expression per cell. An approach sometimes used to determine the relationship between EC_{50} and receptor expression following transient transfection is to alter the amount of receptor DNA being transfected into cells. However, the interpretation of results obtained is not conclusive because it is not known whether decreasing the amount of transfected plasmid causes a change in the expression of receptors per cell or in the number of cells expressing the receptor. We have evaluated the relationship between measured EC_{50} and the concentration of the gonadotropin-releasing hormone receptors (GnRHR) in COS-1 cells by partial irreversible antagonism. Functional receptors were progressively eliminated by pretreating cells with 2,4,6-trinitrobenzenesulfonic acid (TNBS). With the greatest reduction in receptor concentration, EC_{50} values obtained from concentration-response curves increased no more than 3-5 fold. In addition, a decrease in the maximal response was observed. Using the analysis developed by Furchgott (Advances in drug research,3,21-55), the KA of the WT human GnRHR was determined to be approximately 4 nM. These data indicate that the presence of spare receptors can be accurately evaluated in a transient transfection system and therefore this system can be utilized to determine agonist affinity for mutated receptors via the functional response. (Supported by NIH R01 DK-46943 and G3-5615 training grant)

NOVEL ACTIVATION AND INTERACTION OF SYMPATHETIC NEURON SIGNAL TRANSDUCTION PATHWAYS BY PITUITARY ADENYLATE CYCLASE POLYPEPTIDES. K. M. Braas* and V. May. Department of Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

Pituitary adenylate cyclase activating polypeptides (PACAP-27 and -38) belong to the VIP/secretin/glucagon family of bioactive peptides and have diverse neuroendocrine regulatory effects. The PACAP-selective type I receptor is positively coupled to adenylate cyclase and phospholipase C (PLC); splice variants of the type I PACAP receptor differentially stimulate adenylyl cyclase and PLC. In the current studies, cultured superior cervical ganglion (SCG) neurons, which expressed predominantly the HOP cassette-containing type I PACAP receptor isoform, displayed potent and efficacious stimulation of catecholamine and NPY secretion by PACAP peptides. Unlike previously studied tissues, SCG inositol phosphate and cyclic AMP production were potently stimulated by both PACAP27 and PACAP38. PACAP38 was more potent than PACAP27 in stimulating SCG cyclic AMP levels; PACAP38 exhibited a half-maximal effect at 0.4 nM compared to 4.0 nM for PACAP27. PACAP27, however, was more efficacious than PACAP38. In contrast to other tissues, PACAP27 and PACAP38 were nearly equipotent in stimulating inositol phosphate production exhibiting a half-maximal response at approximately 0.5 nM. PACAP27- or PACAP38-elicited interactions of these two signaling pathways were investigated using the PLC inhibitor U73122 and/or the adenylyl cyclase inhibitor SQ22536. U73122 attenuated both PACAP27- and PACAP38-stimulated inositol phosphate production, while SQ22536 had no effect. In contrast, PLC inhibition potentiated PACAP27- and PACAP38-stimulated cyclic AMP production. These results indicate that the concerted interactions of these two signal transduction pathways contribute to SCG responses to PACAP. Supported by HD27468 and NS01636 (VM) and AHA94015540 (KMB).

CHARACTERIZATION OF CALCITONIN RECEPTORS EXPRESSED IN DIFFERENTIATED IMR 32 HUMAN NEUROBLASTOMA CELLS. G. Campana, L.Carboni, M. Canossa E. Speroni, S. Ferri and S.Spampinato*. Dept. Pharmacol., Univ. Bologna,I40126 Bologna, Italy.

Neuroblastoma-derived cell lines express different neuropetide receptors and represent an useful model to investigate their molecular functions in differentiated cells which acquire several phenotypes of mature neuronal cells. We have examined a series of human neuroblastoma cell lines with the aim to detect, by polymerase chain reaction, any mRNA coding for the calcitonin receptor by using two primers complementary to an unique sequence of a cDNA described by Kuestner et al. (Mol.Pharmacol.46,246,1994). Electophoretic analysis of reverse-transcribed total RNA, provided evidence that mRNA coding for this receptor occurs in IMR 32 cells. In these cells, differentiated with 1 mM dibutyril cAMP for 12-14 days and loaded with fura-2, human calcitonin (IC_{50}= 10^{-8}M) and salmon calcitonin (IC_{50}=10^{-9}M) antagonized Ca^{2+}entry evoked by high extracellular K^+(50 mM) or ATP (1 mM). This response was not observed following removal of extracellular Ca^{2+} or in the presence of ω-conotoxin GVIA (20 nM).Therefore, differentiated IMR 32 cells represent an useful tool to study the gene expression and molecular interactions of human calcitonin receptor in neuronal cells.

NEUROTRANSMITTER PROCESSING

***APLYSIA* CARBOXYPEPTIDASE E: MOLECULAR CLONING, STRUCTURE, AND CELLULAR LOCALIZATION.** G.T. Nagle*[1], W.R.A. van Heumen[2], R. Rodriguez[1], and X. Fan[1]. [1]Marine Biomedical Institute and Department of Anatomy & Neurosciences, University of Texas Medical Branch, Galveston, TX 77555 and [2]Vision, Touch and Hearing Research Centre, University of Queensland, Brisbane, Australia.

The abdominal ganglion neuroendocrine bag cells of *Aplysia* express the egg-laying hormone (ELH) gene and process the resulting polyprotein ELH precursor at multiple sites. Carboxypeptidase E (CPE)-like removal of C-terminal basic amino acids has been previously detected in neural tissue of *Aplysia*. To characterize this processing enzyme, an abdominal ganglion cDNA library was constructed and screened using a CPE-related PCR product generated from the bag cells. The longest clone that was isolated contained the entire open reading frame and encoded a preproenzyme that was most closely related to vertebrate CPE sequences. The cellular localization of *Aplysia* CPE is currently being examined by *in situ* hybridization. The C-terminal region of vertebrate CPE contains the membrane anchor and may contribute to the sorting of this protein into the regulated pathway. Interestingly, the C-terminal region of *Aplysia* CPE showed a low sequence identity with the C-terminal region of vertebrate CPEs.

725.2

***APLYSIA* PEPTIDYLGLYCINE α-AMIDATING MONOOXYGENASE: MOLECULAR CLONING, STRUCTURE, AND CELLULAR LOCALIZATION.** X. Fan[1], W.R.A. van Heumen[2], S.D. Painter*[1], R. Rodriguez[1], H. Shen[1] and G.T. Nagle[1]. [1]Marine Biomedical Institute and Department of Anatomy & Neurosciences, University of Texas Medical Branch, Galveston, TX 77555 and [2]Vision, Touch and Hearing Research Centre, University of Queensland, Brisbane, Australia.

The abdominal ganglion neuroendocrine bag cells of *Aplysia* express the egg-laying hormone (ELH) gene and process the ELH precursor to generate amidated ELH and other peptides. In addition, these cells and other abdominal ganglion neurons express a homolog of neuropeptide Y that is also amidated. To characterize *Aplysia* peptidylglycine α-amidating monooxygenase (PAM), an abdominal ganglion cDNA library was constructed and screened using a PAM-related PCR product generated from the bag cells. The clone that was isolated encoded a PAM-related enzyme that was most closely related to vertebrate PAM sequences. The cellular localization of *Aplysia* PAM is currently being examined by *in situ* hybridization.

SUBTILISIN LIKE ENZYMES PC2, PC3/PC1 AND FURIN IN UNDIFFERENTIATED AND DIFFERENTIATED HL-60 CELLS. Osvaldo Vindrola[a]*, Maria Claudia Kleid[b] and Maria Rosa Padros[a]. [a]Instituto de Fisiologia. Universidad Autonoma de Puebla. Puebla. Mexico. [b]Instituto de Investigaciones Medicas. Facultad de Medicina. Universidad de Buenos Aires. Buenos Aires. Argentina.

Prohormone converting enzymes PC2 and PC3/PC1 (PC3) have been detected in rat neutrophils and alveolar macrophages, respectively. In order to ascertain in which stage of the myeloid differentiation processes these enzymes are produced, we studied PC2, PC3 and furin content in undifferentiated (UD) and differentiated (D) human promyelocytic leukemic cell line HL-60. PC2, PC3 and furin were assayed by gel electrophoresis and immunoblotting in UD-HL-60 cells, in neutrophil-like (NL) and macrophage-like (ML) D-HL-60 cells. 68 kDa PC2 protein was detected in UD-HL-60 cells and its levels decreased dramatically in NL and ML D-HL-60 cells. Comparative low concentrations were observed in NL D-HL-60 cells and peripheral human neutrophils. Furthermore, a decrease of PC2 content occurred in peripheral rat neutrophils when compared with enzyme levels in rat bone marrow neutrophils. High concentrations of 66 kDa PC1 protein were detected in UD- and D-HL-60 cells, reaching the highest values in ML D-HL-60 cells. PC3 did not appear in human peripheral neutrophils. 97 kDa furin was not found in HL-60 cells nor in human peripheral neutrophils. However, furin antibody recognized the 66 kDa PC3 protein, reproducing the results obtained with PC3 antibody. HL-60 is a regulated non-endocrine and non-nervous cell, and contained high levels of PC2 and PC3 enzymes, with the absence of furin. These results suggest that PC2 enzyme may be involved in the processing of proproteins in early stages of HL-60 differentiation processes, while PC3 may participate in early as well as in late stages of HL-60 differentiation, specially in ML cells.

725.4

PURIFICATION AND CHARACTERIZATION OF RECOMBINANT PC2. N.S. Lamango and I. Lindberg*, Dept. of Biochemistry and Molecular Biology, Louisiana State University School of Medicine, New Orleans, LA 71002

Following the finding that the neuroendocrine polypeptide 7B2 is necessary for the biosynthesis of enzymatically active prohormone convertase 2 (PC2) (Zhu and Lindberg, J. Cell Biol., *in press*) we have obtained large quantities of the recombinant enzyme from the conditioned medium of PC2-producing CHO cells supertransfected with cDNA coding for 21 kDa 7B2. We have purified the recombinant enzyme to apparent homogeneity with a 40 % recovery. Three protein bands of M_rs 66, 71 and 75 kDa were observed after SDS-PAGE followed by either Coomassie staining or Western blotting with PC2 antiserum. Spontaneous conversion of the 71 and 75 kDa species to the 66 kDa form was observed during incubation; the degree of conversion correlated with increased activity.

Active site titration with the specific PC2 inhibitor $h7B2_{155\text{-}185}$ showed that 27 % of the total protein was active enzyme. K_ms of 124 μM and 131 μM and Kcats of 0.49 ± 0.01 S^{-1} and 0.81 ± 0.02 S^{-1} for the substrates Cbz-Arg-Ser-Lys-Arg-AMC and Pyr-Arg-Thr-Lys-Arg-AMC were observed. The pH optimum of recombinant PC2 was 5.0, and the enzyme was inhibited by $h7B2_{155\text{-}185}$, ρ-CMS and EDTA but not by 1,10-phenanthroline, leupeptin, pepstatin, TPCK, TLCK, E-64 or soybean trypsin inhibitor. Rat proenkephalin was cleaved at multiple sites by the enzyme, suggesting that recombinant PC2 will prove to be a useful tool in the investigation of prohormone maturation.

725.5

EXPRESSION OF PC1 OR PC2 ANTISENSE IN STABLY TRANSFECTED STC-1 CELLS INHIBITS PROCESSING OF PRO CCK. J. Y. Yoon* and M. C. Beinfeld. Dept. Pharm. Physiol. Sci., St. Louis Univ. Med. Ctr., St. Louis, MO 63104 and Dept. Pharm. Exp. Ther., Tufts Univ. Sch. Med., Boston, MA 02111.

The predominant form of cholecystokinin (CCK) in the brain is CCK 8, the second most abundant neuropeptide next to NPY. CCK 8 is an eight amino acid peptide produced from a larger pro CCK precursor and has been implicated in a number of physiological effects including satiety, anxiety, memory and analgesia. A number of posttranslational modifying enzymes are involved in the biosynthesis of bioactive CCK 8 including tyrosine sulfotransferases, endoproteases and amidating enzymes; the identification of many of these enzymes are still under investigation.

Candidate endoproteases include PC1 and PC2, subtilisin like enzymes of the furin family that cleave peptides at monobasic or dibasic residues. Evidence suggesting roles for PC1 and PC2 in pro CCK processing include similar tissue distribution with CCK, both found in endocrine and neuronal tissue, and the expression of both PC1 and PC2 in several tissue culture cell lines that have the ability to processes pro CCK to CCK 8.

In order to further evaluate the role of PC1 and PC2 in CCK processing we have inhibited PC1 or PC2 by constitutively expressing antisense message in the murine intestinal tumor cell line STC-1, which produces not only CCK 8 but also CCK 22, the predominant form of CCK found in rat intestine. We have identified lines that show expression of antisense message by Northern hybridization and significantly reduced levels of PC1 or PC2 protein levels by Western analysis. By radioimmunoassay of G-50 chromatography fractions, preliminary data suggests that the inhibition of PC1 in STC-1 cells specifically inhibits the production of CCK 8 and inhibition of PC2 in STC-1 cells specifically inhibits the production of CCK 22. These data suggest the possible role of both PC1 and PC2 endoproteases in the processing of pro CCK. Supported by NIH grant NS 31602.

DEVELOPMENTAL EXPRESSION OF PROPROTEIN PROCESSING ENZYMES AND THE PC2 REGULATOR 7B2. M. Zheng[1]*, R. Day[2], N. G. Seidah[2], and J. E. Pintar[3]. [1]Dept. of Anat. & Cell Biol., Columbia Univ. P&S, New York, NY 10032; [2]Lab. of Biochem. Neuroendocrinol., Clin. Res. Inst. of Montreal, Montreal, Quebec H2W 1R7, Canada; [3]Dept. of Neurosci. & Cell Biol., UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854.

Many peptides modulating cellular growth and differentiation in development are first synthesized as precursors that require proteolytic processing by the "prohormone convertase" (PC) family of endoproteases. Previously we have presented the developmental expression profiles of PC1, PC2, and furin, and compared their patterns to those of potential substrates. We have since compared the expression of PC2 and its regulator 7B2 in development. Expression of these two genes often overlaps but 7B2 expression is dramatically reduced, if not absent, at e17 in multiple CNS regions where PC2 expression is high, such as the dorsal thalamus, hippocampus, and striatum. These differences could result in significant differential stoichiometry of 7B2 and PC2 proteins in these regions. We have also determined that two recently identified PC members, PC5 and PACE4, are also expressed prenatally. PC5 is expressed in the floor plate at e10 and, by midgestation, a low to middle level of PC5 is expressed in several regions including hypothalamus, brain stem, and spinal cord. In contrast, PACE4 expression is detected at high levels in hippocampus and low levels in the thalamus, brain stem, choroid plexus, and spinal cord. In several peripheral organ systems, including lung and gut, we observed remarkably complimentary patterns of PC5 and PACE4 gene expression. In the heart and liver, PACE4 transcripts are expressed (as is furin) at mid- to high levels, whereas PC5 is not expressed to any significant level in these organs. Taken together, these results suggest that both PC5 and PACE4 may be involved in neuropeptide precursor processing in the developing nervous system; the general nonoverlapping expression patterns in peripheral tissues suggest that PC5 and PACE4 may process distinct sets of proprotein substrates. Supported by DA-08622 (JEP).

MOLLUSCAN PROHORMONE CONVERTASES: STRUCTURAL DIVERSITY IN THE CENTRAL NERVOUS SYSTEM OF *LYMNAEA STAGNALIS* A.B. Smit*, S. Spijker, J. Klumperman and W.P.M. Geraerts. Graduate School of Neurosciences Amsterdam, Institute of Neurosciences, Faculty of Biology, Vrije Universiteit, 1081 HV Amsterdam, The Netherlands

In the central nervous system (CNS) of the mollusc *Lymnaea stagnalis* various prohormones have been characterized, from which (sets of) different neuropeptides can be generated by proteolytic cleavage and posttranslational modifications.

In order to address the enzymes involved in the processing of neuropeptide prohormones in the CNS, we used a PCR and cDNA cloning strategy, and characterized cDNAs corresponding to three different putative endoproteases. One cDNA encodes a protein of 653 residues with an overall sequence identity of ~80% with the catalytic domain of vertebrate PC2, and was called *Lymnaea* PC2 (LPC2). Expression of the LPC2 gene was exclusively found in neurons of the CNS, and two LPC2 transcripts of 3.0 and 4.8 kb were detected. Two other cDNAs were cloned using PCR and furin specific primers and were tentatively called Lfur1 (968 amino acids) and Lfur2 (837 amino acids). Lfur1 shows highest sequence identity to human furin (72%) in the catalytic domain and also the C-terminal region is highly conserved. Lfur2 is structurally related to furin and shows ~70% homology in the catalytic domain with PACE4 and PC5/6, whereas the sequence conservation in the C-terminal part of the protein is low. The Lfur1 gene is expressed in a broad range of tissues, and several sizes of transcripts can be detected. Expression of the Lfur2 gene is also found in many tissues and shows a single transcript of ~6.0 kb. Immunocytochemistry has indicated that the various *Lymnaea* convertases show cell-specific expression, that can be related to the maturation of specific prohormone substrates.

SECOND MESSENGER EFFECTS ON PROHORMONE CONVERTASES IN THE MEDULLARY THYROID CARCINOMA CELL LINE WE 4/2. B.L. Mania -Farnell*, I. Botros, R. Day, N.G. Seidah and T.P. Davis. Dept. of Bio. Sci., Purdue Univ. Calumet, Hammond, IN 46323; Clinical Res. Institute of Montreal, Montreal, Quebec H2W 1R7; Dept. of Pharmacology, Univ of Arizona, Tucson, AZ 85724.

Regulation of prohormone convertase mRNA expression was studied in the neuropeptide producing cell line WE 4/2, a rat medullary thyroid carcinoma line. To examine the effect of the cyclic AMP (cAMP) second messenger pathway on prohormone convertase 1 (PC1), PC2 and furin mRNA levels, WE 4/2 cells were treated with the phosphodiesterase inhibitor isobutyl-methylxanthine (IBMX, 0.5 mM). Phorbol-12-myristate-13-acetate (PMA, 0.5 uM) was used to determine if the protein kinase C (PKC) pathway regulated prohormone convertase mRNA levels. Messenger RNA levels were quantitated using Northern blot analysis in combination with cRNA hybridization probes, rat (r) PC1, rPC2 and rfurin. In this cell line activation of the cAMP pathway increased mRNA levels of all three prohormone convertases. PC1 mRNA levels increased 1.4 -fold after 3 hour treatments and 1.5 -fold after 6 hour treatments. PC2 mRNA levels increased 1.6 -fold and 1.8 -fold and furin mRNA levels increased 1.5 -fold and 1.8-fold, after 3 and 6 hours respectively. Treatment with PMA or PMA combined with IBMX did not produce significant changes in PC1, PC2 or furin mRNA levels. This pattern of regulation differs from one seen previously in the human neuroepithelioma cell line SK-N-MCIXC (Soc. Neurosci. Abs. 19, 1993), suggesting that prohormone convertases may be differentially regulated by cAMP and PKC mechanisms in a tissue specific manner. Supported by N.I.M.H. # MH42600.

PRODUCTION OF RAT PRO CCK IN INSECT CELLS INFECTED WITH A RECOMBINANT *BACULOVIRUS*. Margery C. Beinfeld* and Liza Yum. Dept. Pharm. Exp. Ther., Tufts Univ. Sch. Med., Boston, MA. 02111 and Dept. Pharm. Physiol. Sci., St. Louis Univ. Med. Ctr., St. Louis, MO. 63104.

Previous unsuccessful attempts to produce recombinant rat pro CCK in bacteria led us to the *baculovirus* expression system. The rat CCK cDNA was inserted into a transfer vector and was transfected with linearized wild type baculovirus DNA into Sf9 cells. Live virus particles were recovered and amplified by multiple rounds of infection. Production of pro CCK was monitored with the V9M antiserum which detects the amino terminal of pro CCK. Recombinant virus infected Sf9 cells produced a protein of about 10,000 molecular weight and about 80% of this material was secreted, indicating that insect cells recognize the rat signal and sorting sequences. At least half of it appears to be intact prohormone, an additional smaller protein is recovered which appears to be the amino terminal of pro CCK_4. This peptide is a normal cellular product of rat pro CCK processing in rat brain and CCK secreting cell lines which we have also shown to be secreted. Several of our antisera directed against different regions of the pro CCK detects this material, while the CCK 8 antiserum does not. Sf9 cells secrete at least 10 ng/ml while High 5 cells secrete about 5 times more. Secretion is maximal 3 days after infection. Pro CCK could be biosynthetically labeled with ^{35}S sulfate indicating that insect cells are able to sulfate tyrosine residues like other eukaryotic cells. In summary, the *baculovirus* expression system produces significant quantities of intact rat pro CCK for enzymatic and structural studies. Supported by NIH grant NS31602.

INHIBITION OF DIPEPTIDYL PEPTIDASE IV (CD 26) AND PROLYL OLIGOPEPTIDASE BY PEPTIDYL NITRILES. S. Wilk*, J. Li and E. Wilk Dept. of Pharmacology, Mount Sinai Sch. Med. of CUNY, New York, N.Y. 10029

Dipeptidyl peptidase IV (DPP IV; E.C. 3.4.14.5) and prolyl oligopeptidase (EC 3.4.21.26) are serine proteinases which cleave peptide bonds after proline residues. DPP IV, a membrane-bound ectoenzyme, cleaves dipeptides from the amino terminus of peptides which contain proline as the penultimate amino acid. Substrates include substance P and neuropeptide Y. DPP IV is also identical to the T-cell activation antigen CD 26. Prolyl oligopeptidase, a cytosolic enzyme, cleaves peptidyl prolyl peptide and peptidyl prolyl amino acid bonds. Substrates include substance P, bradykinin, neurotensin, TRH, LHRH and angiotensin. Peptidyl nitriles generally believed to be weak inhibitors of serine proteinases, were found to potently inhibit these two enzymes. DPP IV is inhibited competitively by aminoacyl prolyl nitriles such as Ala-ProCN (Ki=0.2uM). Prolyl oligopeptidase is inhibited non-competitively by Fmoc-aminoacyl prolyl nitriles. The most potent inhibitors were FmocPro-ProCN and FmocAla-ProCN (Ki=5nM). These nitriles are readily synthesized and are stable. They should be of value in studies probing the physiological significance of these enzymes. Supported by NS-17392 and a Research Scientist Award MH-00350 to S.W.

725.11

EXPRESSION OF PROENKEPHALIN (PE) AND IN VITRO PROCESSING OF PURIFIED PE BY THE 'PROHORMONE THIOL PROTEASE' (PTP). V.Y.H. Hook*, M.R. Schiller, and L. Mende-Mueller+. Dept. of Medicine, Univ. of Calif., San Diego, #Dept. of Biochem., Uniformed Services Univ., Bethesda, MD., and +Dept. of Biochem., Med. College of Wisconsin, WI.

The 'prohormone thiol protease' (PTP) is a novel cysteine protease involved in proenkephalin processing. This study examined PTP processing of proenkephalin (PE) to intermediate products, and assessed kinetics of PE processing. Recombinant PE was obtained by high level expression in *E. coli*; PE was then purified by DEAE-Sepharose, gel electrophoresis, and reverse-phase HPLC. Authentic purified PE was confirmed by amino acid composition analyses and peptide microsequencing. In time course studies, PTP converted PE (12 μM) to intermediates of 22.5, 21.7, 12.5, and 11.0 kDa that represented NH_2-terminal fragments of PE, as assessed by peptide microsequencing. Differences in M_r's of the 22.5, 21.7, 12.5, and 11.0 kDa products reflect PTP processing of PE within the COOH-terminal region of PE, which resembles PE processing in vivo. Products of 12.5, 11.0, and 8.5 kDa resulted from PTP cleavage between Lys-Arg at the COOH-terminus of (Met)enkephalin-Arg^6-Gly^7-Leu^8. PTP has a $K_{m(app)}$ value of 18.6 μM PE and $V_{max(app)}$ of 1.98 mmol/hr/mg. These kinetic constants are consistent with intragranular levels of PE and PE-products. Results demonstrating PTP conversion of PE to intermediates resembling those in vivo, and kinetics that are compatible with in vivo PE processing, implicate a role for PTP in PE processing.

INITIAL PROCESSING OF PROENKEPHALIN IN CHROMAFFIN CELLS OCCURS AT FOUR DIBASIC SITES. S.P. Wilson*, F. Liu and P.R. Housley. Dept. of Pharmacology, University of South Carolina School of Medicine, Columbia, SC 29208.

Processing of proenkephalin was examined in bovine chromaffin cells using recombinant plasmids containing the human prepro-enkephalin (hPPE) cDNA under the control of the cytomegalovirus immediate early enhancer/promoter. Following transfection of hPPE-containing plasmids into the cells, several immunoreactive bands were observed on Western blots with monoclonal antibodies that recognize human, but not bovine, proenkephalin sequences. The pattern of immunoreactive peptides observed was similar to that of endogenous proenkephalin processing products. A series of recombinant plasmids containing mutations in the hPPE sequence at the twelve dibasic processing sites were then constructed. Conversion of Lys-Lys and Lys-Arg sequences to Lys-Gln and of Arg-Arg to Arg-Gln did not alter initial hPPE processing at eight of the twelve putative processing sites. Mutations at the remaining four sites altered the pattern of processing products consistent with blockade of processing at the individual sites. When hPPE cDNA containing mutations at all four of the initially processed sites was expressed none of the normal processing products were found, and a single, novel peptide was produced. These data confirm the importance of dibasic amino acid sequences in proenkephalin processing, but also suggest the importance of secondary or tertiary precursor structure in cleavage of these sites. (Supported by NSF Grant IBN 94-09201)

PROENKEPHALIN PROCESSING IN NEUROENDOCRINE CELLS: CONTRIBUTION OF PC2. K. Johanning, J.P. Mathis, J. Lyles* and I. Lindberg. Dept. of Biochemistry and Molecular Biology, Louisiana State University School of Medicine, New Orleans, LA 70112.

The biosynthetic pathway for proenkephalin was examined in primary cultures of bovine chromaffin cells, in the rat insulinoma cell line Rin5f stably transfected with rat proenkephalin cDNA (Rin/PE) and in a mouse anterior pituitary tumor cell line, AtT-20 (AT) transfected with either rat proenkephalin (AT/PE) alone or with both pro-enkephalin and mouse prohormone convertase 2 (AT/PC2/PE). In chromaffin cells, pulse-chase experiments showed that within 2 h, proenkephalin was mostly processed to Peptide B, at a rate similar to that previuosly observed in transfected AtT-20 cells. Initial processing of proenkephalin in Rin/PE proceeded much more slowly; full conversion of proenkephalin to Peptide B required at least 12 h. Cleavage of the Peptide B fragment to free Met-enkephalin-Arg-Phe occurred within 6 h in chromaffin cells, more slowly than the identical cleavage event in AT cells (4h). In AT/PC2/PE, this cleavage was complete at 2 h.

RIAs of cellular extracts of Rin/PE cells indicated a a more complete processing profile as compared to AT/PE cells and to chromaffin cells. AT/PC2/PE cells exhibited a similar processing profile as that of Rin/PE cells. These results indicate that PC2 is responsible for the later events of proenkephalin processing.

HALOPERIDOL DECREASES MET-ENKEPHALIN DEGRADATION AND METABOLITE ACCUMULATION ON REGIONAL BRAIN SLICES. C.S. Konkoy*, S.M. Waters and T.P. Davis. Dept. Pharmacology, Univ. of Arizona, Tucson, AZ 85724.

Previous work in our laboratory provided evidence for regional specificity in the metabolism of met-enkephalin (ME) by intact brain slices. For example, studies with selective peptidase inhibitors suggested that aminopeptidase activity represents the predominant pathway for ME degradation in frontal cortex (FC) whereas other proteases, in addition to aminopeptidases, participate in the degradation of ME in caudate-putamen (CP). Also, subchronic administration (7 day, i.p.) of neuroleptics alters the metabolism of neuropeptides (sub P, CCK and ME) by regional brain slices (JPET, in press). In the present study, selective inhibition of aminopeptidase activity by bestatin (50 μM) decreased the recovery of ME fragments Tyr and Gly-Gly-Phe-Met on FC and CP slices. We inhibited neutral endopeptidase (NEP) and angiotensin converting enzyme (ACE) by phosphoramidon (50 μM) and captopril (50 μM) respectively, thereby decreasing recovery of ME fragment Tyr-Gly-Gly on CP slices. Tyr-Gly-Gly accumulation was sparse in FC, which is consistent with low levels of NEP and ACE activity in this region. Subchronic, but not acute, administration of haloperidol (1 mg/kg) decreased ME degradation on FC (16% vs. control) and on CP (10% vs. control) slices. Haloperidol treatment also decreased accumulation of aminopeptidase-derived fragments Tyr and Gly-Gly-Phe-Met in both brain regions. The accumulation of Tyr-Gly-Gly, however, was not altered by haloperidol treatment in either brain region. These data suggest that the haloperidol-induced decrease in ME degradation results from a selective reduction in the activity of aminopeptidase(s). (Supported by NIMH grant MH42600)

EFFECT OF DOPAMINERGIC DRUG ADMINISTRATION ON SUBSTANCE P DEGRADATION BY REGIONAL RAT BRAIN SLICES. S.M. Waters*, C.S. Konkoy and T.P. Davis. Dept. Pharmacology, Univ. Arizona, Tucson, AZ 85724.

The neuropeptide substance P (SP) interacts with nigrostriatal and mesocorticolimbic neurons to modulate dopamine (DA) release. Neuroleptic drugs have been shown to decrease the level and mRNA of SP following subchronic administration. Additionally, our laboratory has shown that the metabolism of SP is altered in a regionally specific manner following 7 day administration of the typical neuroleptics haloperidol (1mg/kg) and chlorpromazine (20mg/kg) suggesting altered neuropeptidase activity (J. Pharmacol. Exp. Ther., in press). In the present study, the effect of subchronic (7 day, i.p.) administration of atypical antipsychotics and selective dopamine receptor agonists and antagonists on SP degradation was determined using intact, rat frontal cortex (FC), caudate-putamen (CP) and nucleus accumbens (NA) slices.

In contrast to the decrease in SP degradation in CP and NA following typical neuroleptics, the nonselective DA agonist apomorphine (5mg/kg, bid) significantly increased SP metabolism in NA while the atypical antipsychotic clozapine (20mg/kg) had no effect on SP metabolism in any region studied. Selective DA receptor compounds were used to determine through which receptor subtype haloperidol, chlorpromazine and apomorphine produce their effect on SP metabolism. Neither the selective DA_1 agonist SKF 38393 (1 or 5mg/kg, bid) or the DA_1 antagonist SCH 23390 (0.5 or 2.5 mg/kg, bid) had an effect on SP degradation. Interestingly, the DA_2 antagonist sulpiride (100 mg/kg, bid) was also without significant effect. Therefore, these data suggest that neuroleptic-induced alterations of SP-metabolizing neuropeptidases are mediated through additive interactions at multiple DA receptor subtypes. (Supported by NIMH grant MH42600 and an AFPE fellowship).

OPIOIDS: ANATOMY, PHYSIOLOGY AND BEHAVIOR III

726.1

LOCALLY ADMINISTERED MORPHINE REDUCES VENTRAL PALLIDAL OPIOID PEPTIDE RELEASE. M.F. Olive* and N.T. Maidment. Neuroscience Ph.D. Program & Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024, USA.

Previous work from our laboratory has demonstrated a morphine-induced elevation in pallidal extracellular opioid peptide levels following peripheral administration (NeuroReport, in press). In an initial attempt to determine the site of action for this effect, morphine was locally administered into the ventral pallidum and changes in opioid peptide release in this region were studied in freely moving rats using in vivo microdialysis coupled to highly sensitive radioimmunoassay procedures. We have previously shown that the opioid peptides recovered from pallidal dialysates are primarily met- and leu-enkephalin (Neuroscience 33:549-557, 1989). Male Sprague-Dawley rats were implantated with guide cannulae and allowed at least four days of recovery prior to implantation with dialysis probes (2 mm membrane length) into the ventral pallidum. Following an overnight equilibration period, dialysis samples were collected at 30 min intervals. When morphine was incorporated into the perfusion medium for 30 min at 2 h intervals, opioid peptide release was slightly but not significantly decreased with respect to baseline during each 90 min post-injection period at 10 μM (16.7±18.5%, n=7) and 100 μM (30± 15.3%, n=6) doses. However, when 100 μM morphine was incorporated into the perfusion medium for 120 min at 4 h intervals, opioid peptide release was significantly reduced during each 2 h period post-injection, with the second administration producing a more profound (46.9±14.9%, n=6) decrease. These data demonstrate that opioid peptide release in the ventral pallidum is suppressed by local administration of morphine and suggest that this peptide release is perhaps under control of presynaptic μ opioid receptor autoregulatory mechanisms. Supported by DA05010, DA05634 & the W.M. Keck Fdn.

726.2

INTRASTRIATAL MORPHINE DECREASES THE RELEASE OF DOPAMINE IN THE STRIATUM: TOLERANCE PRODUCED BY REPEATED MORPHINE ADMINISTRATION. T.P. Piepponen, J. Mikkola, M. Ruotsalainen & L. Ahtee*. Dept. of Pharmacy, Div. of Pharmacology and Toxicology, P.O.Box 15, FIN-00014 University of Helsinki, Finland.

It is well-known that systemic administration of opioids increases the synthesis, metabolism and release of dopamine (DA) in the striatum thereby increasing DA transmission. It appears, however, that morphine can also have an inhibitory effect on nigrostriatal DA release as reflected in striatal 3-methoxytyramine in rats (Ahtee et al., J. Pharmacol. Exp. Ther. 1990, 255, 803-808). The effect of morphine challenge on DA transmission is augmented during withdrawal from chronic morphine treatment (Ahtee et al., J. Pharmacol. Exp. Ther. 1989, 249, 303-310; Attila and Ahtee, N-S Arch. Pharmacol. 1984, 327, 201-207; Honkanen et al., Neurosci. Lett. 1994, 180, 119-122). Therefore, it is possible that the sensitization of DA release during withdrawal results from tolerance to the inhibitory effect of morphine on DA release. To study this inhibitory effect rats were implanted with microdialysis probes into the striatum under pentobarbitone anesthesia, and allowed to recover for 40 h after surgery. Morphine (1, 10, and 100 μM) was dissolved in Ringer-solution and given directly into the striatum through the microdialysis probe (2 μL/min) for 4 h. Extracellular concentrations of DA and its metabolites DOPAC and HVA were determined by HPLC with electrochemical detection. Morphine significantly and dose-dependently reduced striatal DA release (by up to 60 %, $P<0.001$). The concentrations of DA metabolites were only slightly decreased (by 10-15 %). The effect of morphine (100 μM) was reversed by naltrexone (2.5 mg/kg s.c.). In rats withdrawn for 48 h from repeated morphine treatment (20 to 50 mg/kg s.c. for 7 days) morphine (100 μM) reduced the release of DA significantly less than in rats treated repeatedly with saline ($P<0.01$). Our results confirm the assumption that there is an inhibitory component to the effect of morphine on striatal DA release. Further, development of tolerance to the inhibitory effect of morphine on striatal DA release may at least partly account for the sensitization of nigrostriatal DA transmission to morphine challenge during withdrawal. (Supported by grants from the Finnish Cultural Foundation, the University of Helsinki and the Academy of Finland)

726.3

POTASSIUM AND 4-AMINOPYRIDINE EVOKED RELEASE OF STRIATAL DOPAMINE AND HIPPOCAMPAL NOREPINEPHRINE DURING MORPHINE WITHDRAWAL. Kenneth Grasing*, Stefan D. Schlussman, and John J.Woodward Program in Clinical Pharmacology, Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, New Jersey 08901

Microdialysis studies have shown that opiate withdrawal can diminish *in-vivo* levels of extracellular dopamine (DA). Using a striatal slice preparation, previous studies have demonstrated that the electrically evoked release of DA is decreased for periods of up to three weeks following opioid withdrawal. We attempted to extend these findings by examining the potassium (K^+) and 4-aminopyridine (AP) stimulated release of DA in the striatum and norepinephrine (NE) release in the hippocampus following withdrawal from morphine dependence.

Wistar rats received continuous infusions of morphine sulfate (MS) at 6.4 mg/kg-hr delivered by subcutaneous osmotic pumps (n= 6) or sham operations (n = 6) for 7 days. Following 2 to 15 days of withdrawal, animals were sacrificed by decapitation, the striatum and hippocampus were removed and cross cut to 350 μm slices with a McIlwain tissue chopper. Tissue slices were washed extensively and then loaded with [^{3}H] neurotransmitter. After determining levels of baseline release, slices were exposed to 25 mM K^+ or 300 μM AP (stimulation 1[S1]), with a second release stimulated after an additional baseline period (S2). Tissue from morphine (MS) treated and control (CTL) subjects demonstrated similar levels of neurotransmitter release. Mean and standard deviation for striatal tissue S1 was 9.5% ± 3.4 and 10.4 ± 2.1 for CTL and MS K^+ stimulated with 6.0% ± 2.1 and 7.8% ± 3.9 for CTL and MS AP stimulated. Values for hippocampus were 7.5% ± 2.3 and 7.0 % ± 0.9 for CTL and MS K^+ stimulated and 3.9% ± 1.0 and 4.7% ± 1.7 for CTL and MS AP stimulated. In conclusion, niether K^+ or AP evoked release of striatal DA or hippocampal NE were altered during MS withdrawal.

726.4

EFFECT OF NITRIC OXIDE SYNTHASE INHIBITION ON ACUTE MORPHINE AND CLONIDINE WITHDRAWAL RESPONSE IN THE RAT LOCUS COERULEUS. S. Hall, S. Duggan, B. Milne, K. Jhamandas*. Departments of Pharmacology & Toxicology, and Anesthesia, Queen's University, Kingston, Ontario, Canada. K7L 3N6.

Activation of NMDA and non-NMDA receptors contributes to the hyperactivity of noradrenergic neurons of the locus coeruleus (LC) associated with opioid and non-opioid drug withdrawal syndromes. Using an *in vivo* voltammetric approach, we have examined the role of nitric oxide (NO), which mediates NMDA receptor function, in this hyperactivity. In the anesthetized rat, an acute intraventricular injection of morphine (10 μg) or clonidine (10 μg) suppressed catechol oxidation current (CA.OC) recorded from the LC using differential normal pulse voltammetry. A subsequent injection of the opioid antagonist naloxone (2 mg/kg IV) given 45 minutes after morphine, or the α_2-receptor antagonist atipamezole given 45 minutes after clonidine, reversed drug-induced inhibition of LC response and produced an increase in CA.OC above baseline (LC withdrawal response). Pretreatment of animals with Nω-nitro-L-arginine methyl ester (L-NAME), an inhibitor of NO synthase, blocked the LC withdrawal response. This treatment, however, did not influence the inhibitory effect of morphine or clonidine action on LC activity. The results suggest that NO plays a role in the genesis of acute morphine and clonidine withdrawal at the level of LC. [Supported by Medical Research Council of Canada]

726.5

EFFECTS OF THE NO SYNTHASE INHIBITOR, L-NAME ON MORPHINE TOLERANCE: AN EEG STUDY IN THE RAT X. Guo, L. R. King, A. Mattia and J. E. Moreton*. Pharmacology and Toxicology, Univ. Maryland Sch. Pharmacy, Baltimore, MD 21201.

A previous study has shown that N^G-nitro-L-arginine methyl ester (L-NAME), a NO synthase inhibitor, attenuated the development of tolerance to the analgesic effects of morphine in mice (Majeed et al., 1993). In this study, electroencephalography (EEG) was used to investigate the effect of L-NAME on morphine tolerance in three groups of female Sprague-Dawley rats bearing chronic i.v. cannulas and cerebrocortical electrodes. Groups I, II and III received chronic saline, chronic morphine, or chronic morphine plus L-NAME (5 mg/kg/day), respectively. Cumulative dose-response curves for EEG total power and edge frequency were generated in each group by giving morphine (2.5, 5, 10, 20, 40 and 80 mg/kg, i.v.). Relative to Group I, Group II demonstrated morphine tolerance as shown by decreased EEG total power and increased edge frequency. Coadministration of L-NAME (Group III) did not prevent morphine tolerance except at the highest morphine dose. Similar to the report of Rauhala et al. (1994) for hyperthermic and hormonal responses in the rat, our data likewise suggest that tolerance to the EEG effects of morphine are not attenuated by L-NAME.

726.6

5-NITRO-6,7-DIMETHYL-2,3-QUINOXALINEDIONE (ACEA-1328), A NOVEL NMDA RECEPTOR/GLYCINE SITE ANTAGONIST BLOCKS CHRONIC TOLERANCE TO MORPHINE IN THE TAIL FLICK TEST. **K. Lutfy[1], P. Doan[1], S.X. Cai[2] and E. Weber[1]. [1]Dept. of Pharmacology, University of California, Irvine, Irvine, CA 92717; [2]Acea Pharmaceuticals, Inc., A subsidiary of CoCensys, Inc., 213 Technology Drive, Irvine, CA 92718.**

The results of recent studies suggest that activation of the N-methyl-D-aspartate (NMDA) receptor is critical in the genesis of tolerance to morphine. In the present study we have tested the hypothesis that blockade of NMDA receptors via antagonism of the glycine co-agonist site can block opioid tolerance. To study the acute effect of ACEA-1328 on morphine-induced antinociception, mice were injected with either Bis-Tris (0.2 M) or ACEA-1328 (1, 10, and 20 mg/kg, i.p.). Mice were then immediately injected with morphine (1-8 mg/kg, s.c.), and tested in the tail flick assay 30 min later. In tolerance studies, mice were daily injected with either Bis-Tris or ACEA-1328 (20 mg/kg, i.p.) immediately followed by an injection of either saline or morphine (10 mg/kg, s.c.) for 9 days. On day 10 (test day), a baseline (pre-drug) tail flick latency was measured for each mouse; mice were then injected with morphine (3-10 mg/kg, s.c.). Thirty min later, mice were tested for post-drug tail flick latencies. ACEA-1328 acutely potentiated but chronically had no significant effect on the antinociceptive effect of morphine. Chronic administration of morphine produced an approximately 2-fold decrease in the potency of morphine which indicates tolerance developed to the antinociceptive effect of the drug. Co-administration of ACEA-1328 with morphine blocked morphine tolerance. These data suggest that blockade of the NMDA receptor/glycine co-agonist site can prevent morphine tolerance. (Supported in part by NIDA Grant DA 06726)

726.7

THE EFFECT OF MK-801 ON THE EXPRESSION OF MORPHINE TOLERANCE IN THE NEONATAL RAT SPINAL CORD. J.A. Bell* and C.L. Beglan. Neuroimaging & Drug Action Sec, IRP, NIDA, Balto, MD 21224.

We have previously shown chronic co-treatment with MK-801 does not prevent the development of morphine tolerance in the isolated spinal cord of the neonatal rat. In the present study we tested the effect of acute MK-801 on the expression of tolerance in this preparation. Acute morphine reduces the area of the ventral root potential (VRP) without reducing the peak amplitude. MK-801 (300nM) alone has no effect on the peak amplitude or area of the VRP, but enhances the morphine induced depression in saline treated neonates. Thompson et al., (1992) have characterized various components of the electrically-evoked VRP relating to various types of afferent input. In the present study we evaluated the peak of the prolonged component of the VRP which occurs 2 seconds after a single shock stimulation of the dorsal root of sufficient intensity to activate C-fibre afferents. MK-801 (300nM) alone had no effect on the amplitude of the VRP 2 seconds after the stimulus. Morphine in concentrations of (10nM, 100nM, 1uM, 10uM) also had no effect on the peak of the prolonged component; however, morphine reduced the area of the VRP by reducing the prolonged late portion of the response. Acute MK-801 with morphine in the above concentrations, decreased the 2 second peak by 23, 37, 55, 69 percent respectively in saline treated neonates. In chronic morphine treated neonates acute MK-801 (300nM) with morphine in the above concentrations decreased the 2 second peak by 11, 34, 53, 64 percent respectively. These results show, in the presence of morphine tolerance, acute MK-801 still acts in synergy with morphine to reduce the peak of the prolonged VRP. Thus tolerance to this synergistic effect is not produced by chronic morphine administration.

INTRACEREBRAL INJECTION OF MORPHINE IN THE SUBSTANTIA NIGRA INDUCES C-FOS PROTEIN IN THE STRIATUM ASSOCIATED WITH A ROTATIONAL BEHAVIOUR. B. Bontempi, J. Liu, S. S. Massa* and F.R. Sharp. Dept. of Neurology, Univ. of California at San Francisco and SFVAMC, San Francisco, CA 94121.

We previously showed that systemic adminstration of morphine induced c-fos mRNA and fos protein in neurons of the medial and ventral striatum (ST) and in the nucleus accumbens. The induction was completely blocked by a pretreatment with the D1 antagonist SCH23390 and the NMDA receptor antagonist MK-801. (Liu et al.,1994, PNAS, 91, 8537-8541). However, these results do not demonstrate where morphine is actually acting nor what neuronal pathways and receptors are mediating the morphine induciton of fos. In an attempt to answer these questions, using standard stereotaxic surgical techniques, local intracerebral injections of morphine have been performed into brain regions hypothesized to be involved in mediating fos induction. The injection of 10 ug of morphine in the substantia nigra (SN) induces two different behavioral responses associtaed with two different patterns of Fos proteins in the ST. Some animals remain quiet after the injection and their fos pattern in the ST is similar to the one received systemic injection of morphine (refered as medio-dorso pattern). Others develop a rotation behaviour controlateral to the injection side, associated with striatal fos pattern much more latero-dorsal. The unilateral injection in the SN of the mu1 selective antagonist naloxonazine given 30 minutes prior to the systemic injection of morphine prevents c-fos induction in the ST ipsilateral to the naloxonazine injection, showing that morphine acts mainly through the mu1 receptors located in the SN to induce dopamine release and fos protein in the ST. Taken together, these results suggest tht fos induction reflects the activation of D1 receptors and could be used as a potential marker for dopamine release in particular areas of the ST that may be responsible for rotational behaviour.

EFFECT OF NALOXONE AND NEUROPEPTIDE FF (NPFF) ON THE EXPRESSION OF c-FOS IN THE BRAIN OF MORPHINE-DEPENDENT RATS. K.H. Jhamandas, K.H. Harris*, M. Sutak and J.H. Jhamandas. Department of Pharmacology & Toxicology, Queen's University, Kingston, Ontario & Department of Medicine (Neurology) & Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada.

NPFF has been designated as an endogenous morphine modulatory peptide with a potential to exert anti-opioid or opioid-like effects. To assess the potential of this peptide as an anti-opioid, we examined the effect of NPFF, 1DME (a synthetic NPFF analog resistant to degradation), and naloxone on behaviour and CNS expression of Fos in morphine-dependent and control rats. Animals received intracerebroventricular infusions of morphine (15μg/hr) or saline for 5 days, following which central injections of either naloxone, NPFF, or 1DME were made. In saline-infused animals naloxone produced few behavioural signs and minimal expression of brain Fos immunoreactivity. Injection of naloxone (2μg) into the lateral ventricle of morphine-dependent animals produced signs of autonomic and somatic hyperactivity. It also produced significant elevation of Fos positive neurons in the area postrema, nucleus tractus solitarius, locus coeruleus and paraventricular nucleus. Injection of NPFF (5μg) or 1DME (10μg) produced behavioural signs and induced Fos levels comparable to those seen after naloxone injection in saline-treated animals. These results suggest that centrally administered NPFF or its analog do not appear to mimick the actions of naloxone in morphine-dependent animals.

CHRONIC EXPOSURE TO MORPHINE ATTENUATES THE EXPRESSION OF INTERLEUKIN-1β CONVERTING ENZYME IN THE RAT BRAIN. S.L. Chang*, G. Wu, J. Graf, [1]J.E. Zadina and N.A. Patel Department of Biology, Seton Hall University, South Orange, NJ 07079; [1]VA Medical Center and Tulane Medical School, New Orleans, LA

Alterations in the production, activity, or metabolism of interleukin-1β (IL-1β), an immunocytokine, by exogenous factors may have modulatory effects on the neuro-endocrine-immune system. We previously reported that chronic morphine treatment attenuates interleukin-1β activation of FOS expression in the rat hypothalamic paraventricular nucleus (Chang, et al 1994). Recently, we found that chronic exposure to morphine attenuates IL-1β immunoreactivity in the rat hippocampus (Patel, et al 1995). A cysteine protease, interleukin-1β converting enzyme (ICE), has been shown to cleave the inactive 31 Kd precursor to yield the biologically active 17 Kd form of IL-1β. In this study, we examined the expression of ICE by reverse transcriptase polymerase chain reaction (RT-PCR) in the rat hypothalamus and hippocampus following chronic treatment with morphine versus placebo. Adult male Harlan Sprague-Dawley rats (275-300 g) were implanted subcutaneously with 2 pellets of either morphine sulfate (75 mg/pellet) or placebo on Day 1 and 4 pellets on Day 2. On Day 5, the animals were decapitated and the hippocampus and hypothalamus were collected and frozen on dry ice until total RNA isolation. The RT-PCR procedures were performed on the total RNA samples. The expression of ICE in both hypothalamus and hippocampus of the rat given chronic morphine treatment was less than that of animals given placebo. These data suggest that a decrease in ICE may mediate, or contribute to the attenuation of IL-1β expression in the rat brain following chronic treatment with morphine.

CHRONIC MORPHINE (MOR) TREATMENT LEADS TO COMPARABLE REDUCTIONS IN RESPONSES OF GUINEA PIG nTS NEURONS TO MOR, MUSCIMOL (MUS) AND 2-CHLOROADENOSINE (2-CADO). C.J. Malanga, W.W. Fleming and D.A. Taylor*, Dept. of Pharmacology, WVU School of Medicine, Morgantown, WV 26506-9223.

Chronic implantation with MOR pellet leads to a 5.6-fold subsensitivity of guinea pig nTS neurons ***in vitro*** to MUS and a 3-fold supersensitivity to elevations in extracellular K^+. Since cumulative addition of either MOR or 2-CADO leads to acute desensitization in control preparations, the specificity of the chronic subsensitivity of opioid tolerant nTS neurons was examined using single concentrations of the agonists. Extracellular action potentials of individual nTS neurons were recorded and drug responses quantified as the percent reduction in frequency. Each neuron was exposed to MOR (1μM) and either MUS (0.3μM) or 2-CADO (1μM). Chronic treatment with MOR led to a magnitude of reduction in the inhibitory activity of each agent that was similar among brain slice preparations for each agonist employed. MUS produced 50% while MOR produced 75% inhibition of neuronal activity in placebo treated preparations. Chronic treatment with MOR reduced the inhibitory activity of MOR by 41% and that of MUS by 47%. 2-CADO reduced neuronal activity by 65% while MOR inhibited the activity of the same neurons by 60%. Chronic ***in vivo*** treatment with morphine reduced the inhibitory effects of these nTS neurons ***in vitro*** by 66% for MOR and 65% for 2-CADO. Thus, the development of tolerance to opioids in the guinea-pig brainstem is associated with a nonspecific change in responsiveness to a variety of agonists. The data are consistent with a cellular mechanism of adaptation involving general neuronal responsiveness, such as membrane properties, rather than specific receptors. Supported in part by NIH grant DA03773.

NORADRENERGIC BLOCKADE DISSOCIATES BIOCHEMICAL AND NEUROSECRETORY RESPONSES OF RAT OXYTOCIN NEURONES TO MORPHINE WITHDRAWAL EXCITATION.

C.H. Brown*, L.E. Johnstone, T. Onaka†, N.P. Murphy, G. Leng & J.A. Russell.

Department of Physiology, University of Edinburgh, EH8 9AG, U. K., †Department of Physiology, Jichi Medical School, Japan, 329-04.

Magnocellular oxytocin (OT) cells develop morphine dependence, seen as increases in firing rate, supraoptic nucleus (SON) Fos protein expression and OT secretion following naloxone (NLX)-precipitated withdrawal (Bicknell *et al*, J. Physiol., 396, 297-317, 1988). Brainstem noradrenergic (NA) cells, principally the A2 group in the nucleus tractus solitarius (NTS), project to SON OT cells (Cunningham & Sawchenko, TINS, 14, 406-411, 1991) and also develop morphine dependence (Stornetta *et al*, Brain Res., 624, 19-28, 1993). Acute intracerebroventricular (i.c.v.) infusion of the α_1-antagonist, benoxathian (BEN), delays the increase in firing rate of SON OT cells and the increase in plasma OT concentrations following withdrawal. Thus, withdrawal excitation of OT cells may passively follow excitation in the afferent A2 projection. Expression of the protein product (Fos) of the immediate early gene *c-fos* was used to determine the activation of SON OT cells during NLX-precipitated withdrawal in barbiturate-anaesthetised Sprague-Dawley rats challenged with a prolonged infusion of BEN. Projections to the SON were retrogradely-labelled with fluorescent microspheres and this was coupled with Fos immunocytochemistry to determine which inputs to the SON are activated during withdrawal excitation. Contrary to the electrophysiological and plasma OT results, the increased Fos expression in the SON was unaltered by i.c.v infusion of BEN indicating that, while electrical and secretory activity is attenuated by α_1-antagonism, biochemical excitation progresses within OT cells regardless. Of retrogradely-labelled cells, NTS cells are selectively activated during withdrawal. Thus, dependence is an intrinsic property of OT cells but synaptic activity in afferent NTS NA projections is required for expression of withdrawal excitation as neurosecretion. Supported by the B.B.S.R.C.

MORPHINE-INDUCED ANALGESIA IS DIFFERENTIALLY AFFECTED BY DURATION AND TYPE OF SUCROSE FEEDING. K. E. D'Anci, R. B. Kanarek*, R. Marks-Kaufman and H. Blohm. Dept. of Psychology., Tufts Univ., Medford, MA 02155.

Previous research shows that intake of palatable foods alters morphine-induced analgesia (MIA). Some of these studies found an enhanced MIA after sucrose feeding whereas others showed a decreased MIA. The purpose of the present studies was to examine whether acute versus chronic exposure to sucrose solutions differentially alters MIA, and whether availability of water in addition to sucrose is necessary to enhance MIA.

Experiment 1 used 20 adult male Long-Evans VAF rats. All rats had ad lib access to ground chow and water. Ten rats were also given a 32% sucrose solution in addition to water. The acute test phase took place after 5 hr of access to either sucrose or water alone. The chronic test phase took place after rats had been consuming sucrose for 3 wks. MIA was assessed with the tail-flick method. Injections of 2.5 mg/kg (ip) of morphine sulfate were given in a cumulative dose paradigm every 30 min. until a final dose of 15 mg/kg was achieved. In the acute feeding test, sucrose suppressed MIA, whereas chronic intake of sucrose significantly enhanced MIA.

The second study examined if a choice between water and sucrose was necessary to alter MIA. Three diet conditions were used with 10 rats in each: water alone, sucrose and water, and sucrose alone. All rats were also fed ground chow. There was an acute test after 5 hr of fluid availability, and a chronic test after 3 wks. In the acute phase, sucrose alone suppressed MIA relative to water and sucrose and water. During the chronic stage, however, exposure to sucrose regardless of a water choice enhanced MIA.

These results indicate that duration of exposure to palatable foods influences MIA. Acute exposure may release endogenous opioid peptides and induce tolerance to morphine, while chronic intake may alter opioid receptors.

CHRONIC MORPHINE AND ACUTE ESTROGEN: CONVERGENCE ON μ-OPIOID RECEPTOR COUPLING TO THE INWARDLY-RECTIFYING K^+CHANNEL IN HYPOTHALAMIC ARCUATE NEURONS (ARC) . G. Zhang*,E.J. Wagner, A.H. Lagrange, O.K. Ronnekleiv and M.J. Kelly.

Department of Physiology, Oregon Health Sciences U., Portland, OR 97201.

We have demonstrated that chronic morphine treatment (7 days) causes tolerance of ARC neurons to μ-opioid receptor activation (*Reg Peptides* 54:145, 1994), and that acute 17-β estradiol (E_2) rapidly uncouples the μ-opioid receptor from its K^+ channel in a subpopulation of ARC neurons (*J. Neurosci* 14:6196, 1994). The aim of this study was two-fold: (1) to investigate the effects of a 4 day chronic morphine regimen on the potency and efficacy of μ-agonist DAMGO-mediated hyperpolarization of ARC neurons; and (2) to measure the acute effects of E_2 on ARC neurons from morphine-treated animals. Intracellular recordings were made in hypothalamic slices from ovariectomized guinea pigs (GP) implanted s.c. with morphine- or placebo-pellets (4x75 mg for 2 days plus 6 more for a total of 4 days). The EC_{50} and V_{max} of DAMGO elicited hyperpolarization in control (n=5) was 45±4 nM and 14±3 mV, respectively. Based on the analysis of DAMGO potency data using an ANOVA with post-hoc tests for the morphine-treated GP, the ARC neurons were divided into three distinct groups ($p < 0.01$): non-tolerant with an EC_{50} of 52 ±7 nM (n=7); tolerant with an EC_{50} of 117 ±11 nM (n=4); and super-tolerant with an EC_{50} of 241±30 nM (n=4) and a decreased V_{max}. This data from the 4-day regimen further confirm previous findings of multiple expression of tolerance to μ-opioids in ARC neurons with a 7 day-morphine treatment. Moreover, in morphine-tolerant animals there was no significant change (paired t-test, n=9, $p>0.05$) in the EC_{50} of DAMGO after acute exposure (20 min) to E_2 (100 nM). The apparent occlusion of E_2's actions by chronic morphine may provide valuable information for determining the underlying mechanisms of these two modulators (Supported by PHS Grant DA05158).

HOMOLOGOUS VS. HETEROLOGOUS DESENSITIZATION OF RECEPTOR-MEDIATED POTASSIUM CURRENTS IN THE RAT LOCUS COERULEUS. S.L Ingram*, C.D. Fiorillo and J.T. Williams. Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

μ-opioid and α_2-adrenergic receptors both activate the same potassium channels in rat locus coeruleus (LC). Acute or chronic treatment with opioid agonists induces tolerance that is specific to the μ-opioid response, with little change in the α_2 mediated response. We have performed intracellular recordings to make a quantitative comparison of desensitization to opioid and α_2 agonists in a brain slice preparation of rat LC. Drug-induced outward potassium currents were measured in neurons voltage-clamped at -60 mV. A supramaximal concentration of the opioid agonist met-enkephalin induced a profound homologous desensitization, but little heterologous desensitization to α_2 agonists or somatostatin. A supramaximal concentration of the α_2 selective agonist UK14304 showed relatively little desensitization. Current-voltage plots revealed that both the opioid and α_2 desensitization observed at -60 mV was due only to a reduction in potassium current. Opioid and α_2 desensitization could also be distinguished by muscarinic modulation. In the presence of muscarinic agonists, the rate and magnitude of opioid desensitization was increased, while α_2 desensitization was not altered. The acute desensitization examined here shares a number of characteristics with the desensitization observed in chronically morphine treated animals and may play a role in the initiation of chronic tolerance to opioids.

INTERACTION BETWEEN OPIOIDS AND EXCITATORY NEUROTRANSMITTERS IN THE MEDIAL PREFRONTAL CORTEX. J.L. Giacchino* and S.J. Henriksen. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Mu opioids can mediate reinforcing effects of heroin in the rat. This mediation may involve alteration of endogenous neurotransmitter systems. Medial prefrontal cortex (mPFC) circuitry is a significant component of reinforcement pathways, and the activity of its neuronal population has been previously shown to be modified by both systemic and electrophoretically administered opioids. In this study we sought to determine possible mechanisms for this action.

Extracellular recordings were made from neurons in the mPFC in halothane-anesthetized rats. Areas investigated included the dorsal anterior cingulate, prelimbic and infralimbic components of the mPFC. Systemic morphine (2.5 mg/kg, sc) and electrophoretically-applied DAMGO, a mu opioid agonist (1 mM), were evaluated in terms of their effect on mPFC neuronal firing in response to electrophoretically-applied acetylcholine (ACh, 1M) and glutamate (Glu, 0.2M). As expected, prior to the application of opioids, many mPFC cells were found to increase firing rate in response to both ACh and Glu. Systemic morphine attenuated or blocked the Glu-induced excitation in the majority of these cells, whereas the ACh excitatory effect remained unaltered. However, some neurons exhibited no changes in response to ACh or Glu following systemic morphine. As noted previously, electrophoretic application of DAMGO decreased the spontaneous firing of most mPFC neurons. When applied concurrently with either ACh or Glu, this mu agonist was found to have different effects as a function of the individual mPFC neuron studied. DAMGO attenuated the response to ACh and Glu in some cells, but in other neurons it clearly blocked the excitatory Glu response without altering the response to ACh. In a third group of neurons, DAMGO was found to have no effect on either the ACh- or Glu-induced responses.

BACLOFEN-INDUCED INHIBITION OF HYPOTHALAMIC NEURONS: PHARMACOLOGY AND POTENTIAL FOR CROSS-TOLERANCE WITH A μ-OPIOID AGONIST FOLLOWING CHRONIC MORPHINE. E.J. Wagner*, G. Zhang, A.H. LaGrange, O.K. Ronnekleiv and M.J. Kelly. Dept. of Physiology, Oregon Health Sci. Univ., Portland, OR 97201.

The γ-aminobutyric acid $(GABA)_B$ receptor agonist baclofen has prominent inhibitory actions in neuroendocrine regions of the mammalian CNS. For example, baclofen inhibits arcuate nucleus neurons by membrane hyperpolarization attributed to an increase in an inwardly rectifying K^+ conductance. This response is identical to that following activation of μ-opioid receptors, which couple to the same effector in this brain region. The purpose of the present study was to characterize the pharmacology of the baclofen response, and to determine if cross-tolerance develops with μ-opioid agonists following chronic morphine treatment (subcutaneous implantation of 4 pellets each containing ~5mg of morphine on day 0, followed 2 days later with the implantation of 6 additional pellets) for 4-7 days. To this end, intracellular recordings of arcuate nucleus neurons were made in coronal hypothalamic slices (450μm) prepared from ovariectomized female guinea pigs. At a concentration of 30μM, the $GABA_B$ receptor blockers CGP 35348 and 2-hydroxysaclofen shifted the baclofen dose-response curve to the right with an estimated K_i of 3.2±1.4μM (mean±SEM; n=3) and 15.8±4.9μM (n=2), respectively. Compared to placebo-treated controls, chronic morphine treatment reduced the potency of the μ-opioid receptor agonist DAMGO but not of baclofen. Taken together, these results show that: 1) the inhibitory effect of baclofen on arcuate nucleus neurons is consistent with its actions as a $GABA_B$ receptor agonist, and 2) chronic morphine exposure does not produce cross-tolerance between $GABA_B$ and μ-opioid receptor agonists. This latter finding suggests that convergence of the two receptors systems to the same effector may not be a sufficient criterion for cross-tolerance between receptor systems. (This work was supported by Grants DA05158 and DA07262).

ACTION OF MU-SELECTIVE OPIOIDS ON COMMISSURAL PATHWAY MODULATION OF DENTATE GYRUS CIRCUITRY. J.H. Mayer*, S.J. Henriksen. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037

In order to better understand the effects of mu-selective opioids on the physiology of the dentate gyrus of the hippocampus, we stimulated (conditioning stimulation) the contralateral hilus (CH) while concurrently recording single neurons and population spikes (PSs), evoked by stimulation of the ipsilateral perforant path (PP), extracellularly in halothane anesthetized rats. Single cells were characterized electrophysiologically as dentate granule cells (DGCs), interneurons (INTs), or hilar mossy cells (HMCs). Subsequently, [D-Ala^2, NMe-Phe^4, Gly-ol]-Enkephalin (DAMGO), a mu-selective opioid, was administered electrophoretically. We found that stimulation of the commissural pathway prior to stimulation of the PP reduced the PS amplitude. This effect was dependent on the stimulus intensity and the interval between the two stimuli. CH stimulation by itself did not produce a PS and individual DGCs could not be driven. However, CH stimulation orthodromically activated INTs, both in the granule cell layer and within the hilus. HMCs were typically either not activated by CH stimulation, or were driven antidromically. Administration of DAMGO tended to reverse the inhibition produced by CH stimulation on perforant path PSs; however, this effect was less impressive when the stimulus intensity at the PP was adjusted to control for the primary PS amplitude. DAMGO did not affect the latency of INTs to activation by CH stimulation at stimulus intensities that were relevant for inhibition of the PS. We conclude that stimulation of the commissural pathway reduces PP-evoked PSs through the excitation of INTs, both within the granule cell layer and the hilus. Furthermore, the influence of mu-selective opioids on this pathway is not as pronounced as the mu-related effects on the PP or on the spontaneous activity of cells within the dentate gyrus. cAMP CASCADE: ROLE IN μ OPIOID-MEDIATED INHIBITION OF NMDA CURRENTS IN DENTATE GRANULE CELLS. C.W. Xie[1]* and D.V. Lewis[2] [1] Dept. Psychiatry, UCLA, Los Angeles, CA 90024. [2] Dept. Pediatrics, Duke Univ. Med. Ctr, Durham, NC 27710

We have previously reported that activation of μ opioid receptors inhibited NMDA-mediated synaptic currents in dentate granule cells. The present study further characterized this effect and examined possible involvement of the cAMP cascade. Synaptic currents were evoked by stimulating the dentate outer molecular layer, and recorded from granule cells using whole-cell voltage-clamp techniques in the hippocampal slice preparation. NMDA receptor-mediated excitatory postsynaptic currents (NMDA EPSCs) were isolated in the presence of the AMPA antagonist DNQX and the $GABA_A$ antagonist bicuculline methiodide. A dose-dependent reduction in the amplitude of NMDA EPSCs was observed following bath application of the μ agonist PL017 (0.3 -10 μM). This reduction seemed not dependent upon the presence of extracellular Mg^{2+}, and could be effectively prevented by pertussis toxin included in the recording pipette. In contrast, the adenylate cyclase activator forskolin (10-100 μM) was found to increase the amplitude of NMDA EPSCs in a dose-dependent manner. Forskolin (100 μM) also significantly attenuated PL017-induced reduction of NMDA currents. These results suggested that the cAMP cascade may be involved in μ opioid-induced inhibition of NMDA currents.

DEMONSTRATION OF μ-OPIOID RECEPTOR SUPPRESSION OF Ca^{2+} CURRENTS IN CENTRAL NEURONS. B.L. Soldo* and H.C. Moises. Department of Physiology, University of Michigan, Ann Arbor, MI 48109.

Opiates and opioid peptides have been shown to suppress voltage-sensitive Ca^{2+} conductances in peripheral neurons and a variety of neuron-like cell lines; however, this effect has only recently been demonstrated in central neurons. In this study, whole-cell Ca^{2+} channel currents were recorded from acutely isolated neurons of rat ventral forebrain, a region rich in opiate receptors, to examine the possible coupling between opioid receptors and neuronal Ca^{2+} channels. High voltage-activated (HVA) currents were elicited by 100 ms depolarizing steps (-10 mV to +10 mV) from a holding potential of -80 mV, using 4mM Ba^{2+} as charge carrier. Bath application of the μ-opioid selective agonist H-Tyr-D-Ala-Gly-Phe(N-Me)-Gly-ol (DAGO, 3μM) reversibly suppressed the peak amplitude of HVA currents (with 40% maximal effect) and slowed their rate of activation. The L- and N-type Ca^{2+} channel blockers, nifedipine and ω-conotoxin GVIA, respectively, blocked pharmacologically distinct components of the HVA current in these neurons. The DAGO-sensitive component was reduced after blockade of N-type currents by GVIA. In addition, cells that showed Ca^{2+} inhibitory responses to DAGO exhibited morphological features of principal neurons and stained positive for acetylcholinesterase. These data suggest that postsynaptic μ-opioid receptors are negatively coupled to N-type Ca^{2+} channels in rat forebrain cholinergic neurons. (Supported by NIH grant DA-03365).

SEROTONIN RECEPTORS: 5-HT_1

727.1

BLOCKADE OF 5-HT_{1A} RECEPTORS EXPRESSION USING LOCAL INJECTIONS OF ANTI-SENS OLIGONUCLEOTIDES. M.-C. Miquel[1], Y. Sari[1], C. Sibella[1], H.K. Kia[1], G. Daval[1], B. Emerit*[2], M. Hamon[2] and D. Vergé[1]. [1]CNRS URA 1488, Univ. Paris VI, 75005 Paris. [2]INSERM U288, CHU Pitié-Salpêtrière, 75013 Paris, France.

5-HT_{1A} receptors (5-HT_{1A}-R) are involved in a lot of various physiological functions. 5-HT_{1A}-R are principally localized postsynaptically in the limbic structures and in the raphe nuclei as somato-dendritic autoreceptors. With the aim of further analyzing the role of 5-HT_{1A}-R in each of their precise localizations, we have locally blocked their expression in the adult rat, using anti-sens oligonucleotides (ONs). Different ONs, complementary to the N-terminal portion of the mRNA coding for 5-HT_{1A}-R, were designed as either unmodified, phosphorothioate or 3'end-alkylamine-attached ONs.

In order to validate this approach, stereotaxic injections were performed in the dorsal hippocampus using mixtures of ONs (anti-sens, sens or scrambled) and lipofectin. The mixtures were delivered either in single or repeated injections, or in a continuous mode using Alzet osmotic minipumps. The resulting effect on 5-HT_{1A}-R density was analyzed by receptor quantitative autoradiography. Specificity and histological controls were performed.

Experiments using single injections (2.5 μg/2 μL) demonstrated that the 3'end-alkylamine-attached ONs were the most efficient, giving up to 60% decrease of 5-HT_{1A}-R density. The unmodified ONs were almost inefficient and phosphorothiate ONs exhibited cytotoxicity. Maximum effect was observed 4 days after injection.

Another approach using plasmids containing anti-sens RNAs is currently under investigation in order to obtain a continuous blockade for a longer period of time. Both approaches will be used to block the expression of 5-HT_{1A} autoreceptors in the raphe nuclei to assess their specific role in anxiety.

727.2

IN VITRO AND *IN VIVO* ALKYLATION OF CENTRAL 5-HT1A RECEPTORS. F. Radja*, E.K. Nénonéne, M. Carli and T.A. Reader. *CRSN, Département de physiologie, Faculté de Médecine, Université de Montréal, (Qc) Canada.*

Saturation binding of the serotonin agonist [^{3}H]8-OH-DPAT in cerebral cortex and hippocampus is best fitted to a two-site model, indicating an *heterogeneity of receptors* or several binding *affinitity states*. For cerebral cortex the affinities are of about 0.7 n*M* and 36 n*M*, and for hippocampus of 0.8 n*M* and 22 n*M*. Also, binding of 1 n*M* [^{3}H]8-OH-DPAT is inhibited by several 5-HT agonists and antagonists and, except for ritanserin, all competition curves are best described by a two-site model. The *in vitro* treatment of the membranes with *N*-ethylmaleimide (NEM) to alkylate sulfhydryl groups causes dose-dependent decreases of [^{3}H]8-OH-DPAT binding; all the inhibition curves are biphasic and the effects irreversible. After *in vivo* alkylations, carried out by treating rats with *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydro-quinoline (EEDQ; 10 mg/Kg i.p.), the saturation curves from both control and EEDQ-treated rats are best fitted to a two-site model. However, for EEDQ-treated animals there is a drastic decrease in 5-HT1A receptors; this loss is greater in the hippocampus than in the cerebral cortex. In contrast, the low-affinity binding sites remained unchanged, indicating that this site is not a *G* protein coupled receptor. Since the decrease in 5-HT1A receptors is not associated with changes in low-affinity binding, the results suggest independent regulations of the two [^{3}H]8-OH-DPAT binding sites. Altogether, the present data further supports the concept that [^{3}H]8-OH-DPAT, besides labelling 5-HT1A receptors, also binds to other sites in rat cerebral cortex and hippocampus.

727.3

NCS-MPP (4-(2'-METHOXY-PHENYL)-1-[2'-(N-2"-PYRIDINYL)-P-ISOTHIOCYANOBENZAMIDO]-ETHYL-PIPERAZINE): A HIGH AFFINITY AND IRREVERSIBLE LIGAND FOR 5-HT$_{1A}$ RECEPTORS. H. F. Kung*, M.-P. Kung, M. Mu and Z.-P. Zhuang. Departments of Radiology and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

The successful development of a new pure 5-HT$_{1A}$ receptor antagonist, *p*-MPPI, provides a fresh impetus in developing affinity labels to further characterize the physiological roles and to elucidate the molecular structure of 5-HT$_{1A}$ receptors. An irreversible binding ligand, NCS-MPP (4-(2'-methoxy-phenyl)-1-[2'-(n-2"-pyridinyl)-p-isothiocyanobenzamido]-ethyl-piperazine), was prepared, and its binding characteristics were evaluated in *in vitro* binding with rat hippocampal membranes. The inhibition of NCS-MPP for [I-125]*p*-MPPI binding to 5-HT$_{1A}$ receptors resulted in a K_i = 1.8 ± 0.2 nM. NovaScreen of NCS-MPP exhibited low binding affinities to *alpha* -1, *alpha*-2, *beta* and 5-HT$_2$ receptors (K_i = 350, 420, >1000 and 103 nM, respectively). These data strongly suggest that the ligand bound to 5-HT$_{1A}$ receptors with high affinity and high selectivity. Irreversible inhibition of [I-125]*p*-MPPI binding by NCS-MPP, following a 5 min incubation at room temperature, was concentration dependent; the inhibition increased to 50% at the concentration less than 10 nM and became more pronounced (~90%) at 400 nM. Under similar assay conditions, NCS-MPP was significantly less efficient in irreversibly inhibiting agonist [I-125]8-OH-PIPAT (<10 nM). After pretreatment of membranes with a low concentration of NCS-MPP (2 nM), there was an apparent loss of [I-125]*p*-MPPI binding sites, as expected, but no change in binding affinity (K_d). However, the significant increase in K_d at a higher concentration of NCS-MPP (50 nM) indicated that there may be a secondary alkylation site not directly involved in *p*-MPPI binding; nevertheless, it would increase K_d. The irreversible ligand, NCS-MPP, may provide a useful tool for studies of 5-HT$_{1A}$ receptors in central nervous system. (supported by NS-24538 and MH-48125)

AGE-RELATED ALTERATIONS IN SEROTONERGIC RECEPTOR FUNCTION IN FOREBRAIN REGIONS FOLLOWING EEDQ TREATMENT. B.J. Keck* and J.M. Lakoski. Departments of Pharmacology & Anesthesia, The Pennsylvania State University College of Medicine, Hershey, PA 17033.

EEDQ (1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline) is a neurotoxin which binds irreversibly to serotonin (5-HT) receptors and renders them permanently inactive; it is useful for investigating spare receptor reserves. Spare receptor capacities of 5-HT receptor subtypes have not yet been investigated with aging. Female Fischer 344 rats (3 and 22 mo) treated with EEDQ (6 mg/kg, s.c.) or vehicle (ETOH/propylene glycol/H_2O, 1:1:2, s.c.) 24 hr prior to sacrifice were used to examine changes in 5-HT$_{1A}$ function with age. Scatchard analyses using the 5-HT$_{1A}$ ligand [^{3}H]8-OH-DPAT were conducted in forebrain regions which contain high densities of this receptor subtype.

A significant decline in [^{3}H]8-OH-DPAT binding in hippocampal tissue was demonstrated in EEDQ treated rats of both age groups compared to controls (3 mo, $p=0.001$; 22 mo, $p=0.002$). Both ages were equally sensitive to the toxin-induced decrease (65%) in B_{MAX} for 5-HT$_{1A}$ hippocampal sites. In frontal cortex the 3 mo, but not the 22 mo, group demonstrated a significant reduction (70%, $p=0.02$) in 5-HT$_{1A}$ sites. K_D values were increased following EEDQ treatment in the hippocampus and frontal cortex in both ages. While a fourfold increase in the K_D was observed in the 3 mo group, an eightfold increase was demonstrated in the 22 mo group.

Overall, significant changes in B_{MAX} and K_D values at the 5-HT$_{1A}$ receptor were observed following EEDQ treatment. Additionally, site-dependent differences were revealed in age-related responses to EEDQ. Using quantitative autoradiographic techniques, studies of the aging 5-HT$_{1A}$ receptor will be expanded to include analyses of brainstem raphe nuclei known to contain spare 5-HT$_{1A}$ receptors.

Pub. No. 29A supported by U.S.P.H.S. Grant PO1 AG10514 awarded by the NIA.

727.5

IRREVERSIBLE BLOCKADE OF 5-HT$_{1A}$ RECEPTORS *IN VITRO* BY A SELECTIVE ALKYLATING AGENT. S. Bhamre[1*], H.F. Kung[2] and A. Frazer[1]. [1]Dept. of Pharmacol, UTHSCA, San Antonio, Texas 78284 and [2]Dept. of Radiol & Pharmacol, Univ of PA, Philadelphia, PA 19104.

Using an irreversible alkylating agent, EEDQ, it has been inferred that there is a greater receptor reserve at somatodendritic 5-HT$_{1A}$ receptors than at postsynaptic ones (Mol Pharmacol 41:1066, 1992). However, results with EEDQ need to be interpreted cautiously as it is nonselective. We have evaluated the effects *in vitro* of a novel selective alkylating agent 4-(2'-methoxyphenyl)-1-[2'-(N-2"-pyridinyl)-p-isothiocyanobenzamido]ethylpiperazine (p-MPPSCN). p-MPPSCN has at least 10 fold greater affinity for 5-HT$_{1A}$ receptors than for other biogenic amine receptors. The binding of [^{3}H]8-hydroxy-2-(di-n-propylamino)tetralin ([^{3}H]8-OH-DPAT) to 5-HT$_{1A}$ receptor sites in rat hippocampal homogenates, using membranes that had been pre-incubated with either vehicle or p-MPPSCN, was studied. The membranes were washed 4 times before being added to the assay tubes. Concentrations of p-MPPSCN below 5nM did not inhibit the binding of [^{3}H]8-OH-DPAT, whereas concentrations of ≥ 10nM did. Analysis of saturation experiments carried out with [^{3}H]8-OH-DPAT revealed that p-MPPSCN (10 nM) caused no change in Kd (0.93±0.2, CTRL; 1.1±0.2 nM, p-MPPSCN), but decreased Bmax (237±20, CTRL; 151±5 fmol/mg protein, p-MPPSCN; $p<0.025$). Upon pre-incubation of membranes with WAY100135 (200 nM), a competitive antagonist of 5HT$_{1A}$ receptors, followed by washing, there was no inhibition of binding of [^{3}H]8-OH-DPAT. When membranes were pre-incubated with both p-MPPSCN (10nM) and WAY100135 (200nM), there was less inhibition of binding of [^{3}H]8-OH-DPAT (11± 6%) compared with that in membranes incubated with p-MPPSCN alone (36±9%; $p<0.05$). p-MPPSCN appears to irreversibly block 5-HT$_{1A}$ receptors *in vitro*. Its effects *in vivo* are currently under evaluation. (Supported by research funds from the VA and USPHS MH48125).

MOLECULAR CHARACTERIZATION OF ANTIPEPTIDE ANTIBODIES AGAINST RAT BRAIN 5HT$_{1A}$ RECEPTOR [1]T.E. Anthony, [1]N.M. Kheck, [2]P.R. Albert, [3]P.M. Whitaker-Azmitia, and [1]E.C. Azmitia*, and [1]Dept. of Biology, New York University, NY, NY 10003; [2]Dept. of Pharmacology and Therapeutics, McGill University, Montreal, Canada H3G 1Y6; [3]Dept. of Psychiatry, SUNY, Stony Brook, NY 11794.

The cloning and sequencing of the rat 5HT$_{1A}$ receptor gene has allowed for the production of antipeptide antibodies against its receptor protein product. We are currently characterizing the localization of the 5HT$_{1A}$ receptor protein in the rat and primate brain, using antipeptide antibodies targeted against two distinct regions of the receptor which share low homology with other known proteins. The S1A170 is a polyclonal antibody raised in rabbit against amino sequence 170 - 186, a region spanning from the fourth transmembrane domain to the second extracellular loop, which is structurally linked to the agonist binding site. The S1A258 recognizes amino acids 258-274,a region within the third cytoplasmic loop that comprises the putative G protein binding site. Characterization of these antibodies employing SDS-PAGE and immunoblotting of adult hippocampal membrane preparations has shown the S1A170 antibody labels a major band at approximately 64 kDa. Immunoblots of LZD-7 fibroblasts transfected with the cDNA for the rat 5HT$_{1A}$ receptor have also shown this protein band, which was absent in Ltk- nontransfected cells. In the rat, developmental and brain regional differences have been noted through the differential intensites of the protein banding pattern obtained from immunoblots. In addition to molecular studies, immunocytochemical studies using these antibodies have demonstrated a pattern of 5HT$_{1A}$ receptor distribution in rat, cat and monkey brain that correlates well with previously reported radioligand binding sites. For example, in the brainstem raphe nuclei of these three species, 5HT$_{1A}$ receptor-IR is localized to the soma and dendrites of serotonergic neurons, thus labeling the known population of presynaptic autoreceptors. Our findings indicate that these site-directed antipeptide antibodies provide another specific means for the localization and quantification of 5HT$_{1A}$ receptor protein in the mammalian CNS. (NIA#:PO1-AG10208)

QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF 5-HT$_{1A}$ RECEPTORS USING AGONIST AND ANTAGONIST RADIOLIGANDS. P. A. Scott*& A. Frazer. Dept. of Pharmacology, UTHSCSA, and Audie L. Murphy Memorial. Veterans. Hospital, San Antonio, TX, 78284.

Only recently have radiolabeled antagonists for the 5-HT$_{1A}$ receptor become available. We have compared the binding characteristics of one such radioligand, ^{3}H-4-(2'methoxy-)phenyl-1-[2'-(n-2"-pyridinyl-)p-flourobenzamido-]ethylpiperazine (^{3}H-p-MPPF), with that of two agonist radioligands, ^{3}H-8-hydroxy-2-(di-n-propylamino)tetralin (^{3}H-8-OH-DPAT) and ^{3}H-(+)4-[n-5(methoxychroman-3yl)n-propylamino]butyl-8-azaspiro[4,5]decane-7,9 dione (^{3}H-(+) S-20499), using slide-mounted sections of rat brain. The radioactivity in each section was measured by either liquid scintillation spectrophotometry or by quantitative autoradiography. Optimal times of incubation were 60 min for ^{3}H-8-OH-DPAT and 90 min for ^{3}H-(+) S-20499 and ^{3}H-p-MPPF. To reduce non-specific binding with ^{3}H-(+) S-20499, it was necessary to wash the sections for 60 min at 4°C after incubation , rather than the 10 min that was sufficient for the other two radioligands. The K_D values for the three radioligands were about 0.6, 1.0, and 1.6 nM for ^{3}H-8-OH-DPAT, ^{3}H-(+) S-20499 and ^{3}H-p-MPPF respectively. Addition of Gpp(NH)p (10 μM) to the incubation medium reduced the binding of the two agonist radioligands (about 70% for ^{3}H-8-OH-DPAT and 50% for ^{3}H-(+) S-20499), but did not alter the binding of ^{3}H-p-MPPF. At the K_D concentration of ^{3}H-p-MPPF, nonspecific binding was 5% of total binding, which compared favorably with the 2% nonspecific binding of ^{3}H-8-OH-DPAT. By contrast, nonspecific binding of ^{3}H-(+) S-20499 was 15% of total binding. Autoradiographic analysis of the regional distribution in brain of the binding of the three radioligands showed a high correlation. The rank order of binding was entorhinal cortex ≥ dorsal raphe nucleus > dentate gyrus > CA2/3 > CA1. Only in the dorsal raphe nucleus did the binding of ^{3}H-p-MPPF appear to be greater than that of the two agonist radioligands. Supported by funds from the VA, USPHS Grant MH48125, and IRI Servier.

DISTRIBUTION OF GABA AND 5-HT1A IMMUNOPOSITIVE NEURONS IN THE RAT HIPPOCAMPUS. T. D. Patel* and F. C. Zhou. Medical Neurobiology Program and Dept. of Anatomy, Indiana Univ. Sch. of Med., Indianapolis, IN 46202.

GABA and serotonin (5-HT) through the 5-HT1A receptor are major inhibitors of excitatory neurotransmission in the hippocampus. GABA interneurons send inhibitory input to the granule cells of the dentate gyrus (DG) and the pyramidal cells of Ammon's horn (CA). 5-HT also inhibits axonal firing of these cells through activation of the 5-HT1A receptor. Little is known regarding the interactions between these two systems regulating hippocamapal circuitry. In this study we used double immunocytochemistry to correlate the distribution of 5-HT1A receptors with GABA neurons and their terminal fibers in the rat hippocampus. GABA neurons were identifed using an antibody against glutamate decarboxylase (GAD), and 5-HT1A using an anti-peptide (a.a. 170-186 of rat 5-HT1A) antibody (Azmitia et al., 1992).

Consistent with our previous report (Patel et al., 1995), 5-HT1A-immunopositive (im) staining was most prominent in the DG granule cell layer and the CA pyramidal cell layer where it was detected on the initial segment of the axon. In contrast, fine GAD-im punctate terminals were distributed as dense clusters outlining the soma of granule and pyramidal cells. GAD-im cell bodies and processes with cytoplasmic staining were detected in the molecular and polymorphic layers of DG and stratum oriens, radiatum, and lacunosum moleculare of CA. Relatively sparse 5-HT1A-im cell staining was detected in these layers. Most cells were singly labeled for GAD or 5-HT1A. In the polymorphic layer 5-HT1A-im staining was found on large Mossy cells which send excitatory projections to the granule cells. Also in the DG, few scattered cells did exhibit both GAD and 5-HT1A immunoreactivity.

These findings suggest that in the hippocampus (1) 5-HT1A and GAD are mostly differentially expressed with little colocalization, (2) 5-HT and GABA may exert their inhibitory influence on the excitatory granule and pyramidal cells at spatially distinct subcellular sites, (3) 5-HT can indirectly influence granule cells through 5-HT1A receptors on Mossy cells, and (4) 5-HT may regulate some GABA neurons.

IMMUNO-ELECTRON MICROSCOPIC VISUALIZATION OF 5-HT$_{1A}$ RECEPTORS IN THE RAT BRAIN. D. Vergé[1], H.K. Kia[1], M.J. Brisorgueil[1], M. Hamon[2] and A. Calas*[1]. [1] CNRS URA 1488, Univ. Paris VI, 75005 Paris. [2] INSERM U288, CHU Pitié-Salpêtrière, 75013 Paris, France.

5-HT$_{1A}$ receptors (5-HT$_{1A}$-R) have been visualized in the rat brain with specific antibodies in various areas, including raphe nuclei and limbic regions. We used anti-peptide antibodies to investigate the localization of 5-HT$_{1A}$-R at the subcellular level in several of these areas.

Vibratome sections from rat brains were incubated with rabbit anti-peptide polyclonal antibodies against 5-HT$_{1A}$-R and processed for the ABC staining method. The peroxydase activity was revealed using DAB as a chromogen. Sections were then processed for electron microscopy.

The 5-HT$_{1A}$-R immunoreactivity (5-HT$_{1A}$-R-ir) was found exclusively in the somato-dendritic compartment of neurons and was never observed within glial processes. 5-HT$_{1A}$-R-ir could never be found in axons or nerve terminals. In the dorsal hippocampus, the immunolabeling was associated exclusively with dendrites. In the dorsal raphe nucleus as well as in the septal complex, 5-HT$_{1A}$-R-ir was found in dendritic processes and in somas. Some immunoreactivity was observed within the cytoplasm of cell bodies, but not in cell nuclei. In somas as well as in dendrites, 5-HT$_{1A}$-R-ir was unevenly distributed at the level of the plasmic membrane. It was frequently associated with synapses, but was also found extra-synaptically. This result indicates that the action of 5-HT via 5-HT$_{1A}$-R could occur through 'wire' as well as 'volumic' transmission. Non-labeled synapses were also observed. In the septal complex, choline acetyltransferase and 5-HT$_{1A}$-R could be found colocalized in the same neuron, in agreement with previous results indicating that serotonin can exert through 5-HT$_{1A}$-R a functional control of part of the septal cholinergic neurons which project to the hippocampus.

DIFFERENTIAL EXPRESSION OF SEROTONIN RECEPTORS 5-HT1Dα AND 5-HT2A mRNA IN HUMAN BRAIN VESSELS, VASCULAR CELLS AND ASTROCYTES IN CULTURE. Z. Cohen*, I. Bouchelet, W.V. Yong, J.-G. Villemure, D. Stanimirovic[1], and E. Hamel. Montreal Neurol Inst, McGill Univ, Montréal, QC and [1]National Research Council of Canada, Ottawa, ON, Canada.

Intraparenchymal blood vessels in the cerebral cortex are innervated by serotonin nerve terminals (Cohen *et al.*, 1995, *Neurosci.*, in press) and stimulation of their cells of origin affects cerebral blood flow and possibly blood brain barrier functions. However, the type and cellular localization of the 5-HT receptor(s) involved in these effects remain unknown. We studied the expression of 5-HT1Dα and 5-HT2A receptors mRNA in 1) freshly isolated human brain microvessels (MVs) and capillaries (CAPs) from post-mortem cortices, 2) subcloned endothelial (HBEC) and primary cultures of smooth muscle (HBSM) cells, respectively dissociated from CAPs (< 112 μm) and MVs (> 112 μm or > 350 μm) isolated from temporal cortex biopsies, and 3) astrocytes cultured from human fetal brain (HFBA). Tissue RNA was extracted, reverse transcribed, and submitted to polymerase chain reaction (PCR) using receptor-specific oligonucleotide primers. The effects of 5-HT on IP_3 formation and intracellular Ca^{+2} in HBEC were also evaluated. MVs, CAPs, and HBEC were enriched in γ-glutamyl transpeptidase and alkaline phosphatase; HBEC and HFBA were selectively immunoreactive to Factor VIII and GFAP, respectively. Gel electrophoresis of the PCR products showed expression of mRNA for the 5-HT1Dα in MVs (n=3), CAPs (n=4), HBEC (n=3 of 5), HBSM (n=2 of 3) but in only one of three HFBA preparations. Conversely, PCR using 5-HT2A primers yielded products of the expected size in MVs (n=4), CAPs (n=4), and HFBA (n=2 of 3) but not in any HBEC or HBSM cell preparations. 5-HT (1-100 μM) failed to alter IP_3 production or intracellular Ca^{+2} levels in HBEC. Altogether, the data suggest expression of 5-HT1Dα mRNA in brain vascular elements whereas 5-HT2A receptors appear predominantly expressed in astrocytes, including those associated with isolated MVs and CAPs. Further investigation should clarify the role of these 5-HT receptors in microvascular physiology. Supported by MRC and NRC of Canada and a McGill Major Studentship (Z.C.).

727.11

EXPRESSION OF SUMATRIPTAN-SENSITIVE SEROTONIN RECEPTORS mRNA IN HUMAN NEURONAL AND VASCULAR TISSUES. I. Bouchelet*, Z. Cohen, B. Case[1], P. Séguéla and E. Hamel. Montréal Neurological Institute and [1]Royal Victoria Hospital, Montréal, Québec, Canada H3A 2B4.

Sumatriptan is highly effective in the treatment of acute migraine attack. This effect has been related to serotonin 5-HT1Dα receptors on dural trigeminovascular afferents (Rebeck *et al.*, PNAS.,1994, 91: 3666.) and/or 5-HT1Dß receptors in cerebral blood vessels (Hamel *et al.*, Mol. Pharm., 1993, 44: 242.). A better knowledge of sumatriptan-sensitive 5-HT receptors in neuronal vs vascular tissues appears important for the understanding of migraine treatment. We studied the expression of mRNA coding for 5-HT1Dα, 5-HT1Dβ and 5-HT1F receptors in post-mortem human trigeminal ganglia (TG) and pial vessels (PV) using RT-PCR and receptor-specific oligonucleotide primers. In TG preparations, PCR products of the expected sizes for 5-HT1Dα and 5-HT1Dß receptor subtypes were both identified. In preparations from PV and from one coronary artery, PCR products corresponding to the 5-HT1Dß subtype were present while only an occasional and faint signal was detected for the 5-HT1Dα subtype. Preliminary experiments on TG and PV preparations suggested the presence of 5-HT1F mRNA in both tissues. Altogether, these results show that multiple sumatriptan-sensitive 5-HT receptors mRNA are co-expressed in neuronal and vascular tissues. Further, they may provide a basis for the sumatriptan-associated peripheral side-effects. Complementary studies by *in situ* hybridization are required to define the respective localizations and density of neuronal populations expressing these 5-HT receptors in putative target tissues for migraine therapy. Supported by the Québec Heart and Stroke Foundation.

727.12

5-HT$_{1A}$ AGONIST AND ANTAGONIST BINDING IN RAT BRAIN AND SPINAL CORD FOLLOWING 5,7-DHT TREATMENT. R. K. Raghupathi*, A. Singh, I. Lucki, M. -P. Kung, H. Kung and P. McGonigle. Departments of Pharmacology, Psychiatry and Radiology, University of Pennsylvania, Philadelphia, PA 19104-6084.

Changes in rat brain and spinal cord 5-HT$_{1A}$ receptors following 5,7-DHT treatment were examined using an agonist ligand [^{125}I]8-OH-PIPAT (PIPAT) as well as a newly developed antagonist ligand [^{125}I]-p-MPPI (MPPI). Adjacent coronal sections of control and 5,7-DHT treated rat brains (n=14/group) and spinal cords (n=7/group) were labeled with each ligand and binding was measured with the use of quantitative autoradiography. (1) Levels of MPPI binding were higher in hippocampal subfields compared to PIPAT binding, whereas, in cortical layers PIPAT binding levels were higher. (2) Agonist (PIPAT) binding in hippocampal or cortical regions of 5,7-DHT treated animals was similar to controls, as has been previously observed. (3) Antagonist (MPPI) binding in hippocampal or cortical regions of 5,7-DHT treated animals was also unaltered compared to controls, except in the CA1 subfield of the hippocampus. (4) In the cervical but not the lumbar portion of the spinal cord, 5,7-DHT-treated rats showed increased levels of MPPI binding in the most superficial layer of the dorsal horn. In conclusion, the lack of changes in 5-HT$_{1A}$ agonist binding in rat brain following 5,7-DHT treatment has been extended to antagonist binding, except in the CA1 region of the hippocampus. Regional differences in the ratio of agonist to antagonist binding suggest regional differences in the coupling of 5-HT$_{1A}$ receptors to G-proteins. (Supported by MH-48125, MH-43821)

727.13

METHYLENEDIOXYMETHAMPHETAMINE INCREASES 5-HT$_{1A}$ RECEPTOR DENSITY AND mRNA EXPRESSION IN THE RAT FRONTAL CORTEX. J. Del Río*, D. Frechilla, A. García-Osta, B. Lasheras and N. Aguirre. Dept. of Pharmacology, University of Navarra, Pamplona, Spain.

Administration of 3,4-methylenedioxymethamphetamine (MDMA,"ecstasy") damages serotonergic (5-HT) axon terminals arising from the dorsal raphe. In the present study, MDMA.HCl (30 mg/kg) was given b.i.d. for 4 consecutive days to rats and the animals were sacrificed 3 h or 7 days later. As expected, 5-HT content and [^{3}H]paroxetine binding sites were markedly decreased in the frontal cortex but not in the dorsal raphe nucleus. At both survival times there was a significant increase in the density of [^{3}H]8-OH-DPAT-labelled 5-HT$_{1A}$ receptors in the frontal cortex and a concomitant decrease in receptor density in the dorsal raphe. Quantitative RT-PCR was used to measure 5-HT$_{1A}$ receptor mRNA in the two brain regions. Primers were designed to amplify a 133 bp fragment of 5-HT$_{1A}$ receptor cDNA and a 300 bp fragment of ß-actin used as the internal standard. After Southern-blot and hybridization with specific probes, an increase in 5-HT$_{1A}$ receptor mRNA expression was found in the frontal cortex of MDMA-treated rats after a 7 day survival time. It seems consequently that increased cortical receptor synthesis is promoted after lesion of 5-HT terminals. In keeping with these data, the hypothermia response to 8-OH-DPAT (1 mg/kg) was significantly potentiated 7 days after MDMA treatment. The results raise the possibility of an involvement of 5-HT$_{1A}$ receptors in the behavioral effects of MDMA. (Supported in part by SAF94-1381)

727.14

THE EFFECTS OF REDUCED pH DURING SERIAL DILUTIONS IN RADIOLIGAND COMPETITION BINDING STUDIES. W.N. Morgan, M.J. Owens, J.T. Daley, D.L. Knight, Z.N. Stowe', and C.B. Nemeroff. Dept. Psychiatry & Behav. Sci., Emory Univ. Sch. of Med., Atlanta, GA 30322.

In the performance of radioligand competition binding studies, most investigators dissolve drugs initially in ethanol, if necessary, and subsequent serial dilutions in assay buffer. Using this method, we observed competition curves that had Hill coefficients (n_H) that were much greater than unity (n_H>1.5). This also altered the apparent inhibition binding affinities (K_i). In our study, the initial use of 50% ethanol followed by serial dilutions with 5 mmol/L HCl was compared to ethanol followed by serial dilutions with assay buffer as a solvent. The former gave n_H equal to unity ($n_H \approx 1.0$) as previously predicted.

Competition binding studies were performed in triplicate on at least three separate occassions using several antidepressant drugs at the serotonin (5-HT) transporter and the 5-HT$_{1A}$ and 5-HT$_{2A}$ receptors. [^{3}H]-citalopram, [^{3}H]-8-OH-DPAT, and [^{3}H]-ketanserin were used to label these receptor sites respectively. The antidepressants were dissolved in 50% ethanol and subsequently in either 5 mmol/L HCl or assay buffer. The 5-HT transporter K_i values (nM) in HCl and assay buffer, respectively, are: nefazodone (239; 1586), desipramine (141; 199), amitriptyline (17; 55), trazodone (258; 388), sertraline (0.32; 3), fluoxetine (2; 8), paroxetine (0.058; 0.459), venlafaxine (21; 30), and chloroimipramine (0.52; 7). At the 5-HT$_{1A}$ receptor, K_i values (nM) for HCl and assay buffer, respectively, are: nefazodone (59; 2200), desipramine (2568; 3186), amitriptyline (146; 318), trazodone (47; 185), and sertraline (4114; 7740). At the 5-HT$_{2A}$ receptor, K_i values (nM) in HCl and assay buffer, respectively, are: nefazodone (7; 2716), desipramine (161; 177), amitriptyline (5; 30), trazodone (20; 137), fluoxetine (142; 332), and paroxetine (6371; >10,000). These findings unequivocally demonstrate the need for certain drugs to be serially prepared in dilute acid to obtain curves fulfilling theoretical criteria for competitive one-site receptor-ligand interactions (i.e., $n_H \approx 1.0$).

727.15

[^{3}H]ALNIDITAN, A NEW HIGH AFFINITY AGONIST LIGAND FOR HUMAN 5HT$_{1D\alpha}$- AND HUMAN 5HT$_{1D\beta}$-RECEPTORS. J.E. Leysen*, W. Gommeren*, W.H.M.L. Luyten*, P. Vanhoenacker°, G. Haegeman°, A.S. Lesage*, *Department of Biochemical Pharmacology, Janssen Research Foundation, B-2340 Beerse, Belgium, °Laboratory of Molecular Biology, University of Gent, B-9000 Gent, Belgium.

Alniditan, (-)-(R)-*N*-[(3,4-dihydro-2*H*-1-benzopyran-2-yl)methyl]-*N'*-(1,4,5,6-tetrahydro-2-pyrimidinyl)-1,3-propanediamine dihydrochloride, is a new antimigraine agent. The compound shows high binding affinity for 5HT$_{1D}$- and 5HT$_{1A}$-receptors and weak to no binding to various other neurotransmitter or neuropeptide receptor subtypes. It is a potent constrictor of cranial blood vessels. [^{3}H]Alniditan proved to be a suitable high affinity ligand for cloned human (hu) 5HT$_{1D\alpha}$- receptors expressed in C6 glioma cells, for 5HT$_{1D\beta}$-receptors expressed in L929 cells and for 5HT$_{1D}$-receptors in calf substantia nigra tissue. The binding properties of the 5HT$_{1D}$-receptor subtypes in the three tissues were investigated using [^{3}H]alniditan in comparison with [^{3}H]5HT. [^{3}H]Alniditan revealed K_D-values (nM) of 1.25, 2.26, 1.05 and B_{max}-values (fmoles/mg protein) of 900, 1770, 750 for the receptors in the three tissues above, respectively. Investigations of binding affinities for various 5HT agonists and antagonists revealed that receptors labelled by [^{3}H]alniditan and [^{3}H]5HT were similar in the tissues, respectively. Distinctions in the binding properties of the hu 5HT$_{1D\alpha}$-, hu 5HT$_{1D\beta}$- and 5HT$_{1D}$-receptors in calf brain tissue were noted. The binding properties of the latter were more similar to those of the hu 5HT$_{1D\beta}$-receptors, although not completely identical.

Alniditan was a potent inhibitor of forskolin stimulated cAMP formation in the recombinant cells expressing the hu 5HT$_{1D\alpha}$- and hu 5HT$_{1D\beta}$-receptor, revealing full agonist properties with subnanomolar IC_{50}-values. [^{3}H]Alniditan is an advantageous ligand for both 5HT$_{1D\alpha}$- and 5HT$_{1D\beta}$-receptors, its potent agonist activities at these receptors probably underlie its antimigraine properties.

727.16

PHARMACOLOGICAL ACTIVITY OF SOLUBILIZED HUMAN 5HT1A RECEPTOR. J.T. Weber, K. Hayataka, and K. K. Parker*. Dept. of Pharm. Sci., School of Pharmacy, Univ. of Montana, Missoula, MT 59812.

The serotonin 5HT1a receptor is thought to play a role in a variety of biomedically significant disorders such as anxiety, panic disorder, and migraine. The receptor is a member of the superfamily of G protein coupled receptors, characteristically having seven transmembrane domains. The studies to be reported involve detergent solubilization of the membrane-bound receptor, analysis of agonist binding to the solubilized receptor, and probing of the receptor-G protein interface with specifically designed peptides. Solubilization of the cloned human receptor transfected into CHO cells (gift of Dr. John Raymond, Duke U.) with soldium cholate, as reported in the literature, produces receptor which binds agonist; this solubilized receptor shows nearly identical displacement of bound agonist by the partial agonist buspirone compared to non-solubilized CHO membrane receptor. CHAPS is even more effective in solubilizing activity. Agonist binding of solubilized receptor assayed with glass fiber filters has been compared to assays with G50 columns.

INTERACTIONS OF *(S)*-UH-301 DERIVATIVES WITH RECOMBINANT 5-HT$_{1A}$ RECEPTORS. Y. Gao, S. Lu, J.R. Raymond, M.N. Garnovskaya, and J.W. Kebabian*. Research Biochemicals International, Natick, MA, 01760-2447, & Duke University/VA Medical Centers, Durham, NC 27710.

(S)-UH-301 has been proposed as a specific 5-HT$_{1A}$ receptor antagonist. To test this, HeLa cell monolayers transfected with 5-HT$_{1A}$ receptor (≈2 pmol/mg of protein) were screened for alteration in the rates of H^+ efflux using a Cytosensor™ microphysiometer. Acidification rate was increased ≈45% by 5-HT, ≈35% by ±8-OH-DPAT, 40% by (+)8-OH-DPAT, 32% by (-)8-OH-DPAT, 35% by *(R)*-UH-301, and not at all by *(S)*-UH-301 (n = 3 or more for each). Those studies support a lack of agonist properties for *(S)*-UH-301. To further test that issue, ^{3}H-*(S)*-UH-301 was synthesized and saturation analyses performed. Specific binding to 5-HT$_{1A}$ receptors was ≥85%, was saturable, and of high affinity (17 ± 6 nM, n = 5). The binding was partially sensitive to 100 µM GTP, suggesting the possibility of at least some agonist properties. Several derivatives of *(S)*-UH-301 were synthesized, including two biotinylated, two affinity, and two chemical intermediate compounds. Those were tested in competition assays against ^{3}H-8-OH-DPAT using MDCK cell membranes bearing transfected 5-HT$_{1A}$ receptors (≈1 pmol/mg of protein). The results are presented below.

Compound	K_D (nM) ± SE	(n)
(S)-UH-301	20 ± 3	4
(R)-UH-301	64 ± 24	4
(S)-UH-301-biotinylated #1	96 ± 20	4
(S)-UH-301-biotinylated #2	103 ± 17	3
(S)-UH-301-photoaffinity probe	833 ± 524	5
(S)-UH-301-affinity probe	947 ± 441	4
(S)-UH-301-intermediate compound #1	63 ± 27	7
(S)-UH-301-intermediate compound #2	60 ± 23	4
p-MPPI	0.9 ± 0.3	3
WAY-100635	1.2 ± 1	3

These compounds may prove to be useful tools to study the 5-HT$_{1A}$ receptor.

727.18

WAY 100635 REVERSES THE DECREASE OF 5-HT LEVELS PRODUCED BY THE PUTATIVE 5-HT1A ANTAGONIST, WAY 100135. M.-B. Assié and W. Kock*. Neurobiology II, C.R.P.F., 17 av. Jean Moulin, 81100 Castres, France.

Using microdialysis, it was shown previously that the 5-HT1A antagonist WAY 100135, which reversed the 8-OH-DPAT-induced decrease of 5-HT levels in rat ventral hippocampus, induced, by itself, a moderate but significant decrease of 5-HT levels. The present work was aimed at characterizing this decrease using the recently described, more potent 5-HT1A antagonist WAY 100635. Chloral hydrate-anaesthetized, male Sprague Dawley rats, were implanted with a 2 mm probe in the ventral hippocampus (mm: r -4.8, l +4.6, v -7.5 according to Paxinos and Watson, 1986). The probe was perfused with artificial CSF at 1.1 µl/min. After a 2 hour stabilisation period, 20 min samples were collected and analyzed for 5-HT content by HPLC-EC. After four control samples (used to define basal level, mean = 100 %), WAY 100635 0.16 mg/kg s.c. was injected 40 min before WAY 100135 10 mg/kg s.c. or 8-OH-DPAT 0.31 mg/kg i.p., and sampling was continued for a further 140 min period. WAY 100635 produced no major changes in 5-HT levels. In some rats, however, WAY 100635 alone produced a weak and transient decrease of 5-HT levels, at 0-40 min after injection to a maximum of about 72% of the basal level. 8-OH-DPAT decreased 5-HT levels to a maximum of 36% of the basal level, and this decrease was completely abolished by pretreatment with WAY 100635. WAY 100635 also prevented the decrease induced by WAY 100135 (maximum effect: 56% of the basal level). These results are further evidence that WAY 100135 may act as a partial agonist at presynaptic 5-HT1A receptors modulating the release of 5-HT. In addition, the results suggest the possibility that the novel 5-HT1A antagonist, WAY 100635 may not be entirely devoid of intrinsic efficacy at 5-HT1A receptors.

727.19

DIRECT ACTIVATION BY DOPAMINE OF RECOMBINANT HUMAN 5-HT$_{1A}$ RECEPTORS EXPRESSED IN *XENOPUS* OOCYTES. Murat- Oz*, Xue-Tao Li, David A. Nielsen, Forrest F. Weight and Li Zhang Lab. Molecular & Cellular Neurobiology and Lab. Neurogenetics, NIAAA, NIH, Bethesda, MD, 20892-8205.

Although an interaction between dopamine and several 5-HT receptor subtypes has been suggested, whether or not dopamine can directly activate 5-HT$_{1A}$ receptors has not been reported. In present study, cRNA of human 5-HT$_{1A}$ and the G-protein activated K^+ channel, GIRK, were coexpressed in *Xenopus* oocytes and investigated electrophysiologically. Although 5-HT, the 5-HT$_{1A}$ receptor agonist 8-OH-DPAT, and dopamine failed to induce any detectable currents in uninjected oocytes (n=5), in oocytes expressing both 5-HT$_{1A}$ receptors and GIRK, 0.1 µM 5-HT, 1 µM 8-OH-DPAT, and 500 µM dopamine activated inward currents (n=17) that were reversibly inhibited by 0.1 µM pindobind-5-HT$_{1A}$, a 5-HT$_{1A}$ antagonist (n=5). On the other hand, a 1 µM concentration of dopamine antagonist, SCH-23390 (D_1) or spiperone (D_2), did not affect the amplitude of currents activated by 5-HT or dopamine (n=4). In addition, both 5-HT- and dopamine-induced currents had similar current-voltage relationships in the same oocytes (n=4). In oocytes coinjected with µ-opioid receptor and GIRK, even though µ-opioid agonists did not activate a current, dopamine and 5-HT did not induce detectable current suggesting that dopamine does not directly activate G-proteins or GIRK (n=5). The results suggest that dopamine can directly activate human 5-HT$_{1A}$ receptors expressed in *Xenopus* oocytes.

727.20

EFFICACY OF ANTIPSYCHOTIC DRUGS AT CLONED HUMAN SEROTONIN (5-HT)$_{1A}$ AND DOPAMINE D_4 RECEPTORS, DETERMINED BY STIMULATION OF [^{35}S]GTPγS BINDING. A. Newman-Tancredi*, V. Audinot, M. Spedding, C. Chaput L. Verrièle and M.J. Millan. Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, Paris, France.

Dopamine D_4 and 5-HT$_{1A}$ receptors are concentrated in limbic structures associated with control of mood and emotion. We compared the ability of novel atypical antipsychotics and the neuroleptic haloperidol to stimulate [^{35}S]GTPγS binding in membranes of Chinese Hamster Ovary cells stably expressing either human 5-HT$_{1A}$ (h5-HT$_{1A}$) or D_4 (hD_4) receptors. Efficacy was defined as a percentage of the activation produced by 5-HT (10 µM) or dopamine (10 µM), respectively (= 100%). Affinity (K_i) values were determined in competition binding experiments with [^{3}H](±)8-OH-DPAT (h5-HT$_{1A}$) or [^{3}H]spiperone (hD_4). Drugs were tested at concentrations of 0.1 nM to 10 µM.

	h5-HT$_{1A}$		hD_4	
Antipsychotic	**Ki (nM)**	**Efficacy (%)**	**Ki (nM)**	**Efficacy (%)**
Haloperidol	**2148**	**0**	**1.9**	**0**
Clozapine	**160**	**59**	**35.5**	**0**
S 16924	**1.9**	**66**	**6.2**	**0**
S 17828	**169**	**0**	**2.0**	**0**

Whereas haloperidol and S 17828 acted as (low affinity) antagonists at h5-HT$_{1A}$ receptors, clozapine and S 16924 had partial agonist activity at this site. S 16924 had the highest affinity. All compounds showed significant affinity, but low intrinsic activity, at hD_4 receptors. These interactions of antipsychotic drugs at h5-HT$_{1A}$ and hD_4 receptors may be of importance for their therapeutic properties.

727.21

[^{3}H]S 15535, A NOVEL, SELECTIVE RADIOLIGAND AT SEROTONIN (5-HT)$_{1A}$ RECEPTORS: CHARACTERISATION OF BINDING TO CLONED HUMAN AND RAT HIPPOCAMPAL 5-HT$_{1A}$ RECEPTORS. J-L. Peglion*, A. Newman-Tancredi, L. Verrièle and M.J. Millan, Institut de Recherches Servier, 125 Chemin de Ronde, 78290 Croissy, Paris, France.

The novel benzodioxopiperazine, S 15535 (4-(benzodioxan-5-yl)1-(indan-2-yl)piperazine) is a highly selective ligand for serotonin 5-HT$_{1A}$ receptors (Millan et al, J.P.E.T., 268, 337-352, 1994). The compound was tritiated (8 Ci/mmol) and its binding profile characterised in CHO cells stably expressing the human 5-HT$_{1A}$ (h5-HT$_{1A}$) receptor. At 22 °C, [^{3}H]S 15535 associated to h5-HT$_{1A}$ receptors with a half-time of 3.4 minutes. In saturation binding experiments, [^{3}H]S 15535 displayed a K_d (1.3 nM) and a B_{max} (1.4 pmol/mg) similar to that observed in this cell line with the prototypic 5-HT$_{1A}$ agonist, [^{3}H](±)-8-OH-DPAT (1.0 nM and 1.1 pmol/mg). The K_d for S 15535 agreed well with the K_i value derived from competition of unlabelled S 15535 with [^{3}H]8-OH-DPAT (0.8 nM). In competition binding experiments with [^{3}H]S 15535, serotonergic ligands, including (±)-8-OH-DPAT, 5-HT, (+)-WAY 100,135 and spiperone, displayed K_is consistent with those observed with [^{3}H](±)-8-OH-DPAT, with values of 1.2, 1.7, 14 and 460 nM respectively. GppNHp (100 µM) only slightly reduced the binding of S 15535 (- 18 %) as compared to that of [^{3}H]8-OH-DPAT (- 70 %) to h5-HT$_{1A}$ receptors. Further, ATP (100 µM) also inhibited (- 10 %) [^{3}H]S 15535 binding. [^{3}H]S 15535 showed high affinity, saturable binding to rat hippocampal membranes (K_d = 2.4 nM; B_{max} = 820 fmol/mg) although its association rate was slower (half-time = 7.3 min). As for h5-HT$_{1A}$ receptors, the binding of [^{3}H]S 15535 to hippocampal membranes was slightly reduced (- 10 %) by GppNHp (100 µM). These results suggest that [^{3}H]S 15535 exerts antagonist (or weak partial agonist) properties at both human and rat 5-HT$_{1A}$ receptors for which it represents a novel, useful radioligand.

727.22

EFFECTS OF 5-HT$_{1A}$ AND 5-HT$_{1B}$ AGONISTS ON VENTRAL PALLIDAL NEURONAL ACTIVITY. **B.A. Heidenreich*, F. Rehman & T.C. Napier. Dept. Pharmacol., Stritch Sch. Med., Loyola Univ. Chicago, Maywood, IL 60153.**

The ventral pallidum (VP) of the basal forebrain contains high levels of serotonin (5-HT). In addition, 5-HT$_{1A}$ receptors exist on the somata of VP neurons and 5-HT$_{1B}$ receptors are found on the pallidal terminals of striatal projection neurons. The present study compared the effects of the 5-HT$_{1A}$ agonist (±)8-OH-DPAT (1-256 µg/kg i.v.) and the 5-HT$_{1B}$ agonist CP-94253 (0.01-6.4 mg/kg i.v.) with the non-selective 5-HT agonist TFMPP (0.01-2.9 mg/kg i.v.) on single-neuron activity in the VP of chloral hydrate-anesthetized rats. TFMPP dose-dependently reduced the firing rate of 100% of VP neurons tested (n = 7). In contrast, 8-OH-DPAT produced dose-dependent increases (n = 7) and decreases (n = 4) in VP activity. CP-94253 had no effect on 5 VP neurons and produced only transient and/or variable changes in the activity of 7 additional neurons. Within the latter group, 3 neurons decreased firing rate but these responses were not antagonized by the 5-HT$_{1A/1B}$ antagonist (-)pindolol (0.1-0.2 mg/kg). These results suggest that the alterations in VP neuronal activity produced by TFMPP were not mediated by 5-HT$_{1B}$ receptors. While 5-HT$_{1A}$ receptor activation decreased the firing rate of some VP neurons, other 5-HT receptor subtypes are also likely to contribute to the effects of the TFMPP on VP activity.

SEROTONIN INHIBITS NUCLEUS ACCUMBENS NEURONS RECEIVING INPUTS FROM PARAFASCICULAR NUCLEUS OF THALAMUS VIA 5-HT1A RECEPTORS BUT NOT THOSE FROM HIPPOCAMPUS. I. NAGAOKA*[1], A. TAKU[2], M. SASA[2], S. YAMAWAKI[1]. Departments of [1]Psychiatry and Neurosciences and [2]Pharmacology Hiroshima University School of Medicine, Minami-ku, Hiroshima, 734, Japan.

The nucleus accumbens (Acc) neurons receives innervation from various areas of the brain such as parafascicular nucleus (Pf), hippocampus, amygdala and ventral tegmental area. Serotonin (5-HT) nerve terminals and 5-HT receptor subtypes (5-HT1A, 5-HT1B, 5-HT1C, 5-HT2 and 5-HT3 receptors) are found in Acc. However, the role of 5-HT receptors in Acc neurons functionally remains unknown. Therefore, microiontophoretic studies were performed to elucidate the role of 5-HT1A receptors of Acc neurons receiving inputs from Pf and hippocampus (HPC). Single neuronal activities were recorded with a glass microelectrode attached along a seven-barreled micropipet in chloral hydrate-anesthetized rats. Each of the barrels was filled with dopamine (DA), 5-HT, 8-OH-DPAT(5-HT1A agonist), NAN-190 (5-HT1A antagonist), noradrenaline, glutamate and 3M NaCl, accordingly. Drugs were applied to the immediate vicinity of the target neuron recorded using by microiontophoresis method. Spikes elicited by the Pf stimulation were inhibited by iontophoretically applied DA or 5-HT and 8-OH-DPAT in a dose-dependent manner. Glutamate-induced firing was also inhibited by simaltaneous application of DA, 5-HT or 8-OH-DPAT. 8-OH-DPAT induced inhibition of glutamate-induced firing was antagonized drug application of NAN-190. However, spikes elicited by HPC stimulation were not affected by iontophoretically applied DA or 5-HT. These results suggest that the DA-sensitive Acc neurons receiving inputs from Pf are inhibited by 5-HT via 5-HT1A receptors but those from hippocampus are not affected.

727.24

EFFECTS OF 8-OH-DPAT ON RELEASE OF CORTICOTROPIN RELEASING FACTOR IN AMYGDALA. E.A. Johnson*, V. Garlapati and D.L. Birkle. Dept.s of Behavioral Medicine and Psychiatry, Neurology, Pharmacology and Toxicology, West Virginia University. School of Medicine, Morgantown, WV 26506.

Corticotropin Releasing Factor (CRF) is a 41 amino acid peptide neurotransmitter with putative roles in stress and anxiety. Release of CRF from the hypothalamus results in increased release of ACTH from the anterior pituitary, ultimately leading to glucocorticoid release in the stress response. Increasing evidence indicates that release of CRF from sites in the central nervous system, other than the hypothalamus, may play a role in anxiety. The amygdala is a brain region rich in CRF neuronal terminals. Furthermore, the amygdala functions as a modulator of anxiety. The amygdala is innervated by serotonergic neurons originating in the dorsal and medial raphe nuclei. Amygdala contains a moderate level of 5-HT$_{1A}$ receptors. Since 8-OH-DPAT, a selective agonist of 5-HT$_{1A}$ receptors, has been demonstrated to stimulate CRF release in hypothalamus, we investigated its effect on CRF release from amygdala. Amygdala minces were incubated *in vitro* with 8-OH-DPAT (0.01-100 nM) under basal and depolarizing conditions. 8-OH-DPAT caused no change in basal CRF release but dose dependently increased potassium-induced release of CRF from amygdala minces ($p < 0.05$). The maximal effect was observed using 1 nM 8-OH-DPAT which is consistent with the affinity reported for 8-OH-DPAT binding to 5-HT$_{1A}$ receptors (0.7-2.0 nM). These results are consistent with previous reports of the stimulatory action of 8-OH-DPAT on hypothalamic release of CRF.

AGONIST-INDUCED [^{35}S]GTPγS BINDING AT HUMAN 5-HT$_{1A}$ RECEPTORS STABLY EXPRESSED IN HeLa CELLS

M.S. Beer, A. Heald, A.T. Stagg, K.L. Hadingham* and J.A. Stanton, Merck Sharp & Dohme Research Laboratories, Neuroscience Research Centre, Terlings Park, Eastwick Road, Harlow, Essex, CM20 2QR, U.K.

In this study the pharmacological characterisation of agonist-induced [^{35}S]GTPγS binding to the human 5-HT$_{1A}$ receptors stably expressed in HeLa cells (HA7) was investigated. This response was also used to investigate the presence of receptor reserve in this cell line.

HeLa cells expressing human 5-HT$_{1A}$ receptors (5mg wet weight/tube) were labelled with 100pM [^{35}S]GTPγS in the presence of 30µM GDP (Lazareno and Birdsall, 1993). Pretreatment of these cells with 3µM, 6µM and 10µM benextramine, resulted in reduced 5-HT maximal response and potency. Furchgott analysis (1966) yielded a pK_A 6.98±0.03 compared with a pK_{obs} of 8.4±0.3, obtained from [^{3}H]5-HT radioligand binding saturation studies, indicating the presence of receptors in mixed affinity states. Plots of receptor occupancy verses maximal response indicate the presence of some receptor reserve. In unpretreated cells 5-HT, 5-CT, 8-OH DPAT, RU24969, and buspirone displayed full and NAN 190 partial agonism. WAY 100135 had no intrinsic activity whereas methiothepin dose dependently reduced basal levels.

This method offers an efficient means of assessing the potency and efficacy of compounds at the human cloned 5-HT$_{1A}$ receptor.

728.1

THE 5-HT5 RECEPTORS: CHARACTERIZATION OF THE HUMAN 5-HT5A RECEPTOR; ABSENCE OF THE HUMAN 5HT5B RECEPTOR; KNOCKOUT OF THE MOUSE 5HT5A RECEPTOR. R. Grailhe, S. Ramboz, U. Boschert+ and R. Hen*. Center for Neurobiology and Behavior, Columbia University, New York, NY 10032, USA. +Glaxo Institute for Molecular Biology, Geneva, Switzerland.

We have isolated from a human genomic library, the homologues of the mouse 5-HT5A and 5-HT5B genes. The human 5-HT5A gene encodes a protein with similar characteristics as the mouse 5-HT5A receptor. When expressed in Cos-7 cells, the human 5-HT5A receptor displayed a high affinity for the radiolabelled ligands [^{3}H]5-CT (Kd=2,8nM) and [^{125}I]LSD (Kd=187pM). These sites were insensitive to GppNHp and displayed a similar pharmacological profile as the mouse 5HT5 receptors. We are currently analyzing the coupling of the human 5-HT5A receptor in NIH3T3, 293 and GH3 cells. Reverse PCR experiments revealed expression of the human 5-HT5A mRNA in cortex, hyppocampus, amygdala, thalamus, raphe nuclei and spinal cord .

The human 5-HT5B gene is composed of two exons and is transcribed at very low level. However, unlike the 5-HT5A gene, the 5-HT5B gene does not appear to encode a functional protein, since the putative coding sequence is interrupted by several stop codons. In addition, Southern and PCR experiments performed on samples from different individuals, have revealed that this non-functional gene is the only human homologue of the rodent 5HT5B gene. These results indicate that humans do not express a functional 5-HT5B receptor and suggest that this protein has been lost after the divergence between rodents and primates.

In order to study the function of the 5-HT5A receptor, we have generated by homologous recombination, mutant mice lacking the gene encoding this receptor. These homozygous mutant mice develop, move, feed and breed apparently normally. We are currently investigating their behavior in various experimental paradigms as well as their response to drugs that have a high affinity for the 5-HT5A receptor, such as LSD.

728.2

THE 5-HT$_{5A}$ SEROTONIN RECEPTOR IS EXPRESSED PREDOMINANTLY ON ASTROCYTES WITHIN THE DEVELOPING AND ADULT RAT CNS. M. J. Carson*, P. E. Danielson, E. A. Thomas, and J. G. Sutcliffe. The Scripps Research Institute, La Jolla, CA 92037

Serotonin (5-hydroxytryptamine, 5-HT) elicits a wide array of sensory, motor, and behavioral processes in the mammalian central nervous system (CNS). Identification and characterization of the individual receptors which mediate these responses is crucial to understanding the mechanisms of serotonin's actions within the CNS. Using antisera to two synthetic peptides corresponding to non-overlapping regions of the rat 5-HT$_{5A}$ receptor, we detected primarily astrocytes in immunocytochemical analysis. Throughout all time points examined (P1 through adulthood), 5-HT$_{5A}$ immunoreactivity colocalized with the astrocyte specific marker glial fibrillary acidic protein. 5-HT$_{5A}$ immunoreactivity was present on both the cell body and the stellate processes of the astrocyte. RT-PCR analysis confirmed the expression of 5-HT$_{5A}$ in neuron-depleted astrocyte cultures. By northern blot analysis, 5-HT$_{5A}$ expression was detected as early as E18 in rat CNS and peaked by P20 declining only slightly in adulthood. Together, these results indicate a mechanism for glial-neuronal serotonergic interactions which develops *in vivo* in concert with astrocyte development. To understand the consequences of these interactions, we are comparing the signal transduction events mediated by 5-HT$_{5A}$ in glial cell lines naturally expressing 5-HT$_{5A}$ with non-glial cell lines transfected with 5-HT$_{5A}$.

728.3

5-HT$_4$ RECEPTORS IN RAT BRAIN: mRNA AND RECEPTOR DISTRIBUTIONS SUGGEST BOTH SOMATODENDRITIC AND PRESYNAPTIC LOCALIZATIONS. M.T.Vilaró[1], G.Mengod[1], R.Cortés[1], C.Gerald[2], T.A.Branchek[2], and J.M.Palacios[3]* 1:Dpt.Neurochem. CID/CSIC, Barcelona 08034, Spain; 2:Synaptic Pharmaceutical Corporation, Paramus, NJ 07652.

Oligonucleotide probes and *in situ* hybridization were used to study the distribution of mRNA encoding the long (5-HT$_{4L}$) and short (5-HT$_{4S}$) splice variants of the serotonin 5-HT$_4$ receptor. With a probe common to both variants, the strongest hybridization signals were detected in olfactory tubercle (OTu), islands of Calleja (ICj) and medial habenula (MHb). Strong signals were observed in nucleus accumbens (Acc) and caudate-putamen (CPu), this latter showing a rostro-caudal increasing gradient of signal. Intermediate and low signals were seen, respectively, in the granule cell layer of the dentate gyrus and in the pyramidal cell layer of Ammon's horn. With a probe specific for 5-HT$_{4L}$, essentially the same pattern was observed. Finally, a probe specific for 5-HT$_{4S}$ presented a more restricted pattern of distribution, with low levels of signal in OTu, ICj, MHb, Acc and caudal parts of CPu and very low levels in dentate gyrus.

5-HT$_4$ receptor binding sites were visualized with the 5-HT$_4$ antagonist [^{125}I]SB 207710. The highest densities of receptors were observed in OTu, Acc, CPu, globus pallidus (GP), substantia nigra (SN) and interpeduncular nucleus (IP). Lower densities were present in medial and lateral habenula and hippocampus, among many others. Comparison of mRNA and receptor distributions suggests two different subcellular localizations for 5-HT$_4$ receptors. Receptors present e.g. in OTu, Acc, CPu and hippocampus would be located somatodendritically, whereas receptors present e.g. in GP, SN and IP would be located pre-synaptically on axon terminals of, respectively, the striatopallidal, striatonigral, and habenulo-interpeduncular projections.

5-HYDROXYTRYPTAMINE 4 RECEPTORS (5-HT$_4$R) ARE LOCATED PRESYNAPTICALLY IN THE STRIATONIGRAL PATHWAY AND CODISTRIBUTED WITH 5-HT$_{1D}$ RECEPTORS. G.Mengod[1*], R. Cortés[1], C. Salcedo[2], and J.M. Palacios[2]. [1]Dept. Neurochem., CID/CSIC, 08034 Barcelona, Spain.

The localization of 5-HT$_4$ receptors in the basal ganglia of guinea-pig has been studied using autoradiographic techniques and ^{125}I-SB 207710 as a ligand. In consecutive sections, 5-HT$_{1D}$ receptors were visualized using ^{125}I-GTI. Caudate-putamen, globus pallidus and substantia nigra pars reticulata were some of the areas presenting the highest densities of receptors. In order to examine the possible cellular localization of these receptors, neurotoxic lesions were performed. Dopamine neurons were destroyed by direct injection of 6-OHDA into the substantia nigra. In animals bearing these lesions no modification on the distribution or density of 5-HT$_4$ and 5-HT$_{1D}$ receptors were measured. In contrast, lesion of the intrinsic neurons of the caudate-putamen nucleus with quinolinic acid, resulted in a marked reduction of receptor densities in areas of the caudate-putamen surrounding the lesion placement and also in limited regions of the ipsilateral substantia nigra pars reticulata. The localization and extension of 5-HT$_4$ receptor losses coincided with those of 5-HT$_{1D}$ sites. These results suggest that 5-HT$_4$ in the guinea-pig basal ganglia are not located in dopaminergic neurons but rather on neurons intrinsic to the striatum which project to the substantia nigra such as those utilizing substance P, enkephalin and GABA as neurotransmitters, where these sites are codistributed with 5-HT$_{1D}$ receptors.

728.5

5-HT$_4$ RECEPTOR LEVELS ARE REDUCED IN THE PUTAMEN FROM PATIENTS WITH SCHIZOPHRENIA.
L.J. Steward* & N.M. Barnes. University of Birmingham, Department of Pharmacology, The Medical School, Birmingham, U.K., B15 2TT.

Relatively high densities of the 5-HT$_4$ receptors are expressed in human mesolimbic and nigro-striatal systems, as detected using the high affinity and selective radioligand [^{3}H]GR113808. Our recent studies in rat brain indicate that the 5-HT$_4$ receptor can modulate the release of dopamine. It is generally accepted that an overactivity of the mesolimbic dopamine system is associated with schizophrenia. Therefore, in the present studies we investigated the levels of 5-HT$_4$ receptors in human brain regions from schizophrenic patients and matched control patients who had died without a neurological or psychological disorder.

Saturation studies with [^{3}H]GR113808, revealed specific binding (non-specific defined by SDZ 205-557, 10 μM) in all examined tissues from control and schizophrenic patients (putamen, amygdala, nucleus accumbens and substantia nigra). There was a significant ($p < 0.05$) reduction in [^{3}H]GR113808-labelled 5-HT$_4$ receptor density in putamen tissue from schizophrenic patients when compared to control putamen tissue (approximately 50 %). Whilst no significant differences in the densities of the radiolabelled 5-HT$_4$ receptor were detected in amygdala, nucleus accumbens and substantia nigra from schizophrenic and control patients. Whether the reduction in 5-HT$_4$ receptor density in the putamen of schizophrenic patients, is part of the pathology of the psychiatric disorder or a consequence of chronic psychotropic drug therapy, remains to be established. We would like to thank the MRC Brain Bank (Cambridge, UK) for the donation of tissue.

ABILITY OF THE 5-HYDROXYTRYPTAMINE$_4$ RECEPTOR TO MODULATE DOPAMINE AND 5-HYDROXYTRYPTAMINE RELEASE IN RAT BRAIN

N.M. Barnes*, L.J. Steward, J. Ge, R.L. Stowe, P.R.A. Stokes and D.C. Brown. Department of Pharmacology, Medical School, University of Birmingham, Birmingham B15 2TT UK.

In the present study we assess the ability of the 5-hydroxytryptamine$_4$ (5-HT$_4$) receptor to modulate dopamine (DA) and 5-hydroxytrptamine (5-HT) release in the rat forebrain.

The 5-HT$_4$ receptor agonist renzapride enhanced dopamine release from both rat striatal slices and in the striatum of freely moving rats assessed by the microdialysis technique in a concentration dependent manner (maximal increase; 214±35% in slices (10 μM renzapride) and 161±10% in vivo (100 μM renzapride administered via the probe, mean±SEM, n=4-14). The renzapride-induced increase in DA release (both preparations) was prevented by the selective 5-HT$_4$ receptor antagonist, GR113808 (in vitro 100 nM , in vivo 1 μM) and the protein kinase A inhibitor, H7 (in vitro 100 nM, in vivo 1 μM). Similar responses were detected with the 5-HT$_4$ receptor agonist 5-methoxytryptamine (5-MeOT).

The 5-HT$_4$ receptor agonists 5-MeOT (10 μM; with concomitant 5-HT$_1$/5-HT$_2$ receptor blockade) and renzapride (100 μM), maximally increased 5-HT release in the hippocampus, assessed by the microdialysis technique, by 451±40% and 214±30%, respectively (mean±S.E.M., n=3-5). Lower concentrations of renzapride (1-10 μM) were less effective. GR118303 (1 μM), reduced dialysate levels of 5-HT (maximally 50±8%, mean±S.E.M., n=4) and also completely antagonised the increase in 5-HT release induced by either 5-MeOT (10 μM) or renzapride (100 μM).

The present studies indicate that the 5-HT$_4$ receptor modulates DA and 5-HT release in the striatum and hippocampus, respectively.

Supported by the Wellcome Trust.

CO-LOCALIZATION OF SEROTONIN 5-HT6 AND 5-HT2C RECEPTORS IN NEUROPEPTIDE CONTAINING NEURONS OF THE RAT STRIATUM

R.P. Ward* and D.M. Dorsa. Dept. of Pharmacology and Dept. of Psychiatry and Behavioral Sciences, Univ. of Washington, Seattle, WA 98195.

The striatum is the largest nucleus of the basal ganglia, and has two main outputs: a projection to the globus pallidus, and a projection to the substantia nigra. Dopamine receptors and certain neuropeptides which are expressed in the striatum are differentially distributed between these two pathways. Specifically, enkephalin and the dopamine D2 receptor are expressed in neurons projecting to the globus pallidus, while substance P and dynorphin along with the dopamine D1 receptor are expressed in neurons projecting to the substantia nigra. The striatum also receives a prominent serotonergic input, but little is known about how serotonin receptors fit into the molecular neuroanatomy described above. In the present study we used double label *in situ* hybridization to determine the distribution of the mRNAs of two of the serotonin receptors, the 5-HT6 and the 5-HT2C, in relation to enkephalin, substance P, and dynorphin expressing output neurons.

Coronal sections of rat brain were simultaneously hybridized with an ^{35}S riboprobe for one of the serotonin receptors and a digoxygenin labeled riboprobe for one of the neuropeptides. Sections were examined using brightfield microscopy, and the relationship of expression of the two mRNAs to each other was determined.

mRNA for the 5-HT6 receptor was found to be evenly distributed throughout the striatum and nucleus accumbens and to co-localize with all three of the neuropeptides examined. This indicates that signals mediated via this receptor will affect both of the major striatal output pathways.

The 5-HT2C receptor also showed co-localization with all three of the neuropeptides examined, however its distribution is considerably more complex. Levels of 5HT-2C mRNA were much higher medially than laterally, and ventrally than dorsally. Additionally discreet regions found throughout the striatum exhibited much higher levels of expression. These small scattered regions represent the striatal patch compartment, as shown by their overlap with regions which exhibit high levels of dynorphin mRNA expression. Supported by NS20311 and a P.M.A.F. Fellowship.

728.8

AFFINITY OF TYPICAL AND ATYPICAL NEUROLEPTICS FOR THE CLONED HUMAN 5-HT$_6$ SEROTONIN RECEPTOR

R.Kohen[1]*, M.A.Metcalf[1], N. Khan[2], D.R.Sibley[3], B.L.Roth[2], M.W.Hamblin[1] [1]University of Washington, and GRECC, Seattle VAMC, Seattle, WA 98108; [2]Case Western Reserve University, Cleveland, OH 44022; [3]NINDS/NIH, Bethesda, MD 20892.

The 5-HT$_6$ receptor is a G_s coupled serotonin receptor with relatively low sequence homology to other known serotonin receptor subtypes. One of the most striking features initially described for the rat 5-HT$_6$ receptor was its high affinity for the atypical neuroleptic clozapine and related compounds. This affinity and its distribution in brain areas such as striatum, nucleus accumbens and hippocampus thought to be involved in neuroleptic drug action suggested that the 5-HT$_6$ receptor might be important in mediating some of the advantageous differences of atypical over typical antipsychotic drugs.

We have now extended the studies on neuroleptic affinity for the rat 5-HT$_6$ receptor by Roth and co-workers to the cloned human 5-HT$_6$ receptor expressed in COS-7 cells. It also has high (approximately 10 nM) affinity for several atypical neuroleptics including clozapine, olanzepine, ICI 169369, rilapine and (-)octoclothepin. Although chlorpromazine and (+)octoclothepin, both typical neuroleptics, also have high 5-HT$_6$ affinity, affinities for most typical neuroleptics is lower, as are those of atypical drugs with some residual liability to produce extrapyramidal symptoms. These data suggest that 5-HT$_6$ receptors, along with others such as 5-HT$_{2A}$, may play an important role in mediating some of the differences between typical and atypical antipsychotic drugs. *Supported by the Department of Veterans Affairs.*

728.9

EFFECTS OF CLOZAPINE AND HALOPERIDOL ON EXPRESSION OF 5HT$_6$ AND 5HT$_7$ RECEPTORS

J.A. Frederick, J.F. Lopez*, and J.H. Meador-Woodruff. Mental Health Research Institute, Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109. The distribution and regulation of messenger RNA encoding two recently cloned serotonin receptors was examined by in situ hybridization in the rat brain. 5-HT$_6$ labelling was observed in the striatum, olfactory tubercle, neocortex, and hippocampus. 5-HT$_7$ labelling was observed in the thalamus, hypothalamus, piriform cortex, entorhinal cortex, superficial layers of neocortex, septum, amygdyla, and the CA2 and CA3 regions of the hippocampus. Most striking was the lack of 5-HT$_7$ expression in the dentate gyrus or CA1 regions of hippocampus, or in the striatum. The high affinity of 5-HT$_6$ and 5-HT$_7$ receptors for atypical antipsychotic drugs, and their localization in limbic and cortical regions, suggests that they may play a role in the pathophysiology of schizophrenia. To determine if expression of these receptors is regulated by antipsychotic drugs, rats were injected with clozapine (20 mg/kg/day, N=8), haloperidol (2 mg/kg/day, N=8), or vehicle (N=8) for two weeks. Preliminary evidence suggests that clozapine and haloperidol increase expression of 5-HT$_6$ receptors in the nucleus accumbens, and decrease 5-HT$_6$ expression in frontal cortex. Meanwhile, no differences in 5-HT$_6$ expression were observed between haloperidol- and clozapine-treated animals in all regions studied. Further results of this study are expected and will be presented.

728.10

CORRELATION BETWEEN 5-HT$_7$ RECEPTOR BINDING AND ITS mRNA IN THE RAT AND GUINEA PIG BRAIN VISUALIZED AUTORADIOGRAPHICALLY.

A. Raurich[1], G. Mengod[1], S. Hurt[2], J.M. Palacios[3] and R. Cortés[1]*. [1]Dept. of Neurochemistry, CID/CSIC, Barcelona, Spain.[2]DuPont NEN Products, Med.Prod.Dept., Boston, MA 02118.

We have used receptor autoradiography with ^{3}H-5-carboxytryptamine (^{3}H-5-CT) as ligand and *in situ* hybridization histochemistry using ^{32}P-labeled oligonucleotides to visualize the anatomical localization of the 5-HT$_7$ receptor and its mRNA in the rat and guinea pig brain.

By analyzing the displacement of 5 nM ^{3}H-5-CT binding by the selective 5-HT$_{1A}$ and 5-HT$_{1D}$ antagonists WAY 100135 and GR 127935 and 8-OH-DPAT, a 5-HT$_{1A}$ and 5-HT$_7$ ligand, conditions were selected allowing for the direct visualization of 5-HT$_7$ binding sites. In the guinea pig, 5-HT$_7$ receptors could be selectively labeled with 5 nM ^{3}H-5-CT in the presence of high concentrations of WAY 100135 (100 μM) and GR 127935 (200 μM), whereas in the rat, a small population of 5-HT$_{1B}$ receptors remained still labeled.

In these conditions, in the guinea pig 5-HT$_7$ binding sites were found to be enriched in layers I-III of the neocortex, claustrum, several hypothalamic and midline nuclei of the thalamus (i.e paraventricular, paratenial, mediodorsal nuclei), dentate gyrus, and superior colliculus, among others. These areas were also enriched in 5-HT$_7$ mRNA signal, both in rat and guinea pig. In contrast, neither 5-HT$_7$ binding nor mRNA were detected in structures such as the globus pallidus or the pars compacta and reticulata of the substantia nigra.

[3H]-THIOPERAMIDE-A NEW RADIOLIGAND FOR THE HISTAMINE H3 RECEPTOR

A. Alves-Rodrigues, R. Leurs*, T. S. Wu, and H. Timmerman. Leiden/Amsterdam Center for Drug Research, Department of Pharmacochemistry, Vrije Universiteit, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands

Thioperamide is the first selective high affinity antagonist described for the H3 receptor. Its use as a radioligand has, sofar, never been reported. In the present study, the binding of [3H]-thioperamide was characterized in membranes of rat brain cortex. Transformation of saturation curves showed non-linear Scatchard plots suggesting labelling of two different populations of sites by [3H]-thioperamide. Up to a concentration of 1 µM, H3 agonists hardly displaced the total binding of 5 nM [3H]-thioperamide. Moreover, although H3 antagonists fully displaced the total binding of 5 nM [3H]-thioperamide Ki's obtained were different from the values expected for the H3 receptor. These results showed that, at 5 nM, [3H]-thioperamide was mainly labelling a non-H3 receptor site. The total binding of 0.3 nM [3H]-thioperamide, however, was, inhibited up to 60% by H3 agonists. Stereoselectivity for the R and S isomers of a-methylhistamine and guanine nucleotides sensitivity for the displacement by R-a-methylhistamine was established. H3 antagonists fully displaced the binding of 0.3 nM [3H]-thioperamide. Displacement curves of the antagonists were biphasic with the Ki for the high affinity site similar to values expected for the H3 receptor. In conclusion, in rat brain, [3H]-thioperamide, labels with high affinity both the H3 receptor and a indentified non-H3 binding site. Most of the H3 antagonists also show high affinity for the non-H3 site. Because agonists do not show high affinity for the non-H3 component of the binding of [3H]-thioperamide, they should be used to define the nonspecific binding of [3H]-thioperamide when studying the H3 receptor.

OXIDATION OF HISTAMINE IN RODENT BRAIN HOMOGENATES: EVIDENCE FOR AN ALTERNATIVE PATHWAY OF BRAIN HISTAMINE METABOLISM.

B Thomas, AM Morrishow and GD Prell* Dept Pharmacology, Mount Sinai Medical Center, NY, NY 10029

There is extensive evidence from early studies that histamine is mainly, if not exclusively methylated in mammalian brain. However, we recently showed that imidazoleacetic acid (IAA), histamine's oxidative metabolite in the periphery and a potent GABA$_A$ agonist, is present in brain where its levels increase when histamine methylation is blocked. IAA does not enter brain from periphery. ^{3}H-histamine (icv) formed ^{3}H-IAA and its ribosylated metabolites in rat brain, a process that increased when histamine methylation was blocked (*J. Neurochem.* **65** [in press]). To assess which enzyme(s) may be involved, we examined metabolism of 2-10 ng ^{3}H-histamine in whole brain homgenates of male rats, mice and guinea pigs (2 ml; 5 vol; NaP buffer, pH 7.4) incubated (37°C) with amine oxidase inhibitors (e.g. clorgyline, deprenyl or aminoguanidine [AG]), then boiled after 30 min. Aliquots (5 µl) were applied to Polygram silica TLC plates (250 µ); t-Butanol, formatic acid, water (70,15,15) separated histamine (R_F 0.31), *tele*-methylhistamine (0.14), *tele*-methylimidazoleacetic acid (0.50) and IAA and its metabolites (0.63-0.66). In all species examined, ^{3}H-IAA (and/or its metabolites) was produced. Clorgyline and deprenyl, at concs selective for MAO-A and -B, respectively, did not affect recoveries of ^{3}H-histamine or ^{3}H-IAA (and its metabolites). In contrast, at concs expected to abolish DAO activity (up to 1 µM), AG inhibited, but did not abolish oxidation. These results confirm that histamine is not oxidized by MAO-A or -B and suggest that an AG-sensitive enzyme, possibly DAO or another amine oxidase(s), can oxidize histamine in brain and form IAA and its metabolites. (NINDS-NS-28012)

729.3

COMPARISON OF HISTAMINE H_3 RECEPTOR ANTAGONISTS (GT-2016, THIOPERAMIDE, AND CLOBENPROPIT): RECEPTOR BINDING AND HISTAMINE TURNOVER. C.E. Tedford*, J.G. Phillips, M.A. Khan, R.C.A. Frederickson, R. Leurs**, H. Timmerman**, and S.L. Yates. Gliatech Inc., 23420 Commerce Park Rd. Cleveland, OH 44122 and **Vrije Universteit, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands.

The release of histamine (HA) in the CNS is under the negative tonic control of presynaptic HA H_3 autoreceptors. Once released, HA is metabolized to N^{π}-methylhistamine (TMH). Selective H_3 receptor antagonists block the negative feedback of HA, resulting in increased HA release and metabolism. GT-2016, a nonthiourea-containing H_3 antagonist, has been developed at Gliatech. *In vivo* CNS penetration of GT-2016 and changes in HA turnover were studied in male Sprague Dawley rats, and compared to the thiourea- and isothiourea-containing H_3 antagonists, thioperamide and clobenpropit. The *in vitro* K_i's for GT-2016, thioperamide, and clobenpropit were 44, 1.6, and 0.2 nM, respectively, using rat cortical membranes and 1 nM ^{3}[H]N^{α}-methylhistamine (NAMHA). The ability of these compounds to penetrate the CNS was assessed using an *ex vivo* binding technique. Rats were pretreated with drug (1 hr) and an inhibition binding assay was performed using unwashed cortical homogenates. Each of the drugs (1 to 30 mg/kg; ip) produced a dose-dependent inhibition of NAMHA binding. The CNS bioavailability of GT-2016 was 10 to 15 fold greater than that of thioperamide and approximately 150 fold greater than the CNS bioavailability of clobenpropit. Clobenpropit produced minimal changes in HA and TMH levels. GT-2016 and thioperamide produced dose-dependent increases in the TMH/HA ratio, indicative of increased HA release and metabolism. These increases in the TMH/HA ratios were directly correlative with the degree of receptor binding shown in the *ex vivo* binding studies. In summary, GT-2016, a novel nonthiourea H_3 antagonist, provides good CNS bioavailability and corresponding functional blockade of CNS H_3 receptors.

HISTAMINE AGONISTS AND ANTAGONISTS: RECEPTOR SUBTYPE AFFINITIES AND SELECTIVITIES. N.A.Sharif* and S.Xu. Molecular Pharmacology Unit, Alcon Laboratories Inc., Fort Worth, TX 76134.

Specific [^{3}H]pyrilamine, [^{3}H]tiotidine and [^{3}H]N-methyl histamine binding to rodent brain H_1, H_2 and H_3 histamine receptors was studied. Drugs with high affinity (K_i = 0.8-3 nM) for H_1 sites included emedastine (a novel ocular anti-histamine), triprolidine, pyrilamine and ketotifen. Ranitidine showed the highest affinity for H_2 sites (K_i = 187 nM). Drugs with high affinity (K_i = 0.2-5 nM) for H_3 sites included imetit, thioperamide and histamine. Emedastine showed the highest H_1-selectivity (37,000-fold) relative to its H_2-affinity. Ranitidine was the most H_2-selective, and thioperamide (254,000-fold) and imetit (240,000-fold) the most H_3-selective relative to their H_1-affinities. Histamine stimulated phosphoinositide (PI) turnover in human corneal fibroblasts (EC_{50} = 1 μM), and the H_1-antagonists, emedastine (IC_{50} = 0.6 nM), levocabastine (IC_{50} = 11 nM) and triprolidine (IC_{50} = 4 nM) potently inhibited the histamine PI responses. These potencies matched their H_1-receptor binding affinities. These data have shown emedastine to be an high-affinity and high potency histamine antagonist with the highest H_1-selectivity. Emedastine may therefore be a useful H_1-antagonist for use in the eye to treat allergic diseases and in the brain for affective and other disorders.

Effects of Histamine on Phospholipase C and Adenylyl Cyclase Activities in Porcine Spinal Arachnoid Cells in Culture. Martin T. Taylor* and Edward L. Orr, Department of Anatomy and Cell Biology, U.N.T. Health Science Center, Fort Worth, TX 76107

Structural and biochemical interactions between arachnoid cells form the basis of the cerebrospinal fluid (CSF)-blood barrier. Using cultured porcine spinal arachnoid cells, we have begun to assess the types of receptor/second messenger systems expressed by arachnoid cells that may be involved in regulating the CSF-blood barrier. Activation of phospholipase C (PLC) was measured in confluent arachnoid cells by monitoring the conversion of ^{3}H-myoinositol to ^{3}H-inositol phosphates. Adenylyl cyclase (AC) activity was measured by preincubating the cells in ^{3}H-adenine to form ^{3}H-ATP then measuring the conversion of ^{3}H-ATP into ^{3}H-cyclic AMP. Porcine spinal arachnoid cells *in vitro* expressed both PLC and AC activity. Specifically, both carbachol and histamine stimulated PLC at EC_{50}s of 34 μM and 11 μM, respectively. The effect of carbachol was inhibited with atropine. The histamine effect was inhibited by H_1-receptor antagonists, but not by H_2- or H_3-receptor antagonists. Arachnoidal AC activity was stimulated by forskolin and prostaglandin D_2 (PGD_2). Histamine did not stimulate AC activity, indicating that H_2-receptors were not present on the cells. In fact, histamine *inhibited* the stimulation of arachnoidal AC by forskolin and PGD_2. In conclusion, porcine arachnoid cells in culture express muscarinic and histamine H_1-receptors linked to PLC, and PGD_2-receptors linked to AC. These receptors may be involved in regulating arachnoid cell dependent permeability of the CSF-blood barrier. Supported by a Burroughs Welcome Osteopathic Fellowship and a grant from the National Multiple Sclerosis Society.

CRANIECTOMY ACTIVATES DURAL MAST CELLS AND INCREASES CEREBRAL CORTICAL HISTAMINE. Edward L. Orr* and Martha E. Stokely. Department of Anatomy and Cell Biology, U.N.T. Health Science Center, Fort Worth, TX 76107

The dura mater contains numerous mast cells which are degranulated in response to various types of head trauma such as cryogenic lesions (Orr, 1988, Neurochem. Pathol. 8:43-51) or a simple craniectomy (Olesen 1987, Acta Physiol. Scand. 130:63-68. Since degranulated mast cells release large quantities of histamine (HA) and, since exogenous HA can alter the diameter and permeability of pial blood vessels (Yong, et al., 1994, J. Neurotrauma. 11:161-171), the possibility exists that histamine from dural mast cells may cross the meninges to enter the subarachnoid space and affect adjacent brain tissue and pial blood vessels. To test this possibility, adult female Lewis rats were anesthetized by inhalation of methoxyflurane, subjected to unilateral craniectomies, then killed 10 min. later. Samples of cerebral cortex and meninges subjacent and contralateral to the craniectomies were assayed for HA using a specific radioenzymatic assay. Compared to contralateral tissues, the meningeal HA concentration was 62.7 ± 11.8% (mean ± SEM, n=5) of control, while the subjacent cerebral cortical HA concentration was 452.5 ± 165.3% (mean ± SEM, n=5) of control. Since the concentration of HA in the meninges (2.13 ng/mg wet weight) is 140-fold higher than the concentration in the cerebral cortex (0.015 ng/mg wet weight), the decrease in dural HA can easily account for the increased cortical HA observed on the lesioned side of the head. These results suggest that HA, and possibly other products of dural mast cells can cross the meningeal barrier to enter the subarachnoid space and affect underlying brain and associated tissues. (Supported by a grant from the National Multiple Sclerosis Society.)

STIMULATORY EFFECT OF HISTAMINE ON CALCIUM EFFLUX FROM CULTURED BOVINE ADRENAL CHROMAFFIN CELLS. H. Houchi *, K. Kitamura, K. Minakuchi, Y. Ishimura, M. Okuno, T. Ohuchi and M. Oka. Department of Pharmacology, Tokushima University School of Medicine, Kuramoto, Tokushima, 770, Japan.

Histamine is known to have several effects on adrenal chromaffin cells mediated by its H_1 and H_2 receptors. The histamine H_1 receptor is associated with secretion of catecholamine, accumulation of inositol phosphates, increase in the intracellular level of free Ca^{2+} ($[Ca^{2+}]_i$), synthesis of opioid peptides and phosphorylase of tyrosine hydroxylase in bovine adrenal chromaffin cells. On the other hand, the histamine H_2 receptor is associated with accumulation of cyclic AMP in these cells.

In this study, the effect of stimulation of the histamine receptor on Ca^{2+} mobilization in cultured bovine adrenal chromaffin cells was examined. Histamine (10^{-5}M) increased $[Ca^{2+}]_i$ to a peak in the presence or absence of extracellular Ca^{2+}, followed by decrease with time. Histamine (10^{-8} - 10^{-5}M) also stimulated $^{45}Ca^{2+}$ efflux from cultured bovine adrenal chromaffin cells in a concentration dependent manner. Its stimulatory effect on $^{45}Ca^{2+}$ efflux was inhibited by the specific histamine H_1 receptor antagonist mepyramine. The increase in histamine-stimulated $^{45}Ca^{2+}$ efflux was inhibited by deprivation of extracellular Na^+ and by the Na^+/Ca^{2+} exchange inhibitor amiloride. In addition, histamine stimulated $^{22}Na^+$ influx into the cells, and this action was inhibited by amiloride.

These results suggest that stimulation of the histamine H_1 receptor induces extracellular Na^+-dependent Ca^{2+} efflux from cultured bovine adrenal chromaffin cells, probably acceleration of Na^+/Ca^{2+} exchange.

DETERMINATION OF AGONIST OR ANTAGONIST ACTIVITY AT THE MELATONIN RECEPTOR BY AN AFFINITY SHIFT METHOD. A. M. Lovelace, R. F. Bruns*. Eli Lilly and Company, Indianapolis, IN 46285.

Receptors exist in resting and activated conformations. Agonists bind preferentially to the activated state. In the present study, we investigated whether this phenomenon can be used to distinguish agonists from antagonists at the melatonin receptor. Binding of [125I]2-iodomelatonin to chicken brain membranes was measured in the presence of 10 mM $MgCl_2$ (activated state) and 1mM EDTA, 100 μM GTP, and 150 mM NaCl (resting state). The Ki of melatonin under activated conditions was 0.22 nM and under resting conditions was 1.70 nM, a 7.04 fold shift in affinity. In contrast, the antagonist luzindole had an activated state Ki of 0.79 nM and a resting state Ki of 0.80 nM, a shift of 1.01 fold. This confirms that the affinity shift method can distinguish melatonin receptor agonists from antagonists.

THE SYNAPTIC VESICLE GLUTAMATE UPTAKE SYSTEM: RECONSTITUTION WITH ATPASE AND A PARTIALLY PURIFIED GLUTAMATE TRANSLOCATOR. S. M. Lewis*† and T. Ueda†‡. Mental Health Research Institute†, the Departments of Pharmacology and Psychiatry‡, Medical School, University of Michigan, Ann Arbor, MI 48109.

The synaptic vesicle glutamate uptake system has been proposed to play an important role in directing glutamate to the neurotransmitter pathway, away from the metabolic pathway, and has been extensively characterized. Glutamate uptake by synaptic vesicles requires both proton-pump ATPase and glutamate transport activity. The goal of this study is the separation of these two functional components. A fraction rich in ATPase activity, but poor in ATP-dependent glutamate uptake, was obtained by subjecting synaptic vesicles to CHAPS extraction. A fraction with minimal ATPase activity, exhibiting little or no ATP-dependent glutamate uptake activity, was prepared by extracting synaptic vesicles with cholate, followed by glycerol density gradient centrifugation (this fraction was distinct from the major ATPase peak). When these two solubilized fractions were combined into proteoliposomes, significant ATP-dependent glutamate uptake was observed. This suggests that the second fraction contains a partially purified glutamate transporter, largely free of ATPase. This represents the first evidence for the physical separation of the puntative glutamate translocator from the ATPase. This work was supported by NIH grants NS 26884, 1 F32 NS09737-01, and 5-T32-MH15794.

SH-GROUPS OF CYSTEINE RESIDUES ON GLUTAMATE TRANSPORTERS ARE CRITICAL FOR UPTAKE ACTIVITY. D.Trotti, N.C.Danbolt*, D.Rossi, G.Racagni, O.Gjesdal*, J. Storm-Mathisen** and A.Volterra. Ctr. of Neuropharmacol., Inst. Pharm. Sci., Univ. of Milano, Italy 20133 and *Dept. Anatomy, Univ. of Oslo, Norway P.O.Box 1105.

L-glutamate is the major excitatory transmitter in brain and its transport represents the mechanism by which it is removed from the synaptic cleft and kept below toxic levels. So far, three different glutamate transporters (glu-tps) from rat brain have been cloned: GLT1, GLAST (glial origin) and EAAC1 (neuronal). In this study, we address the possibility that SH-groups of cysteine residues on glu-tps are critical and regulate their uptake activity. We have tested the effect of $HgCl_2$ 0.1-10 μM, a specific SH reagent, on transport activity by (1) a purified to homogeneity rat brain glu-tp (found to be GLT1) and (2) EAAC1, GLAST, GLT1 clones expressed in HeLa cells. Purified or recombinant proteins were functionally reconstituted in artificial liposomes as described (Biochemistry 29:6734-40,1990; Nature 360:464-7,1992). In the purified preparation, $HgCl_2$ decreased transport activity within 1 min in a dose dependent manner with ~40% of inhibition at 10 μM. The inhibition remained following gel-filtration which removes not reacted Hg^{++}. However transport activity could be fully restored by addition of DTT 3mM, a specific disulphide reducing agent. Kinetic uptake parameters were evaluated after exposure to $HgCl_2$ and gel-filtration. Km was not affected, while Vmax was reduced suggesting a non-competitive mode of inhibition. Hg^{++} was found to inhibit also all three the recombinant transporter subtypes, with highest efficacy against GLT1. Parachloromercuribenzoic acid (pCMB 1-100 μM), another SH-reagent also dose dependently inhibit uptake activity mediated by the purified and reconstituted glu-tp. Our data indicate that a modification of SH groups on cysteine residues of glu-tps strongly affects uptake function.

730.3

MOLECULAR CHARACTERIZATION AND DEVELOPMENTAL EXPRESSION OF A MURINE HIGH-AFFINITY GLUTAMATE TRANSPORTER. M.L. Sutherland[a,b]*, T.A. Delaney[b], J.L. Noebels[a,b]. [a]Division of Neuroscience and [b]Department of Neurology, Developmental Neurogenetics Laboratory, Baylor College of Medicine, Houston TX 77030.

Glutamate is the major excitatory neurotransmitter of the mammalian central nervous system (CNS) acting as a ligand for glutamate metabotropic, AMPA/KA and NMDA receptor subtypes. Transport through high-affinity, Na^+-dependent uptake proteins located in the plasma membrane of presynaptic terminals and surrounding glial cells is the mechanism that maintains glutamate below neurotoxic levels in the synaptic cleft. Through Rt-PCR we have cloned the mouse glutamate transporter (mEAAT2) and demonstrated CNS-specific transcript expression though PCR and southern blot analysis. High-affinity transport of D-aspartate, K_m value (17 $\mu M \pm 5$) was determined in a vaccinia/T7 RNA polymerase expression system. The predicted amino acid sequence of mEAAT2 shares 93 and 96% identity with the human EAAT2 and rat GLT1 homologues, respectively. RFLP analysis and C57BL/6J X *M. Spretus* backcross DNA hybrid panel screening localizes the mEAAT2 gene to mouse chromosome 2, in the vicinity of the recessive neurological mouse mutant, *anx*.

In situ hybridization analysis indicates that the expression of the mEAAT2 transcript during embyrogenesis is CNS-specific and localized to the E15, E17 and E19 day telencephalon, hindbrain and spinal cord. During postnatal development the mEAAT2 transcript is expressed in astrocytes throughout the neuroaxis and in neurons of the cortical subplate and pyramidal cell layer of the hippocampus. At the single cell level, the signal for mEAAT2 mRNA is found not only over cell bodies but also in dendritic, Bergman glia and astrocytic processes. The mEAAT2 mRNA *in situ* distribution provides a clear demonstration that this transporter has both a neuronal and glial localization.

MODULATION OF GLUTAMATE TRANSPORTER PROTEINS IN AMYGDALA-KINDLED ANIMALS. H.K. Prince Miller*, J.D. Rothstein, P.J. Conn and A.I. Levey. Departments of Neurology and Pharmacology, Emory University, Atlanta, GA 30322 and Department of Neurology, The Johns Hopkins University, Baltimore, MD 21205.

There has been increasing evidence for elevated levels of glutamate in brain regions thought to play a role in the induction and propagation of seizures. Theoretically, this phenomenon could be mediated by modulation of high-affinity uptake systems for glutamate. To date, three distinct glutamate transporters have been cloned: GLT-1, GLAST and EAAC-1. Immunocytochemistry studies have shown that GLT-1 and GLAST are localized to glia, whereas EAAC-1 is localized to neurons. We investigated whether there were changes in the levels of these transporters in rats that had undergone kindling-induced epilepsy by stimulation of the amygdala. Levels of GLT-1, GLAST and EAAC-1 were examined in three brain regions (hippocampus, piriform cortex/amygdala and limbic forebrain) by quantitative immunoblotting using subtype specific antibodies. Immunoblotting revealed a 60% decrease in GLAST protein in the piriform cortex/amygdala region 24 hours after the last seizure. No changes in GLAST were observed in the other regions that were examined. EAAC-1 levels were found to be increased to 130% of control in the hippocampus, with no changes in the other regions examined. No changes in GLT-1 were observed in any region examined. Future studies will be aimed at determining whether these changes result in any functional consequence to the levels of extracellular glutamate. *HKPM is the recipient of a PhRMA F predoctoral award.*

POSTSYNAPTIC UPTAKE OF EXCITATORY AMINO ACIDS IN RAT CEREBELLAR PURKINJE CELLS. [1]Y. Kataoka, [1]H. Ohmori and [2]K. Kataoka*. [1]Dept. of Physiology, Kyoto Univ., Kyoto, Kyoto 606-01 and [2]Dept. of Physiology, Ehime Univ. Sch. of Med., Shigenobu, Ehime 791-02.

Postsynaptic activities of released excitatory amino acids (EAAs) are known to be terminated by uptake mechanisms into presynaptic neurons and glial cells. The existence of postsynaptic uptake system of EAAs has not been confirmed. We found a current component which was induced by EAAs (L-glutamate, L-aspartate and L-homocysteate) and was not suppressed by the antagonist for NMDA receptors (200 μM APV) and by the antagonist for non-NMDA receptors (20 μM CNQX) in rat cerebellar Purkinje cells with the whole cell patch recording technique. We call this current as the APV & CNQX resistant current. Dose dependencies of three amino acids for inducing this current had dissociation constants from 15.7 μM to 25.0 μM. The induction of this current did not increase current noise, and was suppressed by a removal of Na^+ from extracellular medium or by an application of the inhibitor for high affinity glutamate transporters (D-threo-β-hydroxyaspartate). The APV & CNQX resistant current was induced all over the subcellular regions studied by ionophoretic application of EAAs including dendrites and cell somata. These observations indicate that the APV & CNQX resistant current is likely induced by the Na^+ dependent high affinity uptake mechanism of EAAs in postsynaptic Purkinje cells.

GLUTAMATE UPTAKE INHIBITORS: DIFFERENTIATION OF SUBSTRATES AND NON-SUBSTRATES. H. Koch*, F. Lovering+, S. Esslinger+, A.R. Chamberlin+, and R.J. Bridges. Dept of Pharm. Sci., Univ. of Montana, Missoula MT 59812, Dept. of Chem.+, Univ. of Calif., Irvine CA 92717.

High-affinity, sodium-dependent glutamate transport plays a key role in the regulation of extracellular glutamate and the prevention of excitotoxic damage. During the course of delineating transporter pharmacology, we identified several conformationally constrained analogues of glutamate that potently block the uptake of ^{3}H-D-asparatate into rat cortical synaptosomes, *e.g.*, L-*trans*-2,4-pyrrolidine dicarboxylate (L-*trans*-2,4-PDC), L-*anti-endo*-3,4-methano-pyrrolidine dicarboxylate (L-*anti-endo*-3,4-MPDC) and *meso*-3,4-MPDC. A key question that remains to be answered is whether or not these novel inhibitors are also substrates that can be translocated into the synaptosomes. While all competitive blockers would be expected to bind to the transporter, it is likely that inhibitors can be further subdivided between substrates and non-substrates. In lieu of preparing radiolabeled derivatives, we have addressed this issue by quantifiyng the ability of the analogues to participate in the process of heteroexchange. Compounds that act as substrates stimulate the rate of exodus of ^{3}H-D-asparatate previously loaded into the synaptosomes. Using this approach we find that while each of the three structurally constrained PDC analogues exhibited similar abilities to block uptake (Ki values 1-6 μM), the compounds varied significantly in their ability to serve as substrates. The observed rank order of exchange with ^{3}H-D-asparatate was *meso*-3,4-MPDC>L-*trans*-2,4-PDC>L-*anti-endo*-3,4-MPDC, with rates comparable to about 90, 75, and 40% of that produced by L-glutamate, respectively. Knowledge of an uptake inhibitor's ability to serve as a substrate is a key factor in interpreting its actions in physiological investigations. Modeling studies have been initiated to delineate the chemical basis that differentiates transportable and non-transportable inhibitors. This work was supported in part by NIH/NINDS NS 30570 and NS 27600.

INHIBITION OF HIGH AFFINITY GLUTAMATE UPTAKE BY AMINO ACID CARBAMATES. R.J. Bridges*, C.A. Baker, and P.B. Nunn+. Dept. of Pharm. Sci., Univ. Montana, Missoula, MT, 59812 and Biomed. Sci. Div. +, King's College London, England.

A number of amino acids have been identified that are capable of interacting with CO_2 and forming carbamates that induce excitotoxic neuronal injury, *e.g.*, β-N-methylamino-L-alanine (BMAA) and α,β-diaminopropionic acid (DAP). Although the parent amino acids bear little resemblance to glutamate, the resulting carbamate can closely resemble the dicarboxylic amino acid character shared by most EAA agonists. In the present study a number of these potentially neurotoxic amino acids were tested to determine if their resulting carbamates could also inhibit high-affinity, sodium-dependent glutamate transport. Amino acids were assayed, in the presence and absence of $NaHCO_3$ (20 mM), as blockers of the uptake of ^{3}H-D-aspartate into rat forebrain synaptosomes. Compounds found to be inactive as inhibitors, either by themselves or as carbamates, included D- and L-cysteine, D- and L-serine, D- and L-α,γ-diaminobutyric acid (DAB), and BMAA. In contrast, we found that L-DAP was a potent inhibitor when added with $NaHCO_3$, and that the extent of the inhibition was significantly reduced in the absence of $NaHCO_3$. This activity was stereoselective, as L-DAP was considerably more potent as an inhibitor than D-DAP. Kinetic plots yielded patterns consistent with a competitive inhibitor (Ki ≈ 5 μM). Further, preliminary studies demonstrated that the L-DAP carbamate could undergo heteroexchange with ^{3}H-D-aspartate preloaded into synaptosomes, suggesting that it was not only an inhibitor, but also a substrate. While the CO_2 may interact with either amino group on L-DAP, molecular modeling studies indicated that the β-carbamate is the likely active inhibitor. These results suggest that the neurotoxic action of DAP, but not BMAA, may include the action of its carbamate not only at EAA receptors, but also at the high-affinity glutamate transporters. This work was supported in part by NIH/NINDS NS30570.

CALCIUM-INDEPENDENT EXTRACELLULAR ALKALINE SHIFTS EVOKED BY GLUTAMATE. S.E. Smith* and M. Chesler Depts.Physiol./Neurosurg. NYU Med. Ctr., 550 1st Ave., NY, NY 10016.

Extracellular alkaline shifts evoked by glutamate (GLU) receptors are generated by a Ca^{2+}-dependent mechanism [1, 2]. We tested whether other alkalinizing processes are unveiled with zero Ca^{2+} (EGTA) media. Alkaline shifts were evoked in hippocampal slices (CA1) by pressure ejection of agonists near a pH microelectrode. In zero Ca^{2+}, GLU, AMPA and NMDA caused no alkaline shift, or a small acidification. Slowing buffer kinetics with the carbonic anhydrase inhibitor benzolamide (10 μM) uncovered a slow alkalinization evoked by GLU (0.03 ± .01 pH units, n=5 slices) but not by AMPA, NMDA or the metabotropic agonist trans-ACPD. A similar Ca^{2+}-independent alkaline shift was noted following ejection of L-trans-2,4-PDC (0.05 ± .01 pH units n=6), a GLU uptake inhibitor transported by the GLU carrier. Both GLU and L-trans-2,4-PDC-evoked alkaline shifts persisted in the presence of APV (50 μM) and CNQX (≤ 100 μM). These observations are consistent with efflux of base by the GLU transporter [3]. Since detection of the Ca^{2+}-independent mechanism required greatly diminished buffering, its contribution to bulk extracellular alkalinization is normally minimal. Supported by NIH grant NS32123. [1] Paalasmaa et al. (1994) *J. Neurophys.* 72(4):2031. [2] Smith et al. (1994) *NeuroReport* 5:2441. [3] Bouvier et al. (1992) *Nature* 360:471.

730.9

EXPRESSION OF NEURONAL AND GLIAL GLUTAMATE TRANSPORTERS IN THE RAT OPTIC NERVE. I. Choi, S. Y. Chiu* and J. D. Rothstein. Dept. of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706; Johns Hopkins Univ., Dept. of Neurology, Baltimore, MD 21287.

The rat optic nerve consists only of axons and glia, and are devoid of classical synapses. Recent studies, however, revealed dynamic axon-glial signaling in this nerve postulated to be mediated by non-vesicular release of glutamate (Kriegler & Chiu, 1993). One release mechanism for glutamate in the optic nerve is reversal of high-affinity glutamate transporters. Here we examined the expression of two glial glutamate transporters (GLAST and GLT) and one neuronal transporter (EAAC1) in the rat optic nerve. RT-PCR analysis revealed the presence of mRNAs for GLT and GLAST, but not EAAC1, in rat optic nerves. RNase protection assays were used to quantify the mRNA expression using a housekeeping gene, GAPDH, to control for RNA loading. Of the two glial transporters, mRNA for GLAST is expressed about 20 times higher than GLT, both in developing and in adult rat optic nerves. GLAST mRNA level in the optic nerve is about 2-fold higher than in cortex (grey matter). Intriguingly, optic nerve expresses slightly higher level of GLAST mRNA than cerebellum, a brain region previously shown to express the the highest level of GLAST. Developmentally, GLAST mRNA level in the rat optic nerve is highest at P2, and drops slightly by adult. Nerve transection results in little or no changes in mRNA levels for GLAST and GLT at 4-6 days post-transection. Western blot analysis performed on rat optic using peptide specific antibodies raised against GLT, GLAST and EAAC1 reveals major bands of 72, 70, and 70 kDa respectively. Light-level immunocytochemistry shows that GLT and GLAST stain glial processes, EAAC1 stains axons. In conclusion, we suggest that these glial and neuronal transporters mediate neurotransmitter signaling in the optic nerve, by modulating glutamate level in the periaxonal space during nerve activity. In particular, the unusually high level of expression of GLAST in the optic nerve suggests novel roles for this glial transporter in the optic nerve.

EFFECTS OF NATRIURETIC PEPTIDES ON SODIUM TRANSPORT AND GLUTAMATE UPTAKE IN RAT BRAIN ASTROCYTES. C.F. Deschepper*, S. Picard, K.L. Grove, E.L. Schiffrin and R. Touyz, IRCM, Montréal, Canada H2W 1R7

Natriuretic peptides (NP) in the brain have been shown to control a variety of neuronal functions. The actions of these peptides are generally believed to be mediated via the intracellular generation of cGMP. Since astrocytes appear to be the only brain cells generating cGMP in response to NP, we investigated the effects of C-type NP (CNP) and/or cGMP on secondary cultures of rat brain type-1 astrocytes. We observed that CNP 10^{-6} M diminished intracellular free sodium (as determined by fluorescence of SBFI) in astrocytes. Conversely, intracellular pH (as determined by fluorescence of BCECF) was decreased in a dose-dependent fashion by exposure to CNP. Both effects were mimicked by membrane-permeant analogs of cGMP, and were most likely to be carried out by the Na^+-H^+ antiporter, since they were blocked by pre-incubation of the cells with the specific inhibitor 5-N,N-(hexamethylene)-amiloride (HMA). In contrast, CNP and/or cGMP analogs had no effects on Na^+-K^+-ATPase function nor on Na^+-K^+-$2Cl^-$ transport. We also found that both CNP 10^{-6} M and 8-bromo cGMP 10^{-3} M diminished the uptake of [^{3}H]-glutamate by lowering the V_{max} but without affecting the K_m of this transport. This effect could be explained partially by inhibition of the Na^+-H^+ antiporter, since HMA had a similar effect. However, glutamate uptake could be decreased even further by CNP in HMA-pretreated cells, indicating that this peptide could affect glutamate uptake by an additional mechanism independent of Na^+-H^+ exchange. Activation of protein kinase G (PKG) is the most likely mechanism, since the effect of CNP was blocked by KT5823, a specific PKG inhibitor. The effects of NP on Na^+-H^+ exchange and glutamate uptake in astrocytes may constitute mechanisms by which these cells could enhance the actions of glutamate on neighboring neurons. EPSC SHAPING, AND GLUTAMATE RELEASE IN ISCHAEMIA, BY GLUTAMATE UPTAKE CARRIERS Michiko Takahashi, Brian Billups, Monique Sarantis and David Attwell*. Dept. of Physiology, University College London, Gower St., London, WC1E 6BT, England.

Glutamate uptake is often thought of as being presynaptic or in glial cells, but immunostaining suggests that rat cerebellar Purkinje cells express EAAC1 carriers (Neuron 13, 713). By applying glutamate analogues iontophoretically to Purkinje cells in cerebellar slices, we detected a membrane current component attributable to glutamate uptake. To investigate the role of this postsynaptic uptake, currents evoked by climbing fibre stimulation were recorded. By altering intracellular ions via the patch pipette, we examined shaping of the EPSC by glutamate uptake. Inhibiting uptake by removing pipette Cs^+ (countertransported by the uptake carrier) or adding D-aspartate to the pipette slowed the EPSC decay. These data suggest that removal of glutamate from the synaptic cleft by postsynaptic glutamate uptake can shape the EPSC.

In brain ischaemia $[K^+]_o$ rises, making the uptake carrier reverse. We monitored reversed uptake from salamander retinal glia electrically, and by detecting Glu^- release from the opening of AMPA receptor channels in rat Purkinje cell bodies positioned near the glia. Acidifying the external solution, as also occurs in ischaemia, decreased both the reversed uptake current, and the release of glutamate produced by glial depolarisation in raised $[K^+]_o$. These data suggest that the acidification occurring in ischaemia could slow the release of glutamate occurring by reversed uptake, and thus protect neurons against transient (but not sustained) ischaemia.

COMPARISON OF GLUTAMATE TRANSPORTER GLT-1 mRNAs IN BRAIN AND PERIPHERAL TISSUES. Y. Kanai*, N. Tate, H. Endou. Dept. of Pharmacology and Toxicology, Kyorin Univ. Sch. of Med., 6-20-2 Shinkawa, Mitaka, Tokyo 181, Japan.

Glutamate transporters play central roles to keep extracellular glutamate concentration below neurotoxic level in the central nervous system. In peripheral tissues, glutamate transporters are also important to absorb glutamate from intestine and kidney epithelia and to provide cells with glutamate for nutritional purpose. In this study, we show that glutamate transporter GLT-1 which is expressed in astrocytes in brain is also expressed in peripheral tissues such as liver and testis in mice. In contrast to 11.3kb mRNA in brain, liver and testis express 2.2 kb mRNA. We have isolated four GLT-1 cDNAs from random primed mouse brain cDNA library and five GLT-1 cDNAs from oligo dT primed mouse liver cDNA library. Mouse brain GLT-1 shows 98% amino acid sequence identity to rat brain GLT-1 and has the identical N-terminus. Liver type GLT-1, however, exhibits difference in its predicted N-terminus amino acid sequence compared to brain GLT-1. When expressed in *Xenopus laevis* oocytes, both brain and liver GLT-1s induce Na^+-dependent L-glutamate uptake. Liver GLT-1 mRNA uses polyadenylation sites close to the stop codon for polyA tail addition. Brain and liver GLT-1 cDNAs have different 5'-untranslated regions. This suggests that GLT-1 mRNA is alternatively spliced at the 5'-ends and that brain and peripheral tissues possess different mechanisms for the regulation of expression of GLT-1 gene.

730.13

DIFFERENTIAL EXPRESSION OF THE GLUTAMATE TRANSPORTER SUBTYPES DURING MOUSE BRAIN DEVELOPMENT. Takashi Shibata, Masahiko Watanabe, Kohichi Tanaka and Yoshiro Inoue*. Dept. of Anatomy, Hokkaido Univ. Sch. of Med., Sapporo 060, and Dept. of Degenerative Neurological Diseases, National Inst. of Neuroscience, NCNP, Tokyo 187, Japan.

The glutamate transporter terminates physiological action of excitatory amino acid glutamate in the synapse. In the present study, *in situ* hybridization was employed to clarify developmental regulation of three glutamate transporter subtypes (GluT1 (GLAST), GLT1, and EAAC1) in the mouse brain from embryonic day 13 to postnatal day 120. The GluT1 mRNA was prominently expressed in the ventricular (proliferative) zone throughout the brain during embryonic stages. In the late embryonic and early postnatal development, the expression in the ventricular zone gradually diminished and disappeared, while that in the mantle zone increased progressively. In particular, the expression increase was outstanding in the superficial layer of the cerebellum (Bergmann glial cells). The GLT1 mRNA was also expressed in the ventricular zone, but its expression was virtually restricted to the telencephalon at perinatal stages. During the second postnatal week, the expression levels were augmented prominently in the telencephalon, including the cerebral cortex, hippocampal CA3, and septum. In contrast, the EAAC1 mRNA in the ventricular zone was below the detection threshold at any developmental stages. According to postnatal maturation, signals for the EAAC1 mRNA increased gradually over the brain gray matter, with higher levels in the hippocampal CA1 region and dentate gyrus. These findings suggest that the glutamate transporter may play an important role in early differentiation of the brain, in which the transporter subtypes would be involved differentially.

730.14

GLIAL SWELLING BY AP3 AND GLUTAMATE TRANSPORT INHIBITORS IN THE RETINA C.O. Kirby-Sharkey, Y. Izumi*, S. Mennerick, Ann M. Benz, J. Labruyere, C.F. Zorumski, M.T.Price & J.W.Olney
Dept. of Psychiatry, Washington Univ., School of Med., St.Louis, MO 63110.

Using rat retinal preparations, we observed a characteristic glial swelling induced by amino-3-phosponopropionate (AP3). Although AP3 has been widely used as an inhibitor of metabotropic glutamate receptors (mGluRs), AP3 is also known to have properties of mGluR agonists. Thus, we examined whether the effects of AP3 were through the modulation of mGluRs. However, alpha-methyl-4-carboxyphenylglycine (MCPG), a selective competitive antagonist of mGluRs, 1S3R-ACPD, DHPG or L-CCG-I, agonists of mGluRs, did not produce glial swelling. Moreover, the effects of AP3 were not prevented by the administration of MCPG or 8-bromo-cAMP. These results suggest that the modulation of mGluR, activation or inhibition, was not likely responsible for the glial swelling. Furthermore, the glial swelling by AP3 was not prevented by DNQX and MK-801, antagonists of non-NMDA and NMDA ionotropic receptors.

The glial swelling by AP3 was attenuated by replacement of extracellular Na^{++} but not Cl^-, and was mimicked by D,L-threo-3-hydroxyaspartate (THA), L-trans-pyrrolidine-2,4-dicarboxylic acid (PDC), glutamate transport inhibitors. Moreover, AP3 produced a Na^{++} inward current in hippocampal glial cells that was occluded by THA. Like THA, AP3 also prolonged glutamate-mediated synaptic currents in hippocampal neurons suggesting that AP3 inhibits glutamate uptake. These results suggest that AP3 induces glial swelling in the retina by serving as a substrate for glutamate transporters. Taken together, AP3 may be a useful substrate to elucidate the mechanism of glial swelling, which is also produced by glutamate but is not prevented by DNQX, MK-801 or MCPG.

FUNCTIONAL CHARACTERIZATION AND LOCALIZATION OF A HUMAN EXCITATORY AMINO ACID TRANSPORTER WITH PROPERTIES OF A LIGAND-GATED CHLORIDE CHANNEL. W.A. Fairman, R.J. Vandenberg, J.L. Arriza, E.M. Shannon, G.H. Murdoch*, M.P. Kavanaugh, & S.G. Amara Howard Hughes Medical Institute and Vollum Institute, Oregon Health Sciences University, Portland, Oregon 97201.

The reuptake of excitatory amino acids (EAA's) plays an important role in regulating synaptic and extracellular concentrations of glutamate. The functional properties of a novel member of the glutamate transporter gene family, EAAT4, were examined in *Xenopus* oocytes. Application of L-aspartate or L-glutamate to EAAT4 expressing oocytes generated an inward current at hyperpolarized potentials and an outward current at depolarized potentials. In contrast to other members of this gene family, the EAA-induced current in EAAT4 expressing oocytes had a linear voltage dependence and reversed near the chloride equilibrium potential. This EAA-elicited current is not solely due to the movement of cotransported ions, but also appears to reflect a ligand-activated chloride conductance associated with the carrier. The reversal potential of the L-aspartate-induced chloride conductance shifted 57 ± 1.5 mV per ten fold change in $[Cl^-]_o$, approaching the Nernst prediction for a chloride selective conductance. Both the EAA-induced chloride conductance and the radiolabeled amino acid flux are sodium-dependent, but flux does not appear to depend on extracellular chloride. Comparison of the current and radiolabeled flux observed under voltage clamp conditions suggest that the chloride conductance represents greater than 95% of the L-aspartate induced current at -60mV. Additional studies demonstrate that EAAT4 does not appear to activate any known endogenous chloride channels in oocytes. Northern blotting analysis indicates that EAAT4 is most abundant in the cerebellum, with *in situ* hybridization studies indicating that this carrier prominently expressed in Purkinje cells. The chloride conductance associated with EAAT4 is activated by micromolar concentrations of L-glutamate and L-aspartate at physiologically relevant membrane potentials. Thus, EAAT4's dual properties as a ligand-gated chloride channel as well as a transporter could regulate neuronal excitability and serve as a monitor of extracellular EAA levels.

730.16

TOPOLOGICAL STUDIES OF THE SODIUM-DEPENDENT GLUTAMATE TRANSPORTER FAMILY [1,2]R.P. Seal, [2]J.L. Arriza and [2,3]S.G. Amara*
[1]Program in Neuroscience, [2]Vollum Institute and [3]Howard Hughes Medical Institute, Oregon Health Science Univ., Portland OR. 97201

In contrast to several other transporter families which appear to contain twelve α-helical transmembrane (TM) segments, the precise number and orientation of TM domains in the sodium-dependent glutamate carriers remains unclear. Hydropathy analyses of four human glutamate transporters, EAATs1-4, suggests the presence of six to ten α-helical TM domains. To resolve this apparent ambiguity, the membrane topology of the glutamate carriers was investigated by multiple strategies. A FLAG epitope was introduced into the EAAT1 subtype in several domains. The membrane orientation of the epitope for each FLAG-tagged construct was determined by transfecting mammalian cells and carrying out immunofluorescence under permeabilized and non-permeabilized conditions, as well as by assessing protease sensitivity of the epitope in a microsomal membrane-coupled translation system. To examine whether putative TM segments span the membrane, a series of C-terminal truncations of EAAT1 were made following putative TM segments and each deletion was linked to a prolactin reporter epitope. These constructs were expressed in the *in vitro* system and examined for protease sensitivity of the prolactin reporter as a determinant of membrane orientation. The results of these experiments support a model in which both the N- and C-termini are intracellular, the loop between TM domains three and four is extracellular and the first six hydrophobic segments span the membrane, most likely as α-helices. Studies of the last four putative TM segments (7-10) suggests that they are membrane associated, but may not span the membrane as α-helices. Further investigation into the topology of this region is currently underway.

Isolation and Characterization of Mouse Excitatory Amino Acid Transporter(EAAT) Genes Marc A. Kirschner[1,2], and Susan G. Amara[2,3], Oregon Health Sciences University, Portland, Oregon 97201. Department of Neurology[1], the Vollum Institute for Advanced Biomedical Research[2] and the Howard Hughes Medical Institute[3].

A family of four distinct high-affinity sodium-dependent excitatory amino acid transporter cDNAs has been isolated from mouse. These reuptake carriers may modulate neurotransmitter concentrations at the excitatory glutamatergic synapses of the mammalian central nervous system. Mouse EAAT subtypes were isolated from a λzap cDNA library with PCR-generated probes. PCR reactions were performed on mouse cerebellum cDNA with degenerate oligonucleotide primers homologous to highly conserved regions of human and rat EAAT cDNAs. The mouse EAATs show similarity to subtypes identified in other species. Functional expression of specific subtypes demonstrates apparent affinity constants(K_t's) in the 40 to 60 μM range--values comparable to those obtained for corresponding subtypes isolated from other species. Each transporter is prominently expressed in the CNS. EAAT2 and EAAT4 transcripts are principally found in the CNS. However, EAAT3 is highly expressed in kidney whereas EAAT1 is expressed in lung and skeletal muscle outside the CNS.

EAAT genes have been mapped in mouse and human genomes and subtypes have been found to lie on syntenic chromosome regions. Neuroexcitability loci that may have a role in mouse models of epilepsy have been found near *Eaat2*. *Eaat2* is also located in the vicinity of two mouse recessive disorder loci, fidget(*fi*) and anorexia (*anx*).

We have also isolated and characterized 4 distinct EAAT genomic clones from a λDASH library using full length cDNAs as probes. These range in size from 14 to 18 kb. Further study of EAATs will elucidate their role in mammalian development and may provide models of neurological disease.

DIHYDROKAINATE (DHK) BLOCKS L-*TRANS*-PYRROLIDINE-2,4-DICARBOXYLIC ACID (PDC) NEUROTOXICITY AND ^{45}CALCIUM INFLUX IN ASTROCYTE-RICH CORTICAL CULTURES. R.C. Blitzblau, X. Gan*, and P.A. Rosenberg. Dept. of Neurol., Children's Hospital & Harvard Medical School, Boston MA 02115.

PDC is a potent inhibitor of high affinity glutamate uptake (Bridges et al. *J.Med.Chem.* 34: 717-725). Transportable inhibitors of high affinity glutamate uptake such as PDC, DL-threo-β-hydroxyaspartate, and 1-aminocyclobutane-*trans*-1,3-dicarboxylic acid have been shown to be neurotoxic by an NMDA-receptor mediated mechanism that seems to involve reversal of glutamate transport (Blitzblau et al. *Soc.Neurosci.Abstr.* 20: 274). In contrast, the non-transportable inhibitor dihydrokainate (DHK), in concentrations up to 1 mM, had no neurotoxicity in cortical cultures. In these experiments we sought to further test the hypothesis that the toxicity of PDC was mediated by an effect on glutamate transport, by testing whether the toxicity of of the transportable, toxic, uptake inhibitor PDC could be blocked by the non-transportable, non-toxic, uptake inhibitor DHK. We found that 1 mM DHK significantly reduced the toxicity of 1 mM PDC. Survival of neurons in the presence of PDC was increased from 29 ± 9 % to 87 ± 5 % ($n = 3$; $p < .05$). NMDA-receptor activation stimulates the influx of ^{45}Ca in cortical cultures. Exposure of cortical cultures to PDC stimulated ^{45}Ca influx, whereas exposure of cortical cultures to DHK had no effect on ^{45}Ca influx. DHK at 1 mM reduced the influx of ^{45}Ca into cortical cultures exposed to 1 mM PDC to control levels ($n = 2$), supporting the results obtained in the neurotoxicity paradigm.

This work was funded by grants from the NINDS (NS31353) and from the United Cerebral Palsy Foundation.

MOLECULAR KNOCKOUT OF NEURONAL, BUT NOT GLIAL, GLUTAMATE TRANSPORT PRODUCES EPILEPSY.

M Dykes-Hoberg[1]*, LA Bristol[1], Y Wang[2], G Schielke[2], D Welty[2], and JD Rothstein[1]. [1]Johns Hopkins Univ, Dept. of Neurology, Baltimore, MD 21287, and [2]Parke-Davis, Ann Arbor, MI.

Glutamate transport is believed to be essential for the inactivation of synaptically released glutamate. Three glutamate transporters have been cloned; EAAC1 is specific for neurons, while GLT-1 and GLAST have an astroglial localization. Both EAAC1 and GLT-1 have the highest brain expression in the hippocampus. To understand the relative role of each transporter in glutamate neurotransmission, antisense oligonucleotides (ODN) were used to selectively inhibit the synthesis of individual transporter subtypes. Antisense ODN were administered intraventricularly over a 7 day period by mini-osmotic pumps (1μL/hr; 10nmoles/day). Hippocampal EAAC1, GLT-1, and GLAST protein levels were each decreased by more than 50% after one week of individual chronic antisense treatment, as determined by semi-quantitative immunoblot analysis. Functional glutamate transport was decreased in hippocampus by about 20% after EAAC1 antisense ODN, 50% after GLT-1antisense ODN, and 20% after GLAST ODN. Furthermore, sense ODN and random ODN (containing identical proportions of each nucleotide) for each transporter did not alter transporter protein levels, functional transport, or have behavioral effects. Preliminary microdialysis studies indicated that antisense knockout of glutamate transporter elevated extracellular glutamate levels. Behaviorally, after 3 days treatment, 4 out of 8 EAAC1 antisense treated animals developed hyper-irritability, and stimulus-evoked tonic seizures. By 7 days of treatment, 7 out of 8 EAAC1 antisense treated rats exhibited tonic, and occasionally tonic-clonic seizures. Only 2 out of 11 GLT-1 antisense treated rats developed tonic seizures and none of the 10 GLAST antisense treated rats developed seizures after 7 days of treatment. These studies suggest that dysfunction of *neuronal* glutamate transport, and to a small extent glial glutamate transport, contributes to glutamate induced seizures.

STRUCTURE AND FUNCTIONAL CHARACTERIZATION OF GLUTAMATE TRANSPORTER cDNAS AND GENES.

K. Tanaka[1]*, T. Hagiwara[1], Y. Mukainaka[1], T. Shibata[2], M. Watanabe[2] and K. Wada.[1] [1]Dept. of Degenerative Neurological Diseases, National Inst. of Neuroscience, Kodaira, Tokyo 187 ; [2]Dept. of Anatomy, Hokkaido Univ. Sch. of Med., Sapporo 060.

Glutamate is the major excitatory neurotransmitter in the central nervous system. Like many small neuroactive compounds, it is thought that the physiological action of glutamate is terminated by Na^+-dependent high affinity transport proteins that are found in the plasma membrane of both presynaptic nerve terminals and glial cells.

We have isolated mouse cDNAs and genes encoding three subtypes of glutamate transporters(two are of glial, one of neuronal origin). The amino acid sequences of the three transporters are very similar to each other, displaying ~50% identity and ~60% similarity. The pharmacological properties and the tissue distribution of the mouse three glutamate transporters are almost identical to those of glutamate transporters previously isolated from other species.

Genomic organization of the two subtypes of glial glutamate transporters shows closely related exon-intron arrangements(they contain 10 exons interrupted by 9 introns). On the other hand, the gene encoding the neuronal subtype of glutamate transporter is comprised of 12 exons.

The cloning and functional analyses of mouse three subtypes of glutamate transporter cDNAs and genes provide a basis for future research into the structure, function, pharmacology and the in vivo functional roles of glutamate transporters.

730.21

CHARACTERIZATION OF THE RELEASE OF DOPAMINE AND 1-METHYL-4-PHENYLPYRIDINIUM(MPP+) THROUGH THE RAT DOPAMINE TRANSPORTER EXPRESSED IN COS CELLS.

S. Kitayama*, K. Morita and T. Dohi. Dept. of Pharmacology, Hiroshima Univ. Sch. of Dentistry, Kasumi 1-2-3, Minami-ku, Hiroshima 734, JAPAN.

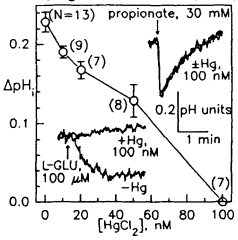
In addition to the principal role of neurotransmitter transporter in terminating synaptic transmission by reaccumulating released neurotransmitter, revasal of the transport process participates in the neurotransmitter release observed in a certain physiological condition while distinguishable from vesicular release. To explore physiological relevance of the transporter-mediated release in correlation to the action of psychostimulant such as cocaine or neurotoxin, we characterized the release of dopamine(DA) and the parkinsonism-inducing neurotoxin 1-methyl-4-phenylpyridinium(MPP^+) through the rat DA transporter expressed in COS cells. COS cells expressing the transporter revealed the ability to release the preloaded [^{3}H] DA and [^{3}H] MPP^+ in different degrees and time-course. Release of [^{3}H] DA was enhanced in the presence of extracellular DA, but not affected by cocaine or GBR-12935. On the other hand, release of [^{3}H] MPP^+ was enhanced by DA and MPP^+, while it was inhibited by cocaine, nomifensine and GBR-12935. These different properties between the transporter-mediated releases of DA and MPP^+ suggest the different mode of translocation / reorientation of the transporter for these substrates. This might be important for the re-distribution of substrates for the transporter, especially for the neurotoxic substance such as MPP^+.

730.22

GLUTAMATE UPTAKE IS UNCOUPLED FROM THE COUNTERTRANSPORT OF HYDROXYL EQUIVALENTS BY VERY LOW CONCENTRATIONS OF $HgCl_2$.

T. N. Nagaraja and N. Brookes*. Dept. of Pharmacol. & Exptl. Therap., Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Uptake of L-GLU acidifies astrocyte cytoplasm (Brookes & Turner, *Neurosci. Lett.* 160:73, 1993) consistent with OH^- countertransport (Bouvier et al., *Nature* 360:471, 1992). We examined the effect of $HgCl_2$ on intracellular pH (pH_i) using the fluorescent pH indicator BCECF in mouse cerebral astrocytes grown on glass coverslips. In HEPES/Tris-buffered solution (pH 7.4, 35°C; containing ~0.1 mM HCO_3^- derived from air), 100 nM $HgCl_2$ transiently acidified pH_i by 0.095±0.008 (SE, N=13), but did not affect the response of pH_i to acid loading with 30 mM propionate or to alkaline loading with 10 mM methylamine, indicating that buffering capacity and acid extrusion were unaffected. Alkalinization induced by 9 mM K^+ (Brookes & Turner, *Am. J. Physiol.* 267:C1633, 1994) was 52% inhibited ($p<0.001$) by 100 nM $HgCl_2$, but unaffected by 50 nM. Acidification induced by 100 μM L-GLU (ΔpH_i, see Fig.) was completely blocked by 100 nM $HgCl_2$, and partially blocked by [$HgCl_2$] as low as 10 nM ($p<0.05$). Yet, uptake of 100 μM [^{3}H]-L-GLU was not inhibited by 100 nM $HgCl_2$ (Brookes & Kristt, *J. Neurochem.* 53:1228, 1989; confirmed here). Possible interpretations are that, in the presence of very low [$HgCl_2$], the Na^+-L-GLU symport can countertransport Cl^- or $HgCl_3^-$, or is uncoupled from anion countertransport. (Supported by USPHS grant ES03928).



730.23

DOWN REGULATION OF GLIAL GLUTAMATE TRANSPORTERS FOLLOWING FIMBRIA-FORNIX (FF) TRANSECTIONS AND CORTICOSTRIATAL LESIONS.

JD Rothstein*[1], LJ Martin[2], and SD Ginsberg[2]. [1]Dept. of Neurology, and [2]Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21287.

High-affinity sodium-dependent glutamate transport is the primary means to maintain low extracellular glutamate levels. Three glutamate transporters have been cloned: EAAC1 is localized to neurons, while GLT-1 and GLAST are astroglial. The expression of glutamate transporter subtypes in rats was evaluated following: 1) unilateral FF transections to disrupt glutamatergic hippocampal/subicular efferents to the septum and hypothalamus, or 2) unilateral lesions of motor-sensory cortex to remove glutamatergic corticostriatal input. The hippocampus and striatum were collected from animals sacrificed at 3, 7, 14, and 30 days and tissue homogenates were 1) assayed for functional glutamate transport and 2) immunoblotted using GLT-1, GLAST, EAAC1, and GFAP, a marker for astrocytes. GLT-1 and GLAST immunoreactivity was significantly decreased in hippocampus ipsilateral to the FF transections at 7 and 14 days postlesion, and total hippocampal glutamate transport was decreased ipsilaterally by 50% at 7 and 14 days postlesion. GLT-1 and GLAST immunoreactivity was significantly decreased within the striatum ipsilateral to the cortical-callosal lesions at 7 and 14 days postlesion, and total striatal glutamate transport was decreased ipsilaterally by 60% at 7 and 14 days postlesion. By 30 days postlesion, glial glutamate transporter protein immunoreactivity and functional glutamate transport returned to control levels. The decrease in astrocytic glutamate transporters was associated with an increase, rather than a decrease, in GFAP immunoreactivity. No significant changes in EAAC1 immunoreactivity were observed at any of the postlesion time points. This study demonstrates that alterations in glial, rather than neuronal, glutamate transporters occur following axotomy of glutamatergic pathways. We hypothesize that glial glutamate transporters may play a dynamic role in plasticity associated with hippocampal and striatal disconnection.

730.24

LOCALIZATION AND CHARACTERIZATION OF HIGH AFFINITY GLUTAMATE TRANSPORTERS IN RAT RETINA.

T. Rauen* and K. Kuhlbrodt, Max-Planck-Institut für Hirnforschung, 60528 Frankfurt, Germany.

The major component of excitatory neurotransmission in the mammalian central nervous system is mediated by L-glutamate. Termination of such neuronal activity is achieved by sodium-dependent, high affinity uptake systems located in glial cell processes or in presynaptic nerve endings. To date, three related but distinct glutamate transporters have been cloned: GLT-1 and GLAST-1 from rat brain as well as EAAC-1 from rabbit intestine. The retina provides an excellent model system to investigate the cellular localization, function and molecular properties of these transporter molecules, because of its highly ordered anatomical organization, particularly with regard to the glutamatergic circuitry.

Reverse transcribed-polymerase chain reaction of rat retina mRNA, using specific primers for GLAST-1, GLT-1 and EAAC-1, revealed the presence of message for all three transporter subtypes in the retina. Immunocytochemistry indicated that Müller glial cells are exclusively reactive for GLAST-1, whereas GLT-1 is restricted to cone photoreceptors and a subpopulation of cone bipolar cells. Comparative immunoblots of retinal membrane proteins using polyclonal antibodies against GLAST-1 and GLT-1 revealed a significantly higher content of GLAST-1 transporter protein in retinal tissue. Additionally, accumulation of L-[^{3}H]glutamate occurs predominately in Müller glial cells.

These results suggest that Müller glial cells are responsible for the removal of most synaptically released glutamate in the retina, and that this uptake is mediated by GLAST-1.

730.25

MOLECULAR CHARACTERIZATION OF GLUTAMATE TRANSPORTER SUBTYPES IN THE SALAMANDER RETINA. J.L. Arriza*, S.D. Eliasof, M.P. Kavanaugh, C.E. Jahr, and S.G. Amara, Vollum Institute, OHSU, Portland OR 97201

Electrogenic glutamate transporters have been characterized previously in photoreceptors and in glial cells isolated from the salamander retina. The glutamate-evoked current in cone cells exhibits many of the properties of the prototypic glial cell glutamate transporter (i.e., sodium-dependence and similar pharmacology) but differs in that much of the cone cell current appears to be carried by chloride ions. To investigate the molecular basis of this difference and to characterize the properties and distribution of subtypes expressed in this model system, we have isolated glutamate transporter cDNAs from salamander retina. Evidence for the expression of seven distinct subtypes was obtained by nucleotide sequencing of partial cDNAs isolated with polymerase chain reaction. Four different functional glutamate transporters subtypes, termed SR6, SR24, SR27, and SR30, were subsequently isolated from a salamander retina cDNA library. These transporters exhibit structural similarities with human glutamate transporters (J. Neurosci. 14: 5559,1994); SR6 has 92% sequence similarity to EAAT1, SR24 and SR27 have 92% and 85% similarity to EAAT2, and SR30 is a novel subtype with no reported mammalian counterpart. Using two electrode voltage clamp recordings from *Xenopus* oocytes expressing synthetic RNAs, we find that each subtype exhibits sodium-dependent inward currents in response to application of excitatory amino acids. SR24 and SR27 are inhibited by low micromolar kainate. We are currently determining the localization of these transporters in the retina by *in situ* hybridization and immunocytochemistry.

730.26

ION FLUXES THROUGH EXCITATORY AMINO ACID TRANSPORTERS J.I. Wadiche, E.W. McCleskey*, S.G. Amara, and M.P. Kavanaugh, Vollum Institute, OHSU Portland, OR 97201.

Currents and uptake of radiolabeled excitatory amino acids mediated by cloned human excitatory amino acids transporters (EAAT 1-3) were measured under voltage clamp in *Xenopus* oocytes. Consistent with a model predicting translocation of net positive charge with each transport cycle, superfusion of the transport substrate D-Asp induced inward currents in oocytes expressing EAAT2 which did not reverse at potentials up to +80mV. In contrast, D-Asp induced currents which reversed in oocytes expressing EAAT1 (E_{rev} = +9.3 ± 0.7 mV; n=46) and EAAT3 (E_{rev} = +38.0 ± 2.7 mV; n=28). The reversal potentials of the EAAT1 and EAAT3 currents shifted 54.1 ± 1.8 (n=5) and 53.7 ± 4.3 mV (n=5) per 10-fold change in $[Cl^-]_{out}$. The outward currents were abolished upon substitution of extracellular chloride with gluconate. The component of the current carried by chloride was resolved by subtraction of currents recorded before and after depletion of internal chloride andexternal chloride; this current reversed near E_{Cl}. For EAAT1, the quantity of charge translocated per molecule of [^{3}H]D-Asp varied as a function of membrane potential (from +3.5 e_0 at -100mV to -2.5 e_0 at +25mV) and was approximately +1 at E_{Cl} or when chloride ions were absent. The uptake of [^{3}H]D-Asp was not thermodynamically coupled to the chloride electrochemical gradient. The selectivity sequence of the excitatory amino acid-activated conductance was NO_3^->I^->Br^->Cl^->F^->>gluconate$^-$. The results suggest that the net current flowing through the transporter reflects translocation of one net positive charge per transport cycle plus a second current resulting from activation of a gated channel-like activity. This novel behavior provides a potential mechanism for the transporters to dampen cell excitability in addition to removal of transmitter.

730.27

POSSIBLE REGULATION OF GLUTAMATE UPTAKE BY SECOND MESSENGERS J.G. Ortiz*, O. Claudio, G. Santiago, M. L. Cordero, and J. Nieves, Dept. of Pharmacology, Univ. of Puerto Rico Medical School, PO Box 365067, San Juan, **Puerto Rico** 00936-5067

Glutamate (**GLU**) reuptake is the primary mechanism for its removal from the synapse. Several GLU transporters have been cloned. Glycosylation and possibly protein kinase C (PKC) appear as a common feature of the cloned transporters (Kanai et al., 1993). GLU uptake is increased in whole mouse brain synaptosomes preincubated with NO synthase inhibitors aminoguanidine or nitroarginine, implying that NO inhibits GLU uptake. Arachidonic acid also inhibits GLU uptake. Pertussis toxin, a G_i-protein inhibitor markedly reduces GLU uptake, while 1.0 mM Li^+, possibly by inhibiting phophatidylinositol turnover, potentiates it. These observations suggest possible regulation of GLU uptake by second messengers. Many of these effects are not observed in synaptosomes from mice with genetic audiogenic seizures, pointing to the possible relevance of these observations to experimental epilepsy. (Supported by the NIH/MBRS, RCMI and CIDIC Institutional Programs and Animal Resource Center).

730.28

PHARMACOLOGY AND REGULATION OF THE RAT SODIUM-DEPENDENT GLUTAMATE TRANSPORTER, EAAC1. L.A. Dowd,*[1] A.J. Coyle,[1] J.D. Rothstein,[2] and M.B. Robinson[1]. [1]Children's Seashore House, Depts. of Peds and Pharm., Univ. of Penn., Philadelphia, PA 19104; [2]Dept. of Neurology, The Johns Hopkins Univ., Baltimore, MD 21287.

Recently, three distinct cDNAs (EAAC1, GLT1, and GLAST) encoding SDHA Glu transporters have been isolated but these transporters do not fully reconstitute the pharmacology of transport observed in brain tissue. The first purpose of the present investigation was to determine if EAAC1 reconstitutes the properties of transport observed in synaptosomes, C6 glioma, or primary astrocyte-enriched cultures. Glu transport into EAAC1-injected oocytes and C6 glioma have similar affinities for Glu and sodium, and these values markedly differ from those observed in rat synaptosomes. Several excitatory amino acid (EAA) analogs were tested as inhibitors of L-[^{3}H]-Glu transport in oocytes expressing EAAC1 cRNA. Although EAAC1-mediated transport and cortical synaptosomal transport have similar pharmacological profiles, five EAA analogs were at least 3-fold more potent as inhibitors of cortical synaptosomal transport than as inhibitors of EAAC1-mediated transport. In contrast, all of the compounds examined inhibit transport observed in C6 glioma with similar potency to that observed in oocytes injected with EAAC1 cRNA. Consistent with these data, C6 glioma express EAAC1-like immunoreactivity. The molecular weight of EAAC1 in C6 glioma is, however, 7-10 kDa larger than the protein recognized in crude cortical synaptosomes. At present it is unclear if this difference in glycosylation contributes to the pharmacological differences observed in C6 glioma and synaptosomal membranes. Activation of PKC by TPA caused a 2.5-fold increase in EAAC1 Glu transport and this increase was due to an increase in V_{max} with no change in K_m. This increase in activity was observed within 2 minutes and remained elevated for at least 60 minutes. (NS29868)

SECOND MESSENGERS: G-PROTEINS

731.1

DESENSITIZATION OF A CATIONIC CONDUCTANCE ACTIVATED BY METABOTROPIC GLUTAMATERGIC AND MUSCARINIC RECEPTORS IN CA3 NEURONS IN VITRO: ROLE OF G-PROTEINS. N.C. Guérineau, J.-L. Bossu, B.H. Gähwiler and U. Gerber*

Brain Research Institute, University of Zurich, CH-8029 Zurich, Switzerland

Desensitization of responses mediated by activation of metabotropic receptors is a commonly observed phenomenon. In the case of the cationic conductance activated by bath-application of 1S,3R-ACPD or MCh, the desensitization is characterized by a decrease of 50 % in the current amplitude when the agonist is reapplied 3 minutes after the initial application. This desensitization occurs at the second messenger level rather than at the receptor, since the second response to agonist is still reduced when neurons were exposed first to 1S,3R-ACPD and second to MCh, or vice versa. Interestingly, the desensitization appears to be related to activation of a G-protein. In the presence of GTPγS (500 μM, non-hydrolyzable analogue of GTP) in the patch-pipette, the first application of 1S,3R-ACPD or MCh is already desensitized (50% of the amplitude of control cells). By contrast, intracellular dialysis with high concentration of GDPβS (1 mM, non-hydrolyzable analogue of GDP) inhibits the desensitization process such that the cationic current amplitude is greatly enhanced (~200 % of the control response) and in most cells persists without returning to baseline. In further experiments, we show that the G-protein involved in the desensitization is pertussis toxin-insensitive. We are now attempting to determine whether this G-protein is directly linked to the cationic channel or is coupled to subtypes of mGluRs and muscarinic receptors different from those responsible for the cationic current.

731.2

SIGNALLING PATHWAYS OF THE DOPAMINE D2S RECEPTOR: DISSECTION USING PERTUSSIS TOXIN-INSENSITIVE G PROTEIN MUTANTS M.H.Ghahremani* and P.R.Albert, Department of Pharmacology and Therapeutics, McGill University, Montreal ,Canada H3G 1Y6.

The dopamine D2S receptor couples to multiple signalling pathways through pertussis toxin (PTX) sensitive heterotrimeric guanine nucleotide binding proteins ($G_{i/o}$). When transfected in Ltk- fibroblast cells (LD2S), the dopamine D2S receptor decreases forskolin-stimulated cAMP levels and increases both PI turnover and calcium mobilization (Liu *et al.*, 1992), actions which were blocked by PTX pretreatment. In order to investigate the different subtypes of $G_{i/o}$ that mediate D2S signalling, mutation of the G_i/G_o proteins which render them insensitive to PTX treatment were made. The C-terminal Cys residue in the α subunit of $G_{i/o}$ proteins (α_o, α_{i1}, α_{i2} and α_{i3}) was converted to Ser by site-directed mutagenesis. The mutant G proteins were separately transfected in LD2S cells and clones were detected by Northern analysis. The amount of protein expressed in each clones was determined by Western Blot using antibodies against G_o or $G_{i1,2}$. In non-transfected cells G_{i2} was found to be the dominant $G_{i/o}$ protein expressed endogenously at both mRNA and protein level; G_o was at the limit of detection. Clones transfected stably with mutant G proteins showed levels of specific mRNA and protein expression which varied from one to several-fold endogenous levels of G protein. To study the role of these G proteins in signalling of the D2S receptor, $[Ca^{++}]_i$ was measured by using Fura-2 in clones expressing mutant G proteins. Clones that express amounts of mutant G protein comparable to endogenous levels were treated with PTX (50 ng/ml, 16h). This eliminates the function of endogenously expressed $G_{i/o}$ which are PTX sensitive while the mutant G protein remains unaltered. Preliminary results indicate that the D2S receptor couples most strongly to G_o over G_{i1} or G_{i2} to enhance calcium mobilization. The role of G protein subtypes in receptor coupling to adenylyl cyclase and PI turnover is being examined. The mutant G proteins provide a useful tool for the investigation of G protein coupling to receptors.

731.3

ANTISENSE KNOCKOUT OF THE STIMULATORY-TYPE G-PROTEIN, GOLF, IN THE RAT BASAL GANGLIA.

L.A. Williams*, S. Das & S.R.Vincent. Dept. Psychiatry, Div. Neuroscience, University of British Columbia, Vancouver, B.C., Canada.

Stimulatory-type guanine nucleotide binding proteins (G-proteins) couple neurotransmitter- and hormone- activated receptors to the stimulation of adenylyl cyclase, an enzyme that catalyzes the synthesis of the intracellular second messenger, cyclic adenosine monophosphate (cAMP). We have previously shown that G-olfactory (Golf)α protein and its mRNA are selectively localized to the neural tissue of the caudate-putamen, nucleus accumbens, and olfactory tubercle. Striatonigral and striatopallidal nerve terminals appear also to contain Golfα protein. This distribution suggests that Golfα may couple the D1 dopamine and or A2a adenosine receptors found in these brain regions to adenylyl cyclase. To investigate this possibility, we have used intrastriatal antisense injections with oligonucleotides complementary to bases surrounding the initiation region of Golfα mRNA, while oligonucleotides complementary to this region in Gsα mRNA have been used as control. Oligonucleotides are 17-20 bases in length with a phosphorothioate modified backbone. Immunohistochemistry of the rat striatum at 24 and 48 hours post injection show block of Golf protein expression by Golf antisense oligonucleotides, while Western blots confirm the loss of a 43-44 kD protein, consistent with the loss of Golf. These antisense oligonucleotides will be used to investigate the functional role of Golf in the brain.

731.4

MONONUCLEAR LEUKOCYTE G-PROTEIN LEVELS AND FUNCTION IN MAJOR DEPRESSION: EFFECTS OF ANTI-DEPRESSANT TREATMENT. L. T. Young*, P. P. Li and J. J. Warsh. Dept. Psychiatry, McMaster Univ. Hamilton, ON, L8N 3Z5 and Clarke Instit. Psychiatry, Toronto, ON, Canada.

The molecular pharmacology of antidepressants (ADs) suggests their site of action may be in the β-adrenoceptor-G-protein-adenylyl cyclase pathway. In the present study levels of G-proteins which regulate adenylyl cyclase (AC) activity and function were measured in mononuclear leukocytes (MNLs) obtained before and after 5 weeks of AD treatment in 12 subjects with major depressive disorder (MDD). MNLs were obtained from drug-free (>10 days) outpatients meeting RDC criteria for MDD and a Ham-D score >16. G-protein (α_s and α_i) levels were determined by immunoblotting and AC (basal, GTPγS-stimulated 100 μM, Forskolin-stimulated 10 μM) were determined with a radioimmunoassay. There were no pretreatment differences in either G-protein levels or functionality in patients compared with controls. Responders (1.83±0.26 pmol/mg/min, N=6) but not nonresponders (3.06±0.52, N=6) showed lower basal AC activity compared with controls (2.45±0.33, N=12, T=2.73, df16, $p<0.01$). Furthermore, there were no significant differences pre- and post- AD treatment in α_s or α_i levels or in GTPγS- or forskolin-stimulated AC activity in the depressed patients as a whole or when subgrouped into responders and nonresponders. These data do not support a G-protein mediated action for AD in the treatment of MDD. Desensitization of the AC signalling pathway may be present in treatment responders as suggested previously.

731.5

CORTICOSTERONE ALTERS G PROTEINS IN THE HIPPOCAMPUS.

D.Y. Okuhara*, S.G. Beck, and N.A. Muma. Dept. of Pharmacology. Loyola University Medical Center. Maywood, IL 60153.

The highest concentration of glucocorticoid receptors is located in the hippocampus, an area of the brain associated with memory and emotions. Several laboratories have demonstrated that the glucocorticoid corticosterone (CT) alters the response of several neurotransmitter receptors in the hippocampus that are linked to several types of G proteins. We used Western blot analysis and immunohistochemistry to determine the effects of CT on G protein α-subunit (G_s, $G_{i1\ and\ 2}$ and G_o) levels and distribution in the hippocampus. Four treatment groups were used in our investigation: SHAM, ADX (bilateral adrenalectomy); BS (ADX + 12.5 mg CT pellet to produce basal plasma CT levels); HCT (ADX + 300 mg CT pellet to produce stress levels of CT in the plasma). Treatment was for 2 weeks. In Western blots ADX had no effect on G protein levels when compared to SHAM animals. BS increased G_s levels while HCT increased the levels of G_s, $G_{i1\ and\ 2}$ and G_o when compared to SHAM. In immunohistochemistry experiments, BS increased G_s levels in subfield CA3 when compared to ADX. BS increased G_o levels in CA1 when compared to SHAM. BS also increased G_o levels in the dentate when compared to ADX, SHAM, and CT. We conclude that 1) CT does not alter the intracellular distribution of G proteins in the hippocampus, 2) CT alters the G protein levels in the hippocampus and 3) changes in G protein levels may be a compensatory response. Supported by MH-00880 and NS-28512 to S.G.B. and BRSG784 to N.A.M. and S.G.B.

731.6

DIFFERENTIAL DOWNREGULATION OF MORPHINE AND MORPHINE-6-β-GLUCURONIDE ANALGESIA IN THE RAT BY MOR-1 AND G-PROTEIN ANTISENSE OLIGODEOXYNUCLEOTIDES. Rossi, G.C.*, Standifer, K.M., and Pasternak, G.W., Cotzias Laboratory of Neuro-Oncology, Memorial Sloan Kettering Cancer Center and Department of Pharmacology and Neurology, N Y, NY 10021.

Opioid actions are mediated through G-protein coupled receptors. The recent cloning of the four families of opioid receptors (μ, δ, κ_1 and κ_3) has confirmed their place in the seven transmembrane superfamily. Raffa et al (1994) showed that antisense oligodeoxynucleotides (ODN's) to $G_i\alpha 2$, but not $G_i\alpha 1$ or $G_i\alpha 3$ decreased morphine analgesia in mice. Using this strategy and a strategy developed against δ and κ_1 opioid receptors, we examined an antisense sequence directed against the 5' non-coding region of the MOR-1 clone and three G-protein ODN's ($G_i\alpha 1$, $G_i\alpha 2$ and $G_o\alpha$). Rats were injected into the periaqueductal gray with MOR-1 antisense or it's mismatch (4 bases changed) on Days 1, 3, and 5. Morphine, DADLE or morphine-6-glucuronide (M6-G) analgesia was then assessed after 24 hours. Other rats were injected with antisense ODN's to $G_i\alpha 1$, $G_i\alpha 2$ or $G_o\alpha$. Thirty-eight to fourty-four hours after the antisense treatment (25 μg) rats were given morphine (2.5 μg) or M6-G (18 ng) and tested for analgesia. Morphine antinociception was significantly reduced by $G_i\alpha 2$ antisense, and the MOR-1 antisense ODN. In contrast, M6-G antinociception was blocked by $G_i\alpha 1$ antisense, but not the MOR-1 antisense ODN. Both morphine and M6-G induced analgesia were unaffected by administration of $G_o\alpha$ antisense. DADLE analgesia was also significantly reduced by the MOR-1 antisense sequence. Over a period of 4-5 additional days, the animal's analgesic state returned to those values consistent with that of controls. These observations raise the possibility that M6-G, a morphine metabolite, may be mediated through an analgesic system distinct from that of two other mu_1 agonists, morphine and DADLE.

731.7

MORPHINE- (μ), NALBZOH- (κ_3), AND MORPHINE-6β-GLUCURONIDE-(M6G) MEDIATED ANALGESIC SYSTEMS ARE DIFFERENTIALLY BLOCKED BY ANTISENSE DNA DIRECTED AGAINST DISTINCT G-PROTEIN α SUBUNITS. Standifer, K.M.*, Rossi, G.C[1], and Pasternak, G.W. Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Opioids mediate analgesia through distinct spinal and supraspinal pathways, each pathway containing at least one μ, δ, and κ receptor subtype. Opioid receptor activity is pertussis-toxin sensitive, indicating G-protein α subunit involvement. Recently, several groups have tried to determine those G-protein α subunits responsible for mediating opioid analgesia. Administration of antisense DNA directed against $G_i\alpha 2$, but not $G_i\alpha 1$ or $G_i\alpha 3$, reduced supraspinal morphine analgesia in mice tested 18-24 hr later (Raffa *et al.*, 1994, *Eur. J. Pharmacol.*, **258**, p.R5). We now present data indicating μ-, κ_3-, and M6G-mediated analgesic systems show distinct sensitivity profiles to antisense directed against various G-protein α subunits. Mice (male, CD-1, 25-30 g) were injected with antisense to $G_i\alpha 1$, $G_i\alpha 2$, $G_i\alpha 3$ or $G_o\alpha$ (5 μg, i.c.v.). The effects of this supraspinal antisense DNA treatment on morphine- (700 ng, i.c.v.), M6G - (20 ng, i.c.v.) or NalBzoH- (15 μg, i.c.v.) mediated analgesia was assessed using the radiant heat tailflick assay. NalBzoH-induced analgesia was completely blocked 24 hours after administration of $G_i\alpha 1$, $G_i\alpha 3$ or $G_o\alpha$ antisense DNA ($p<0.01$), but was unaffected by $G_i\alpha 2$ antisense DNA treatment. Morphine- and M6G-mediated analgesia were reduced only by administration of antisense DNA directed against $G_i\alpha 2$ ($p<0.01$) or $G_i\alpha 1$ ($p<0.05$), respectively. These results are consistent with the existence of distinct μ- and κ_3-mediated analgesic systems (as well as distinct morphine- and M6G-induced antinociceptive systems), and underscores the complexity of opioid-mediated antinociception.

731.8

EFFECT OF CHRONIC ADMINISTRATION OF ANTIDEPRESSANTS ON THE LEVELS OF VARIOUS SUBTYPES OF G-PROTEINS ($G_s\alpha$, $G_i\alpha$, $G_{q/11}\alpha$) IN RAT BRAIN. Y. Dwivedi*, S.C. Pandey, and G.N. Pandey. Dept. of Psychiatry, University of Illinois at Chicago, IL 60612.

Antidepressants have been shown to cause changes in neurotransmitter receptors and second messenger systems. Several receptors are coupled to effector proteins through G proteins. In order to examine the role of G proteins in the mechanism of action of antidepressants and anti-anxiety drugs, we studied the effect of these drugs on the levels of expressed $G_s\alpha$, $G_i\alpha$, and $G_{q/11}\alpha$ subunits in rat cortex and hippocampus. Male Sprague-Dawley rats were given i.p. injections of desipramine (10 mg/kg), lithium chloride (2 meq/kg, twice) phenelzine (10 mg/kg), alprazolam (10 mg/kg), buspirone (10 mg/kg) and mCPP (10 mg/kg) daily for 15 days. The rats were sacrificed 24 hrs. after the last injection. The levels of expressed $G_s\alpha$, $G_i\alpha$ and $G_{q/11}\alpha$ were quantified by Western blotting using specific antibodies in cortices and hippocampi of rats treated with different drugs. We observed that lithium caused a significant decrease in the $G_i\alpha$ subunit (36%) in both cortex and hippocampus, while immunolabelling of $G_s\alpha$ and $G_i\alpha$ remained unchanged. There was no significant change in the levels of $G_s\alpha$, $G_i\alpha$ and $G_{q/11}\alpha$ proteins in cortex or hippocampus after desipramine and phenelzine treatment. We did not observe significant changes in immunolabelling of any of the G protein subunits after treatment with alprazolam, buspirone, or mCPP. However, the immunolabelling of $G_i\alpha$ protein in cortex after buspirone treatment tended to decrease and $G_s\alpha$ protein in cortex of desipramine-treated rats tended to increase, although it did not reach a statistically significant level. These results suggest that $G_i\alpha$ protein may be related to the mechanism of action of lithium.

ANTISENSE CONSTRUCTS DIRECTED AGAINST $G_{\alpha q/11}$ REDUCE MUSCARINIC M-CURRENT INHIBITION AFTER INTRANUCLEAR INJECTION IN RAT SYMPATHETIC NEURONS F.C. Abogadie, D.A. Brown, M.P. Caulfield, J.E. Haley, Y. Vallis, and N.J. Buckley*. Wellcome Laboratory for Molecular Pharmacology, University College London, Gower St, London WC1E 6BT, UK.

Our previous studies with injections of antisera against the C-terminal decapeptide of G-proteins established that $G_{\alpha q}$ and/or $G_{\alpha 11}$ are involved in the transduction of M-current inhibition by muscarinic receptor agonists (Caulfield et al. (1994), J.Physiol., 477,415). Such antisera do not discriminate functionally between $G_{\alpha q}$ and $G_{\alpha 11}$, so we have explored the use of constructs expressing sequences antisense to parts of G-protein gene sequences, as more specific tools to define G-protein involvement in muscarinic receptor modulation of the M-current.

Intranuclear injection of rat cultured superior cervical ganglion neurons was achieved using a variant of our method for injection of antisera; we verified injection by inclusion of fluorescein-isothiocyanate labelled dextran, which also enabled identification of injected cells 2 days later. In a parallel series of experiments, we established that cells injected in a similar manner with a cytomegalovirus promoter-driven β-galactosidase expressed functional protein 2 days after injection. Two days after injection with the "antisense" construct, cells had highly significant reductions in immunocytochemically-detectable Gαq/11. This was accompanied by a reduction in M-current inhibition by oxotremorine-M (1μM) from 64%±9.2% ("sense"-injected cells) to 28.8%±4% in antisense-injected neurons (n=4). These data encourage us to believe that antisense-expressing constructs will be useful tools for defining the functions of proteins involved in signal transduction in primary neurons.

731.10

CHRONIC ANTIDEPRESSANT TREATMENT INCREASES COUPLING BETWEEN THE G PROTEIN, Gs AND TYPE VI ADENYLYL CYCLASE.
J. Chen, K. Chaney and M. M. Rasenick*. Dept. of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60612

Earlier studies from this lab have suggested that chronic antidepressant treatment (electroconvulsive shock, tricyclic and atypical compounds) increases the coupling between Gsα and adenylyl cyclase, without changing the intrinsic activity of these proteins. More recently, these studies were repeated on cultured C6 glioma cells where it was demonstrated that chronic treatment with several antidepressant drugs showed a similar augmentation of GppNHp-stimulated adenylyl cyclase without altering the intrinsic activity of that enzyme (J. Neurochem, 64:724-732, 1995). These results suggested that antidepressants had a direct post-synaptic effect, and that the target of antidepressant action was some component of the membrane or cytoskeleton which regulated coupling between Gsα and adenylyl cyclase. Rats were treated chronically with ECS, amitriptyline, desipramine or amphetamine and membranes were prepared from cerebral cortex. The ability of Gsα to stimulate adenylyl cyclase was enhanced in all but the amphetamine group. Western blotting with a battery of antibodies against Gα or Gβγ showed no change in the expression of these proteins. Immunoprecipitation of membrane extracts with an anti-Gsα antibody showed that, despite no change in Gs expression, about 50% more adenylyl cyclase activity was precipitated from the antidepressant treated animals. In order to probe the nature of the increased coupling between Gsα and adenylyl cyclase, various cells were treated with antidepressants. While cells displaying Ca^{2+}-inhibited adenylyl cyclase (C6, SK-N-SH) showed increased activation of that enzyme by GppNHp or forskolin after antidepressant treatment, cells without Ca^{2+} inhibited adenylyl cyclase (COS-1, HEK 293) showed no changes in enzyme activity. This was investigated further by treating HEK 293 cells which expressed type VI adenylyl cyclase (from J. Krupinski) with amitryptiline. In the type VI-expressing cells (but not the controls), chronic antidepressant treatment increased GppNHp-activated adenylyl cyclase. Thus, it is possible that Gα interactions with type VI adenylyl cyclase are enhanced preferentially by chronic antidepressant treatment.

731.11

TUBULIN REGULATES Gαq-MEDIATED PHOSPHOLIPASE $C\beta_1$ SIGNALING. J. S. Popova[1]*, S. G. Rhee[2], J. Garrison[3] and M. M. Rasenick[1]. [1]Dept. Physiol. & Biophys., Univ. Illinois at Chicago, Chicago, IL 60612, [2]Natl. Heart, Lung & Blood Inst., Natl. Inst. Health, Bethesda, MD 20892 and [3]Dept. Pharmacol., Univ. Virginia, Charlottesville, VA 22908.

Coimmunoprecipitation and autoradiography studies have revealed that the cytoskeletal protein tubulin, with the hydrolysis-resistant photoaffinity probe [^{32}P]AAGTP (azidoanilido GTP) bound, interacts with the G protein Gαq and thus, is a potential candidate for regulation of phospholipase $C\beta_1$ ($PLC\beta_1$) activity. To study this phenomenon further, we infected Sf9 cells with recombinant baculoviruses encoding Gαq and $PLC\beta_1$ and compared the effects of GppNHp and tubulin-GppNHp (concentration-response) on membrane-associated $PLC\beta_1$ activity using exogenous [^{3}H]PIP_2 as a substrate. GppNHp stimulated the high basal $PLC\beta_1$ activity in a concentration-dependent manner. Under the same conditions, the higher concentrations of tubulin-GppNHp (500nM to 5 μM) inhibited the enzyme. In order to study the possibility that tubulin has an effect on receptor-dependent stimulation of $PLC\beta_1$ as well, we infected Sf9 cells, simultaneously, with baculoviruses bearing M_1 muscarinic receptor (E. Ross, Dallas), Gαq or $PLC\beta_1$ cDNAs. The coexpression of the three different cDNAs was verified by Western Blotting. Receptor binding studies using [^{3}H]QNB as a ligand revealed 240 fmol/mg membrane protein of expressed M_1 muscarinic receptors with an apparent Kd of 0.162 nM. Carbachol (at 1 mM) increased the transfer of [^{32}P]AAGTP from tubulin (at 1 μM) to membrane Gαq. Carbachol-stimulated $PLC\beta_1$ activity was increased in a concentration-dependent and saturable manner by GppNHp. Furthermore, carbachol (at 1 mM) appeared to blunt the inhibition of $PLC\beta_1$ by tubulin-GppNHp. Since calcium is known to increase microtubule depolymerization, these studies suggest a potential role for tubulin in the regulation of phosphatidylinositol/calcium signaling within the cell.

731.12

IDENTIFICATION OF THE G PROTEIN DOMAIN RESPONSIBLE FOR TUBULIN-ACTIVATED SIGNAL TRANSDUCTION. S. Roychowdhury*, N. Skiba, A. Greene, A. Mathew, H. Hamm and M. M. Rasenick. Department of Physiology & Biophysics, U. Illinois College of Medicine, Chicago, IL 60612

Evidence from our laboratory suggests that the cytoskeletal protein tubulin, modifies neurotransmitter receptor signaling, activating certain G proteins (Gs, Gi1 and Gq) by transferring GTP to them. In order to establish the physiological role of tubulin -Gα interaction , it was necessary to determine the interacting domains on the molecules. Initial proteolytic and chemical cleavage studies suggested a common sequence for tubulin binding (NNR/KW) exists in Gαs (272-275) and Gαi1 (256-259). Transducin lacks the above sequence and it does not interact with tubulin. To confirm the above data and to determine the relevence of the domain for functional interaction with tubulin, a number of transducin-Gαi1 chimeras were made, expressed in E. coli and purified. Restriction enzyme sites were introduced with PCR in the pHis6Gαi1 expression vector (obtained from Maurine Linder) and either Gαi or transducin sequences were filled in. These chimeras were tested for their ability to bind to tubulin by dot blot and tubulin overlay studies. Functional interaction of the chimeras with tubulin were studied by measuring the transfer of AAGTP from tubulin to chimeras and stabilization of bound nucleotide. In one chimera , a small region of Gαi1 (220-299) in transducin sequence was sufficient to allow activation of the molecule by tubulin. In a second chimera, where the region of Gi between 243-271 was replaced by transducin, activation by tubulin did not occur. Consistent with proteolytic studies, the first chimera bound tubulin with similar affinity as rGαi1 and rGαs. The second chimera did not bind tubulin. A synthetic peptide corresponding to the suspected tubulin-binding region of Gαi1 blocked the tubulin-AAGTP activation of Gαi1. The result suggests that the region NNKW in Gαi1 is important for binding and activation by tubulin. It is hoped that a synthetic peptide which blocks tubulin activation of Gα, will be valuable for in situ studies aimed at determining the "in vivo significance" of the tubulin activation of G proteins.

SECOND MESSENGERS IV

732.1

EFFECTS OF INTERLEUKIN-1β AND TUMOR NECROSIS FACTOR α ON PHOSPHOLIPID METABOLITES IN C6 GLIOMA CELLS. Robert S. Dotson[1]*, Charles F. Ide[1,2], and Sanda Clejan[3]. [1]Neuroscience Program, [2]Department of Cell and Molecular Biology, and [3]Department of Pathology, Tulane University School of Medicine, New Orleans, LA 70112.

Cytokines have been implicated in the regulation of astrocytic response to injury. Also, phospholipase activation is involved in the signal transduction cascades for cytokines in a number of mammalian cells types. The main goal of this work is to examine the involvement of phospholipase activation in the signalling pathways of the cytokines interleukin-1β (Il-1β) and tumor necrosis factor α (TNFα) using the C6 rat astrocytoma cell line as an *in vitro* model. Il-1β exposure initiates a biphasic increase in diacylglycerol levels, as measured by high-performance liquid chromatography. This suggests the activation of more than one phospholipase. TNFα-stimulated diacylglycerol production is also biphasic but continues for a longer time course than that for Il-1β. Both cytokines stimulate diacylglycerol production in a concentration-dependent manner. Phospholipase D hydrolyzes phosphatidyl-choline into phosphatidic acid and choline. Phosphatidic acid can be rapidly dephosphorylated to contribute to diacylglycerol levels. Both Il-1β and TNFα stimulate, in the presence of ethanol, phosphatidylethanol production, as measured by thin layer chromatography. This unambiguously indicates phospholipase D involvement. In the presence of ethanol, phospholipase D catalyzes the transphosphatidylation reaction, producing phosphatidyl-ethanol. The involvement of phospholipase D and the extended time course of diacylglycerol production suggest an interaction with protein kinase C.

KAPPA OPIOID RECEPTOR AGONIST INHIBITION OF NE-STIMULATED PHOSPHOINOSITIDE HYDROLYSIS: TWO POSSIBLE MECHANISMS OF ACTION. D. Paul*, L. D. Minor and N. Duan. Department of Pharmacology and Centers for Neuroscience and Alcohol and Drug Abuse, LSU Medical Center, New Orleans, LA 70112.

Kappa opioid agonists inhibit norepinephrine-stimulated phosphoinositide (PI) hydrolysis in neural tissue. Rat hippocampal slices labelled with ^{3}H-myoinositol were incubated in a lithium buffer for 60 min with 10 μM NE and various concentrations of one of the following kappa receptor agonists: U50,488, U62,066, bremazocine, BRL 52656-A, BRL 52974, BRL 53001-A or BRL 53117-A. PI hydrolysis was measured as the ratio of dpm released / dpm incorportated and analyzed as a percent of control PI hydrolysis. All of the kappa agonists dose-dependently attenuated NE-stimulated PI hydrolysis. BRL 5256-A (IC_{50} = 34 ±3.3 μM), U62,066 (40 ±7.4 μM), U50,488 = 41 ± 6.6 μM) and BRL 529974 (43 ±10.6 μM) were most potent and not significantly different from each other. Bremazocine (64 ± 25 μM) and BRL 53001-A (158 ± 78 μM) were of intermediate potency, and BRL53117-A (1420 ± 356 μM) was the least potent. The rank order of potencies for inhibition of NE-stimulated PI hydrolysis is similar to that reported for kappa receptor binding competition by these drugs. However, additional studies demonstrated that the K_i values for kappa agonist inhibition of PI hydrolysis is not significantly different than the K_i values for inhibition of [^{3}H]prazosin binding. Thus, it is possible that kappa agonist inhibition of NE-stimulated PI hydrolysis is mediated by competitive inhibition of α receptors.

732.3

GLUTAMATE RECEPTOR-MEDIATED PHOSPHOINOSITIDE TURNOVER IN BERGMANN GLIA CELLS IN CULTURE.

E. Trueba-Elizalde, G. Fragoso, M. Romo-de-Vivar*, A. Ortega and A.M. López-Colomé. Instituto de Fisiología Celular, U.N.A.M. Apartado Postal 70-253, México, D.F., 04510.

Primary cultures of cerebellar Bergmann glia cells were prepared from 14-day-old chick embryos. We identified and characterized glutamate metabotropic receptors coupled to phosphoinositide turnover in these cells. Glutamic acid at a concentration of 1 mM induced an 85 % increase in [^{3}H]-inositol phosphates (InsPs) acumulation within 30 minutes in cells preincubated with [^{3}H]-myo-inositol in the presence of 10 mM lithium chloride. Glutamic acid analogues (1 mM) stimulated InsPs accumulation in the following order: L-aspartate>L-glutamate>quisqualate>N-methyl-D-aspartate>Kainate>1-Aminocyclopentane-1,3-dicarboxylate. NMDA-induced response was significant since one minute of stimulation. The potency of excitatory amino acid analogues for stimulating InsPs formation was determined within a concentration range from 10 nM to 1 mM. The L-glutamate-induced response was blocked most effectively by MK-801(5μM)> CPP(200 μM)>>DNQX(50 μM); AP5 and MCPG showed no effect. The effect of NMDA was inhibited by verapamil (10μM), which blocks T-type Ca^{2+} channels whereas nifedipine (10 μM) and dantrolene (30 μM) showed no effect. These studies provide clear evidence for the presence of glutamate receptors coupled to phosphoinositide metabolism on Bergmann glia cells, perhaps involved in the modulation of synaptic transmission in the cerebellum, through their close apposition to glutamatergic synapses in this organ. Supported by Grant 3375-N from CONACYT.

732.4

A NOVEL DIACYLGLYCEROL (DG) KINASE ISOZYME (TYPE IV) FROM RAT BRAIN RESEMBLES EYE-SPECIFIC DG KINASE OF DROSOPHILA WHICH IS ENCODED BY RETINAL DEGENERATION A GENE.

K.Goto* & H.Kondo Department of Anatomy Tohoku University School of Medicine, Sendai 980, Japan.

In the process of signal transduction, (DG) kinase is thought to be involved in the resynthesis of phosphatidylinositol by converting the second messenger DG to phosphatidic acid. DG kinase is thus regarded as an attenuator of the activity of protein kinase C. Recent studies have shown that DG kinase can participate in signal transduction through not only G protein-coupled receptors but also receptor tyrosine kinase. In order to clarify the functional significance of DG kinase in various cascade, we have so far cloned three DG kinase isozymes from a rat brain cDNA library and characterized their enzymatic properties and localizations. In this study we isolated a novel cDNA for DG kinase (DGK-IV) from a rat brain cDNA library. This cDNA encoded a protein of 929 amino acids with a calculated molecular weight of104kDa. The primary structure of type IV was distinct from those of type I, II and III in that type IV contained no EF-hand motifs and four ankyrin-like repeats were attached to the carboxyl terminus. This structural feature of DG kinas-IV closely resembles the recently cloned eye-specific DG kinase of Drosophila which is encoded by retinal degeneration A gene. However, the rat mRNA for type IV was much more dominantly detected in the brain than the eye, the expression was localized in all neurons, rather intensely in the cerebral and cerebellar cortices. These morphological and structural features of DG kinase-IV suggest that DG kinase-IV belongs to a new family of DG kinase distinct from type I, II and III.

732.5

THE EFFECT OF ETHER LIPIDS ON PHOSPHATIDYLINOSITOL (PI) METABOLISM IN PRIMARY NEURONAL CULTURES OF CORTEX, HIPPOCAMPUS AND CEREBELLUM.

H.S. Ved, J.R. Dave, B.P. Doctor and D.L. Yourick*. Divs. Biochem. and Neurosci., Walter Reed Army Institute Research, Washington, DC 20307-5100.

Platelet activating factor (PAF) and dodecylglycerol (DDG) are structurally similar ether lipids, both exhibiting a variety of biological effects including antibacterial activity and altered differentiation of neurons and oligodendrocytes. However, PAF, unlike DDG, stimulates Ca^{++} mobilization, platelet aggregation and serotonin secretion from isolated platelets. Interestingly, both DDG and PAF stimulate acetylcholinesterase and choline acetyltransferase activity differentially in primary neuronal cultures. To continue investigation of Ca^{++} mobilization, DDG and PAF were examined for effects on PI metabolism in primary cultures from cerebral cortex, cerebellum and hippocampus. Brain regions from embryonic day 17 rat embryos were separated by gross dissection taking care to discard meninges and blood vessels. Cells were dissociated and plated in a serum containing medium. After 24 hrs, cultures were treated with cytosine arabinoside for 4 hrs, and the medium was changed to a chemically defined serum free medium. Acetylcholinesterase and choline acetyltransferase activities were measured to assess the differentiation of the neurons. PI metabolism was measured as previously described (DeCoster and Yourick, Int. J. Dev. Neurosci. 12(3):227-233, 1994) excepted incorporation and agonist incubations were increased to 2 hrs. DDG, but not PAF, increased PI metabolism 76% over basal in hippocampal cultures. PAF, but not DDG, caused a statistically significant reduction of 17% in PI metabolism in cerebellar cultures. Neither compound had any effect when compared to control in cultures from cortex. DDG and PAF have substantially different effects on PI metabolism dependent on brain regions analyzed.

732.6

ACTION OF CHOLERA TOXIN ON CARBACHOL-STIMULATED PHOSPHOINOSITIDE HYDROLYSIS IN CEREBELLAR NEURONS.

A. Surin*, R. Raulli, E. Surina and J.T. Wroblewski. Department of Pharmacology, Georgetown University School of Medicine, Washington D.C. 20007

Cholera toxin (CTX) and pertussis toxin (PTX) are conventional tools used to study the role of G-proteins in receptor-effector interactions. Activation of the phosphoinositide (PI)-specific phospholipases by transmitter receptors is mediated trough PTX-sensitive $G\alpha_{o,i}$ proteins or PTX-insensitive $G\alpha_{q,z}$ proteins. So far, direct regulation of PI-specific phospholipases by G-proteins which can be ADP-ribosylated by CTX has not been observed. In primary cultures of cerebellar granule cells, the stimulation of muscarinic receptors by carbachol (Carb) results in enhanced PI hydrolysis that was inhibited by about 50% when granule cells were treated overnight with CTX (3 ug/ml). A similar treatment of cells with PTX failed to affect this Carb-induced response. The pretreatment of granule cells with CTX caused a drastic decrease of [^{32}P] labeling of a 50 kDa protein band as revealed by CTX-dependent ADP-ribosylation of granule cell homogenates in the presence of [^{32}P]NAD followed by SDS-PAGE. The half-maximal blockade of back ADP-ribosylation of this protein band appeared after 45 min, and reached 80% in 3 h. However, a 3 h preincubation of granule cells with CTX failed to decrease the Carb-induced PI hydrolysis. The 50 kDa protein band was identified by Western blot using an anti-$G\alpha_q$ antiserum. Pretreatment of granule cells with CTX (20 min to 3 h) diminished the immunostaining intensity of this protein band and led to the appearance of a new 52 kDa band. This later band was never observed if CTX was incubated in vitro with granule cell homogenate. The presence of Carb during the incubation of granule cells with CTX failed to affect the CTX-induced ADP-ribosylation. However, Carb decreased twice the intensity of immunostaining of the 50 kDa band, as compared with the effect of CTX alone. These results indicate that a short-term (less than 3 h) action of CTX on cerebellar granule cells either promotes a fast degradation and/or modification of $G\alpha_q$, or inhibits its biosynthesis. However, these changes are not responsible for the inhibition of Carb-stimulated PI hydrolysis. In contrast, a long-term (overnight) treatment of granule cells with CTX results in the uncoupling of muscarinic receptors from PI hydrolysis through mechanisms which are not directly related to the ability of CTX to ADP-ribosylate $G\alpha_q$.

732.7

ENDOTHELIN STIMULATES THE HYDROLYSIS OF PHOSPHATIDYLCHOLINE BY PHOSPHOLIPASE D IN MOUSE STRIATAL ASTROCYTES.

M. Tencé*, S. Desagher, J. Cordier and J. Glowinski. INSERM U114, Collège de France, 75005 Paris, France.

In striatal astrocytes, receptors for endothelins (ETs) are associated with several intracellular signaling pathways: ETs induce a sustained influx of calcium, inhibit adenylate cyclase activity and markedly activate phospholipases C and A2 (Marin et al., *J. Neurochem.* 56:1270-1275, 1991; Tencé et al., *Eur. J. Neurosci.* 4:993-999, 1992). We report here that ET-1 and ET-3 also stimulate a phospholipase D (PLD) activity which hydrolyses phosphatidylcholine into phosphatidic acid (PA).

In primary cultures of mouse astrocytes prelabelled with tritiated myristic acid, ET-1 (0.1 μM) induced a sustained production of both tritiated PA and diacylglycerol (DAG). This effect resulted from the activation of a PLD since in the presence of ethanol, ET-1 and ET-3 also stimulated time- and dose-dependently the formation of tritiated phosphatidylethanol (EC50: 2-4 nM). The ET-1 activation of PLD required extracellular calcium and involved a pertussis toxin-sensitive G-protein. Protein kinase C seemed to play a role in this activation since inhibitors of this enzyme, as well as a prolonged pretreatment with a phorbol ester (PMA), substantially reduced the formation of phosphatidylethanol. PMA also stimulated PLD activity. However, this effect was additive with that of ET-1 and furthermore it did not require extracellular calcium. These results suggest that at least two distinct mechanisms are involved in the control of PA formation in striatal astrocytes.

The stimulation of PLD by ETs could have particular physiological consequences. Indeed, a sustained production of PA and of its derivative DAG, the physiological activator of protein kinase C, could account for the mitogenic effects of ETs on astrocytes.

732.8

IN UTERO ISCHEMIA ENHANCES QUISQUALATE-STIMULATED PHOSPHOINOSITIDE HYDROLYSIS IN RAT HIPPOCAMPAL CELL CULTURES.

Z. Cai*, N. Zhu and P. G. Rhodes. Dept. of Pediatrics/Newborn Medicine, Univ. of Miss. Med. Ctr., Jackson, MS 39216.

Hypoxic-ischemic (HI) insult in perinatal life is a major cause of neuronal injury and impaired postnatal development. Effects of intrauterine HI on quisqualate (QA)-stimulated phosphoinositide (PPI) hydrolysis were studied in rat hippocampal cell cultures prepared from 19 day fetal rats which experienced an HI insult on G15. On gestation day 15, ischemia conditions were achieved by complete clamping of the uterine blood vessels for 30 min followed by removal of the clamps to permit reperfusion. Sham operation (surgery without vasculature clamping) was conducted in the control groups. The uterine horns were returned to the dam's abdomen after surgery and hippocampal neuronal cultures were prepared from the G19 fetuses. At time 14 days in vitro, cell density and protein content of the cultures were not significantly different between the sham-operated and HI groups. Cells were labeled with [^{3}H]-myoinositol (2 μCi per well) 24 hr before they were stimulated with quisqualate (100 μM) in the presence of 10 mM LiCl. The formation of labeled inositol monophosphate was measured as a representative of receptor-stimulated PPI hydrolysis. Intrauterine HI did not affect the incorporation of radioactive inositol into the cell membrane nor the basal level of PPI hydrolysis (3125 and 3051 dpm/mg protein for the HI and the sham groups, respectively). Stimulation with QA induced a 4.6-fold increase in PPI hydrolysis over the basal level in HI cells, whereas this increase in the sham groups was only 3.6-fold. PPI hydrolysis stimulated by carbachol was not affected by intrauterine HI insult. These data suggest that intrauterine HI may have long-lasing effects on glutamate metabotropic receptor-mediated signal transduction in hippocampal cells.

732.9

CALCIUM, GTP AND CARBACHOL STIMULATION OF HIPPOCAMPAL PHOSPHOINOSITIDE HYDROLYSIS FOLLOWING CHOLINERGIC DENERVATION AND SYMPATHETIC INGROWTH.
K.Kolasa*, D.Parsons and L.E.Harrell. Alzheimer's Disease Center, Dept.Neurology, VA&Univ.Alabama Med.Ctr., Birmingham, AL 35294.

Decreases in central cholinergic activity accompanied by increases in norepinephrine (NE) concentration have been described in Alzheimer's patients. To determine how these changes might affect brain biochemistry, our laboratory has utilized the model of hippocampal sympathetic ingrowth, in which peripheral sympathetic fibers, originating from the superior cervical ganglia, grow into the hippocampus following cholinergic denervation via medial septal lesions. Since sympathetic ingrowth can be prevented by ganglionectomy (Gx), the effects of cholinergic denervation alone (CD; MS lesions + Gx) can clearly be separated from the effects of hippocampal sympathetic ingrowth (HSI; MS lesion+sham Gx). HSI and CD have been found to differentially affect cholinergically stimulated phosphoinositide hydrolysis (PI) and the affinity of muscarinic receptors (mAChR) in a manner suggesting an alteration in coupling efficiency between the mAChR and PI turnover. To test this hypothesis, we have utilized newly developed methods in which prelabeled phosphoinositides (i.e., [^{3}H]-PI) are added to hippocampal membranes and hydrolysis assessed after the addition of calcium, to activate phospholipase C (PLC), GTPγS, to activate G-proteins, or GTPγS + carbachol, to activate the entire receptor complex. PLC activity in dorsal and ventral hippocampus was similar in HSI, CD and control animals. However, GTPγS stimulated PI hydrolysis in dorsal hippocampus was found to be significantly decreased in CD, when compared to control and HSI, animals ($p<0.02$), with HSI increasing PI turnover by 27% to control levels. Carbachol+GTPγS stimulated PI hydrolysis in dorsal hippocampus was also found to be decreased in CD when compared to control and HSI animals ($p<0.004$), with HSI increasing PI turnover by 15% to control levels. The results suggest that both sympathetic ingrowth and cholinergic denervation alone alter G-protein function, which may be the mechanism by which HSI and CD induce changes in mAChR affinity and cytosolic PI turnover.

732.10

SIGMA RECEPTOR REGULATION OF NMDA-STIMULATED [^{3}H]ARACHIDONIC ACID RELEASE FROM CEREBELLAR GRANULE CELLS IS PERTUSSIS TOXIN-SENSITIVE.
G.M. Gonzalez-Alvear* and L.L. Werling, Dept. of Pharmacology, The George Washington University Medical Ctr., Washington, D.C. 20037.

We have previously reported that sigma (σ) receptors are involved in the regulation of arachidonic acid release from cerebellar granule cells. We have now investigated the effects of the sigma agonists (+)pentazocine and BD737 on NMDA-stimulated [^{3}H]arachidonic acid ([^{3}H]AA) release from cerebellar granule cells in the absence and presence of pertussis toxin.

Cerebella of eight-day old neonatal rats were dissected and chopped into pieces. Cells were mechanically and enzymatically dissociated, subjected to differential centrifugation, resuspended and plated on polyethyleneimine coated dishes. Cell cultures were treated with 10 μM cytosine arabinofuranoside to prohibit growth of non-neuronal cells. After at least eight days in culture, cells were incubated with 1 μCi/dish [^{3}H]AA for 24 hrs ± pertussis toxin (0.1 nM), then washed to remove residual, unaccumulated labeled eicosanoid. Release of [^{3}H]AA was stimulated by a 10 min exposure to 50 μM NMDA in the presence or absence of a sigma drug.

Increasing concentrations of sigma agonists (+)pentazocine and BD737 completely inhibited NMDA-stimulated [^{3}H]AA release from cerebellar granule cells. Furthermore, the sigma$_1$ antagonist DuP 734 reversed the inhibition of [^{3}H]AA release by both agonists. In contrast, (+)pentazocine and BD737 failed to inhibit [^{3}H]AA release from pertussis toxin-treated cells. These data suggest that sigma receptors regulating NMDA-stimulated arachidonic acid release in cerebellar granule cells are G_i or G_o protein coupled. (Supported by a grant from NIDA to LLW and by a NIGMS predoctoral fellowship to GMG.)

CHARACTERIZATION OF PLASMALOGEN-SELECTIVE PHOSPHOLIPASE A_2 FROM BOVINE BRAIN CYTOSOL.
L.A. Horrocks*, H.-C. Yang and A. A. Farooqui, Dept. of Medical Biochemistry, The Ohio State University, 1645 Neil Ave., Rm. 465, Columbus, Ohio 43210.

The release of arachidonate from plasmalogen may be a receptor-mediated process catalyzed by 39 kDa plasmalogen-selective phospholipase A_2 (PLA_2). The purified enzyme is markedly inhibited by polyvalent anions such as phosphate, sulfate and citrate, with IC_{50} values of 400 mM, 150 mM and 5 mM, respectively, and stimulated by Triton X-100 and Tween-20. Octyl glucoside, sodium deoxycholate and taurocholate markedly inhibit enzymic activity. Non-specific inhibitors of PLA_2, such as quinacrine, nordihydroguaiaretic acid and manoalide, produce a dose-dependent inhibition. However, arachidonyl trifluoromethyl ketone (a potent inhibitor of 85 kDa cytosolic PLA_2) and bromoenol lactone (an irreversible inhibitor of 40 kDa plasmalogen-selective PLA_2 from myocardium) have no effect on enzymic activity. Finally, the 39 kDa plasmalogen-selective PLA_2 is inhibited by free fatty acids in a dose-dependent manner. Docosahexaenoate is the most potent inhibitor, followed by arachidonate, eicosapentaenoate and heptadecanoate. The inhibition by docosahexaenoate can be reversed with bovine serum albumin.

INDUCIBLE PROSTAGLANDIN SYNTHASE AND *ZIF*-268 mRNA UPREGULATION IN VASOGENIC CEREBRAL EDEMA: INHIBITION BY A PAF ANTAGONIST.
V.L. Marcheselli* and N.G. Bazan, Neuroscience Center, LSU Medical Center, New Orleans, LA 70112

Cerebral hypoxia, like global brain ischemia, triggers the release of glutamate which, in excess, leads to neuronal damage. Free fatty acids and diacylglycerols also accumulate *(BBA* **218**:1-10, 1970) due to activation of phospholipases A_2 and C. Platelet-activating factor (PAF), a product of PLA_2, is a mediator of neuronal damage. Prostaglandin H synthase (PGS, cyclooxygenase) is the rate-limiting enzyme in the synthesis of PGE_2, PGF_{2F}, PGD_2, prostacyclins, and thromboxanes. The inducible prostaglandin synthase mRNA (PGS-2, TIS-10), increases rapidly in response to a wide variety of stimuli such as mitogens and inflammation. Ischemia-reperfusion, single electroshock (ECS), and brain injury increase PGS-2 message levels in nervous tissue. After cryogenic injury, a model of vasogenic brain edema, the levels of PGS-2 mRNA rose rapidly reaching a peak at 2 hours, and remained upregulated after 24 hours. Levels of TIS-8 mRNA, a zinc-finger synthesis and a transcription factor, peaked after 1 hour of the injury and returned to control levels after 6 hours. The PAF antagonist BN-50730 partially inhibited the increase in both PGS-2 and TIS-8 mRNAs. Levels of tissue edema were measured by plasma Evans Blue extravasation. The animals pretreated with BN-50730 or dexamethasone were partially protected. Thus, PAF receptors may be involved in brain damage after injury and the PAF antagonists may be useful as pharmacological tools to protect the brain from that damage. Supported by DAMD-17-93-V-3013.

ACTIVATION OF THE PLA_2-AA SIGNALING CASCADE REGULATES 5-HT_{1A} RECEPTOR FUNCTION IN CHO CELLS.
K.L. Jameson*[1], K.A. Berg[1], A. Saltzman[2] and W.P. Clarke[1]. Dept. of Pharmacology[1], Univ. Texas Health Science Center, San Antonio, Texas 78284 and Dept. of Molecular Biology[2], Rhone-Poulenc Rorer, Collegeville, PA 19426.

We have reported that CHO cells naturally express a 5-HT_{1B} receptor subtype (Berg *et al*, Mol Pharmacol. 1994. vol 46: 477- 484) which is regulated by a cyclooxygenase-dependent arachidonic acid (AA) metabolite produced when phospholipase A_2 (PLA_2) is activated with melittin or the purinergic receptor agonist ATP (Berg *et al, Soc. Neurosci.* 1994. vol 20:1158). Currently, we are investigating the effect of activation of the PLA_2-AA signaling cascade on the 5-HT_{1A} receptor system in CHO cells expressing the human 5-HT_{1A} (G21) receptor (≈ 130 fmol/mg protein). The inhibition of forskolin (1 μM)-stimulated cAMP accumulation (FScA) by dipropyl-5-carboxamidotryptamine (dp-5-CT) in the presence and absence of melittin (2.5 μg/ml) or ATP (1 mM) was measured. In control experiments, both melittin and ATP increased AA release by 620% and 100% above basal, respectively, and, as we found previously, reduced 5-HT_{1B}-mediated inhibition of FScA. Melittin also reduced 5-HT_{1A} responsiveness. The EC_{50} for dp-5-CT was shifted to the right (pEC_{50} = 7.53 ± 0.06 {30 nM} vs 7.74 ± 0.05 {18 nM}; $p \leq 0.05$; n=4) and the maximal inhibition was reduced (74% ± 2% vs 83% ± 1%; $p \leq 0.01$) in the presence and absence of melittin, respectively. In contrast, ATP had no effect on 5-HT_{1A}-mediated inhibition of FScA (n=2). Thus, although the responsiveness of the 5-HT_{1A} receptor system may be regulated by the PLA_2-AA signaling cascade, the mechanism of this regulation may differ from that for the 5-HT_{1B} receptor system. SPREADING DEPRESSION ELEVATES INDUCIBLE CYCLOOXYGENASE IMMUNOREACTIVITY IN DISCRETE CORTICAL REGIONS.
R.P. Kraig*, C. Breder & P. Park. Dept. Of Neurology, The University of Chicago, Chicago, IL

Eicosanoids are powerful paracrine signals which may be involved in such diverse phenomena as conduction of messages in sensory neuronal pathways and the transformation of glia into reactive species. Spreading depression (SD) is a phenomenon that can induce gliosis uncompromised by cellular necrosis. Accordingly, to begin examining how eicosanoids might influence gliosis we characterized how recurrent SD altered the immunoreactivity (ir) for the inducible form of cyclooxygenase (iCOX).

Male, Wistar rats (n=72) were anesthetized with halothane. SD was induced in parietal cortex by superfusion of potassium chloride (1.0M, 3 hrs). Micropipettes placed in both frontal cortices recorded the occurrence of SD ipsilateral to the stimulus and its absence in contralateral, control cortex. Animals were allowed to recover for 1, 3, & 6 hr; and 1, 2, 3, 7, 14, 21, & 28 days. They were then re-anesthetized and processed for iCOX-ir. Blocking studies established the specificity of immunostaining. Computer-based and semi-quantitative image analyses of the log ratio of left, experimental versus right, control cortex were done in six distinct cortical regions showing iCOX-ir: insular, motor, piriform, and perirhinal cortex as well as the lateral nucleus of the amygdala and hippocampus. SD caused a significant ("p" values varying between less than 10^{-6} to 0.05) increase in iCOX-ir from 3 hr to 3 days after SD in all brain regions except amygdala and hippocampus. The lack of significant change in these two zones may stem from a symmetric increase in iCOX-ir. Pretreatment with indomethacin and mepacrine had no affect on SD-induced iCOX-ir changes while pretreatment with dexamethasone and L-NAME reduced the rise in iCOX-ir to a nonsignificant difference between sides. Treatment with sodium nitroprusside and ephedrine also altered iCOX-ir.

These results show that neocortical SD results in a significant rise in iCOX-ir within discrete cortical regions. Furthermore, these rises in iCOX-ir can be reduced by modulation of eicosanoid and nitric oxide metabolism.

DISTRIBUTION OF CYCLOOXYGENASE ISOFORMS & NEURONAL NITRIC OXIDE SYNTHASE IN MAMMALIAN CORTEX. [1]C.D. Breder*, [2]W.R. Tracey & [1]R.P. Kraig. [1]Dept. of Neurology, The University of Chicago, Chicago, IL 60637 and [2]Central Research Division, Pfizer, Inc., Groton, CT 06340.

Inflammation is a complex reaction that includes increased production of powerful, paracrine mediators such as eicosanoids and nitric oxide (NO). NO can modulate the activity of cyclooxygenase (COX), an enzyme that produces one class of eicosanoids, prostaglandins. For such interactions to be of potential importance to CNS function, COX and NO synthase (NOS) enzymes should be regionally co-localized since diffusion distances for products of these enzymes is relatively small. Accordingly, we have begun to characterize the regional distribution of constitutive (COX1) and inducible (COX2) cyclooxygenase compared to neuronal NOS (gift from H. Schmidt, Medizinische Universitatsklinik; Wurzburg, Germany) using immunohistochemistry.

COX1 data was derived from sheep[1] and COX2[2] from rat. Blocking studies established the specificity of staining. Within neocortex, COX1 showed a dense localization to granular and infragranular cells; COX2 was densely localized to supragranular cells; and nNOS was sporadically localized to infragranular cells with many fine fibers being stained. Within allocortex, COX1 was densely localized to cells of layer 3&5 and COX2 to cells of layers 2,3,&5. In this same area, nNOS immunoreactive cells were seen in infragranular layers. Fibers positive for nNOS were densely packed in a putative terminal field in layer 2 of the agranular insular cortex and dorsolateral entorhinal cortex, a region where many COX2 cells were seen. Similar regional co-localizations of COX isoforms and nNOS were seen in hippocampus and amygdala.

These studies show that COX isoforms and nNOS co-localize to similar brain regions of cortex. Thus, products from these enzymes conceivably could interact in the CNS. Furthermore, since co-localization of these enzymes is seen in resting brain, such interactions may be an important component of normal brain function. 1. Breder, et al. **J. Comp. Neurol.**, 1993. 2. Breder et al., **J. Comp. Neurol.**, 1995.

FIVE-LIPOXYGENASE AND ITS ACTIVATING PROTEIN (FLAP) ARE EXPRESSED IN HIPPOCAMPAL NEURONS AND REQUIRED FOR SOMATOSTATIN SIGNALING. P. Schweitzer*, C.-H. Lammers[1], S.G. Madamba, G.R. Siggins and D. Piomelli[2]. Neuropharmacology, The Scripps Research Inst., La Jolla, CA 92037, [1]Max-Planck-Inst. of Psychiatry, Munich, Germany, [2]The Neuroscience Institute, San Diego, CA 92121.

The 5-lipoxygenase activating protein (FLAP) is required, in peripheral cells, for the activation of 5-lipoxygenase (5-LO) and for the resulting synthesis of leukotrienes from arachidonic acid. In the brain, leukotrienes have been implicated in several pathophysiological events and in the electrophysiological effect of somatostatin (SST) on CA1 hippocampal neurons, where the neuropeptide enhances the voltage-dependent K^+ current $I_{K(M)}$. Yet, the cellular origin and role of these messengers are still poorly understood. Therefore, we localized 5-LO and FLAP mRNA in rat brain by *in situ* hybridization and found the highest labeling densities in hippocampus and cerebellum where 5-LO and FLAP appeared to overlap. Immunostaining experiments showed that FLAP protein was associated with pyramidal neurons of CA1 to CA3 and with dentate granule cells. Moreover, most neurons in the CA1 pyramidal cell layer showed both FLAP immunostaining and 5-LO hybridization signals, confirming the co-localization of 5-LO and FLAP. Electrophysiological studies using intracellular voltage-clamp recordings in the rat hippocampal slice preparation showed that the ability of SST to augment $I_{K(M)}$ in CA1 neurons was prevented by treatment with MK-886, a potent and selective FLAP inhibitor. Leukotriene C4 overcame the blocking effect of MK-886 on $I_{K(M)}$ augmentation by SST. Furthermore, we characterized a second effect of SST that involved activation of a voltage-insensitive K^+ conductance different from $I_{K(M)}$. Our results provide strong evidence for the presence and signaling role of 5-LO and FLAP in central neurons and support a participation of the 5-LO pathway in the SST receptor transmembrane regulation of $I_{K(M)}$.

***IN VITRO* ACTIVATION OF *LIMULUS* BRAIN AND CARDIAC PROTEIN KINASE C BY PHORBOL ESTERS AND ARACHIDONIC ACID: DEPENDENCE ON CALCIUM AND PHOSPHOLIPID.** Byron D. Ford*, Easton A. Reid and James G. Townsel. Department of Physiology, Meharry Medical College, Nashville, Tennessee 37208

Protein kinase C (PKC) is a multifunctional serine/threonine phosphorylating enzyme and plays an important role in numerous cellular functions. Twelve isoforms of PKC have been identified in mammalian tissues by molecular cloning. The isoforms are grouped into three subtypes based on co-factor requirements for activation. The activation of conventional PKC's (cPKC's) requires calcium, phosphatidylserine (PS) and diacylglycerol (DAG). Novel PKC's (nPKC's) require PS and DAG but are calcium independent. Phorbol esters (PE) can substitute for DAG in the activation of both cPKC's and nPKC's. Atypical PKC's (aPKC's) are not activated by calcium, DAG or PE but by PS and unsaturated fatty acids. Our laboratory has previously reported the presence of seven PKC isoforms in *Limulus* cardiac and neuronal tissues (Ford *et al.*, Biochem. and Biophys. Res. Comm., 1995). In addition, data from our laboratory and others have suggested a possible role for multiple PKC subtypes in the regulation of choline uptake (Saltarelli *et al.*, J. Neurosci., 1990; Ford and Townsel, Soc. Neurosci. Abs., 1994). This study demonstrates the presence of multiple PKC subtypes in *Limulus* brain and cardiac tissues based on co-factor requirements of PKC activity. The phorbol esters PMA and PDBu were both shown to activate PKC in brain and cardiac extracts. Arachidonic acid (AA) also activated PKC in both tissues. PE and AA stimulated PKC activities were additive. PE stimulated PKC activity was partially inhibited in the absence of calcium while AA stimulated PKC activity was calcium independent. Kinase activation by both PE and AA required the presence of PS. These results will aid in the elucidation of the specific roles of PKC subtypes in choline uptake. This project was supported in part by NSF grant HRD-9106096, DOE P200-A40516 and NIH grants GM08037, RR03032 and MH 19843.

LIPID METABOLISM MODIFICATION IN THE HUMAN NEUROBLASTOMA SK-N-BE DIFFERENTIATED WITH RETINOIC ACID. A.Petroni*, N. Papini, P.La Spada, M.Blasevich, and C.Galli.Institute of Pharmacological Sciences, University of Milan, via Balzaretti 9, 20133, Milan, Italy.

We have studied the effect of retinoic acid (RA) in the human neuroblastoma SK-N-BE. RA, an analogue of vitamin A, has been shown to inhibit cell growth, to change the morphology of neuroblastoma cells. RA is also an activator of peroxisome function and is possibly involved in the control of lipid homeostasis.

To investigate the degree of cell differentiation and the inhibition of cell growth by RA we have measured neurite outgrowth and labeled timidine incorporation. We have evaluate if RA could also modify lipid metabolism in SK-N-BE.The following parameters have been investigate : the fatty acids (FA) composition of cell lipids, the conversion of labeled linoleic acid (LA) to longer chain FA, the incorporation of [3H]glycerol in all major lipid classes. All the indicated parameters were evaluated in undifferentiated and RA-differentiated SK-N-BE at different time periods. RA was incubated at the concentratio 10 µM. Undifferentiated and differentiated cells were incubated with labeled LA (0.5 µCi/dish,18 hours)or glycerol (1 µCi/dish,24 hours). The cells were scraped and extracted, FA composition was evaluated by GLC. Extracted of LA labeled metabolites were injected in HPLC connected with a radiodetector on line. FA of the n-6 series: arachidonic acid and 22:4 increased, also 22:5 and 22:6 of the n-3 series was increased. The conversion of LA was enhanced at 24 hours than after 7 day differentiation. Glycerol incorporation into the main lipid classes differed according to the different incubation periods. After treatment with RA neurite outgrowth was markedly enhanced and cell growth inhibited. Our data indicate a certain modification of lipid parameters, the molecular mechanism involved in RA-differentiation will be investigated.

LYSOPHOSPHATIDIC ACID IS A PUTATIVE MESSENGER IN NEURONS. R. Diaz-Arrastia*, and E. Hashemi, Dept. of Neurology, University of Texas Southwestern Medical School, Dallas, TX 75235.

Lysophosphatidic acid (LPA) is a messenger molecule which has potent effects in a number of cell types, including neurons. Because LPA is relatively water soluble, it can diffuse from the site of production to neighboring cells, and may play a role during synaptic plasticity and in the response of neurons to injury. We have found that (1) mammalian brain contains a PLA_2 activity which preferentially hydrolyses phosphatidic acid (PA) to form LPA; (2) cultured neural cells produce LPA in response to activation of cell-surface receptors; and (3) exogenously added LPA potentiates cell death induced by glutamate in an *in-vitro* model of excitotoxicity. PA-specific PLA_2 was identified in membranes prepared from rat brain. The enzyme was solubilized using 1% cholate and 1 M KCl, and enriched several hundred-fold by gel filtration, anion-exchange, and hydroxylapatite chromatography. The enzyme does not require Ca^{2+} for activity and while selective for phospholipid polar head groups, does not discriminate between phosphatidates with different acyl chains in the *sn*-2 position. [^{3}H]-LPA production was measured in NG108-15 neuroblastoma x glioma cells which had been labelled with [^{3}H]-palmitate. Treatment of cells with ATP or thrombin resulted in 3 - 5 fold increase in levels of [^{3}H]-LPA, an effect which was mimicked by phorbol esters. There was a parallel but quantitatively greater production of [^{3}H]-PA in response to activators. Finally, the effect of exogenously added LPA on excitotoxicity was studied in cultures of NT2-N neurons which had been terminally differentiated by exposure to retinoic acid. Addition of 1 µM LPA increased tha amount of LDH released into the medium induced by subthreshold doses of glutamate (100 µM). These results suggest that LPA is a messenger in neurons which may play a role in excitotoxicity.

ECLOSION HORMONE STIMULATES THE PRODUCTION OF CMP-PA WITH LITTLE CHANGE IN DAG LEVELS. P. J. Simpson* and D. B. Morton
ARL Division of Neurobiology and the Department of Biochemistry, University of Arizona, Tucson, AZ, 85721

Eclosion hormone (EH) is a 62 amino acid neuropeptide which triggers ecdysis behavior at the end of each molt in the tobacco hornworm, *Manduca sexta*. Stimulation of this behavior by EH is mediated by a rise in cGMP in the central nervous system prior to ecdysis. Previous work in this laboratory indicates that this rise is due to activation of a soluble guanylate cyclase (GC), perhaps through the interaction of GC with a lipid messenger. GC activation is not associated with nitric oxide (NO) production, but is blocked by a number of inhibitors of lipid metabolism, such as phospholipase C, phospholipase A_2, diacylglycerol lipase, and lipoxygenase blockers.

This study examines the action of EH on a variety of lipids in the CNS. Previous studies have shown that EH stimulates the production of inositol trisphosphate in the nervous system. Here we show that there is no, or little, evidence for a parallel increase in the levels of diacylglycerol in response to EH. There is, however, an increase in the levels of cytidine monophosphate-phosphatidic acid (CMP-PA). CMP-PA is produced downstream of DAG as part of the inositol recycling pathway. This increase is similar in both time course and EH sensitivity to the increase in cGMP and is blocked by many of the same inhibitors that block the EH-stimulated increase in cGMP.

Additionally, the fates of several other phospholipids were examined in response to EH. These phospholipids include phosphatidic acid and phosphatidylinositol as well as the major membrane phospholipids; phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. Preliminary evidence suggests that exposure of the CNS to EH results in a decrease in the incorporation of [^{32}P]-PO_4 in a number of these phospholipid species.

DEOXYCORTICOSTERONE INCREASES NEUROPEPTIDE-mRNA LEVELS IN THE STRIATUM L. R. Lucas*†, J. A. Angulo††, and B. S. McEwen† †Lab of Neuroendocrinology, Rockefeller University and ††Dept of Biological Sciences, Hunter College CUNY, New York, NY 10021

Glucocorticoids have been shown to increase tachykinin- and enkephalin-mRNA levels in the striatum of adrenalectomized rats [Chao and McEwen (1991) Mol. Brain Res., 9, 307-311]. To investigate the effects of Type I or mineralocorticoid activation on striatal neuropeptide mRNA levels, we administered deoxycorticosterone (DOCA), an adrenal steroid with higher affinity for Type I receptors, to adrenalectomized (ADX) animals. Adult male rats were either sham operated or ADXed. After one week recovery, animals were either injected with sesame oil, corticosterone (CORT, 0.5mg/kg), or DOCA (5mg/kg), s.c., daily for 3 or 7 days and sacrificed 18h after the last injection. Neuropeptide-mRNA levels in the striatum were determined by high-resolution *in situ* hybridization histochemistry with ^{35}S-labelled riboprobes on 20μm thick coronal brain cryostat sections. After stringent washing and drying, sections were dipped in NTB-2 photographic emulsion (Kodak) and exposed for 1 to 2 weeks. Reduced silver grains were observed over mRNA-positive cells and grains per cell were quantified with the help of a computer-assisted image analysis system. Enkephalin (ENK)-mRNA levels were 128% higher in ADX + CORT ($p<0.001$) and 81% higher in ADX + DOCA ($p<0.01$) compared to 3 day sham treated rats. There were no significant differences in tachykinin-mRNA levels after 3 days or ENK-mRNA levels after 7 days. From these results we conclude that CORT and DOCA have similar effects on striatal ENK-mRNA levels. Whether CORT and DOCA bind to their cognate receptors or whether glucocorticoid receptors are occupied by DOCA in ADXed animals to effect increases in striatal ENK-mRNA levels remains to be determined.

PROLACTIN (PRL) INCREASES TYROSINE HYDROXYLASE (TH) ACTIVITY IN FETAL HYPOTHALAMIC CELLS. L. A. Arbogast* and J. L. Voogt, Dept. of Physiology, University of Kansas Medical Center, Kansas City, KS 66160-7401

A short loop feedback mechanism provides the main control of PRL secretion *in vivo*. The tuberoinfundibular dopaminergic neurons are a site for PRL feedback, such that high circulating PRL levels increase the synthesis and secretion of dopamine, the major PRL inhibiting hormone. TH is the rate-limiting enzyme in the dopaminergic biosynthetic pathway and thus a key control point. However, studies on intracellular mechanisms for PRL's action have been hampered by the lack of an *in vitro* model. The aims of this study were: 1) to evaluate media composition on the ability of PRL to increase TH activity *in vitro* and 2) to establish time and concentration dependency for PRL action on TH activity. Ventral hypothalamic cells of fetal day 19-20 rats were dispersed with trypsin and plated at 200,000 cells/well and maintained for 10 days. TH activity was determined by incubating cells for 1 hour with 100 μM brocresine, a dihydroxyphenylalanine (DOPA) decarboxylase inhibitor, and measuring DOPA accumulation in the medium. Exp 1: Hypothalamic cells were incubated for 10 days in either a serum-free defined or a serum (5% fetal bovine serum)-containing medium with either low (5 mM) or high (25 mM) potassium (K^+) concentrations. Rat PRL was included in some wells for the 10 days *in vitro*. PRL did not alter TH activity in serum-free medium with either low or high K^+ or in serum-containing medium with low K^+. However, TH activity was significantly increased to 162%, 177% or 172% of control values after 10 days of rPRL-treatment (10, 100 or 1000 ng/ml, respectively). Exp 2: Hypothalamic cells were treated with rPRL (100 ng/ml) for various times. TH activity was not altered by 1, 6 or 12 hours of PRL-treatment, but was increased to 140-145% of control values after 1-3 days, and further increased to 180-185% after 5-10 days. Conclusions: 1) A factor present in fetal bovine serum imparts PRL responsiveness to hypothalamic dopamine neurons *in vitro*. 2) The 24 hour delay for TH responsiveness to PRL to be expressed *in vitro* is similar to the time course *in vivo*. 3) The effective PRL concentrations are within the physiological range of circulating PRL levels *in vivo*. Supported by NIH grant HD24190.

733.3

MU OPIOID RECEPTOR-LIKE IMMUNOREACTIVITY IN THE RAT MEDIAN EMINENCE : DISTRIBUTION AND PLASTICITY IN EXPRESSION. P. Ciofi*[a], F. Vandenbulcke[a], S. Dutoit[a], D. Deneux[a], A. Mansour[b], S.J. Watson[b], G. Tramu[c] and J.C. Beauvillain[a]. [a]U422 INSERM, Place de Verdun, 59045 Lille (France); [b]Mental Health Res. Inst., Univ. Michigan, Ann Arbor, MI 48109; [c]Lab. Neurocyto. Fonct., URA CNRS 339, Univ. Bordeaux I, 33405 Talence (France).

Opioid peptides (OP) are thought to regulate adenohypophysial functions indirectly through hypothalamic circuitry rather than by a direct action at the gland itself. The presence of OP in neuroendocrine terminals (NT) of the median eminence (ME) suggests OP modulate the neurohumoral output via autocrine/paracrine mechanisms. In line with this, we studied the distribution of the mu-receptor in the ME of the adult male rat using an affinity purified antiserum directed at the C-t of the recently cloned rat sequence (Mol. Pharmacol. 44:8; Neuron 11:903; PNAS 90:10230).

Immunocytochemical single or double staining techniques at the light microscopic (fluorescence) or ultrastructural (DAB/peroxidase-colloidal gold combination) levels allowed us to ascribe the ME mu-immunoreactivity (ir) to the gonadoliberin (GnRH)ergic endings, the corticoliberin (CRF)ergic endings and the tanycytes. At the ultrastructural level, after DAB/peroxidase pre-embbeding staining, mu-ir in NT was observed : in dense core vesicles, in the form of sub-membrane patches or in the form of restricted as well as extended thickenings of the membrane, with no strict polarity respectively to the pericapillary space. Mu-ir NT were seen apposed to other NT or to tanycytic processes. In the tanycytes, mu-ir was observed in the form of intracytoplasmic or sub-membrane patches as well as invading spine-like processes.

Orchidectomy and adrenalectomy each resulted in a marked decrease in mu-ir of GnRH and CRF endings, respectively.

These results (1) strenghten the concept of opiatergic autocriny and paracriny in the ME : the GnRH axis do not contain OP while the CRF axis contain enkephalins, and (2) have to be paralleled with the known inhibitory and stimulatory effects of OP on GnRH and CRF axes, respectively.

CHOLECYSTOKININ (CCK) INDUCES cFOS EXPRESSION IN BRAINSTEM CATECHOLAMINE CONTAINING NEURONS OF THE RHESUS MONKEY DA Schreihofer*, L Rinaman, JL Cameron, GE Hoffman, JG Verbalis Depts of Neuroscience, Psychiatry, Cell Biology and Physiology, Neurobiology, and Medicine, University of Pittsburgh, Pittsburgh, PA 15260

In monkeys and other species, systemically administered CCK stimulates the release of many pituitary hormones. In rats, the release of oxytocin and ACTH appear to be mediated by CCK-induced activation of vagal afferents that, in turn, activate medullary projections from the nucleus tractus solatarius (NTS) and ventrolateral medulla (VLM) to the hypothalamus. The current study examined the hypothesis that CCK activates similar ascending pathways in adult male rhesus monkeys. Monkeys were given CCK (3 or 15μg/kg iv; n=3 and 2, respectively) or saline vehicle (n=2). Two additional bilaterally vagotomized animals were treated with 15μg/kg CCK. Seventy five minutes after the infusion of CCK, monkeys were deeply anesthetized and perfused with 4% paraformaldehyde. Every sixth section (30μm) through the NTS was processed for immunocytochemical detection of the immediate early gene product cFos as a marker of neuronal activation. Because CCK activates catecholamine neurons that project to the hypothalamus in rats, sections were also stained for tyrosine hydroxylase (TH). Very few cFos positive neurons were present in tissue sections from control animals. In contrast, numerous cFos positive neurons were visualized in the NTS and VLM of monkeys treated with both doses of CCK, and many of the activated neurons were catecholaminergic (TH positive). Vagotomy virtually eliminated CCK-induced cFos expression in the NTS and VLM. These results indicate that CCK activates medullary neurons in the monkey, including many catecholaminergic neurons in the NTS and VLM, and that this activation depends on vagal afferents. These results are consistent with previous studies in rats and suggest common mechanisms of CCK action across these species.

SEXUAL DIFFERENCES IN THE CIRCADIAN CHANGES OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURON ACTIVITY IN THE RAT: THE ROLE OF THE CHOLINERGIC CONTROL. K.R. Shieh, S.H.H. Chan and J.T. Pan, Inst. Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan R.O.C.

We recently reported that a circadian change of the tuberoinfundibular dopaminergic (TIDA) neuron activity exists in ovariectomized rats treated with or without estrogen (1), and the endogenous cholinergic system is responsible for its induction (2). Whether a similar rhythm exists in intact female or male rats was the focus of this study. In intact female Sprague-Dawley rats, rhythmic changes in TIDA neuron activity were observed during all stages of the estrous cycle, i.e., proestrus, estrus or diestrus I, and they were nearly identical. No such rhythm, however, was observed in intact or castrated male rats treated with or without estrogen. Central administration of mecamylamine (1 μg/3 μl/rat, icv), a nicotinic receptor antagonist, had no effect on the TIDA neuron activity in intact male rats, no matter it was given in the morning or in the afternoon. It appears that the circadian rhythm of TIDA neuron activity is sexual dimorphic, and may under a differential control by the cholinergic system.

VASOACTIVE INTESTINAL PEPTIDE ANTAGONIST ATTENUATES THE NOCTURNAL PROLACTIN SURGE OF PREGNANCY. K. M. Humpherys, L. A. Arbogast, J. D. Radel* and J. L. Voogt, Department of Physiology, University of Kansas Medical Center, Kansas City, KS 66160-7401.

Nocturnal and diurnal prolactin (PRL) surges occur during the first half of pregnancy in the rat. The PRL surges are circadian in nature and the suprachiasmatic nucleus (SCN) serves as a neural locus for generating the surges. Vasoactive intestinal peptide (VIP) is found in the SCN and has been implicated in the control of PRL release. However, the role of VIP in generating the nocturnal PRL surges during pregnancy is unclear. The aims of this study were: 1) to compare the effects of two different VIP antagonists on the nocturnal PRL surge and 2) to assess the dose response relationship of the more potent antagonist. Exp. 1: Female rats received jugular vein cannulas on day six of pregnancy. On day seven, the experimental rats were infused continuously with [p-Chloro-D-Phe^6, Leu^{17}]-VIP antagonist (0.1 μg/kg-min) between 2200 h and 0700 h. Control rats were infused with saline. Serial blood samples were obtained immediately before infusion and hourly thereafter. Circulating PRL levels during the nocturnal surge in control and VIP antagonist treated pregnant rats were similar at all times examined. Exp. 2: A neurotensin/VIP hybrid, which is a more potent VIP antagonist without VIP agonist activity, was examined at three different doses (0.001, 0.01, and 0.1 μg/kg-min) repeating the protocol described above. In control rats serum PRL levels were low (1-10 ng/ml) between 2200 h and 0100 h, were elevated to 200-300 ng/ml during the peak of the nocturnal PRL surge at 0200 h to 0400 h, and then declined between 0500 h and 0700 h. The groups with the antagonist doses of 0.001 and 0.01 μg/kg-min had plasma PRL levels similar to the control group. In contrast, circulating PRL levels were reduced in the group receiving the dose of 0.1 μg/kg-min by 83%, 74%, 50% and 43% at 0100, 0200, 0300, and 0400 h, respectively. In conclusion, the more potent VIP antagonist attenuated the nocturnal PRL surge of pregnancy suggesting that VIP plays a positive role in generating the surge. Supported by NIH Grant HD24190.

FOS EXPRESSION IN THE NTS AFTER HYPERTENSIVE STIMULI BUT NOT CCK INJECTIONS CORRESPONDS TO AREAS RETROGRADELY LABELED FROM THE VLM. R.G. Mayne*[1], S.L. Bealer[2], W.R. Crowley[3] and W.E. Armstrong[1]. Depts. of [1]Anat.& Neurobiol., [2]Physiol. & Biophys., and [3]Pharmacol.; Univ. Tenn., Memphis, TN 38163.

Most visceral inputs make their first synapses within the nucleus tractus solitarii (NTS) where information is then relayed to other brain regions that regulate autonomic and neuroendocrine responses. Hypertension and gastric stimuli elicit Fos expression in functionally distinct regions of the NTS and in overlapping regions of the ventrolateral medulla (VLM) of rats. Fos-like immunoreactivity (FLI) and retrograde tracing were used to determine if the NTS neurons that respond to phenylephrine-induced hypertension or stimulation from cholecystokinin (CCK) project to the VLM.

Male rats were injected with either Rhodamine-labeled beads or Fluoro-Gold unilaterally into the VLM and allowed to survive one week. Then these rats were either made hypertensive (30-40 mm Hg over baseline) by constant intravenous infusion of phenylephrine (5-10 µg/kg/min for 90 mins) or received an injection of CCK (100 µg/kg, i.p.). Tissue sections were then processed for FLI.

Retrogradely labeled somata were distributed in the NTS similar to hypertension-induced FLI but were distinct from neurons expressing Fos after CCK injection. Hypertensive stimuli elicited FLI in the dorsal part of the commissural NTS caudal to area postrema, overlapping the distribution of retrogradely labeled neurons. In contrast, after CCK injection FLI was scattered throughout the commissural NTS caudal to the area postrema. At the level of the area postrema, the majority of Fos-labeled neurons after hypertension were in the dorsolateral and medial subnuclei. Retrograde labeling was present in the dorsolateral and sparsely in the medial subnuclei, but not in the commissural NTS at this level. After CCK, FLI was present primarily in the commissural nucleus, the medial subnucleus, and area postrema at this level. These results show that NTS neurons responding to hypertension but not CCK overlap with a population of neurons that project to the VLM. NADPH-DIAPHORASE ACTIVITY AND FOS EXPRESSION IN BRAIN NUCLEI FOLLOWING NITROGLYCERIN ADMINISTRATION. Cristina Tassorelli* and Shirley A. Joseph. Department of Surgery, Division of Neurological Surgery, University of Rochester Medical Center, Rochester, NY 14642 and *Department of Neurology "C. Mondino" Foundation, University of Pavia, I 27100.

Organic nitrates are considered nitric oxide (NO) donors since they have been shown to form NO *in vitro* and *in vivo*. Nitroglycerin (NTG) is an organic nitrate which possesses several centrally-mediated effects, some of which have been shown to be influenced by the noradrenergic system. Recently it has been demonstrated that NTG can directly influence the electrical activity of neurons in the nucleus tractus solitarius, probably by way of the local release of NO. In a previous report we have shown that systemic NTG is able to induce Fos expression in brain nuclei which are known to contain also the NO synthesizing enzyme (NOS). Neuronal NADPH-diaphorase (NADPH-d) has been shown to be a NOS. In this study NADPH-d histochemistry was used to evaluate the distribution of the neurons which express Fos following the systemic administration of NTG within the pool of neurons which contain the NOS.

These data demonstrate that Fos was significantly co-localized with NADPH-d activity in specific subsets of neurons in the paraventricular and supraoptic nuclei of the hypothalamus. Only a few neurons were double labeled for Fos and NADPH-d activity in the brainstem, but NADPH-d positive fibers were found consistently co-distributed with Fos immunoreactive neurons in the locus coeruleus, parabrachial nucleus, nucleus tractus solitarius and spinal trigeminal nucleus caudalis.

These findings demonstrate that NTG administration activates a selective group of neurons which are a source of NO or which are in close proximity with neuronal processes containing NOS and suggest a possible involvement of NO as a mediator of the central effect of NTG. ALPHA-2 ADRENOCEPTORS MODULATE HYPOTHALAMIC FOS-LIKE IMMUNOREACTIVITY IN THE CONSCIOUS SUCKLED RAT.

Bailey, A.R.T., Clarke, G.[1], Russell, J.A*. and Tolchard, S[1].
Department of Physiology, University of Edinburgh, Edinburgh. EH8 9AG. U.K.
[1] Department of Anatomy, University of Bristol, Bristol. BS8 ITD. U.K.

The supraoptic nucleus (SON) has a high density of alpha-2 adrenoceptors and previous studies have indicated a role for these receptors in controlling the activity of SON neurones in the anaesthetised suckled rat. To investigate the role of alpha-2 adrenoceptor mediated transmission in the unanaesthetised animal we have examined the effects of a systemically administered alpha-2 adrenoceptor agonist, clonidine and an antagonist, idazoxan, on SON Fos-like immunoreactivity (Fos-LI) in the conscious suckled rat. Lactating Wistar rats, chronically implanted with an intravenous catheter, were separated from their litter for two hours which was then weighed. The mothers were then given an intravenous injection of either clonidine (50µg/kg, n=7), idazoxan (0.5mg/kg, n=6) or saline (0.2ml, n=7). The pups were returned and maternal behaviour recorded for 90 minutes then the litters were reweighed. Rats were then killed and brain sections immunocytochemically processed for Fos-LI. Saline-treated animals had a mean litter weight gain of 7.9±1.4g and displayed 7.9±0.8 milk-ejections in 90 minute. Fos-LI was observed in the SON of all saline-treated rats (99.9±4.9 cells/section). Clonidine reduced both litter weight gain (5.8±1.4g) and milk-ejection number (5.1±1.1) and SON Fos-LI was also significantly reduced compared to saline-treated controls (19.4±2.7 cells/section, P<0.01 Mann Whitney U-test). Idazoxan also decreased litter weight gain (4.2±0.5g) and milk-ejection number (4.0±1.4) in addition to reducing Fos-LI in the SON (30.9±2.8 cells/section, P<0.05 Mann Whitney U-test). These results indicate that activation of neurones in the SON can be attenuated by systemic injection of clonidine and idazoxan providing evidence for the involvement of alpha-2 adrenoceptors in the control of SON neuronal activity in the conscious lactating rat.

EFFECTS OF ACUTE AND CHRONIC HALOPERIDOL TREATMENT ON MELATONIN SYNTHESIS IN RAT PINEAL GLAND. L. Steardo*, P. Monteleone+, M. Persichella, M. Mazzoccoli, A. Attanasio and V. Cuomo. Dept. of Pharmacology, Universitary Medical School, Bari (Italy). +Dept. of Psychiatry, Universitary Medical School, Naples (Italy).

The nocturnal production of melatonin by the mammalian pineal gland occurs in response to noradrenergic stimulation. It is well established that noradrenaline (NA) acting on a β_1 receptor, and to a lesser extent on a α_1 receptor, activates the rate-limiting enzyme serotonin-N-acetyltransferase (NAT). However, recent data indicate that receptors others than NA can play an important modulatory role in the process of melatonin production. Preliminary evidence from in vitro studies has been provided suggesting that dopamine (DA) may affect melatonin synthesis in rats. To characterize the precise role of this cathecolamine on the physiological activity of the rat pineal gland, the authors have investigated the effects of acute and chronic administration of haloperidol (1mg/kg, i.p.) on the nocturnal NAT activity and melatonin pineal content.

Results have shown that, as compared to saline, both acute and chronic haloperidol treatment significantly antagonized the nocturnal increase of pineal NAT activity ($p < 0.0005$ for the acute experiment, and $p < 0.001$ for the chronic one) and melatonin levels ($p < 0.001$ for both acute and chronic experiments).

Therefore, the present data support the view that DA partecipates to the complex mechanisms which regulate the physiological production of melatonin in the rat pineal gland.

VAGINOCERVICAL STIMULATION INDUCES C-FOS

R Guevara-Guzmán*, G A Donatti-Albarrán and M L Weiss+, Dept de Fisiologia, Facultad de Medicina, UNAM ; Department of Anatomy and Physiology, Kansas State University, Manhattan, Kansas+

It has been published that vagino-cervical stimulation (VCS), induces reproductive behaviors in female animals. In the present study, we investigated the effect of VCS to induce Fos in different brain nuclei in the female albino rat. For one week, the animals were familiarized with the investigator, then the animals were placed in a special box and a Foley catheter was inserted into the vagina until the tip reached the cervix. 0.5-0.8 ml of room temperature water was infused into the balloon and it remained distended for 5-20 min. In the control group, the catheter was inserted but not distended for the same period of time. The animals were allowed to survive for a 60 min after VCS was completed. Then, the animals were deeply anaesthetized and perfused with 0.9% NaCl solution followed by 500 ml of 4% paraformaldehyde. Fos immunoreactivity in the nuclei of neurons (Fos labelled cells) was visualized by conventional ABC immunohistochemistry using DAB dehydrochloride as the chromogen agent. Fos-like immunoreactivity was induced differentially depending upon the duration of the VCS. The nuclei mainly labelled were: lateral septal, mPOA, diagonal band of Broca, BNST, VMH, medial amygdala, paratenial thalamus, paraventricular thalamus, lateral central gray. Control animals showed the same labelling pattern as the animals which received VCS for 5-10 min. On the contrary the group of 15 min up of VCS shown a higher amount of labell cells. In contrast, animals which received greater than 15 min of VCS had more labelled cells. The animal that in diestrus-proestrus had more labelled cells than those in diestrus. These results have important implications concerning the neural mechanisms involved in the control of female sexual behavior.

DOPAMINERGIC ANTAGONISTS ENHANCED THE NEUROSTEROID-INDUCED MODULATION OF THE NMDA-EVOKED [^{3}H]NE OVERFLOW IN THE RAT HIPPOCAMPUS. F. Villemain*, F.P. Monnet & E.E. Baulieu, DRC-DPIM AP-HP, CNRS-UPR2212 & INSERM-U33, F-94276 Kremlin Bicêtre, France.

We have recently shown that both dehydroepiandrosterone sulfate (DHEAS) and pregnenolone sulfate (PREGS) potentiated and reduced, respectively, concentration-dependently the *N*-methyl-D-aspartate(NMDA)-evoked [^{3}H]norepinephrine ([^{3}H]NE) overflow from preloaded hippocampal slices of spayed rats. While haloperidol, via acting on sigma sites antagonized both DHEAS- and PREGS-induced modulations of the NMDA response, spiperone, another butyrophenone with low affinity for sigma sites enhanced the neurosteroid-mediated responses. Spiperone, like haloperidol, binds to dopaminergic, serotoninergic and cholinergic sites. The present experiments were thus carried out to determine the nature of the effect of spiperone on neurosteroid-induced modulation of the NMDA response in the *in vitro* release model by measuring actions of various (non)selective ligands for these sites. Hippocampal slices from spayed Sprague-Dawley rats were incubated with 0.1 µmol/l [^{3}H]NE for 30 min and superfused continuously with Mg^{++}-free Krebs'solution containing PREGS or DHEAS in the presence or absence of the following antipsychotics: haloperidol, chlorpromazine, sulpiride as well as ritanserine and atropine. 40 min later, the [^{3}H]NE overflow was evoked by NMDA (200 µM). In the presence of the D_2 dopaminergic antagonists sulpiride and chlorpromazine, PREGS (300 nM) failed to reduce, whereas DHEAS (300 nM) further potentiated the NMDA-evoked [^{3}H]NE overflow. Conversely, ritanserine and atropine, devoid of affinity for dopaminergic sites, were ineffective in modifying both DHEAS- and PREGS-induced modulation of the NMDA response. The present results constitute the first evidence supporting the notion that neurosteroids, such as DHEAS and PREGS, interact with central monoaminergic neurotransmission and support the notion that neurosteroids may constitute relevant probes for neuropsychiatric diseases.

SERUM PREVENTS STELLATION OF CULTURED PITUICYTES INDUCED BY CYCLIC NUCLEOTIDE. K.D. Ramsell* and P. Cobbett. Dept. Pharmacol./Toxicol. and Neuroscience Program, Michigan State Univ., E. Lansing, MI 48824.

Pituicytes (neurohypophysial astroglia) from adult rats exhibit morphological changes when intracellular cAMP is raised by activation of adenylate cyclase (Ramsell & Cobbett, Soc. Neurosci. Abstr.:**20**,96,1994). Since a component of serum, lysophosphatidic acid, reverses β-adrenoreceptor mediated stellation of rat C6 glioma cells (Koschel & Tas, Exp. Cell Res.: **206**,162-166,1993), we have investigated the effects of newborn calf serum (NCS) on cAMP mediated stellation of cultured pituicytes. The fraction of stellate pituicytes was significantly increased when cultures were incubated in medium containing forskolin (5μM, 0.94±0.01) compared to that seen in control medium (0.06±0.01). The effect of forskolin was significantly reduced when 0.5% NCS was also included in the incubation medium. NCS also blocked stellation induced by the phosphodiesterase inhibitor IBMX (50μM) and by 8bromo-cAMP (100μM). These data indicate that serum prevents stellation of pituicytes by a mechanism independent of intracellular cAMP concentration. Supported by NINDS (NS28206).

733.14

CHARACTERIZATION AND EXPRESSION OF LOBSTER PREPROHORMONES INVOLVED IN METABOLISM, MOLTING AND REPRODUCTION Dominique P.V. De Kleijn[1,3], Susan L. Waddy[2], Gerard J.M. Martens[1], Ronald Verwer[3]* and François Van Herp[1]. 1 Department of Animal Physiology, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands. 2 Invertebrate Fisheries Section, Biological Station, St Andrews, New Brunswick, Canada E0G 2X0. 3 Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam

The crustacean hyperglycemic hormones (CHH-A and -B) are primarily involved in the regulation of carbohydrate metabolism while the gonad-inhibiting hormone (GIH), inhibits vitellogenesis and belong to a new neuropeptide family. In order to get more information on the synthesis, storage, release and possible function(s) of CHH-A, CHH-B and GIH during the reproductive cycle, we measured the levels of their mRNAs in the X-organ, their peptide storage in the neurohemal organ and their hemolymph peptide levels at different stages of the female reproductive cycle. For CHH, a high CHH-A mRNA level was found at the previtellogenic stage while CHH-B mRNA levels were higher in the mature as well as in the previtellogenesis stages when compared to the other stages. During previtellogenesis, high storage levels for both CHHs were found in the sinus gland. In the hemolymph, the total amount of CHH (CHH-A plus -B) was high only during maturation. For GIH, a low level of mRNA in the X-Organ and a low amount of the GIH-I isoform in the sinus gland were found only in the immature stage. In contrast, GIH hemolymph levels were high during the immature and previtellogenic stages. Together, we conclude that CHH-A and -B are probably involved in triggering the onset of vitellogenesis and especially CHH-B seems to be responsible for stimulating oocyte maturation before spawning, while GIH prevents the start of vitellogenesis in the ovary. Moreover, the balance between the hemolymph levels of CHHs and GIH may regulate the synchronization of reproduction and molting during the bi-annual reproductive cycle of the American lobster.

733.15

CALCIUM ENTRY FROM EXTRACELLULAR FLUID IS NOT REQUIRED FOR PROLONGED HORMONE SECRETION FROM *APLYSIA* NEUROENDOCRINE CELLS. N. L. Wayne*, Dept. Physiology, UCLA School of Medicine, Los Angeles, CA 90024.

In most neurosecretory systems investigated, membrane depolarization opens voltage-gated calcium channels and Ca^{++} enters the cell from extracellular fluid, stimulating exocytosis of secretory granule contents. This does not seem to be the case for neuroendocrine bag cells of *Aplysia* that secrete the peptide hormone egg-laying hormone (ELH). Recently we have shown that once a bag-cell electrical afterdischarge is initiated, Ca^{++} influx is not required for prolonged ELH secretion (Wayne and Frumovitz, 1995). However, it is possible that brief Ca^{++} entry during the afterdischarge triggers prolonged Ca^{++} release from intracellular stores, thereby stimulating prolonged peptide secretion. In an initial test of this hypothesis, bag-cell preparations maintained *in vitro* were treated with the calcium ionophore X537A (50 μM) dissolved in artificial seawater (ASW) containing 5 mM Ca^{++}/10 mM EGTA. This ionophore can carry Ca^{++} from extracellular and intracellular sources. By blocking entry of Ca^{++} from extracellular fluid with the calcium chelator, the only source of Ca^{++} should be from intracellular stores. This treatment stimulated significant ELH release during the entire 120-min treatment period in the absence of action-potential firing. Total ELH release from preparations treated with X537A (1.2 ± 0.6 μg/ml, n=3) was similar to that from a control group treated with normal ASW and in which secretion was stimulated by an electrical afterdischarge (1.5 ± 0.3 μg/ml, n=5). These results show that a sustained rise in intracellular calcium is sufficient to stimulate ELH release in the absence of an electrical afterdischarge, and are consistent with a model of secretion in which peptide hormone release does not require Ca^{++} influx from extracellular fluid. Supported by NIH NS-33548.

733.16

PATTERNS OF AFTERDISCHARGE (AD) AND EGG-LAYING HORMONE (ELH) RELEASE FROM BAG CELLS UNDER DAILY ELECTRICAL STIMULATION. W. Lee* and N. L. Wayne. Dept. of Physiology, UCLA Sch. of Med., Los Angeles, CA 90024.

ELH of the marine mollusk, *Aplysia*, is synthesized by neuroendocrine bag cells and its secretion is triggered by an electrical AD. During the breeding season, ELH synthesis rate is elevated, and egg-laying behavior often occurs daily in response to ELH secretion. To investigate how ELH synthesis and the pattern of its secretion are regulated when the demand is high, we used a bag cell preparation that remains stable for days *in vitro* (n=4). To determine their electrophysiological and ELH secretory capacities with repeated stimulation, bag cells were dissected from the abdominal ganglion, and individual clusters were separated and placed in artificial sea water containing 100 μCi/ml ^{3}H-leucine for 20-24 hours, and then electrically stimulated on each successive day for up to 5 days, which would mimic daily bouts of AD and ELH release that induce egg laying in freely-behaving animals. During these days each cluster was maintained in HEPES-buffered Eagle's medium II except during the 130-min experimental period. The results showed that while the pattern of action potential firing remained stable, total ELH release per day gradually decreased over time. This gradual decline in release was shown to be a function of repeated stimulation rather than time in culture. Also, secretory patterns of ^{3}H-labeled acid-precipitable peptides appeared to be consistent with those of ELH, but this release of newly synthesized peptides was highest on the third day of the experiment. These results suggest that daily release of ELH (as often occurs during breeding season) can eventually exhaust the synthetic/secretory machinery underlying peptide secretion. Supported by NIH-NS33548 (NLW).

LONG DISTANCE DIFFUSION OF DEXTRAN ALONG NERVE FIBRE BUNDLES. ASPECTS ON VOLUME TRANSMISSION

B. Bjelke[1]*, R. England[2], C. Nicholson[3], M. E. Rice[3], J. Lindberg[1], M. Zoli[4], L. F. Agnati[4], K. Fuxe[1]

[1]Department of Neuroscience, Karolinska Institutet, 171 77 Stockholm, Sweden. [1]Kebo Lab AB, Fagerstag 18, 163 94 Spånga, Sweden. [3]Department of New York University Medical Center, New York, USA. [4]Department of Human Physiology, University of Modena, Modena, Italy

The mapping out of preferential diffusion pathways in the living brain is basic to the concept of Volume Transmission. Texas Red labelled dextran, a marker for the extracellular space, was injected from the dorsal side of the brain unilaterally into the neostriatum in rats (0.3 - 30 μg/μl) and evaluated 1 min to 5 h later. Confocal laser microscopy including co-localization analysis in combination with myelin basic protein staining demonstrated that the Texas Red labelled dextran (5 min, 3 μg/μl) was associated with small channel-like pathways parallel to the myelinated fiber bundles and separate from the MBP-1 immunoreactivity of the fiber bundles. In addition, strong labelling along the myelinated fibre bundles was seen reaching into the entire neostriatum as well as into the corpus callosum and external capsule on the contralateral side. A diffusion in the neuropil was observed with a clearance starting after 30 min. A marked cellular uptake and accumulation of labelled dextran was found in putative perivascular pericytes. Thus, in the living brain preferential extracellular fluid pathways for diffusion may exist along myelinated nerve fiber bundles.

734.1

MAPPING MICTURITION CONTROL AREAS IN THE CENTRAL NERVOUS SYSTEM WITH POSITRON EMISSION TOMOGRAPHY (PET)

Bertil F. M. Blok[1]*, Antoon T. M. Willemsen[2] and Gert Holstege[1] [1]Department of Anatomy and Embryology, University of Groningen, The Netherlands; [2]PET Center, University Hospital Groningen, The Netherlands.

Little is known about the brain structures controlling micturition or voiding. Indirect evidence from patients with cerebrovascular lesions, large brain tumors or lobotomies suggest that voluntary control of micturition in humans depends on the integrity of the medial surface of the frontal lobe (including the anterior cingulate gyrus) and the septal and preoptic regions of the hypothalamus. In this study an attempt was made to identify cortical and subcortical areas involved in micturition in healthy human volunteers.

Cerebral activation was monitored in 7 right-handed male volunteers (23-50 years) using a CTI ECAT 951/31 whole body positron emission tomograph. Changes in regional cerebral blood flow (rCBF) were measured using the intravenous radioactively labeled water ($H_2{}^{15}O$) bolus technique. An injection of 1.85 MBq $H_2{}^{15}O$ was given for each run. Scanning was made during 3 successive conditions: 1) with a filled bladder, 2) during micturition, and 3) with an empty bladder. Shifting from the condition with a filled bladder to the condition in which the micturition took place indeed altered the pattern of rCBF. During micturition, a significant increase ($p<0.01$) in rCBF was found in the ventral hypothalamus, parts of the striatum, the left anterior cingulate gyrus, the caudal periaqueductal gray (PAG), and the possible human M-region or pontine micturition center. The results support previous animal research which indicated that the M-region, the PAG and the preoptic area of the hypothalamus play a central role in the control of micturition (Holstege, 1987; Blok and Holstege, 1994). The results suggest a remarkable similarity between the organization of micturition in cats and humans. Understanding the control of micturition in the human might help to understand the pathophysiology of urge incontinence, one of the major problems in elderly.

734.2

BRAIN AND SPINAL NEURONS IDENTIFIED IN THE FEMALE RAT AFTER INJECTION OF PSEUDORABIES VIRUS (PRV) INTO THE BLADDER BODY, BASE AND EXTERNAL URETHRAL SPHINCTER (EUS). L. Marson,* Division of Urology, University of North Carolina School of Medicine, Chapel Hill, NC 27599

Bladder disorders are common in females. Continence and voiding are dependent upon the functional integration and co-ordination of detrusor and urethral mechanisms. These mechanisms are modulated by neural inputs from the brain and spinal cord. Transneuronal tracing with PRV was used to identify the spinal and brain neurons that innervate the female bladder and urethral sphincter. Bartha's K strain of PRV was injected into either the bladder body, bladder base or EUS (1-4 µl. 10^8pfu/ml). Rats were perfused 4 or 5 days after the injections. Bladder injections labelled neurons in the IML and dorsal grey commissure (DGC) of segments L6-S1 and T13-L3 and in the medial cord of the intervening segments. After a 5 day survival, PRV cells were also found in laminae II and III of the dorsal horn. Fewer and more localized cells were found after PRV injections of the bladder base. PRV injected into the EUS, labelled motoneurons in the dorsolateral subdivision of Onuf's nucleus. Longer survival times also labelled neurons in the dorsomedial and ventrolateral subdivisions of Onuf's nucleus. PRV labelled cells were also found in the IML and DGC of segments L6-S1 and T13-L3, after EUS injections. In the brain, areas common to both bladder and EUS injections were: paragigantocellular and gigantocellular medullary reticular formation, raphe magnus, A5, locus coeruleus and subcoeruleus, Barrington's nucleus and the lateral and ventral central grey. More rostrally PRV cells were found in the posterior, dorsal and lateral hypothalamic areas, tuber cinereum, paraventricular nucleus of the hypothalamus and the preoptic region. These studies demonstrate a high degree of overlap between bladder smooth muscle and EUS striated muscle central nervous system projections. However, some differences were observed in the extent of labelling. (Supported by NIH grants NS29420 and DK49503).

734.3

TRANSYNAPTIC LABELING OF NEURONS WITHIN THE CNS WHICH CONTROL THE BLADDER OR PENIS OF THE CAT. V.Erickson, J.R.Roppolo, A.M.Booth*, M.A.Vizzard, J.P.Card, and W.C.de Groat Depts. of Pharmacol. & Neurosci., Univ. of Pittsburgh, Pgh, PA 15261

This study used the transynaptic tracer pseudorabies virus (PRV) to determine the location of efferent neurons and interneurons within CNS pathways that control the bladder or penis. Under halothane anesthesia PRV (10-20µl, $1.7x10^8$ pfu/ml, Becker strain) was injected unilaterally into the bladder wall or penis of cats. Animals were perfused 60-115 hours later. PRV injected into the bladder, labeled neurons (L-NEU) in the S_1-S_3 and L_1-L_4 segments of the spinal cord with the majority of the L-NEU in S_2 and L_3. In the sacral cord L-NEU were in the lateral, sacral parasympathetic nucleus (SPN), the dorsal commissure (DC), in the superficial layers of the dorsal horn (DH), and a few L-NEU were also in Onuf's nucleus. At the lumbar level L-NEU were in the intermediolateral cell column (IML), in the DC and in the superficial layer of the DH. In animals allowed to survive >96 hours, brainstem labeling was medial to, and overlapping with locus coeruleus (LC) neurons and extending into the periaqueductal grey and the pontine reticular formation. A few L-NEU were also in the raphe nucleus at the level of the pons. In two separate animals either the S_1-S_3 dorsal roots (DRX) or ventral roots (VRX) were transected prior to bladder injection. Following 60 hour survival little labeling was seen the VRX animal. However many labeled preganglionic neurons (PREG) and interneurons were seen in the SPN and DC of the DRX animal. After injection of PRV into the penis L-NEU were in the S_1-S_3 and L_1-L_4 spinal cord with the majority in S_1, rostral S_2 and L_3. In the sacral cord L-NEU were in the DC, the ventral horn and the medial SPN. L-NEU in the lumbar cord were primarily in the IML. L-NEU were also seen in the brainstem medial to the brachium conjunctivum and lateral to the LC. This data suggests: 1) that penile PREG are adjacent to but separate from bladder PREG in the sacral cord, 2) there is considerable overlap of the interneurons serving the two organs and 3) that brainstem neurons controlling bladder or penis are present in separate regions of the pons. [Supported by NINDS N01-NS-2-2374].

MODULATION OF EXTERNAL URETHRAL SPHINCTER (EUS) BY MICROSTIMULATION OF THE SACRAL SPINAL CORD. J.R.Roppolo*, A.M.Booth & W.C.de Groat. Dept. of Pharmacol., Univ. of Pittsburgh, School of Medicine, Pgh., PA 15261.

The purpose of the present study was to determine sites within the sacral spinal cord where electrical stimulation with fine tipped microelectrodes produced EUS contraction or relaxation, either in the presence or absence of accompanying bladder contractions. Both α-chloralose anesthetized and precollicular decerebrate unanesthetized cats were used in this study. EUS pressure was recorded via a catheter passed transurethrally with its tip located at the level of the EUS. Bladder pressure was recorded isovolumetrically by a catheter through the bladder dome. Sites which produced EUS contractions were in S_2 and caudal S_1 of both anesthetized and decerebrate cats and included: (1) areas on or near (200-400µ deep) the surface of the spinal cord at the dorsal root entry zone (DREZ) and 200-400µ medial or lateral to the DREZ; (2) deep in the ventral horn and ventral funiculus near the cell bodies and axons of pudendal motoneurons; (3) in the lateral funiculus, ventrolateral to the dorsal horn. Although sites which inhibit EUS were sometimes identified in anesthetized animals the EUS relaxations were usually of small (10-15cm H_2O) magnitude and often difficult to reproduce even in the same animal. EUS relaxation was best demonstrated in decerebrate unanesthetized cats. Sites which produce EUS relaxation were often preceded by a small EUS contraction. Sites which produced EUS inhibition include: (1) sites in and near the sacral parasympathetic nucleus (SPN), (2) the dorsal horn just dorsal and dorsomedial to the SPN and (3) along the lateral edge of the ventral horn. Evoked bladder activity was not correlated with the magnitude of the EUS relaxation. Some sites (ie. deep in ventral horn and ventral funiculus of S_2) produced large bladder contractions with little or no EUS inhibition (often small EUS contractions were seen); while small bladder contractions produced by dorsal horn stimulation were often associated with large EUS relaxation. These studies suggest that focal microstimulation of the sacral spinal cord may be a useful technique for producing bladder emptying. [Supported by N01-NS-2-2374].

PROPERTIES OF NEURONS IN THE REGION OF THE SACRAL PARASYMPATHETIC NUCLEUS (SPN) IN THE ISOLATED SPINAL CORD OF THE NEONATAL RAT. Y.B.Yu*, A.M.Booth, W.C.de Groat. Dept. Pharmacology, Univ. Pittsburgh, Pittsburgh, PA 15261.

Parasympathetic preganglionic neurons (PGN) and interneurons (INT) in the L6-S1 spinal cord are involved in the control of the urogenital tract and distal bowel. The present study examined the properties of these neurons in the isolated spinal cord of neonatal rats (6-11 days old). Extracellular recording in the SPN region identified two types of neurons. PGN were activated antidromically at high frequencies (100 Hz) at latencies of 7.5-20 ms by electrical stimulation (EStim) of ventral roots (VRT). Some neurons responded synaptically to EStim of dorsal roots (DRT). The synaptic responses consisted of single spikes and followed only low frequencies (less than 1 Hz) of EStim. INT did not respond to VRT EStim but did fire synaptically at 10-25 ms latency to DRT EStim. INT exhibited multiple spikes (2-4) in response to a single DRT EStim and followed frequencies up to 2-5 Hz. DRT EStim elicited early (4-13 ms latency) and late reflexes (up to 30 ms latency) on L6 and S1 VRT's. Neurons labelled by extracellular iontophoresis of biocytin in the SPN region were stellate, oval or round in shape and ranged from 10 to 20 µm in diameter. Some neurons presumably PGN which exhibited long axon-like processes extending deep into the ventral horn had dendrites which extended into the lateral funiculus and medially toward the central canal. Small round or oval neurons in the SPN had dorsoventrally oriented processes. Neurons with long mediolateral dendrites were identified in the region of the dorsal commissure. These neurons might be labelled by retrograde axonal transport of biocytin from the SPN. It is concluded that some PGN and INT in the SPN are activated by primary afferent inputs via polysynaptic pathways. Thus the late component (25-30 ms) of the DRT to VRT reflexes could reflect in part autonomic neuron firing.

C-*FOS* EXPRESSION IN SPINAL NEURONS AFTER IRRITATION OF THE LOWER URINARY TRACT DEPENDS ON SYNERGISTIC INTERACTIONS BETWEEN NMDA AND AMPA GLUTAMATERGIC TRANSMISSION. H. Kakizaki, M. Yoshiyama and W.C. de Groat*. Dept. of Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15261

Chemical irritation of the lower urinary tract (LUT) of the rat increases the expression of immediate early gene c-*fos* in the dorsal horn (DH), dorsal commissure (DCM) and intermediolateral region including parasympathetic nucleus (SPN) of the L6-S1 spinal cord. This c-*fos* expression is decreased by a large dose (3.5 mg/kg i.v.) of NMDA receptor antagonist MK-801 (Birder & de Groat, 1992). The role of glutamatergic synapses in c-*fos* expression following LUT irritation was further examined using a selective, competitive AMPA receptor antagonist (LY 215490). Chemical irritation was performed by a continuous transvesical infusion of 1% acetic acid in urethane anesthetized female Wistar rats. The total number of c-*fos*-positive cells following 2-hr LUT irritation was 110±2.4 cells/L6 section (45±1.3, 34±1.0 and 31±1.1 cells/L6 section in DCM, SPN and DH, respectively). LY 215490, administered 1 hr before LUT irritation, decreased significantly the number of c-*fos*-positive cells in DCM and SPN in a dose-dependent manner (mean % decrease following 3 and 10 mg/kg i.v. : 22% and 51% in DCM, 25% and 43% in SPN, respectively). In DH, only a large dose of LY 215490 (10 mg/kg, i.v.) decreased (27-33%) the number of c-*fos*-positive cells. A low dose of either MK-801 (15 min before irritation) or LY 215490 alone (1 mg/kg i.v. of each) did not alter c-*fos* expression. However, combination of the low doses of MK-801 and LY 215490 significantly decreased the number of c-*fos*-positive cells in all regions of the spinal cord (mean % decrease: 29 - 44%). These results indicate that AMPA as well as NMDA receptors are involved in the spinal processing of nociceptive input from the LUT and that these two glutamatergic receptors play a synergistic role in visceral nociceptive processing.

DENERVTION AND INFLAMMATION INDUCED INCREASE OF LOW -AFFINITY NGF RECEPTOR IMMUNOREACTIVITY IN THE RAT URINARY BLADDER. Y. Wakabayashi, A. Buchan* and Y. N. Kwok. Dept. of Physiology, University of British Columbia, Vancouver, B.C. Canada V6T 1Z3

The level of NGF in the urinary bladder has been shown to be increased following urethral obstruction, denervation or inflammation, thus suggesting that NGF may play a role in the control of bladder function. However, little is known about the distribution and localization of NGF receptors in the urinary bladder. The objective of the present experiments was to examine immunohistochemically the distribution and localization of the low-affinity NGF receptor (LNGFR), which binds all neurotrophins, in the male adult rat urinary bladder using a specific antibody (192 IgG). In controls LNGFR positive fiber bundles were shown to be present in the muscle layer. In cyclophosphamide (CYP)-induced cystitis animals, LNGFR positive fine fibers were observed in the muscle layer 2 days after CYP treatment (150 mg/kg, i.p.). Three days after unilateral major pelvic ganglionectomy, LNGFR immunoreactivity was also increased in fine fibers of the muscle layer of the denervated side, and this increase peaked at 7 days. Electron microscopic examination showed that reaction products were located on the surface of Schwann cells and on the interface of axons and Schwann cells. Although the significance of the present findings and the role of LNGFR in the urinary bladder are not certain, these receptors may play a role in nerve regeneration, sprouting and/or neural plasticity. (Supported by BCHRF).

REGULATION OF MICTURITION BY CORTICOTROPIN-RELEASING HORMONE (CRH) FROM BARRINGTON'S NUCLEUS. L. A. Pavcovich and R. J. Valentino*. Dept. of Psychiatry, Hahnemann Univ., Philadelphia, PA 19102.

Barrington's nucleus, a pontine nucleus implicated in micturition, contains numerous CRH neurons that project to the spinal parasympathetic nucleus that innervates the bladder. This study characterized the effects of selective chemical stimulation of Barrington's nucleus on bladder function, and determined the role of CRH-Barrington's projections in these effects. Bladder pressure was continuously recorded during intracerebral glutamate microinjection (10 mM, 15-60 nl) in halothane-anesthetized rats. Selective chemical activation of Barrington's nucleus by glutamate microinjection evoked bladder contractions corresponding to an increase in pressure of 1-9 mm Hg, and this effect was regionally specific. The CRH antagonist, D-Phe CRH_{12-41}, (3 μg) administered intrathecally (it) increased the magnitude of Barrington's stimulated contractions. Moreover, the magnitude of this increase was correlated with the magnitude of chemical activation, eg., bladder contractions evoked by 15, 30 and 60 nl of glutamate were increased by 34±13%, 87±21% and 110±23%, respectively (n=7-9). In contrast to D-Phe CRH_{12-41}, CRH (3 μg, it) decreased Barrington's stimulated bladder contractions (n=7), and artificial cerebrospinal fluid (3 μl, it; n=5) had no effect. CRH did not alter bladder contractions evoked by it administered N-methyl-D-aspartate (10 mM). The results suggest that activation of Barrington's nucleus releases an excitatory neurotransmitter responsible for bladder contractions, and CRH, which presynaptically inhibits this neurotransmitter. Through this interaction, CRH may regulate the micturition reflex.

SENSORY INNERVATION OF THE RAT LOWER URINARY TRACT: A ROLE FOR NITRIC OXIDE? K. Persson*, K. Johansson, P. Alm, B. Larsson and K.-E. Andersson. Departments of Clinical Pharmacology, Zoology and Pathology, University of Lund, Lund, Sweden.

Retrograde axonal tracing studies have demonstrated nitric oxide synthase (NOS) positive neuronal structures in segments of the spinal cord which receive afferent input from the bladder and urethra. Thus, besides being an efferent messenger in the lower urinary tract, NO may also be involved in afferent neurotransmission. It is possible that NOS-containing fibres in the detrusor represent sensory fibres, since no clear role of NO in efferent neuromuscular transmission has been established in this tissue. The objective of this study was to perform a morphological investigation of the suburothelial/urothelial innervation of the rat lower urinary tract with special reference to NOS-containing fibres. The bladder and urethra from control and capsaicin treated female Sprague Dawley rats were fixed in 4% formaldehyde and the specimens processed for immunohistochemistry. Calcitonin gene related peptide (CGRP)- and substance P (SP)-immunoreactive (IR) nerves were observed in the suburothelial region of the bladder and urethra. NOS-IR fibres were also observed in the suburothelial region, although more sparse compared to CGRP- and SP-IR fibres. Occasionally, CGRP-, SP- and NOS-IR fibres penetrated into the urothelial cell layer. Electronmicroscopy confirmed the existence of single, unmyelinated and vesicle-containing nerve fibres located between the urothelial cells. Capsaicin treatment resulted in disappearance of both CGRP- and SP-IR fibres. In contrast, the number of NOS-IR fibres both in the musculature and suburothelium appeared to be unchanged. In conclusion, the sensitivity to capsaicin and the presence of free nerve endings primarily suggest a sensory role of fibres in the suburothelium/urothelium. Morphological data do not support the existence of NOS in the capsaicin-sensitive afferent nerve population in the rat lower urinary tract.

734.10

EFFECTS OF AMPA/KAINATE (LY215490) AND METABOTROPIC (MCPG) GLUTAMATERGIC RECEPTOR ANTAGONISTS, ON THE MICTURITION REFLEX IN RATS. M. Yoshiyama*, J.R. Roppolo, K.B. Thor & W.C. de Groat. Univ. of Pittsburgh, Sch. Med., Dept. Pharmacol., Pittsburgh, PA 15261 and Lilly Res. Lab., Indianapolis, IN 46285.

The role of glutamatergic transmission in voiding function was evaluated in unanesthetized decerebrate rats, by determining the effects of glutamatergic receptor (GluR) antagonists on urinary bladder and external urethral sphincter (EUS) EMG activity during cystometrograms. In spinal cord intact (SI) rats, LY215490 (LY), a competitive AMPA/kainate receptor antagonist, in small doses (1-3 mg/kg i.v.) decreased bladder contraction amplitude (BCA) and the EUS EMG by 15-35%; whereas in a large dose (10 mg/kg i.v.), it abolished bladder and EUS EMG activity. The intrathecal (i.t.) injection of LY (0.1-10 μg) decreased BCA by 30-100% and increased bladder capacity by 25-90%. Combined administration of LY (0.1 μg i.t.) and an NMDA receptor antagonist, MK-801 (MK, 1 μg i.t.) which individually had little effect on BCA, completely suppressed BCA. In chronic (3-4 weeks) spinal cord transected (ST) rats, LY (10 mg/kg i.v.) decreased BCA only 25% whereas it abolished EUS EMG activity. In ST rats, i.t. injection of LY (10 μg) decreased BCA by 50%. MK (1 mg/kg i.v.) administered prior to LY (10 mg/kg i.v.) abolished EUS EMG activity but had no significant depressant effect on BCA or on the depressant effect of LY on BCA. The intrathecal injection of (±)-α-methyl-4-carboxyphenylglycine (MCPG, 3-100 μg), a competitive metabotropic receptor ($mGluR_1$ and $mGluR_5$) antagonist, did not alter bladder activity but increased EUS EMG activity by 85% in SI rats. These data suggest that AMPA/kainate GluRs have a major role in the excitatory pathways controlling BCA and bladder capacity in SI rats. However, in ST rats, AMPA/kainate GluRs which are essential for EUS reflexes, appear to play only a minor role in bladder reflexes. Metabotropic receptors ($mGluR_1$ and $mGluR_5$) are also involved in control of EUS but not bladder activity.

734.11

MUSCARINIC FACILITATION OF TRANSMITTER RELEASE OPERATES VIA PRESYNAPTIC L-TYPE Ca^{2+} CHANNELS IN THE RAT URINARY BLADDER. G.T. Somogyi*, M. Tanowitz, G. Zernova and W.C. de Groat, Department of Pharmacology, University of Pittsburgh, Pittsburgh PA, 15261.

The effect of N and L type Ca^{2+} channel blockers were studied on muscarinic receptor mediated facilitation of ^{14}C-acetylcholine (ACh) and ^{3}H norepinephrine (NE) release in the rat urinary bladder strips. After prelabelling the strips with ^{14}C-choline and ^{3}H-NE, two periods of electrical stimulation (S1 and S2) were applied (20 Hz, and 0.25 ms) to increase the release of ACh and NE from nerve terminals. Control strips yielded an S_2/S_1 ratio of 0.88±0.06 for NE and 0.5±0.11 for ACh. Drugs were added 20 min before S_2. The Ca^{2+} channel activator, BAY-K 8644 (2μM) increased the release of NE and ACh (S_2/S_1 ACh: 6.44±2.41 and NE: 1.36±0.21). The N-type blocker omega conotoxin (CTX) (20 nM) reduced the S_2/S_1 values to 0.26 for NE but did not change that of ACh. The L-type channel blocker, nifedipine (1 μM) did not change the non-facilitated NE or ACh release. Transmitter release was facilitated by the cholinesterase inhibitor, eserine (5μM), which produced an S_2/S_1 value of 9.62±0.3 for ACh and 4.06±1.28 for NE. This facilitation was blocked by atropine (1 uM), but was not altered by CTX (20 nM) (S_2/S_1: ACh 9.02 and NE 3.41). In contrast, 1 μM nifedipine significantly reduced the eserine facilitated release of ACh and NE (S_2/S_1=2.05±0.53 and 1.48±0.27, respectively). These results suggest that N-type channels modulate the non-facilitated release of NE, whereas, the facilitated release of both ACh and NE is modulated by L-type channels. Previously we have shown that M1 facilitation utilizes a PKC dependent pathway. It is possible that PKC phosphorylates Ca^{2+} channels which are an essential link in muscarinic facilitation. Thus, inhibition either of M1 muscarinic receptors, PKC activity or L-type Ca^{2+} channels will prevent the facilitation of NE or ACh release. Supported by the NIH grant DK-45741.

734.12

CHEMICAL IRRITATION OR MECHANICAL DISTENSION OF THE URETHRA ELICITS ANO-EXCITATORY AND VESICO-INHIBITORY REFLEXES IN THE URETHANE-ANESTHETIZED RAT. M.A. Muhlhauser* and K.B. Thor, Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285

Transvesical infusion of dilute acetic acid (aa) in the intact or chronic spinal rat evokes a reflexive increase (5 fold) in anal sphincter (AS) activity *via* nociceptive fibers. Urinary bladder (BL) inhibition is frequently observed as well. Additionally, capsaicin (CAP) applied to urethra (UR) has been shown to inhibit BL. Because transvesical infusion exposes both BL and UR to aa, studies were conducted to determine whether it is specifically the irritation of BL, or UR, or both, that is triggering this ano-excitatory and vesico-inhibitory reflex. Rat BL were infused with saline or aa, BL pressures and AS EMG activity were recorded. Rats with BL isolated from urethra showed a modest (50%) increase in AS activity from aa infusion into BL alone but a 10 fold increase from infusion into the urethra. Infusion of aa into, or mechnical distension of, the isolated UR inhibited BL activity. CAP pretreatment (75mg/kg 4 days prior) significantly reduced AS activity elicited from urethral stimulation. Urethral pressure-AS activity response curves were generated by incremental pressure increases with either saline or aa. Increasing pressure with saline produced a linear increase in AS with BL inhibition occuring at 60 cmH2O. Acetic acid produced a steeper increase in AS with BL inhibition at 30 cmH2O. Finally, histology of BL tissue exposed to aa showed damage to epithelium but not underlying muscle. These studies suggest that rat urethral nociceptive afferent fibers are highly sensitive to chemical irritation or mechanical distension and mediate spinal ano-excitatory and vesico-inhibitory reflexes. These findings explain observed urologic phenomena in the rat and have clinical relevance to conditions associated with urinary retention accompanying prostatitis or perineal irritation.

734.13

DESENSITIZATION OF BLADDER SENSORY FIBERS WITH INTRAVESICAL CAPSAICIN IN HUMANS WITH DETRUSOR HYPERACTIVITY. F. Cruz *, M. Guimarães, C. Silva, M.E. Rio, M. Reis and A. Coimbra. Institute of Histology and Embryology, Dept. of Urology and Dept. of Neurology, Faculty of Medicine of Porto, 4200-Porto, Portugal.

Experimental studies have shown that detrusor hyperactivity very often follows the emergency of a strong spinal micturition reflex triggered by unmyelinated C-fibers. In the treatment of the urinary symptoms associated with this condition desensitization of C afferent fibers may constitute an alternative to anticholinergic drugs. With this purpose, capsaicin, the pungent extract of red peppers which is known to desensitize cutaneous C-afferents, is currently under investigation. We treated 10 patients with bladder hyperactivity associated with neurological disorders (8) pelvic radiotherapy (1) or idiopathic hypersensitive bladder (1). All patients gave informed written consent. A 1mM capsaicin solution in 30% alcohol was instilled through an urethral catheter and left in contact with the mucosa for 30 minutes. Patients mentioned a burning sensation immediately after capsaicin instillation that began waning slowly 15 minutes later. After 3 months day and night urinary frequency decreased about 50% in average and urge incontinence had disappeared. The average volume at which first desire to void occurred increased from 103±39ml to 218±113ml ($p<0.02$) and maximal cystometric capacity increased from 167±83ml to 350±211ml ($p<0.05$). Seven patients have been followed for 6 months and the clinical condition has deteriorated slightly in one of them. Average volumes of first desire to void and maximal cystometric capacity were 204±53ml ($p<0.001$) and 348±178ml ($p<0.05$), respectively. Three patients that completed one year of follow-up showed a pronounced deterioration of the clinical condition and the cystometric data returned to pretreatment levels.These findings suggest an important role for bladder afferent desensitization in the treatment of detrusor hyperactivity.

734.14

OPPOSITE EFFECTS OF DULOXETINE, A SEROTONIN (5HT) AND NOREPINEPHRINE (NE) RE-UPTAKE INHIBITOR, ON NOCICEPTIVE REFLEXES TO THE BLADDER AND URETHRAL SPHINCTER. K.B. Thor* and M.A. Katofiasc, Eli Lilly and Co., Indianapolis, IN 46285

5HT and NE systems are intimately associated with CNS control of LUT function. The present study has examined the effects of duloxetine (DUL) on bladder capacity and urethral sphincter EMG activity in chloralose-anesthetized cats. Cystometrograms (CMGs) were performed under conditions of saline infusion into the bladder or saline followed by dilute acetic acid (0.5%) infusion. Under saline conditions, bladder capacity was large (5ml) and sphincter EMG activity was low. During acetic acid infusion, bladder capacity was reduced (hyper-reflexia) and sphincter activity was increased. DUL had weak, non-significant effects on bladder capacity and sphincter activity during saline infusion. However, during acetic acid infusion, DUL (0.1 - 3 mg/kg) produced dose-dependent inhibition of bladder activity (*i.e.* increase in capacity) and facilitation of sphincter activity. Various experiments confirmed that the effects were mediated centrally through 5HT and/or NE receptors. These results indicate that monoaminergic systems can either inhibit or facilitate nociceptive-driven input depending on the efferent system studied. Since inhibition of the bladder and facilitation of the sphincter would be a coordinated, appropriate behavioral response under "fight or flight" conditions, it is tempting to speculate that the monoaminergic system "directs" nociceptive inputs to, or away, from specific efferent pathways to produce physiological changes useful in the context of "fight or flight" situations.

UROGENITAL REGULATION: SEXUAL FUNCTION

735.1

OXYTOCINERGIC INNERVATION OF THE SACRAL PARASYMPATHETIC NUCLEUS IN THE MALE RAT. Y. Tang, F. Giuliano*, O. Rampin, J.P. Rousseau and A. Calas. Dept of Urology and Lab. Chir. Exp., Fac. Méd. Paris-Sud, F-94270 Bicêtre: CNRS URA 1488, Univ. Paris 6, F-75005 Paris; CNRS URA 1449, Univ. Paris 6, F-75005 Paris.

The sacral parasympathetic nucleus (SPN) contains preganglionic autonomic neurons destined to the pelvic organs, and is the source of proerectile neurons. Oxytocin (OT) administered into the cerebral ventricles induces penile erection and yawning in the male rat. Oxytocinergic cell bodies are present in the paraventricular nucleus of the hypothalamus. We searched for the presence of oxytocinergic fibers in the SPN using retrograde labeling combined with immunocytochemistry. In adult anesthetized male rats, a solution of wheat-germ agglutinin-horseradish peroxidase (WGA-HRP, 25 % in distilled water) was applied on the central cut end of the left pelvic nerve. Rats were sacrificed two days later and serial sections of the lumbosacral spinal cord were treated with tetramethylbenzidine paratungstate and stabilized with diamidinobenzidine-cobalt complex to reveal retrograde-labeled SPN neurons. Immunocytochemistry was performed on the same sections using an anti-oxytocin antibody stained by the immunoperoxidase method. Retrograde labeled neurons were localized in the intermediolateral column at the L6 and S1 level of the spinal cord. They formed a dense and homogeneous population. At the same levels, OT-like immunoreactivity was associated with varicose fibers which were mainly found in the SPN, in the marginal zone and in the dorsal commissure. Rare OT-positive fibers were seen in the ventral horn. In the SPN, OT-immunoreactive fibers appeared in close apposition with retrograde-labeled neurons. At the ultrastructural level, OT-positive fibers containing DAB precipitates contributed varicose fibers which surrounded retrograde-labeled neurons and could make on them synaptic contacts. We conclude that oxytocinergic projections exist on SPN neurons. These results provide a morphological support for supraspinal control of oxytocin-mediated pelvic functions.

735.2

THE AUTONOMIC AND SENSORY INNERVATION OF THE RAT PROSTATE K.E. McKenna*, C.R. Georges, X.-B. Guan, and K.T. McVary. Depts. of Physiology and Urology, Northwestern University Medical School, Chicago, IL 60611

We have previously demonstrated that the autonomic innervation exerts a trophic influence on the prostate. Specifically, unilateral sympathectomy induced an ipsilateral atrophy, while unilateral parasympathectomy induced a contralateral hyperplasia.

The goal of the present studied was to identify the source of sensory and autonomic innervation of the prostate. Adult male rats were anesthetized and Fluorogold (2 µl, 4%) was injected unilaterally into the ventral prostate under aseptic conditions. After a 7-10 day survival period, rats were reanesthetized and perfused with fixative. The sympathetic chain, inferior mesenteric and major pelvic ganglia and dorsal root ganglia (DRG) were removed. Labeled neurons were counted in each ganglion.

The vast majority of labeled postganglionic neurons were located in the major pelvic ganglion, a mixed sympathetic-parasympathetic ganglion. Some labeled postganglionic neurons were observed in the sympathetic chain. Very few labeled neurons were seen in the inferior mesenteric ganglion. Labeled neurons were observed bilaterally in approximately equal numbers.

The afferent cell bodies from the prostate were localized predominantly in the dorsal root ganglia of L6, followed by L5 and S1. Approximately one third of the labeled DRG neurons were located in the T13-L2 segments. Labeling of sensory neurons was observed bilaterally.

735.3

ESTROGEN RECEPTOR-IMMUNOREACTIVE NEURONS ARE PRESENT IN THE FEMALE RAT LUMBOSACRAL SPINAL CORD. S.J. Williams* and R.E. Papka. Department of Anatomical Sciences, University of Oklahoma HSC, Oklahoma City, OK 73190.

Estrogens are gonadal steroids which stimulate secondary sex characteristics as well as growth, maturation and behavioral patterns in the CNS. Previous studies have examined potential sites of action of estrogen in the CNS by elucidating sites of neurons containing estrogen receptors, e.g., the hypothalamus, preoptic area and the amygdala. However, little attention has been directed to revealing estrogen receptor-containing neurons in the spinal cord, whether such neurons are involved in innervation of female reproductive organs, or if such neurons project information about reproductive organs to higher centers. A few studies have mentioned, somewhat in passing, the presence of estradiol-concentrating neurons in the spinal cord. Thus, we have undertaken a study of the location and distribution of estrogen receptor-immunoreactive (ER-IR) neurons in the female rat spinal cord by using immunohistochemistry.

Intact and ovariectomized rats were anesthetized, perfusion fixed and the spinal cords removed. The lumbosacral region was sectioned and immunostained with a rat monoclonal antibody (H222, Abbott Laboratories). ER-IR was observed mainly in the nuclei of neurons. ER-IR neurons were located predominately in the dorsal one-half of the spinal cord; specific sites containing ER-IR neurons include the dorsal horn, the sacral parasympathetic nucleus, lamina V, lamina X around the central canal and also extending into the lateral funiculus. The presence of ER-IR neurons in these regions suggest that neurons can be influenced by circulating estrogen. The ER-IR neurons could be involved in transmitting information either peripherally or to higher centers in the CNS. (Supported by NIH Grant NS22252 and Presbyterian Health Foundation.)

735.4

EXPRESSION OF ESTROGEN RECEPTOR (ER) IN NEURONS OF RAT SPINAL CORD, DORSAL ROOT GANGLIA (DRG) AND PELVIC AUTONOMIC GANGLIA (PG). B. Srinivasan, R.E. Papka, and K.E. Miller. Dept. Anatomical Sciences, University of Oklahoma HSC, Oklahoma City, OK 73190.

This study was directed to identify spinal cord neurons, sensory neurons and autonomic ganglionic neurons that could be responsive to estrogen. Ultimately, we want to use these data in assembling information regarding central and peripheral neural circuits related to uterine innervation. In situ hybridization histochemistry and immunohistochemistry were used to examine the presence and distribution of neurons producing estrogen receptor (ER) mRNA and ER protein respectively, in the lumbosacral cord levels L6-S1, L6-S1 DRG and PG of ovariectomized (ovex) and intact female rats. Unfixed spinal cords and ganglia were harvested from adult Sprague-Dawley rats, sectioned on a cryostat and sections processed for in situ hybridization histochemistry using oligonucleotides [48 bases] labelled with digoxigenin d-UTP. Immunohistochemistry was performed on sections of aldehyde-fixed spinal cords and ganglia using antisera from several different sources; sites of ER-immunoreactivity(IR) were visualized with an ABC reaction. Neurons with ER-IR nuclei were identified in the dorsal one-half of the spinal cord including preganglionic parasympathetic nuclei, lamina X and dorsal horn; labeled neurons were also present in the DRG and PG. ER mRNA expression was evident in many neurons in the spinal cord including those areas containing ER-IR neurons. Numerous neurons in the PG and DRG expressed ER mRNA; those in the DRG were mainly small and medium-size. Labeling was more evident in the ovex rats. These data suggest there are abundant neurons in the spinal cord and peripheral ganglia which could be responsive to circulating estrogen. (Supported in part by NIH grant NS-22526).

735.5

IDENTIFICATION OF 5-HT RECEPTOR SUBTYPES INVOLVED IN SEXUAL REFLEXES IN THE SPINAL CORD OF MALE RAT. X.-B. Guan*, K.T. McVary and K.E. McKenna. Depts of Physiology and Urology, Northwestern University Medical School, Chicago, IL 60611

We have previously demonstrated that spinal sexual reflexes are under the control of a descending inhibitory 5-HT pathway from the nucleus paragigantocellularis (nPGi). However, the specific receptor mechanism involved in this process has not been identified. The purpose of this study was to identify the 5-HT receptor subtype(s) involved in the descending control of sexual reflexes. Primers for 5-HT receptor subtypes 5-HT_{1A}, 5-HT_{1B} and 5-HT_{1F} were designed and synthesized. A reverse transcription followed by polymerase chain reaction (RT-PCR) for these three 5-HT receptor subtypes were conducted to observe the expression of these receptors at the message level in the lumbosacral segments of the spinal cord. Male Sprague-Dawley rats were used in this study. The spinal cord was dissected into L_{1-2}, L_{3-4}, and L_{5-S1} segments and then further dissected into dorsal and ventral portions. Total RNA was used for reverse transcription. The PCR products were resolved on a 2% MetaPhor agarose gel stained with ethidium bromide. The expected size of products for all three receptor subtypes were obtained (342 bp for 1A, 244 bp for 1B and 494 bp for 1F, respectively). Glyceraldehyde-3-phosphate dehydrogenase (G3PDH) was co-amplified as an internal standard. The density ratio of the 5-HT receptor and G3PDH was used to quantitate the mRNA amount. While the 1B receptor has been clearly identified in the lumbosacral segments of the spinal cord, the distribution of the other receptor subtypes and the control mechanism are still under the investigation.

BIOCHEMICAL EVALUATION OF NITRERGIC INNERVATION OF THE RAT PENIS. J. Bernabé*, A. Meulemans, O. Rampin and F. Giuliano. Lab. Neurobio. Végétative, I.N.R.A., F-78352 Jouy-en-Josas, Lab. Biophysique, Hôpital Bichat, F-75018 Paris and Lab. Chir. Exp., Fac. Médecine Paris-Sud, F-94270 Bicêtre.

In vitro and in vivo experiments have demonstrated the role of nitric oxide (NO) in the relaxation of smooth muscle fibers of penile erectile tissue. Nitric oxide synthase (NOS) catalyzes the formation of NO and L-citrulline from L-arginine. NO reacts with oxygen to produce nitrite (NO_2-) and nitrate (NO_3-). Nitrergic axons to the penis are derived from the major pelvic ganglion and conveyed by the cavernous nerve. Using biochemical tools, we quantified the nitrergic mediation of neural origin in the corpora cavernosa. Cavernous nerves were cut bilaterally in 35 adult male rats (CNx) and 35 rats were sham operated (Co) and allowed a 7-day recovery period. Total amounts of NOS (µg) and NOS specific activity (pM/hour/mg NOS) were measured by quantification of [3-H] citrulline (Bredt et al., 1990) in homogenates from the corpora cavernosa. NOS specific activity in the cerebellum was used as the reference. NO_2- + NO_3- assays were performed using a sensitive method of capillary electrophoresis with direct U.V. detection (Meulemans and Delsenne, 1994). Total amounts of NOS were comparable in Co and CNx rats (33.6 ± 2.1 and 28.6 ± 4.1, respectively). In Co rats, NOS specific activity was 0.025 ± 0.004 in the corpora, and 0.071 ± 0.019 in the cerebellum. In CNx rats, NOS specific activity was decreased by 20 % in the corpora (0.020 ± 0.004), but not in the cerebellum (0.064 ± 0.012). NO_2- + NO_3- levels were 1.23 ± 0.12 in the corpora of Co rats and 0.90 ± 0.06 in the corpora of CNx rats (a decrease of 27 % relative to Co rats). These results indicate that neuronal NOS represents a small part of total NOS in the corpora. Nevertheless, a decrease in NOS specific activity in CNx rats suggests that neuronal NOS plays a significant physiological role. This hypothesis is reinforced by the fact that the total amount of NO_2- + NO_3- decreased in the corpora cavernosa in CNx rats. Moreover, from comparison of total amounts of NOS and NOS specific activity in control and denervated corpora, we infer that neuronal and non-neuronal NOS display different specific activities.

CYTOCHROME OXIDASE STAINING IN THE RAT MAJOR PELVIC GANGLION (MPG). W. G. Dail*, R. Galindo, F. Harji, L. Leyba and V. Barba. Dept. of Anatomy, Univ. New Mexico, School of Medicine, Albuquerque, NM 87131

Pelvic autonomic neurons display a variety of neurochemical and functional differences, which in part reflect the diverse reproductive and eliminative organs they regulate. This study localizes cytochrome oxidase (CO) activity to determine if the heterogeneity in pelvic neurons extends to a marker of metabolic activity. A distinct topography is apparent in that neurons which stain lightly for CO are localized in the ventral portion of the MPG near the entry of the hypogastric nerve (HN), while darker neurons predominate in the dorsal pole. The most intensely reactive neurons are located in a longitudinal band in the central region of the MPG. Terminals (verified by their disappearance after cutting the HN) around lightly stained neurons vary in size and are foci of intense CO activity, whereas terminals surrounding neurons in the dorsal pole are less apparent. Topographic relationships and immunoreactivity for tyrosine hydroxylase suggest that large cells with relatively low CO activity are adrenergic neurons while penile neurons (located by retrograde tracer) are moderately active. These findings suggest that the varied basal metabolic activity of neurons in the MPG mirrors the level of synaptic activity needed to regulate respective pelvic organs. Supported by NIH RO11983-11.

HORMONAL CONTROL OF CHOLINERGIC, NORADRENERGIC AND PEPTIDERGIC TRANSMITTERS IN AUTONOMIC GANGLIA. R. W. Hamill*, V. May, and K. M. Braas. Departments of Neurology, and Anatomy & Neurobiology, Univ. of Vermont College of Medicine, Burlington, VT 05405.

Hormonal influences regulate biochemical and morphological features of neurons. Previous studies indicate that androgens influence the neurochemistry of the hypogastric ganglia (HG). The current studies using adult Sprague-Dawley rats, examine the effects of castration on noradrenergic, cholinergic, and peptidergic systems in the major pelvic ganglia (MPG), sexually dimorphic ganglia innervating the urinary bladder and reproductive organs in the pelvis. Adult castration alters the catalytic activities of Tyrosine Hydroxylase (TH), the rate limiting enzyme in noradrenaline biosynthesis and a marker of noradrenergic adaptability, and Choline Acetyltransferase (ChAT), a marker of cholinergic components of autonomic ganglia. Four weeks following castration TH and ChAT activities are 25% and 50% of control, respectively. At 8 and 12 weeks post-castration, ChAT levels remain at 50%, whereas TH activity gradually declines reaching a nadir of 15% of control by 12 weeks. Castration also alters the levels of vasoactive intestinal peptide (VIP), which is colocalized with ChAT in MPG. VIP levels are reduced approximately 25% at 4 weeks following surgery. In all paradigms, testosterone replacement therapy fully restores TH, ChAT, and VIP levels. These studies indicate that the biosynthesis of noradrenergic, cholinergic, and peptide neurotransmitters in the adult MPG are regulated by testosterone. Taken together with previous studies of the HG, the results indicate that parasympathetic and sympathetic ganglia involved in reproductive function respond to gonadal steroids during adulthood. CLOMIPHENE CITRATE (CC) IMPROVES SPERM MOTILITY IN SPINAL CORD INJURED (SCI) MEN. C.M. Lynne* and N.L. Brackett. Dept. Urology, The Miami Project to Cure Paralysis, and Dept. of Neurological Surgery, U. Miami Sch. Med., Miami, FL 33136

The majority of men with SCI are in the parenting age group. Most of these men suffer from low numbers of motile sperm. This pilot study assessed the efficacy of CC for improving sperm motility in SCI men. Four volunteer SCI men had monthly semen analyses for 6-12 months prior to CC ("-CC"), and then again for 6-12 months during treatment with CC, ("+CC") given as 25 mg orally every other day. The following semen parameters were measured in the "-CC" and in the "+CC" conditions: (a) total number of sperm per ejaculate, (b) number of motile sperm per ejaculate, (c) percent motile sperm per ejaculate, (d) total number of sperm with rapid linear motion per ejaculate, (e) the percent of motile sperm per ejaculate with rapid linear movement, and (f) the percent motile sperm in the antegrade fraction only. ANOVA was used to evaluate the statistical significance of any changes in the "-CC" and "+CC" conditions. All measures of sperm motility improved significantly with CC treatment. There was no difference in the total number of sperm per ejaculate with CC treatment. Based on this small group of subjects, it appears that CC may improve sperm motility in SCI men. To our knowledge, no treatment regimen has heretofore been shown to have any efficacy in these subjects. A larger study is needed evaluate the effect in more SCI men and to evaluate the effect on fecundity.

735.10

SEMINAL PLASMA OF SPINAL CORD INJURED (SCI) MEN INHIBITS SPERM MOTILITY OF NORMAL MEN N.L. Brackett*, R.C. Davi, O.F. Padron, and C. M. Lynne, The Miami Project to Cure Paralysis, Dept. of Neurological Surgery, Dept. of Urology, Univ. of Miami Sch. Med., Miami, FL 33136.

SCI men have sperm of normal concentration but poor motility (Brackett et al., J Urol, 151:114-119, 1994). No single factor has been identified as a cause for this condition. **Objective:** The present study investigated if the seminal plasma of SCI men contributes to their poor sperm motility. **Method:** Aliquots of washed sperm from normal men (n=13) were mixed either with seminal plasma from SCI men or with seminal plasma from other normal men. Similarly, aliquots of washed sperm from SCI men (n=13) were mixed either with seminal plasma from normal men or with seminal plasma from other SCI men. **Results:** Percent of motile sperm in normal men decreased significantly, from 72% to 45% ($p<0.001$), when mixed with seminal plasma from SCI men. Percent of motile sperm in SCI men was significantly higher when mixed with seminal plasma of normal men (42%), than with seminal plasma from SCI men (29%) ($p<0.05$). **Conclusions:** Seminal plasma of SCI men appears to contribute to their poor sperm motility. There may be toxic factors present and/or nutritive factors absent which, when mixed with sperm during ejaculation, act to impair sperm motility.

735.11

STIMULATION OF THE DORSAL NERVE OF THE PENIS INCREASES C-FOS EXPRESSION IN SPINAL NEURONS IN THE RAT. O. Rampin*, S. Gougis, F. Giuliano and J.P. Rousseau. Lab. Neurobio. Fonctions Végétatives, I.N.R.A., F-78352 Jouy-en-Josas.

Physiological evidence of a reflex loop mediated at the spinal level and controlling reflexive penile erection has been reported in the rat (Rampin et al., Neurosci. Lett. 1994, 180:138). The dorsal nerve of the penis (DNP) represents the afferent limb of this reflex. In the present study, c-Fos immunohistochemistry was used to identify neurons in the spinal cord that receive afferent input from the DNP. Electrical stimulation of the left DNP (6V, 5 Hz, 0.1 ms) was applied for 10 minutes in anesthetized male adult rats. Segmental distribution of c-Fos positive neurons was studied over the T13 to S1 levels. Average numbers of positive neurons per spinal segment and differences in distribution of positive neurons in specific areas of the spinal cord were calculated. In control rats, c-Fos positive neurons were present mainly at the L5-S1 levels. They were located in the dorsal gray commissure (DGC, 35.7±2.1 %), and bilaterally in the intermediolateral cell column (sacral parasympathetic nucleus, SPN, 6.3±1.1 %) and in the dorsal and ventral horns (DH, 56.8±2.7 %; VH, 0.8±0.3 %). Following acute T8 spinalization, DNP stimulation elicited an increase of c-Fos positive neurons over the L5-S1 levels, compared to control rats. Percent distribution was increased in SPN (12.2±0.8 %, $p < 0.001$) and VH (2.2±0.7 %), decreased in DH (45.2±2.7 %, $p < 0.05$) and unchanged in DGC (39.9±2.2 %). These findings provide a morphological support for a reflex loop mainly organized at the L5-S1 levels of the spinal cord, and responsible for penile erection. Localization of c-Fos positive neurons outside of the SPN suggests the hypothesis of the presence of interneurons between afferent terminations and proerectile preganglionic parasympathetic neurons, and/or possible sites for supraspinal projections modulating reflexive erections. Furthermore the increase in c-fos expression observed after acute T8 spinalization supports the presence of a supraspinal inhibitory control exerted on the lumbosacral circuitry responsible for reflexive erection (Sachs and Garinello, J. Comp. Physiol. Psychol. 1980, 94:530).

RESPIRATORY REGULATION: AMINO ACID TRANSMITTERS

736.1

THE ROLE OF BRAINSTEM RETROTRAPEZOID NUCLEUS (RTN) METABOTROPIC RECEPTORS IN THE PROLONGED STIMULATION OF RESPIRATION PRODUCED BY RTN INJECTION OF GLUTAMATE. Aihua Li, and Eugene E. Nattie*. Department of Physiology, Dartmouth Medical School, Lebanon, NH 03756-0001

Stimulation of metabotropic glutamate receptors (mGluRs) in the RTN of chloralose-urethane anesthetized rats by the mGluR agonist (1S,3R)-aminocyclopentanedicarboxylic acid (1S,3R-ACPD) increases integrated phrenic amplitude (PNA) for > 60 min. This long-lasting PNA stimulation can also be mimicked by the long duration (60 sec) injection of glutamate. Here we show the mGluR antagonist (±)-α-methyl-4-carboxyphenylglycine (±-MCPG) can block both of these long lasting effects. Using multi-barreled micropipettes, we first identified RTN sites associated with respiration by observation of glutamate induced short-lived PNA stimulation. In group 1, five rats received only mGluR antagonist (±)MCPG (10nl, 10mM); in group 2, six rats received mGluR antagonist (±)-MCPG (10nl, 10mM) followed by the agonist 1S,3R-ACPD (10 nl, 1mM) injection every 30min until the PNA response to the agonist recovered. In group 3, five rats received 6 injections of inactive mGluR antagonist (-)-MCPG (10nl, 10mM) followed by agonist 1S,3R-ACPD (10nl, 1mM) after 30min. In group 4, five rats received (±)-MCPG followed by long duration (60 sec) injection of glutamate (10nl, 100mM) every 30 min until the PNA response to glutamate was evident. The active antagonist (±)-MCPG had no significant effect on PNA but it blocked a) subsequent 1S,3R-ACPD induced PNA stimulation for 99±11min and b) the PNA response to 60 sec glutamate injection for 66±6 min. The inactive form (-)-MCPG had no effect on ACPD-induced PNA stimulation. We conclude: 1) RTN mGluRs are involved in respiratory control, 2) they are not active in eupnea and 3) their stimulation may require prolonged glutamate release. (Supported by HL 28066)

GLUTAMATE SYNTHESIS BY EXCITATORY RESPIRATORY NEURONS IN THE VENTROLATERAL MEDULLA. P.M. Pilowsky*, Q.-J. Sun, I.J. Llewellyn-Smith, L.F. Arnolda, J.P. Chalmers and J.B. Minson. Dept of Medicine and Centre For Neuroscience, Flinders Medical Centre, Bedford Park 5042, South AUSTRALIA.

Excitatory respiratory pre-motoneurons are located in the ventral respiratory group (VRG) of the brainstem, while inhibitory pre-motoneurons are found in the Bötzinger region. Together they regulate the activity of phrenic motoneurons. In this study we aimed to determine if these brainstem respiratory neurons are immunoreactive for the glutamate synthesizing enzyme, phosphate activated glutaminase (PAG). Respiratory neurons in the ventrolateral medulla of pentobarbitone-anaesthetised Sprague-Dawley rats were labelled by intracellular injection of Neurobiotin (Vector, CA). After histochemical processing and immnuohistochemistry, sections of brainstem were examined by fluorescence and light microscopy. Four types of respiratory neurons were identified. 1) Six inspiratory neurons in the VRG: five PAG immunoreactive and one PAG negative. 2) Six expiratory neurons in the VRG: five neurons were PAG immunoreactive and one PAG negative. 3) Five neurons in the Bötzinger area: four PAG negative and one PAG immunoreactive. 4) Seven ambigual motoneurons that were all PAG immunoreactive. Our results support the use of PAG as a marker for glutamatergic respiratory neurons since most of the excitatory VRG neurons contained moderate to strong levels of immunoreactivity while most Bötzinger neurons, which are believed to be inhibitory, contained none. These findings also suggest that glutamate is synthesized and released as a neurotransmitter by excitatory respiratory neurons.

736.3

COMPARISON OF GAD- AND GABA- IMMUNOREACTIVE NERVE TERMINALS IN THE RAT PHRENIC MOTOR NUCLEUS Susan M. Murphy*, Paul M. Pilowsky and Ida J. Llewellyn-Smith, Dept. of Medicine, Flinders Medical Centre, Bedford Park, South Australia, 5042.

γ-aminobutyric acid (GABA) mediates synaptic inhibition of phrenic motoneurons during expiration. About 30% of nerve terminals that make synapses or direct contacts with phrenic motoneurons are immunoreactive for GAD, the GABA synthetic enzyme, whilst only about 18% of inputs identified by post-embedding immunogold are GABA-positive (SN 1994, Poster 231.8). In this study, we examined the distribution of these two markers in adjacent pairs of ultrathin sections containing retrogradely-labelled phrenic motoneurons. Both sections were labelled for GAD-immunoreactivity by pre-embedding immunocytochemistry, and one section of each pair was subsequently processed for post-embedding immunogold labelling for GABA. We examined terminals that synapsed on or directly contacted phrenic motoneurons, as well as other non-synaptic terminals. Many terminals containing high densities of gold particles also proved to be GAD-positive. However, not all GAD-immunoreactive nerve terminals were strongly labelled for GABA. Comparisons of the density of gold labelling over GAD-positive and GAD-negative terminals suggest that there is overlap in the frequency distributions of the two populations. Assuming GAD is itself a reliable marker for GABAergic terminals, we must conclude from these and our previous results that in this part of the spinal cord, post-embedding immunocytochemistry for GABA alone does not provide a sufficient basis to discriminate between GABAergic and non GABAergic terminals that provide synaptic input to phrenic and other motoneurons.

736.4

PROXIMAL SYNAPSES IN THE LUNG C-FIBER AFFERENT PATHWAY: POTENTIAL TRANSMITTER ROLE OF EXCITATORY AMINO ACIDS (EAAs). C.G. Wilson*, Z. Zhang, A.C. Bonham. Univ. California, Davis, Davis, CA 95616.

We previously identified synapses in the lung C-fiber afferent pathway in the mediocaudal commissural nucleus tractus solitarius (cNTS) which were essential for C-fiber evoked apnea and rapid shallow breathing (RSB). Here we examined the role of EAAs as potential neurotransmitters. Phrenic nerve activity, blood pressure and heart rate were continuously recorded in urethane-anesthetized, paralyzed, and ventilated rats. C-fibers were stimulated by injecting phenylbiguanide (PBG; 0.05-0.1ml, 50μg/ml) in the right atrium (RA) and left ventricle (LV). In some rats we cut both vagi below the diaphragm and denervated the baroreceptors and chemoreceptors. Medial cNTS was screened for vagally-evoked units with a 7-barrel electrode containing 2% pontamine dye in 0.5M NaAc for extracellular recording, EAA agonists and antagonists for iontophoresis, and normal saline for balancing currents. RA PBG (n=25) evoked immediate increases in unit activity: (1±2 to 16±18Hz) (p=.0004) for 17±20s, that coincided with apnea or RSB. In 9 cells RA PBG compared to LV PBG produced greater increases in activity (14±16 vs 8±6Hz; $p < .04$) for longer durations (8±6 vs 3±4s; p=.01)(n=9). The EAA agonists NMDA (-8 to -30nA; 100mM) and QUIS (-8 to -60nA; 100mM) evoked dose-dependent increases in unit activity. NMDA (24±7nA) and Quis (29±15nA) increased unit activity from 0.5±0.8 to 7±2Hz and from 0.4±0.4 to 11±5Hz, respectively. The NMDA receptor antagonist, AP5 (-90 nA, 100 mM) in doses that blocked NMDA- but not QUIS-evoked increases in unit activity, did not alter PBG-evoked increases in activity. Activation of both NMDA and nonNMDA receptors stimulates cNTS neurons in the C-fiber afferent pathway, but NMDA receptors are not involved in neurotransmission. Supported by NIH HL48584.

736.5

DESENSITIZATION OF GLUTAMATE RECEPTORS MODULATES RESPIRATORY DRIVE IN FETAL SHEEP. J.M. Bissonnette*, A.R. Hohimer and S.J. Knopp. Department of Obstetrics and Gynecology, Oregon Health Sciences University, Portland, OR 97201.

Blockade of non-N-methyl-D-aspartate (NMDA) receptors in the medulla of fetal sheep inhibits respiratory output (FASEB J. 9:A836, 1995). Both kainate and α-amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA) preferring non-NMDA glutamate receptors rapidly desensitize in the presence of ligand (eg. Neuron 11:1069, 1993). Studies were carried out in unanesthetized fetal sheep to examine the effect of preventing desensitization on respiratory drive measured from transient pressure changes in a tracheal catheter. Following a control period cyclothiazide which has been shown to block desensitization of AMPA preferring receptors (Ibid.) was instilled in the cerebrospinal fluid of the fourth ventricle (75 μg). Breath to breath analysis showed that the slope of inspiration (rate of pressure change) increased by 62 to 221 percent from baseline values which ranged from 7.8±0.2 (SEM) to 13.4±0.2 $mmHg \cdot sec^{-1}$. There was a variable effect on respiratory timing either no change or a shortening of both inspiratory and expiratory time. The effect lasted between 30 and 60 minutes after a single injection. The benzothiadiazides have carbonic anhydrase inhibitory properties but equivalent doses of acetazoleamide did not result in similar changes in respiratory output. These experiments suggest that AMPA preferring glutamate receptors at respiratory related neurons undergo desensitization and modulation of this characteristic results in an increase in respiratory output. (Supported by HL 38039)

CENTRAL ADMINISTRATION OF ASPARTIC ACID AFFECTS VENTILATION AND O_2 CONSUMPTION DIFFERENTLY IN MALE & FEMALE RATS. E. H. Schlenker*, S. R. Inamdar & D. Rivera-Hopkins. Univ. of S. D. School of Medicine, Vermillion, SD 57069

Aspartic acid (AA) injected subcutaneously induces a long lasting depression of ventilation (VE) in male but not in female rats. Systemic administration results in uptake of AA into the arcuate nucleus-median eminence area of the hypothalamus. In this study AA in doses of 100 & 200 nmol/0.5 μl relative to vehicle (CSF) injected into the arcuate nucleus of male rats resulted in a depression of $\dot{V}E$ and O_2 consumption ($\dot{V}O2$). Similar treatment of female rats caused in a depression of $\dot{V}O2$ without an effect on $\dot{V}E$. Intracerboventricular (ICV) injection of 3 μl of AA in doses of 0.5, 1 & 2 ng into the lateral ventricles of females affected $\dot{V}E$ & $\dot{V}O2$ similar to the arcuate injection, but resulted in an increase of $\dot{V}O2$ in male rats with no effect on $\dot{V}E$. In both sets of experiments the effects of AA were long lasting and reversible with time. We conclude that 1. AA injected into the arcuate nucleus has different effects on $\dot{V}E$ in male and female rats, although $\dot{V}O2$ is depressed in both groups; 2. depression of $\dot{V}E$ in males is not nonspecific (comparing arcuate and ICV results); & effects of AA on $\dot{V}E$ are not always coupled with similar effects on $\dot{V}O2$.

DIFFERENTIAL EFFECTS OF $GABA_A$ RECEPTOR ANTAGONISTS SUGGEST THE EXISTENCE OF A POTENT GAIN-CONTROL MECHANISM IN BULBOSPINAL RESPIRATORY NEURONS. Z. Dogas, E. Stuth, F. Hopp, D. McCrimmon, and E. Zuperku*. Zablocki VA Med. Ctr., Med. Col. of WI, Milwaukee, WI 53295 and Northwestern U., Chicago, IL 60611.

The role of $GABA_A$ receptors in the control of inspiratory (I) and expiratory (E) bulbospinal neurons (BSNs) was studied *in vivo* using pressure microejection while recording single unit activity in the caudal ventral respiratory group of anesthetized, ventilated, paralyzed dogs. Bicuculline (BIC; 0.5 mM), picrotoxinin (PTXN; 5 mM), and artificial cerebral spinal fluid (aCSF) were ejected from multibarrel glass micropipettes and volumes were measured via meniscus changes (50X microscope). The competitive antagonist, BIC, (3-35 pmol) produced 100-200% increases in the spontaneous phasic discharge frequency (F_n) without increasing activity during the normally silent phase of these neurons. The noncompetitive antagonist, PTXN, (40-720 pmol) produced slight increases (≈10% of control) in phasic F_n, however, during the silent phase, there was a dose-dependent increase in F_n (EBSNs: 52.5±18.9%- IBSNs: 36.7±4.9% of peak phasic control F_n). Thus, BIC amplified the underlying phasic pattern, while PTXN antagonized the silent phase inhibition. Phrenic nerve activity and I and E durations were not altered by these microejections. These studies suggest the existence of a BIC-sensitive, PTXN-insensitive gain-control mechanism in both IBSNs and EBSNs which may be mediated via $GABA_A$ receptors with novel pharmacology, and that the inhibition which produces the normally silent phase in these neurons is primarily mediated by $GABA_A$ receptors. Supported by VA Med. Research Funds.

BLOCKADE OF $GABA_A$ BUT NOT GLYCINE RECEPTORS IN THE PRE-BÖTZINGER REGION PRODUCES AN AUGMENTED OR GASP-LIKE PATTERN IN THE PHRENIC NEUROGRAM IN CATS. I.C. Solomon*, J.E. Melton, N.H. Edelman, and J.A. Neubauer. Department of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ.

Progressive brain hypoxia results in a shift from respiratory depression to gasping. Previous work from our laboratory has identified a region in the pre-Bötzinger (pre-Böt) complex in which chemical activation of neurons evokes an augmented or gasp-like pattern in the phrenic neurogram. To test the role of disinhibition in the production of gasping, we examined the effects of blockade of $GABA_A$ and glycine receptors in this region on respiratory patterning. In chloralose-anesthetized, vagotomized, and paralyzed cats, we identified a region in the pre-Böt complex that produced a gasp-like pattern in the phrenic neurogram when chemically stimulated unilaterally with DL-homocysteic acid (DLH; 10 mM; 21 nl). After recovery, we recorded phrenic neurogram (PN) responses to unilateral microinjection of bicuculline methiodide (BIC; 5 mM; 42 nl) and/or strychnine (STR; 2 mM; 42 nl) in the same region. Microinjection of BIC into 8 of 9 sites produced either an augmented (n = 4) or gasp-like (n = 4) pattern in the PN. In many of these sites, a series of eupneic breaths was interspersed between each augmented or gasp-like burst. In contrast, microinjection of STR into 5 sites was ineffective in changing the pattern of PN activity. Further, microinjection of STR 20-30 minutes after microinjection of BIC (n = 5) produced no additional change in PN activity. These findings suggest that $GABA_A$-mediated, but not glycine-mediated, inhibition of the pre-Böt region may play a role in suppression of gasping during eupnea. MK-801 ALTERS THE RESPIRATORY RESPONSE TO HYPOXIA IN ADULT RATS. S.K. Coles*, M.F. El-Khatib, and T.E. Dick. Dept. of Medicine, Div. of Pulmonary and Critical Care Medicine, Case Western Reserve Univ., Cleveland, OH 44106

Blocking NMDA receptor channels with the non-competitive NMDA antagonist, MK-801, prolongs T_I without changing T_E. Reversible bilateral inhibition of cellular activity (10mM muscimol) in the dorso- or ventrolateral pons produces a similar breathing pattern and, further, selectively attenuates the depressant effect of acute, severe hypoxia on respiration (i.e., post-hypoxic frequency depression, PHFD). The purpose of this study was to determine if blocking NMDA receptor channels would selectively affect PHFD.

Adult, male Sprague-Dawley rats (360-525 g) were anesthetized with Equithesin, vagotomized, paralyzed, and ventilated with 100% O_2. Animals were exposed to 8% O_2 for 30 s (n=6) or for 60s (n=1) before and after intravenous injection of MK-801 (0.3mg/kg). Phrenic nerve activity was recorded to determine respiratory cycle. Blood pressure, air flow, pCO_2, and body temperature were monitored.

During hypoxia before MK-801, respiratory frequency increased initially then decreased, and it decreased further following hypoxia, i.e., PHFD. These changes in frequency were primarily due to changes in T_E; T_I remained relatively unchanged. Injection of MK-801 at this low dose elicited minimal changes in respiratory frequency (n=4). However, in 3 animals, respiratory frequency decreased 30%. MK-801 altered the respiratory response to hypoxia in all animals. In 6 animals, respiratory frequency decreased rather than increased; this was primarily due to an increase in T_I rather than in T_E which changed inconsistently. Following hypoxia, T_E did not increase, and PHFD was attenuated in all rats.

We conclude that NMDA receptors have a significant role in determining the frequency response to hypoxia. Thus, blocking NMDA receptors altered either directly or indirectly the role of the lateral pons in mediating PHFD.

EFFECTS OF NBQX ON RESPIRATION IN ADULT RATS. Caroline A. Connelly*, Department of Surgery, University of California-Davis, Sacramento, CA 95817

N-methyl-D-aspartate (NMDA) receptors are significantly involved in respiratory pattern generation in adult rats (Connelly et al., *Brain Res.*, 596: 99-110, 1992), but not neonatal rat brainstem/spinal cords in *vitro*. Non-NMDA receptor activation is critical for maintaining respiratory rhythms *in vitro* (Funk et al., *J. Neurophysiol.* 70(4):1497-515, 1993). The present study examined the role of non-NMDA receptors in the generation of respiratory rhythm in spontaneously breathing adult rats.

6-Nitro-7-sulphamoylbenzo(f)quinoxaline-2,3-dione (NBQX) is an AMPA/kainate receptor antagonist that crosses the blood-brain barrier. NBQX (40 mg/kg, i.v., pH= 7.45-7.49 in 5.5% glucose) was administered to anesthetized Sprague-Dawley rats while diaphragm EMG activity and arterial pressure were monitored. Respiratory frequency significantly decreased ($p<0.01$, n=6); inspiration and expiration were both prolonged. Significant decreases in arterial pO2 and pH indicated that NBQX depressed ventilation. Arterial pCO2 increased in 5/6 rats. Changes in arterial pressure were insignificant. When the NMDA receptor-channel blocker, MK-801 (1mg/kg, i.v.), was injected 5-15 min after NBQX, respiratory frequency decreased further and apnea occurred within 45 s to 1 min. 5/6 rats had apneustic breaths (1.5 to 18 s duration) immediately prior to the onset of apnea. The rats were artificially ventilated until spontaneous breathing resumed after 7-85 min.

These data indicate that non-NMDA receptor activation is significantly involved but not necessary for respiratory rhythm generation in adult rats. These results support the hypothesis that combined activation of NMDA and non-NMDA receptors underlies excitatory transmission necessary for respiratory rhythm generation. (NBQX was generously provided by Novo Nordisk).

SEROTONIN IN THE DORSAL RESPIRATORY GROUP DECREASES HYPOGLOSSAL (XII) NEURAL ACTIVITY. M.A. Douse*, E.J. Puglisi and D.P. White. Dept. of Medicine, UCHSC, and Respiratory Care, VAMC, Denver, CO 80220.

Serotonin (5HT) is known to increase XII motoneuron activity when applied directly into the XII motor nucleus, but nothing is known concerning 5HT modulation of XII activity via other integration sites in the brainstem. We determined the effects of 5HT and methysergide (broad 5HT antagonist) pressure microinjection into the dorsal respiratory group (DRG; 25-100 nl; pH=7.2-7.4) on XII whole nerve activity in 6 decerebrate, vagotomized, paralyzed and artificially ventilated cats. The DRG was located by recording inspiratory activity at the appropriate co-ordinates and confirmed by antidromic activation from the C3 spinal cord. Surprisingly, pressure microinjection of 0.005 mM 5HT into the ipsilateral DRG resulted in a volume dependent bilateral decrease in XII whole nerve activity, measured as the inspiratory peak height of XII integrated neural activity (time constant=100 msec). XII neural activity ipsilateral to the injection site significantly decreased to 85.0 ± 5.4 % (25 nl); 74.2 ± 9.1 % (50 nl); and 50.4 ± 10.5 % (100 nl) of control values (n=5; all $p<0.05$). Contralateral XII activity decreased to 92.7 ± 2.8 % (25 nl; $p>0.05$); 91.2 ± 4.2 % (50 nl; $p>0.05$); and 74.0 ± 8.3 % (100 nl; $p<0.05$) of control (n=5). Pressure microinjection of 1.0 mM methysergide (100 nl) into the DRG had no effect on XII neural activity (97.6 ± 4.4 % of control; n=5) but did result in a full (99.5 ± 3.9 % of control; n=3) or incomplete (decreased to 53.0 ± 28.8 % of control; n=2) antagonism of subsequent pressure microinjection of 0.005 mM 5HT (100 nl). We conclude that exogenous 5HT in the DRG decreases XII neural activity. The data further suggest that the DRG may be an important site of 5HT modulation of respiratory drive to the XII motoneurons.

EFFECT OF SEROTONERGIC 1A AND 1B AGONISTS ON HYPOGLOSSAL MOTONEURONS. S. Okabe and L. Kubin*. Center for Sleep and Respiratory Neurobiology, Departments of Medicine and Animal Biology, University of Pennsylvania, Philadelphia, PA 19104.

Serotonergic effects on hypoglossal (XII) motoneurons have been implicated in sleep-related decrements in upper airway tone that may lead to airway obstructions. So far, serotonergic excitation, presumably mediated by type 2 receptors, was studied in some detail. However, the XII nucleus also contains type 1 receptors whose role in the control of XII motoneurons remains largely unknown. Our goal was to assess the effects of microinjections into the XII nucleus of 1A (8-OH-DPAT) and 1B (CGS12066) receptor agonists on XII nerve activity.

In 25 urethane anesthetized, paralyzed, vagotomized and artificially ventilated rats, we recorded XII nerve activity bilaterally. Microinjectionsof 8-OH-DPAT (0.1-10 mM) or CGS12066 (0.02-5.0 mM) were performed (10 nl, saline as vehicle) in histologically verified sites. At the highest concentrations used, both drugs suppressed XII nerve activity by about 20%. The suppression occurred within 2 min after the injection and lasted for at least 20 min. At a concentration of 0.1mM for 8-OH-DPAT and 0.02 mM for CGS12066, there was only a residual suppression of less than 5%.

Given that the affinity of 8-OH-DPAT to 1A receptors is at least 20-200 times higher than that of CGS12066 to either 1A or 1B receptors, it is unlikely that the observed effect is mediated by 1A receptors. Thus, it appears that 1B rather than 1A receptors play a role in these relatively weak suppressant effects on spontaneous XII nerve activity. (Supported by HL47600 and HL42236).

A STATISTICAL DESCRIPTION OF THE FIRING PATTERNS OF PHRENIC MOTONEURONS. W.-X. Huang*, M.I. Cohen, and Q. He. Dept. of Physiol., Albert Einstein Col. Med., Bronx, NY 10461.

To describe the discharge patterns of phrenic motoneurons (PMNs) statistically, we studied the relation between the interspike interval (ISI) and the order of firing during the inspiratory (I) phase for discharges of 151 PMNs in 8 unanesthetized, decerebrate and vagotomized cats. PMNs were classified as early (n = 62) and late (n = 89) based on the onset delay (border line 20 ms). Statistical analysis showed that for all late-I and 38/62 early-I PMNs, the second ISI in the I phase was significantly shorter than the first. However, for a minority of early-I PMNs (n = 18), all having oscillations that were locked to I onset, the second ISI was longer than the first. Thereafter, for all the PMNs, the ISIs became continually shorter due to gradually increasing drive. The decrease of ISI during the I phase was analyzed with regression and correlation techniques. With the method of least squares, curve-fitting was done to three types of curve: 1) straight line, 2) exponential curve, and 3) power function. We found that, for a given PMN discharge, the power function was the best fit for the relation between ISI and the order of firing in the I phase. This power function had the general form

$$Y = \alpha \cdot (X + c)^{\beta}$$

where Y is the ISI and X is the order of firing in an I phase. This relation held for most PMNs, with a correlation coefficient of 0.996 ± 0.007 (mean ± SD, n = 109), except for the 18 early-I PMNs whose second ISI was longer than the first. This pattern of time dependence of interval decrease may reflect the properties of the medullary inputs and the PMN responses. (Supported by N.I.H. Grant HL-27300.)

PHRENIC INTERNEURONS DO NOT CONVEY RESPIRATORY DRIVE TO PHRENIC MOTONEURONS. Steve Iscoe* and James Duffin, Department of Physiology, University of Toronto, Toronto, ON, Canada M5S 1A8.

Medullary respiratory neurons may drive phrenic motoneurons directly via monosynaptic connections, indirectly via interneurons, or a combination of the two. We tested the role of phrenic interneurons in transcribing central respiratory drive to phrenic motoneurons by cross-correlating the spontaneous activity of 26 C5 phrenic inspiratory interneurons to that of the ipsi- and contralateral phrenic nerves in decerebrate cats. Ten interneurons discharged only during inspiration (phrenic burst) and 16 tonically with increased firing during inspiration. The cross-correlograms of 21 of the interneurons to the ipsilateral phrenic were flat; 3 cross-correlograms had broad peaks centred about time zero, indicating common activation of the interneurons and motoneurons. The other two had troughs. Of the 22 cross-correlograms to the contralateral phrenic, 20 were flat and 2 had a broad peak at time zero. Despite inspiratory-modulated discharge patterns, phrenic interneurons do not convey central respiratory drive to phrenic motoneurons.

CYCLIC ADENOSINE MONOPHOSPHATE (cAMP) MEDIATES SHORT-TERM MEMORY WITHIN THE PHRENIC MOTOR NUCLEUS. Y. Sun, P.G. Wagner, and M.S. Dekin*. Department of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903-0019

Within the phrenic motor nucleus (PMN), thyrotropin-releasing hormone (TRH) causes presynaptic facilitation via an increase in cAMP while baclofen, a specific $GABA_B$ agonist, has the opposite effect (Sun *et al., Neurosci. Abstr.*, **20**:544, 1994). In this study we tested the hypothesis that brief exposure to TRH or baclofen would have persistent effects on presynaptic cAMP levels resulting in short-term memory within the PMN. Spinal cord slices containing the PMN (C3 to C5) were obtained from 3 to 7 day old rats. Whole cell recordings were made from motoneurons identified by antidromic stimulation of the ventral root. Excitatory postsynaptic potentials (EPSP) were elicited by stimulating the ventral (or lateral) funiculus. A separate pressure ejection electrode was used to apply TRH (10 μM) or baclofen (100 μM). Pressure ejection of TRH for 30 sec increased the EPSP amplitude while similar application of baclofen reduced the EPSP amplitude. These changes in EPSP amplitude persisted for as long as 1 hour. Motoneuron membrane properties, EPSP kinetics, and responsiveness to exogenous L-glutamate were not altered. Bath application of Rp-cAMP, a competitive inhibitor of cAMP at its binding site on protein kinase A, reduced the EPSP amplitude and antagonized the effects of both TRH and baclofen. These data demonstrate that transient exposure to neuromodulators of cAMP have long lasting effects on neurotransmitter release resulting in short-term memory within the PMN. PROTEIN KINASES A and C MODULATE THE ACTIVITY OF AN OUTWARD RECTIFYING $GABA_B$ ACTIVATED K^+ CHANNEL IN CULTURED PREMOTOR RESPIRATORY NEURONS. P.G. Wagner*, Y. Sun and M.S. Dekin Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, N.J. 08903.

Baclofen, a $GABA_B$ agonist, activates a Ba^{++}-insensitive outward rectifying K^+ channel [$K_{(OR)}$] in premotor respiratory neurons (Wagner and Dekin, *J. Neurophysiol.* 69:286, 1993). $K_{(OR)}$ channels are inhibited by both cAMP and thyrotropin-releasing hormone (TRH). Both 8-bromo-cAMP and TRH cause an increase in the interval between bursts of channel openings resulting in a dercrease in nPo. These data suggested that cAMP and TRH shared a common mechanism of action.TRH receptors, however, are usually associated with the activation of PKC (Joels and Drummond, *Brit. J. Pharmacol.* 96:450, 1989). In this study, therefore, we compared the ability of antagonists of PKA and PKC to protect $K_{(OR)}$ channels from TRH mediated inhibition. All recordings were made using the patch clamp technique in the cell-attached configuration. $K_{(OR)}$ channels were activated with 100 μM baclofen in the presence of Rp-cAMP (1 μM) or chelerythrine (1 μM). Both Rp-cAMP (n=10) and chelerythrine (n=4) caused a change in the conductance state of the channel from >100 pS (baclofen alone) to < 40 pS and an increase in nPo from <30% (baclofen alone) to >70%. The cells were then exposed to TRH (1 μM) in the presence of baclofen and either Rp-cAMP or chelerythrine. Both antagonists prevented the inhibition caused by TRH. These data suggest that not only does TRH produce its effects via PKC, but that there is an interaction between the PKA and PKC signaling pathways. (Supported by NIH Grant HL02314, the UMDNJ Foundation and Parker B. Francis Foundation).

SYNAPTIC MODULATION OF PHRENIC MOTONEURON EXCITABILITY IN RATS. D.R. McCrimmon*, F. Hayashi & C. Hinrichsen. Dept. Physiology, Northwestern University Medical School, Chicago, IL 60611-3008.

Modulation of the excitability of phrenic motoneurons was examined in response to stimulation of their descending inputs. Urethane-anesthetized Sprague-Dawley rats were paralyzed and their spinal cords transected at C1-2 to remove spontaneous respiratory drive. Descending pathways were activated using a concentric bipolar electrode in the lateral funiculus just caudal to the transection. Single-pulse stimulation of the descending pathway gave rise to a single, short-latency peak in phrenic nerve activity. In response to paired-pulse stimulation (intervals ≤ 20 msec), the second stimulus elicited two peaks. The first peak was identical to that elicited by the first pulse but was followed at short latency by a second peak, the amplitude of which was dependent upon the interpulse interval. The shorter the stimulus interval, the greater the amplitude of the second peak. Repetitive stimulation (50-100 Hz, 0.2 ms pulse, 3-120 μA, 10-30 sec train) of the descending pathway increased the spontaneous activity on the phrenic nerve for about 1 min. Intracellular recording revealed that the increased excitability arose from a depolarization of individual phrenic motoneurons and an increase in synaptic noise. There was also an increase in the amplitude and duration of individual EPSPs in response to single (test) pulse stimulations of the descending pathway following periods of repetitive stimulation. These data suggest that increases in phrenic motoneuron excitability may contribute to short-term potentiation of breathing. Supported by HL 40336.

MODELING OF NEURAL MECHANISMS FOR RESPIRATORY PATTERN GENERATION. I. A. Rybak, J. F. R. Paton[1], P. J. Kruk* and J. S. Schwaber. Neural Computation Group, DuPont Central Research, Wilmington DE 19880-0328 [1]Department of Physiology, University of Bristol, Bristol, BS8 1TD, UK

The objectives of the research were: (i) to develop computational models of neural mechanisms that provide the genesis and control of both respiratory oscillations and specific patterns of respiratory neurons, and (ii) to understand the mechanisms of integration and specific roles of intrinsic properties of respiratory neurons, network properties of their interconnections, and effects of afferent feedback in the genesis and control of the respiratory pattern.

Models of the central respiratory rhythm generator (CRG) were developed in the framework of the network theory of respiratory rhythmogenesis. The models of single respiratory neurons were developed in the Hodgkin-Huxley style and include sodium and a series of potassium and calcium channels. The single neuron models produce the specific firing patterns of respiratory neurons recorded experimentally (i.e. adapting and ramping bursts).

Different model versions of the CRG have been considered. They consist of interconnected neurons with different intrinsic properties and peripheral feedback from pulmonary stretch receptors (PSR) and chemoreceptors. The models have the same inspiratory off-switch but different expiratory-off switch mechanisms. They demonstrate both a stable respiratory rhythm and specific patterns of respiratory neuronal discharges. The models are compared and analyzed on the basis of their performance under normal conditions and under the influence of different perturbations applied to the PSR feedback and to afferent inputs from different nerves.

The simulation results indicate the most plausible network architecture and expiratory off-switch mechanism. Our models show how the intrinsic biophysical properties of individual neurons and groups of neurons along with the network properties provide the shaping of the specific respiratory patterns.

The effect of severe hypoxia on expiratory motor unit activity in the spontaneously breathing cat. J.H. Mateika, E. Essif, D. Fuller and R.F. Fregosi*. Dept. of Physiology, Univ. of Arizona, Tucson, AZ 85721

These experiments examined the effect of steady state severe hypoxia on the discharge frequency of expiratory motor units in anesthesized cats. Expiratory units were localized from the external oblique muscle while the cats expired against a positive end expiratory pressure (PEEP) of 1-2.5 cmH_2O. Subsequent to unit localization, PEEP was removed and unit activity, inspiratory and expiratory airflow, end-tidal oxygen (O_2) and carbon dioxide (CO_2), and external oblique electromyograph (EMG) activity were measured for 3-4 minutes during hyperoxia (F_IO_2 = 1.0) and severe hypoxia (F_IO_2 = 0.08-0.1). Throughout severe hypoxia end-tidal CO_2 was maintained at levels equivalent to that measured during hyperoxia. A total of 15 expiratory motor units were analyzed; 7/15 were active during hyperoxia while 12/15 were active during severe hypoxia. The number of impulses/expiratory period (N/T_E) and discharge frequency (f) of the units increased from a mean (± sd) of 9.5 ± 1.3 and 7.3 ± 3.0 (Hz) during hyperoxia to a mean of 14.1 ± 2.9 and 10.1 ± 3.1 (Hz) during severe hypoxia, respectively. This increase was accompanied by a significant increase in EMG activity (% of EMGmax) from 19.8 ± 18.0 to 48.1 ± 31.3. Cycle triggered histograms of N/T_E and f revealed that during both hyperoxia and severe hypoxia the majority of motor units did not begin to discharge until 30 % of the expiratory phase was completed. In addition, the impulse rate and discharge frequency for a given interval of the expiratory period was always greater during severe hypoxia compared to hyperoxia. Therefore, activation of the external oblique muscle contributes to lung deflation during the last 70% of the expiratory period during severe hypoxia. In addition, both rate coding and recruitment of motor units contribute to the increase in expiratory muscle activity.

MODULATORY PROCESSES IN THE ISOLATED RESPIRATORY SYSTEM OF NEONATAL AND MATURE MICE. F. Elsen*, U.J.A. Quellmalz, J.M. Ramirez, D.W. Richter. Department of Physiology, University of Göttingen, 37073 Göttingen, FRG.

Transverse medullary slices of mice containing the pre-Bötzinger complex generate spontaneously respiratory rhythmic activity. Inspiratory activity can be recorded at all postnatal stages (P0-31) as mass-activity from hypoglossal (XII) rootlets (Funk et al. 1994, J. Neurophys. 72: 2538; Ramirez et al. 1995, Eur. J. Physiol. 429: 599). Contained within this slice are the anatomical regions C1 and C2 which are characterized by their alpha-2 adrenergic binding sites (Flügge et al. 1990, J. Comp. Neurol. 297: 253). Using the transverse slice as an *in vitro* model, we examined the modulatory action of catecholamines on the isolated respiratory network of the developing mouse. At all postnatal stages (P0-18), blockade of alpha-2 adrenergic receptors by the antagonist yohimbine (1-5 μM) led to a decrease in the frequency of rhythmic activity in XII rootlets and in neurons of the pre-Bötzinger complex, an area which is essential for respiratory rhythm generation (Smith et al. 1991, Science 254: 726). Thus, endogenously released adrenaline seems to modulate central respiratory activity. Consistent with an endogenous adrenergic drive was the finding that adrenaline (5 μM) increased the frequency of XII rhythmic activity in neonatal (P0-5, n=8) and mature mice (P9-18, n=5) by 114 +/-29% and 83.5+/-15%, respectively. The duration of inspiratory XII bursts was increased in neonates (by 47%) and mature mice (by 61%) which correlated with a reduction in the interburst interval. Modulatory changes in XII rootlet activity were also reflected in neurons recorded intracellularly within the pre-Bötzinger complex. Whole-cell patch recordings from inspiratory neurons indicate that amplitude, slope and duration of depolarizating drive potentials were increased in the presence of 5μM adrenaline. Expiratory neurons were depolarized and rhythmic hyperpolarizations enhanced. The data demonstrate that the adrenergic system plays an important role in central respiratory control.

ELECTROPHYSIOLOGY OF MEDULLARY RAPHE NEURONS IN SLICES AND TISSUE CULTURE. G.B. Richerson* & J.H. Pizzonia, Dept. of Neurology, Yale University & VAMC, West Haven, CT. 06516

Neurons in the medullary raphe project widely to other respiratory nuclei, and contain neurotransmitters which strongly influence breathing. Respiratory acidosis alters the firing rate of pacemaker neurons in this region and in the ventrolateral medulla (Richerson, 1995; J. Neurophysiol. 73(3):933-44), making neurons in both regions candidates for central respiratory chemoreceptors. Changes in CO_2 / pH alter the firing rate of these neurons by modulating pacemaker currents; however, the specific currents responsible for the pacemaker potential are unknown.

In the present work, patch clamp recordings were made from medullary raphe neurons in slices in order to determine which currents were present which could potentially be modulated by respiratory acidosis. Results were compared to data from cultures of microdissected rostral medullary raphe. Neurons had similar properties using both preparations. In current clamp, neurons displayed delayed activation, spike frequency adaptation, short and long duration afterhyperpolarizations, and a voltage sag with maintained hyperpolarization. Whole-cell voltage clamp recording demonstrated a rapid, transient outward current activated by depolarization from potentials negative to resting potential, as well as inward rectification. These findings suggest that currents in neurons of the medullary raphe include A-current, calcium currents, calcium-activated K^+ currents, and an inwardly rectifying K^+ current, each of which can contribute to pacemaker potentials. Any of these currents could be the site of action of pH / CO_2 in modulating repetitive firing in these neurons. Characterization of the electrophysiologic properties of these neurons is essential for determining which ion channels are modulated by respiratory acidosis, and may help define the cellular basis of respiratory chemoreception. (Supported by the VAMC)

MEDULLARY RAPHE NEURONAL RESPONSES DURING FICTIVE COUGH. R. Shannon*, K.F. Morris, Z. Li, and B.G. Lindsey. Physiol. and Biophy,. Col. Med., Univ. South Florida, Tampa, FL 33612

Raphe neurons influence breathing. Serotonin is known to modulate the cough pattern. This study was motivated by the possibility that raphe neurons may modulate airway sensory information and the respiratory motor pattern during coughing. Decerebrated, thoracotomized, paralyzed, phrenic-triggered ventilated cats (8) were used. Extracellular single neuron activity, and phrenic and lumbar neurograms were monitored during fictive cough produced by mechanical stimulation of the intratracheobronchial tree. Up to 6 neurons were recorded simultaneously with a microelectrode array. Neurons were tested for respiratory modulation of firing rate by cycle-triggered histograms and 2 statistical tests, and for functional linkage to phrenic and lumbar motoneurons by spike-triggered averaging. Of 80 neurons, 10 were expiratory and 7 were inspiratory modulated; 63 had no respiratory modulation. Cells in each category showed either increases, decreases or no change in firing rate during fictive cough. The respiratory modulated cells had only small variations in discharge rate during control respiratory cycles. The results provide evidence for changes in the raphe neuronal network consistent with a modulatory role during coughing. (Supported by NIH HL49813)

SPATIOTEMPORAL IMPULSE PATTERNS DISTRIBUTED AMONG BRAIN STEM NEURONS RECORDED IN PARALLEL. E. Chang, K. F. Morris*, R. Shannon, and B. G. Lindsey. Dept. Physiol. & Biophysics, Univ. South Florida Med. Ctr., Tampa, FL 33612.

We have reported favored patterns in the spike trains of single neurons that are elements of brain stem cardiorespiratory-related neuronal assemblies identified by their impulse synchrony (FASEB J. 9:A839, 1995). Those results motivated a search for multineuron patterns of impulses that repeat more often than expected by chance. Spike trains were recorded in parallel with electrode arrays in the n. raphe obscurus, n. raphe magnus, and the region of the ventral respiratory group of 9 anesthetized (Dial), vagotomized, artificially ventilated cats. Samples of "spontaneous" activity from 4 to 11 simultaneously recorded single neurons were analyzed with the algorithms of Abeles and Gerstein (J. Neurophysiol. 60:909, 1988). The number of different recurring distributed patterns composed of 4 or 5 spikes exceeded ($p < 0.01$) that expected under the null hypothesis in 12 of 14 data sets. In 6 of 7 data sets, single neurons with previously identified favored patterns were also elements of groups of neurons with "excess" distributed patterns. The results: a) are consistent with the possibility that single neuron patterns may be fragments of distributed impulse sequences, b) provide another line of evidence for the hypothesis that brain stem neurons operate in coordinated assemblies, and c) encourage the search for coding functions of spike patterns in parallel channels. Supported by NS19814.

RESPIRATORY DEPRESSION BY CARBACHOL INJECTION IN THE PONTINE RETICULAR FORMATION IN NEONATAL RATS. M.-L. Fung* and W.M. St.John. Department of Physiology, Dartmouth Medical School, Lebanon, NH 03756.

In adult animal, injection of cholinergic agonist, carbachol, in the pontine reticular formation decreases phrenic activity (H. Kimura et al., *J. Appl. Physiol.* 69: 2280-9). I postulated that the pontine cholinergic mechanism mediated respiratory depression is present in the neonatal animal. Phrenic activity was recorded in decerebrate, paralyzed, ventilated and vagotomized neonatal rats from 4 to 22 days after birth. Small volume (10-60 nl) of carbachol (44-88 mM) was injected in the medial portion of the rostral pons. The injection of carbachol decreased phrenic peak activity and respiratory frequency in most animals. The site of injection was confirmed by histology. Result suggests that endogenous cholinergic mechanism in the medial pons depresses respiratory activity in neonatal animal. This study provide preliminary data for future studies of the nature of the mechanism underlying respiratory depression in developing animal and the possible link of the mechanism to the sudden infant dead syndrome.

AXONAL PROJECTIONS FROM THE PONTINE PNEUMOTAXIC REGION TO THE BÖTZINGER COMPLEX IN CATS. M. Aoki*, G. Song, Y. Sato, and I. Kohama. Dept. Physiology, School of Medicine, Sapporo Medical University, Sapporo 060, Japan.

We investigated axonal projections of respiratory and non-respiratory neurons in the pontine parabrachial -Kölliker- Fuse nuclear complex (NPB- KF, the pneumotaxic region) to a distinct group of expiratory neurons, the Bötzinger complex (BOTC), in the medulla by an antidromic mapping technique in chloralose-urethane anesthetized cats. Among 91 respiratory neurons extracellularly recorded in the NPB-KF, 13 neurons (11 inspiratory, 2 phase spannig type) were considered to have axons projecting to the BOTC. Antidromic mappings indicated that those descending axons terminate in the BOTC. Other 55 non-respiratory neurons were also antidromically activated by electrical stimulation of the BOTC. Recording sites of antidromically activated respiratory and non-respiratory neurons were distributed in the lateral NPB and KF nuclei. For histological identification of the projections, a small amount of WGA-HRP (30-50 nl, 5%) was injected into the BOTC. A number of retrogradely labeled cells were observed in the NPB- KF and the distribution of labeled cells was similar to that of recording sites. These results suggested that the pathway from the pontine pneumotaxic region to the BOTC is involved in respiratory control.

THE KÖLLIKER-FUSE NUCLEUS MEDIATES CARDIO-RESPIRATORY RESPONSES TO TRIGEMINAL NERVE STIMULATION IN THE RAT. M. Dutschmann & H. Herbert*, Dept. Animal Physiol., Univ. Tübingen, Auf der Morgenstelle 28, D-72076 Tübingen, Germany.

Stimulations of the nasal mucosa strongly influences the cardiovascular and respiratory outflow. These responses are trigeminally mediated. Recent studies have shown that the parabrachial (PB) and Kölliker-Fuse (KF) nuclei receive prominent somatosensory inputs from the spinal dorsal horn and the spinal trigeminal nuclei. The PB/KF itself has prominent projections to autonomic and respiratory cells groups by which he can strongly modulate their activity. In the present study we investigate whether the PB/KF plays a role in relaying the trigeminally induced cardiovascular and/or respiratory responses. To do so, we stimulated the ethmoidal nerve (EN5) and recorded cardiovascular and respiratory responses before and after injections of the calcium channel blocker $CoCl_2$ into the PB/KF.

Unilateral electrical stimulation of the EN5 resulted in a pronounced depression of respiration (apnoe) and a moderate, but significant bradycardia and pressor response. EN5 stimulations immediately after unilateral injections of $CoCl_2$ into the caudal KF resulted in a significant blockade of the respiratory depression. In contrast, $CoCl_2$ injections into rostrally located parts of the PB/KF showed only weak effects. A recovery of the respiratory response to EN5 stimulation (apnoe) was observed 30 to 60 minutes after the $CoCl_2$ injections. Injections of glutamate into the most effective blocking sites in the KF also caused an apnoe, suggesting that the trigeminal input to the KF is mediated by glutamatergic neurotransmission. The cardiovascular responses were also altered after $CoCl_2$ injections. However, whether these effects are statistically significant has to be evaluated by further experiments.

From our data we conclude, that the KF is an obligatory relay site for the trigeminally induced apnoe. Thus, one biological function of somatosensory inputs to the PB/KF might be the mediation of trigeminal nasopharyngeal (protective) reflexes. (Supported by DFG He 1842/3-2)

APPLICATION OF *IN SITU* PCR TECHNIQUE REVEALS THE DISTRIBUTION OF AN INWARD RECTIFYING K^+ CHANNEL IN RAT BRAINSTEM. J.S. Lai*, Y. Li, M. Kokhab, & J.L. Feldman. Systems Neurobiology Laboratory, Department of Physiological Science, UCLA, Los Angeles, CA 90095-1527.

We postulated that an inwardly rectifying K^+ channel (IRKC) plays an important role in the modulation of respiratory rhythm *in vitro* (Johnson *et al*, Soc Neurosci Abstr 18: 488, '92). Oligonucleotides identical to the M1 and M2 regions of mouse IRK1 (Kubo *et al*, *Nature* 362: 127, '93) were used as polymerase chain reaction (PCR) primers to amplify cDNA from neonatal brainstem (Lai *et al*, Soc Neurosci Abstr 19: 704, '93). A rat IRKC was detected, cloned, and characterized--rat brainstem K^+ channel 1 (RBSK1) (Lai *et al*, Soc Neurosci Abstr 20: 75, '94). In the present study, our goal is to localize its distribution within the medulla relative to regions affecting respiratory control.

Initial attempts to study the distribution of mRNA for RBSK1 were unsuccessful using conventional *in situ* hybridization techniques, perhaps due to its low copy gene expression. To increase sensitivity of detection, we employed *in situ* PCR, using a modified protocol on paraffin embedded sections of adult rat medulla (Nuovo, G. PCR *In situ* Hybridization: Protocols and Applications. New York: Raven Press, 1992). Supported by NIH Grants HL37941 and NS24742.

IMAGING OF VENTRAL MEDULLARY SURFACE ACTIVITY DURING TRANSIENT RESPIRATORY EVENTS. G. R. Poe*, D.M. Rector, H.V. Forster, P.J. Ohtake, L.G. Pan, T.F. Lowry, D. Gozal and R. M. Harper. Dept. Anatomy and Cell Biology, UCLA, Los Angeles, CA 90095; Dept. Physiol., Medical College of Wisconsin and Zablocki VA Hospital, Milwaukee, WI 53226.

We examined activity from the ventral medullary surface (VMS) during spontaneous sighs occurring within sleep and waking states in goats, using scattered light imaging procedures. Under sterile surgery, 5 goats were instrumented with electrodes to acquire sleep physiology and diaphragmatic EMG measures, and a miniaturized video CCD camera coupled to a coherent fiber bundle. The optic probe was placed over a site on the rostral VMS which, when cooled, elicited apnea. Following recovery, all-night sleep recordings were taken, and images were collected at 1/s. Sighs, (sustained inspiratory efforts > 2.5 x interval mean) were preceded by a substantial decline in moment-to-moment variability for a period of 4-9 sec prior to onset of the sigh. A significant decline in overall activity accompanied the sigh. We conclude that transient respiratory events such as sighs follow alterations in neural activity within the VMS. *Supported by HL-22418, USPHS-25739 and NIDR DE 07212. IMAGING OF VENTRAL MEDULLARY SURFACE ACTIVITY CHANGES WITH SPONTANEOUS DIAPHRAGMATIC ACTIVITY. R.C. Frysinger*, G.R. Poe, D.M. Rector, H.V. Forster, P.J. Ohtake, L.G. Pan, T.F. Lowry, D. Gozal and R. M. Harper. Department of Anatomy and Cell Biology, UCLA, Los Angeles, CA 90095; Department of Physiology, Medical College of Wisconsin and Zablocki VA Hospital, Milwaukee, WI 53226.

We examined activity from the ventral medullary surface (VMS) during spontaneous breathing occurring within sleep and waking states in goats using scattered light imaging procedures. Under sterile surgery, 5 goats were instrumented with electrodes to acquire diaphragmatic EMG and sleep physiology measures, and with a miniaturized video camera and coherent fiber optic probe placed over a site on the rostral VMS which, when cooled, elicited apnea. Following recovery, all-night sleep recordings were taken, images were collected at 1/sec, and diaphragmatic activity was integrated over a long time constant. Slow variation in overall diaphragmatic activity was cross correlated with light reflectance. Relatively synchronous correlations occurred for variance with a period of less than 10 sec. This lag calculation varied considerably across sleep-waking states, and sometimes disappeared entirely during slow-wave sleep. This finding suggests variable links between respiratory effort and the VMS, and underscores the importance of state in the central control of respiration. *Supported by HL-22418, USPHS 25739 and NIDR DE 07212. G.P. is supported by a Howard Hughes Medical Institute predoctoral fellowship.*

RESPIRATORY REGULATION: CENTRAL CHEMORECEPTION

738.1

POWER SPECTRA OF GASP-LIKE ACTIVITY IN THE PHRENIC NEUROGRAM ELICITED BY CHEMICAL ACTIVATION OF NEURONS IN THE PRE-BÖTZINGER REGION. M. Akay, I.C. Solomon, N.H. Edelman, and J.A. Neubauer*. Department of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903.

Progressive brain hypoxia results in a shift from respiratory depression to gasping in peripherally chemodenervated animals. In addition, there is a shift in the autoregressive (AR) spectra of the phrenic neurogram such that peaks are seen only in the 0-30 Hz and 60-120 Hz ranges. Recently, we demonstrated that a gasp-like pattern in the phrenic neurogram can be evoked by chemical activation of neurons in the pre-Bötzinger (pre-Böt) region. To determine whether the power spectra of such gasp-like activity is similar to that seen during hypoxia-induced gasping, we examined the AR spectra of chemical-induced gasp-like activity. Gasp-like activity was evoked by microinjecton of either DL-homocysteic acid (DLH; 10 mM; 21 nl; n=5) or sodium cyanide (NaCN; 1 mM; 21 nl; n=3) into the pre-Böt region in chloralose-anesthetized, vagotomized, and paralyzed cats. We also examined the AR spectra of the eupneic pattern immediately prior to microinjection of DLH or NaCN. The AR spectra of the eupneic pattern consisted of a discrete peak in the 30-60 Hz range and another in the 60-120 Hz range. During chemical-induced gasp-like activity there was a downward shift of the 30-60 Hz peak to frequencies < 30 Hz. Prior to cessation of the chemical-induced gasp-like activity, the low frequency power (< 30 Hz) began to shift back towards the eupneic pattern (30-60 Hz range). These findings demonstrate that the changes seen in AR spectra during chemical-induced gasp-like activity in the phrenic neurogram are similar to those seen during hypoxia-induced gasping. INTRINSIC EFFECTS ON MEMBRANE POTENTIAL AND INPUT RESISTANCE OF CHEMICAL HYPOXIA ON CULTURED NEURONS FROM THE ROSTRAL VENTRAL LATERAL MEDULLA (RVLM). E. Mazza*, N.H. Edelman and J.A. Neubauer. Department of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903.

In the face of a hypoxic insult, central neurons will decrease activity as a means of conserving energy and avoiding cell death. Recent work *in vivo* has also demonstrated subpopulations of neurons that are excited by hypoxia. The goal of this study was to determine the intrinsic effects of chemical hypoxia on membrane potential (V_m) and input resitance (R_m) on cultured neurons from the RVLM, a brainstem area containing neurons important to central cardiovascular and respiratory control. The studies were performed on neonatal rat neurons (>3 days old) plated on astrocyte monolayers using the whole cell perforated patch clamp technique. The cells were perfused in either mock-CSF or mock-CSF containing low Ca^{2+} (0.5 mM) and high Mg^{2+} (4.0 mM) to block synaptic transmission and were equilibrated with 95% O_2/5% CO_2. Sodium cyanide (NaCN, 1-10 mM) was given as a bolus into the perfusion line and the V_m, R_m, and firing frequency (FF) were analyzed in 18 neurons. Of these 18 neurons, 7/18 (39%) were hyperpolarized and decreased FF, while 11/18 (61%) were depolarized and increased FF with NaCN. These responses were unaffected by synaptic blockade. Excitation was associated with a decrease in R_m while depression was associated with an increase in R_m. In all cases responses were repeatable and reversible. Thus, cells cultured from the RVLM show responses that are intrinsic and not synaptically mediated, similar to those demonstrated *in vivo*. These results further suggest the existence of a population of neurons that are excited by hypoxia and that may act as central O_2 sensors. (Supported by HL16022 and HL07467).

IN VITRO RESPONSES OF PERIAQUEDUCTAL GRAY NEURONS TO HYPOXIA AND HYPERCAPNIA. J.M. Kramer*, P.C. Nolan and T.G. Waldrop. Depts. of Physiology & Biophysics, Kinesiology, Neuroscience Program and College of Medicine, Univ. of Illinois, Urbana, IL 61801.

Previous studies from this laboratory have demonstrated that hypoxia and hypercapnia stimulate neurons in the ventrolateral medulla and in the caudal hypothalamus both *in vivo* and *in vitro*. In addition, we have recently shown that caudal hypothalamic neurons which respond to hypoxia and possess a cardiorespiratory related discharge project to the periaqueductal gray (PAG). The purpose of the present study was to determine if neurons in the PAG are responsive to hypoxic and hypercapnic stimuli in the absence of input from peripheral chemoreceptors and other brain regions. Brain slices (400-500 μm) containing the PAG were obtained from Sprague-Dawley rats and placed in an interface chamber perfused with nutrient medium bubbled with 95% O_2/5% CO_2. Single unit, extracellular responses of PAG neurons to hypoxia (10% O_2/5% CO_2/85% N_2) and to hypercapnia (7% CO_2/93% O_2) delivered for 60-120 sec. and 3 min., respectively, were recorded. Hypoxia altered the discharge rate in 73% of the neurons tested; only 9% of the neurons responded to hypercapnia. Most (85%) of the hypoxia sensitive neurons were stimulated by hypoxia. Perfusion of the slices with a synaptic blockade medium (low Ca^{++}/high Mg^{++}) did not block the excitatory responses to hypoxia. These findings demonstrate that PAG neurons have an inherent response to hypoxia. These results and our prior findings are consistent with a hypothalamic-PAG-medullary pathway involved in the mediation of cardiorespiratory responses to hypoxia. (Supported by NIH grants HL38726 and HL06296).

738.4

ACETAZOLAMIDE-INDUCED ACIDOSIS IN THE CAUDAL HYPOTHALAMUS INCREASES RESPIRATORY FREQUENCY AND HEART RATE. C.Z. O'Connor and T.G. Waldrop*. Depts. of Physiology & Biophysics, Neuroscience Program and College of Medicine, Univ. of Illinois, Urbana, IL 61801.

Prior results from this laboratory have shown that the respiratory response to hypercapnia is modulated by a GABAergic mechanism in the caudal hypothalamus. Moreover, hypercapnia stimulates a population of caudal hypothalamic neurons with cardiorespiratory basal discharge patterns *in vivo* and *in vitro* in the absence of classical synaptic transmission. The purpose of the present investigation was to determine if a hypercapnic/acidotic stimulation isolated to the caudal hypothalamus elicits changes in cardiorespiratory activity. Therefore, respiratory (diaphragmatic EMG activity) and cardiovascular (arterial pressure and heart rate) responses to microinjections of acetazolamide into the caudal hypothalamus of anesthetized, male rats (Sprague-Dawley) were examined. Coates et al. (*J Appl Physiol* 75:5-14, 1993) have shown that acetazolamide, a carbonic anhydrase inhibitor, causes an increase in PCO_2 and an acidosis at the site of injection. Microinjections of acetazolamide ($\bar{x}$=80 nl, 5 $\times 10^{-6}$ M) into many caudal hypothalamic sites produced significant increases in respiratory frequency and heart rate. Microinjection of equivalent volumes of Ringers (pH and osmotically-adjusted) solution into the same hypothalamic sites had no effects upon cardiorespiratory activity. In contrast, large increases in diaphragmatic activity, heart rate and arterial pressure were elicited by microinjection of a GABA antagonist, bicuculline (5 ng/nL). These results indicate that local hypercapnic/acidotic stimulation of caudal hypothalamic neurons stimulates breathing and heart rate. Thus, the caudal hypothalamus appears to be a site of central chemoreception involved in cardiorespiratory control. (Supported by NIH HL38726).

738.5

EXPOSURE TO HYPERCAPNIC STRESS INDUCES C-FOS EXPRESSION IN THE BRAINSTEM CATECHOLAMINERGIC NEURONS. N.S. Cherniack*, K. Yung, B. Erokwu, and M.A. Haxhiu. Department of Medicine, Case Western Reserve University, Cleveland, Ohio 44106 (USA).

The response of catecholaminergic cells to hypercapnic stress was examined using c-fos as a tracing marker. Exposure of unanesthetized rats (n=8) to 15% $C0_2$ for 60 min induced activation of the c-fos gene, expressed as fos like immunoreactive protein (fos), within brainstem, mesencephalon, diencephalon, and cortical regions. Colocalization studies of tyrosine hydroxylase (TH) and fos protein revealed that the majority of the brainstem TH-containing cells expressed fos immunoreactivity. Numerous double labeled neurons were found in the ventrolateral medullary reticular formation (A1/C1 cell groups), in the dorsomedial and ventromedial subnuclei of nucleus tractus solitarius (A2/C2). TH-containing neurons in the ventrolateral pons (A5 cell group), and in the locus coeruleus also expressed fos like immunoreactivity in response to hypercapnic loading. These results suggest that catecholamine-containing neurons are part of the neuronal network involved in the response to $C0_2$. Supported by HL-25830 and HL-50527.

738.6

LOCALIZATION OF C-FOS IN RESPONSE TO ACIDIC STIMULATION OF THE ROSTRAL VENTROLATERAL MEDULLA. S.D. James, C.O. Trouth*, R.M. Douglas, R.W. Durant, and J.S. Allard. Department of Physiology and Biophysics, Howard University College of Medicine, Washington, D. C. 20059.

The rostral ventrolateral medulla(RVLM) has been implicated in the central CO_2 chemosensory regulation of cardiovascular and respiratory function. In this investigation, the effect of acidic mock cerebrospinal fluid at the RVLM was evaluated for c-fos immunoreactivity. c-fos was found in small interneurons embedded in the marginal glia(MG) of the caudal VLM and RVLM. c-fos-positive cells were also detected in nucleus retroambigualis, lateral reticular nucleus, the area postrema, cranial nerve nuclei X and XII and the n. tractus solitarius of the **caudal medulla. Rostrally**, positively stained cells were noted in the nucleus of the trapezoid body, medial parabrachial nucleus,olivary nuclei, cerebellar nuclei, pontine nucleus, the reticulotegmental nucleus of the pons, and the interpeduncular, red and oculomotor nuclei of the midbrain. These studies demonstrate that acidic mock CSF applied to the RVLM induces c-fos in several respiratory related nuclei and indicates that multiple sites of respiratory chemosensitivity may exist within the brainstem.

CYTOCHROME OXIDASE ACTIVITY AT THE VENTRAL BRAINSTEM ASSOCIATED WITH HYPOXIA. S.M. Johnson, M.E. Reynolds, C.O. Trouth, and R.M. Millis*. Dept. of Physiology & Biophysics, Howard Univ. College of Medicine, Washington, D.C. 20059.

Intramitochondrial cytochrome oxidase activity (CCO) has been used as a marker for hypoxia in myocytes and central neurons. Neurons involved in cardiorespiratory regulation at the caudal ventrolateral medulla (CVLM) respond to hypoxia. The present studies quantified differences in CVLM CCO levels in neurons of rats with a.) ligation of carotid of basilar arteries (10-60 min), b.) topically applied mock CSF (mCSF) 5 min at pH 7.40 or c.) KCN (5 min) control. Incubation of frozen sections was done for 0.5-2.0 h with DAB and cytochrome *c*; and computer analysis of DAB reaction product was calibrated in optical density units (ODU) to a colorimetric standard optimized at 2-h incubation (NIH Image Program). Topical mCSF and carotid or basilar ligation produced CCO levels (.38 ± .01 ODU to .49 ± .02 ODU) that was decreased to .18 ± .01 ODU in apneic (KCN induced; 3-5 s) rats and decreased further to .05 ± .01 ODU in controls. CCO in CVLM neurons appears to decline during hypoxia associated with apnea.

(Support: ONR Grant No. N00014-94-1-0523).

CYANIDE EFFECTS ON CYTOCHROME OXIDASE ACTIVITY AT THE VENTRAL BRAINSTEM. M.E. Reynolds, S.M. Johnson, C.O. Trouth R.M. Millis & J.A. Holloway*. Dept. of Physiol. & Biophys., Howard Univ. Coll. of Medicine, Washington, D.C. 20059.

Hypoxic responses of cardiorespiratory control neurons at the ventrolateral medulla (VLM) have been described. After a 5-min topical application of KCN (20 mg/mL) to chloralose-urethane anesthetized rats, cytochrome oxidase activity (CCO) was quantified by DAB histochemistry in 20 μm frozen coronal caudal VLM (CVLM) tissue sections. A timed study showed that 2-h incubation was optimal for densitometric analysis of the DAB reaction product (NIH Image Program), calibrated to a colorimetric step-tablet that transforms pixel values from linear light transmittance to optical density units (ODU) or concentration. Control CCO was found in CVLM sections exposed to KCN-free mock CSF (mCSF) and was compared to histochemical (HC) controls incubated for 2 h in 0.7 mg/mL KCN. At the CVLM, KCN produced 3-5 s of apnea. KCN decreased CVLM CCO from .38 ± .01 ODU in mCSF controls to .12 ± .01 ODU and to .05 ± .01 ODU in HC controls. CCO appears to be a marker for the effects of hypoxia and cyanide at the CVLM.

A TECHNIQUE TO MEASURE pH_i IN NEURONS OF BRAINSTEM SLICES. N.A. Ritucci, J.S. Erlichman*, J.B. Dean and R.W. Putnam. Department of Physiology & Biophysics, Wright State University School of Medicine, Dayton, OH 45435.

Certain chemosensitive neurons in dorsal and ventral regions of the medulla respond to acid/base changes in the brainstem and are thought to be involved in central chemoreception. **We have developed a technique to measure pH_i of neurons in brain slices using a fluorescence imaging system.** The medullae of 3-12 day old rat pups were excised and sectioned into 100-150 μm slices (unless otherwise stated, all steps conducted at room temperature in 5% CO_2/HCO_3^- buffer: (in mM) 5 KCl, 124 NaCl, 1.3 $MgSO_4$, 26 $NaHCO_3$, 1.24 KH_2PO_4, 10 glucose, 2.4 $CaCl_2$, pH=7.4). Slices were loaded with 4 μM BCECF-AM at 37°C for 15 minutes and then washed for 10 minutes. Individual slices were placed into a 750 μl chamber on the stage of an inverted microscope and superfused with CO_2/HCO_3^- buffer at 2 ml/min. Dye-loaded slices were excited alternately at 500 and 440 nm. The emitted fluorescence at 530 nm was directed through a GeniSysII image intensifier and an MTI CCD72 camera. The subsequent images were processed by Image1/Fluor software. The ratio of 500 to 440 nm fluorescence was measured and converted to pH by constructing a calibration curve using high K^+/nigericin solutions at pH values between 5.8 and 8.6. Slices labeled with a neuron-specific antibody, neuron-specific enolase, showed staining that correlated with that of BCECF-loaded cells. Slices labeled with a glial-specific antibody, glial fibrillary acidic protein, showed staining that was very different from that of BCECF-loaded cells. This indicates that our pH_i measurements were taken from neurons. Average pH_i values of neurons in the ventral and dorsal medullary regions were 7.38 ± 0.02 (n=85) and 7.32 ± 0.02 (n=110), respectively. **These values are the first *in situ* measurements of pH_i in the dorsal and ventral regions of the medulla.** [Supported by NIH HL 46308 and the WSU BMS program.]

IN VITRO MEASUREMENT OF pHi IN NEURONS IN MEDULLARY CHEMOSENSITIVE AREAS. J.S. Erlichman, N.A. Ritucci, R.W. Putnam, R.-Q. Huang* and J.B. Dean. Department of Physiology and Biophysics, Wright State University, Dayton, OH 45435.

Specific dorsal and ventral sites of the medulla have been identified as chemosensitive, however, the proximate stimulus to these cells is unknown. Previous studies suggest that intracellular pH (pHi) may be the physiologically relevant chemostimulus. We hypothesize that pHi and/or rate of pHi recovery during and after hypercapnia may be unique to cells located within CO_2-chemosensitive areas of the medulla as compared to cells located outside these areas. To this end, we have developed a method for measuring pH_i in neurons in thin (100-150 μm) medullary slices loaded with the pH-sensitive, fluorescent dye, BCECF (see: N.A. Ritucci *et al.*, this volume). Brain slices were prepared from 3-12 day old rats and superfused with a 5% CO_2/HCO_3^- artificial cerebral spinal fluid (ACSF) medium containing (in mM): NaCl 124, KCl 5, $NaHCO_3$ 26, $MgSO_4$ 1.3, $CaCl_2$ 2.4, KH_2PO_4 1.24 and glucose 10 (pH_{ACSF} 7.4). pHi was measured in chemosensitive areas of n. tractus solitarii (avg. ± S.E.; 7.23 ± 0.02, n= 51), dorsal motor n. (7.22 ± 0.09, n= 22) and near the ventrolateral surface (7.44 ± 0.04, n= 41). Non-chemosensitive areas included the spinal trigeminal n. (7.70 ± 0.08, n= 18), *n.* retroambiguus (7.20 ± 0.02, n= 19), inferior olive (7.46 ± 0.03, n= 7), gigantocellular reticular n. (7.20 ± 0.08, n= 7) and ventral reticular n. (7.25 ± 0.03, n= 8). Hypercapnia (10% CO_2) decreased pHi in all cells at all sites to varying degrees (0.77 ± 0.11 pH units, n= 9). Moreover, the rates of recovery of pHi during hypercapnia differed among cells at a given site as well as between sites. We have also found that the ability of cells to regulate pHi during hypercapnic acidosis was critically dependent upon pH_{ACSF}: decreases in pH_{ACSF} of ~0.3 pH units impaired pHi regulation during hypercapnia. ANATOMICALLY COUPLED CO_2/H^+-CHEMOSENSITIVE NEURONS IN THE DORSAL MEDULLA. J.B. Dean, R.-Q. Huang and R.E.W. Fyffe*[,1]. Depts. of Physiol. and Biophysics, and Anatomy[1], Wright State Univ., Dayton, OH 45435.

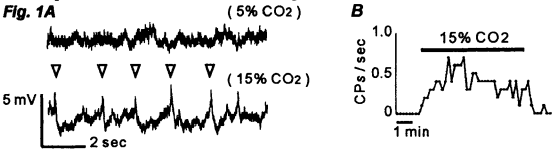
Morphological properties of CO_2/H^+-excited neurons in the solitary complex (SC; *i.e.*, n. tractus solitarius, dorsal motor n.) were investigated via perforated-patch recordings in transverse, thin slices (~150 µm) prepared from rats (0-14 days old). Chemosensitivity was tested by increasing CO_2 (bal. O_2) in HCO_3^--buffered medium from 5% to 10 or 15% for 5-10 min. The patch was ruptured after establishing the cell's response to CO_2/H^+, thereby permitting lucifer yellow *and* biocytin to stain the cell. Fifteen neurons were anatomically coupled to a second cell; 11/13 coupled neurons were CO_2/H^+-excited. Coupling potentials (CPs ; *Fig. 1A*, ∇) were observed only in anatomically coupled cells, and were maintained during chemical synaptic blockade. CP frequency often increased with high CO_2/H^+ indicating that the adjacent coupled cell was also chemosensitive (*Fig. 1A, B*). CPs were also seen in adult



SC neurons indicating that coupling was not a developmental phenomenon unique to neonates. Our findings demonstrate that anatomical coupling and CPs occur primarily in chemosensitive SC neurons, suggesting that they are electrically coupled via gap junctions. Moreover, CPs are still observed during and after repeated exposures to high CO_2/H^+ suggesting that SC neurons, unlike most other types of cells, are not uncoupled by intracellular acidosis. [NIH Grants HL 46308 and NS 25547]

738.12

ELECTROPHYSIOLOGICAL PROPERTIES OF NEURONS IN CHEMOSENSITIVE AREAS OF THE DORSAL AND VENTRAL BRAINSTEM. T.L. Southard*, R.-Q. Huang, J.B. Dean. Dept. of Physiology and Biophysics, Wright State University, Dayton, OH 45435.

Neurons in the dorsal medullary (i.e., solitary complex, SC) and ventrolateral medullary (VLM) chemosensitive areas are hypothesized to function in central chemoreception. The present study employed the perforated-patch technique (amphotericin B) in thin slices (~150µm; 0-14 day old rats) to characterize electrophysiological responses (e.g., membrane potential, Vm; firing rate; input resistance, R_N) of neurons in SC and VLM to hypercapnia. Individual neurons were visualized using Hoffman Modulation Contrast Optics and exposed for tight-seal recording. Cell sensitivity to hypercapnia was tested by increasing the % CO_2 (bal. O_2) aerating the nutrient medium from 5% (control) to 10% or 15% (hypercapnia) for 5 to 10 min; most experiments were conducted in high Mg^{++}-low Ca^{++} synaptic blockade medium. In the ventral medulla, 28% of neurons tested were CO_2/H^+-excited (i.e., chemosensitive), 32% were CO_2/H^+-inhibited and 40% were CO_2/H^+-insensitive. Twenty-four percent of the neurons in the SC were CO_2/H^+-excited, 29% were CO_2/H^+-inhibited and 47% were CO_2/H^+-insensitive. R_N was either increased or unchanged in CO_2/H^+-excited cells during hypercapnia; R_N changes were variable in CO_2/H^+-inhibited cells and CO_2/H^+-insensitive cells demonstrated no changes in R_N. Depolarizing, excitatory responses to hypercapnia reversed at membrane potentials ~ -90 mV for both SC and VLM chemosensitive neurons. Pretreatment with the potassium channel blocker 4-aminopyridine (4-AP, 2-10 mM) abolished CO_2-induced depolarization. We conclude that CO_2/H^+-excited neurons comprise ~1/4 of the cells tested in the SC and VLM. We hypothesize that CO_2-induced depolarization involves a decreased K^+ conductance based on 1) increased R_N during hypercapnia, 2) reversal of the response at Vm ~ -90 mV, and 3) blockade of CO_2/H^+-excitation by 4-AP (NIH HL 46308, WSU BMS Program).

RESPIRATORY REGULATION: SIGNAL TRANSDUCTION IN THE CAROTID BODY

739.1

ACETYLCHOLINE INCREASES INTRACELLULAR CALCIUM OF CULTURED CAT CAROTID BODY CELLS. M. Shirahata*, J.S.K. Sham, and R.S. Fitzgerald. Departments of Environmental Health Sciences & Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD 21205

Acetylcholine (ACh) is present in glomus cells of the carotid body (CB). ACh receptors are located on glomus cells as well as carotid sinus nerve (CSN). Exogenous application of ACh to the CB increases CSN neural activity and dopamine release. Perfusion of the CB with blockers of ACh receptors inhibits neural response of the CB to hypoxia. These data suggest ACh may have multiple actions in the CB. As one of the steps to elucidate possible roles of ACh in the CB chemotransduction we examined the effect of ACh on intracellular calcium concentration (Ca_i) of cultured cat CB cells with microfluorometric technique using Indo-1. CB cells were loaded with Indo-1 for 1 hour, and extracellular dye was removed by superfusion of Krebs solution for 45 min. Experiments were performed at 37 °C, and cells were continuously superfused with Krebs solution or Krebs solution containing pharmacological agents. All solutions were equilibrated with 5 % CO_2/16 % O_2. Ca_i was measured from clusters. ACh (1-100 µM) dose-dependently increased Ca_i, and approximately 80 % of clusters tested responded to ACh. Nicotine mimicked ACh effect, and pilocarpine occasionally caused very small increase in Ca_i. Increase in Ca_i by ACh was not blocked by caffeine which depletes Ca from intracellular storage sites. A L-type calcium channel blocker, nifedipine, did not block the effect of ACh. The results suggest that ACh increases Ca_i of cultured CB cells through activation of nicotinic channels. Supported by HL 47044, HL 50712, and HL 52652.

739.2

HYPOXIA DEPOLARIZES CULTURED CAT GLOMUS CELLS BUT DOES NOT INCREASE INTRACELLULAR CALCIUM. Chung-Long Chou*, J.S.K. Sham, Y. Ishizawa, and M. Shirahata. Departments of Environmental Health Sciences & Medicine, The Johns Hopkins Med. Inst., Baltimore, MD 21205

Our previous data using *in vivo* adult cats indicate involvement of voltage sensitive calcium channels (VSCC) for the CB response to hypoxia. We have been culturing CB cells from adult cats, and the cultured glomus cells released dopamine in response to hypoxia. These data are well fit to a current hypothesis of carotid body (CB) chemotransduction. That is, hypoxia depolarizes glomus cells followed by an activation of VSCC. Ca influx through activated VSCC increases intracellular calcium (Ca_i) of glomus cells and triggers neurotransmitter release. We tested the following possibilities if the cat glomus cells are depolarized during hypoxia, and if Ca_i increases during hypoxia. The CB cells cultured on glass coverslips were superfused with Krebs solution equilibrated with 5 % CO_2/21 % O_2, 5 % CO_2/16 % O_2, or 5 % CO_2/0 % O_2. PO_2 in the recording chamber was monitored continuously. Membrane potentials (E_M) of glomus cells were measured with patch clamp techniques. E_M changed from -54±3 mV during hyperoxia to -26±5 mV during hypoxia (20-30 torr; n=4). Sheath cells and other non-glomus cells in the cluster were not significantly depolarized during hypoxia. Ca_i of clusters was measured with microfluorometric technique using Indo-1, and it did not show significant changes during hypoxia. On the other hand, application of 100 mM K^+ clearly increased Ca_i, suggesting the presence of functioning VSCC. Data suggest that under these experimental conditions depolarization of glomus cells during hypoxia may not enough to fully activate VSCC. Supported by HL 47044, HL 50712, and HL 52652.

CATECHOLAMINE RELEASE FROM RAT CAROTID BODY CULTURES REARED IN NORMOXIC AND HYPOXIC ENVIRONMENTS. A. Jackson and C.A. Nurse*. Dept. of Biology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1.

Chronic hypoxia *in vivo* produces adaptive changes in the chemosensory carotid body (CB) resulting in time-dependent modifications in respiratory functions. Several adaptations to hypoxia have been identified in CB O_2-chemoreceptors (glomus cells) including cell hypertrophy, changes in ion channel expression and neurotransmitter function. By exposing cultures of dissociated Wistar rat CB to different O_2 tensions, we have uncovered some plastic properties of glomus cells that are likely due to direct effects of hypoxia (*P.N.A.S.* 89: 9469, *J. Neurobiol.* 26: 485, *J. Neurosci.* 15: 2192). In this study we begin an investigation of the neurotransmitter status of these cultures by measuring dopamine (DA) release using HPLC (with electrochemical detection). Both acute hypoxia (6 or 10% O_2) and high K^+ medium stimulated DA release from control cultures grown in normoxia for 1-2 weeks. Compared to controls, basal DA release was consistently higher in chronically hypoxic cultures. Further, K^+-evoked DA release (pmol/1000 glomus cells) was significantly higher in chronically hypoxic compared to control cultures after 2 weeks *in vitro*. We are investigating whether these modifications in neurotransmitter function can be correlated with other known physiological and biochemical changes that have been identified in these chemoreceptors after chronic hypoxia. Supported by MRC Canada and the Heart and Stroke Foundation of Ontario.

CARBONIC ANHYDRASE AND CO_2 CHEMORECEPTION IN FROG OLFACTORY RECEPTOR NEURONS. E.L. Coates* and R.P. Smith. Department of Biology, Allegheny College, Meadville, PA 16335.

There is substantial evidence that the enzyme Carbonic Anhydrase (CA) plays an important role in the detection of CO_2 by central (Coates, Li, and Nattie, 1991; Hanson, Nye, and Torrance, 1981; Erlichman, Coates, and Leiter, 1994) and carotid body chemoreceptors (Lahiri et al., 1993). The objective of the present study was to determine whether the olfactory CO_2 neurons in bullfrogs also use CA to detect changes in CO_2.

To test this hypothesis, olfactory generator potentials were recorded from the ventral epithelium of bullfrogs using glass electrodes (tip diameter = 15-25 µm). Olfactory receptor neurons were tested for their response to 2 second pulses of 5% CO_2 and amyl acetate before and after (up to 90 min) topical CA inhibition with acetazolamide (10^{-2}M) or before and after application of an inactive acetazolamide analog (CL 13850).

In 52 bullfrogs, 1222 sites on the ventral epithelium were checked resulting in 23 locations that exhibited a response to CO_2. It was found that CA inhibition caused an immediate 65% reduction in the generator potential amplitude in response to CO_2 while the response to amyl acetate was not affected. Application of the inactive acetazolamide analog had no affect on the receptor response to either CO_2 or amyl acetate. These results indicate that CA plays a role in the detection of CO_2 by frog olfactory receptor neurons but not in the detection of "normal" odorants and that CO_2 receptors are relatively rare in the olfactory epithelium. The sparse distribution of CO_2-sensitive olfactory neurons was confirmed by histochemical localization of CA in 20 µm cryostat sections, which showed that relatively few olfactory neurons in the bullfrog contain CA. (Supported by NSF grant # IBN 94-09236)

THE ROLE OF PROTEIN PHOSPHORYLATION IN THE REGULATION OF INTRACELLULAR Ca^{2+} LEVELS AND CATECHOLAMINE (CA) RELEASE IN CULTURED RABBIT CAROTID BODY TYPE I CELLS. L. He, J. Chen*, B. Dinger and S. Fidone. Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108.

Although previous studies have demonstrated that Ca^{2+} currents rapidly degenerate (rundown) in chemosensory type I cells during patch-clamp experiments, it has nonetheless been suggested that Ca^{2+}-channel function in these cells is not regulated by cyclic AMP-initiated protein phosphorylation (*J. Neurochem.* 57: 1992-2000, 1991). In the present study, the presence of MgATP and the catalytic subunit of protein kinase A (PKAc) in patch pipettes markedly slowed the rundown and significantly enhanced the peak values of sustained inward (L-type) Ca^{2+} currents recorded in freshly dissociated chemosensory cells, an effect which was mimicked by okadaic acid, a protein phosphatase inhibitor. Ratiometric imaging revealed that agents which increase cAMP in carotid body type I cells (forskolin, 10 μM; adenosine, 100 μM) also potentiate hypoxia-evoked intracellular Ca^{2+} responses. Finally, a sulfur substituted cell permeant PKA inhibitor, Rp-cAMPS, depresses ^{3}H-catecholamine (synthesized from ^{3}H-tyrosine) release evoked from superfused carotid bodies. The current results are consistent with the hypothesis that hypoxia, which elevates cAMP in type I cells, initiates a cascade of events resulting in elevated intracellular Ca^{2+} levels and enhanced CA release. DIFFERENTIAL STIMULUS TRANSDUCTION PATHWAYS IN ARTERIAL CHEMORECEPTOR ORGANS. J. Chen, B. Dinger* and S. Fidone. Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108

In the present study calcium- and calmodulin-dependent protein phosphorylation was evaluated in tissue homogenates of rabbit carotid bodies previously treated with either nicotine (100 μM) or hypoxia (10% O_2 media) *in vitro* (10 min). Initial experiments established the relationship between ^{32}P incorporation (from ^{32}P-γ-ATP) in trichloroacetic acid protein precipitates and varying amounts of Ca^{2+} and calmodulin. Using optimum concentrations of these reagents (0.5 mM $CaCl_2$; 26 μg/ml calmodulin), we subsequently assessed ^{32}P incorporation in the presence or absence of Ca^{2+}/calmodulin as an indicator of calcium/calmodulin protein kinase II (CaMKII) activity. The data show that compared to intact carotid bodies superfused in 100% O_2, prior stimulation with 10% O_2 media did not affect ^{32}P incorporation. In contrast, exposure to nicotine significantly reduced ($p<0.001$) the Ca^{2+}/calmodulin-dependent ^{32}P incorporation. Because these assays were conducted in tissue homogenates following stimulation of intact carotid bodies, the data are consistent with the notion that nicotine, but not hypoxia, had previously activated CaMKII thus occupying many target phosphorylation sites with unlabeled phosphorus groups from the endogenous pool of ATP. Our findings support the hypothesis that nicotine vs. hypoxia activate fundamentally different signal transduction pathways in rabbit chemosensory type I cells. Supported by USPHS grants NS12636 and NS07938.

RESPIRATORY REGULATION: DEVELOPMENTAL MECHANISMS

740.1

DEVELOPMENTAL CHANGES IN THE ISOLATED RESPIRATORY SYSTEM OF MICE: AN *IN VITRO* STUDY USING THE TRANSVERSE RHYTHMIC SLICE. J.M. Ramirez*, U.J.A. Quellmalz, P. Telgkamp and D.W. Richter, Department of Physiology, University of Göttingen, 37073 Göttingen, FRG.

The transverse brainstem slice containing the pre-Bötzinger complex (pBC) has recently been introduced as an *in vitro* system to study the postnatal development of the respiratory system in mice (Funk et al. 1994, J. Neurophys. 72: 2538; Ramirez et al. 1995, Eur. J. Phys. 429: 599). This medullary slice generates at all examined postnatal stages (P0-31) spontaneous rhythmic activity that can be recorded as mass activity from hypoglossal (XII) rootlets. XII rootlet activity is in phase with inspiration and was used to determine phase-relationships of simultaneously recorded rhythmic neurons in the pBC, an area critical for respiratory rhythm generation.

During the first 3 postnatal weeks the duration of XII bursts remained unaltered. However, the pattern of XII bursts changed from decrementing (P1-7) to bell-shaped (P8-22), correlated with a significant decrease ($p=0.008$) in the rise of integrated bursts (-43.3 %). The degree of coupling between bursts in the pBC and those in XII rootlets changed during postnatal development, being 1:1 in a neonatal and on average 3:1 in a mature mouse. No obvious developmental change occurred in rhythm generating mechanisms. At all examined postnatal stages (P0-31) rhythmic activity was abolished by 10μM of the non-NMDA antagonist CNQX. Rhythmicity was maintained in the presence of glycinergic (strychnine, 0.2-20μM) and GABAergic (bicuculline up to 200μM) antagonists. Although inhibitory synaptic mechanisms seem not essential for *rhythm generation*, they are important for *pattern generation*. In XII rootlets blockade of inhibitory mechanisms caused an increase in frequency and burst amplitude and a decrease in burst duration. In the pBC blockade of inhibitory synapses increased rhythmic drive potentials and intraburst spike frequency of inspiratory neurons. The phasic hyperpolarization generated in expiratory neurons was decreased in the presence of strychnine. Following blockade of both glycinergic and GABAergic inhibition expiratory neurons were found to discharge in phase with inspiration.

740.2

DIFFERENTIAL EFFECT OF DOXAPRAM ON THE ISOLATED RESPIRATORY NETWORK OF NEONATAL AND MATURE MICE. B. Wilken*, J.M. Ramirez, U.J.A. Quellmalz, F. Hanefeld, D.W. Richter; Depts. of Physiology and Pediatric Neurology, University of Göttingen, 37073 Göttingen, FRG.

Doxapram is often used in the treatment of idiopathic central apnea in premature infants. It is effective in some cases which do not respond to aminophylline, although in other cases neither of these drugs is successful in treating apnea. These inconsistent effects may be due to maturational changes in the responsiveness of the respiratory system (Peliowski and Finer, 1990 J Pediatr 116:648-653). At present the site of doxapram action and possible developmental dependency remain uncertain. Thus, we examined at different postnatal stages (P0-16) the effect of doxapram on the isolated respiratory network using the transverse rhythmic brainstem slice preparation of mice (Ramirez et al., 1995 Eur J Phys 429:599). These slices (650 - 700 μm) contain the pre-Bötzinger complex (pBC), a region critical for respiratory rhythm generation. Spontaneous respiratory rhythmic activity was recorded extracellularly from hypoglossal (XII) rootlets and intracellularly from neurons within the pBC using the whole cell patch technique. In neonates (P0-4) 20 μM doxapram caused a decrease in cycle length of XII bursts (-74.5% +/- 66) without affecting burst amplitude (5% +/- 13, n=4). In contrast, in mature animals (P5-16), there was a significant increase in cycle length of XII bursts and burst amplitude (56% +/-59 and 79% +/-43, n=8), respectively. This developmental change was not abrupt and at an intermediate developmental stage (P5-8) alteration in cycle length was not significant (65%+/-67, n=4). First effects on burst amplitude were seen at postnatal day 6. Alterations in frequency and amplitude of XII rootlet activity were reflected in similar changes in pBC neuronal activity. Doxapram caused a depolarization of inspiratory neurons. We are currently investigating the cellular basis for this effect. Our data suggest that doxapram acts directly on the central neural network for respiration and that its action is dependent on dramatic maturational changes in the developing mouse.

740.3

DEVELOPMENTAL CHANGE IN THE HYPOXIC RESPONSE OF THE *IN VITRO* RESPIRATORY SYSTEM OF MICE. U.J.A. Quellmalz*, J.M. Ramirez, D.W. Richter, Dept. of Physiology, Univ. of Göttingen, 37073 Göttingen, FRG.

The response of the mammalian respiratory system to hypoxia changes dramatically during postnatal development and several different sites within the respiratory system have been proposed to be responsible for this phenomenon. We examined developmental changes in the hypoxic response of the isolated respiratory network using a rhythmically active medullary slice preparation of mice (Funk et al. 1994, J. Neurophys. 72: 2538; Ramirez et al. 1995, Eur. J. Physiol. 429: 599). Respiratory rhythmic activity at all postnatal stages (P0-31) was recorded extracellularly from hypoglossal (XII) rootlets and intracellularly from pre-Bötzinger complex neurons. Hypoxia, maintained for 20 - 30 minutes, was induced by replacing carbogenated artificial CSF with one containing a mixture of 95% N2 and 5% CO2. In slices obtained from neonatal mice (P0-P7, n=15) hypoxia induced a significant decrease in frequency (34.7% +/-5) which never led to a cessation of rhythmic activity. Duration (-2.1% +/-3.5), amplitude (-5.4% +/-6) and rise (+1.5% +/-5) of XII bursts were not significantly affected by hypoxia. In contrast, in mature animals (P7-P14, n=9) hypoxia caused an initial increase in the frequency of XII activity (+73.5% +/-20) which was accompanied by a dramatic increase in burst duration (+45.5% +/-12), amplitude (+85.6% +/-29) and rise (+29% +/-10) of XII bursts. We refer to this initial phase as *augmentation*. Augmentation was followed by *depression* characterized not only by a decrease in frequency (-20.2% +/-9), but also in burst duration (-9.1% +/-8), amplitude (-21.2% +/-17) and rise (-5.5% +/-18). Depression led always to abolition of rhythmic XII activity (*central apnea*). Inspiratory neurons in the pre-Bötzinger complex were initially depolarized and subsequently hyperpolarized. Expiratory neurons were only hyperpolarized. Under normoxic conditions, both groups showed complete recovery. Our results indicate that the isolated central network for respiration undergoes dramatic maturational changes in its hypoxic response which can now be analyzed under *in vitro* conditions.

740.4

GLOMUS CELL EXCITABILITY AND CAROTID BODY REFLEXES IN NEONATAL AND ADULT RATS ACCLIMATIZED TO CHRONIC HYPOXIA. S.C. Hempleman, F.L. Powell*, and S.M. Asgedom. Dept. of Medicine, University of California, San Diego, La Jolla, CA, 92093.

Chronic hypoxia (CHX) for several days to weeks increases the acute hypoxic ventilatory response (HVR) in adult rats, but has variable effects in neonatal rats. To investigate, we studied HVR and carotid body glomus cell Na^+ and K^+ currents in chronically normoxic (CON, PO_2=140 mmHg) and chronically hypoxic (CHX, PO_2=80 mmHg) adult (24-30 wks old) and neonatal rats (1 week old). Rats were acclimatized to CON or CHX for 3-4 weeks (CHX neonates were gestated and born in hypoxia). HVR was measured by body plethysmography; voltage-gated Na^+ and K^+ currents were measured in dissociated carotid body glomus cells using whole cell patch clamp. In neonates, CHX blunted the acute HVR (10% O_2 for < 1 min; $p<0.05$). Blunting persisted when hypocapnia was prevented with 4% CO_2 in 10% O_2. This contrasts with adult rats in which CHX significantly increases the acute isocapnic HVR. In neonatal glomus cells, CHX decreased I_K density (pA/pF, $p<0.05$), and increased I_{Na} (pA, $p<0.05$). In adult rat glomus cells CHX also decreased I_K density ($p<0.05$), and tended to increase I_{Na}. These results are consistent with increased glomus cell excitability in both adults and neonates after CHX, and suggest that blunting of the HVR in neonates is a CNS effect of CHX. CCK8-SULFATED ALTERS THE TIMING AND PATTERN OF RESPIRATORY BURSTS IN THE NEONATAL RAT *IN VITRO* BRAINSTEM-SPINAL CORD PREPARATION. H. H. ELLENBERGER* and F. M. SMITH, Department of Anatomy and Neurobiology, Dalhousie University, Halifax N.S., Canada, B3H 4H7.

Anatomical evidence suggests a role for cholecystokinin (CCK) in respiratory control (Ellenberger et al., J. Chem. Neuro., 5:375, 1992.). CCK receptors can directly affect neuronal membrane conductances or can act through a variety of second messenger systems. We examined the role of CCK-A and -B receptors on respiratory pattern in the *in vitro* neonatal rat brainstem-spinal cord. Long Evans rats (0-3 day old) (n=12) were anesthetized with ether and the caudal brainstem and cervical spinal cord were removed *en bloc* and placed in flowing artificial CSF solution (pH 7.4, 27°C). Respiratory burst activity was recorded extracellularly from C5 ventral roots. Activation of CCK-A receptors by bath application of CCK8-Sulfated (CCK8-S) doubled respiratory burst frequency at a concentration of 30 and 60 nM. At a CCK8-S concentration of 120 nM, burst duration became prolonged with long augmenting and decrementing phases. There was little or no change in burst amplitude or tonic activity. Bath application of similar volumes and concentrations of the CCK-B agonist, CCK8-Unsulfated, did not produce these effects. The CCK-A specific antagonist, lorglumide (600 nM) blunted or abolished responses to all concentrations of CCK8-S. These results suggest that CCK-A receptors can alter rate and pattern of respiratory burst discharge by acting primarily within the medullary respiratory network and not directly on respiratory motoneurons.

PERIODICITY OF SPONTANEOUS RESPIRATORY BURST ACTIVITIES IN NEONATAL RAT MEDULLARY SLICE. Y. Nakazono*, A.Watanabe, H.Shimizu, and M.Aoki, Dept. of Physiol., Sapporo Medical Univ. Sch. of Med., Sapporo 060, Japan

To investigate the neuronal mechanisms of spontaneous respiratory rhythm generation in the brainstem, we analyzed the periodicity of burst intervals in brainstem slice preparations of neonatal rats (1 - 7 days). Transverse slices (750 μm thick rostral to the obex, pre-obex region) were prepared. Spontaneous burst discharges were extra-cellularly recorded from the hypoglossal nucleus (XII n.) and/or the ventrolateral region including the pre-Bötzinger complex. The onset time of each burst was detected with a Schmitt trigger circuit. During the recording (20 - 60 min), burst to burst intervals (T) were automatically determined by means of a digital clock counter. The bursting rhythm of XII n. steadily continued for a few hours in the seven days after birth preparation, with the mean interval of 7.52 s and coefficient of variance of 0.16. We compared these statistical rhythm properties between of medullary neuronal discharges and of C5 rootlet nerve discharges obtained from the brainstem and spinal cord preparation (previously reported). The results showed that the rhythm from a single medullary slice had similar statistical properties to that from the brainstem and spinal cord preparation. It is suggested that the pre-obex region is a sufficient subsystem for generating the respiratory rhythmic bursting in the brainstem and spinal cord in neonatal rats.

740.7

SEROTONERGIC INNERVATION OF MEDULLARY RESPIRATORY CENTERS DURING RAT PRE- AND POSTNATAL DEVELOPMENT. S. M. Wagner and S. W. Schwarzacher*. Department of Clinical Anatomy, Univ. of Göttingen, D-37075.

Serotonin (5-HT) exhibits powerful modulation of central respiratory control during ontogenesis of the mammalian brainstem respiratory network. In addition, it has potential trophic effects on development of synaptic interaction.

We mapped for 5-HT-Immunoreactivity (5-HT-IR) in the ventral respiratory group (VRG) including the pre-Bötzinger-Complex in pre- and postnatal rat brainstems. 5-HT-IR cell bodies of the local caudal raphe nuclei appeared at embryonal day 14 (E 14), terminals with varicosities were detected in the VRG at E15. The number and density of 5-HT-IR fibres as well as fibre branchings within the VRG increased rapidly during the following three weeks reaching adult levels at postnatal day 14 (P 14). In contrast, 5-HT-IR terminal varicosities were densely distributed already at E16-17 and remained at a constant level of density during maturation. Therefore, local serotonergic innervation appears to be present during the entire period of pre- and postnatal development of medullary respiratory centers. The increase in 5-HT-IR fibre density may reflect the development of synaptic interaction within the respiratory network. *Supported by DFG*

SPATIOTEMPORAL EXPRESSION OF POLYSIALATED NCAM DURING PHRENIC NERVE OUTGROWTH AND INTRADIAPHRAGMATIC BRANCHING. Allan, D.W.*and Greer, J.J., Div. of Neuroscience, U. of Alberta, Edmonton, Alberta T6G 2S2, Canada

During the second and third trimesters of rat gestation, phrenic motoneurons grow out from the cervical spinal cord (C3-C5) through the developing thoracic cavity to innervate the diaphragm in a highly stereospecific manner. Towards understanding some of the molecular events associated with these processes, we examined the pattern of expression of growth associated protein (GAP-43) and polysialyated neural cell adhesion molecule (PSA-NCAM) in the phrenic nerve and diaphragm (E11-P0). Immunohistochemical detection of GAP-43, PSA-NCAM and NCAM was performed using anti-GAP-43 MAb (Sigma), 12E3 MAb (T. Seki) and polyclonal anti-NCAM (E. Bock), respectively.

PSA-NCAM expression was discretely localised along growing phrenic axons at three major directional decision areas: i) at the brachial plexus, where phrenic and brachial axons diverge; ii) at the primary branching site within the diaphragm, where three distinct branches form; iii) along intramuscular branches, where axons separate from the nerve trunk to innervate developing myotubes. The expression of PSA-NCAM in the phrenic nerve thus correlates spatiotemporally with episodes of defasciculation and motoneuron pool-specific guidance. There was also a clear spatiotemporal distribution of PSA-NCAM in developing diaphragmatic myotubes which was correlated with the regional innervation and intramuscular branching of the phrenic nerve and possibly secondary myogenesis. Functional studies of the role of PSA-NCAM were performed by looking at perturbations induced by cleavage of the PSA moiety from the NCAM molecule via intra-amniotic administration of the enzyme endoneuraminidase (U. Rutishauser). Funded by MRC and AHFMR.

MEDIUM FREQUENCY OSCILLATIONS DOMINATE THE PHRENIC NERVE DISCHARGE OF NEWBORN RATS. R.P. Vertes* and B. Kocsis.
Center for Complex Systems, Florida Atlantic University, Boca Raton, FL, 33431

In adult animals, the discharge of the phrenic nerve, representing central inspiratory activity contains two components termed medium frequency oscillations (MFO), in the range of 20-50 Hz, and high frequency oscillations (HFO), in the range of 50-100 Hz. It was demonstrated in the cat and pig that while MFOs were present in newborn animals, HFOs appeared later in the development and were therefore considered an index of maturation of the respiratory system. It has also been found in kittens that the switch in phrenic nerve activity from MFO to HFO dominance coincided with a characteristic change of the respiratory response to hypoxia from a biphasic response to sustained facilitation of respiration, suggesting that the respiratory system in these species exhibits an abrupt transition from immature to mature pattern in early infancy and that the two measures reflect this transition (Sica & Gandhi, 1990). Although the biphasic respiratory response to hypoxia has been described in the rat, frequency characteristics of the rat phrenic nerve discharge have only been studied in an *in vitro* preparation (Smith et al.,1990).

In this study we examined the synchronization of the discharge of phrenic motoneurons in anesthetized rat pups 14 to 27 days of age. We found that the inspiratory phrenic nerve activity, its first half (ramp) in particular, consisted of synchronized bursts separated by 20-35 ms, corresponding to MFOs. Accordingly, the autospectra of the neurograms had two peaks, one at the respiratory rate and the other at 30-35 Hz. The latter was relatively broad, occupying a range of frequencies from 15 to 50 Hz. These findings demonstrate that phrenic nerve discharge of rat pups, like that of kittens and piglets, is in the MFO range, and suggest that MFO activity is an index of an early developmental stage of the respiratory system.

SEIZURES AND ELECTROCORTICOGRAPHIC DEPRESSION AFTER RAPID-ONSET HYPOXIA IN YOUNG PIGLETS. K.A. Waters, C. Beardsmore, G.A. Turner, J. Paquette, B. Meehan, I.R. Moss*. Developmental Physiology Lab., McGill Univ., Montreal Children's Hospital, Montreal, PQ, H3H 1P3.

To determine whether the severity or the pattern of hypoxia is important to the induction of seizures, electrocorticographic (ECoG) depression and gasping respiration, cortical electrodes and an arterial cannula were implanted chronically in 16 piglets age 10-22 d. In 48 studies, piglets were exposed to rapid-onset hypoxia of 6%, 8% or 10% on alternate days. Animals were awake, moving freely and hypoxia was either continuous (CH) or repetitive (RH), lasting 21 min in total. RH comprised 7 x 3-min epochs alternating with 3-min recovery epochs in air. ECoG & respiratory responses were filtered and digitally acquired, to permit spectral analysis of the ECoG signals. The ECoG frequency spectrum shifted towards the delta band during hypoxia. Seizures and ECoG depression occurred repeatedly in 6 of 12 piglets exposed to 6% RH, whereas a single event occurred in 2 of 8 piglets during 6% CH. Cortical depression was more marked when hypoxia occurred in brief, repeated cycles as compared to CH of equivalent severity and duration, suggesting particular sensitivity of the cortex to rapid changes in oxygen tension at the onset of hypoxia. Respiratory and metabolic adjustments in CH may aid in the recovery from ECoG events.

MATHEMATICAL MODELLING OF PERIODIC BREATHING AT HIGH ALTITUDE: A COMPARATIVE STUDY OF NORMAL ADULTS DURING SLEEP AND AWAKE CONDITIONS. K. Sentrayan[1], A. Thorpe, Jr.[1], A. J. Trouth[2], C.O. Trouth[1,2], S. Rapisardi[3], Depts. of Physio. & Biophys.[1], Neuro.[2], Anatomy[3], Coll. of Med., Howard Univ., Wash., D.C. 20059

A mathematical model has been developed for a comparative study of normal adults during sleep and awake conditions at high altitude. The model considers the controlling effects of both central and peripheral chemoreceptors and has lung, body, and brain tissue compartments. This model also considers time delays and circulatory mixing. We have calculated the peripheral CO_2, O_2, and central CO_2 loop transfer functions using a perturbation approach. Vector addition of the peripheral CO_2, O_2 and central CO_2 loop transfer functions is used to calculate the overall system loop gain (LG) and phase lag (ϕ). The stability and oscillating conditions for periodic breathing of normal adults, during sleep and wakefulness at various altitudes have been compared using the calculated LG and ϕ. The increase in overall system loop gain and decrease in cycle time is observed at high altitudes both in sleeping and awake normal adults. We postulate that during sleep at high altitudes both central and peripheral controllers are affected whereas at sea level, only the central controller is being affected by sleep while the peripheral controller remains unchanged. Supported by ONR Grant No.: N0014-94-1-0523.

741.2

SPINAL SEROTONIN RECEPTORS MODULATE BREATHING PATTERN DURING EXERCISE WITH INCREASED DEAD SPACE IN GOATS. D.L. Turner*#, G.S. Mitchell, K.B. Bach and K.T. Foley. University of Wisconsin, Madison, WI 53706, USA and #University of Leeds, Leeds LS2 9NQ, UK.

Increased dead space (ΔV_D; 0.2-0.3 L) augments the exercise ventilatory response, maintaining arterial PCO_2 regulation from rest to exercise (short term modulation, STM). Thoracic, intrathecal administration of the 5-HT receptor antagonist, methysergide, attenuates the ventilation increase (ΔV_I) and increases $PaCO_2$ during exercise with ΔV_D (*FASEB J.*, 9: A666, 1995). As STM is mediated by an increased tidal volume (ΔV_T), without change in the frequency response (ΔF_R) to exercise, we hypothesized that intrathecal methysergide would attenuate ΔV_T and respiratory drive ($\Delta[V_T/T_I]$) without effect on ΔF_R during exercise with ΔV_D. Goats ran on a treadmill at 4.0-4.8 km/hr, 5% grade, with and without ΔV_D, before and after intrathecal (T_8-T_{10}) methysergide (0.03 mg/kg) or saline. Methysergide significantly attenuated ΔV_I, $\Delta[V_T/T_I]$ and ΔF_R during exercise with ΔV_D (mean±SEM; n=7; *, $p<0.05$), but there was no change in ΔV_T after drug administration. Intrathecal ketanserin (0.3mg/kg, n=4), a more selective 5-HT_2 receptor antagonist, increased $PaCO_2$ during exercise with ΔV_D, indicating a loss of STM, but did not significantly affect ΔF_R.

	ΔV_I	ΔV_T	$\Delta[V_T/T_I]$	ΔF_R
Saline	46±6	0.32±0.07	1.41±0.20	43±6
Methysergide	38±5*	0.29±0.07	1.05±0.15*	34±4*

Thus, during STM: 1) spinal 5-HT receptors modulate respiratory drive (*ie.* V_T/T_I), possibly *via* changes in spinal respiratory neuron excitability mediated by 5-HT_2 receptors; and 2) respiratory timing (F_R) is altered *via* effects on primary afferent transmission, possibly *via* 5-HT_1 receptors in the dorsal horn (NIH HL36780).

741.3

INCREASED SPINAL MONOAMINE CONCENTRATIONS FOLLOWING THORACIC DORSAL RHIZOTOMY (TDR) IN GOATS. G.S. Mitchell*, K.T. Foley, P.A. Martin, E.B. Olson, V. Miletic and M.S. Brownfield. University of Wisconsin, Madison, WI, 53706.

In goats, TDR from T_2 to T_{12} increases spinal serotonin (5-HT) immunoreactivity in rostral thoracic segments (*FASEB J* 6: 1507,1992). To determine if changes in other descending modulatory systems occur following TDR, dopamine (DA), norepinephrine (NE) and 5-HT concentrations were assessed *via* HPLC in the cervical and thoracic spinal cords of unoperated control animals (n=4), following sham surgery (n=3) and 3-12 months following TDR (n=7). Following barbiturate overdose, spinal cords were harvested and frozen for HPLC analysis of homogenized samples. Compared to sham and control goats, TDR increased DA in the cervical (C_5-C_7, 125%), rostral thoracic (T_2-T_7, 190%) and caudal thoracic (T_8-T_{12}, 220%) spinal cord (all $p < 0.0003$). Smaller NE elevations were observed in these regions (28-50%, $p < 0.0006$). 5-HT was elevated 34% between T_2-T_7, but only 16% between T_8-T_{12}; 5-HT concentrations were elevated 68% in the cervical region ($p < 0.002$). The results indicate that TDR increases spinal concentrations of neurotransmitters associated with descending modulation of spinal sensory-motor integration. Since effects were observed in both the denervated thoracic region, and in cervical regions associated with the phrenic motor nucleus, it is possible that changes in monoaminergic brainstem-spinal cord pathways play a role in the functional deficits and/or recovery of ventilatory control that are observed in goats following TDR (NIH HL 36780).

HYDRALAZINE DECREASES APNEA-INDEX IN SPONTANEOUSLY HYPERTENSIVE RATS. D. W. Carley, S. Trbovic, D. Monti, M. Radulovacki*. Departments of Medicine and Pharmacology, University of Illinois College of Medicine, Chicago, IL 60612

Spontaneous apneic events have been described in normotensive Sprague-Dawley and Wistar rats, and compared to central apneas in man. In view of the epidemiological association between apnea and hypertenison in man, we hypothesized that spontaneously hypertensive (SHR) Wistar-derived rats would exhibit sleep related apnea which could be suppressed acutely by anti-hypertensive agents. We administered 2 mg/Kg of hydralazine to 9 adult male SHR rats implanted with EEG and EMG electrodes for sleep/wake scoring and placed in unrestrained body plethysmographs for respiratory monitoring. For each rat, sleep and respiratory activity were polygraphically recorded for 6 hours on 2 different days. Immediately prior to each recording, saline or drug was given by intraperitoneal injection. We defined apnea as cessation of respiratory effort for at least 2.5 seconds and expressed apnea indexes (AI) as apneas per hour. The effect of hydralazine, documented on a different day by tail-cuff plethysmography, was significant ($p<.0001$) and consistent for 6 hours after injection: baseline = 219.7±4.2, 2Hrs = 157.4±6.0, 4Hrs = 167.0±8.4, 6Hrs = 169.6±7.3 mmHg. During NREM sleep, AI decreased from 12.9±1.4 for saline injection to 5.1±1.3 following hydralazine ($p < .025$). In contrast, during REM sleep, AI did not decrease ($p > .97$); 14.9±3.0 after saline, 14.0±4.1 after hydralazine. The response to hydralazine was not affected by the presence or absence of an augmented breath preceding the apnea ($p > .2$). We conclude that SHR rats exhibit frequent apneas during all stages of sleep. Further, we conclude that acute lowering of mean blood pressure significantly reduces apnea expression in NREM but not in REM sleep. We speculate that baroreflexes may play a state-dependent role in apnea genesis in the rat.

ROLE OF THE FASTIGIAL NUCLEUS (FN) ON VAGALLY MEDIATED RESPIRATORY RESPONSES IN CATS F. Xu and D.T. Frazier*. Dept. of Physiology, Univ. of Kentucky, Lexington, KY

The FN within the cerebellum has been shown to modify the respiratory responses to hypoxia and hypercapnia (Xu, et al., FASEB, 1995). The goal of this study was to determine the involvement of the FN in the respiratory reflexes evoked by activation of vagal afferents. Experiments were performed in anesthetized (chloralose), paralyzed, and artificially ventilated cats with an occipital exposure of the cerebellum. The phrenic neurogram was used as an index of respiratory motor output. Administration of capsaicin (CAP, 5 μg/kg) via the right external jugular vein and Lung inflation (LI, 10 cmH_2O) were carried out to stimulate non-myelinated and myelinated vagal afferents, respectively. The cardiorespiratory baseline variables and immediate responses (expiratory and inspiratory duration, T_E and T_I; arterial blood pressure, ABP) were compared before and after bilateral lesions (thermal) of the FN. We observed that both stimuli led to a remarkable prolongation of T_E (apnea) and reduction of ABP (with little change in T_I). Bilateral vagotomy abolished all the responses except the decrease in ABP noted during LI. FN lesions did not alter baseline variables and the responses to LI, however, did significantly prolong the response of T_E to administration of CAP. It is concluded that the FN is involved in vagally mediated respiratory responses elicited by activation of non-myelinated vagal afferents. (NIH P01 40369)

CENTRAL COMMAND INCREASES TOTAL LUNG RESISTANCE IN DECEREBRATE CATS. A.M. Motekaitis, A.C. Bonham*, and M.P. Kaufman. Division of Cardiovascular Medicine, University of California, Davis, CA 95616

The neural mechanisms mediating the airway dilation evoked during exercise are not completely understood. Two mechanisms believed to play important roles in the cardiovascular and respiratory adjustments are the muscle reflex and central command. For example, activation of group III and IV endings in the skeletal muscles reflexly dilates the airways and increases ventilation, heart rate and arterial pressure. Similarly, stimulation of central locomotor regions (central command) increases ventilation, heart rate and arterial pressure. Whether central command plays a role in the control of airway caliber during exercise is not known. Therefore, we tested the hypothesis that stimulation of the mesencephalic locomotor region (MLR) in paralyzed, decerebrate cats decreased total lung resistance (TLR). Electrical stimulation of the MLR increased TLR (27.3±2 to 37.5±3 cm H_2O/l/s, $p<0.05$; n=21). Similarly, microinjection of a GABA antagonist (100-800 nl of 5 ng/nl picrotoxin) into the MLR also increased TLR (24.1±4 to 30.8±6 cm H_2O/l/s, $p<0.05$; n=7). In one site, picrotoxin decreased TLR. All of the changes evoked by electrical and chemical stimulation of the MLR were accompanied by an increase in ventral root discharge and arterial pressure. In 10 cats, the tibial nerve was electrically stimulated at C-fiber intensity, which decreased TLR (30.4±3 to 23.0±2 cm H_2O/l/s, $p<0.05$). Our findings provide little evidence for a role of central command in mediating the airway dilation during exercise. Instead, this dilation may be mediated by peripheral feedback mechanisms, one of which is the muscle reflex. Supported by NIH HL40910.

REFLEX VOCAL CORDS ACTIVITY ELICITED BY SUPERIOR LARYNGEAL NERVE (SLN) STIMULATION. J. García Ramos*. A. Hernández A. C. Eguía Lis, and L. Hernández A. Neurophysiological Laboratory. Univ. A. de Querétaro and E.S. de Medicina del IPN México D.F. C.P. 11340.
Inhibitory effects upon breathing followin SLN stimulation are widely known, but excitatory effects upon this, or any other structures, have not been described. In pentobarbital anesthetized cats and rabbits observations were made by recording pressure changes in the separated larynx or the mechanical changes obtained from a separated vocal cord, tying a thread at a piece cut from the anterior medial part of the thyroid cartilage and connecting it to a myograph (Model FT 0.3 Grass). The findings were: 1. Single shocks to the SLN 0.1 msec (threshold about IV, maximal 4-5V) elicited phasic laryngeal pressure reductions, 20 msec latencies, or tension increases of the Vocal cord with similar characteristics. Sometimes the responses were followed by changes in the opposite direction thatsuddenly or gradually appeared turning a monophaphasic into a disphasic response. 2. A train, (10-20 Hz) applied for 5-30 sec, produced potentiation of the responses to single shocks lasting for minutes depending on the duration of the train. Similar long lasting potentiation occurred after a long duration pressure pulse to the larynx. It is concluded that afferents in the SLN have excitatory effects upon the premotoneurons of the vocal cords apart from its inhibitory action upon brathing.

CENTRAL AFFERENT AND EFFERENT PROJECTIONS OF THE TRACHEA - A COMPARATIVE STUDY. M.A. Haxhiu* and A.D. Loewy. Department of Medicine, Case Western Reserve University, Cleveland, OH 44106 (USA)* and Department of Anatomy and Neurobiology, Washington University School of Medicine, St.Louis, MO 63110 (USA).

The central sensory projections arising from the extrathoracic trachea was determined using cholera toxin ß-subunit as a transganglionic tracer in dogs, ferrets and rats. In all three species, tracheal sensory fibers were found to terminate in three subnuclei of the nucleus tractus solitarius (NTS). The most dense concentration of afferent terminals was localized in a restricted part of the medial NTS found at the rostral levels. Less dense projections were identified in the ventrolateral NTS subnucleus and very light projections were seen in the commissural NTS subnucleus. No labeling was identified in the area postrema. In addition, the pattern of retrograde cell body labeling was studied in all three species. The vagal motor supply to the trachea arises from two main sites: the rostralmost part of the dorsal vagal nucleus and the rostral nucleus ambiguus (NA). In the NA, cell labeling was found in both the compact and ventral (or external) portions, with a considerable concentration in the latter. In addition, labeled neurons were consistently seen in the dorsomedial part of the ventral horn in the C1-C2 spinal cord. The present study demonstrates that three different types of mammals share a common pattern of central sensory innervation and motor outflow that is involved in airway control. Supported by HL-50527.

VESTIBULAR EFFECTS ON THE UPPER AIRWAY.
Alan D. Miller* and Marina S. Siniaia. Lab. Neurophysiology, The Rockefeller University, New York, NY 10021.

Activation of the vestibular nerve produces reflex responses recorded from respiratory muscle nerves of the thorax and abdomen (Yates, Jakus, Miller, *Brain Res.* 629: 209-217, 1993). In order to better understand the functional significance of vestibulo-respiratory reflexes, we investigated the extent to which such responses are also present on respiratory muscle nerves of the upper airway.

Experiments were conducted on adult cats that had a midcollicular decerebration. The vestibular nerves were electrically stimulated at intensities less than those required to produce current spread to the nearest non-target (i.e., facial) nerve. Vestibular-evoked responses were recorded from the following nerves: recurrent laryngeal, superior laryngeal, hypoglossal, glossopharyngeal, and pharyngeal branch of the vagus nerve. The responses could consist of an increase and/or decrease of nerve discharge. Response latencies (from the 1st stimulus of a 5-shock train) were less than 20 ms; response durations were typically between 12-27 ms. Injections of the neurotoxin kainic acid into the medial and inferior vestibular nuclei abolished the responses.

Thus, the widespread presence of vestibular-evoked responses on respiratory muscle nerves of the upper airway, as well as those of the thorax and abdomen, suggests that one function of vestibulo-respiratory reflexes is to provide adjustments in breathing and airway patency during movements and changes in posture. This does not exclude additional possible roles for vestibular-respiratory reflexes, e.g. in assisting venous return to the heart to counter orthostatic hypotension or in maintaining posture. RELATIONSHIP BETWEEN EXPIRATORY RESISTIVE LOAD MAGNITUDE AND EVOKED POTENTIAL AMPLITUDE IN ADULTS. C. Smith Hammond,* P.W. Davenport. Dept. of Physiol. Sciences, JHMHC, University of Florida, Gainesville, Florida, 32610.

Respiratory related evoked potentials (RREP) recorded from frontal, temporal, parietal and central sites have been elicited by occlusion of expiration. The initial positive peak (P_1) peak observed in the central electrodes is believed to represent the sensory cortical response to the activation of the afferents transducing the expiratory load. An earlier positive peak P_F was observed in frontal sites only. It was hypothesized that the P_1 peak amplitude is proportional to the expiratory load magnitude in adults. Normal adults were studied semi-reclined at rest. They respired through a mouthpiece and non-rebreathing valve connected to a loading manifold. EEG activity was recorded from C_3, C_4, C_Z, C_3', C_4', C_Z', P_3, P_4, P_Z, T_3, T_5, F_Z, F_3, referenced to joined earlobes. The expiratory resistive (R) load magnitudes were 5.0 and 20.0 cm H_2O/L^{-1} and complete occlusion. A control trial obtained by interruption of expiration with the no-load, R_0, port open. The P_1 and P_F peaks of the RREP elicited by expiratory occlusion were measured for peak amplitude and latency. No characteristic peaks were were observed with the control R_0. The P_1 peak was found with both R loads and occlusion. The P_1 and P_F amplitude increased with increasing R load magnitudes. There were no significant differences between P_1 latencies for all loads. The P_F was found consistently in the frontal electrodes and there were no significant differences between P_1 latencies for all loads. These results support the hypothesis that graded increases in expiratory load are correlated with increased activation on sensory cortical neurons. Supported by NIH/NHLBI grant HL 48792.

A COMPARISON OF CEPHALIC REFERENCED WITH JOINED EARLOBE REFERENCED INSPIRATORY OCCLUSION ELICITED RREP RECORDS. H. Gaeta , C. Smith-Hammond, P.W. Davenport.* Dept. of Physiol. Sci., JHMHC, University of Florida, Gainesville, Florida, 32610.

Respiratory related evoked potentials (RREP) elicited by inspiratory occlusion were initially recorded from C_3 and C_4 with a cephalic reference. Subsequent respiratory related evoked potentials have also been reported using either an earlobe or Spinal C7 reference. The differences in the RREP waveforms raise the question whether changes in reference site alters the characteristics of the signals recorded. This study compares RREP records referenced to joined earlobe with C_z referenced records. Children between 7-15 years were the subjects. Electrodes were applied to C_3 and C_4 and referenced to C_z and joined earlobes. Two trials of 80 inspiratory-interrupted occluded breaths and 1 control trial of 80 unoccluded breaths were presented. Averaged control and occlusion records were compared to determine the presence or absence of the first short-latency positive peak (P1). When P1 was observed, the peak latency and amplitude were determined. Analysis of the results showed that with C_z referencing P1 was observed bilaterally. With joined earlobe referencing P1 was also observed bilaterally. The P1 amplitude with C_z referencing was greater and had a longer latency than with joined earlobe referencing. The observed differences in the RREP P1 peak with the different references can be explained in terms of the increase in noise using a joined earlobe reference. This increases the threshold for resolution of the P1 component from background noise and decreases the amplitude. We conclude that if the reference site is changed when recording RREPs, then consideration must be given to the number of sweeps necessary to maintain a comparable signal to noise ratio between records. (Supported by NIH-NHLBI#HL48792).

IMMUNOHISTOCHEMICAL CHARACTERIZATION OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH)-ASTROGLIA INTERACTIONS: EFFECTS OF ASTROGLIA-DERIVED AND EXOGENOUSLY-DELIVERED GROWTH FACTORS (GFs). E. Gallo[1]*, B. Marchetti[2] and A. Beaudet[2]. [1]Department of Pharmacology, Medical School, University of Catania, 95125 Catania, Italy and [2]Montreal Neurological Institute, 3801 University, Montreal, Quebec, H3A 2B4

In recent studies we have provided experimental support for the concept that a significant degree of communication between neurons and their associated glial cells contributes to the developmental regulation of luteinizing hormone-releasing hormone (LHRH) neuronal function. To further characterize and quantify the morphogenic impact of LHRH neuron-astroglia interactions, we have used the immortalized hypothalamic LHRH GT_{1-1} neuronal cell line and astroglial cells in primary culture. In this experimental design, astroglial cells at different "ages", ranging from 7 to 16 days for "young" glia and 21 to 40 days for "aged" glia, and GT_{1-1} neurons were grown in the same wells, and the analyses carried out at different time intervals (2-8 DIV) during LHRH neuron differentiation. In this paradigm, astrocyte-derived factors (ADFs) induced dramatic effects in the morphology and functional capacity of the GT_{1-1} neurons. First there was an acceleration in the acquisition of the mature neuronal phenotype as evidenced by the extension of multiple lengthy neurites that contact distant cells, or end in apparent growth cones, as well as the establishment of cell-cell contacts. Quantification of the morphometric features of the GT_{1-1} neurons for process length and branching revealed a 3- to 4-fold increase in the number of LHRH processes per cell, as well as a significant increase in the length and branching of individual process, as compared to neurons grown in the absence of glia. Such effects were accompanied by a sharp stimulation of LHRH release in the medium at each time-interval studied. Some of these effects were mimicked by epidermal growth factor (EGF), insulin (In), insulin-like growth factor I (IGF-I) and basic fibroblast, alone and/or in combination. These results provide a morphological and functional basis supporting LHRH-astroglia interactions and further underscore the importance of growth factors not only in regulating axon growth on astroglia in vitro but also contributing to signal transduction involved in the regulation of LHRH release.

KAINATE GLUTAMATE RECEPTORS IN TANYCYTES AND TYPE II ASTROCYTES OF THE RAT ARCUATE NUCLEUS. F. Naftolin[1], S. Diano[1], J. Lerma[2]*, L.M. Garcia- Segura[2], C. Leranth[1] and T.L. Horvath[1]. [1]Yale University, Dept. of Ob/Gyn, New Haven CT, 06520, and [2]Instituto Cajal, Madrid, 28002, Spain.

It has been suggested that neuro-glial interactions play important roles in the central regulation of neuroendocrine processes. For example, estrogen-sensitive tanycytes that ring the third ventricle and extend to the median eminence providing morphological organization of the area, have been implicated in the regulation of neurotransmitter and peptide release into the pituitary portal vessel. Furthermore, type II astrocytes were demonstrated to participate in the estrogen-induced synaptic remodelling of arcuate neurons. Since glutamate is a dominant neurotransmitter in the neuroendocrine hypothalamus, we tested the possibility that tanycytes and type II astrocytes in the arcuate nucleus express receptors for glutamate offering a possible mechanism for neuro-glial crosstalk. **Experimental:** Single label immunocytochemistry for different ionotropic glutamate receptors (GluR 1-7, NMDAR 1-2) were carried out on sections containing the rat arcuate nucleus. The avidin-biotin-peroxidase method was used to visualize the immunolabeled profiles. While all of the antibodies were found to label neurons in the hypothalamus, only labeling for GluR 5-7 resulted in immunopositivity in glial elements. From the retrochiasmatic area to the mammillary bodies, heavy peroxidase staining of tanycytes and astrocytes could be observed in the arcuate and periventricular nuclei and th emedian eminence. These findings were confirmed by electron microscopy. **Conclusions:** The observation of immunoreactive kainate glutamate receptors in specific hypothalamic glial elements indicates a hitherto unexplored division of glutamate function in the hypothalamus. This may provide an underlying mechanism for neuro-glial interactions which are implicated in hypothalamic synaptic plasticity and regulation of neuroendocrine functions. 742.3

PERSISTENT INDUCTION OF GALANIN GENE EXPRESSION IN GnRH NEURONS FOLLOWING THE LH SURGE IN RATS. P.D. Finn,* M.R. King, D.K. Clifton, R.A. Steiner. Ob/Gyn & PBio, University of Washington, Seattle, WA 98195.

In female rats, galanin is a cotransmitter in GnRH neurons, and its expression is regulated by sex steroids. During the preovulatory LH surge, levels of galanin mRNA in GnRH neurons are elevated; however, the full time-course of the rise and decline of galanin mRNA in GnRH neurons with respect to the LH surge is unknown. To address this issue, we measured and compared levels of galanin mRNA in GnRH neurons and plasma levels of LH during a 30 h period bracketing the LH surge, beginning 6 h before and continuing for 24 h after a steroid-induced surge. Ovariectomized rats were treated with estradiol benzoate on Day 0 at 1030 h and progesterone on Day 2 at 1200 h to induce an LH surge (lights on at 0700 h and off at 2100 h), and groups (n=4-6/time point) were sacrificed at 1200, 1400, 1500, 1600, 1800, and 2400 h (Day 2) and 0600, 1200, and 1800 h (Day 3). GnRH neurons were identified with a digoxigenin-labeled GnRH cRNA probe, and galanin mRNA was simultaneously measured in the GnRH neurons with an ^{35}S-UTP-labeled cRNA probe and a computerized image analysis system. Results showed that the LH surge began at 1600 h on Day 2, peaked at 1800 h, and returned to baseline by 2400 h that day. On Day 2, levels of galanin mRNA levels in GnRH neurons were low between 1200 and 1600 h (18 ± 2 to 27 ± 2 grains/cell), increased by two-fold by 1800 h (46 ± 10 grains/cell; $p < 0.05$ vs. 1600 h), by 4-fold by 2400 h (80 ± 6 grains/cell; $p < 0.05$ vs. 1600 h), and remained elevated at all time points on Day 3 (75 ± 5 to 80 ± 7 grains/cell). **Conclusion:** The induction of galanin mRNA in GnRH neurons persists for at least 24 h following the transient LH surge, indicating that galanin may serve a physiological role in events that *follow* the surge itself, e.g. behavioral estrus.

742.4

GALANIN AND NEUROPEPTIDE Y IMMUNOREACTIVITY IN HYPOTHALAMIC NUCLEI IN RELATION TO THE ESTROUS CYCLE. J.T. Alexander*, A. Akabayashi, S.M. Gabriel, L.E. Baskin, C.J. Owen and S.F. Leibowitz. The Rockefeller University, New York, N.Y., 10021.

The hypothalamic peptides, galanin (GAL) and neuropeptide Y (NPY), are known to change in relation to circulating gonadal steroids, in an anatomically- and gender-specific manner, and to control the secretion of pituitary hormones. This relationship, between gonadal steroids and brain peptides, was further investigated in relation to the estrous cycle. Female rats (n=32) were sacrificed at dark onset at different stages of the estrous cycle, and trunk blood was collected. Peptide levels were measured (via RIA) in 10 hypothalamic areas: medial (mPVN) and lateral (lPVN) portions of the paraventricular nucleus, median eminence (ME), medial preoptic nucleus (MPO), the arcuate (ARC), dorsomedial, suprachiasmatic, and supraoptic nuclei, ventromedial and lateral hypothalamic areas. During proestrous, when luteinizing hormone surges ($p<0.01$), GAL levels are found to peak sharply in a site-specific manner. This peak occurs in the MPO (+36%, $p<0.05$), lPVN (+62%, $p<0.05$) and ME (+42%, $p<0.05$), and is followed by a decline to low levels at metestrous. These shifts in endogenous GAL may be distinguished from those of NPY. This peptide rises during proestrous, specifically in the ARC (+73%, $p<0.05$), mPVN (+36%, $p<0.05$), and MPO (+58%, $p<0.05$); during metestrous, NPY declines to low levels in the ARC and mPVN. Other hypothalamic areas exhibit no temporal shifts in the peptides. These results provide indirect support for strong activational effects of gonadal steroids, during proestrous, on GAL and NPY production in specific brain sites.

742.5

PHENOTYPIC CHARACTERIZATION OF A POPULATION OF PREOPTIC AREA NEURONS ACTIVATED DURING AN LH SURGE W.-W. Le, K.A. Berghorn, H.-J. Wang and G.E. Hoffman*. Department of Neurobiology, Univ. Pittsburgh, Pittsburgh, PA, 15261.

The periventricular zone of the preoptic area (pePOA) is an area which sends a projection to the vicinity of the LHRH neurons. At the time of an LH surge, pePOA neurons are activated in synchrony with LHRH neurons. Previous studies from our laboratory identified a dopaminergic subcomponent of pePOA neurons, but the phenotypes of the remaining neurons in the area were still unknown. In the present study, we explored further the phenotypic characterization of the pePOA neurons using immunocytochemical and *in situ* hybridization procedures. With immunocytochemistry, we observed that while only a small fraction (less than one third) of the pePOA neurons expressed tyrosine hydroxylase, more than half of the pePOA neurons activated on proestrus contained the l-amino acid decarboxylase. Additionally, *in situ* hybridization (ISH) for galanin mRNA with biotinylated riboprobes using immunocytochemistry (ICC) for biotin visualization in free-floating acrolein-paraformaldehyde fixed brain sections revealed that galanin was found not only within the LHRH neurons at the time of an LH surge, but also in many neurons of the pePOA. Double labeling of galanin mRNA combined with ICC staining of cFos showed that galanin mRNA was detected in cFos-positive pePOA neurons at the time of an LH surge. These data suggest that multiple effectors are present in the activated pePOA neurons and that while galanin within LHRH neurons may provide one means of affecting LHRH function, activation of afferent galanin neuron populations may contribute to the LH surge as well. (*Supported by NIH NS 28730*)

742.6

PHARMACOLOGICAL ANALYSIS OF NEUROPEPTIDE Y (NPY) RECEPTORS MEDIATING NPY FACILITATION OF LH SURGES. S.M. Leupen, C. Berg, and J.E. Levine*, Dept.of Neurobio. & Physiology, Northwestern Univ., Evanston, IL 60208

We previously showed that NPY facilitates LHRH-induced LH surges, and that endogenous NPY is critical for normal elaboration of preovulatory gonadotropin surges. The NPY receptor subtype mediating this action has not been identified. Three subtypes have been described, based on rank order of affinities for NPY receptor agonists: Y1 (PYY≥NPY≥Y1-a>>Y2-a), Y2 (PYY> NPY >Y2-a>>Y1-a), and Y3 (NPY≥ Y1-a≥Y2-a>>PYY) receptors. These experiments were designed to pharmacologically characterize anterior pituitary receptors which mediate NPY's actions on LH secretion. Adult female rats were prepared for peptide infusion and blood sampling on proestrus. Animals received pentobarbital at 1330h to block endogenous LHRH release, and thereafter received pulsatile infusions of LHRH paired with saline or one of four NPY agonists: NPY, PYY, [$Leu^{31}Pro^{34}$]NPY (Y1-a), NPY(13-36)(Y2-a). Each rat received pulse infusions containing either LHRH (15ng/pulse) or LHRH (15ng/pulse) & agonist (10 ug/pulse) at 30min intervals from 1400-1800h. Hourly blood samples were stored for LH RIA. As previously shown, NPY significantly augmented the LH response to LHRH ($p<.03$). Both PYY and Y1-a also significantly potentiated LHRH-induced LH surges, while the Y2-a was without effect. The rank order of potency was found to be PYY = Y1-a > NPY >>> Y2. These findings implicate a Y1 or Y1-like receptor subtype in the mediation of NPY's facilitatory effects on LH secretion. In current work we are attempting to determine if this pituitary NPY receptor is identical with the cloned Y1 receptor expressed in other tissues, or if it is a variant with Y1-like pharmacology.

EFFECTS OF ESTRADIOL (E2) AND PROGESTERONE (P4) ON PROOPIOMELANOCORTIN (POMC) AND NEUROPEPTIDE Y (NPY) GENE EXPRESSION IN THE ARCUATE NUCLEUS: A POSSIBLE ROLE IN THE ABILITY OF PROGESTERONE TO SEQUENTIALLY ENHANCE AND THEN INHIBIT THE LH SURGE. P.M. Wise*[1], A. Cai[2], K. Scarbrough[3]. [1]Department of Physiology, University of Kentucky, Lexington, KY 40536 and [2]Department of Physiology, University of Maryland School of Medicine, Baltimore, MD 21201 and [3]Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

POMC and NPY neurons, whose cell bodies are located in the arcuate nucleus, are thought to play roles in the cyclic release of LH. We tested the hypothesis that changes in the gene expression of these neuropeptides can explain the ability of P4 to enhance the LH surge induced by E2 on the day that it is administered and then to inhibit the surge on the following day. Rats were ovariectomized and 1 week later were implanted with Silastic capsules containing E2. Two days later (day 2), animals received an i.p. injection of P4 (1.5 mg/rat) or sesame oil at 1000h. Using this protocol, E2 induces an LH surge during the afternoon of day 2 and 3; P4 enhances the surge on day 2 and suppresses the surge on day 3. E2-treated rats were killed at 0600, 1400, 2300 on day 2, 0600 and 1400h on day 3. E2P4-treated rats were killed at 1400, 2300 on day 2 and 0600 and 1400h on day 3. The anterior and posterior arcuate nuclei were dissected, RNA was extracted and POMC and NPY mRNA levels were quantitated by solution hybridization/ RNase protection using ^{32}P-labelled cRNA probes. E2 induced a rhythm in POMC gene expression in the anterior arcuate nucleus: levels reached their nadir at 2300h; P4 prevented this decrease. NPY mRNA levels in the anterior arcuate nucleus appeared to be lowest at 0600h and to increase during the day. P4 increased NPY mRNA levels at 0600h on day 3. Thus, POMC and NPY may play a role in the suppression of LH surges the day after P4 is administered (Supported by NIH AG02224 to PMW).

742.8

CENTRAL VIP-ANTISERUM INJECTIONS ALTER THE TIMING OF AN ESTROGEN-INDUCED LH SURGE E.M. van der Beek*, J.J.M. Swarts and V.M. Wiegant Dept Human & Anim Physiol, Agricult Univ, Wageningen & Rudolf Magnus Inst Neurosci, Utrecht University, Utrecht, The Netherlands

Lesion and tracing studies of the suprachiasmatic nucleus (SCN) have suggested the exisistence of a vasoactive intestinal polypeptide (VIP)-containing pathway between the SCN and the gonadotropin-releasing hormone system (GnRH). Recently, we provided evidence for the involvement of this pathway in the activation of the GnRH system during the LH surge (Van der Beek et al, Endocrinology 1994 134;2636).

In the present study, we investigated the effect of intracerebroventricular VIP-antiserum (VIP-Ab) injections on the timing and height of an estrogen (E)-induced LH surge in mature ovariectomized (OVX) female rats. Wistar rats (N = 20) were housed under LD12:12 (lights on from 2:00-14:00) and OVX on day 0. The LH surge was induced by two consecutive sc E-injections on day 7 and 8. Animals received two saline or VIP-Ab injections (day 8; 22:00 h, day 9; 8:00 h), and hourly blood samples were collected from 9:00 to 18:00 on day 9 and assayed for LH. Two weeks later, rats were used in a second experiment and treatments were reversed (VIP-Ab or saline). During the second experiment, rats were sacrificed between 15:00-16:00 h, and the activation of the GnRH system was evaluated using c-fos immunocyto-chemistry. VIP-Ab treatment delayed the onset as well as the peak of the LH surge for 1 to 2 h, and significantly reduced the height of the surge. The percentage of c-fos-activated GnRH cells in saline animals (39.9 ± 6.5%) did not differ from that in VIP-Ab treated females (43.8 ± 8.3%), and was comparable with that previously found in E + P-treated animals.

These data demonstrate that blockade of central VIP-activity alters the timing as well as the height of the E-induced LH surge, but does not affect the activation of the hypothalamic GnRH system.

742.9

IMMUNOHISTOCHEMICAL LOCALIZATION OF GONADOTROPIN RELEASING HORMONE, GLUTAMATE AND KAINATE-2 RECEPTOR PROTEIN IN RAT BRAIN. O. Eyigor* and L. Jennes. Dept. Anatomy & Neurobiology, Univ. Kentucky, Coll. Medicine, Lexington, KY 40536

Glutamate is the most abundant neurotransmitter in the brain and has been implicated to participate in the regulation of gonadotropin releasing hormone (GnRH) release. The first aim of the present study was to determine if glutamate is contained in axon terminals which could innervate GnRH neurons at their perikarya or at their nerve terminals in the median eminence. Immunofluorescence double stainings for GnRH and glutamate show that glutamate is present in numerous punctae juxtaposed to GnRH perikarya as well as to GnRH containing axons in the median eminence suggesting that, from an anatomical point of view, glutaminergic neurons can provide axo-somatic and axo-axonal input to GnRH neurons. The effects of glutamate are mediated through activation of 2 families of receptors, the ionotropic and the metabotropic receptors. The second aim of the present study was to determine if GnRH neurons express the kainate receptor and where in the GnRH neurons the receptor protein is located. Immunofluorescence double stainings for GnRH and kainate-2 receptors show that some but not all GnRH perikarya in the medial septum-diagonal band and GnRH-containing axon terminals in the median eminence contain immunoreactive kainate-2 receptor protein. Together, the results suggest that glutaminergic axons are in an appropriate position to provide excitatory input to the GnRH neuronal system and that some, but probably not all of this input is mediated by activation of kainate-2 receptor subtypes. Supported by NIH HD 24697 (LJ).

PULSATILE NOREPINEPHRINE (NE) AND LH RELEASE IN OVARIECTOMIZED (OVX) RATS. S. J. Legan.* Department of Physiology, University of Kentucky, Lexington, KY 40536.

In OVX monkeys, NE and LHRH pulses in the stalk-median eminence are coincident (Terasawa et al., 1988), suggesting that NE neurons projecting to the median eminence control pulsatile LH secretion and constitute part of the LHRH pulse generator. In rats, however, the majority of LHRH cells are located in the septum/ diagonal band area (S/DB) of the hypothalamus. Therefore, to examine the correlation between NE release in the S/DB and LH pulses in OVX rats, NE release was determined in microdialysates of the S/DB which were obtained every 5 min (2 μl/min) for 2 hours beginning at 1000 h four weeks after ovariectomy. Blood samples (0.1 ml) were also collected every 5 min from a right atrial cannula. Placement of microdialysis probes was verified histologically. Pulses of LH and NE were detected using the ULTRA software. Plasma LH concentrations, determined by radioimmunoassay, averaged 17.62 ± 2.73 ng/ml (X ± SE, n=6) and were characterized by a frequency of 1.92 ± 0.30 pulses per hour. NE release, determined by HPLC, averaged 34.09 ± 8.18 pg per fraction (n=6) and NE pulse frequency was 2.58 ± 0.37 per hour. Only 22% of the NE pulses, however, occurred within 5 min before, or coincident with, LH pulses. These results indicate that in OVX rats, each NE pulse does not stimulate a corresponding LH pulse, thus the noradrenergic neurons that project to LHRH cells in the S/DB may not be an intrinsic part of the LH pulse generator in the rat.

IMMORTALIZED LHRH CELLS (GT1-7) EXPRESS TYPE I PITUITARY ADENYLYL CYCLASE-ACTIVATING PEPTIDE (PACAP) RECEPTORS. J. Olcese*[a], R. Middendorff[b] and C.A. McArdle[c]. Inst. for Hormone & Fertility Research[a], Inst. of Anatomy.[b], Univ. of Hamburg, 22529 Hamburg, Germany; Dept. of Medicine[c], Univ. of Bristol, Bristol BS2 8HW, U.K.

The regulation of LHRH release involves signal transduction pathways often linked to the elevation of cyclic nucleotide production. A potent stimulator of cyclic AMP accumulation is the peptide PACAP, whose specific receptor has recently been cloned. The goals of the present investigation were to determine whether PACAP can activate cAMP production and/or LHRH release from GT1-7 cells, and whether these cells express the type I PACAP receptor. Both PACAP-38 and its truncated form PACAP-27 were potent in elevating cAMP. Similar experiments revealed that these peptides elevated LHRH release 2-3 fold within 10 minutes of treatment, with an EC50 in the low nM range. Six splice variants of the type I PACAP receptor have been described - the short form and five additional forms having 1 to 2 inserts in the third intracellular loop. RT-PCR using primers encompassing this region revealed the presence of the short transcript and a single insert transcript in GT1-7 cells. On the basis of these results, we propose that PACAP may be important not only via its actions at the pituitary gonadotrope level but also via the direct regulation of LHRH secretion.

742.12

DO LHRH NEURONS OF MALE SYRIAN HAMSTER EXPRESS GLUTAMATE RECEPTORS? H.F. Urbanski, V.T. Garyfallou, S.G. Kohama, G. Munro* and C. Lee. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Although excitatory amino acids (EAAs) can profoundly stimulate the hypothalamo-pituitary-testicular axis of male Syrian hamsters it is unclear whether they directly influence the secretory activity of luteinizing hormone-releasing hormone (LHRH) neurons. In the present study adult male hamsters *(Mesocricetus auratus)* were either maintained in a reproductively active phase under long days or were induced to revert to a sexually quiescent condition by 12 weeks of exposure to short days. Two different double-labeling histochemical techniques were then performed on 4%-paraformaldehyde-fixed coronal brain sections (30 μm) in order to disclose whether the LHRH neurons of hamsters express glutamate receptors. The first technique involved double-label fluorescence microscopy; the sections were labeled sequentially with an FITC-tagged monoclonal LHRH antibody and then with rhodamine-tagged polyclonal antibodies to either GluR1 or NMDAR1 (i.e. two glutamate receptor subtypes). In the second technique, the sections were sequentially processed for LHRH immunocytochemisty and then *in situ* hybridization histochemistry using RNA probes to either GluR1 or NMDAR1. In total, 829 LHRH neurons were examined for colocalization of either GluR1 protein or mRNA but in no instance was double-labeling of the LHRH neurons observed, regardless of the animals photoperiodic history or reproductive status. Similarly, in preliminary observations there did not appear to be any obvious expression of NMDAR1 protein nor mRNA in the LHRH neurons. Taken together, these results do not support the hypothesis that EAA's primary influence on the reproductive axis of adult hamsters is mediated by a direct stimulatory action on the LHRH neurons but, rather, suggests that interneurons may be involved. *Grant support: HD-24312, HD-29186, RR-00163 and NSF 93-09368.*

DISTRIBUTION OF FOLLISTATIN mRNA IN THE RAT BRAIN: IMPLICATIONS FOR A ROLE IN THE REGULATION OF CENTRAL REPRODUCTIVE FUNCTIONS. L.A. MacConell*, S. Barth and V. J. Roberts. Dept. Repro. Med., UCSD, La Jolla, CA 92093

Follistatin (FS) is a glycosylated single-chain protein originally isolated from porcine follicular fluid. FS binds to the inhibin/activin βA or βB subunit, therefore allowing activin two binding sites for FS and inhibin only one (Shimonaka et al. 1991; Endocrinol. 128:3313). This association is consistent with the apparent specific action of FS on the regulation of activin-mediated effects. The tissue specific localization of FS gene expression generally coincides with that of activin subunit expression (Roberts and Barth 1994; Endocrinol. 134:914). However, in contrast to the wide distribution of activin subunit proteins and mRNAs in the brain, weak FS mRNA signal has only been observed in the olfactory tubercle and layer II of the frontal cortex (Shimasaki et al. 1989; Mol. Endocrinol. 3:651). We hypothesized that central FS gene expression is more widely distributed and localized in regions coinciding with inhibin/activin β subunits and possible activin-mediated effects.

The present investigation utilized *in situ* hybridization with a ^{33}P-labeled RNA probe specific for rat follistatin. Abundant FS mRNA is expressed in mitral cells of the olfactory bulb and layer II and IV of the frontal cortex. In addition, FS mRNA signal was observed in hypothalamic regions where GnRH neurons are localized (nucleus of the diagonal band), in areas associated with the activin-oxytocin pathway (solitary tract nucleus, paraventricular nucleus), and in aspects of the brain with abundant βA immunostaining in cell nuclei (striatum, medial vestibular nucleus). These results suggest that FS is localized in sites compatible with a role in the regulation of central reproductive functions.

AGE RELATED CHANGES IN THE ABILITY OF ESTROGEN TO INDUCE PROGESTERONE RECEPTOR (PR) mRNA IN FEMALE RATS. G.M. Hejna, A.H.Nagahara*, R.F. Mcgivern+, Y. Li and R.J. Handa. Dept of Cell Biology Neurobiology and Anatomy Loyola University,. Chicago, Stritch School of Medicine. Maywood, IL 60153 and +Dept. of Psychology, San Diego State University, San Diego, CA 92120.

Previous studies have shown that PR mRNA and PR binding increases following administration of estrogen (E). These increases correlate with the ability of progesterone to induce female reproductive behaviors. In this study, we examined age related changes in the ability of estrogen to induce PR mRNA in the medial preoptic area (MPOA), ventromedial hypothalamus (VMH) and arcuate nucleus (ARC). PR mRNA was measured by *in situ* hybridization with a ^{35}S labelled cRNA probe (rat PR cDNA template kindly provided by Dr. J. Kato) Female rats of 2-3, 7-8 and 15-17 months of age were ovariectomized and one week later injected with 17β estradiol (0.5ug in sesame oil) or sesame oil in the A.M. for three consecutive days prior to sacrifice. Animals were sacrificed in the evening following the third injection. Estrogen treatment significantly ($p<0.01$) increased PR mRNA when compared to controls in all three brain regions and at all ages. In the MPOA of 15 month old rats there was a significant ($p<0.05$) decrease in the ability of E to induce PR mRNA. In the VMH of 15 month old rats there was a significant increase in the ability of E to induce PR mRNA ($p<0.01$) There was no age related effects in the ARC. However, cohorts of these animals showed no age related deficits in lordosis quotient in response to estrogen and progesterone treatment. These data demonstrate that there are region specific effects of age on the ability of E to induce PR mRNA. The importance of these changes in the ability of progesterone to reduce female reproductive behavior remains to be determined. Supported by NSF IBN 94-08890 (RJH) USPHS AA008696 (RJH) and AA06478 (RFM).

DEVELOPMENT OF AN OVINE Y3 cDNA AND EXPRESSION OF THE Y3 RECEPTOR mRNA IN THE OVINE HYPOTHALAMUS AND PITUITARY. C.J. Dyer[1], R.M. Matteri[2] and D.H. Keisler[1]. [1]Department of Animal Science, University of Missouri, Columbia; [2]Animal Physiology Research Unit, Agricultural Research Unit, USDA, Columbia, Missouri 65211.

Neuropeptide Y (NPY) has been shown to exert effects upon the hypothalamic-pituitary-gonadal axis, but the mechanisms through which this peptide acts remain unclear. We report here the development of an ovine cDNA to the putative NPY receptor Y3 (also called LCR1). Ovine hypothalamic RNA was used in RT-PCR with primers derived from the published bovine Y3 sequence to amplify a 578 base pair cDNA. Cloning and sequencing revealed a >90% homology to the corresponding bovine sequence. Radiolabeled riboprobes derived from this ovine cDNA were used in a ribonuclease protection assay (RPA) to detect Y3 mRNA in ovine anterior and posterior hypothalamic and pituitary RNA extracts. High levels of Y3 mRNA expression were consistently detected in the pituitary extracts; much lower levels were detected in the posterior hypothalamus (containing the arcuate nucleus). No expression was detected by RPA in the anterior hypothalamus (containing the pre-optic area). The RNA extracts were then subjected to RT-PCR and Southern hybridization. Expression of Y3 mRNA was detected in all samples, demonstrating that low levels of Y3 mRNA, undetectable by RPA, exist within the anterior hypothalamus. These data suggest that the Y3 receptor mRNA is only weakly expressed in the hypothalamus but strongly expressed in the pituitary. Work is now underway to determine if gonadotrophs within the pituitary express Y3 mRNA.

ESTRADIOL REGULATION OF NITRIC OXIDE SYNTHASE mRNAs IN RAT HYPOTHALAMUS. S. Ceccatelli *[1,2], R. Scott[1], L. Grandison[1], D.W. Pfaff[1], L.-M. Kow[1]. [1]Lab. of Neurobiology and Behavior, The Rockefeller University, New York, NY 10021 and [2]Inst. of Environmental Medicine, Karolinska Institute, S-171 77 Stockholm, Sweden.

We have used *in situ* hybridization to investigate estradiol regulation of the mRNAs of neuronal, endothelial and macrophage forms of the nitric oxide (NO)-synthesising enzymes NOS. Our study focused on regions of the hypothalamus which contain estrogen receptors and are related to specific neuroendocrine functions. Ovariectomized (OVX) rats were treated with vehicle or 3 μg/100 g estradiol benzoate (EB) for 7 days. Brains were sectioned and hybridized with ^{35}S-antisense riboprobes for the mRNAs of the 3 NOS isoforms. Sections were exposed to X-ray film and/or autoradiographic emulsion. Only the neuronal NOS mRNA was clearly detectable in the hypothalamic regions examined with a strong hybridization signal in supraoptic, paraventricular (PVN) and ventromedial (VMN) nuclei. Quantitative analysis showed a 3 fold increase in neuronal NOS mRNA in the VMN of the OVX rats treated with EB. The increase was restricted to the ventrolateral aspect of the VMN. No significant changes were observed in the hypothalamic PVN. These data suggest that the expression of neuronal NOS mRNA in VMN is regulated by estrogen. Moreover, since VMN is an integral part of the neural circuitry controlling lordosis, NO may play a role in female sexual behaviors.

742.17

HORMONAL REGULATION OF PHOSPHORYLATION OF CREB IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS (AVPV). G. Gu*, A. A. Rojo , M.C. Zee, J. Yu and R.B. Simerly. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

The AVPV is a nodal point in neural circuits regulating secretion of gonadotropin and contains sexually dimorphic populations of dopaminergic and dynorphin containing neurons. Despite clearly documented effects of estrogen on TH and PDYN gene expression in the AVPV, consensus estrogen response elements have not been identified in these genes, suggesting that the observed regulatory patterns are not due to a direct action of the hormone-bound receptors on transcriptional activation of TH or PDYN. However, both the TH and PDYN genes contain sequences in their promoters that bind transacting factors thought to mediate the actions of calcium and cAMP, such as the cAMP response element binding protein (CREB). The present histochemical study was undertaken to determine if estrogen alters expression of CREB in the AVPV, and since the ability of CREB to activate transcription is dependent on phosphorylation of Ser^{133}, we also evaluated the effects of acute estrogen treatment on levels of phosphorylated-CREB (PCREB) in AVPV neurons by using an antibody that differentiates between CREB and PCREB. Ovariectomized rats were perfused at 5, 15, 30 mins, and 1, or 4 hrs. after treatment with exogenous estradiol. Although these treatments did not alter CREB immunostaining in the AVPV, a significant induction in the number of PCREB-immunoreactive nuclei was observed within 30 min. of treatment and was maintained for at least 4 hrs. Pretreatment with the estrogen antagonist nafoxidine blocked this induction. In contrast, acute administration of progesterone to estrogen primed animals suppressed and then increased PCREB staining in the AVPV at 30 and 60 minutes, respectively; no significant differences between experimental and control animals were apparent by 2 hrs. after progesterone treatment. Double labeling experiments are being used to determine if PCREB is preferentially regulated in TH or PDYN neurons.

742.18

HORMONAL REGULATION OF SUBSTANCE P RECEPTOR (NK-1) mRNA IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS OF THE RAT. M.C. Zee, G.B. Gu, J.E. Krause, and R.B. Simerly*. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006 and Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The anteroventral periventricular nucleus (AVPV) of the preoptic region is a sexually dimorphic cell group that plays a critical role in the control of gonadotropin secretion. It contains high densities of receptors for sex steroid hormones and receives strong sexually dimorphic substance P (SP) containing inputs from the principal bed nucleus of the bed nuclei of the stria terminalis (BSTp) and posterodorsal part of the medial nucleus of the amygdala (MeApd). Although both SP, the BSTp and MeApd appear to play stimulatory roles in the neural control of gonadotropin secretion, cellular levels of SP are not acutely upregulated in the BSTp or MeApd. The present in situ hybridization study was undertaken to examine the possible hormonal regulation of neurokinin-1 (or SP) receptor (NK-1R) gene expression in the AVPV. Levels of NK-1R mRNA fluctuate during the estrous cycle from a minimum during metestrus to maximum levels during proestrus. The correspondence between this regulatory pattern and that of circulating estrogen is supported further by the observation that treatment of ovariectomized rats with estradiol results in a 2 fold increase in NK-1R mRNA in the AVPV. Short term (3 hrs.) treatment of estrogen primed ovariectomized rats with progesterone did not alter levels of NK-1R mRNA in the AVPV, but after an additional 24 hrs NK-1R levels fell by approximately 40%. These findings suggest that the impact of SP on AVPV neurons is greatest on the morning of proestrus, when estradiol levels are greatest. Elevated levels of progesterone that characterize the afternoon of proestrus, together with reduced levels of estradiol, lead to diminished expression of NK-1R s on the day of estrus, and presumably reduced responsiveness of AVPV cells to the release of SP from neurons in the BSTp and MeApd.

742.19

EXPRESSION OF NUCLEAR TRANS-ACTING FACTORS IS REGULATED DIFFERENTIALLY BY OVARIAN STEROIDS IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS (AVPV) OF THE RAT. J. W. Pendleton*, A. M. Carr, M.C. Zee, and R B. Simerly. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

The AVPV represents an attractive model system for identifying cellular factors involved in neuroendocrine regulation of hypothalamic neurons because it plays a critical role in the neural control of gonadotropin secretion and contains sexually dimorphic populations of neurons that display distinct patterns of transmitter gene expression. In situ hybridization was used to examine the expression of mRNAs encoding nuclear trans-acting factors in the AVPV, including the estrogen (ER) and progesterone (PR) receptors as well as the protooncogenes cfos, cjun and jun B. Estradiol treatments suppressed expression of ER mRNA in the AVPV, and increased levels of PR mRNA 5-fold. Acute treatment of estrogen-primed ovariectomized rats with progesterone (3 hrs.) increased levels of ER mRNA in AVPV neurons, but did not affect PR mRNA expression, although 27 hrs. after progesterone treatment PR mRNA appears to decline in the AVPV. ER gene expression fluctuated during the estrous cycle with minimal levels observed on the afternoon of proestrus, and the highest levels during metestrus. In contrast, PR mRNA levels were highest during diestrus and lowest on the morning of proestrus suggesting that PR expression in the AVPV is regulated in a complex manner that does not correspond to circulating ovarian steroid hormones. The expression of cfos mRNA in the AVPV also fluctuates over the estrous cycle with maximal levels occurring on the morning of proestrus and with significantly lower levels on the day of metestrus. Preliminary work indicates that acute administration of estradiol may induce c-fos mRNA in the AVPV. In addition, the protooncogene cjun is expressed in the AVPV, but displays no apparent regulation during the estrous cycle, and jun B is undetectable in the AVPV at any point during the cycle.

HYPOTHALAMIC-PITUITARY-GONDAL REGULATION V

743.1

RU486 ADMINISTRATION ATTENUATES LH SURGES IN THE ABSENCE OF ENDOGENOUS PROGESTERONE. P.E. Chappell, T. Porkka-Heiskanen and J.E. Levine. Dept. of Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

Progesterone (P) amplifies and advances LH surges in estrogen-primed rats, and pharmacological blockade of P receptors (PRs) greatly attenuates spontaneous preovulatory LH surges in proestrous rats. Measurements of P during the afternoon of proestrus, however, have revealed that little secretion of the steroid occurs prior to the onset of the LH surges. It has therefore been proposed that ligand-independent activation of PRs, which has been demonstrated in vitro (Turgeon & Waring, 1994) may instead function as a component of the surge-generating process. To test this hypothesis in vivo, adult female rats were ovariectomized (OVX) on diestrus 2 and administered an s.c. injection of estradiol benzoate (EB; 30ug) sufficient to stimulate LH surges on the following day of presumptive proestrus. Additional animals were adrenalectomized (ADX) at the time of OVX, ruling out actions of adrenal P. On presumptive proestrus, rats received either RU486 (6mg/kg s.c.) or oil at 1230h and were killed at 1730h. RIA of LH in trunk blood revealed that EB stimulated LH surges in OVX and OVX & ADX rats which subsequently received oil. Administration of RU486, however, significantly attenuated LH levels in both groups by 50%. Since endogenous P was eliminated in these animals, our data suggest that RU486 blocks ligand-independent activation of PRs which may normally occur as an important component of the LH surge-generating process. The role of ligand-independent activation of PRs in the generation of LH surges remains to be confirmed by further pharmacological analysis. In current work we are also attempting to characterize the anatomical distribution of hypothalamic and/or pituitary PRs which may be activated towards this end. (Supported by NIH R01-HD20677, P30-HD28048, P01-HD21921).

ESTRADIOL INCREASES FOS EXPRESSION IN A SUBSET OF ESTROGEN RECEPTOR-CONTAINING NEURONS IN THE PREOPTIC AREA. B.A. Adrian*, H.T. Jansen#, M.N. Lehman# and R.L Goodman. Dept. Physiology, West Virginia Univ., Morgantown, WV 26506 and #Dept. Cell Biology, Neurobiology and Anatomy, Univ. Cincinnati, Cincinnati, OH 45267.

In the ewe, estradiol (E) inhibits luteinizing hormone (LH) pulse frequency during anestrus but not the breeding season. Previous studies have demonstrated a role for dopaminergic cell groups in this effect of E. However, since neither these dopamine cell groups, nor gonadotropin-releasing hormone neurons possess estrogen receptors (ER), another neural system must mediate E action. As a first step to identify this system, we examined the effect of E treatment on the expression of the immediate early gene product, Fos (a marker of neuronal activation), in cells that also contain ER. Ovariectomized ewes were implanted with either a blank (n=3), or E filled (n=3), 0.5 cm Silastic capsule during anestrus to suppress pulse frequency without inducing an LH surge. Seven days later animals were bled for 6 hours at 12 min. intervals and then sacrificed. After fixation, brains were removed, sectioned and stained for ER and Fos using a dual immunofluorescence procedure. E treatment inhibited LH pulses and significantly increased the percentage of ER-containing neurons expressing Fos (2.07% vs 16.75%) in the rostral preoptic area (POA), but not in other regions of the POA. E had no effect on colocalization of Fos and ER in any other hypothalamic area (AHA, MBH, ARC). E also did not alter the number of neurons containing ER in any area examined. These data suggest that a subset of ER-containing neurons in the POA are involved in the inhibition of LH pulse frequency by E during anestrus. (Supported by NIH HD17864 and HD21968)

SEX DIFFERENCES IN SERUM LUTEINIZING HORMONE (LH) RESPONSE TO GONADECTOMY ARE NOT EXPLAINED BY CHANGES IN mRNA FOR GONADOTROPIN RELEASING HORMONE (GnRH) OR THE SECRETAGOGUE INDUCED RELEASE OF GnRH A.A. Elskus, S.C.H. Hood, and N.B. Schwartz*. Dept. of Neurobiology and Physiology, Northwestern University, Evanston IL 60208

A continuing puzzle in reproductive endocrinology is the striking sex difference in serum LH response to gonadectomy (gnx); male levels rise within hours, while levels in females do not rise significantly for several days. We have ruled out sex differences at the pituitary level. We measured GnRH transcription and release as a possible source for this sex difference. *In situ* hybridization was performed using brains from intact, 12, and 24 h post-gnx male and female rats. Serum LH in the males was significantly elevated by 12 h; levels in females had not changed by 24 h. The average number of GnRH mRNA expressing cells, as well as the intensity, rose by 12 h post-gnx in both males and females and remained elevated or began to decline by 24 h. These data demonstrate that the difference in initial rate of serum LH rise in gnx males (rapid) versus females (slow) is not reflected in differences in the early timing of GnRH mRNA synthesis. GnRH release was measured *in vitro* from perifused median eminences of intact and 24 h post-gnx male and female rats. Tissue was stimulated with NMA, and the resulting GnRH release was measured by RIA. No significant differences were found in GnRH release between groups. This does not rule out sex differences in hypothalamic innervation or other regulatory factors such as NPY, not present when the tissue is isolated *in vitro*. Together these data suggest that an upstream sex difference, yielding differences in pulse frequency or amplitude of GnRH release, is likely responsible for sex differences in LH release following gnx. Supported by NRSA 1-F32-HD07657 (to AAE), PO1 HD-21921 and P30 HD28048.

CHANGES IN DOPAMINE CONCENTRATION AND ACTIVITY OF HYPOTHALAMIC DOPAMINERGIC NEURONS DURING PROLACTIN SURGES IN PSEUDOPREGNANT RATS A. Lerant, M.E. Herman & M.E. Freeman* *Department of Biological Science , Florida State University, Tallahassee, FL 32306*

The role of tuberoinfundibular dopaminergic (TIDA) neurons originating from the caudal arcuate nucleus (ARN) in modulating prolactin (PRL) secretion is well established. However, the significance of tuberohypophyseal DAergic (THDA) neurons and periventricular hypophyseal DAergic (PHDA) neurons from rostral ARN and periventricular nucleus (PeVN) terminating in the neurointermediate lobe of the pituitary gland is less understood. The aim of this study was to assess the role of THDA and PHDA neurons in PRL secretion by measuring DA concentration and characterizing neuronal activity in ARN and PeVN during the diurnal (D) and nocturnal (N) PRL surges of pseudopregnant rats. On the fifth day of pseudopregnancy brains were harvested after decapitation or fixation at 11.00, 13.00, 15.00, 18.00, 21.00 (D surge) and 24.00, 03.00, 06.00, 09.00 (N surge). PeVN's and ARN's of fresh frozen brains were micropunched and DA concentration was mearured by HPLC. The DAergic neuronal activity was assessed by quantitating double label immunocytochemistry for Fos and tyrosine hydroxylase on the fixed brains. Results indicate a decrease in DA concentration accompained by a decrease in neuronal activity of both PeVN and rostral ARN coinciding with the initiation of PRL surges. Middle portions of ARN demonstrated an increase in DA concentration which peaked during the descending phase of PRL secretion. Caudal ARN had a decrease in both DA concentration and neuronal activity during the D PRL peak. These data suggest that changes in DA content of cell populations in PeVN and ARN can be attributed to PHDA, THDA and TIDA neuronal activity. Taken together PHDA, THDA and TIDA neurons appear to have differential roles in modulating the dynamics of PRL secretion. Supported by NIH: DK 43200 and HD 11669.

EFFECTS OF CENTRALLY ADMINISTERED PROLACTIN ON LHRH CONTENT AND PITUITARY RESPONSE TO LHRH IN DOVES. J.D. Buntin,* J.P. Advis, M.A. Ottinger, R.W. Lea, and P.J. Sharp. Dept. Biol. Sci., U. Wisconsin-Milwaukee, Milwaukee, WI 53201; Dept. Animal Sci., Rutgers U., New Brunswick NJ 08903; Dept. Poultry Sci., U. Maryland, College Park MD 20742; Dept. Applied Biol., U. Central Lancashire, Preston PR1 2HE, U.K.; Div. Develop. & Reprod., Roslin Institute, Midlothian EH25 9PS, U.K.

Intracerebroventricular (ICV) injections of prolactin (PRL) exert potent antigonadal and antigonadotropic effects in ring doves (*Streptopelia risoria*) at doses that are insufficient to stimulate prolactin-dependent crop growth. To explore the physiological basis of these effects, we tested the ability of ICV-injected PRL to influence pituitary responsiveness to luteinizing hormone releasing hormone (LHRH) and to alter LHRH content in the preoptic area (POA) and median eminence (ME). LHRH-induced changes in plasma LH were monitored in photostimulated male doves pretreated for 5 days with ovine PRL (1μg/day, ICV) or saline vehicle (2μl). Although PRL reduced basal plasma LH levels and testes weight, it did not attenuate the plasma LH response to an effective LHRH challenge (0.5μg chicken LHRH/kg, intravenous injection). This suggests that ICV-injected PRL does not suppress LH by reducing pituitary responsiveness to LHRH. In separate studies, changes in LHRH content in the POA and ME were measured by RIA in male doves given 5 days of ICV PRL (1μg/day) or vehicle (2μl) pretreatment and in female doves tested at 1, 6, 12 and 24 h after a single ICV injection of PRL (2μg) or vehicle (2μl). Although reductions in plasma LH were observed following ICV PRL in both studies, no effects of PRL on LHRH content were apparent. Competitive enzyme immunoassay for LHRH also failed to detect differences in median eminence LHRH content between PRL- and vehicle-pretreated male doves. These results suggest that ICV PRL may suppress the gonadal axis by influencing LHRH synthesis, degradation, and/or release; however, integrated measures such as LHRH content do not reflect the specific changes involved. EFFECTS OF BICUCULLINE ON THE LH RELEASE IN THE PERIPUBERTAL MALE RAT. Dai Mitsushima* and Fukuko Kimura Deptartment of Physiology, Yokohama City University School of Medicine, Yokohama 236, Japan.

In order to examine a role of γ-aminobutylic acid (GABA) in the control of onset of puberty in rats, a GABAA receptor antagonist, bicuculline methiodide, was infused intravenously in prepubertal (16-17 days of age), midpubertal (30-31 days of age) and adult (over 45 days of age) male rats for 30 min. Sequential blood samples (110 μl) were obtained every 15 to 30 min from unanethetized freely moving rats through intraartrial cannula and serum LH concentrations were determined by RIA. Although neither bicuculline nor saline infusion significantly altered LH release in prepubertal stage, in midpubertal stage, 6 of 8 rats were increased in LH release by 20 mg/kg of bicuculline and 5 of 6 rats by 40 mg/kg of bicuculline. The significant responses continued for15 min at 20 mg/kg and 30 min at 40 mg/kg doses. In adult stage, infusion of both doses of bicuculline induced a prompt increase in LH release in all rats. The significant responses continued for 30 min in 20 mg/kg and 45 min in 40 mg/kg. In addition, direct bicuculline injection into the 3rd ventricle (60 ng/μl) also induced a prompt LH release in adult male rats ($p<0.01$). In order to examine whether some testicular factors change the GABAA receptor mediated inhibition, similar experiments were performed in orchidectomized adult rats. Neither 20 mg/kg of bicuculline nor saline infusion induced significant changes in LH release, but 40 mg/kg of bicuculline significantly inhibited the release of LH. It is concluded that, in the male rat, the maturation of the GABA neuronal system to inhibit the release of LH occurs sometime after the onset of puberty and GABA neurons may partly mediate the testicular effect on the control of LH release.

ANALYSIS OF THE STIMULATING EFFECT OF BICUCULLINE INFUSION ON LH SECRETION IN PROESTROUS RATS. F. Kimura* and K. Jinnai. Department of Physiology, Yokohama City University School of Medicine, Yokohama 236, Japan.

We have shown that an iv infusion of $GABA_A$ receptor antagonist bicuculline (BIC) in the morning produced a premature LH surge in the proestrous rat [Kimura and Jinnai, Horm Behav, 28, 424, 1994]. Present study was performed to further analyze this BIC effect. Female rats of Wistar-Imamichi strain received two intraatrial cannula implantations, one for blood sampling and the other for infusion. BIC ((-)bicuculline methiodide) dissolved in saline was infused iv at a dose of 50 mg/kg/h for 3 h with a peristaltic pump. Pentobarbital sodium (PB) was injected ip at a dose of 32 mg/kg. Serum concentrations of LH were measured by RIA. The result was as follows. 1. On the day of proestrus, BIC infusion between 900-1200 h did not advance the LH surge of LH, but if the infusion was extended to 1300 h, LH surge began at 1200 h. When BIC infusion was started at 1000 h, LH surge began at 1200 h, but If the infusion was started at 1100 h, LH surge began at 1300 h. 2. On the days other than proestrus, BIC infusion between 1000-1300 h did not induce LH secretion at all. 3. PB injection at 1145 h during BIC infusion between 1000-1300 h prevented LH surge which otherwise should have begun at 1200 h. Further, BIC (70 mg/kg/h) infusion between 1400-1700 h, after PB injection at 1400 h, produced LH secretion which began at 1600 h.

The results indicate that, 1) $GABA_A$ receptor system inhibiting the LH surge begins to be relieved from the tension around 1200 h on the day of proestrus but not on the other days, and 2) bicuculline methiodide iv injected acts at the site of barbiturates action to block the surge of LH secretion. Since $GABA_A$ receptors have both the GABA- and barbiturate-binding site, it is concluded that $GABA_A$ receptor system is the major neural substrate involved in the regulation of LHRH surge.

SURGE GENERATING AND PULSE GENERATING GnRH NEURONS IN RATS. T.FUNABASHI*, K.JINNAI and F.KIMURA. Department of Physiology, Yokohama City Univ. Sch. of Med., Yokohama 236, Japan

In the present study, we examined whether gonadotropin-releasing hormone (GnRH) neurons that expressed Fos in response to the stimulation to the GnRH surge generator were different from those in response to the stimulation to the GnRH pulse generator by double labeling immunocytochemistry (Fos; PC05, Oncogene, GnRH; LRH13 Dr. Wakabayashi).

Rats which had exhibited regular 4-days estrous cycle were used. On the morning of proestrus (08:00-09:00), each rat received an implantation of intraatrial cannula. Naloxone (5 mg/h, iv., 10:00-11:30) or bicuculline (50 mg/kg/h, iv, 10:00-13:00) was infused with a microinfusion pump through the cannula. Control rats received saline infusion. Then, rats were killed by injection with an overdose of pentobarbital sodium (PB, 80mg/kg, iv) at 11:30-12:00 for naloxone treatment and 14:00-14:30 for bicuculline treatment. Some of naloxone-treated rats were pre-treated with PB (32mg/kg, ip).

We found that naloxone treatment, which has been shown to activate GnRH pulse generator, induced Fos within GnRH neurons mainly in the caudal part of the forebrain regardless of PB pre-treatment. On the other hand, bicuculline treatment, which has been shown to advance LH surge, induced Fos within GnRH neurons mainly in the rostral part of the forebrain.

We conclude that GnRH neurons involved in the surge generator are different from those involved in the pulse generator.

INTERACTIVE EFFECTS OF SOCIAL CUES AND STEROIDS ON GONADOTROPIN-RELEASING HORMONE IMMUNOREACTIVE CELL NUMBERS. E.F. Rissman* and W.J. Cholbi. Department of Biology, University of Virginia, Charlottesville, VA 22903

Interactions with males have rapid and pronounced effects on the numbers of immunoreactive gonadotropin-releasing hormone (GnRH-ir) neurons in female musk shrews. Previously we have reported that contact with a male rapidly (within 15 minutes) increases GnRH-ir cell numbers. Mating and subsequent ovulation have delayed effects on the numbers of GnRH-ir cells (15-40 hours later). Around the time of ovulation, estradiol levels are negatively correlated with GnRH-ir cell numbers. In the present study we examined the hypothesis that ovarian steroids are required to facilitate changes in GnRH-ir cell numbers induced by contact with a male. Females were either ovary-intact or ovariectomized (OVX). One week later, half of the females in each group (n=6-7 per group) resided across a screen barrier from a male for 2 days. Animals were sacrificed, perfused with modified Zamboni's fixative, and tissue sectioned to 30 microns. Every fourth section from each brain was processed for ICC, using a monoclonal antibody (SMI-41) specific for the mature form of GnRH peptide. All GnRH-ir cells were counted from the olfactory bulb through the hypothalamus. A significant interaction between the presence or absence of a male and gonadal state on GnRH-ir cell number was noted in the olfactory bulb, total olfactory related brain areas, and the entire forebrain. Ovary-intact animals that resided for 2 days in contact with a male had significantly more GnRH-ir cells in the forebrain as compared with OVX animals in the same housing condition ($P<0.05$). OVX caused a significant decrease in GnRH-ir cells in the areas mentioned above, and in the tenia tecta. ($P<0.04$ at least). The presence of a male decreased the numbers of GnRH-ir cells in the hippocampus and cortex ($P<0.02$). These data show that steroid hormones facilitate the effect of social cues on the amount of GnRH peptide present in cell bodies. This work is supported by NSF grant IBN 94-12605.

743.10

INFLUENCE OF CONSPECIFIC MALES ON THE GnRH NEURONAL SYSTEM IN NORMAL AND HYPOGONADAL FEMALE MICE WITH PREOPTIC AREA GRAFTS (HPG/POA): AN IMMUNOCYTOCHEMICAL STUDY. G.V. Rajendren* and M.J.Gibson, Dept. Medicine, Mount Sinai Sch. Medicine, New York, NY 10029

Immunocytochemical detection of Fos protein in GnRH neurons of normal and HPG/POA female mice was employed to assess GnRH neuronal activation following exposure to conspecific male stimuli. Normal ovariectomized (OVX) mice were primed with estrogen (E) 48 h prior to testing, and subjected to either 2 h mating or 2 h exposure to male-soiled bedding or clean bedding, with or without progesterone (P) 4-5 h before testing. Robust induction of Fos immunoreactivity was observed in the GnRH neurons following mating in E+P-primed mice; several GnRH neurons in the E-primed females exposed to male-soiled bedding were also Fos+. None of the other treatment groups exhibited Fos immunoreactivity in their GnRH neurons. Plasma LH levels were also elevated in the E+P-primed females subjected to mating and in the E-primed females exposed to male-soiled bedding.

In continuing analyses of Fos immunoreactivity in GnRH cells within grafts in HPG/POA mice, we included several mice which failed to exhibit ovarian development after receiving grafts. Since normal OVX E+P-primed females consistently exhibited Fos immunoreactivity in their GnRH neurons, the HPG/POA females were OVX, primed with E+P and subjected to 2 h mating. In one HPG/POA, whose graft was in the lateral ventricle, there was no Fos immunoreactivity in GnRH neurons. In contrast, many GnRH neurons were Fos+ in the graft of another undeveloped HPG/POA after mating. Most of the graft tissue was located above the anterior commissure with a portion of it extending into the third ventricle. Neither of these females had GnRH innervation of the median eminence or elevated LH release. Thus even when POA grafts are not successful in stimulating ovarian development in HPG females, appropriate neuronal connections for activation of mating-induced Fos expression may be present. The identity of such afferents is under study. HD19077

743.11

EFFECTS OF HEMIOVARIECTOMY (Hovx) ON OVULATION AND MONOAMINE CONCENTRATION IN THE PREOPTIC-ANTERIOR HYPOTHALAMIC AREA (POA-AHA).

A. Domínguez-González*, M.E. Cruz and N. Cruz. U.I.B.R, Facultad de Estudios Superiores Zaragoza, U.N.A.M., México.

There is evidence that the mechanisms regulating compensatory ovulation and ovarian hypertrophy present asymmetry and lateralization. Also, that Hovx modifies the contents of monoamines in POA-AHA. Then, the effects of left or right hemiovariectomy (Hovx-L; Hovx-R), performed at 12.00-14.00 h of each day of the estrous cycle on ovulation rate and monoamine concentration on POA-AHA was evaluated. The concentration of norepinephrine and dopamine were not modified by Hovx.

When Hovx was performed on diestrus 2, the ovulation rate was reduced significantly (Hovx-L: 2/6; Hovx-R: 1/6 *vs.* control 8/9, $p<0.05$). The concentration of serotonin in those animal with that did not ovulate, presented a different pattern: when the right ovary was extirpated (Hovx-R) the concentration of serotonin was significantly increased (1.524 ± 0.17 ng/mg wet tissue vs. 0.638 ± 0.08, $p< 0.001$), meanwhile when the left ovary was excised, the serotonine concentration in POA-AHA was similar to control group (0.878 ± 0.26 vs, 0.638 ± 0.08). Present results suggest that the lateralized differences observed on the effects of Hovx on ovulation could be related to changes on the serotoninergic levels in POA-AHA.

PLASMA PROGESTERONE LEVELS IN PREPUBERTAL RATS WITH GONADOTROPIN STIMULATION AND CATECHOLAMINERGIC BLOCKADE.

J. Villavicencio*, E. Méndez , G. López, R. Chávez and V. Díaz. UIBR-FES Zaragoza, UNAM., INNS-Zubirán and UAM-Iztapalapa, México, AP 9-020, CP 15 000.

Gonadotropin administration in prepubertal rats induce a increase in follicular growth and steroid secretion mediated by a interelatioship between ovary-hypothalamus-hypophysis axis and diverse systems of neuromodulators. In this work we investigate the participation of catecholaminergic system on progesterone levels and preovulatory follicular growth in 27 days old rats treated with : a) PMSG (8 iu) , b) PMSG, 48 h after Reserpine (RSP:2.5 mg/kg bw), c) PMSG+RSP, 6 h after hCG (10 iu). Animals were sacrified 54 or 72 h after PMSG. Results are presented in the next table:

Group	Ovulation rate	Ova shed	Progesterone (ng/ml)	Preovulatory follicles
54 h				
PMSG	0/5	0 ± 0	19 ± 2	12 ± 1
PMSG+RSP	0/5	0 ± 0	5 ± 0.3 a	6 ± 3
72h				
PMSG	9/9	16 ± 2	17 ± 2	1 ± 0.3
PMSG+RSP	0/5 a	0 ± 0 a	10 ± 1 a	8 ± 2 a

a, $p < 0.05$ vs group PMSG same hour

All animals treated with hCG ovulated (PMSG+hCG: 6/6, ova shed 28 ± 2; PMSG+RSP+hCG: 6/6, ova shed 17 ± 1). Our results suggest a stimulatory participation of central catecholaminergic system on neuroendocrine regulation of gonadotropin secretion.

743.13

BILATERAL ENUCLEATION AT BIRTH DIMINISHES SIMULATED MIDCYCLE GONADOTROPIN SURGES IN ADULT FEMALE RATS.

T. L. Horvath* and F. Naftolin. Yale University, Dept. of Ob/Gyn, New Haven CT, 06520

In rats the secretion of gonadotrophins is dependent on an intact suprachiasmatic nucleus. Since (1) the circadian secretion of gonadotropins is sexually dimorphic, (2) estrogen is the developmental hormone that regulates the sexual phenotype of the brain nuclei thus far studied and (3) we have demonstrated immunoreactive estrogen synthetase to be present in axons in the optic tract and in central targets of visual afferents including the suprachiasmatic nucleus, we proposed that retinal projections may participate in the development of gonadotrophin control.

Experimental: Newborn female rats were enucleated at birth (n=5), left intact (n=6) or sham operated (n=4). Intact males (n=5) were controls. Three month later all animals were castrated. After 3 weeks a simulated midcycle surge was induced by two daily subcutaneous estradiol injections (10 µg/kg) plus 500 µg progesterone s.c. 24 h later. **Results:** The development of enucleated pups did not differ from controls: vaginal opening occurred between P35-40, followed by 4 day vaginal cycles. Three weeks after castration, LH levels by RIA were elevated in all animals (Σ 16 ng/ml). Blood taken just prior to progesterone showed suppressed LH levels in all cases (Σ 3 ng/ml). Six hours after progesterone, control females' LH was markedly elevated (Σ 15 ng/ml) while enucleated females and control males had no rise (Σ 3 ng/ml). Similar results were obtained when the experiment was repeated in 8 months. **Conclusions:** Despite apparently not impairing the development of ovarian cycles in female rats, neonatal enucleation blocked the induced gonadotrophin surge. In addition to supporting our hypothesis of a developmental role of the visual tract via estrogen formation, these studies indicate that this process may be underway prior to birth. EFFECTS OF GRANULOCYTE-MACROPHAGE COLONY STIMULATING FACTOR (GM-CSF) ON LHRH AND GONADOTROPIN RELEASE *IN VITRO*.

M. Kimura*, W. H. Yu and S. M. McCann. Dept. of Medicine, Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas TX 75235-8873.

Granulocyte-macrophage colony stimulating factor (GM-CSF), a haemapoietic cytokine, is currently reported to play a unique role in gestation. Especially during preimplantation, GM-CSF produced by stimulation of estrogen acts on embryos and results in the success of reproduction. However, no study has been done regarding direct effects of GM-CSF on gonadotropic hormones. Thus, the present study examined *in vitro* whether GM-CSF was implicated in gonadotropin regulation. Hemipituitaries and medial basal hypothalami were dissected from male rat brains and incubated for 2 h and 0.5 h, respectively, in Krebs-Ringer bicarbonate glucose media in a Dubnof metabolic shaker with an atmosphere of 95 % O_2/5 % CO_2. The actions of recombinant murine GM-CSF on pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and luteinizing-hormone releasing hormone (LHRH), were tested *in vitro*, and dose responses of LH and FSH (GM-CSF, 10^{-18} to 10^{-8} M) and LHRH (GM-CSF, 10^{-13} to 10^{-8} M) release were analyzed statistically. At a dose of 10^{-16} M, GM-CSF increased the release of LH ($p < 0.05$) but did not affect FSH release at any doses tested. In contrast, LHRH release was inhibited significantly at doses of 10^{-11}-10^{-12} M, which was evident in a U-shaped dose-dependent manner. The inhibitory effects of GM-CSF (10^{-11} M) on LHRH were reversed by co-incubation with antiGM-CSF (1 µg/ml). The results indicate that GM-CSF acts centrally to inhibit LH release but directly on the pituitary to stimulate LH release. (Supported by MH51853)

ESTRADIOL-17ß ACUTELY INCREASES POMC mRNA LEVELS AND ß-ENDORPHIN SECRETION FROM THE RAT HYPOTHALAMUS.

A. Dey, N. Boyadjieva, S.A. Frautschy, J.P. Advis*, J.L. Roberts and D.K. Sarkar
Dept. of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520; Dept. of Animal Sciences, Rutgers University, New Brunswick, NJ 08903; Mt. Sinai Medical Center, New York, NY 10029-6574.

The role of estrogen in the regulation of hypothalamic ß-endorphin neuronal activity was determined *in vitro* and *in vivo*. Using primary cultures of cells from fetal mediobasal hypothalami, we determined the effect of estrogen (estradiol-17ß) on ß-EP precursor POMC mRNA levels and on the ß-EP secretion *in vitro*. Estradiol-17ß dose-dependently increased the levels of ß-EP from the cultured neurons between 3-24 h. However, these cultured neurons developed desensitization to the stimulatory effect of estrogen at 48 h. The steroid also increased cellular levels of POMC mRNA at 24 h. *In vivo*, 24 h following s.c. injection of 10 µg estradiol benzoate, ovariectomized rats showed a significant increase in ß-EP concentrations in pituitary portal blood when compared with those in oil-treated controls. These data suggest that, in addition to known inhibitory effect of estradiol, the steroid may also stimulate ß-EP synthesis and secretion. Supported by National Institutes of Health Grants AA08757 and HD20498.

EVIDENCE THAT PROGESTERONE INCREASES THE NUMBER OF DELTA OPIOID RECEPTORS IN THE PRE-OPTIC HYPOTHALAMUS OF THE EWE DURING THE LUTEAL PHASE OF THE ESTROUS CYCLE.

I.J. Clarke*, B. Thom and B. Canny, Prince Henry's Institute, P.O. Box 5152, Clayton, Australia 3168.

The extent to which endogenous opioid peptides negatively regulate GnRH secretion may vary with physiological status. We have measured the number and affinity of µ, δ and κ subtypes of the opioid receptor in the preoptic area (POA) of the hypothalamus of groups (n=4) of ovariectomised (OVX) ewes that were either untreated or given estrogen (E), progesterone (P), or E & P for 10 days. We also studied ewes (6-8/group) at various stages of the estrous cycle. POA membranes were used for Scatchard analysis for the 3 subtypes of opiate receptor (Shen et al., 1995, J. Endo. In Press).

In OVX ewes, P increased mean (±SE) δ opioid receptor number (172±44 vs 39±9 fmol/mg protein in Controls) with no change in affinity. P and E had no effect on other receptor subtypes. In cycling ewes there were more δ receptors in the luteal phase of the cycle(133±71fmol/mg protein) than in the early- (64±12 fmol/mg), mid- (68±29 fmol/mg) or late- (35±16 fmol/mg) follicular phase.The number and affinity of the µ and κ receptors was similar across the cycle.

The data suggest that the δ sub-type of opioid receptors in the POA is regulated by P and the higher number in the luteal phase of the cycle could account for increased opioid tone at this time.

743.17

IS A DECREASE IN OPIOID TONE NECESSARY FOR THE TIMING OF THE LH SURGE IN RATS? P.B. Lieberman, C.A. Paronis, J.H. Woods, E.A. Young*. Departments of Physiology, Pharmacology, and Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Based upon previous opioid agonist and antagonist studies it has been hypothesized that a decrease in opioid tone at the mu receptor subtype is the necessary signal to trigger the preovulatory LH surge in rats. To test this we have used an irreversible mu receptor antagonist, clocinnamox (CCam; 5-10 mg/kg), that has been shown to alkylate receptors and completely abolished morphine analgesia as assessed by tail flick latency for at least 1 week. If a decrease in opioid tone at the mu receptor is the critical signal to trigger an LH surge, we hypothesized that this treatment would interfere with the timing of the LH surge. Briefly, rats underwent daily vaginal smearing for a 2 week baseline period and throughout the study, and were injected with vehicle on the afternoon of diestrus II. Blood samples were collected by tailnick in the morning (0830) and at 1 of the following PM timepoints (1200, 1430, 1530, 1630). After a 1 week recovery period, CCam was administered on diestrus II and blood sampling was repeated. CCam caused a significant increase in plasma LH levels at all timepoints except during the surge. In most rats, the surge was initiated between 1430 and 1530, although two rats had reached surge LH levels by 1430 in both their control and C-Cam treated cycles. These data suggest that although tonic LH secretion is inhibited by activity at the mu receptor, it is not the critical trigger for the LH surge. (Supported by MH 45232 and DA 00254 and DA 05653.)

DIRECT EVIDENCE FOR DOWN-REGULATION OF HUMAN GONADOTROPIN- RELEASING HORMONE (GnRH) GENE BY ESTROGEN K.W. Dong[1]* Z.G. Chen[1], K.W. Cheng[2] and K.L. Yu[2]. 1The Jones Institute for Reproductive Medicine, Eastern Virginia Medical School, Norfolk, VA 23507. 2Department of Zoology, The University of Hong Kong, Hong Kong.

Although expression of the human GnRH gene has been reported in hypothalamus and reproductive tissues, the molecular mechanisms underlying the regulation of GnRH gene expression by estrogen in these tissues are largely unclear. The apparent discrepancies among various *in vivo* studies may be due to the complex neuronal circuits and the lack of estrogen receptors in certain populations of GnRH neurons. This study seeks to determine whether estrogen could have a direct effect on human GnRH gene expression in transfected placental tumor cells (JEG). Our previous study identified two promoters in the human GnRH gene with the upstream promoter being used only in reproductive tissues such as placenta . In this study, the downstream GnRH promoter (H-1) containing 0.65 kb of the 5' flanking sequence and the 1.8 kb of the upstream promoter region (H-2) with a deletion of the downstream promoter sequence, were fused to a promoterless luciferase reporter construct. The response of these promoter-luciferase constructs to estrogen was assessed by transfection into the JEG cells. The luciferase activity in the transfected cells was measured after either no treatment or treatment with various concentrations of estradiol, JEG cells transfected with H-1-Luc or H-2-Luc construct showed insignificant changes in luciferase activity in response to estradiol. However, cotransfection of H-1-Luc or H-2-Luc construct into JEG cells with a vector expressing a human estrogen receptor (ER)cDNA resulted in decreases in luciferase activity in response to estradiol. Thus, this study demonstrated that both upstream and downstream human GnRH promoter regions can confer down regulation by estrogen in transfected JEG cells in the presence of cotransfected ER expression vector.

CONSISTENT WITH REMOVAL OF LOCAL INHIBITION, PERIFUSION RATE AFFECTS LH AND FSH SECRETION. **Lemon, WJ, Padmanabhan, V, Favreau, PA, Heinze, K and Midgley, AR*, Reproductive Sciences Program, Cellular Biotechnology Training Program, National Center for Infertility Research, Bioengineering Program, University of Michigan, Ann Arbor, MI 48109-0404.**

In addition to hypothalamic GnRH, local pituitary factors (e.g. inhibin, activin, galanin) play an important modulatory role in regulating secretion of LH and FSH. Since GnRH binding to receptor depends primarily on its concentration, secretion that depends solely on GnRH should occur independently of perifusion rate while secretion that depends on local factors will change as the rate changes. Anterior pituitary cells were obtained from abattoir sheep, dispersed, co-loaded with beads and perifused in a custom, computer-controlled micro-perifusion system from which LH and FSH were measured. Four groups of cells were acclimatized in the chambers for 19 h without GnRH stimulation, then stimulated every 40 min for 8 h with 4 min, 1.0nM pulses of GnRH. The first group was perifused at a constant high flow rate (136μL/min.); the second group at a constant low flow rate (14μL/min.); the third group was switched from the high rate to the low rate (4h/4h); the fourth group was switched from the low rate to the high rate (4h/4h). Secretion (ng/5') decreased when the flow decreased (ratio of means of log-transformed data 4-8h/0-4h for LH=0.79; FSH = 0.85). Release of both gonadotropins increased when the flow rate increased (ratios: LH=1.12; FSH=1.24). At constant flow rate, LH decreased over time (ratios: high flow rate=0.93; low flow rate=0.91) but FSH remained constant (ratio=1.00 at both high and low flow rates). These data are consistent with removal of common local inhibition, but other models cannot be ruled out. Supported by NIH grants U54 HD 29184 & P30 HD 18258.

EFFECT OF PROGESTERONE ON LHRH, LHRH RECEPTOR AND LHβ mRNA LEVELS IN OVARIECTOMIZED AND ESTROGEN-TREATED RATS: AN INSIGHT INTO THE MECHANISM OF LHRH-LH SURGE BY STEROIDS. J. Y. Seong, S. S. Kang, K. Kam, W. Sun and K. Kim.* Dept. of Molecular Biology, Col. of Nat. Sci. Seoul Nat'l Univ., Seoul 151-742, Korea.

The present study is designed to evaluate the stimulatory action of progesterone (P) on the LHRH-LH axis. Using ovariectomized and estrogen (OVX+E)-treated rats, we determined LHRH mRNA level in the preoptic area (POA), and LHRH receptor (LHRHR) and LHβ mRNA levels in the pituitary by competitive RT-PCR or Northern blot analysis. Silastic capsule containing 17β-estradiol (E, 180 μg/ml in oil: 30 mm in length, id 1.575 mm) was implanted to OVX rat, and 2 days later a single injection of P was administered s.c. at 10:00 h. P increased serum LH levels in a dose-dependent manner and 1 mg of P was enough to enhance the maximal increase in serum LH level at 17:00 h. At this time, LHRH mRNA level in the POA was also augmented by P in a dose-dependent manner. In the pituitary, LHRHR mRNA level was increased by P, while there was no significant change in LHβ mRNA level. To determine the temporal changes in such parameters, several time points were chosen according to the profile of serum LH levels. LHRHR mRNA level was increased 2 hr prior to LH surge (at 17:00 h) and declined when serum LH level was decreased. LHRH mRNA level rised at the time of the LH surge and the elevated level was sustained until 22:00 h. No change in LHβ mRNA level, however, was observed. These results show that 1) LHRHR mRNA level in the pituitary was elevated prior to the LH surge, which may be involved in the potentiation of LH surge, and 2) an increase in LHRH mRNA level in the POA is accompanied by the LH surge, and sustained elevated LHRH mRNA level may be related to the desensitization of LHRHR and consequent decrease in LH levels. Taken together, the present study indicates that P may play an important role in regulating LHRH and LHRHR gene expression at the time of the LH surge.

HYPOTHALAMIC-PITUITARY-GONADAL REGULATION VI

744.1

INFLUENCE OF LIFE-LONG MODERATE CALORIC RESTRICTION ON NEUROPEPTIDE-Y GENE EXPRESSION IN THE ARCUATE NUCLEUS OF FEMALE RATS. **T.M. McShane* and P.M. Wise.** *Department of Physiology, University of Kentucky, College of Medicine, Lexington, KY 40536-0084.*

Moderate caloric restriction extends lifespan, reduces the incidence of age-related diseases, and delays reproductive senescence in rats. We have previously shown that life-long moderate caloric restriction delays onset of persistent estrus and enhances pulsatile secretion of LH. Neuropeptide-Y (NPY) is thought to play an important role in maintenance of reproductive cycles, feeding behavior, and metabolic homeostasis. We hypothesized that moderate caloric restriction (CR) works through NPY-mediated mechanisms to delay reproductive aging. Female Sprague-Dawley rats (7 weeks old) were placed on caloric restriction (CR; n=70) which was 60% of ad libitum (AL) intake measured in control rats (n=70). Rats were individually housed under a 14L:10D cycle, and fed daily within 1.5 hours of lights-off. Rats were rapidly decapitated 2.5 weeks following OVX, when rats were 4, 12, or 18 months of age. Brains were dissected, frozen, and coronal sections (12 microns) through the arcuate nucleus were cut at -20°C on a cryostat. Relative levels of NPY mRNA were measured by In situ hybridization. A cDNA clone complementary to rat prepro-NPY was used as a transcription template to synthesize a cRNA probe labeled with [^{35}S]UTP. Slides were dipped in photographic emulsion, exposed for 10 d before developed, and silver grains were quantified using computer assisted image analysis. Number of NPY cells per section in the anterior and mid-arcuate was not different between CR and AL rats and did not change with age. Relative level of NPY mRNA (area of pixels covered by silver grains) was greater in CR rats ($P<.001$), but was not influenced by age or previous cycle history. Increased biosynthesis of NPY may contribute to the enhanced amplitude of LH pulses previously reported in these animals. Supported by NIH AG02224 to PMW and AG05648 to TMM.

744.2

SODIUM PENTOBARBITONE AND THE INHIBITION OF LUTEINIZING HORMONE PULSES IN RATS: THE SIGNIFICANCE OF HYPOTHERMIA. P. H. Strutton and C. W. Coen* Division of Biomedical Sciences, King's College, London WC2R 2LS, U.K.

The role of hypothermia in the suppression of pulsatile luteinizing hormone (LH) release by the general anaesthetic sodium pentobarbitone has been investigated in ovariectomised rats. Each animal was fitted with an intraperitoneal miniature radio transmitter to monitor core temperature and with an indwelling cannula in the right atrium of the heart and in the intraperitoneal space. During the 6-hour sampling period the animal's core temperature was recorded automatically every 5 minutes and a 25 μl blood sample was obtained concurrently using an automated system. After the initial 3 hours of sampling either the drug or the vehicle was administered via the intraperitoneal cannula from outside the cage ensuring minimal disturbance to the animal. Administration of sodium pentobarbitone (40 mg/kg) at an ambient temperature of 21°C resulted in a significant hypothermia throughout the 3-hour post-injection period. During this period there was a significant reduction in mean LH concentration, pulse amplitude and pulse frequency. When the drug was administered at an ambient temperature of 35°C there was no significant reduction in core temperature and no significant change in the LH pulse parameters. Administration of the vehicle had no significant effect on core temperature or on the LH pulse parameters at either 21°C or 35°C. These results indicate that the effects of this barbiturate on the pulsatile release of LH are secondary to the induced hypothermia. We are investigating the extent to which the induction of hypothermia may be of critical importance in the suppression of LH pulses by other drugs.

VOLUNTARY EXERCISE INHIBITS BASAL GONADOTROPIN SECRETION IN OVARIECTOMIZED, NON-REPLACED, BUT NOT OVARIECTOMIZED HAMSTERS TREATED WITH ESTRADIOL.

David Pieper*, Haythem Ali, Subhashini Ladella, Catherine Lobocki, and Katarina Borer, Providence Hospital, Department of Physiology, Southfield, Michigan, and the University of Michigan, Department of Kinesiology, Ann Arbor, Michigan

Recent studies in male hamsters have shown that voluntary exercise facilitates gonadotropin secretion by inhibiting the negative feedback of testosterone. The present study investigated the influence of exercise on basal (morning) gonadotropin levels in ovariectomized hamsters treated with blank capsules or with capsules containing estradiol.

Forty-eight adult female hamsters were ovariectomized and implanted with capsules which were either blank or contained 4 mm of estradiol 17B (E2). One half of each E2 group was placed in cages with wheels (EX group) or in similar cages without wheels (SED). Blood samples were obtained between 8 and 10 AM by retro-orbital puncture before surgery and at weekly intervals following surgery for 5 weeks.

There was a dramatic increase in serum LH and FSH following ovariectomy in both groups without E2, but all E2 treated hamsters had low levels throughout the study. There was no consistent difference in LH or FSH levels between the SED and EX groups with E2, but the serum FSH (and to a lesser extent LH) was consistently significantly lower in the EX than SED groups with blank capsules.

We conclude that exercise has a steroid independent effect to inhibit basal gonadotropin secretion in female hamsters.

EFFECT OF FOOD DEPRIVATION ON ESTROGEN RECEPTOR IMMUNOREACTIVITY IN DIFFERENT HYPOTHALAMIC NUCLEI OF FEMALE SYRIAN HAMSTERS. A. K. Panicker, H-Y Li, J.D.Blaustein and G.N. Wade*. Neuroscience and Behavior program, University of Massachusetts, Amherst, MA01003.

Metabolic fuels have a profound effect on reproductive functions of female Syrian hamsters. Estradiol plays an important role in the physiological and behavioral components of reproduction, ovulation and estrous behavior. Mapping of neural sites where estrogen receptor immunoreactive (ERIR) cells respond to metabolic fuels and the type of response might enable us to find a relation between specific sites and behavioral and neuroendocrine events leading to nutritional infertility. Previous research from this lab showed that 48h of food deprivation (FD) in female Syrian hamsters caused a decrease in the number of ERIR cells in the ventromedial hypothalamus, an increase in the medial preoptic area and no effect in the nucleus of solitary tract. In the present study we looked at ERIR cells in the parvocellular portion of the paraventricular nucleus (pPVN), medial amygdala (MeA) and arcuate nucleus (Arc). The number of ERIR cells in the pPVN increased following 48 h of FD. This is in agreement with the hypothesis that the increased release of corticotropin releasing hormone in acute fasting is facilitated by estrogen action in the PVN. Even though MeA is believed to be involved in female sexual behavior, no significant effects on ERIR cells were observed in this region, consistent with the idea that it has little effect on reproduction related to nutrition. In the Arc FD caused a decrease in the number of ERIR cells, which may contribute to the blockade of preovulatory luteinizing hormone surge in food- deprived animals by neuropeptide Y.

SUPPRESSION OF LH PULSES BY REDUCING GLUCOSE AVAILABILITY IS MEDIATED BY SENSORS IN THE LOWER BRAIN STEM. S. Nagatani[1], K. Murahashi[1], D. C. Bucholtz[2], S. Tsukahara[1], M. A. C. Estacio[1], H. Tsukamura[1], D. Foster[2]* and K.-I. Maeda[1]. [1]Sch. of Agri. Sci., Nagoya Univ., Nagoya 464-01, Japan; [2]Reprod. Sci. Progr., Univ. Michigan, Ann Arbor MI 48109, USA.

Glucose may play a key role in controlling reproductive activity through modulation of GnRH secretion. The present study in the rat determined 1) if glucoprivic suppression of pulsatile LH release is sexually differentiated; 2) if the glucoprivic suppression is potentiated by gonadal steroids; 3) if such glucoprivic suppression of LH secretion is mediated by a glucosensor in the 4th ventricle. Our approach was to monitor pulsatile LH secretion after peripheral (jugular) or central (4th ventricle, 4V) administration of the competitive inhibitor of glycolysis, 2-deoxyglucose (2DG). Fourteen days after gonadectomy, blood samples for LH were collected every 6 min for 3 h. After one hour of sampling, 2DG was administered peripherally (200, 400 or 800 mg/kg BW) in gonadectomized (GDX) males and females in the presence or absence of sex steroids (testosterone or estradiol) or centrally (4 or 40 mg/kg) in GDX or testosterone-treated GDX males. In the presence of steroids, mean plasma LH decreased ($P<0.05$) at all peripheral doses of 2DG, whereas in the absence of sex steroids, the lowest dose was ineffective. The middle dose of 2DG suppressed ($P<0.05$) mean plasma LH in GDX females but not in GDX males. Central 2-DG infusion of 40 mg/kg, but not 4 mg/kg, suppressed pulsatile LH secretion in both GDX and testosterone-treated GDX rats. LH secretion was not depressed by an isosmotic xylose infusion. The site-specificity of the 2DG infusion into the 4V was confirmed by an isovolumetric infusion of dye at the termination of sampling. Collectively, our findings suggest that (1) the hypothalamo-hypophyseal axis of female rats is more sensitive to the decreased glucose availability induced by 2DG than that of males; (2) this glucoprivic suppression of LH pulses is potentiated by gonadal steroids; (3) glucose availability is detected in the 4th ventricle consistent with the notion that the area postrema may serve as an important glucosensor.

LUTEINIZING HORMONE SECRETION IN RHESUS MONKEYS FOLLOWING CORTISOL SYNTHESIS INHIBITION WITH METYRAPONE. D. A. Van Vugt*, J. Piercy, A. E. Farley, and R. L. Reid, Obstetrics & Gynecology and Physiology, Queen's University, Kingston, Ontario K7L 3N6.

Luteinizing Hormone (LH) secretion can be inhibited by Corticotrophin Releasing Hormone (CRH), and various stressors which increase CRH secretion cause inhibition of LH secretion. In an attempt to further elucidate the physiological significance of CRH regulation of LH secretion we determined the effects of metyrapone on LH secretion. Metyrapone has been shown to activate CRH neurons, presumably as a consequence of reduced cortisol negative feedback. We reasoned that this paradigm could be exploited to study CRH regulation of LH secretion in the monkey. Six ovariectomized rhesus monkeys were placed into primate chairs and angiocatheters were introduced into the femoral and saphenous veins for blood collection and metyrapone infusion respectively. Metyrapone (5 mg/kg/hr) or saline was infused for ten hours from 2300 to 0900 hours. Blood samples for LH and cortisol were collected at 15 minute intervals for six hours starting at 0900 hours.

Metyrapone infusion resulted in a pronounced inhibition of cortisol. The mean ($\pm$SEM) cortisol level at the end of a 10 hour infusion of metyrapone was 6.9 $\pm$ 0.6 μg/dL compared to 46.8 $\pm$ 3.9 μg/dL in saline controls. Cortisol levels gradually increased to 22.2 $\pm$ 3.5 μg/dL during the subsequent six hour blood sampling protocol compared to 53.1 $\pm$ 5.4 μg/dL in the control group. M ean LH levels were 73.4 $\pm$ 6.0 ng/mL following metryapone compared to 75.5 $\pm$ 6.1 ng/mL in saline controls. No effect of metyrapone infusion on pulsatile LH secretion was seen. These results indicate that inhibition of LH secretion does not always accompany activation of CRH neurons. The presence of CRH populations that regulate the pituitary - adrenal axis specifically may explain these findings. Alternatively, CRH may not be a critical neuromodulator of LH secretion in the ovariectomized monkey (This work was supported by the MRC of Canada).

GLUCOCORTICOID REPRESSION OF GNRH GENE EXPRESSION AND SECRETION IN MORPHOLOGICALLY DISTINCT SUBPOPULATIONS OF GT1-7 CELLS. B. Attardi*, T. Tsujii1, R. Friedman1, Z.W.Zheng2, J.L. Roberts2, T. Dellovade3, D. Pfaff3, and D.B.DeFranco4. *1Med. and 4Biol. Sci., Univ. of Pittsburgh, Pgh., PA 15213; 2Mt. Sinai Med. Ctr., N.Y., NY 10029; 3Rockefeller Univ., N.Y., NY 10021.

GT1-7 cells possess functional glucocorticoid receptors, and the synthetic glucocorticoid, dexamethasone (dex), represses GnRH gene expression (Endo. 134:1467, 1994). We have now compared the dex sensitivity of two variants of GT1-7 cells with different morphological properties (type I: "neuronal" appearance, phase-bright, many processes; type II: phase-dark, fewer processes). Dex (1 μM, 20-24 h) suppressed luciferase activity in transfections with GnRH-luciferase reporter plasmids as well as GnRH mRNA to a greater extent in type II cells than in type I. ICC for GnRH demonstrated dark reaction product uniformly among type I cells, whereas type II cells had little or no stain. For secretion studies, cells were attached to Cytodex beads and perifused for 8 h with control or dex-containing medium. The high levels of GnRH secreted by type I cells were slightly enhanced by dex. In type II cells, which secreted much lower levels of GnRH, dex decreased GnRH release rapidly and profoundly. Thus, in the type II subpopulation of GT1-7 cells, nuclear alterations leading to greater transcriptional susceptibility to dex, coupled with low GnRH storage levels, may be reflected in exquisite sensitivity of GnRH secretion to glucocorticoid repression.

744.8

CORTICOTROPIN RELEASING HORMONE ANTAGONIST BLOCKS Δ^9-TETRAHYDROCANNABINOL-INDUCED SUPPRESSION OF LUTEINIZING HORMONE SECRETION IN OVARIECTOMIZED RATS. A.L. Jackson and L.L. Murphy *. Dept. of Physiology, Southern Illinois Univ. Sch. of Med., Carbondale, IL 62901.

Findings that marijuana and Δ^9-tetrahydrocannabinol (THC), the major psychoactive component of marijuana, stimulate the hypothalamic-pituitary-adrenal and inhibit the -gonadal axes are well documented in experimental animals. Recent studies have demonstrated that corticotropin releasing hormone (CRH) can suppress gonadotropin-releasing hormone (GnRH) secretion. Thus, this study was designed to determine if THC inhibits luteinizing hormone (LH) release in ovariectomized (OVX) rats, via a CRH-mediated mechanism. Adult rats were OVX and 3 weeks later implanted with stainless steel cannulae within the third ventricle of the brain. One week after brain surgery, polyethylene cannulae were inserted into the jugular vein for THC administration and blood withdrawal. After a 24 h recovery period, the CRH receptor antagonist, α-helical CRF_{9-41} (αh-CRF; 100μg/5μl), or vehicle was infused into the third ventricle (2.5μl/min) after an initial blood sample. THC (0.5 mg/kg b.wt.) or vehicle was administered 30 min after αh-CRF and blood samples were taken at times 30 and 60 post-THC administration. Results revealed that THC produced significant decreases in plasma LH levels at 30 and 60 min post-treatment when compared to vehicle ($p<0.05$). Infusion of αh-CRF did not alter LH levels at any time point relative to its vehicle. However, pre-treatment with the antagonist completely blocked the suppression of LH by THC when compared to animals receiving THC vehicle. These results suggest that CRH mediates the inhibition of LH secretion following acute THC treatment in OVX rats. (Supported by DA-05042)

CROSS-CORRELATION ANALYSIS OF INTERACTIONS BETWEEN HYPOTHALAMIC UNITS ASSOCIATED WITH THE GONADOTROPIN-RELEASING HORMONE (GnRH) PULSE GENERATOR. T. Ördög and E. Knobil*. Laboratory for Neuroendocrinology, Medical School, The University of Texas Health Science Center, Houston, TX 77225.

The electrophysiological correlates of the activity of the GnRH pulse generator, a hypothalamic oscillator that governs the episodic secretion of the pituitary gonadotropic hormones, are abrupt, rhythmic increases in multiunit activity (MUA volleys) in the mediobasal hypothalamus (MBH) that represent the simultaneous increase in firing rate of individual units. This synchrony could be effected by parallel inputs from a "master oscillator" or by other mechanisms. Single units were identified by cluster analysis of multiunit recordings from the MBH of 3 ovariectomized rhesus monkeys and their connectivity analyzed by cross-correlation histograms of time series of their action potentials, a method that determines the probability that the firing of two neurons relative to one another is not due to chance. To relate the results to the generation of the MUA volleys, the analyses were performed separately during the volleys and the intervals between them. Significant ($p<0.01$) interaction was found in ~60% of the 31 pairs of pulse-generator-associated units analyzed. The majority of cross-correlation histograms consisted of a single peak with a delay from time zero of 1-3 ms and a duration of 0.5-1.5 ms between and during volleys. The distinct character and short duration of this peak suggest, in agreement with observations made by others in the cerebral cortex, direct, synaptic, excitatory interactions between these units. Although the specific characteristics of these interactions (*strength* and *contribution*) varied considerably from one unit pair to another, they were not significantly different during and between volleys. The results suggest that the synchronization of the single-unit bursts may be effected by these direct synaptic interactions rather than by a common Zeitgeber. (Supported by NIH grants HD-17438 and HD-08610, and by the Ellwood Foundation.)

MODELING THE AGONIST-INDUCED ELECTRICAL AND CALCIUM ACTIVITY PATTERNS OF PITUITARY GONADOTROPHS
Y.-X. Li*†, S.S. Stojilkovic‡, J. Keizer§, and J. Rinzel†. †Math. Res. Branch, NIDDK, NIH; ‡Endocrinol. Reprod. Res. Branch, NICHD, NIH; §Inst. Theor. Dynamics and Sec. Neurobiol. Physiol. Behav., UC Davis

Pituitary gonadotrophs are ideal for studying Ca^{2+} signaling in excitable cells. Signals can be generated separately or interactively via plasma-membrane Ca^{2+} entry through voltage-gated Ca^{2+} channels and/or via hormone-induced Ca^{2+} release from the intracellular Ca^{2+} store, endoplasmic reticulum (ER), through inositol trisphosphate (IP_3) receptor Ca^{2+} channels on the ER membrane. We account for the complex Ca^{2+} and V_m dynamic patterns using mathematical models in combination with Ca^{2+} fluorescence and whole-cell clamp electrical measurements. Our model incorporates Ca^{2+} diffusion and the IP_3-mediated Ca^{2+} oscillation mechanism spatially-distributed in a spherically symmetric cytoplasm with a boundary condition describing the activity of plasma membrane channels and active Ca^{2+} pumps. Besides explaining various firing patterns observed in both male and female gonadotrophs during IP_3-induced Ca^{2+} oscillations, our modeling gives insights into the mechanisms of Ca^{2+} homeostasis before, during, and after agonist stimulation. The Ca^{2+} handling parameters (diffusion rates, buffering capacities, membrane pump and leakage characteristics) all influence the spatio-temporal patterns of Ca^{2+} and V_m. Quantitative understanding of resetting the Ca^{2+} oscillation's phase with current pulses is also achieved.

A NEURAL NETWORK MODEL OF THE LHRH PULSE GENERATOR: SYNCHRONY AND PULSATILITY. M. D. Loose*, Neuroscience Program, Oberlin College, Oberlin, OH 44074

The secretion of LHRH has a distinctive, pulsatile pattern of short periods of relatively high levels of release followed by longer intervals of low to undetectable levels of release that is thought to result from synchronized release by tens/hundreds of LHRH neurons. To examine how certain variables affect synchronization, I have constructed and tested a simple model consisting of 100 randomly connected LHRH neurodes. All neurodes projected to the median eminence, were endogenous bursters with randomly assigned interburst-intervals (IBI), and had excitatory effects on postsynaptic cells. Each neurode multiplies its inputs by the associated synaptic weights and sums these values. Neurode output was a sigmoid function of the sum and circuit output was the summed neurode output. This process was repeated every sec for 4-8 simulated hours. With 0% connectivity, circuits had only small fluctuations in output over time. If all cells were "stimulated" to burst simultaneously, subsequent pulses decreased in amplitude and increased in duration at a rate dependent on the variability of the IBI. When the chance of a synapse from one neurode to another was set at 1, 2, 3, 5 or 10% and various synaptic weights were tested, circuits were capable of indefinitely maintaining a synchronized output and of creating a pulsatile output from a non-synchronized starting point. "Ablation" of neurodes indicated that pulsatility was a robust feature of circuits exhibiting pulsatile output. This model has numerous variables that require further evaluation but appears to be a useful paradigm for modeling LHRH pulsatility.

ACTIVATION OF PKA: A NOVEL TRANSDUCTION MECHANISM FOR ESTROGEN'S MODULATION OF μ-OPIOID/K^+ CHANNEL COUPLING. A.H. Lagrange*, M.J. Kelly Dept. of Physiology, Oregon Health Sciences U., Portland, OR 97201

Control of the female HPG axis by estradiol (E_2) involves inhibition of hypothalamic GnRH release via modulation of the β-endorphin system. μ-opioid peptides (e.g. β-endorphin) hyperpolarize hypothalamic cells by opening a K^+ inward-rectifier ($I_{K(ir)}$) Intracellular recordings in arcuate neurons from *in vitro* hypothalamic slices from ovariectomized guinea pigs were used to study the mechanism of E_2 action. The potency of the response to the μ-opioid agonist, DAMGO is rapidly decreased nearly four-fold by a brief exposure to E_2 (100 nM, 20 min) in about 35% of neurons tested. The effect of E_2 is stereoisomer-specific and concentration-dependent. μ-receptor/G-protein coupling is altered by cAMP-dependent protein kinase (PKA), and there is evidence that the estrogen receptor interacts with PKA in some systems. The effects of E_2 were blocked by the nonspecific protein kinase inhibitor, staurosporine (100 nM, n=10), and mimicked by stimulation of adenylate cyclase with forskolin (1 - 20 μM, n=6). The more selective PKA activator, S_p-cAMP mimicked the effects of E_2 in a concentration-dependent manner (n=3). Although the selective PKA antagonists, KT5720 (50 nM, n=7) and R_p-cAMP (100 μM, n=7) inhibit PKA by different mechanisms, both agents blocked the effects of E_2. The present work provides a novel transduction mechanism for E_2 (i.e. PKA activation), as well as elucidating the intracellular mechanisms regulating the actions of opioid peptides. (Supported by PHS Grants DA05158 and MH10327)

744.13

PHARMACOLOGICAL CHARACTERIZATION OF THE ESTROGEN RECEPTOR'S RAPID ALTERATION OF μ-OPIOID SYNAPTIC TRANSMISSION. M.J. Kelly*, A.H. Lagrange Dept. of Physiology, Oregon Health Sciences U., Portland, OR 97201

We have previously shown a rapid effect of 17β-Estradiol (E_2) to alter the potency of the μ-opioid agonist, DAMGO, in hypothalamic neurons. This effect is faster than would be expected for the classic genomic model of E_2 action, and appears to involve activation of PKA. To study the mechanism of E_2 action, intracellular recordings were made from arcuate neurons from *in vitro* hypothalamic slices from ovariectomized guinea pigs. DAMGO hyperpolarizes these cells by opening an inwardly rectifying K^+ channel. The potency of this effect is reduced nearly four-fold by a brief exposure to E_2 (100 nM, 20 min) in about 35% of neurons tested. The EC_{50} for E_2's effect was 8 nM, with a Hill slope of 0.7. The biologically inactive isomer, 17α-E_2 was unable to mimic the effects of 17β-E_2. The effects of E_2 appear to be mediated by an intracellular receptor, as the membrane-impermeant conjugate BSA-E_2 did not alter DAMGO potency. Furthermore, the effects of E_2 were blocked by the "pure" antiestrogen ICI 164,384 and the structurally dissimilar estrogenic drug, diethylstilbestrol. By using an antagonist to shift the E_2 concentration-response curve, Schild analysis resulted in an estimated K_e for ICI 164, 384 of 0.3 nM, similar to the K_i for ICI 164,384 binding to the classical estrogen receptor. Therefore, characteristics of the receptor mediating this rapid estrogen effect are in many ways similar to the classical estrogen receptor and this work may represent a novel signal transduction mechanism for this protein. ENDOTOXIN SUPPRESSES GONADOTROPIN-RELEASING HORMONE PULSE GENERATOR ACTIVITY THROUGH TUMOR NECROSIS FACTOR-α. M.J. Yoo, M. Nishihara*, and M. Takahashi. Department of Veterinary Physiology, Veterinary Medical Science, The University of Tokyo, Tokyo 113, Japan.

Bacterial endotoxin lipopolysaccharide (LPS) can induce a variety of immune responses including a release of tumor necrosis factor (TNF)-α into peripheral circulation and suppress gonadotropin secretion as well. We examined in the rat whether LPS could affect the electrical activity of the hypothalamic gonadotropin-releasing hormone (GnRH) pulse generator, which governs pulsatile secretion of gonadotropin from the pituitary, and the involvement of TNF-α, if any, in this process. Ovariectomized rats were fitted with chronically implanted electrode arrays in the medial basal hypothalamus, and multiple unit activity (MUA) was monitored from freely moving animals. By intravenous (IV) injection of LPS (1 μg), MUA volleys and associated luteinizing hormone (LH) pulses were suppressed for several hours. The suppressive effect due to LPS was nullified by the antibody against TNF-α administered intracerebroventricularly (ICV). Graded doses of TNF-α administered either IV (0.4, 1 and 2 μg) or ICV (20, 50 and 250 ng) suppressed both MUA volleys and LH pulses in a dose dependent manner similarly as LPS did. On the other hand, neither IV nor ICV injection of TNF-α affected MUA volleys if animals were pretreated with indomethacin (IV, 1 μg/100 g BW), a cycloxygenase inhibitor, 10 min before. These results suggest that LPS leads to a decrease in hypothalamic GnRH pulse generator activity through TNF-α, and that the suppressive effect of either peripherally or centrally derived TNF-α on the pulse generator depends on the prostaglandins synthesis.

745.1

EFFECTS OF MICROIMPLANTS OF AN ANTIANDROGEN INTO THE ROSTRAL HYPOTHALAMUS ON GABAergic NEURONS AND ON LH SECRETION IN THE INTACT MALE RAT. D.R. Grattan, M.S. Rocca, M.M. McCarthy and M. Selmanoff*. Center for Studies in Reproduction, Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

GABAergic neurons terminating in the rostral hypothalamus are stimulated by testosterone. To investigate whether this action is mediated locally through androgen receptors in the rostral hypothalamus, bilateral microcannulae (28 gauge) containing the androgen receptor antagonist, hydroxyflutamide (HF), were stereotaxically implanted into the rostral preoptic region just dorsal to the major population of GnRH cell bodies. Two days later, blood samples were collected for LH assay and animals were sacrificed for determination of GABAergic neuronal activity in tissue microdissected from the site of the implanted cannulae. Animals were decapitated either without treatment, or 60 minutes after inhibition of GABA degradation by AOAA (100 mg/kg, ip). The rate of GABA accumulation in the tissue after AOAA is a measure of GABA turnover. Levels of mRNA for both forms of glutamic acid decarboxylase (GAD_{65} and GAD_{67}), the rate limiting enzyme responsible for GABA synthesis, also were measured by a microlysate RNase protection assay.

LH levels were significantly increased in HF-treated animals (0.29 ± 0.05 ng/ml) compared with controls (0.15 ± 0.02 ng/ml). In the brain region directly ventral to the microcannula tip (500 µm punch from 300 µm fresh frozen section), GABA turnover was significantly reduced in HF-treated rats. There was no effect of HF on either GAD_{65} or GAD_{67} mRNA levels in this brain region. The results indicate that GABAergic neurons terminating in the rostral hypothalamus are tonically stimulated by testosterone acting at an androgen receptor localized in this region. The findings support the working hypothesis that these androgen-sensitive GABAergic neurons mediate the negative feedback action of testosterone on GnRH secretion in the male rat. (Supported by NIH grant HD21351 awarded to MS).

TESTOSTERONE-INDUCED ACTIVATION OF TYROSINE HYDROXYLASE-CONTAINING NEURONS OF THE A14 AND A15 HYPOTHALAMIC NUCLEI IN THE MALE SHEEP. Lubbers LS[1], Hileman SM[1], Jansen HT[2], Lehman MN[2] and Jackson GL[1]*. [1]Dept. of Veterinary Biosciences, University of Illinois, Urbana-Champaign, Il 61801, [2]Dept. of Anatomy and Cell Biology, University of Cincinnati Medical Center, Cincinnati OH, 45267.

Tyrosine hydroxylase (TH)-containing neurons of A14 and A15 hypothalamic nuclei, which are dopaminergic in nature, appear to mediate the inhibitory effects of gonadal steroids on luteinizing hormone (LH) release in female sheep. However, the role of these neurons in steroid-induced inhibition of LH release in the male is unknown. We tested the hypothesis that in the male TH neurons of the A14 and A15 are activated by testosterone (T). We examined the percent of TH cells which express cFos, a marker of neuronal activation, in castrated male sheep infused with vehicle (n=4) or T (768 µg/kg/d T; n=4) for 72 h. Blood samples were collected every 10 min for 4 h just prior to, and during the final 4 h of infusion. Animals then were euthanized and hypothalami were collected. Coronal sections (16 µm) were cut through the A14 and A15 nuclei and a series of every sixteenth section was assessed for TH and cFos colocalization using a dual-immunoperoxidase procedure. T infusion increased circulating T ($p<0.01$), decreased mean LH ($p<0.01$) and increased LH interpulse intervals ($p<0.01$). T infusion increased the percent of TH cells expressing cFos in the A14 [$p<0.01$; 40.38% (84/208 TH cells) *vs* 21.13% (37/173 TH cells)] and in the A15 [$p<0.01$; 33.07% (209/632 TH cells) *vs* 7.92% (75/947 TH cells)]. These results show TH-containing neurons of the A14 and A15 are activated by T infusion and suggest they may be involved in steroid-induced inhibition of LH release in the male. NONGENOMIC TEMPORAL ACTION OF THE NEUROACTIVE STEROID, 3α-HYDROXY-4-PREGNEN-20-ONE (3αHP) IN GnRH-INDUCED SUPPRESSION OF FSH IN PERIFUSED RAT PITUITARY CELLS. J. P. Wiebe* and M. Wolfe. Hormonal Regulatory Mechanisms, B&G Building, Univ. of Western Ontario, London, Ontario, Canada N6A 5B7.

The recently discovered neuroactive steroid, 3αHP, has been shown to selectively suppress GnRH-induced pituitary FSH release by actions at the level of the gonadotrope membrane/Ca^{2+} channel and the cell signaling pathway involving protein kinase C and Ca^{2+} mobilization (*Endocrinology* 125:41, 1989; 134:371, 1994; 134:377, 1994). To determine the time course of action of 3αHP in FSH suppression, pituitary cells from random cycling female Sprague-Dawley rats were allowed to attach to cytodex beads (4-5 days), transferred to perifusion columns, equilibrated for 1 h and then 10-min samples collected for 330 min. Cells received a 5 min pulse of GnRH (10^{-7}M) at 30 min (Cr; control) and at 270 min (Tr; treatment; Tr-0 = start of pulse). Various regimens of 3αHP and other steroids were applied in conjunction with the Tr pulse. FSH was determined in all samples by specific RIA. GnRH pulses resulted (about 20 min after start of pulse) in a short (10-15 min) 4-30-fold peak (above baseline) of FSH release. When a 5-min pulse of 3αHP (10^{-9}M) was applied at Tr-0, the GnRH-induced FSH release was completely suppressed. A 3αHP pulse at Tr-0.5, Tr-5, Tr-7, Tr-10, and Tr-13, the GnRH-induced FSH release was 0-10%, 5-20%, 50-70%, 80-100%, and 90-100% of the Cr peak, respectively. A 5-min pulse of 3ßHP, progesterone, or estradiol at Tr-0 resulted in 100, 155, and 245%, respectively of the Cr FSH peak. Pretreatment of cells with estradiol prevented the suppressive action of 3αHP. The results indicate that 3αHP most effectively suppresses GnRH-induced FSH release when present at the start of GnRH release and in the absence of estradiol. They suggest that 3αHP action may be at the level of the GnRH-receptor binding. (Supported by NSERC of Canada)

CLONING AND SEQUENCING OF cDNA FOR HAMSTER GnRH. H.T. Jansen*, S.J. Berriman, P.J. Stevens, P. Zeitler, and M.N. Lehman. Dept. Cell Biology, Neurobiology, and Anatomy, Univ. Cincinnati, Coll. Med. and Children's Hospital Research Foundation, Cincinnati OH 45267.

Reproductive activity in a number of species undergoes marked seasonal reversals as a result of changes in the activity of neurons secreting the decapeptide GnRH. In the golden hamster, a seasonal breeder, photoperiod-induced changes in GnRH gene expression have been described (Ronchi et al., *Neuroendocrinol.* 55:146, 1992). The identity of elements within the GnRH gene responsive to photoperiodic influences is unknown, in part, because the GnRH gene of this species has not been cloned. We have used the technique of RT/PCR to amplify, clone and sequence a partial cDNA of GnRH precursor in the golden hamster. Reverse transcribed total RNA from individual adult male hypothalami was amplified using the following oligonucleotide primers: 1) forward, an 18*mer* homologous to the highly conserved GnRH coding sequence within exon 2 in human, mouse, and rat and 2) reverse, a 17*mer* homologous to the conserved 5' end of exon 4 encoding the carboxy terminus of GnRH-associated peptide (GAP) in the same 3 species. The expected 192 bp product containing the GnRH and GAP coding sequences was amplified, cloned, and subsequently sequenced. The results indicate that the nucleotide sequence of the hamster GnRH coding region shares 98%, 93%, and 95% homology with human, rat, and mouse, respectively; the predicted peptide sequence shares 100% homology with all three species. The predicted GAP peptide sequence (amino acids 1-50) shares 82%, 80%, and 82% homology with human, rat, and mouse, respectively. In situ hybridization histochemistry using an antisense oligonucleotide probe to GnRH revealed a distribution of labeled cells similar to that observed with immunocytochemical methods. Upstream regulatory sequences in the GnRH gene are being isolated and analyzed using hamster-specific probes. (Supported by USDA 9102515).

DEVELOPMENT OF TWO GNRH SYSTEMS IN NEURONAL AND IMMUNE CELLS OF A MAMMAL. C.J. Gill*, J.A. King, R.P.Millar and E.F. Rissman. Dept. of Biology, University of Virginia, Charlottesville, VA 22903

The development of neurons containing the mammalian molecular form of gonadotropin-releasing hormone (mGnRH) has been well described for several species, but the development of neurons expressing other GnRH molecular forms is less well understood. Neurons containing mGnRH in the musk shrew, *Suncus murinus*, are observed by immunocytochemistry (ICC) in the olfactory epithelium by embryonic day 15 (of a 30 day gestation) and appear to migrate in to their adult olfactory and forebrain positions before birth. The musk shrew is the only mammal known to have an additional population of GnRH neurons in the midbrain. These cells contain chicken II GnRH (cGnRH-II), the GnRH molecular form considered most ancient and most widespread among non-mammalian vertebrates. Neurons immunoreactive for cGnRH-II are not observed in the musk shrew brain until between postnatal day 2 and 5. At this time, they have assumed their adult positions in the midbrain. However, cGnRH-II containing mast cells are present throughout the brain, but primarily in the habenula, in embryos and postnatal animals.

The concentrations of both GnRH forms in embryonic and postnatal brain tissue were determined by radioimmunoassay (RIA). RIA revealed that mGnRH levels rise on the day before birth, drop on postnatal day 1 (P1), and increase again by P5. The amount of cGnRH-II is low but detectable in embryos and increases between the day of birth and P5. Though neuronal production below ICC detectability may explain these data, it is also likely that these levels of cGnRH-II detectable by RIA are produced by embryonic mast cells. These data suggest a previously unreported association between the development of the mammalian neuroendocrine and immune systems. This work was supported by NIH NRSA 1F31MH10570-01A1 and NSF grant IBN 94-12605.

EFFECTS OF AROMATASE INHIBITOR ON GNRH GENE EXPRESSION IN SHEEP C.S.J. Yang*, A. Benoit[1], M.S. Smith[2] and R. A. Dailey Div. Anim. & Vet. Sci, West Virginia Univ., WV 26505, [1]Depart. Anim. North Carolina State Univ. NC 27695 and [2]Depart. Neurobiol., Univ. Pittsburgh, Pittsburgh, PA 15261.

We reported a change in GnRH mRNA levels during the ovine estrous cycle. Specifically, levels were highest immediately preceding and lowest after the LH surge. To investigate the importance of the preovulatory peak of estradiol-17β (E_2) on postovulatory GnRH gene expression, we treated ewes with an aromatase inhibitor, CGS16949A (CGS, 1 mg/kg wt., i.v.) [Ciba Geigy, Ltd., Basal, Switzerland], beginning 30 min. prior to induction of luteolysis by $PGF_{2\alpha}$ on day 6 of the estrous cycle. The CGS treatment continued every 8 hr until injection of hCG (750 IU, i.m.) given 36 hr after induction of luteolysis. Ewes were sacrificed at either 4, 6, or 8 days (post surge) following hCG. Control animals received saline instead of CGS. Number of ewes sacrificed at each time were 4, 2, and 2 for CGS and 4, 4, and 4 for controls. Mean levels of E_2 in serum at 24 hr after $PGF_{2\alpha}$ averaged 2.66±1.28 for CGS and 7.44±2.51 pg/ml for controls. E_2 levels did not differ between groups when animals were sacrificed. *In situ* hybridization using an ^{35}S-labeled probe for human GnRH mRNA was used to determine the GnRH mRNA levels. Eight anatomically matched, serial sections (S, 40 µm) from the POA of each animal were analyzed by image analysis. Neither number of neurons expressing GnRH-mRNA nor average grains per cell differed with treatment (T), day (D) or T x D. The results indicated that treatment of CGS did not change the GnRH expression pattern. Overall groups, analysis of GnRH neuronal numbers showed an interaction between D and S ($p<0.02$), and levels of E_2 were correlated negatively ($r= -0.35$, $p =0.12$) with number of neurons. Preovulatory levels of E_2 apparently do not play a key role in regulating postovulatory gene expression for GnRH in sheep. Supported by Hatch 321 & HD14643

A DIRECT PROJECTION FROM THE LATERAL SEPTUM TO GnRH NEURONS IN THE RAT. F. Varoqueaux[a], P. Ciofi[a], G. Tramu[b], J.C. Beauvillain*[a] and P. Poulain[a]. [a]U422 INSERM, Place de Verdun, 59045 Lille (France); [b]Lab. Neurocyto. Fonct., URA CNRS 339, Univ. Bordeaux I, 33405 Talence (France).

The lateral septum (LS) relays hippocampal information to a variety of hypothalamic areas modulating the neuroendocrine output. Especially, the LS has long been known to be involved in the regulation of reproductive processes. In line with this and using a tract-tracing technique, we investigated the existence of a direct projection from the LS to neurons of the gonadoliberin (GnRH)ergic apparatus.

Nine adult male rats (400g, b.w.) received a unilateral microiontophoretic injection of a biotinylated-dextran into the ventral LS and anterograde transport was allowed to proceed for 15 days. Brains were fixed (4% paraformaldehyde) and serially cut on a freezing microtome. All sections were doubly-stained to reveal the LS projection fibers with the avidin/peroxidase-diaminobenzidine technique and the GnRH neurons using immunofluorescence. Appositions between LS efferents and GnRH-immunoreactive (ir) neuronal profiles were counted at the light microscopic level.

In all cases such appositions suggestive of potential contacts were found to involve 20-30% of the GnRH-ir neurons located ipsilateral to the injection site. There was no obvious dorso-ventral or antero-posterior topographic arrangement of the contacted neurons that were found in the preoptic region as well as in the suprachiasmatic hypothalamic continuum. Potential contacts between labeled LS efferents and GnRH-ir neurons were observed on the proximal dendrites as well as the perikaryon of the GnRH-ir neurons. The majority (80%) of the contacted GnRH-ir neurons were of the irregular sub-type. The synaptic nature of these appositions between LS efferents and GnRH neurons is presently under study at the ultrastructural level.

These results suggest the existence of a direct, monosynaptic projection from the LS to a sizeable component of the GnRHergic neuroendocrine apparatus. The nature of the LS information relayed to the GnRH apparatus remains to be clarified.

TIME COURSE STUDY OF GNRH AXONAL OUTGROWTH FROM THE PREOPTIC AREA (POA) TO THE MEDIOBASAL HYPOTHALAMUS (MBH) IN ORGANOTYPIC CULTURES. M-C. Rogers*, A-J. Silverman[1], M.J. Gibson. Dept of Medicine and Fishberg Center for Neurobiology, Mount Sinai School of Medicine, NY, NY10029. [1]Dept of Cell Biology and Anatomy, Columbia University, NY, NY10032.

GnRH terminals project *in vivo* to the median eminence (ME) of the MBH along a stereotypic route. When hypogonadal mice receive an embryonic POA graft in the third ventricle, GnRH outgrowth to the ME may be seen as early as 5 days after implantation. In our organotypic culture system tissue was placed inside an insert chamber on a porous membrane coated with collagen and laminin, and fed by capillarity from the underlying defined media. When E15 POA was cultured with MBH and processed for GnRH immunoreactivity 7 days later, significant GnRH axonal outgrowth was observed on the side of the POA directly facing the MBH co-explant as compared with the side away from the MBH ($p<0.0001$). Such differential outgrowth was absent with control co-explants (Endo. Soc. Abst. 1995). This suggests the presence of an MBH-derived chemotropic diffusable substance attractive for GnRH axons. In the present study, when explants were cultured from 1 to 10 days, we documented increased GnRH axonal outgrowth from the POA over time. The number of GnRH fibers was significantly higher on the side facing the MBH after 4, 7 and 10 days of culture ($p<0.01$). At 1 day of culture the number of GnRH fibers was too low to detect significant preferential outgrowth. In addition to being more numerous after 10 days of culture, GnRH fibers appeared longer, often entering the MBH explant. GnRH cell number decreased by 13.9% between 1 and 4 days of culture, by 18.2% between 4 and 7 days, and remained stable thereafter. Preferential GnRH outgrowth to the MBH was observed throughout the time course indicating that the MBH chemotropic action was maintained as long as 10 days in culture. We have observed unidentified cells and processes on the membrane between the co-explants. Further experiments are under way to distinguish potential chemotropism from the possible role of such cellular elements.

POST-TRANSCRIPTIONAL REGULATION OF THE GONADOTROPIN-RELEASING HORMONE (GnRH) GENE IN GT1-7 CELLS: mRNA TURNOVER. T.J. Wu*, A.C. Gore and J.L. Roberts. Fishberg Center for Neurobiology, Mt. Sinai School of Medicine, NYC, NY 10029.

Several groups have reported that treatment of GT1-7 cells with phorbol myristate acetate (PMA), a phorbol ester, caused a decrease in the cytoplasmic GnRH mRNA concentration. While there is an inhibitory transcriptional effect of PMA, there also appears to be an effect on enhancing GnRH mRNA degradation. In support of this latter mechanism, we also found that PMA treatment resulted in a time-dependent decrease in the length of the GnRH mRNA poly-A tail ($t_{1/2} \approx$ 8 h), an index of mRNA turnover. We hypothesized that there must exist regions of the GnRH mRNA that serve as recognition signal targets for the degradation of the mRNA. The mechanism(s) mediating this alteration of mRNA stability is unknown, but previous work in other systems indicates that labile protein(s) are involved in the alteration. To this end, we have identified three potential regions of the GnRH mRNA, two hairpin loops (+128 to +156 and +302 to +328) in the translated region and an AU-rich sequence in the 3'-untranslated region (3'-UTR) (+395 to +422), that may serve in the regulated destabilization of the mRNA. We report the identification of cytosolic factors that bind to the GnRH mRNA using gel mobility shift assays and competition experiments. Serum treatment of cells, which inhibits GnRH mRNA levels, gave cytosolic extracts with attentuated protein binding to the second hairpin loop and the 3'-UTR. These findings should aid in our understanding of how the cell selectively targets the GnRH mRNA for turnover. [DK-08743 (ACG), DK-39029 (JLR)]

GnRH mRNA IS RAPIDLY TURNED OVER *IN VIVO*. J.L. Roberts*, S. Wray#, and A.C. Gore. Fishberg Res. Center for Neurobiology, Mt. Sinai Medical Center, New York, NY 10029-6574, and #Lab of Neurochemistry, NINDS, NIH, Bethesda, MD 20892.

Previous studies analyzing GnRH gene expression *in vivo* and *in vitro* have suggested that there are rapid, post-transcriptional mechanisms involved in its regulation. Interestingly, in the GT1 cells there is a very slow turnover of GnRH mRNA with a half-life of 1-2 days. However, rapid changes in GnRH gene expression in the animal are observed following neurotransmitter or steroid manipulation, and an analysis of RNA turnover by *in situ* hybridization has suggested that turnover of GnRH mRNA occurs more rapidly in explant cultures than in GT1 cells. We have directly addressed this question in male rats using RNA synthesis inhibitors coupled with RNase protection assays to quantitate GnRH primary transcript and mRNA. Actinomycin D injected in the third ventricle or directly into the preoptic area (POA) had no effect on either nuclear or cytoplasmic GnRH RNA species. However, injection into the POA of the water-soluble RNA polymerase II-specific inhibitor dichloro-ribofuranosylbenzimidazole (DRB) caused a significant inhibition in GnRH nuclear RNA primary transcript levels and a subsequent inhibition of cytoplasmic GnRH mRNA. These studies have suggested an upper limit of 6-8 hr for the half-life of the cytoplasmic mRNA. We are currently pursuing similar studies in cultured postnatal hypothalamic explants in which a greater percentage of the GnRH neurons are exposed to DRB. These studies suggest that GnRH mRNA turnover may be a crucial mode of regulation of GnRH gene expression in the intact animal, and differs from that observed in GT1 cells.

745.11

LHRH GENE EXPRESSION IN POSTNATAL CNS SLICE EXPLANT CULTURES: EXAMINATION OF LHRH mRNA TURNOVER. J. A. Maurer and S. Wray*. Laboratory of Neurochemistry, NINDS, NIH, Bethesda, MD 20892.

Using the immortalized LHRH cell line, GT1-7, investigators have reported negative regulation of LHRH gene expression by phorbol 12-myristate 13-acetate (PMA) treatment. Our laboratory saw a similar regulation of LHRH gene expression in postnatal hypothalamic slice explant cultures. In primary LHRH neurons, LHRH mRNA dramatically decreased after a 4 h exposure to either forskolin or PMA. We hypothesized that these changes were the result of increased degradation of LHRH mRNA. To investigate LHRH mRNA stability, actinomycin D, a non-specific blocker of RNA polymerases, and 5,6-dichloro-1-D-ribofuranosyl-benzimidazole (DRB), a selective inhibitor of RNA polymerase-II, were used to inhibit transcription in postnatal LHRH neurons maintained in long-term organotypic roller cultures. Two days prior to treatment, cultures were incubated with 1 µM tetrodotoxin (TTX) to suppress spontaneous electrical activity. On day 18 of culture, in addition to TTX, explants received 4 µM actinomycin D or 150 µM DRB for 2 to 16 h and then processed for *in situ* hybridization histochemistry or immunocytochemistry. Under all treatment conditions numerous LHRH immunopositive neurons were detected suggesting that levels of LHRH peptide are not dramatically altered by treatment with transcription inhibitors. Preliminary data from single cell analysis indicate that exposure to DRB for 2 to 4 h decreases LHRH mRNA. These results are consistent with the hypothesis that second messengers regulate LHRH gene expression by increasing LHRH mRNA turnover.

LONG-TERM EFFECTS OF OVARIECTOMIES IN FEMALE RATS ON RADIAL ARM MAZE PERFORMANCE USING LONGITUDINAL AND CROSS-SECTIONAL DESIGNS. A.C. Bartolomeo, J.A. Moyer, E.A. Muth* and C.A. Boast. CNS Disorders, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

Recent clinical studies have suggested a connection between reduced levels of estrogen and cognitive deficits, especially in Alzheimer's Disease. To determine if estrogen depletion would lead to memory impairments, a longitudinal design was initiated with ovariectomized (OVX) and intact (INT) female Sprague-Dawley rats, in a one hour delay, non-match-to-sample Radial Arm Maze (RAM) task. Subjects had pre-surgical RAM training. Post-surgical (PS) testing started at one week and subjects were retested at four month intervals through 24 months PS. There were no differences in mean post-delay errors (PDE) between groups at any of the times although PDE increased with age. Scopolamine (0.03 - 0.54 mg/kg, s.c.), a cholinergic antagonist, was administered to half of the OVX and all of the INT rats following testing at each time point. At 3 weeks PS and 4 months PS, 0.54 mg/kg SCOP produced significantly more PDE in both treated groups than in OVX-SAL, but there were not any differences in PDE between the treated groups at any of the time points. At 8 months PS, the OVX-SCOP group had more animals unable to complete the pre-delay than the INT-SCOP. At 12 months PS and beyond, there was no difference in the number of rats unable to complete the pre-delay in both treated groups. MK-801 (0.03 - 0.1 mg/kg, i.p.), a non-competitive NMDA antagonist, was administered subsequent to SCOP testing beginning at 16 months PS. At 16 months PS, 0.03 mg/kg MK produced significantly more PDE in both treated groups than in OVX-SAL, but there were not any differences in PDE between the treated groups at any time point. In the second study, a cross-sectional design, naive rats were tested at 4, 8 or 11 months PS in the RAM task. PDE were not significantly different between the OVX and INT at the earlier points, but at 11 months, the INT group consistently made more PDE with statistical significance attained on 5 of 13 trials. Long-term depletion of ovarian hormones does not appear to induce cognitive deficits in rats in a spatial working memory task.

745.13

CELLULAR ANALYSIS OF TYROSINE HYDROXYLASE EXPRESSION IN LACTATING RATS K.A. Berghorn*, B.J. Duska, H.-J. Wang, W.-W. Le, T.G. Sherman and G.E. Hoffman. Departments of Neurobiology and Neuroscience, University of Pittsburgh, Pittsburgh, PA, 15261.

Earlier studies conducted in our laboratory have detected marked reduction in tyrosine hydroxylase (TH) gene expression in the dopamine neurons of the arcuate nucleus during lactation with a resurgence of expression following pup removal. Analysis of the level of TH gene expression by *in situ* hybridization (ISH) using ^{35}S labeled riboprobes did not permit analysis of changes of mRNA levels within individual cells owing to the density of cell clusters and spread of the radioactive signal beyond cell borders. Application of sensitive non-radioactive methods for ISH with biotin labeled riboprobes has enabled detection of granular mRNA label within the cell cytoplasm that appears to reflect accurately the ribosomal compartment without spread into other cellular compartments. Using this approach, we examined the pattern of change in TH mRNA levels in cycling rats and in lactating rats nursing 8 pups and following pup removal. Changes in TH mRNA levels detected with the biotin labeled probes generally paralleled those observed with ^{35}S labeled riboprobes: mRNA levels in the lactating animals nursing their pups were at or below the limit of detection in most arcuate TH neurons, and levels of TH mRNA in the arcuate nucleus increased beyond diestrous levels when pups had been removed for 24-48 hrs. Moreover, by use of double labeling of the TH mRNA and TH protein, we could accurately locate the transcriptionally silent TH population in each condition and define which subpopulations of arcuate dopamine neurons were stimulated transcriptionally after removal of the suckling stimulus. *(Supported by NIH NS 28730 and NSF BNS 9021307).*

MOTOR CORTEX: FUNCTIONAL ORGANIZATION AND PLASTICITY I

INTERHEMISPHERIC ASYMMETRIES IN 2-DEOXYGLUCOSE UPTAKE AND OPEN-FIELD BEHAVIOR OF CALLOSAL AND ACALLOSAL MICE. F. Magara, E. Welker*†, D.P. Wolfer and H.-P. Lipp. Inst. of Anatomy, Univ. of Zürich, †Inst. of Anatomy, Univ. of Lausanne, Switzerland.

In order to study functional lateralization in mice, we measured the uptake of 2-deoxyglucose (2DGU) in the left and right side of the brain of mice while they were freely moving in an open-field. Ten C57BL/6 mice and 12 sex- and age-matched mice with callosal agenesis were injected i.p. with a solution of 1-[14C]-2-Deoxy-D-Glucose (2DG), and immmediately released in a dimly illuminated open-field arena (ø = 150 cm). Their paths were recorded and analysed off-line to assess activity, turning preferences and distance to the wall as a measure for exploration versus anxiety. After 45 min., the mice were sacrificed, and the brains processed for contact autoradiography. The amount of 2DGU in anatomically defined regions (30 subcortical and 11 cortical) was assessed by means of a computer-aided image analysis. Acallosal mice showed a high propensity for circling, the degree of turning preferences to the left or to the right being significantly correlated with 2DGU-asymmetries in the substantia nigra and the diagonal band of Broca. These correlations were missing in the callosal C57 mice. In both groups of mice, the 2DGU asymmetry in the lateral amygdala was correlated with thigmotaxis, animals with high activity in the right amygdala spending most time in the center of the open-field. We conclude that the presence of a corpus callosum helps to correct asymmetrical influences from ascending activation systems on locomotor directedness. Independent of the corpus callosum, there appears to be functional lateralization of fear-related processes in the amygdala. Supported by Swiss National Science Foundation 31-37497.

EYE, HEAD, BODY AND FORELIMB MOVEMENTS EVOKED FROM THE ANTERIOR ECTOSYLVIAN CORTEX OF THE UNRESTRAINED CAT. H. Jiang* and D. Guitton. Montreal Neurological Institute and McGill University, Montreal, Quebec, Canada, H3A 2B4.

The anterior ectosylvian cortex of the cat receives different sensory inputs and has been considered an area for sensor-motor integration. We recorded sensory responses in neurons along the banks of the anterior ectosylvian sulcus of an alert cat and investigated possible motor correlates by electrically micro-stimulating (~60 μA) recording sites. In the head-fixed condition, stimuluation evoked eye movements that were driven to a fixed contralateral orbital position. When the head was freed, with body fixed, the same stimulus drove gaze (eye+head) shifts towards a fixed contra-position relative to the body: both the amplitude and direction of evoked gaze movements were modulated by initial gaze position. When the body was freed, the same stimulus drove coordinated rapid gaze and contralateral reaching forelimb (paw) movements, and body postural adjustments. Gaze looked at, and paw went to, a fixed contra-spatial location relative to the initial body axis. For movements beginnng with gaze, head and body aligned, the location of visual receptive fields and the preferred direction of moving visual targets were correlated with the final position of evoked gaze shifts and paw movements. The cortical area which evoked eye, head and forelimb movements was located mainly in the middle one-third of the ventral bank and the fundus slightly extending to the dorsal bank. A topographic representation of 3-D space re-body may exist in this cortical area. We do not know whether stimulation generated a 'target' that the animal tried to "catch" or an eye-head-limb motor program.

FUNCTION OF MASTICATION-RELATED NEURONS WITH RHYTHMICAL BURST FIRING IN THE OROFACIAL FIRST SOMATOSENSORY CORTEX OF CONSCIOUS CATS. HIRABA, H.*, YAMAGUCHI*,Y., KAMOGAWA, H. and SUMINO, R. Dept. of Physiol., Div. of Pathophysiol.*† Nihon Univ. Sch. of Dent., Tokyo 101, Japan

We have studied the activity patterns of mastication-related neurons (MRN) in the orofacial first somatosensory cortex (SI) of conscious cats. Over 90% of MRNs in the orofacial SI showed activity changes that followed the masticatory rhythm (RB-MRN). About 20% and 40% of RB-MRNs received inputs from the tongue and perioral regions. The RB-MRNs with the receptive fields in the tongue (T-PB-MRN) and perioral regions (P-RB-MRN) showed the regular burst firing corresponded to the jaw-opening to -opened and the jaw-closed phases during food intake respectively. But they showed the irregular one after food intake. T-RB-MRN showed also firing frequency changes in burst firing that were dependent on differences in food texture, but P-RB-MRN did not. Furthermore, to investigate the function of T- and P-RB-MRNs during mastication, we examined the effects of each lesion of perioral or tongue projection area in SI on masticatory behavior.Lesions were created by injection of kainic acid (1%, 2μl). After creation of each lesion, we observed the resulting deficit of orofacial behavior during mastication for 5-6 weeks. We then compared the difference in behavior caused by the lesions in the perioral and tongue projection areas (P-L and T-L animals). P-L animals showed a delay in the start of mastication and the dropping of ingested food during mastication. T-L animals showed the prolongation of the masticatory process. On the basis of these findings, we will discuss the function of sensory information in the orofacial SI for the performance of mastication.

SENSORIMOTOR CORTEX RESPONSES TO FACIAL NERVE STIMULATION IN RATS. J. Okada, S. S. Suzuki*, Y. Harada1 and N. Nagamura. Biosignaling Dept., Natnl. Inst. Biosci. and Human-Technol., Tsukuba 305, and 1Dept. Physiol., Nippon Med. Sch., Tokyo 113, Japan.

The present study was designed to examine the basic characteristics of facial nerve-evoked neural activities in the primary somatosensory (SI) and motor cortex (MI). Under anesthesia, adult rats were implanted with a stimulating electrode on the buccal branch of the left facial nerve. Field potentials (FP) and multiple unit activity (MUA) evoked by facial nerve stimulation were recorded. Facial nerve stimuli elicited primarily negative or negative-positive potentials in layers II-V bilaterally in SI and MI. Large negativities were always accompanied by a salient MUA indicating a synchronous excitation of local neurons. The primary response latency was 4-9 ms for contralateral SI, 9-10 ms for contralateral MI and 13-15 ms for ipsilateral SI/MI. Current source density (CSD) analyses of laminar FP profiles in contralateral SI revealed two primary sinks at 400-800 μm (E1a) and 1000-1200 μm (E1b) from the cortical surface. E1a and E1b were followed by a secondary sink in more superficial (200-600 μm, E2a) and deeper layers (1200-1400 μm, E2b), respectively. Primary sinks in MI were distributed widely at 200-1200 μm. The relationship between the facial nerve-evoked FP map of MI and the output map of MI as revealed by intracortical microstimulation (ICMS) was examined in the same rats. Facial nerve-evoked potentials were obtained not only from the ICMS-defined vibrissal region of MI but also from adjacent regions including the forelimb, jaw and tongue regions. Furthermore, medial parts of the vibrissal region showed no or small responses to facial nerve stimulation.

CORTICAL ACTIVATION OF ORAL MOVEMENTS IN RATS. R.E. See* and A.M. Lynch. Department of Psychology, Washington State University, Pullman, WA, 99164-4820.

Previous studies using electrical stimulation have demonstrated the role of the primary oral motor cortex in regulating oral behaviors. The present experiment examined changes in oral movements after direct pharmacological stimulation of the primary oral motor cortex in the awake, unrestrained rat. Male, Sprague-Dawley rats were implanted with bilateral infusion cannulae (22 gauge) aimed at the primary oral motor cortex (A +3.5, L ±3.5, V -1.5). Following one week recovery, animals were tested in observation chambers for motor activity. Infusion of N-methyl-D-aspartate (NMDA) and the $GABA_A$ receptor antagonist, picrotoxin, produced a concentration dependent increase in orofacial activity. Motor activity consisted primarily of nondirected chewing movements and tremor of the masseter muscles. In addition, both teeth grinding and directed biting were also observed. The effect was selective to oral behavior in that other motor activity did not show a significant increase. These findings demonstrate that a discrete orofacial motor syndrome can be directly elicited by pharmacological probes into the oral motor cortex. The relationship of these movements to subcortical oral motor pathways will be discussed (Supported by NIH DE09678).

EFFECTS ON MASTICATION OF REVERSIBLE COLD BLOCK OF LATERAL PERICENTRAL CORTEX OF AWAKE MONKEY. N. Narita, B.J. Sessle, R. Raouf and C.-S. Huang* Faculty of Dentistry, University of Toronto, Toronto, M5G 1G6, Canada

Our laboratory has shown that intracortical microstimulation (ICMS) of a region of the lateral pericentral cortex can evoke masticatory-like movements in awake monkeys (Huang et al., J. Neurophysiol. 61; 635, 1989). The aim of this study was to determine if mastication could be affected by reversible cold block-induced inactivation of this ICMS-defined region. Two cranial chambers were chronically implanted in the monkey (M. fascicularis). A warm or cold alcohol-water solution was pumped through thermodes placed bilaterally on the dura overlying the lateral pericentral cortex while the monkey chewed standardized amounts of fruit during pre-cool (thermode temperature 37°C), cool (0°C), and rewarm (37°C) conditions. Electromyographic (EMG) activity was recorded from masseter (MA), anterior digastric (AD) and other orofacial muscles, and video recordings made of orofacial movements. The chewing cycle and preparatory phase of rhythmic chewing were significantly prolonged during cold block (mean ± SD, 0.51 ± 0.12s and 2.26 ± 0.93s, respectively, ANOVA, $p<0.05$) compared to pre-cool (0.31 ± 0.06s and 0.75 ± 0.20s) and rewarm (0.32 ± 0.04s and 0.90 ± 0.19s) conditions. EMG burst durations were also significantly prolonged during cold block (MA: 0.35 ± 0.12s, AD: 0.33 ± 0.11s, ANOVA, $p<0.05$) compared to pre-cool (MA: 0.23 ± 0.04s, AD: 0.19 ± 0.03s) and rewarm (MA: 0.25 ± 0.03s, AD: 0.20 ± 0.03s) conditions, and EMG amplitudes were also significantly reduced (MA: 0.82 ± 0.21, AD: 1.74 ± 0.48, A/D units, ANOVA, $p<0.05$) compared to pre-cool (MA: 1.06 ± 0.24, AD: 2.19 ± 0.42, A/D units) and rewarm (MA: 0.98 ± 0.23, AD: 2.20 ± 0.43, A/D units) conditions. These data provide further evidence that the lateral pericentral cortex plays a critical role in the initiation and regulation of primate mastication. Supported by Canadian MRC grant MT-4918.

EFFECTS OF REVERSIBLE COLD BLOCK OF LATERAL PERICENTRAL CORTEX ON SWALLOWING IN AWAKE MONKEY. B.J. Sessle, N. Narita and R.E. Martin*† Fac. of Dentistry, Univ. of Toronto, Toronto, M5G 1G6 and Fac. of Appl. Health Sciences, Univ. of Western Ontario, London, N6G 1H1†, Canada.

We have recently shown that swallowing can be evoked in the awake monkey by intracortical microstimulation (ICMS) of a region of the lateral pericentral cortex (Martin et al., Neurosci. Abstr. 19; 777, 1993). This study was initiated to determine the effects on swallowing of reversible cold block-induced inactivation of this ICMS-defined region. Two cranial chambers were chronically implanted in the monkey (M. fascicularis). A warm or cold alcohol-water solution was pumped through thermodes placed bilaterally on the dura overlying the lateral pericentral cortex while the monkey swallowed following mastication of standardized amounts of fruit, or following sucking or licking of standardized amounts of juice, during pre-cool (thermode temperature 37°C), cool (0°C), and rewarm (37°C) conditions. Electromyographic (EMG) activity was recorded from masseter (MA), genioglossus (GG), anterior digastric (AD), geniohyoid (GH) and thyrohyoid (TH) muscles, and video recordings made of orofacial movements. The incidence of swallowing following chewing was significantly decreased during cold block (14.8%, χ^2-test, $p<0.0001$) compared to pre-cool (88.5%) and rewarm (100%) conditions. Swallow-related EMG activity following mastication, sucking and licking was also affected, e.g. EMG burst duration and amplitude of TH following licking were significantly (ANOVA, $p<0.05$) modulated during cold block (mean ± SD, 0.75 ± 0.35s and 4.75 ± 1.11 A/D units, respectively) compared to pre-cool (0.40 ± 0.04s and 7.62 ± 0.68 A/D units) and rewarm (0.44 ± 0.05s and 7.06 ± 0.91 A/D units) conditions, and the interval between MA and TH swallow-related EMG onset following mastication was significantly increased (0.18 ± 0.06s, ANOVA, $p<0.05$) compared to pre-cool (0.11 ± 0.03s) and rewarm (0.13 ± 0.02s) conditions. These data provide further evidence that the lateral pericentral cortex plays a critical role in the initiation and regulation of swallowing in the primate. Supported by Canadian MRC grant MT-4918.

MODULATION OF OPTICAL INTRINSIC SIGNALS BY INTRODUCTION OF A COMPETING STIMULUS

A. J. Blood* and A. W. Toga
Laboratory of Neuro Imaging, Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024

Optical intrinsic signal imaging was used to detect reflectance changes in two regions of rat somatosensory cortex. Possible interactions of activity between barrel cortex and the forelimb region of the primary somatosensory cortex were investigated. This was accomplished by evaluating intrinsic signal response magnitude and spatial extent in response to simultaneous peripheral stimulation of single whiskers and forelimb digits.

Whisker C1 was deflected at a frequency of 10 Hz for 1 second while vibratory stimuli of varying intensities were applied to forelimb digits. Intrinsic signal responses to simultaneous whisker and forelimb stimulation were compared to whisker stimulated controls. Addition of the forelimb stimulus modulated intrinsic signal activity by increasing or decreasing the magnitude and/or spatial extent of responses over barrel cortex. The degree of modulation was related to the intensity of the competing stimulus. These data suggest that cortical responses at the level of primary sensory processing may be significantly modified by activity in adjacent regions.

PROCESSING OF IPSILATERAL SOMATOSENSORY AFFERENTS IN PRIMARY MOTOR CORTEX OF THE MACAQUE. M.C. Lee* and J.C. Arezzo. Departments of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Direct excitatory afferents from the contralateral hand to primary motor cortex have been demonstrated in single unit studies in primates. The contribution of activity evoked by ipsilateral distal median nerve stimulation was explored to investigate potential excitatory or inhibitory interactions between the bilateral afferents in this area. Local populations of neurons in the hand representation of area 4 in two cerebral hemispheres of an awake adult macaque monkey were sampled with a low impedence (300-500kOhm), multicontact electrode (150-200μ spacing). Somatosensory evoked potentials (SEPs) and concomitant multiunit activity (MUA) were measured simultaneously from up to fifteen sites within and across laminae, and one-dimensional current source density patterns (CSD) were calculated. Stimulation of the contralateral hand elicits an intracortical SEP characterized by an inverting potential, P17/N17, which onsets at about 8ms. This component is associated with a coincident excitatory burst of MUA which returns to baseline at approximately 50ms and is followed by a subtle reduction in MUA. Stimulation of the ipsilateral hand, however, elicits a markedly different response, characterized by a smaller excitatory burst of MUA at about 12ms. This is followed by a prolonged and striking 20-30% reduction below the spontaneous firing level in MUA from about 50 to 110ms. The laminar distribution of MUA and associated current flow in the ipsilateral response is consistent with a pattern of excitatory input followed by the active hyperpolarization of apical dendrites of infragranular pyramidal cells. While the timing of activity suggests that the excitatory inputs are direct rather than callosal, the origins of the inhibitory activity have yet to be elucidated. These data support the hypothesis that primary motor cortex is active in response to somatosensory stimuli, and suggest that the ipsilateral afferents may serve to sharpen the boundary between afferents from contralateral and ipsilateral hands. VESTIBULAR AND OPTOKINETIC SPATIAL TUNING IN NEURONES OF THE PARIETO-INSULAR VESTIBULAR CORTEX IN THE SQUIRREL MONKEY. W. Guldin* and O.-J. Grüsser. Dept. of Physiol., Freie Universität Berlin, 14195 Berlin, Germany

The response characteristics of vestibularly driven units in the parieto-insular vestibular cortex (PIVC) have been tested in four alert squirrel monkeys. Sinusoidal vestibular and optokinetic stimulation was applied in eight different planes orthogonal to the yaw plane. Various forms of somatosensory stimulation were applied, such as brushing the skin, pressing different muscles, moving different joints. The neck-muscle input was tested by moving the body sinusoidally while the head was fixed in space. In the PIVC-region of the squirrel monkey about 60 percent of the units were driven by vestibular stimuli. Frequently vestibular neurones also responded to neck-muscle stimulation, input from other muscles or tendon or joint receptor stimulation. One third of the PIVC-units responded to optokinetic or small-field visual movement stimulation. Polar histograms of spatial tuning of the vestibular driven units in the PIVC showed, as a rule, a sector of maximal response around a preference plane. These preferred response planes did not correspond in most cases to the planes of the semicircular canals. Our results give evidence that the network of the PIVC cells can be interpreted as a cortical integrator of vestibular input from all semicircular canals. The PIVC processes information from the vestibular, somatosensory and optokinetic systems, which is useful in calculating the movement of the head in space and in relation to the other parts of the body.

MOVEMENT REPRESENTATION IN PRECENTRAL MOTOR AND PREMOTOR CORTEX OF OLD WORLD MONKEYS. T.M. Preuss*, I. Stepniewska and J.H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

The lateral premotor cortex of Old World monkeys has not previously been examined in detail using intracortical microstimulation. We used this technique to map the distribution of motor responses across the precentral gyrus in 8 Old World monkeys (7 *Macaca* spp., 1 *Erythrocebus patas*). Animals were anesthetized with ketamine and xylazine and current delivered with tungsten microelectrodes.

We were able to elicit responses reliably from both the dorsal and ventral premotor areas (PMD, PMV), identified architectonically, as well as from caudal and rostral divisions of the primary motor area (M1c, M1r). PMD was less responsive to stimulation than PMV or M1, but even in PMD, many points were responsive with currents of 40—100 μA. We elicited hindlimb, axial, forelimb, and facial movements from both PMD and M1, but only forelimb and facial movements after stimulation of PMV. Thus, we found no evidence of hindlimb representation in PMV. The forelimb representation of PMV is bordered medially by a zone of facial and upper axial responsiveness located in lateral-most PMD. Stimulation yielded both proximal and distal forelimb movements from PMD, but predominantly distal movements from PMV. These results are largely consistent with our previous microstimulation studies in owl monkeys, indicating that stimulation of premotor cortex can yield discrete motor responses. Moreover, our results do not support the widely held view that there is a caudal-to-rostral gradient of distal-to-proximal-to-axial representation in precentral cortex.

MOTOR CORTEX: FUNCTIONAL ORGANIZATION AND PLASTICITY II

747.1

QUANTITATIVE CHANGES OF GABA-IMMUNOREACTIVE CELLS IN THE HINDLIMB REPRESENTATION OF THE RAT SOMATOSENSORY CORTEX AFTER 14-DAY HINDLIMB UNLOADING BY TAIL SUSPENSION. F. D'Amelio,[1]* L. C. Wu,[1] R. A. Fox,[1] and N. G. Daunton,[2] Dept. Psych.,[1] San José St. Univ., San José, CA 95192-0120, and NASA-Ames Res Ctr.,[2] Moffett Field, CA 94035-1000

In the present study γ-aminobutyric acid (GABA) immunoreactivity was evaluated quantitatively in the hindlimb representation of the rat somatosensory cortex after 14 days of tail suspension (TS). The number of GABA-immunoreactive cells was reduced in cortical layers IV, Va, Vb and VI ($p<0.05$, $p<0.0002$, $p<0.02$, and $p<0.03$ respectively) of rats subjected to TS. In addition, the number of GABA-containing terminals, particularly those terminals surrounding the soma and apical dendrites of pyramidal cells in layer Vb, also were reduced throughout the same cortical layers. Since there was no reduction in the total neuronal density of the hindlimb representation as compared with the control animals, we concluded that the reduction was not due to cell death. Findings are discussed in the context of previous morphological and behavioral studies of the neuromuscular system of TS animals and we propose that alterations in the reflex organization of hindlimb muscle groups that are triggered by TS elicit disturbances in the afferent signaling and feedback from intramuscular receptors to the cerebral cortex. We suggest that local circuit GABAergic neurons modulate cortical output in response to this altered afferent feedback.

ROLE OF SOMESTHETIC INFORMATION IN THE PLASTICITY OF THE CEREBELLO-CORTICAL PATHWAY. E.M. Meftah and L. Rispal-Padel*. C.R. Cerveau et Cognition UMR 9940 Fac. Méd. 31062 Toulouse. France.

Long-lasting effects of somesthetic messages on cerebello-thalamo-cortical (CTC) transmission and on the motor responses induced by interpositus nucleus stimulation, were studied under associative conditions. Two α-conditioning procedures, in association with behavioral and electrophysiological approaches, were carried out on awake chronically prepared cats which had previously undergone a red nucleus neurotoxic lesion. In the 1st procedure, a sub-threshold activation of the CTC circuits controlling forearm flexion movements (conditional stimulus CS), was associated with a cutaneous stimulation (unconditional stimulus UCS) of the dorsum of the distal forearm. Both CS and UCS originally produce elbow flexions. In the 2nd procedure, the same CS was paired with another UCS, applied to a more proximal cutaneous receptive field and producing a backwards forearm withdrawal movement, different from that induced by the CS.

Under the 1st procedure, a persistent enhancement of the amplitude of the forearm flexions induced the CS was observed along with an increase of the cerebello-cortical excitatory responses in the elbow area of the motor cortex. In contrast, the 2nd procedure resulted in a decrease and the disappearance of the forearm flexions in favor of the appearence of forearm extensions, the amplitude of which increased concomitantly with a depression of the cerebello-cortical excitatory wave. A secondary inhibitory wave also developed in the cortical elbow area. These changes were long lasting and lead to the following conclusions: The CTC circuits are liable to undergo functional modifications in adult cats. The motor and CTC changes may be of two types depending on the somesthetic messages paired with the CS. The time courses of the changes affecting the CTC transmission and the motor responses are closely related.

747.3

PLASTICITY IN THE CEREBELLAR EFFERENT PATHWAYS. ROLE OF TEMPORAL RELATIONSHIPS BETWEEN CONDITIONAL AND UNCONDITIONAL STIMULATIONS IN THE INDUCTION OF PLASTIC CHANGES. M. Pananceau and L. Rispal-Padel. C.R. Cerveau et Cognition UMR 9940 Fac. Méd. 31062 Toulouse. France. (Spon: ENA*)

The properties of cerebellar output pathways can be modified by sensori-motor experience during the lifetime of an animal. It would appear that this plasticity depends on the convergence of motor-related neural activity with sensory information concerning the environment. The present study was aimed at elucidating the importance of the temporal relationships between such sensory and motor events in the development of these experience related changes. In chronic cats, the cerebello-thalamo-cortical and cerebello-rubral motor circuits controlling the forelimb were subjected to an associative conditioning procedure in which the interpositus nucleus (origin of both pathways) was subjected to sub-threshold conditioned stimulation (CS) in association with an unconditioned stimulus (UCS) which induced a reflex flexion movement of the elbow joint.The movements produced together with the responses in central structures were analysed during the course of the conditioning procedure. Three different CS-UCS delays were tested. When the CS was presented 100 ms after the UCS (UCS-CS 100) there was no effect on either the movement or the central responses. When the CS was applied either at the same time as the UCS (CS-UCS) or 100 ms before (CS-UCS 100), there was an increase in both the amplitude and the probability of the motor responses. In the CS-UCS situation, the motor changes were only transient, and dependent on changes in excitability that affected the entire motor cortex. In contrast, in the CS-UCS 100 situation, the changes were topical and long-lasting and were associated with a reinforcement of thalamo-cortical and cerebello-rubral synapses. Such changes were specific to circuits involved in controlling the elbow joint and were strongly correlated with the changes in the movement. They were only seen when the CS predicted the arrival of the UCS.

RAPID CHANGES IN THE ORGANIZATION OF SENSORY AND MOTOR EVOKED FIELDS FOLLOWING PERIPHERAL ISCHEMIA STUDIED BY MAGNETOENCEPHALOGRAPHY. M.Hund, A.Rezai, E.Kronberg, J. Cappell, U.Ribary*and R.Llinás. Dept. of Physiol. & Neurosci., NY Univ. Med. Center, 550 First Ave, NY, NY 10016.

Magnetoencephalographic (MEG) somatosensory and motor fields of the left hand (mostly middle finger) were recorded in five healthy subjects before, during and after nerve conduction block of their forearms using a pneumatic cuff. In addition, in two subjects the MEG-recording was repeated after total lidocaine block of the left middle finger. During the first 15 minutes of ischemia a 50% decrease of amplitudes of the sensory fields paralleled the progressive sensory loss. Surprisingly, a reduction in the motor field occurred as well. Source locations of the primary motor field components shifted within an area of approximately 1 cm^2. This occurred in all subjects and had a characteristic direction for each individual. Further attenuation of field components was seen in the following 15 minutes of ischemic nerve block. Frequency spectrum analysis showed a suppression of motor mu rhythm as well as a reduction in the 4 Hz band during this period. The fields regained their baseline coordinates and amplitudes 15 minutes after cuff removal. Lidocaine had effects on amplitudes, frequencies and dipole locations selectively on the deafferented middle finger similar to those of ischemia-induced anesthesia, while the non-anesthetized neighboring finger showed normal results. These findings imply that the ischemic effects are not due to cuff-related peripheral anoxia. The decrease of amplitudes in the motor field components during ischemia may be explained by reduced sensory afferent background activity. In summary, temporary peripheral deafferentation, either due to ischemic nerve block or to lidocaine-related digital block, leads to a rapid change in the frequency structure of sensory and motor field components.

MOVEMENT-RELATED NEUROMAGNETIC ACTIVITY DURING TRANSIENT DEAFFERENTATION. R. Kristeva-Feige, S.Rossi, V. Pizzella, A. Sabato, B.Feige, F. Tecchio, J. Edrich and P.-M. Rossini. Inst. Biomed. Engin., Univ. Ulm, 89069 Ulm, Germany. (SPON: EUROPEAN BRAIN AND BEHAVIOUR SOCIETY).

The present study was aimed at investigating the effect of blocking cutaneous input from the moving part of the body on movement-evoked field one (MEFI).

Neuromagnetic fields from the left cerebral hemisphere of three healthy, right-handed subjects were investigated preceding and accompanying voluntary right index finger movements under two different experimental conditions: before (stage A) and during (stage B) transient deafferentation. The last was achieved by anesthetic block of median and radial nerves at the wrist. In this way, during stage B cutaneous and part of the proprioceptive inputs relative to a wide hand area including the entire index finger were suppressed. The voluntary movements were not impaired because the muscles participating in the task were not influenced by the anesthesia.

The magnetic signals of the brain sources corresponding to the main components of the movement-related fields (motor field, MF and movement-evoked field I, MEFI) were mapped and localized by means of a moving dipole model. In the three subjects investigated, the MF and MEFI dipole sources in stage B were stronger (30% on average) than before anesthesia. No significant changes in component latencies and spatial co-ordinates of the estimated dipole sources between stages A and B were observed.

The results are discussed in terms of three hypotheses not mutually excluding each other: „efference copy" hypothesis, spatial attention hypothesis and plasticity hypothesis.

DIFFERENTIAL PATTERNS OF INTRINSIC MOTOR CORTEX PROJECTIONS AS A SUBSTRATE FOR CORTICAL MOTOR MAP PLASTICITY. J.W. Tullai* and G.W. Huntley. Fishberg Reseach Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029.

Reorganization of representational sensory and motor maps in the cerebral cortex can be induced quickly under activity-dependent conditions. In rat motor cortex, transection of the facial nerve leads to a rapid, limited expansion of parts of the forelimb representation into the former whisker representation (Sanes et al., PNAS 85;1988). The connections which mediate such changes may involve intrinsic, horizontally-oriented pyramidal cell axon collaterals which can extend for long distances in motor cortex and cross map boundaries. To investigate whether intrinsic axons are anatomically positioned to mediate and constrain the extent of rapid changes in cortical motor maps, we combined electrical stimulation techniques and anterograde tract-tracing methods in adult rats to correlate the patterns of intrinsic projections with the occurrence and extent of the forelimb border shift induced after facial nerve transection. After nerve cut, small, iontophoretic injections of anterograde tracer (HRP or biocytin) were placed either into former whisker regions exhibiting novel forelimb activity, or into former whisker regions adjacent to the forelimb representation (within 0.3 - 1.0 mm), but from which no movement could be evoked even at high stimulation currents (60-80 μA). Injections placed into whisker regions exhibiting novel forelimb activity gave rise to large numbers of labeled axons and terminal boutons which extended back into the whisker representation as well as ones which crossed the forelimb/whisker border and extended several mm within the forelimb representation. In contrast, injections placed into whisker regions close to the border but from which no activity could be evoked gave rise to labeled axons and terminal boutons which remained mostly restricted to the whisker representation, with few or no axons that crossed the forelimb/whisker border. These data support the hypothesis that the occurrence and extent of motor map plasticity may be constrained by the pattern of intrinsic connections which exist between adjacent representations. (Supported by grants from the Aaron Diamond Foundation and the Sinsheimer Foundation).

NMDA RECEPTOR ANTAGONISTS REVERSIBLY BLOCK PLASTICITY OF ADULT MOTOR CORTEX REPRESENTATIONS. G.W. Huntley1*, F. Liang2, T.M. Woods2, J.W. Tullai1, and E.G. Jones2. 1 Fishberg Res. Ctr. for Neurobiology, Mt. Sinai Sch. of Med., New York, NY 10029; 2 Dept. of Anatomy & Neurobiology, University of California, Irvine, CA 92717.

NMDA receptors have been strongly implicated in forms of synaptic plasticity such as LTP, but any role they may play in the mechanisms contributing to activity-dependent changes in neocortical representational maps is unknown. To investigate the role of NMDA receptors in motor cortex plasticity, we utilized a previously described paradigm (Sanes et al., PNAS 85;1988) in which transection of the facial nerve induces a rapid expansion of the cortical forelimb representation into the former whisker representation. The motor cortices of adult rats were first mapped using low-threshold electrical stimulation techniques to evoke movements, then exposed to antagonists (D-APV or MK-801) via slow-release from the polymer Elvax (DuPont) implanted subdurally. After a 2-7 day exposure period, the contralateral facial nerve was cut, and 2-4 hours later the Elvax was removed and the cortex was immediately re-mapped. Forelimb movements were evoked reliably from all previously mapped forelimb positions at comparable thresholds, but no movements could be evoked from the previously mapped whisker region even at high stimulation currents (60-80 μA). After a 4 hour saline-drip to wash out the drug, the motor cortex was again re-mapped, at which time low-threshold forelimb movements were evoked from all previous forelimb positions as well as new spots corresponding to regions of the former whisker representation. The current thresholds were not statistically different from those obtained in the first mapping. Motor cortices exposed to control solutions (saline or the inactive stereoisomer L-APV) exhibited a forelimb border shift at the first mapping immediately after facial nerve cut. These data suggest that NMDA receptors may be a critical component of the synaptic connections which underlie rapid changes in cortical representational maps, and their functional activation may emerge under conditions in which plasticity is induced. (Supported by grants from the Aaron Diamond Foundation, the Sinsheimer Foundation and NS21377).

747.8

DIFFERENTIAL EFFECTS OF SKILL ACQUISITION AND MOTOR USE ON THE REORGANIZATION OF MOTOR REPRESENTATIONS IN AREA 4 OF ADULT SQUIRREL MONKEYS. E.J. Plautz*, G.W. Milliken, & R.J. Nudo. Dept. of Neurobiology & Anatomy, Univ. of Texas Medical School, Houston, TX 77225.

Previous research has shown that representations in primary motor cortex (area 4) are alterable by behavioral experience (e.g.: Milliken, et al., 1992; Nudo, et al., in press). In the present study, we attempted to dissociate effects of *motor skill acquisition* from effects of *motor use*. Intracortical microstimulation techniques were used to derive detailed maps of movement representations of the hand, wrist, and arm in area 4 before and after two types of motor training.

Monkeys were trained to retrieve food pellets from either a small well (9.5 mm diameter) or a large well (19 mm diameter) in a Plexiglas board (Klüver board). Motor performance was assessed by: a) average number of digit flexions per pellet retrieval and b) frame-by-frame video analysis of movements and movement combinations made during pellet retrieval. Training continued until a criterion number of total flexions had been performed. Monkeys trained on the small well displayed poor performance initially but rapidly improved during the training period. Improvement in behavioral performance was paralleled by a change in movements used during pellet retrieval. In contrast, monkeys trained on the large well exhibited nearly flawless retrieval performance throughout the training period and little variation in retrieval movements. A third group of control subjects were not exposed to the training task.

Following small well training, post-training maps revealed areal expansions in the representations of digit movements and digit/wrist combination movements. These expansions closely paralleled the movements used during successful task performance. In contrast, no systematic changes were found in digit or wrist representations following large well training, despite an equivalent number of total digit flexions. Similarly, control subjects showed little variation in movement representations between mapping sessions. These findings suggest that the reorganization of motor representations in area 4 reflects the *acquisition of new motor skills*, and does *not* simply reflect changes in *motor use*.

747.9

RECOVERY OF FINGER MOVEMENT REPRESENTATION AFTER DISTAL FORELIMB RESTRICTION IN ADULT SQUIRREL MONKEYS. G.W. Milliken*, E.J. Plautz, & R.J Nudo. Department of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77225.

Using intracortical microstimulation techniques, detailed maps of movement representations in primary motor cortex (area 4) were derived before, during, and after restriction of the preferred distal forelimb. Consequences of distal forelimb restriction on the functional topography of motor cortex involved *decreases* in finger and *increases* in wrist representation (Milliken, et al., 1994, *Soc. Neurosci. Abs., 20,* 1394).

In the present study, we examined behavioral and neurophysiological correlates to motor recovery following removal of forelimb restriction. Behavioral recovery was evaluated using a Klüver board pellet retrieval task. By 78 days, 2 of the 3 subjects had returned to use of their previously restricted and preferred (PRP) hand. Subsequent motor mapping experiments revealed that for these 2 subjects the area of the restriction-diminished finger representations had increased substantially and approximated the baseline finger area. The third subject did not display use of his PRP hand and showed no finger representation recovery at 78 and 161 days post restriction. To force this subject to use his PRP hand, we restricted the contralateral forelimb and generated a motor map after 57 days of use. Forced rehabilitation caused recovery of 86% of the finger representation.

These results indicate that recovery of finger representation in primary motor cortex is related to behavioral use of the PRP hand, and that recovery can occur with forced rehabilitation.

Supported by NIH NS 09366 (GWM) and NS 27974 (RJN).

747.10

LIMITED MOTOR CORTEX REORGANIZATION IN A LONG-TERM MONKEY AMPUTEE. M. H. Schieber[1]*, T. W. Anderson[2] and R. K. Deuel[2]. Departments of Neurology and of Neurobiology, [1]University of Rochester, Rochester, NY, 14642 and [2]Washington University, St. Louis, MO, 63110.

After forelimb amputation in neonatal rats, the primary motor cortex (M1) reorganizes such that stimulation in the previous forelimb region can evoke movements of the face (Donoghue & Sanes, 1988). But in adult rat or human amputees, stimulation of the M1 upper extremity region evokes only enhanced contractions of remaining shoulder stump muscles (Sanes et al., 1990; Cohen et al., 1991). We studied M1 in a 15 year old monkey that for unrelated reasons prior to age 2 had undergone amputation of the right arm at the shoulder joint.

We used intracortical microstimulation (ICMS) to explore the region of M1 normally devoted to the arm and hand bilaterally, and to identify its borders with the face region laterally and the leg region medially. In the right M1, conventional ICMS evoked movements of the left face, arm and leg at current thresholds at or below 40μA; the locations of the face/arm and arm/leg borders were normal. In the left M1 contralateral to the amputated right arm, ICMS similarly evoked movements of the right face and leg from typical locations at normal current thresholds. But within the left M1 arm region, ICMS failed to evoke movements of body parts other than the remaining right shoulder stump. Modified ICMS using currents up to 80μA and trains up to 200ms also failed to evoke movements of the right face, neck, abdomen or leg, or of the left arm.

The M1 arm region contralateral to this monkey's amputation was not reorganized to represent the face or leg. Instead, shoulder stump movements were evoked throughout the arm region, which may have resulted from unmasking of the normal widespread shoulder representation. Species, age at amputation, and/or time since amputation, may affect M1's reorganization.

LEARNING AND RETENTION OF A NEOCORTICALLY-DEPENDENT SENSORIMOTOR SKILL IN THE RAT. Michael Coogan*, John Larson, & Gary Lynch. CNLM, Univ. Calif., Irvine, CA 92717.

Traditional models of cortical control of fine, distal limb movements have typically been limited to primate species. However, rats can be trained to use their forepaws to grasp and retrieve small food pellets, and this behavior is similar to the manipulative behaviors of primates. Neuroanatomical and behavioral studies support the notion that rats can serve as a model of primate motor skill learning and performance, and that the normal and pathological reaching behaviors of rats are likely to be directly applicable to the understanding of human cortical pathophysiology. The present experiments describe a paradigm for examining the neural substrates of forelimb reaching behavior in rats.

Adult, male Sprague-Dawley rats were trained to reach for food rewards in an apparatus originally designed by Montoya et al. (1991). This apparatus provides for varying degrees of difficulty in reaching skill. Rats were given a single training trial each day. Analysis of group data suggests that acquisition of this skill is qualitatively and quantitatively similar to acquisition of sensorimotor skills in humans. Analysis of individual learning curves revealed that acquisition of the task consists of three phases, each associated with a plateau of performance. Once acquired, the skill is retained for at least three weeks without practice.

Unilateral sensorimotor cortex ablations profoundly impair performance on this task and, while some recovery occurs, there is a residual deficit in motor control of the contralateral forepaw that is stable for at least five weeks. Videoanalysis demonstrates separate sensory and motor impairments in lesioned rats that are qualitatively similar to those seen in humans following traumatic neocortical damage. Methodological advantages of this paradigm will be discussed, and further applications of this model to the study of human clinical syndromes will be proposed. (Supported by AFOSR, ONR, and NIH).

BASAL GANGLIA: STRIATAL SYSTEMS

748.1

LONGTERM CORTICAL AND STRIATAL SLICE CO-CULTURES: ANATOMY AND ELECTROPHYSIOLOGY OF IDENTIFIED NEURONAL TYPES. B.Teng, D. Plenz, Y. Kuga* and S.T. Kitai, Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

To study cortico-striatal dynamics an *in vitro* system has been developed using organotypic cortex-striatum co-cultures. Previous work showed that the spontaneous activity developing in this system proves to be highly similar to the ones found *in vivo*. Here we further examine the electrophysiological and morphological properties of neurons in longterm (> 4 weeks) co-cultures. Furthermore, as local interneurons were found to profoundly influence cortical and striatal dynamics, a special effort was undertaken to reconstruct those interneurons.

Cortical and striatal slices from rat P0 - P1 were cultured for four to eight weeks using a modified roller-tube technique. Neurons were intracellularly recorded from, electrophysiologically identified and labeled with neurobiotin.

In the cortex, pyramidal neurons, bipolar and multipolar interneurons show similar dendritic and axonal morphologies as *in vivo*. In the striatum, the giant aspiny interneuron class, two GABAergic interneuron classes and medium-spiny projection neurons can be clearly distinguished from each other and are similar to *in vivo*. These results indicate a high degree of similarity in the electrophysiology and morphology between neurons in longterm slice co-cultures and *in vivo*.

CORTEX AND STRIATUM SLICE CO-CULTURES: POPULATION ACTIVITY UNDERLIES HIGH FREQUENCY SUBTHRESHOLD OSCILLATIONS WHICH GOVERN SPIKE DISCHARGE. D. Plenz and S.T. Kitai*. Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

It has been hypothesized that a brief synchronization of spike discharge among a group of neurons is one of the basis for neuronal coding and among cortical neurons has been observed to be ~40 Hz.

In order to study cortico-striatal information processing and the underlying mechanisms of synchronized spike discharge, we have established longterm (4 - 8 weeks) organotypic cortex-striatum co-cultures from rats at age P0 - P1. Simultaneous intracellular recordings were obtained from neurons in the cortex, the striatum or both. Neurons were identified based on their electrophysiological characteristics and their morphological features were revealed by intracellular labeling with neurobiotin.

Findings indicate: (1) In the cortex during periods of spontaneous activity, brief (0.5 - 1.5 s) ~40 Hz subthreshold oscillations were observed to which pyramidal neuron spike discharge is temporally linked. (2) In the striatum, medium-spiny neuron spike discharge is temporally linked to > 20 Hz subthreshold oscillations. (3) In both structures, spike discharge of GABAergic interneurons was closely associated with subthreshold oscillation frequencies.

These results indicate that: (1) The ~40 Hz subthreshold oscillation in the cortex is an emergent property of the cortical network itself. (2) Burst activities (~20 Hz) of striatal medium-spiny projection neurons may be governed by the striatal network, which is driven by cortical inputs. (3) Subthreshold oscillation frequencies in each structure result from population activity in which local GABAergic interneurons strongly participate.

Electrophysiological Characterization of Immunocytochemically Identified Neurons in the Rat Substantia Nigra Pars Reticulata *In Vitro*. C.D. Richards, T. Shiroyama* and S.T. Kitai. Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

Previous studies on the substantia nigra pars reticulata (SNr) have identified two groups of neurons based upon their electrophysiological characteristics. However, the transmitter phenotype of each of these two neuronal classes is unknown. The aim of this study was therefore to record from neurons in the SNr and characterize them electrophysiologically, and subsequently to identify these neurons using immunocytochemical double labelling techniques.

Intracellular recordings were performed in slices of midbrain containing the SNr, prepared using standard techniques. Electrodes contained neurobiotin, which was injected into neurons subsequent to electrophysiological characterization. Two electrophysiological classes of neurons were identified. One had a slow rate of action potential discharge, long duration action potentials, and prominent anomalous inward (I_h) and transient outward (I_A) rectification. The other had a faster rate of action potential discharge, shorter duration action potentials, weak I_h and no apparent I_A.

Both types of neuron were subsequently processed immunocytochemically to reveal the injected biocytin. The former type of neuron, which had electrophysiological characteristics similar to substantia nigra pars compacta neurons, displayed double labelling for biocytin and tyrosine hydroxylase, indicating that they are dopaminergic. The latter, faster firing type of neuron is currently being processed immunocytochemically to determine the presence or absence of glutamic acid decarboxylase (GAD), the marker enzyme for GABAergic neurons.

This study indicates that the SNr contains two classes of neuron which can be distinguished using intracellular recording and electrophysiological criteria.

A FURTHER CHARACTERIZATION OF RAT TEGMENTAL PEDUNCULOPONTINE (PPN) CHOLINERGIC NEURONS. K. Takakusaki*, T. Shiroyama and S.T. Kitai. Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

We have demonstrated that PPN Type II neurons are cholinergic and characterized by a transient outward current in *in vitro* slice preparations (Kang and Kitai, *Brain Res.* 1990). In this study, Type II neurons (n=69) were classified into 2 subgroups according to their electrical membrane characteristics. One group (short-duration neurons; SDNs, n=21) was characterized by short duration spikes (0.7-1.5 ms), a high spontaneous firing rate (m=14 Hz) and high input resistance (m=230 MΩ). Depolarizing current injection increased the firing rate of these neurons with no alterations in duration or fast-AHP of spikes. The other group (long-duration neurons; LDNs, n=48) was characterized by long duration spikes (1.6-2.8 ms), a low firing rate (m=7.8 Hz) and low input resistance (m=140 MΩ). They displayed accommodation of firing frequency with changes in spike duration and fast-AHP. In the presence of TTX (<10 μM), SDNs displayed Ca-dependent high threshold oscillations (HTO) with high frequency (m=13.5 c/s) and low voltage (m=2.8 mV). LDNs had low frequency (m=7.5 c/s) and large amplitude (m=5.2 mV) HTO. An application of TEA (5 mM) generated spontaneous high threshold Ca-spikes in LDNs but not in SDNs. Biocytin injection combined with ChAT immunohistochemistry revealed 60% of each subtype of neurons were cholinergic. Morphologically, SDNs had small cell bodies (<20 μm) with 2-4 thin primary dendrites and LDNs large cell bodies (>25 μm) with 3-6 thick primary dendrites. Both groups of cells were intermingled within PPN. These results suggest that PPN cholinergic neurons are composed of heterogeneous subgroups of neurons with different membrane characteristics and morphology. *Supported by USPHS grants NS20702 and NS26473.*

CORTEX-STRIATUM-MESENCEPHALON SLICE CULTURES AS A MODEL FOR ANALYSIS OF FOREBRAIN DYNAMICS. S.T. Kitai, D. Plenz and E.F. Johnson*, Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

Dopamine influences cortical and striatal activity at the single neuron level as well as at the neural network level. In previous work it has been shown that the spontaneous network activity developing in organotypic cortex-striatum co-cultures is highly similar to the ones found *in vivo*. Here we extend this *in vitro* system analysis of cortical-striatal dynamics by including dopaminergic projection neurons from the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA).

Cortical, striatal and mesencephalic (SNc/VTA) slices from rat P0 - P1 were cultured for up to 8 weeks using a modified roller-tube technique. Triple-cultures were stained for tyrosine hydroxylase (TH) immunoreactivity.

After three weeks in culture TH-positive neurons were found in the mesencephalic tissue region. A high abundance of TH-positive fibers are present in the cortex and the sriatum. Intracellular recordings from 7 week old striatal neurons show that they respond to SNc/VTA, cortical and intrastriatal stimulation, each with unique features.

We propose that the triple-culture will provide a powerful *in vitro* approach to study the role of dopaminergic systems in cortico-striatal network dynamics.

SOMA-DENDRITIC DOPAMINERGIC (DA) MODULATION OF ACTIVATED PREFRONTAL CORTEX→NUCLEUS ACCUMBENS (PFC→NAC) NEURONS *IN VITRO*. Gorelova, N., Yang, C.R., & Seamans, J.K. Dept. of Psychology, & Psychiatry, Univ. of British Columbia, Vancouver, CANADA,V6T 1Z4.

Corticostriatal pyramidal neurons in deep layers V-VI of the PFC link the NAC and receive the mesocortical DA input. This PFC→NAC pathway may be an important route via which DA modulation of PFC signals encoding for cognitive processes is translated into actions. To evaluate the underlying mechanisms of DA modulation in PFC→NAC neurons, we have made biocytin-intracellular recordings in: a) antidromically activated PFC neurons that responded to NAC stimulations in brain slices, and b) PFC slices prepared from rat which received prior microinjection of the retrograde tracer rhodamine beads in the NAC.

Bath applications of DA D1 agonist (SKF38393;10-50μM), but not D2 agonist (qunpirole), enhanced the excitability of intrinsic bursting PFC→NAC neurons in response to depolarizing pulses via its interactions with two opposing voltage-dependent currents: 1) a direct *suppression* of a dendrotoxin (50nM)- and 4AP(0.1-2mM)-sensitive, outwardly rectifying, slowly inactivating K^+ current, but 2) a direct *augmentation* of a somatic, TTX-sensitive, inwardly rectifying, slowly inactivating Na^+ current.

On the other hand, the regenerative dendritic high-threshold Ca^{2+} spikes (HTS) (in TTX+TEA) or the Ba^{2+} plateau potentials (recorded when $[Ca^{2+}]_o$ were substituted by Ba^{2+} to prevent $[Ca^{2+}]_o$ auto-inhibition of HTS) were suppressed markedly by SKF38393. Furthermore, D2 receptor stimulations by quinpirole (50μM) following glutamate receptor blockade (by 10μM CNQX and 50μM APV) increased transiently the frequency of GABAergic IPSPs. Hence, D1 receptor activation augments input signals reaching the deep layer somatic region via its interactions with the slow K^+ and Na^+ currents. D1 receptor stimulation also suppresses the overall HTS-amplification of associative input signals to the apical dendrites (in layers I-II) of the deep layers V-VI PFC→NAC neurons. In addition, D2 receptor activation of the GABAergic interneurons attenuated the excitability of the PFC→NAc neurons. (Funded by B.C.Health Research Foundation & MRC of Canada)

DOPAMINE (DA) MODULATION OF POST-SYNAPTIC RESPONSES IN LAYER V-VI RAT PREFRONTAL CORTEX (PFC) NEURONS EVOKED BY SYNAPTIC ACTIVATION OF THEIR APICAL DENDRITES *IN VITRO*. C. R.Yang* & J.K. Seamans, Dept.of Psychology, & Psychiary, Univiversity of British Columbia, Vancouver, B.C., V6T 1Z4

Activation of NMDA receptors in the dendrites of pyramidal neurons promotes Ca^{2+} influx through dendritic NMDA receptors and high-voltage activated Ca^{2+} channels. We have previously shown *(Yang and Seamans, Soc. Neurosci. Abst*, 1994) that DA D1 receptor stimulation suppressed dendritic high threshold Ca^{2+} spikes (HTS) evoked by intracellular depolarizing current pulses in PFC cells. To determine the functional interactions of D1 receptor with HTS arising from synaptically-evoked, NMDA receptor-mediated EPSPs, the effects of the D1 agonist (SKF38393) and antagonist (SCH23390) were studied in intracellularly recorded PFC neurons in rat brain slices (QX-314 (100mM)-filled electrodes in bicuculline (10μM), CNQX(10μM), V_m held at -60mV).

Lower frequency (0.02-0.1Hz) electrical stimulation of the superficial layers I-II, where the apical dendrites of the layer V-VI neurons are located, synaptically evoked an early NMDA-receptor mediated EPSP, followed by a late, low amplitude, Ca^{2+}-mediated component. This late component developed into an HTS at higher stimulation intensities. Bath-application of SKF-38393 (30-60μM) reduced, while SCH-23390 augmented, the duration of the late Ca^{2+} components. Higher frequency stimulation (>0.2Hz) markedly attenuated the late Ca^{2+} components perhaps due to an inactivation of the voltage-gated Ca^{2+} channels by the elevated $[Ca^{2+}]_i$ under this condition At high frequency stimulations (≥1Hz), only the initial NMDA component persisted and SCH-23390 (20-50μM) reversibly attenuated (28%) the amplitude of this isolated NMDA component. These data suggest that synaptically-released DA activates D1 receptors to potentiate NMDA signals. Additional DA suppression of the overall dendritic signal amplification mediated by the synaptically-evoked dendritic Ca^{2+}-HTS results in a selective "sharpening" of the potentiated NMDA signals. D1 DOPAMINE RECEPTOR-INDUCED IMMEDIATE EARLY GENE EXPRESSION IN THE DOPAMINE-DEPLETED STRIATUM IS LARGELY INDEPENDENT OF EXCITATORY AFFERENT INPUT AND ACTION POTENTIALS. K.A. Keefe* and C.R. Gerfen, Laboratory of Systems Neuroscience, NIMH, Bethesda, MD 20892

Cortical input to striatum produces excitatory post-synaptic potentials and action potentials in striatal efferent neurons mediated primarily by the AMPA subtype of glutamate receptor. Activation of D1 dopamine receptors modifies the response of striatal neurons to cortical input. Although expression of immediate early genes often is used as a marker of neuronal activity, the extent to which D1-mediated induction of immediate early genes in striatum reflects enhanced neuronal activity to excitatory input remains unclear. We therefore examined the effects of intrastriatal administration, via *in vivo* microdialysis probes, of CNQX or TTX on induction of immediate early genes by D1 receptor stimulation in dopamine-depleted rats. Local infusion of AMPA into striatum induced c-*fos* and *zif268* throughout striatum and, in some cases, throughout the ipsilateral cerebral cortex. Co-infusion of CNQX with AMPA blocked the induction, suggesting that CNQX effectively blocks AMPA receptors. However, infusion of CNQX (10 μM - 1 mM) did not alter induction of *zif268* or c-*fos* by SKF 38393, except at the highest concentration where variable effects on c-*fos* expression were observed. Similarly, when SKF 38393 was injected during perfusion of striatum with TTX, induction of *zif268* was not affected. Expression of c-*fos* showed a small (23%), but significant decrease. These data suggest that induction of *zif268* and c-*fos* by SKF 38393 in the dopamine-depleted striatum is largely independent of input through the AMPA subtype of glutamate receptor and action potential activity in striatum.

ENKEPHALIN INHIBITS IMMEDIATE-EARLY GENE EXPRESSION INDUCED BY BLOCKADE OF D2 DOPAMINE RECEPTORS IN STRIATUM. H. Steiner*, R. Mariotti and C. R. Gerfen. Laboratory of Systems Neuroscience, NIMH, Bethesda, MD 20892.

Recent studies showed that dynorphin, an opioid peptide contained in striatonigral projection neurons, regulates dopamine input to these neurons. This opioid-dopamine interaction was demonstrated by using induction of immediate-early genes (IEGs) by dopamine receptor stimulation as a functional marker. Striatal neurons that project to the globus pallidus express D2 dopamine receptors and contain the opioid peptide enkephalin. In the present study, we investigated whether enkephalin has an autoregulatory function in striatopallidal neurons similar to dynorphin in striatonigral neurons. Thus, we examined whether enkephalin or agonists inhibit IEG induction by a D2 dopamine receptor antagonist in striatopallidal neurons. Gene expression was assessed by quantitative *in situ* hybridization histochemistry. Acute injection of the D2 antagonist eticlopride results in rapid induction of the IEGs c-*fos* and *zif 268*. Repeated treatment (1x/day, 1-5 days) with the D2 antagonist produced an increase in expression of enkephalin that was paralleled by suppressed inducibility of IEGs. Moreover, infusion of the delta opioid receptor agonist DADLE (0.05-5 nmol) into the striatum suppressed IEG induction by acute eticlopride. These results suggest that enkephalin acts in the striatum to blunt activation of striatopallidal neurons by D2 blockade and that increased enkephalin expression after repeated D2 antagonist treatment is a compensatory response to limit overactivation.

SYSTEMIC BUT NOT INTRASTRIATAL INJECTION OF THE MUSCARINIC AGONIST, OXOTREMORINE, INDUCES CORTICAL AND STRIATAL IMMEDIATE EARLY GENE EXPRESSION. L.K. Nisenbaum*, S.T. Kitai, and C.R. Gerfen, Dept. of Anatomy & Neurobiology, Univ. of Tennessee, College of Medicine, Memphis, TN, and Section on Neuroanatomy, NIMH, Bethesda, MD.

Acetylcholine and dopamine have been hypothesized to interact within the striatum to influence the output neurons of this structure. Both dopaminergic agonists and muscarinic antagonists alter the expression of enkephalin and substance P mRNA expression in the dopamine-depleted striatum. We have previously demonstrated that whereas local stimulation of dopamine receptors mimics the effect of systemic drug administration, striatal infusion of a muscarinic antagonist does not alter striatal peptide gene expression.

To examine the role of muscarinic receptor activation in immediate early gene regulation, we have used *in situ* hybridization histochemistry to measure the effect of systemic and intrastriatal muscarinic drug administration in normal and 6-hydroxydopamine- (6-OHDA) lesioned rats. Systemic injection of oxotremorine (0.5 mg/kg, i.p.) produced an increase in cortical and striatal *c-fos* and *zif268* expression in normal animals. In 6-OHDA-lesioned rats, the induction of *c-fos* and *zif268* by systemic oxotremorine was significantly reduced. In contrast, intrastriatal infusion of oxotremorine (50 pmol in 0.5 μl) did not increase *c-fos* or *zif268* expression in either the striatum or the cortex of normal or 6-OHDA-lesioned rats. To examine the tonic influence of muscarinic receptor activation on immediate early gene expression, the effect of systemic and intrastriatal administration of the muscarinic antagonist, scopolamine, was tested. No effect of scopolamine was observed on *c-fos* or *zif268* expression in control or 6-OHDA-lesioned rats. These data demonstrate that extrastriatal activation of muscarinic receptors is responsible for the induction of immediate early genes by oxotremorine. In addition, the lack of effect by either systemic or intrastriatal scopolamine administration suggests that immediate early gene expression is not tonically regulated by acetylcholine. *Supported by USPHS grants NS26473, NS09362.*

STRIATAL EXPRESSION OF *ZIF* 268 mRNA TO ACUTE 5HT-2A AND 5HT-2C RECEPTOR STIMULATION AFTER UNILATERAL LESIONING OF THE NIGROSTRIATAL PATHWAY. R. F. Paletzki* and C. R. Gerfen. Laboratory of Systems Neuroscience, NIMH, Bethesda, MD 20892.

The striatum receives a dopamine projection form the substantia nigra and a serotonin projection from the dorsal raphe. Whereas dopamine differentially modulates the function of connectionally distinct striatal neurons, the influence of serotonin on striatal neurons is less understood. In this study the effect of serotonin, via the 5HT-2A and 5HT-2C receptors, on striatal neuron function was investigated in the presence and absence of endogenous dopamine input. Rats were given a single injection of either ±DOI or mCPP (0,1,10 mg/kg) 3 weeks following unilateral lesion of the dopaminergic nigrostriatal pathway. Alterations in striatal neuron function were determined by measuring changes in expression of the immediate early gene *zif* 268 mRNA by *in situ* hybridization with ^{35}S-labeled oligonucleotide probes. ±DOI, which has higher affinity for 5HT-2A over 5HT-2C receptors, increased expression of *zif* 268 in the lesioned striatum, while producing smaller changes in the intact striatum. mCPP, which has greater affinity for the 5HT-2C receptor, significantly reduced *zif* 268 mRNA expression in the lesioned striatum, but had little effect on the intact side. These data indicate that serotonin differentially affects striatal neuron function via the 5HT-2A and 5HT-2C receptors. The 5HT-2A receptor appears to increase striatal neuron function, whereas the 5HT-2C receptor appears to decrease striatal neuron function. Furthermore, these data demonstrate that dopamine can reduce the response of striatal neurons to serotonin receptor stimulation.

GAP-43 EXPRESSION IN THE STRIATUM AFTER THERMOCOAGULATORY AND ASPIRATION LESIONS OF THE SENSORY-MOTOR CORTEX: AN ULTRASTRUCTURAL STUDY. Kunihiro Uryu*, Larami MacKenzie and Marie-Françoise Chesselet, Dept of Pharmacology, University of Pennsylvania , Philadelphia, PA 19104 USA

We have previously reported (Szele et al. , J. Neurosci., in press) that expression of GAP-43, an axonal protein enriched in growth cones and sprouting axons, is decreased in the striatum after unilateral lesions of the sensory-motor cortex induced by acute aspiration, but not after progressive lesions induced by thermocoagulation of pial blood vessels. We have examined GAP-43 immunostaining at the ultrastructural level in the striatum of rats 16 days after both types of lesions. Both lesions induced similar loss of all layers of the sensory-motor cortex . In control rats, GAP-43 immunoreactivity in the dorsolateral striatum was most often associated with axon terminals enriched in varied-sized clear vesicles (Growth cone-like structures). These processes occasionally formed asymmetric contacts with dendritic spines. GAP-43 immunoreactivity was also present in pre- and terminal segments of axons, and to a lesser extend in axon terminals forming asymmetrical and symmetrical synapses and in dendritic spines. After aspiration lesions, extensive degeneration was present in the denervated dorso-lateral striatum; GAP-43 immunoreactivity was undetectable, and growth cone-like axon terminals were absent. In contrast, expression of GAP-43 and growth cone like axon terminals similar to those seen in controls were present in the dorsolateral striatum after thermocoagulatory cortical lesions. Taken together with data showing increased labeling of crossed corticostriatal projections after thermocoagulatory lesions (Napieralski et al., this meeting), the data suggest that compensatory axonal sprouting occurs in the dorsolateral striatum after thermocoagulatory but not aspiration cortical lesions. Sup. by NS29230.

748.13

A ROLE FOR CONTRALATERAL CORTICOSTRIATAL NEURONS IN THE EFFECTS OF THERMOCOAGULATORY LESIONS OF THE CORTEX ON STRIATAL GENE EXPRESSION. J.A. Napieralski*, A.K. Butler, and M-F. Chesselet, Dept. of Pharmacology, Univ. of Penn., Phila, PA 10104

Previous studies in our laboratory have shown that cortical lesions induced by thermocoagulation of pial blood vessels, but not by acute aspiration, result in 1) the preservation of control levels of GAP-43 and 2) a prolonged increase in neurotransmitter gene expression in the denervated dorsolateral striatum. We have examined whether corticostriatal projections from the spared homotypic contralateral cortex contribute to these effects. Adult rats received a unilateral lesion of the cerebral cortex and, after thirty days, received an injection of the anterograde tracer, Ruby red, in the contralateral homotypic cortex. Rats were sacrificed 7 days later and labeled fibers were examined with fluorescence microscopy in the ipsilateral and contralateral striata. Ipsilateral corticostriatal projections were labeled in lesioned and unlesioned rats. Numerous labeled fibers were detected in the contralateral striatum of lesioned but not control animals, suggesting that contralateral cortical neurons may undergo axonal sprouting in the denervated striatum. To determine whether contralateral corticostriatal fibers play a role in the changes in gene expression in the striatum induced by the cortical lesion, the effects of unilateral and bilateral thermocoagulatory lesions of the cortex were compared. In situ hybridization histochemistry revealed an increase in the enkephalin mRNA levels in the striatum of unilaterally but not bilaterally lesioned animals, suggesting that sprouting or over activity of contralateral corticostriatal input is responsible for the increase seen after unilateral lesions. Supported by PHS grants NS-29130 and MH10794.

TOPOGRAPHICAL PATTERNS OF EFFERENTS FROM THE 'BARREL' CORTEX TO RAT NEOSTRIATUM. A.K. Wright, E.A.M. Hutton, L. Norrie, C.A. Ingham, G.W. Arbuthnott.*, *MRC External Scientific Staff, University of Edinburgh Centre for Neuroscience, Preclinical Veterinary Sciences, Summerhall, Edinburgh, EH9 1QH.*

Individual whiskers on the face of rats are represented by an area of S1 cerebral cortex called a 'barrel'. Individual barrels, identified by cytochrome oxidase histochemistry, have been injected in pairs with different anterograde tracers and the projections of neurones within single barrels into the neostriatum, thalamus, and brain stem, examined.

We have used biotinylated dextran amine (BDA) and Phaseolus Vulgaris Leucoagglutinin (PhaL) to fill adjacent barrels in the same rat and after two weeks survival time have stained the two tracers different colours with 'Vector' chromagens DAB and SGA. The axons from the injected cells can be followed into the internal capsule from which they exit at right angles to supply small areas within the somatosensory field of the neostriatum. Axons continue within the internal capsule fibres to other areas of brain including thalamus and brain stem.

There is a topographically arranged pattern of boutons in the dorsolateral portion of the striatum with very little overlap between fibres from individual barrels. Barrels of row A are closest to the callosum while those of row E are deepest in the striatum. A pattern of finer terminals is also visible which may have a different source within the barrel cortex and which seems to have a different topography.

Electron microscopic investigation shows both large boutons making complex synapses with dendritic spines and smaller fibres making simple synapses with individual spine heads. In view of the likely loss of synapses of the asymmetric type when dopamine is lost from the striatum (Ingham et al (1993) Exp.Br.Res. 93 17) it will be important to compare the fate of these synapses after 6-hydroxydopamine treatment.

BASAL GANGLIA: DRUGS OF ABUSE

749.1

COCAINE AND AMPHETAMINE FAIL TO INDUCE C-FOS- AND JUN B-LIKE PROTEINS IN THE STRIATUM OF DOPAMINE D1 RECEPTOR MUTANT MICE . R.Moratalla[1]*, M.Xu[2], S.Tonegawa[2] and A.M. Graybiel[1].. [1]Dept. Brain & Cog. Sci.,[2]Ctr. for Cancer Research, MIT, Cambridge, MA 02139.

Cocaine and amphetamine are psychomotor stimulants that exert powerful acute and long-term effects on behavior. A candidate mechanism for mediating the long-term effects is the induction of cascades of regulation, including regulation of immediate-early genes (IEGs) coding transcription factors and genes coding neuromodulators such as dynorphin in the basal ganglia and associated circuitry. Pharmacological experiments have implicated D1-class dopamine receptors in many of these effects, but actions of other receptors (e.g. dopamine D2-class and 5HT) have also been suggested. We previously reported experiments (Xu et al 1994) showing that D1 mutant mice have severe deficits in dynorphin (and substance P) in the striatum and associated basal ganglia nuclei and exhibit diminished behavioral responses to acute cocaine. We have now tested whether, in such D1 mutants, acute cocaine and amphetamine can induce IEGs in the striatum. Wildtype (wt) and mutant mice were given cocaine (40 mg/kg) or amphetamine (10 mg/kg) under single-blind conditions, and 2 hr later their brains were fixed and processed for c-Fos and Jun B immunostaining with polyclonal antisera. Mutant and wt controls were untreated or given haloperidol (2 or 5 mg/kg). The results were clear-cut. Cocaine and amphetamine strongly induced c-Fos- and Jun B-like proteins in the striatum of wt mice in drug-specific patterns (Graybiel et al 1990), but such induction was virtually absent in the D1 mutant mice as were stereotypies and locomotion. Forebrain IEG induction was also reduced elsewere. By contrast, haloperidol induced both IEGs in mutants as well as in wt mice. We conclude that the D1 receptor is essential for striatal induction of c-Fos and Jun B-like proteins by cocaine and amphetamine. Deficits in IEG induction could contribute to the neuropeptide deficiencies in the basal ganglia of these mice and to their behavioral abnormalities as well. Supported by NIDA DA08037.

WITHDRAWAL FOLLOWING REPEATED AMPHETAMINE TREATMENT INCREASES DYE COUPLING BETWEEN NEURONS AND ACTIVATES OUTPUT PATHWAYS IN RAT LIMBIC CORTICAL/STRIATAL REGIONS S.P. Onn* and A. A. Grace, *Depts Neuroscience & Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260*

Although the mesocorticolimbic dopamine (DA) system has frequently been implicated in behavioral sensitization, its cellular or synaptic mechanisms are unclear. Utilizing *in vivo* intracellular recordings and Lucifer-yellow dye injection, we examined the impact of amphetamine sensitization on dye coupling between dopaminoceptive postsynaptic target neurons in rat striatal and cortical regions. Following amphetamine treatment (2-4 mg/kg; i.p., daily, 1-4 weeks) and 3-7 days of drug withdrawal, significantly higher levels of dye coupling were observed between projection neurons in the infralimbic/piriform cortices (rAMP =5/6 vs basal =1/6) as well as in the ventral striatum (rAMP =13/14 vs basal 2/11). In contrast, no increase in coupling was observed following acute amphetamine (5mg/kg; 0/6). The increased coupling observed following rAMP was similar to that observed following >95% depletions of striatal DA (12/16). Nevertheless, the density of tyrosine hydroxylase (TH)-immunoreactive terminals in the striatum was not substantially altered in the rAMP-treated rats. Thus, these combined data suggest that withdrawal following rAMP produces a functional denervation of the DA system without causing an actual loss of DA terminals. Furthermore, activity within the ventral cortical/striatal output pathways, as revealed by c-fos immunoreactive levels, showed an elevation above control levels in the rats following rAMP withdrawal. CANNABINOID AGONIST WIN 55212-2 MODULATES STRIATO-NIGRAL NEUROTRANSMISSION BY A PRESYNAPTIC MECHANISM. T. Tersigni and H.C. Rosenberg,* Dept. of Pharmacology, Medical College of Ohio, Toledo, Ohio 43699.

The brain cannabinoid receptor has been shown to be present in areas receiving striatal innervation, including the pars reticulata of the substantia nigra (SN), and to be located presynaptically on the GABAergic striatal output neurons. This study tested the hypothesis that cannabinoid agonist, applied locally, could modulate striato-nigral transmission, but would not affect the response of the postsynaptic neuron to locally-applied GABA. Male Sprague-Dawley rats were anesthetized with chloral hydrate. A glass multi-barrel electrode was used to record the spontaneous activity of SN neurons, to iontophoretically apply GABA, and to pressure eject Win 55212-2, a cannabinoid agonist, in vehicle. This electrode assembly was lowered into the SN using stereotaxic coordinates, and SN neurons were identified by the firing rate and shape of the action potential. Recording sites were marked for histological confirmation. Win 55212-2 increased the spontaneous neuronal firing rate by 30-46 percent. The peak effect of Win 55212-2 was reached 4.5-8.5 minutes after onset of pressure ejection. The percent inhibition of neuronal activity produced by GABA was not altered in the presence of Win 55212-2, indicating that Win 55212-2 had no effect on the interactions of GABA at the postsynaptic membrane. Pressure ejection of vehicle, 45% 3-hydroxypropyl-β-cyclodextin, produced a small, non-significant decrease in spontaneous neuronal discharge, and no change in response to GABA. These findings suggest that cannabinoid receptors on the striatal terminals can modulate striato-nigral neurotransmission presynaptically. Supported by NIH grant DA 02194.

PHYSICAL WITHDRAWAL IN RATS TOLERANT TO Δ^9-THC PRECIPITATED BY A CANNABINOID RECEPTOR ANTAGONIST Kang Tsou, Saundra L. Patrick, Russell M. Church* and J.Michael Walker. Schrier Research Laboratory, Departments of Psychology and Neuroscience, Brown University, Providence, RI 02912.

Whereas termination of chronic intake of opiates, barbiturates, and certain other psychoactive drugs leads to serious physical withdrawal symptoms, discontinuation of heavy use of marijuana leads to few if any withdrawal symptoms in animals and humans. This is perhaps due in part to the slow elimination of marijuana's main psychoactive constituent Δ^9-tetrahydrocannabinol (Δ^9-THC). To test the hypothesis that rapid termination of interactions between Δ^9-THC and cannabinoid receptors would lead to withdrawal symptoms in tolerant animals, we precipitated withdrawal with the newly-developed competitive cannabinoid antagonist SR141716A. Tolerance to Δ^9-tetrahydrocannabinol (Δ^9-THC) was produced in rats by twice daily injections (15 mg/kg i.p.) for 6.5 days; a separate group of animals received the vehicle at the same times. One and 1/2 hours following the last injection, animals received an injection of the vehicle or SR141716A. This drug produced few effects in animals that had received previous injections of the vehicle only. By contrast, SR141716A induced a profound precipitated withdrawal syndrome in THC-tolerant animals. The syndrome was characterized by constantly changing brief sequences of behavior resulting in a hyperactive appearance but lacking the sequential organization which remains intact during the hyperactive state produced by psychostimulant drugs. The withdrawal syndrome began about 10 minutes after injection of the antagonist and last for one to two hours. THC-tolerant animals that were treated with vehicle remained quiet throughout the observation period. Administration of the antagonist i.c.v. to tolerant animals produced a milder withdrawal syndrome, suggesting that the site of action of the antagonist for the most profound behavioral changes lies outside the periventricular core of the brain. These findings demonstrate that following long-term use, rapid discontinuation of cannabinoid agonist/receptor interactions leads to profound withdrawal symptoms.

ELECTROPHYSIOLOGICAL EFFECTS OF A CANNABINOID ON NEURAL ACTIVITY IN THE GLOBUS PALLIDUS. A.S. Miller* and J.M. Walker. Schrier Research Laboratory, Department of Psychology, Brown University, Providence, RI 02912.

The high density of cannabinoid receptors in the globus pallidus and the motor effects of cannabinoids microinjected into the globus pallidus suggest that the globus pallidus might be an important site for the regulation of motor activity by cannabinoids. Extracellular single neuron electrophysiology was used to explore the role of cannabinoids on neural transmission in the globus pallidus. The synthetic cannabinoid WIN 55,212-2 (0.0625 - 0.5 mg/kg, i.v.) dose-dependently decreased the basal firing rate of neurons in the globus pallidus. This effect was not observed following administration of the inactive enantiomer, WIN 55,212-3. A second study examined the effect of WIN 55,212-2 on striatal-stimulation-evoked activity in the globus pallidus. Striatal stimulation produced a brief inhibition of neural activity in the globus pallidus. WIN 55,212-2, but not WIN 55,212-3, reversed the inhibition produced by striatal stimulation. The inhibitory effect of WIN 55,212-2 on the basal activity of neurons in the globus pallidus was apparent in the striatal stimulation study as well. These observations suggest that cannabinoids may produce two different effects on neural activity in the globus pallidus - inhibition of basal activity and a reversal of the inhibition produced by striatal stimulation.

749.6

EFFECT OF INTRANIGRAL ADMINISTRATION OF CANNABINOIDS UPON ROTATIONAL BEHAVIOR: INTERACTION WITH THE DOPAMINERGIC SYSTEM M. Clara Sañudo-Peña, Saundra L. Patrick*, Robert L. Patrick and J. Michael Walker. Schrier Research Laboratory, Departments of Psychology and Neuroscience, Brown University, Providence, RI 02912.

Cannabinoid receptors have been reported to be highly concentrated in brain areas involved in the control of movement, which is in accordance with their well known effects on motor behavior. One of the areas with the highest concentration of cannabinoid receptors is the substantia nigra, which is the output of the basal ganglia for movement production and therefore has been classically used for studying neurotransmitter function in rotational behavior. Cannabinoid receptors in this structure have been shown to be on the striatonigral afferents colocalized with D1 dopamine receptors. The aim of this work was to study the effect of cannabinoids on the rotational behavior induced by unilateral infusion of dopamine agonists into the rat substantia nigra pars reticulata. Cannabinoid compounds have little effect on rotation when injected intranigrally. However, they reduced the contralateral rotation induced by the dopaminergic agonists acting mainly through D1 receptors. These results are in accordance with the opposite action of cannabinoid and D1 receptors on second messengers and neurotransmitter release from striatonigral terminals.

BASAL GANGLIA: ANATOMY

D1 DOPAMINE RECEPTORS INFLUENCE FOS IMMUNOREACTIVITY IN THE GLOBUS PALLIDUS AND SUBTHALAMIC NUCLEUS OF INTACT AND 6-OHDA-LESIONED RATS. D.N. Ruskin* and J.F. Marshall, Dept. of Psychobiology, University of California, Irvine, 92717.

The globus pallidus (GP) and subthalamic nucleus (STN) are major nuclei of the basal ganglia. Studies of the dopaminergic physiology of these nuclei have typically emphasized the role of the D2 dopamine receptor. However, effects of D1 receptor activation on GP firing rate and STN metabolism have been reported, especially after nigrostriatal lesion. We have systematically investigated the effects of D1 and D2 receptor activation on the activity of the GP and STN in sham-lesioned and unilateral nigrostriatal 6-OHDA-lesioned rats using immunostaining of brain sections for the immediate-early gene Fos. 4-5 wks post-op, rats were drug-injected and perfused 2 hrs later. Brains were sectioned at 40μm and stained with an anti-Fos antibody, visualized with diaminobenzidine. In intact rats, the D1 agonist SKF 38393 (20 mg/kg) produced a five-fold potentiation of the GP Fos due to the D2 agonist quinpirole (0.5 mg/kg), while having no effect alone. In the STN of intact rats, only the combination of SKF 38393 and quinpirole produced significant Fos. In the lesioned hemisphere of 6-OHDA-lesioned rats, SKF 38393 increased the Fos immunostaining in both the GP and STN, while quinpirole increased it only in the GP. SKF 38393 effects in the GP and STN of 6-OHDA-lesioned rats were blocked completely by the D1 antagonist SCH 23390 and unaffected by the D2 antagonist eticlopride, confirming the specificity of the SKF 38393 effect for the D1 receptor. SKF 38393-induced GP Fos after 6-OHDA lesion may be due to increased input from the STN. An excitatory action of dopaminergic agonists on the STN is unexpected given present basal ganglia models, and it is uncertain what circuitry mediates this effect. These results are a novel demonstration of control of Fos expression by dopaminergic drugs in the STN and by D1 agonists in the GP.

750.2

DESCENDING PROJECTIONS OF THE GLOBUS PALLIDUS AND THE VENTRAL PALLIDUM IN THE RAT: CONVERGENCE OF FUNCTIONALLY DIFFERENT PATHWAYS ONTO INDIVIDUAL NEURONS IN THE BASAL GANGLIA. M.D. Bevan*, A.D. Smith and J.P. Bolam MRC Anatomical Neuropharmacology Unit & Department of Pharmacology, Mansfield Road, Oxford, OX1 3TH, U.K.

It has been proposed that one of the functions of the basal ganglia is to act as a site of integration of motor and limbic information. Although it is clear that there are multiple parallel pathways through the basal ganglia, it is not clear where, or indeed, if these pathways converge. In the present tracing and immunocytochemical study of the descending projections of the globus pallidus (GP; which receives sensorimotor-associational inputs) and the ventral pallidum (VP; which receives limbic input) we address this issue. Double anterograde tracing revealed that medial GP and VP innervated largely separate but to some extent overlapping regions of the entopeduncular nucleus/lateral hypothalamus (EP/LH), subthalamic nucleus/lateral hypothalamus (STN/LH) and the substantia nigra pars reticulata (SNr). The GP and VP also projected to the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA). In zones of overlapping termination, the somata of individual neurons were apposed by GP and VP boutons. Single anterograde tracing in combination with retrograde tracing or immunocytochemistry revealed that neurons in the STN/LH that projected to the substantia nigra were apposed by GP or VP boutons. In addition, the midbrain dopaminergic neurons (i.e. tyrosine hydroxylase-immunoreactive) and SNr output neurons (i.e. tyrosine hydroxylase-immunonegative) were apposed by GP or VP boutons. The synaptic organization underlying these patterns of innervation are currently being examined by correlated light and electron microscopy. This analysis indicates that individual neurons in SNr do indeed receive convergent synaptic input from anterogradely labelled GP and VP boutons. We therefore propose that while the basal ganglia clearly process cortical information arising from different functional regions in parallel, some convergence of information occurs at the level of individual neurons (funded by Wellcome Trust and MRC, U.K.)

EM MORPHOMETRY REVEALS THAT NEUROTENSIN IMMUNOREACTIVITY IS ELICITED IN DIFFERENT SUBPOPULATIONS OF STRIATAL AXONS FOLLOWING DOPAMINE D-2 RECEPTOR ANTAGONIST AND RESERPINE ADMINISTRATION. D.S. Zahm*, E.S. Williams and B. Senger. Dept. of Anat. and Neurobiol., Saint Louis Univ. School of Medicine, St. Louis, Missouri 63104.

Perikaryal neurotensin (NT) immunoreactivity (IR) is undetectable in normal rat striatum, but is elicited following administrations of dopamine D-2 receptor antagonists and reserpine in subpopulations of striatal neurons that differ in terms of sizes and distributions of NT-IR perikarya and fibers (Neurosci., 46:335-350, 1992, 57:649-660, '93 & 65:71-86, '95) and expression of the Fos immediate-early gene product (Neurosci. 57:649-660, '93 & 65:71-86, '95). Whether elicited by D-2 antagonists or reserpine, NT-IR neurons have been shown to project to the globus pallidus and ventral pallidum to the near exclusion of the substantia nigra/VTA complex (Soc. Neurosci Abstr. 19:129, 1993 & Brog and Zahm, unpublished). Rats were given either two injections (2 mg/kg) of haloperidol or eticlopride at four and twenty-four hours prior to sacrifice or a single injection of reserpine (5 mg/kg) twenty-four hours prior to sacrifice and killed by perfusion with buffered aldehydes. Frontal sections were processed for NT-IR and flat embedded for transmission electron microscopy. A random sampling method and computer-assisted morphometric analysis revealed NT-IR bouton profiles that are significantly smaller following reserpine than after haloperidol administration ($p < 0.001$, Mann-Whitney U test). Fewer NT-IR synaptic boutons were observed following haloperidol (1.6% vs 3.0%, $p < 0.012$, paired t-test), probably due in part to the lesser probability of section planes encountering synapses in larger terminals. Synapses were almost exclusively symmetric axodendritic. The EM data are consistent with morphologically distinct subpopulations of striatal neurons that express NT. Supported by USPHS NIH NS-23805 (NINDS).

750.4

REGULATION OF DOPAMINE D_1- AND D_2- RECEPTOR BINDING AND PEK mRNA LEVELS BY SELECTIVE DOPAMINE ANTAGONISTS IN THE BASAL GANGLIA OF THE RAT. A. E. Johnson*, H. Coirini, L. Källström, J. Yu and E.-A. Wiesel. Department of Psychiatry, University Hospital, Uppsala University, S-75017 Uppsala, Sweden.

Chronic treatment with classical neuroleptics affects a number of neurotransmitter systems in the basal ganglia. For example, we have shown that D_1-receptor binding in the EP is enhanced by exposure to a classical neuroleptic. Furthermore, increases in striatal PEK mRNA expression have been reported by several groups. However, the specific dopamine (DA) receptor subtype involved in the regulation of these processes remains to be determined. The purpose of the present study was to examine the regulation of D_1-receptor binding and PEK mRNA levels using selective dopaminergic antagonists. For these studies, adult rats were injected twice daily for 21 days with distilled water, SCH-23390 (0.3mg/kg), Raclopride (0.3mg/kg) or both Raclopride and SCH-23390 (N=6/group). Animals were killed 40hrs after the last injection and brain sections were processed for receptor autoradiographic and in situ hybridization studies. For receptor binding assays, sections were labeled with either [^{125}I]SCH-23982 (D_1) or [^{125}I]NCQ-298 (D_2). An oligonucleotide probe selective for PEK mRNA was used for in situ hybridization experiments. Autoradiographic analysis revealed that Raclopride slightly but significantly increased [^{125}I]NCQ-298 binding in the STR (10%), subthalamic nucleus (16%) and substantia nigra compacta (12%), whereas SCH-23390 significantly enhanced [^{125}I]SCH-23982 binding in the EP (43%), STR (17%) and substantia nigra reticulata (32%). Striatal PEK mRNA levels were significantly elevated by Raclopride (16%), SCH-23390 (41%) and by the combination of Raclopride and SCH-23390 (62%). Two-way ANOVA of the PEK mRNA data revealed that Raclopride and SCH-23390 enhance PEK mRNA expression through separate mechanisms. Supported by grant #8318 and #11274 from the Swedish MRC.

RAPID EFFECTS OF INTRASTRIATAL QUINOLINIC ACID INJECTIONS ON PALLIDAL ENKEPHALIN, SUBSTANCE P AND GAD-67 IMMUNOREACTIVITY IN RATS. Y. Bordelon* and M-F Chesselet
Department of Pharmacology, U. of Penn, Philadelphia, PA 19104.

Intrastriatal injections of quinolinic acid (QA), an NMDA receptor agonist, produce a loss of medium spiny projection neurons (which contain glutamic acid decarboxylase, and either enkephalin or substance P), and sparing of interneurons. Hence, they replicate the neurodegeneration found in Huntington's disease. We have previously shown that DNA strand breaks are present in striatal neurons in HD and after QA injections. DNA damage was detected 12, but not 10 hours after QA injections. Expression of met-enkephalin (ENK), substance P (SubP) and glutamic acid decarboxylase (Mr 67,000: GAD67), was examined with immunohistochemistry in striatal projection areas before and after DNA damage is evident in the striatum.

Male Sprague Dawley rats (250-300 gms) received a unilateral injection of QA (60 nmol in 0.5 µl) or saline over 5 min. in the striatum. This procedure induces a massive loss of striatal efferent neurons 2 weeks later (Qin et al. Exp. Neurol. 115, 1992,200-211). Rats were sacrificed 10 or 12 hrs after surgery by transcardial perfusion with 4% paraformaldehyde under deep anesthesia. Sections were processed for immunohistochemistry with avidin-biotin-peroxidase and diaminobenzidine-HCl as the chromogen. None of the rats sacrificed 10 hrs after QA injection in the striatum showed conspicuous changes in ENK immunoreactivity (IR) in the ipsilateral globus pallidus (GP). In contrast, a marked decrease in ENK IR was already observed in some of the rats sacrificed 12 hrs after QA injection. In these same animals GAD 67 IR in the GP and SP IR in the entopeduncular nucleus were also decreased. Thus, intrastriatal QA induces a rapid decrease in GAD and neuropeptide expression in axons of striatal efferent neurons, which appears to coincide with the onset of detectable DNA damage in their cell bodies. EXPRESSION OF ONCOGENE C-FOS PROTEIN IN THE MARGINAL DIVISION OF THE STRIATUM AND MEYNERT'S BASAL NUCLEUS FOLLOWING CHEMICAL INJURY OF THE RAT BRAIN. S.Y. Shu*, X. Bao and S. Li. Dept of Neurobiology, First Military Med. Univ., Zhu-Jiang Hospit. Guangzhou, 510282, China.

c-Fos induction can occur as a consequence of synaptic activation. This has led to the proposal that c-Fos immunohistochemistry might be used to map functional pathways in the CNS. In our previous study, a new subdivision, the marginal division (MrD), was found in the striatum and it projects to the area of Meynert's basal nucleus. The depression of the learning and memory behavior would be induced by injury of MrD. In the present study, the functional relationship of MrD and Meynert's basal nucleus was investigated by injection of Kainic acid (KA) in the MrD and Meynert's basal nucleus to induce c-Fos-like protein expression in the rat brain. 0.1-0.2% KA was injected in the brain with a stereotaxic instrument.
The rat was perfused 6-8 hours after injection. The brain was removed and sectioned. The sections were processed with c-Fos immunohistochemistry method. The results are: 1) Positive c-Fos protein expression was found in the amygdala and hippocampus after KA injecting in the Meynert's nucleus. The result showed that KA acid injury could induce c-Fos expression to show functional connections in the brain; 2) Positive c-Fos expression was observed in the MrD following KA injecting in the Meynert's nucleus; 3) Positive expression of c-Fos was found in the Meynert's nucleus by injection of KA in the MrD. The results indicate that there are functional connections between the MrD and the Meynert's basal nucleus. This relationship probably sponsors the learning and memory function of the MrD.(supported by NSFC 39270248)

VENTRAL MESENCEPHALIC NEURONS RETROGRADELY LABELED WITH WGA-HRPapoGOLD OR FLUORO-GOLD FOLLOWING INJECTIONS IN THE SHELL, CORE AND ROSTRAL POLE OF THE NUCLEUS ACCUMBENS: IMMUNOHISTOCHEMICAL AND MORPHOMETRIC ANALYSIS Y. Tan, J.S. Brog*, E.S. Williams and D.S. Zahm. Dept. of Anatomy and Neurobiology, Saint Louis University School of Medicine, St. Louis, Missouri 63104.

The mesotelencephalic projection comprises a morphologically and neurochemically heterogeneous population of axons. Ventral mesencephalic dopamine (DA) neurons exhibit several distinct types of somatodendritic morphology. Some studies have concluded that certain morphologically distinct dopaminergic cell types are associated with topographically and morphologically specialized axon projections. In the present study, either WGA-HRPapoGOLD or Fluoro-Gold (FG) were used to retrogradely label neurons in the ventral mesencephalon following injections that were relatively restricted to the core, shell or rostral pole of the nucleus accumbens. Retrogradely labeled neurons were evaluated for calbindin immunoreactivity, perikaryon diameter and labeled dendrite length. Following all injections except those in medial shell, calbindin D-28kD immunoreactivity was colocalized in a subset of retrogradely labeled neurons. Mean perikaryon diameter of FG labeled neurons was significantly less following injections in the medial shell than after injections in the core and rostral pole. Likewise, the median length of FG-labeled dendrites was significantly less following injections in the medial shell than following injections in the core and rostral pole. One hundred neurons from each of three cases for each subterritory were evaluated with a randomized ANOVA and post-hoc Tukey's protected T test. The data are consistent with a small to moderate component of midbrain DA/calbindin projections to core-rostral pole and a morphologically distinct population of DA neurons projecting to medial shell. NIH NS-23805 (NINDS).

FOCAL 6-HYDROXYDOPAMINE LESIONS IN NUCLEUS ACCUMBENS CORE AND SHELL ENHANCE FOS IMMUNOREACTIVITY PREFERENTIALLY IN TERMINAL REGIONS OF THE DOPAMINERGIC MESOTELENCEPHALIC PROJECTION. M.A. Chapman* and D.S. Zahm. Dept. of Anatomy and Neurobiology, Saint Louis University School of Medicine, St. Louis, Missouri 63104.

The nucleus accumbens (Acb) has been designated as a critical site of sensory-limbic-motor interface, neuroanatomically situated to mediate behaviors essential to the organism's survival. The Acb may be divided into subterritories based on neurochemical, morphological and hodological properties. Given the importance of this structure in theories of drug dependence and schizophrenia, it is critical to determine whether the different connectivity patterns of Acb subterritories are functionally relevant. In order to address this question, 6-hydroxydopamine microinjections were made in the Acb core or shell of male Sprague-Dawley rats. The lesion sizes and locations were precisely evaluated using tyrosine hydroxylase immunohistochemistry and Fos expression was assessed immunohistochemically at several post-lesion time points. Preliminary evaluation of the material revealed a robust enhancement of Fos immunoreactivity bilaterally in the medial prefrontal, insular and piriform cortices, septum, Acb and medial caudate-putamen of lesioned animals as compared to ascorbate vehicle and saline controls. Control animals exhibited moderate numbers of Fos-IR cells in the same brain regions; therefore, the numbers of Fos-positive cells will be quantified and statistically compared. Insofar as all of these areas receive mesotelencephalic dopamine input from ventral mesencephalic neurons within the projection field of the Acb, it is hypothesized that Fos immunoreactive neurons are disinhibited following focal Acb lesions through increased inhibition of midbrain dopamine neurons. Supported by USPHS NIH NS-23805 and NS-07254 (NINDS).

750.9

METHYLPHENIDATE TREATMENT AND GENE EXPRESSION IN THE VENTRAL TEGMENTAL AREA, SUBSTANTIA NIGRA, NUCLEUS ACCUMBENS AND STRIATUM IN RATS. M. Mercugliano*,H.Q. Nguyen, A. Cnaan. Children's Seashore House & Departments of Pediatrics and Biostatistics, University of Pennsylvania, Philadelphia, PA. 19104.

Methylphenidate (MPH) is a dopamine re-uptake blocker with effects on mesolimbic and mesostriatal dopamine (DA) systems. To identify neuronal subgroups involved in MPH effects, *in situ* hybridization histochemistry was performed after acute (at 7 wks) or chronic ip treatment (twice daily, 4-7 wks) with saline, low- (1.25 mg/kg) or high-dose (12.5 mg/kg) MPH. mRNA labelling for TH, GAD_{67} and DA_2 receptors were quantified at the single cell level in the VTA and SN, and GAD_{67}, DA_1 and DA_2 receptors and PPE regionally in the NA and STR. Locomotor activity, stereotypy and rearing were measured on days 1, 7, 14 and 21. After acute treatment, all behaviors were increased in the high-dose group ($p's \leq 0.005$) and there were no changes in mRNA labelling. With chronic treament, activity was highest in the high-dose group ($p = 0.0005$), and effects were largest on day 1 ($p's \leq 0.004$) . Stereotypy showed dose-dependent increases ($p < 0.00005$) without time effects. Rearing was increased in the high-dose group ($p = 0.0006$), with marginal effects on day 21. Chronic treatment with either dose resulted in increased TH labelling in the VTA and SNC ($p's \leq 0.05$). High-dose treatment resulted in increased labelling for PPE in the STR ($p < 0.01$). Mazindol binding was unchanged suggesting that this was not due to loss of DA terminals. Chronic MPH treatment alters gene expression in VTA and SNC DA neurons and STR efferent neurons which express PPE. Supported by Tourette Syndrome Association, HD28815 and HD26979.

THE DISTRIBUTION OF MU OPIOID RECEPTORS DEFINES THE CORE AND SHELL OF THE HUMAN NUCLEUS ACCUMBENS.

P.Voorn*[1,3], L.S.Brady[2], H.W.Berendse[1,3], H.E. Vonkeman[1,3], and E.K.Richfield[3,4]. [1]Research Inst. Neurosci., Depts Anat. & Neurol., Vrije Univ., Amsterdam, the Netherlands, [2]NIMH, Bethesda, MD 20892, [3,4]Dept. [3]Neurol. [4]Pharmacol., Univ. Rochester, Rochester, NY 14642.

Selective mu opioid receptor autoradiography with [^{3}H]DAMGO was used to examine regional and subregional mu receptor distribution patterns at five rostrocaudal levels through the human striatum. [^{3}H]DAMGO binding densities were measured in the individual striatal nuclei and in subregions. The distribution of [^{3}H]DAMGO binding sites has a strongly heterogeneous character. At the regional level a U-shaped distribution of density values was observed along the rostrocaudal axis, with highest values in the rostral- and caudalmost levels. Furthermore, a dorsal-to-ventral high-to-low gradient was found, with lowest binding densities in the ventral one-third of the Putamen (Put) and in nucleus accumbens (Acb). Binding in Caudate (Cd) and Put did not show a patch-matrix-like pattern as in the rodent. In the Acb, areas of low, intermediate and extremely high binding density were present. Comparison with ligand binding patterns of other receptors, e.g. the kappa opioid receptor labeled with [^{3}H]bremazocine, indicated that the low-density area represents the "core" region of the Acb, whereas the "shell" is characterized by intermediate density. Along the ventral periphery of the Acb and Put, a string of smaller regions were found that displayed the highest binding values of the entire striatum for [^{3}H]DAMGO. These regions could also be recognized in the distribution of the kappa opioid and dopamine D_1 receptors and in the cyto- and myeloarchitecture of the Acb. Because of these special features they are referred to by the acronym NUDAP: Neurochemically Unique Domains of the Accumbens and Putamen.

LOCALIZATION OF 5-HT2a RECEPTOR mRNA IN OPIOID NEURONS OF THE VENTRAL STRIATUM IN THE RAT. M.J. Mijnster, K. Koskuba, G.J. Docter, L.D. Loopuijt* and P. Voorn. Graduate School Neurosciences, Vrije Universiteit, Dept. of Anatomy, Amsterdam, the Netherlands.

The serotonin 5-HT2a receptor may be involved in the regulation of the opioid peptide dynorphin in the ventral striatum, as is suggested by changes in preprodynorphin (ppdyn) mRNA after a lesion of the serotonergic system. On the other hand, enkephalin synthesis does not seem to be affected by a serotonergic lesion as there is no change in preproenkephalin (ppenk) mRNA levels. We set out to investigate whether there is an anatomical basis for these different responses of opioid neurons. Double-labeling *in situ* hybridisation experiments were performed to demonstrate 5-HT2a and ppenk/ppdyn mRNA in the same sections. 5-HT2a mRNA was visualised with a ^{35}S-labeled riboprobe, whereas a digoxygenin-labelled riboprobe was used to demonstrate ppenk/ppdyn mRNA. Opioid neurons were identified and overlying grains generated by the radioactive probe were counted with an IBAS image analysis system. Our results demonstrate that 5-HT2a mRNA is localized in both enkephalinergic and dynorphinergic cells. In different subregions of the ventral striatum (medial shell, core, olfactory tubercle), 40-45% of the enkephalin neurons contain detectable levels of 5-HT2a mRNA. However, in the lateral shell the percentage of co-localisation is significantly higher (60%) than in the other subregions. Our results further indicate that 35-45% of the dynorphin cell population in the core and medial/lateral shell synthesizes the 5-HT2a receptor. In the olfactory tubercle, there is a significantly higher degree of co-localization (65%) compared to the other ventral striatal regions. On the basis of these data, we would suggest that 5-HT2a receptor manipulation can directly affect subpopulations of both types of opioid output-neurons. The magnitude of the effect of 5-HT2a receptor manipulation might differ between subregions of the ventral striatum.

750.12

CELLULAR LOCALIZATION OF D1 AND D2 DOPAMINE RECEPTOR mRNA IN THE ACCUMBAL-PALLIDAL AND ACCUMBAL-VENTRAL TEGMENTAL AREA PATHWAYS IN THE RAT X.-Y. Lu, L. Churchill and P. W. Kalivas* Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA.

The involvement of the ventral pallidum in mediating motor activity is thought to arise via afferent projections from the nucleus accumbens which in turn receives the dopaminergic input from mesencephalon. Two major families of dopamine receptors have been characterized in the central nervous system and designated D1 and D2 dopamine receptor subtypes. Using retrograde labeling methods combined with in situ hybridization, this study examined the postsynaptic distribution of accumbal D1 and D2 dopamine receptors following deposits of Fluoro-gold in the ventral pallidum (VP) and ventral tegmental area (VTA). The data indicated that the portion of retrogradely labeled neurons with Fluoro-Gold deposits in the VP that contained messenger RNA for D2 dopamine receptor was 19%-37% in the shell, 19%-30% in the core of nucleus accumbens, whereas 40%-67% and 50%-73% were double-labeled neurons for D2 receptor messenger RNA in the shell and core subcompartments, respectively. Preliminary evidence also showed double-labeled neurons with Fluoro-Gold deposits in VTA for D1 receptor messenger RNA ranged from 64% to 100% along a caudal-rostral gradient. These data demonstrate that both D1 and D2 receptors, predominantly D2 receptors, exist in the pathway from the nucleus accumbens to ventral pallidum, suggesting D1 and/or D2 receptors on accumbal neurons may directly modulate neurotransmitter release in the ventral pallidum, alter the firing frequency of pallidal neurons, and subsequently affect locomotor activity. This study also reveal that most accumbal neurons projecting to VTA contain D1 receptor messenger RNA. This suggests that dopamine release may act on D1 receptors in the nucleus accumbens to regulate the activity of dopamine cells in the VTA.

Lithium induces c-fos expression selectively in the "hippocampal district" of limbic striatum. **A. Jayaraman *, H. Kiba and M. Cola. Dept. of Neurology, LSU Sch. of Med. New Orleans, LA 70112.**

Lithium is the most effective agent for the treatment of manic depressive disorder. The forebrain dopaminergic system, among others, has been suggested to play a major role in acute manias. To identify the neuronal circuitry that is responsive to lithium, we mapped lithium induced Fos expression in the forebrain. Injections of lithium chloride induced Fos expression selectively in the "hippocampal district" of the accumbens, but not in rest of striatum. Numerous Fos positive neurons were noted in the hippocampal CA1, CA2 regions, cingulate, prelimbic, infralimbic, agranular insular and pyriform cortex, but only a few Fos positive cells were noted in deep layers of many cortical areas. Fos reactive cells were restricted to the midline and intralaminar nuclei of thalamus. Cells with Fos-Li were conspicuously absent in VTA & substantia nigra complex. The results suggest that the hippocampal district of accumbens & hippocampal and thalamic regions that converge on to this specific area of limbic striatum may mediate lithium induced benefits on acute & recurrent manic attacks. **Supported by Smokeless Tobacco Research Council, NY & Department of Defense.**

TO WHAT EXTENT IS THE BASAL GANGLIA ORGANIZATION OF ANURAN AMPHIBIANS COMPARABLE TO THAT OF AMNIOTES? W.J.A.J. Smeets*[1], O. Marín[2] and A. González[2]. [1]Graduate Sch. Neurosci., Dept. Anatomy & Embryology, Vrije Univ., Amsterdam, The Netherlands. [2]Dept. Cell Biology, Univ. Complutense, Madrid, Spain.

Recent studies have revealed that there are many similarities in the organization of the basal ganglia (BG) between reptiles, birds, and mammals. The intriguing question raises, therefore, whether this basic organization exists also in anamniotes. In amphibians, not only a dopaminergic (DA) cell group in the midbrain, but also distinct plexuses of DA fibers in the ventromedial (accumbens) and ventrolateral (striatum) wall of the telencephalic hemisphere have been identified. In contrast to amniotes, the midbrain DA cell group of amphibians is rostral continuous with DA cells in the dorsomedial part of the posterior tubercle (TPm), and does not extend caudal to the oculomotor nerve. It is also impossible to recognize separate A8-A10 cell groups, indicating a putatively different organization of BG in amphibians. To get more insight into the organization of the DA mesotelencephalic connections, combined tract-tracing/immunohistochemical techniques have been used. Retrograde tracers (biotinylated dextran amine or Texas-Red conjugated dextran amine) were applied to the basal forebrain of anurans (*Rana perezi*, *Xenopus laevis*). As marker for DA cells, we have used tyrosine hydroxylase (TH) immunohistochemistry. Experiments involving the accumbens yielded some double labeled cells in the TPm and, more frequently, in the midbrain tegmentum. Involvement of the striatum, on the contrary, resulted in many double labeled cells in the TPm at intermediate levels, but not in the midbrain. Thus, the nucleus accumbens and the striatum of anurans receive topographically organized DA inputs which, however, display a preferential caudal-to-rostral, instead of a medial-to-lateral arrangement as demonstrated for amniotes. ASTROCYTIC GLUTAMATE AND DOPAMINE RECEPTOR SUBTYPE CO-LOCALIZATION IN THE RAT SUBSTANTIA NIGRA. A.Mateescu-Cantuniari, J.W. Patrickson, K.H. Thomas, J.A. Whittaker.*
Department of Anatomy, Morehouse School of Medicine,Atlanta,GA,30310.

Abnormalities in CNS dopaminergic neurotransmission has been hypothesized to be related to possible excitotoxic actions of excitatory amino acids (EAA). There is increasing evidence that astrocytes may have a functional role in EAA-mediated brain injury and, as well, may mediate their phenotypic expression. Electrophysiological studies have indicated direct signaling between astrocytes and neurons suggesting the possibility of an astrocytic involvement in nigral degeneration and related disease etiology.[1] We have previously localized glutamate and dopamine receptor subtypes within the rat substantia nigra (SNc). This study was designed to further investigate these receptor subtype distributions and their relationships to astroglia within the pars compacta of the rat SNc. Using immunolabelling techniques, we studied D2/3, GluR2/3, NMDAR1, and NMDAR 2A/B receptor subtype expressions, in the adult rat brain. Commercially available primary antibodies (Chemicon; Sigma) directed against the respective receptor subunits and against the astrocytic marker, GFAP, were used in this study. FITC labeled GluR2/3, D2/3, NMDAR1 and NMDAR 2A/B receptor immunoreactivity was observed in a heterogenous pattern throughout the SNc in close association with GFAP/Rhodamine labeled astrocytes. Our results suggest DA and glutamate receptor subtypes are co-localized in the cytoplasmic compartment of SNc astrocytes.

APOMORPHINE TRANSIENTLY REDUCES SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE SUBSTANTIA NIGRA IN 6-OHDA RATS. S Gancher*, A Mayer, S Youngman. Department of Neurology, Oregon Health Science University, Portland, Oregon, 97222.

Substance P is a peptide which is contained in striatonigral neurons and present in high amounts in the SN. Lesioning and repeated drug treatment affect nigral substance P content; 6-OHDA lesioning reduces nigral substance P levels and daily L-DOPA treatment reverses this decrease. In the current study, we wished to determine if acute drug treatment also differentially affects substance P content in the lesioned SN. Eight rats with 6-OHDA lesions received 8 daily doses of apomorphine (0.1 mg/kg), a regimen which produced behavioral sensitization. The next day, four 3.2 mg/kg apomorphine doses were administered at 2 h intervals, a regimen which produced tolerance. Four rats were perfused 1-2 h later; the other four were perfused 1 week later. The density of substance P-like immunoreactivity (SPLI) in the SN on the 6-OHDA and normal side were compared by image analysis. In the acutely treated rats, the SPLI in the lesioned SN was reduced relative to the other side, whereas the rats untreated for 1 week after drug treatment exhibited symmetric staining. These findings suggest that administration of a dopamine agonist temporarily reduces substance P levels in the SN ipsilateral to a 6-OHDA lesion, possibly reflecting an increase in striatonigral neurotransmission from the dopamine-depleted striatum. The observation that acute and chronic treatment produce different behavioral effects and corresponding changes in nigral substance P levels suggests that substance P may have a modulatory role in affecting dopaminergic response in animals with nigrostriatal lesions.

FUNCTIONALLY AND ANATOMICALLY DISTINCT DOPAMINE SYSTEMS IN THE MEDIAL PREFRONTAL CORTEX: AN APPRAISAL. A. Y. Deutch,* Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT and Veterans Administration Medical Center, West Haven, CT 06516.

Several cortical regions in the rat receive dopamine (DA) innervations, the most prominent of these being the medial prefrontal cortex (PFC). DA projections to the PFC are derived from cells in the ventral tegmental area (VTA). The mesoprefrontal cortical DA innervation has been considered to be a functionally homogeneous DA innervation. However, the DA innervation of the rodent PFC appears to be homologous to several spatially distinct in the primate that have different functional attributes. We have recently observed that several DA innervations of the PFC in the rat can be anatomically, biochemically, and molecularly distinguished, and that these different DA innervations respond different to different challenges, including mild stressors and antipsychotic drugs.

We propose that there are several different DA innervations of the PFC in the rat that follow in part cytoarchitectonically-defined regions, that these different DA innervations of PFC regions are derived DA neurons in different subnuclei of the VTA, and that various challenges activate both a DA innervation of a particular part of the PFC (e.g., the infralimbic or dorsal prelimbic cortex) and concomitantly a particular cluster of midbrain DA neurons. CEREBELLUM: PHYSIOLOGY

751.1

THE CEREBELLAR GAIN CHANGE HYPOTHESIS EVALUATED IN THE ANESTHETIZED RABBIT P.L. DiGiorgi, C.I. De Zeeuw, S.K.E. Koekkoek, and J.I. Simpson*. Dept. Physiology and Neuroscience, NYU Med. Ctr., NY, NY 10016

The gain change hypothesis proposed by Ebner and Bloedel states that the climbing fiber input to a Purkinje cell (P-cell) produces a short-lasting enhancement of its responsiveness to mossy fiber inputs. We examined the simple spike (SS) activity patterns that followed the complex spike (CS) of floccular P-cells in ketamine-xylazine-acepromazine anesthetized rabbits. We recorded from 43 P-cells whose CSs were modulated by optokinetic stimulation (OKS). Three conditions were investigated: spontaneous activity in light and dark and constant speed OKS. Data analysis included CS-SS cross-correlation and SS auto-correlation. P-cells were assigned to one of three categories: pure pause (PP), pause-facilitation (PF), or pause-reduction (PR). To be categorized as a PF (or a PR) cell, the average SS activity during at least one 20 msec period within the first 50 msec after the end of the CS pause had to be significantly ($P<0.01$) greater (or less) than the average SS activity during the 100 msec prior to the CS. Of the 43 P-cells, 26 (60%) were PF cells, 9 (21%) were PR cells, and 8 (19%) were PP cells. The categorization distribution was condition independent (Fisher exact test). For about 80% of the cells, the SS auto-correlograms showed a pronounced, exponentially damped oscillation (range, 25-100Hz), also condition independent. In comparison to findings in the awake rabbit (Simpson, Wylie and De Zeeuw, submitted), the percentage of P-cells showing enhancement of responsiveness to mossy fiber inputs doubled and the SS rhythmicity markedly increased. Thus, ketamine-xylazine-acepromazine anesthesia promotes enhancement and SS rhythmicity. (Supported by NS-13742).

ANALYSIS OF CA^{2+} SPIKE AUTORHYTHMICITY IN CEREBELLAR PURKINJE CELLS. Y. Etzion * and Y. Grossman. Department of Physiology, Faculty of health Sciences, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel.

Spontaneous Ca^{2+} spike activity in cerebellar Purkinje cells is characterized by a regular alternation between bursting and quiescence periods and a propensity for firing in doublets. We studied the underlying mechanisms of this behavior in guinea pig cerebellar slices. Slices were constantly perfused with 5mM KCl Ringer's solution equilibrated with 95% O_2, 5% CO_2 at 30°C. Spontaneous Ca^{2+} spike currents were recorded by using a macropatch clamp technique before and after blocking sodium currents with 0.5μM TTX. TTX significantly increased active period duration to 149.5±44.9% (mean ±SD, n=14), silent period duration to 142.1±53.8% and the mean inter spike interval (ISI) to 150.9±63.4% but did not change doublet spiking. Application of CNQX (10μM) and Bicuculline (20μM) did not mimic TTX effects. Heating to 33°C enhanced doublet firing, while cooling to 28°C markedly increased mean ISI and almost abolished doublet spiking. Increasing $[K^+]_o$ to 7.5mM, addition of 4-AP (1μM), or TEA (0.1mM) greatly increased doublet spiking and could counteract the effect of cooling. Whereas, reducing $[K^+]_o$ to 3mM, like cooling, almost abolished doublet spiking. The ISI within doublets changed gradually by these manipulations from few ms to approximately 40 ms. These results indicate : a) Invasion of somatic Na^+ spikes may affect dendritic Ca^{2+} spike autorhythmicity. b) Existence of a highly 4-AP sensitive K^+ current which reduces doublet spiking. c) The range of modulation of ISI within doublets can not be attributed to spike propagation between two zones of the dendritic tree, and therefore support the notion of a single site for doublet generation.

Oscillatory activity at 14-16 Hz in the cerebellar cortex. Relationship with movement initiation in the behaving monkey. J-P Pellerin,C.Valiquette,M-T.Parent,Y.Lamarre*. Centre de recherche en sciences neurologiques, Université de Montréal.

A monkey was trained to move the arm about 1 sec. following an auditory stimulus. In the paramedian lobule of the cerebellum we recorded rhythmic bursting of thin, small spikes at the frequency of 14-16 Hz. The amplitude of local field potential oscillations at the same frequency was maximal in the granular layer and Purkinje cell activity recorded in adjacent layers was not modulated at that frequency. So far we have been able to establish the following properties of this oscillatory process:**1.** It is very much decreased during reduced state of vigilance and after administration of harmaline;**2.** it is reduced and disorganized some 150-250 ms after the external cue, resumes 200-250 ms later and stops abruptly at about movement onset;**3.** the oscillations are enhanced in the 400-500 ms period preceding movement onset. This is not observed with spontaneous movement;**4.** olivo-cerebellar activity tends to increase 150-250 ms after the external cue at a time where the rythmic process appears to be reset. More investigations are needed to establish the functional role of this oscillatory process which could be involved in the precise timing of movement onset in response to external events. Supported by MRC of Canada.

CEREBELLAR GRANULE CELL RESPONSES IN THE AWAKE, FREELY-MOVING RAT: THE IMPORTANCE OF TACTILE INPUT. M.J. Hartmann* and J.M. Bower, Division of Biology, Caltech, Pasadena, CA, 91125.

Using a light-weight microdrive developed in our lab, we have recorded activity of the cerebellar granule cell layer (GCL) from multiple sites in Crus IIa in awake, freely-moving rats. We have previously shown that in the anesthetized animal, cells in this region of the cerebellum respond to light touch of perioral structures. During chronic electrode implantation we determined the receptive field at each recording site, and we later confirmed these fields in the awake rat. Behaviors were videotaped and synchronized with the recorded neural signals.

We compared the spatio-temporal patterns of GCL activation during eating, grooming, drinking, and exploratory behaviors. Each behavior elicited unique and repeatable patterns of neural activity. For the observed behaviors, activity recorded on each electrode was largest when the rat's own movements resulted in tactile stimulation of the appropriate perioral receptive field. In contrast, activity remained close to background levels during perioral behaviors that did not directly stimulate the receptive field. For example, substantial GCL activity was observed when the rat palpated food with its lips, while chewing motions elicited little or no response.

During the highly rhythmic and repeatable sequences of rat drinking, each lick elicited two distinct bursts of granule cell activity. Analysis of the video-tape data suggested that these bursts were related to tongue protrusion and retraction past the perioral receptive fields. During some drinking sequences, rats received an air-puff stimulus to perioral regions; when the stimulus was directed towards a receptive field, large responses superimposed on the rhythmic activity associated with licking. We conclude that GCL responses in crus IIa of behaving rats seem to be most directly related to tactile stimulation of perioral surfaces.

FUNCTIONAL ORGANIZATION OF THE RAT CEREBELLAR CORTEX ELUCIDATED BY PRINCIPAL COMPONENT ANALYSIS OF OPTICAL SIGNALS C. Hanson, Q.-G Fu*, G. Chen, T.J. Ebner Departments of Neurosurgery and Physiology, University of Minnesota Medical School, Minneapolis, Minnesota 55455

The highly regular cellular lattice and circuitry of the cerebellar cortex and its afferent and efferent systems are organized around several spatial plans. Optical imaging is one approach used to record the patterns of activity in the cerebellar cortex. In this study, we used principal component analysis (PCA) to extract spatial patterns of activity from optical images of rat cerebellar cortex under conditions of peripheral or surface stimulation.

Optical signals from stimulus evoked fluorescence changes in cerebellar cortical area Crus II were recorded with a CCD camera in anesthetized rats (ketamine / xylazine). The cortex was stained by superfusion (2.5mg/ml) and intravenous injection (10mg/ml) of the pH sensitive dye neutral red. Stimuli consisted of direct cortical stimulation to evoke responses from parallel fibers or bipolar electrical stimulation of the face.

Principal component analysis of the images obtained with direct surface stimulation showed a clear medial-lateral band of activity consistent with activation of a band of parallel fibers. The PCA analysis extracted parasagittal bands in Crus II from stimulation of the ipsilateral face. In both cases these patterns were derived from the first few principal components (ie. those accounting for a large majority of the variance). These patterns are consistent with those obtained from simple frame averaging then subtraction of control images from stimulation images. The results also suggest that principal component analysis provides the additional power to extract other features of the image, such as the vasculature. This approach offers the potential to not only separate out the various contributions to the total fluorescence change but to quantitize them precisely. Supported by NIH Grants PO1 NS31318 and T32 GM08471

OPTICAL IMAGING OF THE PARASAGITTAL ORGANIZATION IN THE RAT CEREBELLAR CORTEX *IN VIVO* USING THE PH SENSITIVE DYE NEUTRAL RED. G. Chen, C. Hanson, T.J. Ebner*. Departments of Neurosurgery and Physiology, University of Minnesota Medical School, Minneapolis, Minnesota 55455.

A prominent organizational feature of the cerebellar cortex is that some of its afferent and efferent projections are organized into parasagittal zones. In this study we used optical imaging techniques to demonstrate that stimulation of the face activates parasagittal zones in the rat cerebellar cortex *in vivo*.

Crus II was exposed in anesthetized rats (ketamine/xylazine) and stained with the pH sensitive dye, neutral red (2.5mg/ml), by superfusion for 2-3 hours. Staining was supplemented by intravenous administration of 1ml (10mg/ml) neutral red delivered over one hour. After washout, Crus II was imaged (100ms exposure, excitation at 540nm, emission>620nm) with a cooled CCD camera. A series of images was acquired before, during, and after ipsilateral bipolar stimulation of the face (500μs, 5Hz, 10-20s). Subtraction of prestimulation control images from each image obtained after stimulation yielded a spatial and temporal map of the pattern of activation in the cerebellar cortex. The most striking feature of the optical responses was the presence of 3-5 parasagittal zones of increased fluorescence. These zones spanned both Crus IIa and IIb and were 100-500μ in width. The optical response was abolished by TTX and reduced by CNQX. The time course of the optical response peaked after stimulation ended and had a duration of 30 to 120 seconds. The size of the optical signals were as large as 3-4% change in background fluorescence, and the signals were obtainable for up to four hours after staining. Previous work suggests that these optical signals reflect shifts in intracellular pH due to neuronal activity.

These observations are the first optical demonstration of the activation of parasagittal zones in the cerebellar cortex in response to peripheral stimuli. Supported by NIH Grants PO1 NS31318 and T32 GM08471.

RELATIONS BETWEEN PURKINJE CELL SIMPLE SPIKE ACTIVITY AND MOVEMENT VELOCITY AND POSITION IN MONKEYS USING A NOVEL, TWO-DIMENSIONAL TRACKING TASK. J. D. Coltz* and T. J. Ebner, Graduate Program in Neuroscience and Depts. of Neurosurgery and Physiology, University of Minnesota, Minneapolis, MN 55455.

Previous electrophysiological studies of cerebellar Purkinje cells in our laboratory (Fu et al., 1994) found a significant correlation of simple spike discharge with the movement parameters direction, distance, and target position. However, the variance in cell discharge accounted for by these parameters was moderate, suggesting that other variables are needed to describe more fully the activity of these cells. The present study employed a novel, two-dimensional visuomotor task that required monkeys to track moving targets at 5 different velocities, reaching from a centrally located start position to endpoints in 8 different directions. The velocity profiles of these moving targets were bell-shaped, and the peak velocities ranged from 2 to 6 cm/sec. Single trial analyses of the Purkinje cell simple spike discharge utilized a multiple regression model in which the temporal profile of the cell discharge was fitted to the profiles for hand position, velocity, and acceleration. The overall R^2 for all cells was greater than that obtained in the earlier study, having a mean ± s.d. of 0.42 ± 0.12. The relative contributions of each of the parameters were quantified by calculating partial R^2 values. Velocity information contributed more to the overall strength of the model than did position or acceleration information in 19 of 30 cells. In 11 of 30 cells, position information contributed more than that about velocity or acceleration. These preliminary findings indicate that movement velocity and position are important correlates of simple spike activity in the primate cerebellum. Supported by NIH grants NS 18338 and NS 31530.

ESTRADIOL FACILITATES SYNCHRONIZED OLIVARY OSCILLATIONS DURING WHISKER MOVEMENT IN THE RAT INDEPENDENT OF INPUT FROM THE PRINCIPAL TRIGEMINAL NUCLEUS (PrV) OR THE SPINAL NUCLEUS OF V (SpV). R.L. Markowitz, J.K. Chapin, T.M. Fisher and S.S. Smith*Dept. of Anatomy and Neurobiology, MCP/Hahnemann Univ., Phila., PA.

Ongoing studies from this lab have demonstrated that 17β-estradiol (E_2), administered systemically at physiological doses or locally via an indwelling cannula, enhances synchronized, rhythmic discharge of neurons within the rostral dorsal accessory olive (rDAO) during rapid movement of the limbs. This effect is consistent with reports suggesting that increases in circulating levels of E_2 facilitate rapid, alternating movement of the limbs, and is also consistent with the reported functional role of olivary oscillations, as providing the frequency template for rapid limb movement (Llinas, 1991). For the present study, neurons from the whisker receptive area of the rDAO were recorded simultaneously with cells from corresponding areas of the PrV and SpV using chronically implanted microwire bundles (NB Labs, Denison, TX). Activity from these three CNS sites could then be monitored (Spectrum Scientific, Dallas) during active whisking 24 h following injection of E_2 (2 μgs, i.p. for 2 days). Results suggest that periods of active whisking were accompanied by rhythmic rDAO discharge at roughly the same frequency as the average frequency of the movement (~7-9 Hz). In contrast, the PrV and SpV demonstrated minimal oscillatory activity during whisking behavior. E_2 enhanced the oscillatory discharge of the rDAO both by slightly increasing the number of synchronized, oscillating cells (by ~20%) and by enhancing the amplitude of the oscillation (by ~100%). This effect was unaccompanied by facilitation of oscillatory activity in either the PrV or the SpV (15-16 cells recorded per CNS area). Preliminary videoanalysis of concurrent whisking activity, filmed during the recording paradigm, suggests that the rhythmic neuronal activity enhanced by E_2 was correlated with highly rhythmic whisking; E_2 administration produced whisking at a consistent, invariant frequency of 8.5 Hz compared to a highly variable whisking frequency observed under control, diestrous conditions (5-10 Hz). These results suggest that the facilitatory effect of E_2 on rhythmic, synchronized rDAO activity may underlie, at least in part, its observed behavioral effect in facilitating rhythmic whisker movement. 751.9

CODING OF DIRECTION AND POSITION BY DSCT NEURONS.
G. Bosco, R. Anafi and R. Poppele*. Dept of Physiology, Univ. of Minnesota, Minneapolis, MN 55455

Recent data showed that dorsal spinocerebellar (DSCT) activity may encode the direction of hindfoot displacements as well as relative foot position (Bosco & Poppele, J. Neurophysiol. 70:863,1993). It is not clear, though, if these two signals are temporally segregated or if they overlap in time.

We characterized the time course of DSCT directional tuning using a typical center-out paradigm, passively displacing the cat's hindfoot 2 cm in eight different directions in the sagittal plane. Unit activity recorded in each position was significantly modulated by movement direction for 5-6s following displacement, reflecting a broad directional cosine tuning.

In another experiment, the cat's foot was placed in several positions throughout the sagittal workspace, each position being approached from 3-4 directions in separate trials. For 60% of the cells, mean firing rates over 8s were significantly correlated with the position of the foot relative to the hip. However, only 30% of the cells showed significant modulation with position for the first 2s following displacement. The residual modulation was correlated with movement direction according to a directional cosine model. When this modulation component was subtracted from the total modulation over 8s, the overall correlation of activity with foot position improved and became significant in 75% of the cells.

The results suggest DSCT activity represents a combination of two concurrent signals: one related to the current foot position and the other to the direction of prior movement. The latter persists for several seconds after the movement.

VESTIBULAR SYSTEM: VESTIBULAR NUCLEI

752.1

DEVELOPMENTAL CHANGES IN DISCHARGE PROPERTIES OF CHICK VESTIBULAR SENSORY NEURONS.
K.D. Peusner* and C. Giaume. Dept. Anatomy and Neuroscience Program, George Washington Univ., Washington, D.C. 20037.

The chick tangential nucleus is a vestibular nucleus in the brain whose principal cells (PCs) undergo major developmental changes in structure and membrane properties at critical embryonic and hatching ages. During that period, there is evidence to support that changes in membrane excitability are correlated with the outgrowth of dendrites, which start growing at 13 embryonic days (E13), and then double in length during the week between E15 and 1-2 days after hatching (N.Y. Acad. Sci. Abst., 1995). Using intracellular recording in brain slices, we have focused on the membrane responses of PCs to injected depolarizing current pulses of 400 msec duration with intensities ranging from 0.5 to 1.0 nA. At E13, all of the investigated cells (n = 4) responded with a single spike to 1.0 nA of depolarizing current. At E15-16, similar currents produced either a single spike (n = 3) or in 6 other cells, the depolarization induced the firing of several action potentials (APs). This firing was irregular in number, amplitude and time interval between APs and occurred with an average discharge rate of 32 APs/sec. At H1-2, PCs responded to the same depolarizing current by repetitive firing (discharge rate, 68 APs/sec) of APs with regularly-spaced intervals between the APs (n = 7). These observations indicate that by hatching PCs can respond to rapidly occurring synaptic events. Accordingly, parallel to the extensive outgrowth of dendrites in newborns, which could subserve an increasing number of synaptic inputs, PCs begin to acquire membrane properties which allow the cells to follow vestibular stimuli. Supported by NIH grant RO1-DC00970.

752.2

NEURAL CORRELATES OF VISUAL POSTURAL REFLEXES AND NEGATIVE PHOTOTAXIS IN LAMPREY.
F. Ullén*, T.G. Deliagina, G.N. Orlovsky and S. Grillner. Dpt of Neuroscience, Karolinska Institutet, S-171 77 Stockholm, SWEDEN

Eye illumination in lamprey evokes both negative phototaxis (NP), and a roll tilt towards the light (dorsal light response - DLR). DLR can outlast the stimulus with 30-60s, and reflects a change in the set-point of the vestibular roll control system. The neuronal correlate of DLR was investigated with *in vitro*-recordings from reticulospinal neurons (RSNs), which form the main descending system for roll control in lamprey. Optic stimulation gave a long-lasting potentiation of the vestibular response in ipsilateral RSNs, which indicates that the roll control system was reconfigured to stabilize a tilted orientation. The potentiation was largely due to increased excitability in pre-reticular interneurons. To elucidate which interneuronal pathways mediate DLR and NP, behavioural experiments were performed on cronically lesioned animals. Optic nerve fibres in lamprey project bilaterally to tectum, pretectum and thalamus ("lateral geniculate nucleus", LGN). These areas project further bilaterally to RSNs; commissural fibres first course ventrally and cross the midline in the basal plate. Ablation of the tectum, *potentiated* both DLR and NP: after illumination of the eye, the animal rolled several times around its longitudinal axis, and performed repeated yaw turns away from light. This could be explained by a general disinhibition of reticular cells after tectectomy. The same picture was seen after transection of the mesencephalic ventral commissure, which indicates that the tecto-reticular inhibition to a large extent is through crossing fibres. After unilateral ablation of the pretectum, which presumably also may damage some LGN cells and axons, both DLR and NP could still be evoked from the ipsilateral eye; contralateral visual responses were as a rule absent. Transection of the posterior commissure, which connects left and right pretectum, did not influence NP, nor DLR. Transection of the caudal diencephalic ventral commissure saved DLR, whereas NP was replaced with *positive* phototaxis. Cells in contralateral pretectum or LGN thus appear to play a major role both for NP and DLR, with fibres responsible for NP presumably crossing the midline at a diencephalic level.

752.3

VESTIBULAR CONTROL OF HEAD MOVEMENT IN SQUIRREL MONKEY: MORPHOLOGY OF INDIVIDUAL LATERAL VESTIBULOSPINAL AXONS.
R. Boyle*, D. Petrovic and J. Xu. Depts. Otolaryngology/Head-Neck Surgery & Physiology, Oregon Health Sciences Univ., Portland, OR 97201.

The lateral vestibulospinal tract (LVST) provides a pathway through which the vestibular-nerve afferents can affect head stabilization and movement. Individual axons of LVST neurons were intracellularly recorded to determine their short-latency input from the labyrinth and labeled using biocytin. Main morphological features examined are: axon trajectory in brainstem and cervical spinal cord, and termination pattern and segmental distribution in the cervical spinal cord; in several cases the axon's cell body was recovered in the vestibular nuclei. Antidromically identified lumbar-projecting LVST axons often travel in the ventrolateral funiculus, but can course in the lateral funiculus along the cervical cord. <10% of these axons provide a collateral input to the upper cervical ventral horn; the few axons that could be followed more posteriorly passed the cervicothoracic junction without branching. Lumbar-projecting LVST axons thus appear to provide a direct channel to the hindlimbs. LVST axons terminating in the upper cervical segments often enter the spinal cord in the ventral funiculus, but can course from the lateral to the ventral funiculi. The termination pattern of these axons depends on the axon's funicular location; extensive synaptic input is provided to ventromedial lamina IX, and laminas VIII and VII, thus targeting principally the motoneuronal cell groups. In some cases an axon travels and terminates like other LVST axons, but then changes funicular pathway and branches in a manner more characteristic of medial vestibulospinal tract cells. (Supported by PHS NINDS NS27050)

752.4

THE COERULEO-VESTIBULAR PATHWAY IN RATS, RABBITS, AND MONKEYS: QUANTITATIVE IMMUNOHISTOCHEMISTRY, NEUROTOXIN TREATMENT AND RETROGRADE TRACING.
R.J. Schuerger*, C.D. Balaban. Depts. Neurobiology and Otolaryngology, U. Pittsburgh. Pittsburgh, PA 15261

We examined the noradrenergic pathway from locus coeruleus (LC) to the vestibular nuclei (VN) in rats, rabbits, and monkeys. Noradrenergic projections were localized immunohistochemically with antibodies raised against catecholamine biosynthetic enzymes. The density of noradrenergic innervation was quantified. This analysis revealed a differential distribution of noradrenergic projections throughout VN. In all three species, innervation is highest in the lateral (LVN) and superior (SVN) VN. In rats, Deiters' neurons in LVN receive the densest projections. In monkeys, highest levels are seen in lateral portions of LVN, SVN, medio-rostral portions of prepositus hypoglossi and MVN, and to a lesser extent in group y. In rabbit, the highest innervation density was observed in SVN and LVN. Since immunoreactive fibers could be traced from LC to VN, the hypothesis that LC provides noradrenergic innervation of VN was tested by two methods. First, the neurotoxin *N*-(2-chloroethyl)-*N*-ethyl-2-bromobenzylamine (DSP-4), was used to selectively destroy LC projections in rats. DSP-4 treatment greatly reduced noradrenergic innervation of VN. Second, retrograde tracing studies in the VN of rats (FluoroGold, rhodamine-dextran) and rabbits (HRP) indicated that the pathway originates only from the ipsilateral, ventral portion of caudal LC, subcoeruleus and A4. These results suggest that LC activity may play a role in modulating vestibular reflexes by direct action in VN and may therefor offer an anatomical substrate for increased vestibular performance during states of heightened arousal.

752.5

INDUCTION OF IMMEDIATE EARLY GENES DURING VESTIBULAR COMPENSATION. C.L.Darlington*, P.F.Smith, M.Dragunow" Dept. of Psychology, Univ. Otago, Dunedin, N.Z./"Dept. of Pharmacology, Univ. Auckland Med. School, Auckland, N.Z.

Vestibular compensation is aprocess of CNS plasticity that occurs following deafferentation of the vestibular nerve.Despite the severe ocular motor and postural symptoms that develop immediately following the lesion, many of these symptoms have disappeared within 2-3 days; this compensation process is correlated with a return of resting activity to type I neurons in the medial vestibular nucleus (MVN) ipsilateral to the lesion. Using specific antibodies for the immediate early gene (IEG) proteins, c-fos, c-jun and Krox 24, we analysed IEG induction in guinea pig MVN in 4 conditions: sham; immediately post unilateral surgicallabyrinthectomy (UL);10hs post-UL; 50 hs post-UL (n=3 each).c-fos was not induced in any condition; c-jun and Krox 24 were induced in the contralateral MVN at 10 hs post-UL only.It may be that c-fos is induced at another time post-UL, e.g 24 hs. The induction of c-jun is sometimes associated with cell death, however analysis of the contralateral MVN at 10 and 50 hs post-UL indicated no signs of apoptosis. At present, the significance of Krox 24 induction in the contralateral MVN is unclear.

752.6

EFFECTS OF ELECTRICAL STIMULATION ON VOR AND C-FOS LIKE PROTEIN EXPRESSION OF THE MEDIAL VESTIBULAR NUCLEI FOLLOWING UNILATERAL LABYRINTHECTOMY IN RATS. B.R. PARK*, M.S. KIM, M.Y. LEE, O.J. KIM. *Department of Physiology, Wonkwang University School of Medicine & Medicinal Resources Research Center, Iri 570-749, Korea*

The effects of electrical stimulation on vestibuloocular reflex(VOR) and c-fos like protein expression of the medial vestibular nuclei were investigated for 72 hours following unilateral labyrinthectomy(ULX) in Sprague - Dawley rats. Electrical stimulation with 1.0 ms and 100 Hz was applied to the lesioned vestibular system for 6 hours per day.

ULX caused spontaneous nystagmus with fast phase to the intact side, whose frequency was 3.9+0.2 beats/sec (M+SE) just after ULX but disappeared by postoperative 48 hours. On sinusoidal rotation of the whole body, eye movement with fast phase to the intact side persisted by rotation toward intact or lesioned side, but the eye movement induced by rotation toward the lesioned side recovered normal pattern by 24 hours at 0.1 Hz rotation, by 6 hours at 0.2 Hz. Directional preponderance which represents the symmetry of bilateral vestibular functions showed less than 20% on 48 hours, which implies the recovery of symmetry in bilateral vestibular functions. In electrical stimulation group, spontaneous nystagmus disappeared by 24 hours, and directional preponderance of VOR was less than 20 % by 24 hours. On immunohistochemistry of the medial vestibular nuclei the number of c-fos like protein expression was 5.0–8.0 in each nucleus before ULX, but the number increased to 81.5+6.3 in the lesioned side and 208.4+22.0 in the intact side on 2 hours. On postoperative 24 hours the number in the lesioned side was 55.8+1.8 and in the intact side was 7.0+3.0. However, 48 hours after ULX c-fos like protein was expressed equally in both nuclei. By electrical stimulation the number of c-fos like protein expression was symmetrical in both nuclei 24 hours after ULX. These results suggest that electrical stimulation ameliorates the recovery of VOR following ULX by modulation of the bilateral vestibular nuclear activity. SYNAPTIC CONNECTIONS OF THE VESTIBULAR COMMISSURAL PATHWAY IN THE CAT. F.A. Chen* and R.F. Spencer. Department of Anatomy, Medical College of Virginia, Richmond, Virginia 23298-0709.

Vestibular commissural connections are believed to be mainly inhibitory in nature and are thought to play a role in the vestibulo-ocular reflex, the enhancement of vestibular responses, and recovery of function from peripheral lesions of the VIIIth nerve. In the present study, injections of biocytin were made into the medial vestibular nucleus of adult cats to anterogradely label commissural synaptic endings in the contralateral vestibular complex. By light microscopy, biocytin-labelled commissural axons were observed coursing medially from the injection site, crossing the midline ventral to the MLF, and forming terminal arborizations in homotopic regions of the contralateral medial vestibular nucleus. By electron microscopy, labelled commissural synaptic endings contained numerous small mitochondria and were classified on the basis of their content of spheroidal (64.1%), pleiomorphic (31.2%) or flattened (4.8%) synaptic vesicles. Cross-sectional areas of vestibular commissural endings ranged from 0.30 to 4.80 μm^2, with a mean of 1.37 ± 0.79 μm^2. Vestibular commissural synaptic endings were associated predominantly with distal dendrites, but also were seen in association with proximal dendrites and less frequently with somata and spine-like appendages. Postsynaptic diameters ranged from 0.31 to 9.34 μm^2 with a mean of 3.36 ± 1.96 μm^2. Quantitative analysis of the soma-dendritic distribution revealed that 81.3% of endings terminated on distal dendrites, while 12.6% and 5.1% of endings terminated on proximal dendrites and somata, respectively. Only 1.1% of endings were found to terminate on spine-like processes. In most instances, each vestibular commissural synaptic ending established synaptic contact with only one postsynaptic profile. However, multiple synaptic endings arose from single commissural axons and contacted the same postsynaptic process. The results of this study suggest that the vestibular commissural pathway in the cat, like the vestibulo-ocular reflex pathway, is comprised of both excitatory and inhibitory components.

DISTRIBUTION OF THE CALCIUM-BINDING PROTEINS IN THE VESTIBULAR NUCLEI OF THE GUINEA PIG. S. Saussez, L. Ris, P. Mettens*, N. Gerrits, E. Godaux and R. Pochet. Lab. Histologie, U.L.B., 1070 Bruxelles, Belgium and Lab. of Neurosciences, Univ. of Mons-Hainaut, 7000 Mons, Belgium.

In this study, we have undertaken a detailed mapping of calmodulin, calbindin D28k, calretinin and parvalbumin in the vestibular nuclei of the guinea pig.

Serial 10 µ transverse paraffine sections, either stained by cresyl violet, either immunostained (polyclonal antibodies) using peroxidase-antiperoxidase procedure and diaminobenzidine were analysed.

No neurons were parvalbumin positive. In the superior vestibular nucleus, 80 % of the neurons were calmodulin positive and were uniformely distributed. 30 % of the neurons were calretinin positive without any particular spatial distribution. The 3.5 % of the neurons which were calbindin positive were preferentially located in the dorsolateral part of the nucleus. In the medial vestibular nucleus, 70 % of the neurons were calmodulin positive and uniformely distributed. 32 % were calretinin positive. 9 % were calbindin positive and located along the medial side of the nucleus. In the lateral vestibular nucleus, 90 % of the neurons were calmodulin positive. Giant, medium and small-sized neurons were equally labelled. 31 % were calretinin positive. Among them, 35 % belonged to the giant or Deiters neurons. 3 % which were calbindin positive were of small size. In the descending vestibular nucleus, 90 % of the neurons were calmodulin positive. 14 % were calretinin positive. 10 % were calbindin positive.

We conclude that, in vestibular neurons, calmodulin is highly expressed, calretinin and calbindin are less abundant and parvalbumin is absent.

SPATIOTEMPORAL PROPERTIES OF CENTRAL OTOLITH NEURONS IN DEVELOPING RATS. C.H. Lai and Y.S. Chan (SPON: The Hong Kong Society of Neurosciences). Department of Physiology, Faculty of Medicine, The University of Hong Kong, Sassoon Road, Hong Kong.

To examine the postnatal maturation of the spatiotemporal properties of vestibular nuclear neurons, extracellular activities were recorded from neurons in the lateral and descending vestibular nuclei of decerebrate rats (7 - 21 days and adult) during off-vertical axis rotations (OVAR: 1.75 - 15°/s; 10° tilt) that selectively stimulate the otoliths. Two groups of units were identified based on their bidirectional response sensitivity, δ, to OVAR in the CW and CCW directions. One group had symmetric and velocity-stable δ; their gain tuning ratios, σ, were similar to those of narrowly spatiotemporal-tuned neurons. The other group had asymmetric and velocity-variable δ; their σ values were similar to those of broadly spatiotemporal-tuned neurons. The proportion of broadly tuned neurons in the sampled population decreased with age: 50% at 7 days of age and 27% in adult. Both the best response orientations of the narrowly tuned units and the preferred orientations of the broadly tuned units were distributed predominantly in the transverse direction in 7-day old rats but were found in all directions on the plane of rotation in older rats. There was also a significant increase in the response gain of these neurons in older rats. Our results suggest that a coordinate frame of head positions with respect to gravity progressively emerges within the vestibular nucleus in the course of postnatal development.

FUNCTIONAL CHARACTERISTICS OF IPSILATERAL AND CONTRALATERAL INPUTS TO CENTRAL OTOLITH NEURONS OF CATS AFTER ACUTE UNILATERAL LABYRINTHECTOMY. Y.S. Chan*. Department of Physiology, Faculty of Medicine, The University of Hong Kong, Sassoon Road, Hong Kong.

To determine the nature of the ipsilateral and contralateral otolith inputs, extracellular activities of vestibular nuclear neurons on both the lesioned and labyrinth-intact sides were examined during off-vertical axis rotations (OVAR: 1.75 - 15°/s; 10° tilt) in decerebrate cats after acute hemilabyrinthectomy (HL). A bidirectional response sensitivity ratio δ (the sensitivity of each neuron to OVAR in the CW and CCW directions) was used to evaluate the spatiotemporal properties of the neurons. Those with symmetric and velocity-stable δ were grouped as narrowly spatiotemporal-tuned neurons while those with asymmetric and velocity-variable δ were grouped as broadly tuned neurons. More broadly tuned neurons were found in HL cats (a higher proportion on the lesioned side than on the intact side) than in control cats. This suggests that the more prominent broadly tuned responses of HL cats are normally masked by inputs from the contralateral side. On both sides, the directional preference of the broadly tuned neurons and the best response orientations of the narrowly tuned neurons were found predominantly on the segment of the polar diagram ipsilateral to the side of recording, implying that the crossed otolithic inputs carry information to complement inputs arising from the ipsilateral side. Thus, otolith inputs from the two sides contribute to determine the spatiotemporal properties of the vestibular nuclear neurons in coding head orientations. (Supported by H.K. Research Grants Council.)

RESPONSE OF MEDIAL VESTIBULAR NUCLEUS NEURONS TO HORIZONTAL LINEAR AND ANGULAR STIMULATION OF DECEREBRATE CAT. R.H. Schor*, B.C. Steinbacher, B.J. Yates. Dept. Otolaryngology, University of Pittsburgh, Pittsburgh, PA 15213.

Responses arising from the vestibular utriculus encode the direction of linear accelerations in the horizontal plane. Afferents optimally encoding all directions of tilt exist in roughly comparable numbers, especially if considering inputs from both labyrinths. Yet studies of central vestibular neurons located in the lateral and inferior vestibular nuclei, as well as neurons located in the pontomedullary reticular formation, showed a preponderance of neurons responding more vigorously to roll (lateral tilt) than to pitch (fore-aft tilt).

Guided by observations that lesions that include the medial vestibular nucleus (MVN) abolishes (pitch) vestibulo-sympathetic reflexes, we examined the responses of neurons in the MVN and adjacent inferior vestibular nucleus (IVN) of 7 decerebrate cats. Responses attributed to activation of otolith (utricular) receptors were recorded during constant velocity rotation in the animal's horizontal plane about an axis tipped 10° from the vertical (changing linear acceleration). Out of 47 tested neurons, 28 responded to this stimulus; 12 responded best when nose down or nose up, 5 responded best when one ear was down, and the other 11 responded best at intermediate positions near the planes of the vertical canals.

Many of these responsive neurons were also tested for horizontal canal input using sinusoidal rotation (angular acceleration) about an earth-vertical axis. 25/45 neurons were modulated by this stimulus, with response dynamics consistent with canal input. In 41 neurons tested, 16 responded to both stimuli, suggesting convergence between utricular and horizontal semicircular canal afferents.

These results suggest that in addition to its well-known input from the horizontal semicircular canals, the MVN may serve as an important relay for pitch linear acceleration stimuli. Supported by NIH Grants NS24930 and DC00693.

CALCIUM-DEPENDENT CONTROL OF SIGNAL TRANSFORMATIONS IN MEDIAL VESTIBULAR NUCLEUS NEURONS. Sascha du Lac*, UCSF Dept. of Physiology and Keck Center for Integrative Neuroscience, San Francisco CA 94143.

A combination of mechanisms at the cellular and network levels determine how head movement signals are transformed into the appropriate oculomotor commands. To investigate the cellular control of signal transformations in vestibulo-ocular reflex pathways, we have assessed the effects of blocking calcium channels on the gain and dynamics of spike generation in Medial Vestibular Nucleus (MVN) neurons. MVN neurons recorded in avian brain slices were injected with intracellular current to measure spike generation gain (slope of the relationship between mean firing rate and input current amplitude) and dynamics (timecourse of instantaneous firing rate during the step).

In normal MVN neurons, spike generation is highly linear over a wide range of input amplitudes and has highly stereotyped dynamics including little decrease in firing rate during the course of a 1 sec current step. Bath application of the calcium channel blocker cadmium (Cd; 100 uM) had a number of pronounced effects on spike generation in MVN neurons. First, the relationship between current and firing rate became nonlinear in the presence of Cd: a given amount of current produced smaller changes in firing rate as the current amplitude increased. Second, spike generation gain increased, relative to control, at low current amplitudes. Finally, Cd altered spike generation dynamics: firing rate decreased markedly during current steps. The small conductance calcium-activated potassium (SK) channel can not be solely responsible for these effects: blocking the SK channel with apamin (100-200 nM) produced a smaller effect on spike generation gain with no effects on linearity or dynamics. These results demonstrate that calcium influx into MVN neurons modulates spike generation gain, dynamics, and linearity and suggest that regulation of calcium-dependent processes could underlie adaptive changes in the gain and dynamics of the vestibulo-ocular reflex.

752.13

METABOTROPIC GLUTAMATE RECEPTORS IN THE MEDIAL VESTIBULAR NUCLEUS IN VITRO. P.F.Smith*, C.L. Darlington Dept.of Psychology, Univ. Otago, Dunedin, New Zealand

The aim of the present study was to examine the response of guinea pig medial vestibular nucleus (MVN) neurons in brainstem slices to the selective metabotropic receptor agonist, 1S,3R-amino-cyclopentyl-1,3-dicarboxylate (ACPD). Extracellular recordings were made from single MVN neurons using standard in vitro techniques. 60% (12/20) of MVN neurons responded to 1S,3R-ACPD at a concentration of 10^{-6} M, compared to 40% (8/20) and 35% (7/20) of neurons at concentrations of 10^{-8} and 10^{-10} M. Both increases and decreases in firing rate were observed in different neurons: in general, the magnitude of the responses was large and the duration of the responses was long. Recordings from a slice which contained only the MVN confirmed that these responses were produced by the action of the metabotropic agonist within the MVN itself.

EFFECT OF VESTIBULOCEREBELLUM AND INTERACTION OF NECK INPUT WITH VESTIBULAR INPUT TO THE CAUDAL VESTIBULAR NUCLEI. D. B. Thomson* H. Ikegami, R. H. Schor and V. J. Wilson. The Rockefeller University, New York, NY, 10021.

Previously, we studied the vertical vestibular input to neurons in the caudal half of the descending and medial vestibular nuclei (CVN) in decerebrate cats with the caudomedial cerebellum removed. In the present study we investigated whether CVN neurons respond differently to vestibular stimuli when the caudal cerebellar vermis is intact. Little influence was observed. As in the partially decerebellated preparation, neurons classified as receiving input primarily from otoliths displayed, on average, a modest gain increase (<threefold per decade) and phases that led position by 33-39° over the range of 0.05-1 Hz whereas canal neurons displayed a gain slope of 19 per decade and phases that led velocity by more than 30°. In both preparations, the response vector orientations of canal neurons were clustered near the canal planes and those of otolith neurons tended to be in the roll quadrants. The CVN receive direct projections from upper cervical primary afferents, and we further examined the responses of neurons in this region to natural neck rotation and to combined vestibular-neck stimulation. Only 30% of neurons responded to neck rotation in the range of 0.05-0.5 Hz. We investigated neck-vestibular interaction in 17 neurons that showed neck and vestibular responses with phase differences <45°. Only 7/17 neurons had "antagonistic" neck and vestibular vector orientations (i.e. differing by >120°) and 3/17 neurons had "synergistic" vectors (i.e. differing by <60°). In contrast, >50% of neurons in more rostral areas of the vestibular nuclei receive neck input, which is almost always antagonistic. Supported by NIH (DC 02187 and NS 24930) and by HFSPO.

DYNAMIC RESPONSES OF VESTIBULAR NUCLEI AND PREPOSITUS NEURONS IN THE ALERT GERBIL. G.D. Kaufman* and A.A. Perachio. Departments of Otolaryngology, Physiology & Biophysics and Anatomy & Neurosciences, Univ. TX Med. Br., Galveston, TX 77555-1063.

The responses of neurons in the nucleus prepositus hypoglossi (PrH) were recorded in alert gerbils during horizontal angular or linear head acceleration in the dark. Angular acceleration, ranging from 0.05 to 2.0 Hz, 30°/sec. to 120°/sec., was applied in the plane of the horizontal semicircular canals. At frequencies below 0.5 Hz, phasic bursting occurred during the otherwise inhibitory portion of the cycle in some PrH neurons. From 0.2-2.0 Hz gain increased (0.23 S/s/deg/s ± 0.04 SEM to 0.43 S/s/deg/s ± 0.07 SEM). Response phase led 23° ± 7° SEM at 0.2 Hz. Phase gradually decreased with frequency. Above 0.5 Hz phase lag increased to 26° ± 4° SEM at 2.0 Hz. Otolith organ-related responses were recorded to pure linear acceleration during horizontal sinusoidal translational motion, ranging from 0.25 to 5.0 Hz, 0.05 to 0.5 x g peak accelerations. Average response gain at 0.5 Hz and 0.1 G was 194 S/s/g ± 26 SEM. Phase led acceleration 110° ± 26° SEM. Two-dimensional spatio-temporal convergence was observed in most cells for frequencies above 0.25 Hz. In contrast to medial vestibular nuclei (MVN) cells, the response vector maximum sensitivity in PrH neurons phase led acceleration by 90° while the orthogonal vector produced an acceleration phase related response. A model will be presented of the interaction of PrH and MVN neurons at abducens motoneurons to regulate vestibulo-ocular responses. Supported by NIH grants DC00385 and DC00111.

VESTIBULAR NUCLEI NEURON RESPONSE DYNAMICS PRODUCED BY COMMISSURAL CONVERGENCE IN PIGEONS. J.D. Dickman*. Depts. of Surgery (Otolaryngology), Anatomy, and Physiology, University of Mississippi Medical Center, Jackson MS 39216

How do vestibular nuclei neurons synthesize the information from the paired complementary semicircular canals into a unified output signal? To answer this question, the dynamic properties of vestibular nuclei neurons in pigeons were examined by individual and paired stimulation of the horizontal semicircular canals using both mechanical micropushers and rotational acceleration. Extracellular single fiber responses from horizontal canal-related neurons were obtained in awake decerebrate birds that were paralyzed (Pancuronium) and ventilated (250 ml/min, O_2/CO_2). Mechanical micropusher stimulation (0.01 to 10 Hz, ±2.5 μm) of the exposed ipsilateral horizontal membranous duct was delivered first, followed by identical contralateral canal stimulation. Bilateral mechanical stimulation was next delivered, with left and right canal stimuli being 180° phase displaced. Rotational stimulation (0.01 - 4 Hz, 20 deg/sec) was finally delivered as a comparison. All Type I neurons responded to ipsilateral canal stimulation with increasing gains and phase advances relative to inward membranous duct displacement. Contralateral canal stimulation produced responses with much small gains and phases that were generally phase displaced by 180°. Two different response patterns were obtained with bilateral canal stimulation; one with additive gains from ipsilateral and contralateral canal responses and one with subtractive gains. Phase differences in the ipsilateral and contralateral canal high frequency stimulation were correlated with the type of response profile, where differences greater than 180° resulted in subtractive gains. These phase differences suggest that spatio-temporal convergence between inputs from the two complementary labyrinths exist for vestibular nuclei neurons and may be utilized to produce the total output signal that is projected to the target cell.

752.17

RESPONSES OF SECONDARY VESTIBULAR NEURONS TO MECHANICAL VESTIBULAR STIMULATION IN THE TOADFISH *OPSANUS TAU*. A. F. Mensinger* and S. M. Highstein, Dept. of Otolaryngology. Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The response dynamics of toadfish horizontal semicircular canal afferents have been classified into three rough groups (high- and low-gain velocity sensitiveand acceleration; Boyle & Highstein 91, Rabbit *et al.* 95) utilizing rotary and mechanical stimuli. We employed mechanical stimuli (canal indentation) to study the fidelity of transfer of these nerve dynamics to central afferent branches and secondary vestibular neurons. Intra- and extracellular recording and intracellular injection of recorded neurons were utilized. The central branches of primary afferents were labeled and identified by the presence of terminal boutons and nerve trunks traveling peripherally. In general, responses of afferent central branches were 2-5 times less sensitive and phase-lagged control peripheral records. Secondary neurons, primarily in the descending and posterior octaval nuclei demonstrated similar response dynamics as central branches. Both high and low gain responses were observed but phase covered a broader range than in primary afferents. In contrast to peripheral nerve responses, central neurons were insensitive to low frequency stimuli (below 1Hz) but were responsive in the 1-10 Hz range These results suggest that central processes of primary afferents serve to modify response dynamics of peripheral semicircular canal nerve axons.

752.18

RESPONSES OF VESTIBULAR NUCLEUS TO ROTATION OF THE TURTLE HEAD *IN VITRO*. M. Ariel*, T.X. Fan and C.A. Scudder. Saint Louis Univ., MO 63104 and Univ. of Pittsburgh, PA 15213.

Extracellular spike recordings were made from the vestibular nucleus (VN) during rotation of an *in vitro* turtle brainstem in which the temporal bones remained attached. The lateral canals were roughly aligned with the horizontal plane and the vertical axis of rotation was centered between the labyrinths. This preparation responded to vestibular stimulation for up to several days. In some preparations, horizontal canal sensitivity was confirmed by plugging the vertical canals or stimulation about the interaural axis.

Single VN units were isolated when they responded to horizontal sinusoidal stimulation and then quantified for different stimuli. Spike histograms were averaged from many stimulus cycles and fit to a rectified sine function. VN units were then categorized as encoding stimulus velocity or acceleration in the ipsi- or contraversive direction.

Common features of these neurons were their low levels of spontaneous activity and their rectified sinusoidal responses to sinusoidal rotation. Each cell had a characteristic phase (re table velocity) that was invariant below 1 Hz stimulation. Response phase varied substantially between cells, with most phase values between a 45° lag to a 90° lead. The response gain (re table velocity at 1 Hz) was between 0.1 and 25, indicating substantial heterogeneity of these cells' responses. These response features will be described and compared to that of turtle vestibular afferents and VN cells in other species. (Supported by EY 05978 to MA)

CERVICAL INFLUENCES ON THE DIRECTIONAL PROPERTIES OF THE VESTIBULOSPINAL REFLEX. O.Pompeiano*, P.Andre and D.Manzoni. Dept. Physiol. Biochem., Univ. of Pisa, Via S.Zeno 31, Pisa, I-56127.

The vestibular input induced by rotation of the animal in a given direction produces an appropriate postural adjustement. We investigated whether the pattern of the vestibulospinal (VS) reflex recorded from the forelimb extensor triceps brachii (TB) could be modified by a relative body-to-head displacement, as expected in order to preserve body stability. In decerebrate cats, the multiunit EMG activity of the TB was recorded during wobble of the whole animal at 0.15 Hz, 10°. This stimulus allowed to determine the muscle response vector corresponding to the direction of head displacement leading to the maximal EMG response. When the body was kept straight with respect to the head the response vector of the TB was always oriented close to the transverse axis, pointing to the side-down direction. Following 30° of body-to-head displacement around a vertical axis passing through the atlanto-occipital joint, the response vector of the TB shifted in the same direction of body rotation, thus remaining approximately perpendicular to the body axis. The shift of the response vector was consistently reduced by inactivation of the cerebellar anterior vermis following microinjection in lobule V (culmen) of the GABA-A agonist muscimol (0.5 μl at 8 μg/μl saline). These findings indicate that: i) the sensory input of cervical origin is able to modify the pattern of the VS reflex which appears to be organized in a body-centered reference frame; ii) the cerebellar vermis is required for the proper execution of this sensorimotor transformation.

752.20

DIFFERENCES BETWEEN THE UTRICULAR ACTIVATED AND SACCULAR ACTIVATED SECOND ORDER VESTIBULOSPINAL NEURONS IN CATS. H. Sato[1*], M.Imagawa[1], M. Sasaki[1], K. Endo[1], H. Ikegami[1], N. Isu[2] and Y. Uchino[1]. [1]Dept. of Physiol., Tokyo Med. College, Tokyo 160; [2]Dept. of Inform. Eng., Tottori Univ., Tottori 680.

Axonal trajectories and locations of the cell bodies of utricular (UT) and saccular (SAC) activated vestibulospinal neurons (VSNs) were studied in decerebrated or anaesthetized cats. Bipolar stimulating electrodes were placed on either the UT or the SAC nerve with the other vestibular nerve branches transected. Monopolar stimulating electrodes were positioned in the lateral vestibulospinal tracts (LVST) bilaterally and the medial vestibulospinal tracts (MVST) at the C1. Similar electrodes were bilaterally inserted into the ventral funiculi at the C2-4, C7-T1 and L3, and into the third nucleus. The majority of UT-activated VSNs were located in the rostral part of the descending vestibular nucleus, while the SAC-activated VSNs were mainly located in the lateral vestibular nucleus. Almost none of UT- and SAC-activated VSNs were activated from the third nucleus. The numbers of UT-VSNs (n=46) and SAC-VSNs (n=46) activated from the each spinal segment were as follows:

Spinal segments		C1	C2-4	C7-T1	L3
i-LVST	utricular	32	30	28	7
	saccular	14	12	8	3
MVST	utricular	6	4	1	0
	saccular	29	20	10	0
c-LVST	utricular	8	5	0	0
	saccular	3	1	0	0

OCULOMOTOR SYSTEM: BRAINSTEM AND PRETECTUM

753.1

ANATOMICAL SUBSTRATES FOR PRETECTAL CONTROL OF LID MOVEMENTS IN A PRIMATE. P.J. May* Deparments of Anatomy and Neurology, University of Mississippi Medical Center, Jackson, MS 39216.

The eyelids are controlled by two voluntary muscles. The levator palpebrae superioris, whose motoneurons are found in the caudal central subdivision of the oculomotor complex, is active during vertical eye movements, while the orbicularis oculi, whose motoneurons are found in the facial nucleus dorsolateral subdivision, produces blinks. Based on clinical and non-primate experimental evidence, the possibility of pretectal inputs controlling lid movements was investigated by injecting WGA-HRP, biocytin or biotinylated dextran amines (BDA) into the pretectum of macaque monkeys. While large pretectal injections bilaterally labelled terminals in both the orbicularis and levator subdivisions, a smaller WGA-HRP injection centered in the olivary pretectal nucleus did not label terminals in these subdivisions. Nevertheless, a similar olivary biocytin injection did reveal a sparsely distributed collection of fine terminals and boutons among retrogradely labelled levator motoneuons. These were most dense along the ipsilateral edge of the caudal central subdivision. BDA injections that included the nucleus of the posterior commissure bilaterally labelled thick axonal arbors in the caudal central subdivision that had numerous large terminal and *en passant* puncta. Similar terminal arbors were also observed bilaterally among the orbicularis oculi motoneurons in a case with a caudally placed large nucleus of the posterior commissure injection. However, these facial terminals were not present in a case where only the nucleus of the posterior commissure and the anterior pretectal nucleus were involved. A BDA injection in the superior colliculus and posterior pretectum also produced arbors with large puncta in the caudal central subdivision. In conclusion, the light evoked blink reflex pathway that connects the olivary pretectal nucleus to orbicularis oculi motoneurons in both facial nuclei in the cat is not evident in the monkey, although a minor, perhaps inhibitory projection to levator motoneurons is present. A pretectofacial pathway is present, but its precise source remains to be identified. Another pretectal area, the nucleus of the posterior commissure, may supply a major input to levator motoneurons. This projection may modulate lid movements in concert with vertical gaze changes. Support: EY09762.

753.2

THE PIGEON ACCESSORY OPTIC SYSTEM: VISUAL INPUT IN EYE MUSCLE COORDINATES D.R. Wylie*, R.G. Glover, K.L. Lau, B. Morgan, and B.J. Frost. Department of Psychology, University of Alberta, Edmonton, Alberta, Canada, T6G 2E1.

The generation of compensatory eye movements in response to rotational head movements involves the transformation of visual-optokinetic and vestibular signals into commands controlling the appropriate eye muscles. The optokinetic information is analysed by the Accessory Optic System (AOS). It has been demonstrated in rabbits and pigeons that the three systems (AOS, vestibular, eye muscle) share a *similar* three-dimensional reference frame. In this report we suggest that in pigeons the optokinetic system is organized with respect to the eye muscles rather than the vestibular canals. Measurements of the plane of the horizontal recti were obtained from 5 pigeon eyes. Using standard extracellular techniques we recorded from two structures in the pigeon AOS: (1) the pretectal nucleus lentiformis mesencephali (LM), and (2) the nucleus of the basal optic root (nBOR). The LM and nBOR contain neurons responsive to optokinetic stimuli (OKS) moving forward and backward in the contralateral hemifields, respectively. Thus, activity in the LM and nBOR result in contraction of the contralateral medial rectus (MR) and lateral rectus (LR), respectively. We also recorded from Purkinje cells in the flocculus of the vestibulocerebellum (VbC). Neurons in the VbC have binocular receptive fields (RFs). The ipsilateral and contralateral RFs respond to OKS moving forward and backward, respectively. Thus, activity of VbC neurons results in contraction of the ipsilateral MR and contralateral LR, respectively. A close correspondence was found between the plane of the MR, the direction preferences of LM neurons, and VbC neurons in response to stimulation of the ipsilateral hemifield. In all cases the vectors were approximately aligned with the horizontal. A close correspondence was also found between the plane of the LR, the direction preferences of nBOR neurons, and VbC neurons in response to stimulation of the contralateral hemifield. In all cases the vectors were tilted downward from the horizontal by about 30°. In sum, there is a close correspondence between the planes of the horizontal eye muscles and the direction preferences of AOS and VbC neurons providing optokinetic input to those muscles.

753.3

EFFECTS OF MESENCEPHALIC RETICULAR FORMATION (MRF) ELECTRICAL MICROSTIMULATION UPON EYE MOVEMENTS IN PRIMATES. V.L. Silakov*, D.M. Waitzman and S.J. Tinturin. Newington VAMC, 555 Willard Ave, Newington, CT 06111.

While electrical microstimulation (MCS) is known to generate contraversive horizontal eye movements (EM) in monkeys (Cohen et al., 1984), the effects of behavioral state, variation in the rostral-caudal site, and changes in the initial position (IP) of the eyes have not been systematically explored. EMs were elicited using 80-100 µamps of current through tungsten microelectrodes in two head fixed monkeys. The monkeys sat in a dark room and fixated a small spot of light which either remained lit or was extinguished just prior to MCS. Sixty sites throughout the rostral-caudal extent of the MRF were explored. At 23 sites IP was varied across a 5 or 9 point grid which spanned the oculomotor range in 20° steps. Saccades from 0.5° to 25° amplitude were elicited. Direction of elicited EMs varied from primarily horizontal in the caudal regions to vertical in the more rostral regions. At 60% of the sites at which IP was varied, there was a distinct correlation of IP with elicited saccade amplitude ($r^2 > 0.5$) such that shifts of IP toward the direction of the movement (as defined from primary position) were associated with smaller elicited amplitudes. A commensurate change in saccade direction accompanied the reduction in saccade amplitude. The large changes in EMs following MCS suggest that the MRF, distinct from the superior colliculus, may be organized in a craniotopic coordinate system.

Supported by NIH Research Grant EY 09481 and a RAG grant from the Office of Medical Research, Dept. of Veterans Affairs.

753.4

CELLS ENCODING VELOCITY AND DYNAMIC MOTOR ERROR RESIDE IN THE MONKEY OCULOMOTOR COMLEX (III) AND MESENCEPHALIC RETICULAR FORMATION (MRF).
D.M. Waitzman*, V.L. Silakov and D.R. D'Angelo. Newington VAMC, 555 Willard Ave, Newington, CT 06111.

Previous single unit recordings in III have emphasized that the pulse of activity observed in oculomotor neurons (OMNs) is stereotypic and the frequency of the instantaneous discharge during the OMN pulse controls eye velocity. The discharge dynamics of 43 neurons within III and 31 horizontal, saccade related MRF neurons were studied in 2 awake, head-fixed monkeys performing visually guided saccades. Neuronal discharge frequencies were expressed as a spike density function (SD) and individually matched to the temporal dynamics of individual saccades. Motor error (ME) neurons (MRF=8 and III=12) had a monotonic decline of SD with declining motor error. Phase plane plots of SD versus eye velocity generated an open loop indicating a different level of activation during the accelerating and decelerating phases of the saccade. Velocity (VEL) neurons (MRF=16 and III=11) had a "ski-jump" decline of SD with declining ME. These cells showed a closed loop response for the SD versus VEL phase plane. The remainder of the neurons demonstrated a mixture of these two responses. In light of similar responses of saccade related cells in the superior colliculus, these results suggest that both VEL and ME are controlled variables at multiple levels of the primate oculomotor system.

THE NITRIC OXIDE - cGMP PATHWAY CONTRIBUTES TO THE CONTROL OF HORIZONTAL EYE MOVEMENTS BY PREPOSITUS HYPOGLOSSI NEURONS. M. Escudero*, B. Moreno-Lopez, and C. Estrada§. Laboratory of Neuroscience, Faculty of Biology, University of Sevilla, and §Department of Physiology, Faculty of Medicine, UAM, Madrid, Spain.

Nitric oxide (NO) is a difusible gas synthesized by some neurons in the central nervous system, with an intercellular communication function, which is mediated in most cases by activation of guanylate cyclase in target cells. The possible role of nitric oxide as a modulator in the cat oculomotor system was investigated based on the large number of neurons containing NO synthase (NOS) present in the prepositus hypoglossi nucleus (PH).

Alert cats prepared for chronic recording of eye movements by means of the magnetic search-coil technique were used. Local injections of the NOS inhibitors L-nitroarginine methyl ester (L-NAME; 10-40 nmol) and L-N-monomethylarginine (L-NMMA; 30-60 nmol) in the anterior third of the PH produced conjugated nistagmic eye movements with slow phases directed to the contralateral side. This spontaneous eye movement alteration was dose-dependent, appeared within 1-2 minutes after injection, lasted for 30-60 minutes and was more evident in complete darkness. The effect of NOS inhibitors was stereo specific because the isomer D-NAME was without effect, and was abolished by simultaneous administration of the NOS substrate, L-arginine. Injections of the NO donor sodium nitroprusside (SNP) or the permeative analog of cGMP 8-bromo-cGMP in the PH produced an effect opposite to that of NOS inhibitors, this is, conjugated nistagmic eye movements with slow phases directed to the ipsilateral side. These results indicate that NO produced by PH neurons modulates via cGMP the generation of the motor signal that control horizontal eye movements.

MODELING THE OCULOMOTOR EFFECTS OF IBOTENIC ACID LESIONS OF THE MACAQUE NUCLEUS PREPOSITUS HYPOGLOSSI (NPH). R. Soetedjo[1,3] and C.R.S. Kaneko*[2,3] Depts. Bioengineering[1] and Physiology & Biophysics[2] and Regional Primate Research Center[3], Box 359010, University of Washington, Seattle, WA 98195-9010

The nature of the effects of lesions of the nph, the putative position integrator in the oculomotor system, was examined by comparing the behavior of a monkey that had multiple bilateral lesions of its nph with predictions of the Scudder and Robinson models. A multiply nph-lesioned monkey cannot hold its eyes on an eccentric target for fixation after making a saccade and position drift in the dark is greatly exacerbated. The shape of the drift showed two components, an initial fast drift followed by a slower decay. In order to fit the shape of the monkey's drift with either model, the lesion must affect both the time constant and gain of the integrator path. If gain and time constants are adjusted to fit drift in the dark, Robinson's model predicts that saccades will overshoot and Scudder's model predicts undershoot both followed by the drift. Robinson's model also predicts a large overshoot if the gain of the integrator is too low.

ANALYSIS OF PRIMATE INHIBITORY BURST NEURON SPIKE TRAIN DYNAMICS: GAZE VERSUS EYE BASED MODELS DURING COMBINED EYE-HEAD GAZE SHIFTS. K.E.Cullen* and D.Guitton. Aerospace Medical Research Unit & Montreal Neurological Inst. McGill University, Montreal, Canada.

We used metric analysis and systems identification techniques to relate IBN discharges to the dynamics of gaze, eye, and head during head-free gaze shifts. Burst versus gaze durations were similar head-fixed and head-free, and the number of spikes was better correlated to head-free gaze, than eye amplitude. Latencies calculated using dynamic models were significantly lower than those based on the onset of the first spike in head-fixed and head-free conditions. Regardless of an IBN's onset or dynamic lead, simple downstream (velocity based) models were better than upstream models (non-linear function of motor error) at predicting IBN discharges. The most relevant parameters to head-free downstream models were a velocity gain coefficient and a bias term. For all models with a bias term, gaze and eye velocity were equally good at predicting IBN activity, however the bias term estimated for eye based models was significantly higher than that for gaze based or head-fixed models. Head velocity based models provided worse fits than gaze or eye velocity based models. Acceleration and higher order non-linear velocity terms slightly improved the variance accounted for in our models (10%), whereas, use of acceleration and pole terms (the derivative of the IBN firing rate) greatly improved model fits, when initial conditions (ICs) were estimated as parameters (115%). However, these models yielded bias terms that were unrealistically negative. Models with only a gain and bias term, in which the bias term was estimated separately for each gaze shift, provided fits comparable to those with a pole term with estimated ICs. Estimated biases were inversely correlated with the peak gaze velocity and/or amplitude for 39 % of the IBNs, in both head-free and head-fixed conditions (gaze base models). In contrast, these values were related with peak velocity and/or amplitude of the head-free eye movement component for only 18% of IBNs (eye base models). We suggest that the bias term is critical for evaluating the significance of model fits: 1) the bias enables a distinction between head-fixed and head-free fits, and suggests that gaze velocity is more relevant than eye velocity in describing IBN discharges during gaze shifts 2) the bias is strongly related to the metrics of saccades head-fixed and the metrics of gaze, not eye, head-free.

NEURAL NET SIMULATION OF EYE POSITION COMMAND TO MEDIAL RECTUS MOTONEURONS FROM ABDUCENS INTERNUCLEAR NEURONS. Paul Dean*, Dept. of Psychology, University of Sheffield, Sheffield S10 2TP, England.

Ocular motoneuron firing rate is linearly related to eye position (in the relevant direction) with slope K, above recruitment threshold T. Within the population of ocular motoneurons K increases as T increases. It is not known how these relations are derived from the combination of input signals with intrinsic motoneuron properties.

Possible derivations were investigated by simulating the input signal to medial rectus motoneurons (MR-MNs) from internuclear neurons of the abducens nucleus (AINs). AINs were represented as input nodes in a two layer neural-net, each with weighted connections to every output node representing an MR-MN. The output node bias term acted as the intrinsic MR-MN threshold. Inputs to the net were conjugate eye-position commands, used to generate realistic firing patterns in the AINs (Fuchs et al., *J.Neurophysiol.* 60:1874, 1988; Gamlin et al., *J.Neurophysiol.* 62:70, 1989). The output of the net was compared with actual MR-MN firing patterns for that eye position (Gamlin & Mays, *J.Neurophysiol.* 67:64, 1992). Weights were adjusted as a result of the comparison using gradient descent error-reduction.

The simulations showed: (1) MR-MN firing rates were accurately reproduced by AIN populations in which K was unrelated to recruitment threshold T, and in which maximum values of T were up to 25 deg less than those in the MR-MN population. (2) Accuracy could still achieved when the bias term, representing MR-MN intrinsic threshold, was held constant. (3) Weights between AINs and MR-MNs showed that each MR-MN typically received functional connections from a cluster of AINs with similar Ts.

It is therefore possible that appropriate patterning of input connections can determine MR-MN firing rates in relation to conjugate fixation commands, without a major contribution from variation in intrinsic motoneuron properties.

EXTRAOCULAR MUSCLE DEVELOPMENT IN A MODEL OF MIDBRAIN DYSGENESIS. J.D. Porter* and R.S. Baker. Depts. of Anatomy & Neurobiology and Ophthalmology, U. of Kentucky Med. Ctr., Lexington, KY 40536.

The relative importance of genetic and epigenetic factors in developmental regulation of the unique extraocular muscle (EOM) phenotype is unclear. The *Wnt-1* allele is required for the development of the mesencephalon, including the oculomotor and trochlear nuclei. *Wnt-1* mutant mice, by homologous recombination (McMahon and Bradley, *Cell* 62:1073, '90), then may represent a serendipitous model in which to examine the role of neuromuscular interactions in developing EOM. Prior studies have shown that the EOM primordia are innervated prior to migration away from their somitomeric origins. However, innervation may not be a critical factor in guidance of migration since *Wnt-1* mutants showed normal spatial orientation of the six EOMs within the orbit at E14.5-16.5 in spite of the absence of oculomotor and trochlear motoneurons. Lateral rectus muscles contained axons and primitive neuromuscular contacts from the intact abducens motoneurons. However, some of the muscles normally innervated by oculomotor and trochlear nuclei received motor innervation from an alternative source, presumably via collateral sprouting of abducens motoneurons. Muscles receiving either normal or aberrant innervation exhibited myogenic staging comparable to control littermates. By contrast, muscles lacking evidence of innervation contained atrophic and degenerating myotubes. The pattern of pathology in aneural muscles suggests that innervation from oculomotor nerves plays a role in both primary and secondary myogenesis in this muscle system. Taken together, this model may allow characterization of the mechanisms responsible for the tissue-specific properties of the EOM allotype. The pattern of developmental aberrant innervation of EOMs seen in this mouse also may provide insight into the etiology of Duane retraction syndrome in humans. THE PRETECTAL NUCLEUS OF THE OPTIC TRACT (NOT) SUBSERVES LATENT NYSTAGMUS IN VISUALLY DEPRIVED MONKEYS. M.J. Mustari[1]*, A.F.Fuchs[2], R.J. Tusa[3], A. Burrows[1], and C. Livingston[1]. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX[1]; Regional Primate Research Center, University of Washington, Seattle, WA.[2], University of Miami Ear Institute, Miami, FL[3].

Monkeys (Macaca mulatta) binocularly deprived (BD), by lid suture, early in life, develop a permanent horizontal nystagmus, resembling latent nystagmus (LN)[1]. These animals also lack a nasal-to-temporal optokinetic reflex (OKN). To discover the locus for LN, we recorded from and reversibly inactivated the NOT, which is essential for horizontal optokinetic eye movements. We recorded NOT unit activity during spontaneous nystagmus and fixation, and evaluated visual receptive fields in two trained monkeys (> 2 yr old), which had been BD for the first 25 or 55 days of life. NOT units in BD animals were either driven exclusively (55 day BD) or were dominated (62%; N=32) by the contralateral eye (25 day BD). This is in contrast to normal monkeys where all NOT units are binocularly driven[2]. In addition, most NOT units changed their spontaneous firing rates as a function of ambient light levels. Such light intensity dependent firing, together with contralateral ocular dominance, could be the source of an unbalanced drive to caudal brainstem structures, resulting in LN.

To test this suggestion, we placed injections of the GABAa agonist, muscimol (0.3µl; 2%) in the NOT. Prior to muscimol injection, LN was initiated 145ms (±15) after closing a shutter in front of the right eye, with rightward slow phase eye velocity reaching 40°/s within a few seconds. Following unilateral muscimol blockade of the NOT, ipsiversive (slow phase) LN due to occluding the ipsilateral eye was completely abolished. Similarly, bilateral NOT blockade abolished LN in either direction. Horizontal optokinetic eye movements were virtually abolished following such bilateral injections, however, the monkey's ability to fixate or make saccades was preserved.

The results of our studies indicate that the NOT is critical for the production of LN in animals subjected to brief periods of visual deprivation early in life. [1]Tusa et al., Invest. Ophth. Vis. Sci. 32: 134-141, 1991. [2]Mustari and Fuchs, J. Neurophysiol. 64:77-90, 1990. Supported by: EY06069, EY09289, RR 00166, EY00745.

THE PARAFASCICULAR NEURONS IN AND AROUND THE MEDIAL LONGITUDINAL FASCICLE WHICH PROJECT TO THE CEREBELLAR FLOCCULUS AND VENTRAL PARAFLOCCULUS RECEIVE AFFERENTS FROM THE VESTIBULAR NUCLEI IN THE MONKEY. N.M. Gerrits, B. Baggerman, G. Cheron and M. Godschalk*. Dept. of Anatomy, Erasmus Univ., Rotterdam, The Netherlands and Dept. of Neurophysiol., Univ. of Mons-Hainaut, Belgium.

Judged by the number of neurons that can be visualized with retrograde transport of axonal tracers, the dorsomedial pontine reticular formation is one of the major sources of mossy fibers to the flocculus and ventral paraflocculus. Several studies in rat, cat, rabbit and monkey demonstrated in and around the mlf a population of so-called paramedian tract neurons (PMT) with a size similar to that of the population of "secondary" vestibulo-cerebellar mossy fiber neurons. In the monkey (M. fascicularis), approximately 40 percent of the PMT's is located in two clusters, one ± 2 mm caudal to the facial genu, the other directly rostral to the abducens nucleus. The majority of PMT neurons are dispersed between the bundles of the mlf.

Injections with WGA-HRP in the medial (MV) and superior (SV) vestibular nuclei resulted in wide-spread labeling of axon terminals in the entire region containing PMT neurons. Since the ascending connections of the MV and SV are basically related to horizontal and vertical eye movements (EM), respectively, the results suggest an intermingling of horizontal and vertical EM related PMT neurons.

SYNAPTIC ACTIONS OF VERTICAL EYE POSITION-RELATED INTERSTITIOVESTIBULAR NEURONS IN THE ALERT CAT. Y. Iwamoto*, S. Chimoto, E. Nambu, K. Yoshida Dpt. Physiology, Inst. Basic Med. Sci., Univ. of Tsukuba, Tsukuba, 305 Japan

We have recently shown that many vertical eye position-related neurons in and around the interstitial nucleus of Cajal (INC) project to and arborize in the ipsilateral superior vestibular nucleus. In the present study, we investigated in the alert cat possible projections of vertical eye position-related INC neurons to the trochlear nucleus. In two animals, 37 of 113 neurons were activated antidromically from the trochlear nucleus or nearby MLF. Most activated neurons (33/37) had downward on-directions. We performed tracking through the trochlear nucleus to obtain the depth profile of thresholds for antidromic activation. Multiple low threshold peaks and variation in latency were observed in some neurons with downward on-directions, suggesting direct projection of downward-on INC neurons to trochlear motoneurons. Since interstitiovestibular neurons also had downward on-directions, there is a possibility that the same downward-on INC neurons project to both the trochlear and vestibular nuclei. We then made an attempt to decide the synaptic nature of interstitiovestibular neurons by spike-triggered average of field potentials in the superior vestibular nucleus. In three eye position-related neurons with downward on-directions, unitary synaptic field potentials with a negative polarity were detected at monosynaptic latencies, suggesting excitatory actions. The results suggest that vertical eye position-related interstitiovestibular neurons exert excitatory synaptic actions upon both vestibular nucleus neurons and trochlear motoneurons.

EFFERENT PROJECTIONS OF THE PRIMATE INTESTITIAL NUCLEUS OF CAJAL. A.K. Moschovakis*, C.A. Scudder[1], C. Balaban[1], S.M. Highstein[2] and T. Kokkoroyannis. Laboratory of Neurophysiology, Dept. of Basic Sciences, P.O. Box 1393, Faculty of Medicine, University of Crete, Iraklion 71110, Grete, Greece, [1]Eye and Ear Institute, Pittsburgh University, Pennsylvania, U.S.A., and [2] Department of Otolaryngology, Washington University School of Medicine in St. Louis, Missouri, U.S.A.

The efferent projections of the mesencephalic Nucleus Interstitialis of Cajal (NIC) were studied in the squirrel monkey following bulk injections of biocytin and PHA-L near functionally identified oculomotor related burst-tonic neurons of the NIC. Dense terminal fields were encountered: a) contralaterally, in the NIC, the oculomotor nucleus and the trochlear nucleus, and b) ipsilaterally, in the Fields of Forel, the rostral interstitial nucleus of the medial longitudinal fasciculus, the oculomotor and trochlear nuclei, the gigantocellular reticular formation, as well as the ventromedial and commissural nuclei of the first two cervical segments of the spinal cord. Moderate or weak terminal fields were observed: a) bilaterally, in the mediodorsal, centre medianum central lateral, central medial and parafascicular thalamic nuclei, and b) ipsilaterally, in the zona incerta, the mesencephalic reticular formation, the pedunculopontine nucleus, the nuclei reticularis pontis oralis and caudalis, the superior, medial and lateral vestibular nuclei, as well as the nucleus prepositus hypoglossi, the abducens and the hypoglossal nucleus, the magnocellular reticular formation, the inferior olive as well as the pontine and medullary raphe.

AFFERENTS TO THE SIMPLEX LOBULE MICROZONE RELATED TO EYELID MOVEMENTS IN THE CAT. A. Gruart*, J.A. Armengol and J.M. Delgado-García. Lab. de Neurociencia, Fac. de Biología and Dpto. de Ciencias Morfológicas, Fac. de Medicina. Univ. de Sevilla, Sevilla, Spain.

The topographical location of brainstem and deep cerebellar neurons projecting to the eyelid microzone of the simplex lobule was studied in the cat. Under general anesthesia, horseradish peroxidase (Sigma type VI, 1.5-3 μL of a 30% saline solution) was injected in six adult cats in the area of the simplex lobule activated by the electrical stimulation of the supraorbitary branch of the trigeminal nerve. After 24-48 h of survival, animals were perfused and their brains processed according to the tetramethylbenzidine procedure. Deep cerebellar nuclei neurons projecting to the eyelid microzone were located in the dorsomedial aspect of the most rostral part of the posterior interpositus nucleus. Contralateral labeled brainstem neurons were located in the spinal trigeminal and prepositus hypoglossi nuclei, in the rostral medial accessory inferior olive, and in the lateral and dorsal subdivisions of the pontine gray. Ipsilateral projections arised from the lateral reticular, the external cuneate nuclei, and a discrete zone of the medial pontine gray. Bilaterally labeled neurons were placed within the lateral tegmental area, the paramedian reticular nucleus, and the reticularis tegmenti pontis nucleus. This complex pattern of afferents suggests that the simplex lobule plays a key role controlling the different types of lid movement.

ABSENCE OF AGE-RELATED CHANGES IN EYELID KINEMATICS. R.S. Baker*, J.C. Chuke, B.R. Rouholiman, M.W. Stava, and J.D. Porter. Depts. of Ophthalmol. & Anat. & Neurobiol., U. of Kentucky Med. Ctr., Lexington, KY.

Neurologic disorders that affect blinking (e.g., blepharospasm, Parkinson disease) often manifest at ≥50 years of age. Eyelid kinematics provide insight into the altered blink reflex excitability that may accompany disease. To evaluate the normal aging pattern, we used a modified scleral search coil technique to analyze blinks in normal human subjects for each decade between 40-90 years (n=5/decade). Mean amplitude and peak velocity decreased across this interval for both down (amp: 38.8° ± 4.4 to 26.0° ± 2.8, $p<0.05$; vel: 1200°/sec ± 162 to 818°/sec ± 131, $p<0.05$) and up (amp: 36.0° ± 5.3 to 24.2° ± 3.4, $p<0.05$; vel: 587°/sec ± 43 to 439° /sec ± 72.2, n.s.) phases of spontaneous blinks. Much of the decrease could be attributed to reduced palpebral fissure width (12.4 to 10.2 mm, $p<0.05$). Despite down phase amplitude reduction of >30%, down phase duration remained constant. Blink down phase main sequence (amplitude-peak velocity) slope is an indicator of reflex excitability. There was no change in main sequence slope across the age range tested, suggesting that reflex excitability was unchanged. Blink conjugacy also showed no change, with consistently high interocular correlations for amplitude/peak velocity across the intervals studied. Blink rate was unchanged across the age range tested. Together, these studies evaluated the hypothesis that blink excitability changes as a function of age, with the hyperexcitability that is seen in blepharospasm and Parkinsons representing extremes of normal aging. The peripheral eyelid and/or muscle changes leading to age-related ptosis were not accompanied by altered reflex excitability. These data then suggest that disease-related alterations in blink behavior and, by correlation, in the blink neural control systems, are not simply an exaggeration of normal aging changes. Supported by NIH EY010760, the Benign Essential Blepharospasm Research Foundation, and Research to Prevent Blindness.

ACTIVITY OF BRAINSTEM NEURONS DURING BLINK-SACCADE INTERACTIONS. L. E. Mays* and D. W. Morrisse. Dept. of Physiological Optics and Vision Science Research Center, University of Alabama at Birmingham, Birmingham, AL 35294.

Recently, we have shown that pontine omnipause neurons (OPNs) in the monkey pause for blinks as well as for saccades (Soc. Neurosci. p. 1404, 1993). Blink-related pauses last ≈ 140 ms and are easily elicited by air puffs directed at the face. Current models of saccade generation suggest that neuronal activity builds up in other saccade-related neurons prior to each saccade, and that turning off OPNs prematurely during this build-up period will result in slow saccades. We tested this hypothesis in three rhesus monkeys by timing the delivery of an air puff to produce a blink before, during, or after a saccade to a visual target.

The occurrence of a blink just before a saccade resulted in a slowed saccade, often with a complex velocity profile. Blinks which occurred >70 ms prior to the expected onset of the saccade had little or no effect on the saccade. Horizontal short-lead burst (SLB) neurons were recorded during blink-saccade interactions in two monkeys. SLB activity was reduced for those saccades that were slowed by blinks. This result indicates that the slowing of saccades by blinks is not due simply to co-contraction of extraocular muscles or other mechanical effects. Surprisingly, the activity of saccade-related burst neurons in the superior colliculus was also reduced for blink-slowed saccades. (Supported by NIH grants EY03463 and EY03039 and by the McKnight Endowment Fund for Neuroscience.)

EFFECT OF AGE ON BLINK REFLEX EXCITABILITY C. Evinger[1]*, E.J. Schicatano[1], A.K.E. Horn[2], J.J. Pellegrini[3]. [1]Dept. Neurobiol. & Behav, SUNY Stony Brook, Stony Brook, NY 11794-5230, [2]Inst. Neuropathol.,Univ. Munich, Munich, Germany, [3]Dept. Biol., College of St. Catherine, Minneapolis, MN 55105

Uncontrollable spasms of lid closure are most common in middle aged and elderly individuals. Increases in blink reflex excitability accompany the development of lid spasms. Nevertheless, the connection between increased blink reflex excitability, aging and the development of lid closure spasms is unclear. We investigated these associations in old and young guinea pigs (GPs).

Young (<6 months) and old (>2 years) GPs were chronically implanted with electrodes for bilateral stimulation of the supraorbital branch of the trigeminal nerve (SO) and recording of emg activity (OOemg) of the lid closing, orbicularis oculi (OO) muscle. We determined blink reflex excitability by presenting pairs of identical SO stimuli with interstimulus intervals (ISIs) of 50-1250 ms and compared the magnitude of the OOemg evoked by the 2nd stimulus to that evoked by the 1st stimulus. After determining normal blink reflex excitability, the auriculopalpebral branch of the VIIth nerve was crushed to weaken the OO muscle and induce compensatory increases in blink reflex excitability.

Blink excitability and the compensatory response to OO weakening differed between old and young GPs. In old GPs, the lengthened duration of the R2 component of the blink reflex promoted increased excitability of the blink reflex at short ISIs (<250 ms) over that of young GPs. Weakening of the OO muscle potentiated blink reflex excitability at short ISIs for both groups but the increase was larger and recovered more slowly in old GPs. Nevertheless, old GPs did not develop spasms of lid closure. Thus, blink excitability increases with age, but the development of lid spasms is not an inevitable sequelae of increased excitability. BLEPHAROSPASM PRODUCED BY A COMBINATION OF DOPAMINERGIC LESIONS AND ORBICULARIS OCULI WEAKENING. E.J. Schicatano* and C. Evinger, Depts. Neurobiology & Behavior and Ophthalmology, SUNY Stony Brook, Stony Brook, NY 11794-5230

Unilateral destruction of midbrain dopamine neurons dramatically increases the excitability of the blink reflex by reducing tonic inhibition of the trigeminal nucleus. Increases in blink reflex excitability also occur as a compensatory response to weakening of the orbicularis oculi muscle (OO). We investigated the relationship between these two mechanisms of blink reflex plasticity.

Rats were implanted with electrodes to stimulate the supraorbital branch of the trigeminal nerve (SO) bilaterally and record the OO activity (OOemg) chronically. Sensorimotor excitability was measured by presenting pairs of identical SO stimuli with interstimulus intervals of 50-300 ms and comparing the magnitude of the OOemg evoked by the second stimulus to that evoked by the first. Interactions between SO and auditory evoked blinks were also assessed. We tested blink reflex excitability in two groups of alert rats. In both groups, we removed a 2 mm section of the facial nerve innervating the OO. The second group received a small, unilateral 6-OHDA lesion (<30% cell loss) of midbrain dopamine neurons 20 days before the nerve transection.

Both 6-OHDA lesions and facial nerve lesions alone produced modest increases in blink reflex excitability. The combination of the 6-OHDA and facial nerve lesions, however, elicited a large increase in blink reflex excitability accompanied by lid closure spasms such as occur with blepharospasm. Interacting auditory and SO blinks revealed that the facial nerve lesion exerted its greatest effect on trigeminal evoked blinks. Thus, the data suggest that dopamine neuron loss potentiates the normal compensatory increase in trigeminal nucleus excitability induced by weakening of the OO muscle.

PSYCHOPHYSIOLOGICAL STUDIES OF THE BLINK RELFLEX IN THE ALERT CAT. J.F. Lorden*, M.S. LeDoux, J. Smith, & A. Weir. Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

As background for studies to examine the modification of the blink reflex by drugs or manipulation of central pathways, behavioral studies were conducted in seven alert, adult male cats. Under anesthesia, the animals received chronic stimulating electrodes over the supraorbital nerve and recording electrodes in orbicularis oculi muscle for electromyography (OOemg). With a stimulus duration of 0.1 msec and a stimulus magnitude of 1.5X threshold, measures of latency, duration, area, and maximum amplitude (MA) were obtained. The cat, like other mammals, shows both a short-latency (R1) and a long-latency (R2) component in the OOemg. Similar to humans, the mean (± SE) latency for R1 in cat was 10.8 ± .2 msec and for R2, 37.0 ± .1 msec. For both R1 and R2, MA and area measures were significantly correlated. Only area and MA of the R1 and R2 showed significant change as a function of stimulus intensity. In a paired stimulus paradigm in which the interstimulus interval (ISI) was varied from 100-1200 msec, ratios were constructed for the OOemg area and MA by dividing the test response by the conditioning response. In this paradigm, a signficant linear relationship was observed only between ISI and R2 MA. (Supported by the Dystonia Med. Res. Fdn.)

FUNCTION-SPECIFIC SUBDIVISIONS OF THE NUCLEUS OF EDINGER-WESTPHAL AS REVEALED BY TRANSNEURONAL TRANSPORT OF WGA.
J.T. Erichsen*,[1] C. Evinger,[1] W. Hodos[2] and A.P. Adler[1]. [1]Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794 and [2]Dept. of Psychology, Univ. of Maryland, College Park, MD 20742.

In most vertebrates, preganglionic neurons of the midbrain parasympathetic nucleus of Edinger-Westphal [EW] project to the ciliary ganglion. In pigeons, the postganglionic cells innervate the two intraocular muscles, i.e., the iris and the ciliary muscle, and the choroid vasculature. Previous anterograde pathway tracing (Gamlin et al. '84), lesion and immunohistochemical (Reiner et al. '91) studies have provided evidence that EW is organized into three subdivisions corresponding to the postganglionic targets. Retrograde transneuronal transport from the iris or ciliary muscle demonstrates the functional specificity of these subdivisions. WGA injections into the anterior chamber (iris) retrogradely and transneuronally label EW cells in the caudolateral portion of EW. Vitreous injections of WGA label only this same pupillary subdivision, suggesting that the ciliary muscle is not as accessible to WGA as is the iris. Injections into the ciliary muscle label these same "pupillary" cells as well as neurons in a more rostromedial portion of EW. The most ventromedial region of EW remains consistently unlabeled. Counts of transneuronally labeled cells agree with previous estimates of the numbers of pupillary and accommodative neurons, respectively, in EW. Confirming the anatomical results, microstimulation in caudolateral EW produces pupillary constriction; accommodative responses are evoked medially and rostrally. Supported by NEI grants EY04587 (JE), EY07391 (CE) and EY04742 (WH).

CENTRAL CORRELATES OF VISUAL ACCOMMODATION IN HUMANS MEASURED WITH $H_2{}^{15}O$ WATER AND PET

Richter,H.,[1] Lee, J.T.,[2] & Pardo,J.V.,*[2,3] [1]Brain Sciences Center, VAMC, Minneapolis, MN, and Dept. of Physiology, Univ. of Minnesota; [2]Psychiatry PET Unit and VAMC, Minneapolis, MN; [3]Dept. of Psychiatry, Div. of Neuroscience Research, Univ. of Minnesota, Minneapolis, MN.

The purpose of this work was to identify human neural circuits involved in the execution of voluntary positive accommodative eye-movements (VPA). Although accommodative eye-movements can be elicited volitionally, the brain mechanisms subserving higher cortical computations involved in visual accommodation remain elusive. Normalized regional tissue activity (NrTA) was measured using positron emission tomography (PET) and the $H_2{}^{15}O$ bolus technique in 7 healthy, right-handed volunteers with normal vision during three counterbalanced tasks requiring monocular viewing of a checkerboard through a lens introduced into the line of gaze during alternate 1.5 s intervals: (i) passive viewing through 0.00 diopters; (ii) avoiding volitional accommodation and permitting checkerboard blur through -5.00 diopters (i.e., continuous reflexive accommodation); and (iii) attempting to maintain focus through -5.00 diopters (i.e., continuos execution of large amplitude VPA in response to the induced blur). Saccadic eye-movements were suppressed through central fixation upon a cross and were confirmed absent by EOG. Intersubject image averaging of scan pairs showed activation of several structures during VPA: bilateral striate and extrastriate visual cortices; insula; superior and anterior temporal cortices; and cerebellar vermis. VPA recruits an extensive network of heteromodal and unimodal visual association cortices, both novel as well as convergent with previous findings in non-humans (Supported by Department of Veterans Affairs & the Swedish Crown).

LATENCY AND DYNAMICS OF PUPILLOCONSTRICTION DETERMINED BY MICROSTIMULATION OF THE EDINGER-WESTPHAL NUCLEUS AND OCULOMOTOR NERVE IN THE PRIMATE.
R.J. Clarke* and P.D.R. Gamlin. Dept. of Physiological Optics, University of Alabama at Birmingham, Birmingham, AL 35294.

We have been studying the neural control of the pupil in alert rhesus monkeys. To better determine the characteristic latency and dynamics of the pupil plant, we have studied the pupilloconstriction that results from electrical microstimulation of the Edinger-Westphal nucleus (EW) or the pupillomotor fibers of the oculomotor nerve (OMN).

Alert rhesus monkeys fixated a dim laser spot on a tangent screen while the pupil diameter of both eyes was measured under infrared lighting using ISCAN RK-406 pupillometry systems. A microelectrode was lowered under physiological guidance either to the EW or the OMN. Microstimulation was carried out over a wide range of parameters (100-1000 Hz; 10-100 μA; 3-100 ms).

In response to brief stimulus trains, the pupil constricted with a latency of 80-120 ms. The shorter latencies were associated with higher stimulation currents. Peak pupilloconstriction occurred approximately 300-500 ms after stimulation and showed an exponential return to baseline with a time constant of approximately 300-600 ms.

These characteristics indicate that the pupil plant acts as a low pass filter and explain the sluggishness of pupillary responses. The first-order models of the pupil plant that have been proposed do not adequately explain these results and a third-order model is required to provide a more complete description. (Supported by NIH EY09380 and P30 EY03039).

SINGLE-UNIT ACTIVITY RELATED TO THE NEAR-RESPONSE IN AREA 8 OF THE PRIMATE FRONTAL CORTEX.
P.D.R. Gamlin* and K. Yoon. Department of Physiological Optics, University of Alabama at Birmingham, Birmingham, AL 35294.

We have previously reported neurons related to the near-response in a region of the nucleus reticularis tegmenti pontis (Gamlin and Clarke, J. Neurophysiol., 1995) that is reported to receive input from area 8 of the frontal cortex. We have therefore begun to study neurons in area 8 during vergence and ocular accommodation.

Single-unit recording from area 8 of an alert, behaving rhesus monkey identified 15 neurons that showed activity specifically linked to the near-response. Most of these cells exhibited transient increases in their firing-rate during the near-response. Some cells also displayed a tonic firing-rate that increased as a function of increases in convergence and accommodation. Microstimulation (30-50μA; 30-50ms; 500Hz) at the site of some of these neurons elicited increases in accommodation and convergence of approximately 0.2-0.5 diopters and 0.2-0.5 degrees respectively. An injection of fluorescent latex beads at the location of the recording sites showed that they were located immediately posterior and dorsal to the principal sulcus.

The region of area 8 related to saccadic eye movements includes the anterior bank of the arcuate sulcus and the immediate prearcuate cortex. The region involved in smooth pursuit eye movements includes the fundus of the arcuate sulcus. These regions have been termed collectively the frontal eye field (FEF). The present study suggests that the FEF may be involved in all voluntary eye movements and that it may extend anteriorly to include a region of area 8 related to vergence and ocular accommodation. (Supported by NEI Grant EY07558 and P30 EY03039).

THE PRIMATE OLIVARY PRETECTAL NUCLEUS AND ITS ROLE IN THE PUPILLARY LIGHT REFLEX.
W. Sun* and P.J. May. Depts. of Ophthalmology & of Anatomy & Neurobiology, U. of Kentucky Med. Ctr., Lexington, KY 40536 and Depts. of Anatomy & Ophthalmology, U. of Mississippi Med. Ctr., Jackson, MS 39216.

It is generally presumed that an olivary pretectal (OPt) nucleus to Edinger-Westphal (EW) nucleus projection is the central relay in the pupillary light reflex pathway. However, the organization of the OPt nucleus and its projections have not been described in primates. The tracers biotinylated dextran amine (BDA), biocytin and WGA-HRP were used in *Macaca fascicularis* monkeys to investigate these points. BDA injected along the path between the OPt and the oculomotor nuclei homogeneously labelled neurons whose somata were generally located in the periphery of the ovoid-shaped OPt nucleus. Their highly branched dendrites were directed toward and filled much of the center of the nucleus. A combined antero- and retrograde tracing approach was utilized to reveal the relationship between the pretectal projections and the preganglionic motoneurons. Labelled preganglionic motoneurons were restricted to the ipsilateral EW nucleus and its anteromedian nucleus extension following WGA-HRP injections into the ciliary ganglion. Biocytin injections into the OPt nucleus of the same animal labelled pretectal terminals bilaterally in and around the EW nucleus. These labelled pretectal terminals were concentrated within the middle third of the EW nucleus in its rostrocaudal dimension, and were more dense medially. The area in which pretectal axon terminals were found immediately adjacent to labelled preganglionic motoneurons, suggesting a direct connection between these two, was quite restricted. Neither anterogradely labelled terminals, nor retrogradely labelled cells were observed in the contralateral OPt nucleus following the pretectal injections. In conclusion, this study indicates that the dendritic organization of OPt projection neurons is suitable for producing very large visual fields, in agreement with their reported physiology. The bilateral OPt-EW projection, along with the bilateral retinal-OPt projection, represents an anatomical substrate for the direct and consensual components of the pupillary light reflex. Finally, only a small portion of the EW nucleus may subserve this reflex in monkeys. Support: NEI grant EY09762 (PJM).

754.12

THE SIMIAN PUPILLARY LIGHT REFLEX AND THE RESPONSE PROPERTIES OF ITS PRETECTAL INTERNEURON.
Milton Pong and Albert F. Fuchs*. Dept. of Physiology and Biophysics and Regional Primate Research Center, University of Washington, Seattle, WA.

By means of a CCD imaging system, we measured the pupillary response to brief, full-field flashes of light in 4 monkeys. As in man, the flash causes the pupil to undergo a relatively rapid constriction followed by a 50%-slower dilation to its original size. The responses were variable but, on average, the constriction amplitude and peak velocity increased and the response latency decreased with light intensity. The pupillary response was consensual.

To pursue the neuronal substrate of the pupillary light reflex, we recorded unit responses in the pretectum of 2 monkeys to 1 sec light flashes. All of our neurons lay in a tight cluster in close proximity to the pretectal olivary nucleus (PON), a small structure believed to contain the interneurons of the pupillary light reflex. Most of our neurons (32/37) exhibited a burst in firing to the light flash after an average latency of 54 ms (SD=19) followed by a sustained discharge that was less than the burst rate. The sustained discharge continued for the duration of the flash and returned to the pre-burst firing at a fixed latency after the flash turned off. The frequency of the sustained discharge increased with light stimulus intensity. The close temporal correlation of the firing patterns of these neurons with the visual stimulus and not with the pupillary response suggest that movement per se does not influence their discharge. In the vicinity of these "burst-tonic"neruons, a small number of transient neurons discharged only bursts at light on and off. Finally, electrical stimulation at the locations of the burst-tonic cells often evoked pupillary constrictions at currents as low as 20μa.

Taken together, our data suggest that the pupillary light reflex in monkeys closely resembles that in humans and that, as in other species, the PON serves as the site of its interneurons in the pretectum. Supported by grants EY00745, RR00166 and a Visual Training Research Grant #EY 07031.

DESCENDING PROJECTIONS FROM THE CORTICAL ACCOMMODATION AREA TO THE BRAINSTEM IN THE CAT.

A. Sato, K. Ohtsuka, and M. Sawa*. Dept. of Ophthalmology, Sapporo Medical Univ. Sch. of Med., Sapporo, Hokkaido 060, Japan.

Previous studies indicated that the lateral suprasylvian area (LS) is related to the control of lens accommodation in the cat. It is known that the LS projects to the pretectum (PT) and the superior colliculus (SC). We previously indicated that both of the rostral SC and the PT are involved in the control of lens accommodation. In this study, we investigated connections between the cortical accommodation area in the LS and the brainstem accommodation areas in the cat.

This study was conducted in 6 cats, weighing 2.5-3.5 kg. WGA-HRP was injected by glass micropipettes into the accommodation area of the SC or the PT where accommodative responses were elicited with the low intensity < 20 μA, and studied retrogradely labeled cells in the LS. Secondly, accommodative responses to stimulation of the LS were compared before and after injection of muscimol (GABA agonist) into the the rostral SC. Following WGA-HRP injections into the accommodation area in the rostral SC, labeled cells were found mainly in the lower part of the medial bank of the medial suprasylvian sulcus (MSS), where is comparable to the accommodation area of the LS. On the other hand, following injections into the accommodation area in the PT, labeled cells were found mainly in the upper part of the medial bank of the MSS, where is comparable to the pupillary constriction area. After injections of muscimol into the SC, accommodative responses evoked by stimulation of the cortex were almost abolished. These findings suggest that the accommodation area of the LS projects exclusively to the rostral SC.

754.14

ACCOMMODATION-RELATED AREAS IN THE BRAINSTEM OF THE CAT.

S. Konno, and K. Ohtsuka*. Dept. of Ophthalmology, Sapporo Medical Univ. Sch. of Med., Sapporo, Hokkaido 060, Japan.

We previously indicated that the superficial~intermediate layers of the rostral superior colliculus is involved in the control of lens accommodation in the cat (Sawa and Ohtsuka, *Vision Res.*, '94). This area is thought to project to the pretectum (PT) and the mesencephalic reticular formation (MRF), which may be related to the control of accommodation. In this study, we conducted systematic mapping with microstimulation of these areas monitoring accommodative responses by an infrared optometer in the cat. This study was conducted in 8 cats. Tungsten microelectrodes were introduced stereotaxically into the brainstem, and the midbrain area located rostral to the SC was stimulated systematically. Accommodative responses were monitored with an infrared optometer (Nidek, AR-1100). At the end of each experiment, electrolytic lesion was made at the lowest threshold site. After the experiments, the animals were deeply anesthetized with pentobarbital sodium and were perfused transcardially. Locations of the electrolytic lesions and electrode tracks were identified. Low threshold areas for evoking accommodation were located at the postero-lateral portion of the PT, where was almost comparable to the nucleus optic tract (NOT), the olivaly pretectal nucleus (OPN) and the posterior pretectal nucleus (PPN), the nucleus posterior commissure (NPC) and the medial portion of the MRF. The OPN and the MRF are also thought to be involved in the control of pupillo-constriction and vergence eye movements, respectively. Accommodation, pupillo-constriction and vergence are functionally linked with each other as the ocular near response.

754.15

INNERVATION OF THE SMOOTH MUSCLE OF THE EXTRAOCULAR RECTI PULLEYS IN HUMANS AND MONKEYS.

J. L. Demer*, V. Poukens, and P. Micevych. Depts. of Ophthalmology, Neurology, Pathology, and Anatomy, University of California, Los Angeles, CA. 90095-7002.

The recti extraocular muscles pass through connective tissue pulleys, located at the level of posterior Tenon's fascia, that stabilize muscle paths and control muscle pulling direction. Structures supporting these pulleys include substantial smooth muscle (SM) bundles, suggesting possibile dynamic regulation of pulley function.

To investigate neural control of pulley SM, histo- and immunohistochemical studies were performed on rhesus monkey and human orbital tissues. Two weeks prior to paraformaldehyde perfusion, both superior cervical ganglia of a monkey were injected with the lectin anterograde tracer PHA-L. Immunoperoxidase staining with a monoclonal antibody against human SM alpha-actin was used to confirm pulley SM. Mono- and polyclonal antibodies were used to demonstrate immunoreactivity (IR) to tyrosine hydroxylase (TH), dopamine ß-hydroxylase (DBH), catechol-O-methyltransferase (COMT), myelin basic protein (MBP), PHA-L, neuronal nitric oxide synthase (NOS), and snyaptophysin. The NADPH diaphorase reaction was also used as a marker for NOS, and the acetylcholinesterase (AchE) reaction for Ach.

Rich innervation was found in human and monkey pulley SM. Numerous axons terminating in motor endplates within SM bundles had IR to TH, DBH, and PHA-L but not COMT. Smaller axons and motor endplates were also demonstrated in SM using NADPH diaphorase and AchE, as well as NOS IR. The pterygopalatine and to a lesser extent the ciliary ganglia but not Edinger-Westphal nucleus had cells with NOS IR. Although large orbital nerves had MBP IR, none was found in pulley SM.

The smooth muscle suspension of monkey and human recti pulleys has a sympathetic projection employing norepinephrine via the superior cervical ganglion, a nitroxidergic projection from the pterygopalatine ganglion or other sources, as well as a cholinergic parasympathetic projection. These multiple projections suggest the existence of both excitatory and inhibitory control of recti pulley SM potentially subserving a dynamic role in regulation of ocular motility.

CONTROL OF POSTURE AND MOVEMENT: PREHENSION

755.1

SYNCHRONIZATION IN FINGER MOTOR UNITS DURING THE PRECISION GRIP IN MAN.

E.J. Hüsler, G.C. Maissen, M.A. Maier and M.-C. Hepp-Reymond*. Brain Research Institute, Univ. of Zürich, 8029 Zürich, Switzerland.

Since the multi-muscular, multi-joint system of the hand is biomechanically overspecified, the question was raised whether short-term synchronization is a strategy to facilitate the control of motor units (MUs) within and between muscles.

Synchronization was assessed in the precision grip during production of isometric force on 3 consecutive levels (1,2,3 N). Up to 5 simultaneously recorded intramuscular EMG signals were decomposed into their constituent MU potentials yielding 93 MUs (1 to 4 MUs/muscle). The maximal firing rate in the force range investigated was 14 Hz. For the vast majority of the MUs, the firing rate correlated with the force exerted. The MU spike trains were cross-correlated at each force level. In total, 75 of 166 intermuscular and 54 of 69 intramuscular MU pairs showed synchronization at any one force level. In pairs where both MUs were located in the extrinsic or intrinsic muscles, synchronization was more likely and stronger than in mixed pairs. Furthermore, among MUs of intrinsic muscles, pairs between thumb and index finger muscles (33/66) were synchronized to a comparable degree as pairs between muscles moving only one digit (12/21), thus indicating the presence of functional synergies. An important finding was that synchronization is unstable: it occurred on all 3 force levels only in one intermuscular (1DI-1PI) and in four intramuscular pairs (2xAbPL, AdP, FPL). We checked factors that might influence the probability of synchronization. Synchronized MUs had smaller differences between their firing rate (≤ 2 Hz) and lower firing rates than non-synchronized ones. Synchronization occurred preferentially just after recruitment of both MUs or of the MU with higher threshold.

In conclusion, stable synchronization of MUs does not seem to be a prerequisite for the control of finger muscles during force production in the precision grip, thus confirming previous findings at the global EMG level.

MODIFICATION OF PREHENSION KINEMATICS WHEN AVOIDING AN OBSTACLE

M.Saling, J.Alberts, J.R.Bloedel and G.Stelmach*. Motor Control Lab., Arizona State University, Tempe AZ 85287, Barrow Neurological Institute, Phoenix, AZ.

Previously we had shown that, by altering the initial grip posture, the aperture reorganized without influencing the wrist transport. The aim of this study was to determine whether modification of the wrist trajectory affects the kinematics of the aperture. To examine this issue, either of two different plexiglass obstacles (20x1.5x9 cm or 20x1.5x 11 cm) were placed between the hand starting position and object. The subjects were asked to reach over the obstacle and grasp a dowel (9 x 2cm). The results showed that obstacle avoidance significantly prolonged transport duration, deceleration time, time to peak velocity and peak deceleration. Also, the time to peak aperture and the time to the peak opening and closing velocities of grip were significantly longer compared to those of control. However, when expressed as a percentage of transport duration, no differences were found in any temporal parameter of the grip. Primarily these data show that the kinematics of both components were influenced by obstacle avoidance. The temporal aspects of the grip were adjusted to those of the transport and suggest some degree of co-dependence. These findings support a view that grip aperture adjustments are influenced by the temporal profile of the transport component.

CONTROL OF PRECISION GRIP FORCE DURING BEHAVIOR THAT MIMICS SMOOTH PURSUIT. K.J. Cole* and R.S. Johansson. Dept. of Exercise Science, The Univ. of Iowa, and Dept. of Physiology, Univ. of Umeå, Umeå, Sweden.

Ramp loads that pull a gripped handle away from the hand cause the grip force to smoothly track the load force after an initial grip force pulse triggered by the increasing load force. The tracking behavior in 9 subjects was studied to determine the control mechanisms governing pursuit-like tracking, and the saccade-like pulses in grip force that often occur during tracking. We examined the possibility that subjects learn the smooth tracking response from the load shape on previous trials. Ramp loads of 4 N/s followed blocks of trials that began as a ramp load but which accelerated or decelerated after 0.75 s. The grip force during ramp loading was affected little or not at all by the conditioning loads. Also, the grip force closely tracked various load waveforms (ramps, slowly accelerating or decelerating loads). We conclude that the control process for the pursuit-like behavior uses sensory information from loading over a short time interval. Smooth tracking most likely results from a feedforward controller that consecutively extrapolates the current waveform during short time intervals. It operates in addition to a mechanism that is sensitive to unexpected changes in load force rate, or otherwise decreasing grip/load force ratios. Loads that accelerate from an initial ramp often cause repetitive pulsatile grip responses lasting about 250 ms, beginning as soon as 80 ms after acceleration onset. We suggest that stable grasp on the object is maintained by one control mechanism that operates nearly continuously, and by one that responds to discrete mechanical events at the fingertip or finger.

755.4

DEVELOPMENTAL CHANGES IN PREHENSION FOR CHILDREN OF 2 TO 9 YEARS OLD. M.Paré[1] and C.Dugas[2]* 1- Centre de Recherche en Sciences Neurologiques, Université de Montréal, Canada, H3C 3J7; 2- Département des sciences de l'activité physiques, Université du Québec à Trois-Rivières, Canada, G9A 5H7.

Anticipatory control is required to produce skilled manipulation of grasped objects. Adults program the entire movement with a single force-rate pulse by anticipating the required grip and load force to lift the object (Johansson and Westling, 1988). Recently, Forssberg et al. (1991,1992) have demonstrated that children are not capable of doing this until the second year, and that this anticipatory mechanism continues to develop over several years. The goal of the study was to demonstrate that the emergence of an adult pattern of grip and load force coordination is correlated with a an adequate safety margin adapted to the weight of the object. Moreover, we also wanted to quantify the relationship between the grip force and the vertical acceleration of the object during maturation. The subject (N=36) had to lift an object which could vary in size and weight using a precision grip. The object was instrumented with a pressure gauge to measure grip force. The displacement of the arm and object was recorded with a Peak Performance system. The results demonstrate three distinct stages in the development of the precision grip, from to 2 to 5 years old, from 6 to 8 years old and beyond 9 years old. At 2 years of age, the peak acceleration was negatively correlated (r= -0.51) with the peak grip force during lifting. By 3 years of age, the relationship between the peak acceleration and the peak grip force during lifting became positively correlated (r=0.32) and continued to consolidate until 9 years of age. Also, starting at 6 the safety margin steadily decreases and reaches a stable value by 9 years of age. (Supported by NSERC and FCAR)

TASK REQUIREMENTS IN GRASPING: KINEMATICS AND FORCES FOR TRANSPORTING, DRAGGING AND SELECTING. C.L. MacKenzie*, E.D. Graham and C.I. Ivens, Human Motor Systems Lab., School of Kinesiology, Simon Fraser University, Burnaby, B.C. Canada V5A 1S6

Task requirements and object properties affect kinematics (Kunesch, Binkofski & Freund, 1989) and forces (Fearing, 1986; Westling & Johansson, 1990) in grasping and manipulation. We studied tasks that require object transport and manipulation like dragging and selecting in human-computer interaction.

Human adults grasped a dowel (155 g, force transducers) using pad opposition, and placed it on small or large targets, forward or backward. They transported the dowel in three conditions: "naturally", by "dragging" (squeezing during transport), and by "selecting" (squeezing on placement). 3D kinematics of the hand and dowel (OPTOTRAK 3D motion analysis system, 200 Hz), grip and load forces were measured throughout free motion, compliant motion, and loaded motion phases of the movement. Kinematics during free motion had lengthened deceleration phases for "drag" and "select" conditions, compared to "natural"; kinematics during free motion and loaded motion phases had lengthened deceleration for smaller targets, attenuated for "drag" and "select" conditions; grip and load forces changed predictably with tasks, validating that subjects were performing as instructed; load forces during compliant motion peaked earlier for forward than backward transport. Results support anticipatory planning of parameters for using an opposition space (MacKenzie & Iberall, 1995) in the earliest phases of movement.

755.6

THE ROLE OF THENAR MUSCLE ACTIVITY IN THE CONTROL OF INDEX FINGER FORCE. D.H. Laidlaw*, M. Bilodeau, and R.M. Enoka. Dept. Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, OH 44195

Although the control of isometric abduction force by first dorsal interosseous (FDI) has been well characterized, little is known about the contribution of thenar muscle activity to index finger force under these conditions. To address this issue, experiments were designed to examine thenar muscle activity during maximum voluntary contractions (MVCs) and submaximal constant-force contractions (5% and 20% MVC). Surface EMG signals were recorded from the FDI, adductor pollicis (AP) and flexor pollicis brevis (FPB) of 6 young subjects. With the hand positioned so that the palmar surface rested on a horizontal surface, the thumb was either extended by about 90 degrees in the same plane or abducted by about 90 degrees so that it was in a plane perpendicular to the palmar surface. With the thumb in the abducted position, the statistically significant findings were: (1) less FDI EMG during an MVC; (2) reduced EMG in AP and FPB relative to FDI during the MVC and constant-force tasks; (3) decreased MVC abduction force exerted by the index finger; and (4) no effect on the control of submaximal force (coefficient of variation). These results suggest that, while thenar muscles are biomechanically coupled with first dorsal interosseous, activity in these muscles is not related to the control of index finger abduction force under isometric conditions. However, FDI activation appears to be less than maximal with the thumb in the abducted position

TIME-DEPENDENT EFFECTS OF ANTAGONIST MUSCLE VIBRATION ON THE PERCEPTION OF ISOMETRIC FINGER FORCE. H. Henningsen*, B. Ende-Henningsen, S.Knecht, A.M. Gordon. Depts. of Neurology and Neurophysiology, Univ. of Wisconsin, Madison, WI 53705; Dept. of Neurology, Univ. of Münster, Germany; Dept. of Physiology, University of Minnesota, Minneapolis, MN 55455

We examined the contribution of agonist and antagonist muscle spindles to the perception and control of isometric finger force. Nine subjects were trained to produce a force level of 50 ± 25 g with the index finger. Following training, either the agonist (flexor digitorum superficialis) or antagonist (extensor indicis) was vibrated at 100 Hz for 5 sec prior to the onset of force. Agonist vibration resulted in an overshoot of the trained force level, likely due to autogenic reflex facilitation. Surprisingly, antagonist vibration resulted in a similar overshoot of the trained force level.

To further examine the role of antagonist spindles in the control of isometric force, we then vibrated the antagonist at various time periods relative to the onset of force. The time periods included 5 sec vibration 1) again prior to the onset of force, 2) overlapping the onset of force, 3) initiated at the onset of force, 4) initiated during the dynamic force increase, and 5) initiated during the hold phase of contraction. Antagonist vibration caused the largest overshoot of force if it occurred prior to the onset of force. The overshoot diminished progressively as the vibration was initiated later, with no overshoot when the vibration was initiated during the hold phase. We propose that sensory information from antagonist muscle spindles contributes to an internal model of the initial state of the effector prior to the initiation of force. Thus, this information mainly is used for the feedforward control of isometric force.

755.8

ILLUSORY FINGER MOVEMENTS EVOKED BY ENSEMBLE CUTANEOUS INPUT FROM THE DORSUM OF THE HUMAN HAND. D.F.Collins* and A.Prochazka Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada, T6G 2S7.

Movement illusions evoked by tendon vibration have established an important muscle spindle contribution to human kinesthesia. The extent of any cutaneous contribution is unclear, though recordings from skin receptors on the hand dorsum show that they can provide detailed kinematic information (Edin & Abbs, *J. Neurophysiol.* 65(3):657-670, 1991). We have now tested the hypothesis that ensemble stimulation of these receptors results in illusions of movement. Two techniques were used on naive subjects. First, electrical stimuli were delivered through an electrode array (4-16 pairs) on the dorsum of the right hand and fingers. The low intensity (1-1.7x perceptual threshold) stimulus pulses (80 μsec) were frequency-modulated from 0-700 Hz, sinusoidally at 0.3 Hz. Illusory movements were evoked in 11/24 subjects (44%) as revealed by matched movements of the opposite hand. These typically involved perceived flexion of the metarpo-phalangeal (MCP) joint(s) during periods of increasing stimulus frequency. Secondly, mechanical stretch of the skin was used to provide a stimulus more specific to receptors excited during natural movements. Small loops of string or squares of adhesive tape were stuck to the skin on the dorsum of the hand and fingers. These were attached to elastic bands which permitted even application of skin stretch, bi-directionally, away from the MCP joint at approximately 0.3 Hz. Illusory movements were evoked in 10/18 subjects (56%). These typically involved perceived extension of the MCP joint during periods of skin stretch. Six subjects were re-tested in a more controlled experiment to reduce and measure any actual movements of the fingers caused by the skin stretch. Three subjects perceived movements when actual movements were immeasurably small. The results show that cutaneous input alone is sufficient for the perception of movement. However, this cutaneous contribution to human kinesthetic sensibility is likely smaller than that of muscle spindles. Supported by the AHFMR and the Canadian MRC.

TACTILE LOCALIZATION DURING DISCRETE AND CONTINUOUS MOVEMENTS OF DIFFERENT SPEEDS. P. Dassonville* & J. C. Nagode, Brain Sciences Center, Minneapolis VA Medical Center, and Department of Physiology, University of Minnesota Medical School, Minneapolis, MN 55417.

The perceived location of a tactile stimulus in 3-D space has been shown to rely on an internal representation of hand in space that inaccurately encodes the timing and velocity of arm movements (Dassonville et al., Soc. Neurosci. Abs., 1993, 1994). On average, subjects report a stimulus presented to the finger during a fast discrete movement of the arm to be at the spatial location occupied by the hand approximately 90 ms after stimulus onset. Furthermore, the pattern of localization errors from some subjects indicates an internal representation that underestimates the hand's actual velocity. In the present study, we have characterized this representation during discrete and continuous movements of different speeds.

In the discrete movement task, subjects were instructed to point to the spatial location of a tactile stimulus presented to the index finger during a previous visually evoked movement of the hand performed at one of three distinct speeds (average speed = 1.2, 0.6 or 0.4 m/s). Localization errors were somewhat smaller for stimuli presented during the slow movements. However, the pattern of errors was consistent with an internal representation that underestimates movement velocity over a wide range of movement speeds. In a separate task, stimuli were presented to the finger during continuous tracing movements (average speed = 1.0, 0.7 or 0.35 m/s) around a circular template (175 mm diameter) displayed on a video monitor. Using the arrow keys of a keyboard, the subjects moved a cursor to the perceived location of each stimulus. On average, stimuli were perceived to occupy the location of the hand 47 ms after stimulus onset, with significantly smaller temporal shifts for stimuli presented during the fast movements (14 ms) than for those presented during the slow (92 ms). Thus, the representation of hand in space appears to match better the time course of fast movements. (Sponsored by PHS NRSA #1 F32 NS09531 & ONR #N/N0014-92-J-1905)

SPECTRAL ANALYSIS OF CUTANEOUS MECHANORECEPTOR ENG ACTIVITY RECORDED FROM A DIGITAL NERVE IN MAN. P. J. Slot and R. R. Riso*, Center for Sensory-Motor Interaction (SMI), Dept. of Medical Informatics and Image Analysis, Aalborg University, Fredrik Bajersvej 7D, DK-9220 Aalborg, Denmark

Activity recorded from the cutaneous afferents in the skin of the fingers is being studied to develop control signals for FNS based grasp restoration neuroprostheses. Contact, loss of contact and slippage events between the fingers and a grasped object evoke robust neural discharges. The purpose of the present studies is to develop techniques to discern these various mechanical events based only on the recorded nerve signals. The ENG was obtained using a tripolar cuff implanted chronically around the common digital nerve subserving the lateral border of the index finger in a volunteer subject with spinal paralysis and C6 level function. A servo-controlled mechanical stimulator was used to indent the skin at predetermined rates or to produce sliding movements of a rectangular shaped, flat surface, contactor. The recorded ENG activity was rectified, bandpass filtered (1kHz-5kHz), sampled at 12.8kHz and digitally stored for offline analysis. Mechanical signals representing contactor perpendicular and tangential forces and positions were sampled at 400 Hz and also stored. The ENG data were analyzed for spectral components using a PC and Fast-Fourier algorithms from Matlab software. Results, thus far, indicate that the frequency spectrum associated with the neural afferent activity evoked by the loss of skin contact has a more discreet frequency spectral composition then the activity evoked during the initiation of skin contact. These findings are encouraging since the utility of whole nerve afferent recordings for the control of FNS neuroprostheses is dependent on our ability to distinguish the underlying mechanical events at the skin object interface purely by examining the mechanoreceptor afferent activity.

CONTROL OF POSTURE AND MOVEMENT: REACHING II

756.1

ARM MOVEMENT RELATED ACTIVITY IN THE SUPERIOR COLLICULUS OF THE MONKEY DURING DIFFERENT EYE POSITIONS V. Stuphorn, E. Bauswein, W.Werner*& K.-P. Hoffmann; Allgemeine Zoologie u. Neurobiologie, Ruhr-Universität Bochum, D-44780 Bochum

Recently, Werner (Eur. J. Neurosc., 5: 335-340) has shown, that the Superior Colliculus (SC) contains neurons which are active before and during arm movements. Thus the primate SC might be also a part of the arm control system. We wanted to see in which reference frame these neurons operate, and therefore investigated the influence of different eye position and retinotopic target location.

In the first task, the 'Saccade-Reach-Task' (SRT), the monkey had to perform first a saccade and then a reaching movement to the target. So it was presented on the fovea when the monkey made his arm movement. In the second task, the 'Fixation-Reach-Task' (FRT), the monkey had to hold central fixation while reaching to the target. In this condition it was represented in the peripheral retina although the position of the target with respect to the head was the same as in the respective SRT.

We found two different types of reach cells. The first one discharges with an equal pattern of activity during movements to the same visual target in both tasks. So the activity of this group of cells does not depend on the position of the target in retinal coordinates. Therefore a transformation of the target representation into a head- or body-centered reference frame must have taken place upstream of this cells.

The second, much smaller, group of reach neurons discharge only, if the target is in a certain position on the screen and the monkey has to perform the FRT. Two conditions are neccesary for the activation of this cell type: a specific sensory pattern, which is represented in retinal coordinates, and the arm reaching movement. Thus this neurons might be part of a sensory to motor transformation.

We conclude from our data, that the majority of reach related cells in the SC operate in a nonretinotopic coordinate system. The existence of different types of arm related actvity indicates, that part of the reference frame transformation takes place in the SC itself. (Supported by Neurovision and Mucom)

IMPAIRMENT OF VISUOMOTOR TRANSFORMATIONS IN ALZHEIMER'S DISEASE. M.F. Ghilardi*, M. Alberoni, S. Marelli, F. Fazio, C. Ghez, M. Franceschi. INB-CNR, HS Raffaele, Universita' di Milano, Italy; Ctr. Neurobiol. & Behav., Columbia Univ. NYS P I, New York, NY 10032

In planning movements to a visual target, the nervous system integrates multi-sensory information to make the spatial transformations needed to bring the hand to the desired location. Since spatial localization may be impaired in Alzheimer's disease, we ask whether trajectory planning is altered in this condition.

Six patients and age-matched controls moved a cursor to 12 radial targets on a horizontal digitizing tablet from midline and lateral initial hand positions without seeing their arm. Target and cursor positions were displayed on a vertical screen in front of, or lateral to the subject. With cursor feedback, paths of both patients and controls were uniformly distributed. When the cursor was blanked during movement, controls showed directional biases varying with initial position (Ghilardi et al., J. Neurophys.1995). Neither extent nor direction varied with screen location. However, in patients movement paths were biased towards the location of the screen where the targets were being displayed for all initial hand position. For example, when the initial hand position was in the midline, hand paths directed forward were hypermetric and curved towards the midsagittal plane when the screen was also in the midline; when the screen was to the right, movements were biased to the right. For initial positions to the right of midline, paths showed corresponding biases according to the screen location.

We conclude that Alzheimer's disease impairs the ability to transform the arbitrary spatial reference frame of the computer screen into the hand-centered coordinate system normally used for motor planning.

CEREBELLAR PATIENTS MAKE INITIAL DIRECTIONAL ERRORS CONSISTENT WITH IMPAIRED CONTROL OF LIMB DYNAMICS A.J. Bastian*& W.T. Thach, Dept of Anatomy, Program in Physical Therapy, The IWJ Inst. for Rehab. Research, Wash. U. Sch. of Med., St. Louis, Mo. 63110.

The purpose of this study was to determine whether cerebellar patients make errors in early phases of reaching consistent with our hypothesis that the cerebellum generates feedforward signals to adjust for interaction torques. This hypothesis suggests that cerebellar patients would 1) make systematic directional errors during the earliest phase of a reaching and 2) increase the magnitude of these errors during faster reaching (when increased interaction torques are generated). We also addressed whether any such errors could be due to abnormalities in relative timing patterns of muscle activity or scaling of magnitude and/or duration of muscle activity. We studied normal and cerebellar subjects reaching in a parasagittal plane under three conditions: a "slow- accurate" condition where seated subjects made a self-paced reach to touch a 1 cm target on a 4 cm ball, a"fast-accurate" condition where subjects moved as fast as possible and touched any part of the 4 cm ball, and a "fast" condition where subjects moved as fast as possible towards the target, but were not required to stop on the target. Shoulder, elbow, wrist, and finger kinematics were videotaped and analyzed. EMGs from the anterior deltoid (AD), posterior deltoid (PD), biceps (BI), and triceps (TRI) were recorded and analyzed. Inverse dynamics equations were used to estimate elbow and shoulder torques.

Preliminary data show that cerebellar patients made increased errors in the initial direction of movement compared with control subjects. As the reach velocity increased, these errors increased in a direction that is consistent with an inability to adjust for the interaction torques generated at the elbow. The EMG analysis showed that the onset of entire pattern of muscle activity was delayed but the relative timing of the two muscles active during early phases of movement (AD and BI) was normal. These findings support the idea that the cerebellum helps to initiate movement and sends predictive signals that correct for errors caused by interaction torques. We speculate that the cerebellum compensates for interaction torques in the early phases of the movement by scaling of amplitude and/or duration of muscle activity. 756.4

THE USE OF PROPRIOCEPTIVE INFORMATION IN POINTING DEPENDS ON AVAILABILITY OF VISUAL INFORMATION: EVIDENCE FROM A DEAFFERENTED PATIENT. Fookson, O.I.,* Berkinblit, M. B., Cole, J. and Poizner, H. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102, Institute for Problems of Information Transmission, Russian Academy of Sciences, Moscow, 101447, Poole Hospital NHS Trust, Poole, England

Analysis of errors of healthy subjects pointing to remembered targets presented in 3D space in a darkened room has demonstrated that subjects are significantly more accurate when pointing with vision of the moving fingertip than when pointing without any visual feedback (Berkinblit at al., 1995). However, the role of proprioception of the moving arm under these two conditions is unclear. To uncover its role, we tested a subject with a severe large-fiber sensory neuropathy with complete loss of proprioception in the extremities and in the body below the neck. Without visual feedback, this subject's pointing accuracy was about half that of the control subjects. However, when vision of the moving fingertip was available, his 3D pointing accuracy was even better than that of control subjects. We conclude that proprioceptive information from the moving arm is necessary for accurate pointing without visual guidance. However, since this rehabilitated deafferented subject showed the same pointing accuracy as controls when visual information about the moving fingertip was available, proprioceptive information from the moving arm is not critical to accurate pointing when partial visual information is available. Thus, under this latter condition, vision is dominant over proprioception .

Although the accuracy of pointing in darkness was significantly different for control and deafferented subjects, the mean maximum speeds across all target locations were similar. Moreover, the same speed of pointing movements was observed for both groups of subjects when they had vision of the moving fingertip. However, the capacity to vary movement speed was not the same for control and deafferented subjects. When subjects were required to move with different speeds (fast and slow), the speed of pointing varied 3 fold for the deafferented subject, whereas, control subjects could change their speed 8-9 fold.

LEARNING NON-LINEAR VISUOMOTOR MAPPINGS. J. R. Flanagan*, A. K. Rao. Queen's University, Kingston, Canada and Teachers College, Columbia University, New York, U.S.A.

Reaching movements are characterised by roughly straight hand paths in Cartesian space. However, the issue remains whether this reflects constraints on perception or production. To address this issue, we examined two-joint planar reaching movements in which we manipulated the mapping between actual and visually perceived motion. In particular, we used a non-linear transformation such that straight hand paths in Cartesian space would result in curved paths in perceived space and vice versa. Under these conditions, subjects learned, after about 500 trials, to modify their movements so as to generate straight paths in perceived space. This suggests that reaching movements are planned in perceived coordinates.

In a second experiment, we tested whether and how learning this non-linear visuomotor transformation transfers to novel targets. Subjects first performed over 300 trials among 3 training targets and were then presented with novel targets. We observed strong transfer to novel targets located both within and outside the workspace defined by the training set. This indicates that subjects did not simply learn a set of transformations specific to the training targets. However, transfer was not perfect. This suggests that subjects did not develop an accurate "rule-based" representation of the visuomotor mapping. The implications of these findings for theories of trajectory formation and learning are considered.

756.6

TRANSFER OF PRISM ADAPTATION BETWEEN RAPID AND SLOW REACHING MOVEMENTS. S. Kitazawa*[1,2], T. Kimura[1] and T. Uka[1]. [1]Neurosci. Sect., Electrotechnical Lab., Tsukuba 305, Japan; [2]PRESTO, JRDC, Japan.

Accurate reaching towards a visual target is initially disturbed when the visual field is displaced by prisms, but gradually recovers. To clarify whether the mechanisms of improvement are common among reaching movements with different velocities, transfer of the adaptive improvement between rapid and slow reaching movements was studied.

Four human subjects were trained to reach rapidly (<300 msec) or slowly (~5 sec) at a target that appeared at a random location on a tangent screen (400 mm away). Vision of the target and the hand was always blocked during the movement by liquid-crystal shutters, and allowed exactly after the index finger touched the screen. One experiment consisted of 3 sets (set 1-3) of 30 trials. In set 1, the subject wore no prisms and made 15 rapid reaching movements followed by 15 slow, or 15 slow followed by 15 rapid. In set 2, the visual field was displaced to the right or to the left by prisms (15 diopter) and the subject was required to make reaching movements with the same velocity as in the latter half of set 1 throughout the 30 trials. Initially the subject misreached the target by about 60 mm in the direction of the visual displacement, and the errors decreased with trials down to the control level by the end of set 2. In set 3, the subjects wore no prisms and were required to reach with either velocity. The initial errors in set 3 were 51±19 mm (mean ± S.D., n=16) when the movements with the same velocity were required in both set 2 and 3. In contrast, the initial errors were only 17±16 mm (n=16) when the required velocity in set 3 was different from that in set 2. Analysis of variance revealed that the magnitude of the initial error in set 3 did not depend on the velocity in set 2 ($p=0.8$) but on whether the velocity classes in set 2 and 3 were the same or different ($p<0.0001$). These results indicate that the major part of the adaptive improvement in rapid or slow reaching movements does not transfer to the movements with the other velocity, and suggest that independent mechanisms are involved in the improvement of rapid and slow reaching movements.

756.7

MOTOR LEARNING, BIMANUAL TRANSFER AND ISOCHRONY IN A TRACKING TASK. J. Ilmberger* and E. Hendrich. Dept. Phys. Med., Ludwigs-Maximilians-University Munich, 81366 Munich, Germany.

One basic aspect in motor learning is the amount and type of feedback involved in the movement. Freund (1986) proposed two movement categories: type I movements are slow and under focal sensory control, whereas type II movements are fast, overlearned and under sensory field control. The transition from type I to type II movements can be considered as motor learning and may be described as a change in several parameters: reduction in movement time, reduction of the number of velocity changes during the movement and development of isochrony (decoupling of movement time and movement amplitude).

These parameters were measured in a tracking task in healthy subjects. Subjects had to track a figure consisting of straight lines with a pencil; data were recorded with a digitizing tablet. Two groups of subjects started with either the right or left hand. After twenty trials, they changed the performing hand for another twenty trials. An isochrony index was computed for each trial using the movement times for different parts of the figure. The results show a learning effect in the beginning hand and a learning transfer to the contralateral hand in all the parameters described above for both groups of subjects, although the transfer of isochrony was smaller from the left to right hand than vice versa.

The results are contrasted with data from single patients suffering from brain injury or peripheral impairment showing that the learning parameters and the learning transfer are changed in different ways in these patients.

ADAPTIVE INTERNAL MODEL OF INTRINSIC COORDINATES TRANSFORMATION DURING LEARNING OF A REACHING TASK. H. Imamizu*, Y. Uno and M. Kawato ATR Human Information Processing Research Labs., Kyoto, Japan

Recent computational studies have proposed that the central nervous system acquires internal models of coordinates transformation between task-oriented extrinsic space and intrinsic space such as joint angles. To investigate acquisition of the internal model, we virtually minified (1/2) the elbow angle and magnified (5/4) the shoulder angle of human subjects while they were aiming at targets. A position marker was attached to the subject's hand and its current altered position was displayed as a cursor on a CRT screen. This linear transformation in joint angles (intrinsic coordinates) corresponds to a nonlinear one between the hand plane and the screen (extrinsic coordinates). We investigated whether the subjects learn this transformation as the former or the latter one. The aiming error when they learned the transformation of joint angles of one arm using the same arm (consistent condition) was compared to that when they learned the same transformation using the opposite arm (inconsistent condition). The error in the inconsistent condition was significantly larger (p <.002) than that in the consistent condition. Furthermore, the error in the consistent condition became small after they learned the transformation using the opposite arm in the same condition compared with that when they learned it for the first time (p <.0001). That is, intermanual transfer of the learning effect was found in the consistent condition but not in the inconsistent condition. Results suggest that the subjects learned the transformation as a linear one in intrinsic coordinates in the consistent condition and that the central nervous system adaptively represented the transformation including intrinsic coordinates in the control of arm movements.

SELECTIVITY OF ADAPTATION IN MOTOR LEARNING
F. Gandolfo*, F. A. Mussa-Ivaldi+, and E. Bizzi.
Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139. (+) Northwestern University Medical School, Chicago, IL 60611.

We studied the specificity of the adaptation to perturbations during pointing movements. We asked human subjects to execute point-to-point movements between targets arranged in a star-like fashion. The movements were planar and the subjects were coupled to a manipulandum which was used both to record kinematic data and to perturb the subjects. The perturbations, which were normal to the movement and proportional to the movement velocity, significantly altered the trajectories. We tested the subjects after the perturbing forces were discontinued and observed aftereffects as a mirror image of the perturbed trajectories.

We initially trained subjects to make movements to a subset of the targets while being perturbed, and then tested them on all the other targets without applying perturbations. To test for generalization of learning we observed the magnitude of the aftereffects in the unperturbed directions and found that the aftereffects decreased with distance from the trained trajectories.

As a further test of the adaptation, we trained the subjects to two different perturbation patterns, associating each of them to a particular arm configuration while keeping the end point trajectory the same. The subjects learned the tasks and showed aftereffects specific for the field related to the posture to which they had been exposed.

Taken together, these results indicate that the effects of motor adaptation tend to be local to the region where training has occurred. In addition, our experiments are compatible with adaptation being represented in intrinsic coordinates.

GENERALIZATION OF ADAPTATION TO CORIOLIS FORCE PERTURBATIONS OF REACHING MOVEMENTS J.R. Lackner* and P. DiZio. Ashton Graybiel Spatial Orientation Laboratory and Volen Center for Complex Systems, Brandeis University, Waltham, MA 02254

Visually open-loop reaching movements made in a rotating room are initially deviated in the direction of Coriolis force perturbations, C_F, generated during movements; endpoint accuracy and straight line paths are restored within ~10 reaches. Mirror-image aftereffects occur when rotation stops, revealing motor reprogramming to balance the velocity-dependent, non-contacting, inertial C_F perturbations. Here, we studied in seven subjects already adapted to 10 rpm rotation the effects of intensifying C_F by increasing reaching velocity ~1.5 times. Renewed endpoint and curvature errors in the C_F direction were initially generated. Subjects adapted to the new reaching speed, at the same rate as to the original one. Mirror-image aftereffects did not occur when the original reaching speed was resumed. Thus, after being exposed during rotation to the C_F fields generated by just two different reaching velocities, a generalized adaptation occurred such that changing reaching speed again did not affect reaching trajectory or accuracy. DELAYED VISUAL FEEDBACK IN SINGLE JOINT MOVEMENTS. J.D. Cooke*, K.K. Maitra and N. Virji-Babul. Faculty of Applied Health Sciences, University of Western Ontario, London, Canada N6G 1H1

As part of our study of the role of visual and kinesthetic information in coordination of multi-joint movement, we have studied the effect of introducing visual delay in the feedback of limb position information during single joint movements. We studied wrist (30 deg) or elbow (70 deg) movements in a visually guided planar, flexion/extension task while the position of other joint was fixed. EMGs were recorded from wrist and elbow flexor and extensors. We introduced time delays of 100, 200, 400 and 800 ms in the visual feedback to the subject of limb position information.

With visual delay no changes were observed in the kinematics or the EMG patterns of single joint elbow movements compared to no delay condition. In spite of the fact that the wrist position was fixed, clear phasic EMG activity occurred in both the wrist flexor or extensor muscles. In the case of single joint wrist movements, the wrist tended to move slower with short delays (200 ms) and faster with long delays (400, 800 ms) compared to the no delay conditions. These kinematic changes were reflected in the wrist EMG patterns. Clear phasic EMG activity occurred in the elbow flexor and extensor muscles in this condition where the elbow position was fixed.

The data suggest that the CNS can more readily compensate for altered visual input during elbow movements than during wrist movements. EMG activities in muscles acting about the non-moving joint may reflect learned programs related to compensation for or utilisation of reaction torques during multi-joint movements involving the elbow and wrist.

756.12

DELAYED VISUAL FEEDBACK IN A PLANAR TWO-JOINT MOVEMENT. K.K. Maitra*, J.D. Cooke and N. Virji-Babul. Faculty of Applied Health Sciences, University of Western Ontario, London, Canada N6G 1H1

In movements involving more than one limb segment, little is known of the relative importance of the visual and proprioceptive information related to movement about the different joints. In the present study we examined movement kinematics and kinetics and related EMGs in a planar, two joint (elbow/wrist) movement task. The task required accurate positioning about both the wrist and elbow. Movement amplitudes were 30 deg (wrist) and 70 deg (elbow). We inserted temporal delays (200, 400 and 800 ms) in the visual feedback information to the subject of the position of either or both limb segments.

Changes observed in elbow and wrist kinematics were graded with the delay. At smaller delays, movement velocity at both joints was reduced (compared to no delay conditions). As delay was increased, movement velocities increased as did agonist EMGs. At the wrist, this increase in agonist EMGs was not accompanied by change in the antagonists. Kinematic and EMG changes occurred independent of whether delay was applied to either or both limb segments. Movements around the elbow retained their accuracy despite changed movement speed whereas wrist movement under- or overshot the desired amplitude. With increasing delays reaction torques at the wrist increased slightly while muscle torques showed relatively large increases.

The data suggest that altering the normal relation between visual and proprioceptive information not only affects the kinematics of individual joints but also the coordination between them. It also suggests that when this relation is altered, movement about the proximal joint is preferentially preserved.

756.13

RELIANCE ON VISUAL FEEDBACK IN THE PERFORMANCE OF ARM AIMING MOVEMENTS FOR TWO DIFFERENT AGE GROUPS. R. D. Seidler, G. E. Stelmach, and H. L. Teulings*. Motor Control Lab, Arizona State University, Tempe, AZ 85287-0404.

It is well documented that the elderly exhibit longer movement times than the young when performing simple aiming movements. One possible contributing factor to this slowing is that the elderly rely more on visual feedback, requiring them to move more slowly in order to process visuo-motor information. Subjects made a horizontal aiming movement with a lever through the horizontal plane towards the body midline to a target located 30 cm from the home position. When subjects moved the lever, a cursor on a computer monitor directly in front of the subjects moved by a corresponding amount. The elderly subjects were affected more than the young by removal of visual information regarding arm position, reflected by a greater increase in absolute error. Following extensive training, the young subjects exhibited reduced endpoint error when visual feedback of arm position was withheld while the elderly did not. The kinematic results also suggest that the elderly place a greater reliance on visual control when performing simple aiming movements, and that in contrast to younger adults, this reliance is not reduced with practice.

PRACTICE SCHEDULE AND MOTOR LEARNING: CHILDREN VERSUS ADULTS. G. Pinto Zipp * and A.M. Gentile. Teachers College, Columbia University, NY 10027; Seton Hall University, NJ.

When several variations of a novel motor task are learned concurrently, Barth et al (1994) found that blocked practice (successive trials on one variation before switching to another) yielded better retention and transfer than variable practice (random order of variations). It was proposed that stabilizing a topological framework of the movement (Bernstein, 1967) is required during initial learning. Blocked practice permitted such stabilization and advanced learning; variable practice did not. Prior reports of a random practice benefit (Magill and Hall, 1990) had used simple tasks requiring scaling of an available motor pattern: thus, subjects were beyond initial learning. IN the present study, 12 children (8-10 yrs) and 12 adults acquired a novel motor pattern (frisbee throw) under blocked or variable practice. Adults were expected to have positive transfer from prior throwing skills and benefit less than children from blocked practice. Acquisition (ACQ) involved throwing at 3 targets varying in distance using a blocked or variable schedule. Absolute error from the target was measured. Subjects were tested for retention (30-min & 2-days after ACQ) and transfer (different object or different distances). Blocked practice resulted in better retention for children and adults with no evidence of an Age x Practice interaction. Children showed a blocked practice benefit on one transfer condition; adults did not. Thus, only modest support was found that blocked practice would enhance learning more for children than adults. Rather, findings suggest that variable practice of similar movements during early acquisition produced interference, prevented stabilizing a movement framework and impaired learning for both age groups.

RELATIONSHIP BETWEEN CORTISOL AND VERBAL MEMORY IN YOUNG ADOLESCENTS. M.M. Prostak, M.S. Hansen, and B.B. Sherwin*. *Department of Psychology, McGill University, Montreal, PQ, Canada, H3A 1B1.*

As part of a longitudinal investigation of the behavioral and psychological effects of steroid hormones during puberty, the present study examined the relationship between salivary cortisol levels and verbal memory in a sample of healthy young-adolescent males (n=66) and females (n=69). Immediate and delayed verbal memory was assessed by means of a paragraph recall task analogous to the logical memory subtest of the Wechsler Memory Scale. Saliva samples were collected on strips of filter paper at the end of the test session and cortisol levels were determined by radioimmunoassay. Salivary cortisol levels and verbal memory scores were significantly higher for females than for males ($p<.05$). Cortisol levels were not significantly related to immediate paragraph recall scores in either sex. However, girls with higher cortisol levels performed significantly better on delayed paragraph recall and exhibited significantly less verbal memory score decay than did girls with lower cortisol levels ($p<.05$). These results suggest that moderate cortisol elevation may facilitate particular aspects of cognitive performance in female adolescents.

757.2

ASSESSMENT OF COGNITIVE DEVELOPMENT IN ADOLESCENTS BY MEANS OF NEUROPSYCHOLOGICAL TASKS. P.L. Davies* and J.D. Rose. Psychology Dept., Univ. of Wyoming, Laramie, WY 82071.

Research has shown that development of the frontal lobes of the brain continues through late adolescence, in contrast to the earlier maturation of other cortical regions. Six tasks associated with performance of parietal lobe functioning (visual closure, proprioception, graphesthesia, stick construction, relational questions, extrapersonal orientation) and 6 tasks associated with frontal lobe functioning (Road Map Direction Sense, Visual Verbal Test, Wisconsin Card Sorting Task, Stroop test, Wang's test, and personal orientation) were administered to 72 subjects, 36 females and 36 males. These subjects were classified into 3 stages of development: prepubertal, midpubertal, and postpubertal using two pubertal assessment scales. ANOVA with age as a covariate resulted in stage main effects for performance on 10 tasks, nine of which were associated with frontal lobe performance. This suggests that the tasks associated with frontal lobe functioning show more improvement with pubertal development than tasks associated with parietal lobe functioning. These findings demonstrated that neuropsychological tests which are typically used to assess cognitive effects of brain damage are extremely sensitive to developmental changes in normal cognitive function.

ACTIVATION OF ANTERIOR CINGULATE AND PREFRONTAL CORTEX IN CHILDREN DURING A RESPONSE INHIBITION TASK WITH FUNCTIONAL MAGNETIC RESONANCE IMAGING (FMRI).
B.J. Casey*, Trainor, R., Orendi, J., Giedd, J., Castellanos, X., Noll, D.C., Cohen, J.D., Haxby, J., Jezzard, P., and Rapoport, J.L. Psychiatry Depart., WPIC, UPMC, Pittsburgh, PA 15213.

As a follow-up to our first study of prefrontal cortex activation in children with fMRI (Casey, et al, 1995), we have recently collected data from 3 normal children (8 to 11 years) and 2 young adults on a go-no-go task. The task required the subject to respond to any letter but an X with 75% of the trials being targets or non Xs. We have observed significant behavioral deficits in performance on this task by children with Attention Deficit Hyperactivity Disorder. We hypothesized that this task would activate target brain regions of the prefrontal and limbic basal ganglia thalamocotical circuits assumed to be involved in inhibitory control processes. As predicted, all 5 subjects showed activation in the anterior cingulate and dorsolateral prefrontal regions and 3 of the 5 subjects showed activation in the medial orbital frontal cortex. Activation decreased as a function of time on task for both the anterior cingulate and dorsolateral prefrontal cortex. The location and magnitude of activation was similar for the children and adults.

CHILDREN'S VERSION OF THE ALTERNATIVE IMPAIRMENT INDEX: A PILOT STUDY. A. M. Horton, Jr.*. Psych Associates, Towson, MD 21204

Recently, the Alternative Impairment Index (AII) has been proposed as a new measure of neuropsychological impairment in adults. The AII is composed of scores derived from the Halstead-Reitan Neuropsychological Test Battery. This pilot study investigated the feasibility of a Children's Version of the AII. Test records for 16 children (4 Normal Controls, 3 Brain Tumors, 1 Brain Abscess, 1 Hemispherectomy, 1 Encephalitis, 4 Traumatic Brain Injury, 3 Learning Disabled, 1 Behavior Problems) between the ages of 9 and 14, who have been administered the complete Halstead-Reitan Neuropsychological Test Battery for Older Children, were obtained and the Children's Version of the AII and the Children's Total Neuropsychological Deficit Score were compared on agreement for level of severity. The results (i.e., 56% or 9/16 correct agreement) suggest weak levels of agreement.

MISMATCH NEGATIVITY INDICATES SPEECH DISCRIMINATION IN PRETERM INFANTS
M. Cheour-Luhtanen*[1], K. Alho[1], K. Sainio[2], K. Reinikainen[1], M. Pohjavuori[2], M. Renlund[2], O. Aaltonen[3], O. Eerola[3], and R. Näätänen[1]

[1]Cognitive Psychophysiology Research Unit, Dept. of Psychology, Univ. of Helsinki, [2] Dept. of Neuropediatrics, Univ. of Helsinki, [3]Dept. of Cognitive Neuroscience, Univ. of Turku, Finland

Recent studies have demonstrated auditory discrimination in infants. However, there is no direct evidence of auditory discrimination in the infants before the conceptional age of 40 weeks. Here we report first neurophysiological evidence that even preterm infants discriminate speech sounds.

Auditory event-related potentials (ERPs) were recorded to Finnish vowels /i/ and /y/, and to a boundary /y/i/ stimulus in preterm infants (n=11; conceptional age 30-35 weeks) with no major neurological findings. ERPs to the deviant vowel /i/ were significantly negatively displaced in relation to ERPs to the standard vowel /y/. ERPs to the boundary stimulus /y/i/ did not significantly differ from those to the standard vowel /y/.

The negativity to the deviant vowel /i/ resembled the auditory mismatch negativity (MMN), elicited in older children and in adults by change in a repetitive auditory stimulus (even when the sounds are unattended). Judging from the scalp distribution of the present negativity, this response seems to be the preterm equivalent of the adult MMN. Thus MMN might provide a new method for assessing the adequacy of central auditory processing in preterm infants.

LONG TERM CHANGES IN rCBF DURING COGNITION FOLLOWING SEVERE CLOSED HEAD INJURY: A PET STUDY. B.S. Kirkby*, J.D. Van Horn, Esposito, G., T.E. Goldberg, D.R. Weinberger, K.F. Berman. PET Unit, CBDB, NIMH, NIH, 10/4N-317, 10 Center Dr., Bethesda, MD

To assess functional reorganization following closed head injury (CHI), we measured regional cerebral blood flow (rCBF) in 11 unmedicated, severely-injured patients with good recovery (8 males; mean age=31; mean time post-injury=7.3 yrs, range=0.5-18 yrs) during the Wisconsin Card Sorting Test (WCST) and a sensorimotor control task (WCSTcon) using the oxygen-15 water positron emission tomography (PET) method. These subjects were compared to 11 normal controls matched for age, sex, education, and handedness. Absolute rCBF (ml/min/100g) was determined on a pixel-by-pixel basis with a least squares method. Regions of interest were individually drawn on the subjects' coregistered MRIs and applied to the rCBF data after pixel-by-pixel normalization to the global mean. Group differences in activation (WCST-WCSTcon) were analyzed using unpaired t-tests. No differences in mean global flow CBF values were found for either the WCST (CHI =48.2±11.7; controls=46.3±4.46) or WCSTcon (CHI=49.1±8.8; controls=46.6±7.4). Moreover, patients performed equally well as controls on all measures of the WCST. In contrast, patients showed lower activation in the anterior cingulate (p=0.01) but higher activation in the inferior portion of the left inferior frontal gyrus (LIFG) (Brodmann's 44, 45, 47) (p=0.03). In light of recent evidence for a role of the anterior cingulate in attentional processes, reduced activation in this region in patients might relate to difficulties in attention, a commonly reported deficit following CHI, that were not reflected in WCST performance. Increased activation, on the other hand, was unexpected given the predominance of damage to the frontal lobes and its connections following CHI. In the context of normal task performance by the patients, the "over recruitment" of this frontal area might represent an attempt at compensation for inefficiencies in other prefrontal or extraprefrontal areas during performance of this task.

PRE- AND POST-SURGICAL ASSESSMENT OF VISUAL DISCRIMINATION FOLLOWING HEMISPHERECTOMY
A. Schiavetto*[1], P. Poirier[2], Y. Lakmache[1], J.G. Villemure[3] and M. Lassonde[1]

[1]Psychology Departement, U. of Montreal, [2]Physiology Dept., U. of Kansas, [3] Montreal Neurological Institue and Hospital, Montreal, Qué., CANADA

Studies of hemispherectomized patients have often reported the presence of residual visual abilities in the blind field of these patients. These results, however, have often been challenged. The present study aimed at further verifying the presence of such "blind-sight" by comparing the pre- and post-operative performance of a patient submitted to a variety of visual tasks. The patient, A.M., suffered from intractable epilepsy since childhood. She had her first seizure at the age of 2.5 years. An EEG carried-out at the time showed epileptic activity in the central temporo-parietal regions of the right hemisphere. This activity remained unchanged until her hemispherectomy at age 17 (1993). The first set of studies was aimed at evaluating the patient's ability to detect and localize stationary and moving visual targets. In the second set of experiments, color, form and letter discrimination was also assessed. In the localization experiment, A.M. was significantly less precise than controls in the left hemifield before surgery although she could detect the presence of the visual stimuli in that field. After surgery, she no longer detected any light stimulus in her left visual field. As pertains to color, form and letter discrimination, while A.M. consistently made errors in both hemifields before surgery, her performance improved postoperatively, her errors being confined to left hemifield presentations. In fact, A.M. performed at chance whenever visual stimuli were presented in her left field. Overall, these results show that, in a patient with longstanding hemispheric epileptogenic dysfunction, the removal of the deficient hemisphere results in an improvement of the visual abilities of the residual hemisphere. Our results, however, do not support previous findings of the "blindsight" phenomena after hemispherectomy.

EVENT-RELATED BRAIN POTENTIALS (ERPS) INDICATE THAT BLINDNESS WITH LATE ONSET AFFECTS AUDITORY PROCESSING IN HUMANS K. Alho*, T. Kujala, A. Lehtokoski, A. Leinonen, and R. Näätänen Cognitive Psychophysiology Research Unit, Department of Psychology, FIN-00014 University of Helsinki, Finland

Our previous results have shown that blindness with an onset during the first years of life affects the N2 component (peak latency about 200 ms from stimulus onset) of ERP associated with auditory discrimination, the N2 being more posteriorly distributed in early blind adults than in sighted controls. These results, supported by magnetoencephalographic source localization, suggest that in early blind humans, posterior cortical areas normally involved in vision would participate in auditory processing. In the present study, ERPs to repetitive 600 Hz standard tones and to 660 Hz deviant tones occurring infrequently among standard tones were recorded at 23 scalp sites from 8 sighted subjects (age 21-32 yrs) and from 16 blind subjects (age 21-35 yrs). In 8 of the blind, the blindness caused by a peripheral visual deficit had started at the age of 12 or later, and in the other 8, before the age of 2. When the subjects' task was to count the number of deviant tones in the tone sequence, the N2 to these deviant tones was in the early and late blind subjects distributed on the scalp posteriorly to the N2 of the sighted controls. This suggests that even blindness with a late onset may result in participation of visual brain areas in auditory processing.

EVENT RELATED POTENTIALS IN OBSESSIVE-COMPULSIVE DISORDER DURING VERBAL VERSUS NONVERBAL "ODDBALL" TASKS. **J.P. Towey, G.E. Bruder, C.E.Tenke, P.Leite, and M. Leibowitz, NYS Psychiatric Institute, NY**

Prior studies have found abnormal event-related potentials (ERPs) in patients with obsessive-compulsive disorder (OCD) compared to normal controls, including ERP evidence of left hemisphere dysfunction (Towey et al., 1993) and misallocated cognitive resources in OCD (Towey et al., 1994). The present study measured auditory ERPs of OCD patients and normal controls in both verbal (consonant-vowel) and nonverbal (complex tone) oddball tasks. Stimulus intensity, duration and repetition rates were matched to those in our prior study. ERPs were recorded from 4 midline sites (FzCzPzOz) and 13 lateral pairs. After correcting for eye artifact, ERPs were submitted to repeated measures ANOVAs using window averages for the following latency windows (ms): N100 (70-150), N200 (160-250), P300 (280-550) and Slow Wave (560-1000). Preliminary findings for 7 OCD patients and 8 normal controls for midline electrode sites were: (1) N100 amplitude. Whereas the control group produced larger N100 amplitudes to right ear than left ear stimuli; the patient group produced just the opposite asymmetry (Group x Ear, p<.05). This is consistent with prior findings of left hemisphere dysfunction in OCD. (2) P300 amplitude. P300 amplitude in OCD was significantly smaller during the nonverbal than verbal task over posterior scalp sites, but this task difference was not found for normal controls (Group X Task X Electrode: p<.01). (3) Slow Wave. OCD patients showed less positive slow wave than controls at central/parietal sites to targets (but not nontargets), which was evident frontally as greater negativity in OCD patients (Group X Condition, p<.05). OCD patients also showed greater Slow Wave to nontarget stimuli than did normal controls, supporting prior findings of misallocation of cognitive resources in OCD. **(Supported by MH44815)**

ASSOCIATION OF TEMPORAL PROCESSING AS MEASURED WITH AUDITORY ORDER THRESHOLD AND PERSONAL TEMPO IN PATIENTS WITH LESIONS OF THE CENTRAL NERVOUS SYSTEM. N.v. Steinbüchel, M. Wittmann and E. Pöppel.* Inst. Med. Psychol., 80336 Munich Univ., and Research Center (KFA), 52425 Jülich, Germany.

It has been demonstrated some time ago that patients with left hemisphere injuries show considerably prolonged temporal order thresholds (OT) which represent the time needed for event identification in a sequence. Instead of normal values of approx. 30 ms, lesions result in a prolongation of OT up to 100 ms or more. In a new study we replicated this finding and discovered in addition that the disturbance of temporal processing is limited to patients with aphasic speech problems. Patients with injuries of the left hemisphere without aphasic problems and patients with anterior or posterior right hemisphere lesions showed no such effects. Interestingly, a similar dissociation of functional disturbance is observed with a qualitatively different experimental paradigm. The subjects were asked to tap with their index finger a response key in a regular and convenient way ("personal tempo"). With this experiment the two following variables can be analyzed independently: 1. key touching time (KTT), i. e. the interval between the end of an agonistic and the beginning of an antagonistic finger movement, 2. pause interval (PI), i. e. the interval between successive KTTs. Whereas KTT appears to be closely linked to motor execution, PI appears to reflect a more central cognitive component, namely an individually chosen tempo of movement. For both these variables a similar result was observed as for OT. Only patients with aphasic problems showed temporal alterations (a significant prolongation of KTT and PI) whereas all the other patient groups compared to a healthy control group appeared to be unaffected. Thus, different domains of temporal processing (high frequency sensory decoding, motor execution, and volontary temporal control) appear to be closely associated. (Support was obtained by DFG and BMFT)

757.11

INFLUENCE OF ALCOHOL ON FRONTAL MIDLINE THETA ACTIVITY S. J. Laukka*, T. Järvilehto

Laboratory of Developmental Neuropsychology, University of Oulu, P.O. Box 222, Linnanmaa, 90571 Oulu, Finland.

After the discovery of the relationship between the human EEG theta rhythm (4 - 7 Hz) on the frontal area and problem solving task (Arellano & Schwab, 1950) there have been studies indicating a positive correlation between theta activity and the level of performance. However, an increase of theta was reported also with alcohol that is usually associated with deterioration of performance. The occurrence of theta activity was studied in a simulated driving task. Two interdependent decisions had to be made at two crossroads guided by two traffic signs. The subject had to find the correct way to drive a car through a set of roads in a computer game. Feedback about quality of performance was given after each trial. Each trial lasted about 10 s with a pause of 2 s between trials. The EEG was recorded from Fz. Theta activity was analysed during seven consecutive sections (1610 ms) of the game. The results showed that successful behaviour produced more theta than unsuccessful behaviour. Alcohol significantly increased theta activity. Theta activity was enhanced after the second traffic sign and the difference between the correct and incorrect road selections disappeared. The results may be related to the general relaxing effect of alcohol as well as to the deterioration of the estimation of performance by alcohol.

CORTICAL DEFICITS OF SEROTONIN, 5HIAA, AND NOREPINEPHRINE IN ELDERLY DEMENTED SCHIZOPHRENICS: A POSTMORTEM STUDY Powchik P, Davidson M, Knott PJ*, Haroutunian V, Yang RK, McBorrough EM, Davis KL Dept. of Psychiatry Mt. Sinai Sch. of Med., NY, NY 10029

Background: Most persons with schizophrenia have cognitive impairment to some degree. In many elderly persons with schizophrenia, the impairment is severe enough to warrant an additional diagnosis of dementia. Since most cognitively impaired schizophrenics do not show evidence of common neuropathology nor do they show evidence of cholinergic deficits, we investigated whether cortical deficits of norepinephrine (NE), 3-methoxy-4-hydroxyphenolglycol (MHPG), serotonin (5HT), and 5-hydoxyindoleacetic acide (5HIAA) (deficits of which have been described in other dementing illnesses) occur in demented schizophrenics. *Methods:* Postmortem cortical brain tissue (Brodmann areas 8, 9, 24, 20, 21, and 17) derived from 19 elderly chronic schizophrenics who had antemortem cognitive assessments, 12 Alzheimer's disease cases, and 9 normal controls were examined for concentrations of NE, MHPG, 5HT, and 5HIAA using HPLC-EC. *Results:* Alzheimer's subjects showed marked deficits in 5HT, 5HIAA, and NE in all cortical regions as compared to controls. No differences in the entire group of schizophrenic subjects were found compared to controls in any brain region for any metabolite. However, compared to cognitively intacted schizophrenics (n=7), demented schizophrenics (n=12) showed marked deficits of 5HT, and 5HIAA in Brodmann areas 8, 20, and 21 and NE deficits in frontal cortex (all p's <0.001 by independent t-tests). There were no differences in age or history of neuroleptic exposure in demented and non-demented schziophrenics. *Implications:* This study demonstrates a potential cause of severe cognitive impairment in schizophrenia and a possible target for pharmacological remediation. The 5HT, 5HIAA, and NE deficits are consistent with previous findings regarding the role of these neurotransmitters in cognition and suggests that brainstem dysfunction may be present in demented schizophrenics.

PATTERN OF COGNITIVE DEFICITS IN SUBJECTS WITH PARKINSON'S DISEASE AND MULTIPLE SCLEROSIS. M. Best, R.F. White, R. Au, A. Cronin-Golomb*. Department of Psychology, Boston University, Boston MA 02215 and Department of Veterans Affairs Medical Center, Boston MA 02130.

The concept of "subcortical dementia" has been used to describe a pattern of cognitive impairments common to several disorders in which the initial or principal (though not exclusive) locus of pathology is one or more subcortical structures. The pattern comprises deficits in memory, visuospatial function, executive function, and motor skills. The question is raised as to whether subtle deficits in such capacities also may occur in subjects without obvious or generalized cognitive decline. We assessed cognition and motor performance in subjects with two "subcortical" disorders, Parkinson's disease (PD, n=19) and multiple sclerosis (MS, n=20). Both groups showed mild to moderate severity of motor signs on neurological examination. A normal control group was similar to the patient groups in age (mean=53 years) and education (mean=15.5 years). Tests were drawn from the computerized Neurobehavioral Evaluation System and included measures of psychomotor performance, attention, visuospatial function, executive function, language, and memory. The PD and MS groups were impaired on tests of psychomotor performance relative to the control group, and the MS group was additionally impaired on several measures of reaction time. The PD and MS groups differed in regard to which cognitive tests elicited performance levels below that of the control group. The differing patterns of performance raise issues concerning the concept of subcortical dementia.

METABOLIC AND ANATOMIC IMAGING OF THE MEDIAL TEMPORAL LOBES CAN LATERALIZE TEMPORAL LOBE EPILEPSY BUT COMMONLY-USED VERBAL AND NONVERBAL MEMORY TESTS CANNOT. **Z. Caramanos*, F. Cendes, M.A. Thomas, D.L. Arnold, and M. Petrides.**

Montreal Neurological Institute and McGill Univ., Montreal, Canada, H3A 2B4.

We compared, in 36 unoperated temporal lobe epilepsy (TLE) patients (25 left, 11 right), the abilities of commonly-used memory tests and quantitative neuroimaging techniques to lateralise the side of predominant seizure origin as determined by extensive clinical electroencephalographic (EEG) recordings. Patients' delayed recall of the Rey Auditory Verbal Learning Task, the Rey Complex Figure, and the Wechsler Memory Scale's Logical Memory, Associate Learning, and Visual Reproduction Tests was compared with their hippocampal volumes, as well as with their medial-TL levels of the neuronal marker N-acetylaspartate as determined by proton magnetic resonance spectroscopic imaging.

Although results on the neuroimaging measures were highly intercorrelated, they were not related to the patients' memory scores. Moreover, whereas patients with left and right TL EEG disturbances differed on their metabolic and anatomic measures of medial-TL integrity, they did not differ in their preoperative performance on the exmined measures of verbal and nonverbal delayed recall. Furthermore, whereas neuroimaging-based linear discriminant models were able to lateralize patients' EEG disturbance with 100% accuracy, models based on memory testing results were not much better than base rate information alone (*i.e.* 27 versus 25 correct).

These findings suggest that whereas these anatomic and metabolic imaging techniques are useful in the preoperative lateralization of TLE, these widely-used tests of verbal and nonverbal memory are not. Nevertheless, these and other neuropsychological measures provide important information regarding the patients' cognitive abilities and should be included in any thorough clinical evaluation of TLE.

757.15

REGIONAL CEREBRAL BLOOD FLOW DURING REPEATED EXPOSURE TO A VIGILANCE TASK IN ADULTS WITH ATTENTION DEFICIT HYPERACTIVITY DISORDER. J.B. Schweitzer, T. Faber, C.D. Kilts, J.Votaw, J.M. Hoffman, and L.Tune*. Depts. of Psychiatry, Radiology, Neurology, Emory PET Center, Emory University, Atlanta, GA 30322.

There is increasing evidence that Attention Deficit Hyperactivity Disorder (ADHD) has a neurobiologic basis. Behaviorally these symptoms increase with repeated exposure to a task. Using the Paced Auditory Serial Addition Task (PASAT), an auditory vigilance task, we examined changes in regional Cerebral Blood Flow (rCBF) in 4 adult right-handed males with ADHD and 5 normal right-handed male controls. Subjects were scanned on two consecutive days with 2 resting state, 2 control and 2 PASAT conditions per day, each associated with [^{15}O]water administration. In this ongoing study, different task related increases and decreases in rCBF between the groups emerged. ADHD subjects showed significant activations in the primary visual cortex and visual association cortex during the PASAT compared to the control task ($p<.01$). Control subjects showed activations in the right parietal and left inferior frontal regions during PASAT ($p<.01$). Changes in rCBF with repeated task exposure, were assessed by subtracting images acquired on Day 1 during the PASAT from Day 2. In ADHD subjects there were increases in rCBF in the left, superior temporal lobe from Day 1to Day 2 ($p<.01$); however there were no significant decreases in rCBF from Day 1 to Day 2 ($p<.01$). Control subjects showed activations in the inferior frontal lobe, the superior parietal lobes, and the left gyrus rectus from Day 1 to Day 2 ($p<.01$). Control subjects also showed decreases in rCBF from Day 1 to Day 2 in the left temporal lobe and the cerebellum ($p<.01$). These results suggest that different brain regions, and perhaps behavioral strategies, are used by ADHD adults to perform vigilance tasks than adults without ADHD. Furthermore, the lack of decreases in rCBF seen in ADHD subjects with repeated PASAT exposure suggests a sustained processing demand, that is diminished with practice in control subjects.

SUPERIOR TEMPORAL GYRUS IN SCHIZOPHRENIA AND EPILEPSY. M.A.Eckert[a], E. Gautier[b], R. Gilmore[c], J.M. Kuldau[d], D. Bowers[c], T. Flynn[b], R. Quisling[a], & C.M. Leonard[b]. Depts. of Psychology[a], Neuroscience[b], Neurology[c], Psychiatry[d] & Radiology[a], Univ of FL, Gainesville, FL 32610.

Both schizophrenia and temporal lobe epilepsy (TLE) are thought to arise from temporal lobe damage early in development. MRI studies have demonstrated reduced superior temporal gyrus (STG) volume in schizophrenia, and reduced medial temporal lobe volume in epilepsy. To determine if reduced volume of the STG is specific to schizophrenia, we compared the left and right STG of TLE patients (13 left focus, 7 M and 6 F, mean age: 37.5 yrs; 9 right focus, 5 M and 4 F, mean age: 35.0 yrs) with that of schizophrenic patients (11 M and 3 F, mean age: 36.2 yrs). Volumetric analyses were performed on 3d MR images reformatted into 1mm coronal sections. The STG was measured between 5mm anterior and 5mm posterior to the anterior commissure (Barta, et al. 1991). There were no differences in the STG volume among any of the groups. There was a significant and positive relationship between *right* STG size and IQ in the schizophrenia patients. In contrast, in the *left* focus epilepsy patients, IQ was significantly related to the size of the *left* STG ($F=9.61$, $p<.05$). There was no relationship of IQ to the size of either STG in the right focus group. Differences in these brain-behavior relationships may be due to differences in the timing and location of early brain damage. Prenatal damage in schizophrenia may be early enough to allow, or massive enough to force, a shift of cognitive function to the right hemisphere. SPARED FACE PROCESSING IN WILLIAMS SYNDROME: NEW PERSPECTIVES ON BRAIN-BEHAVIOR LINKS IN A GENETICALLY-BASED SYNDROME. M. Rossen* W. Jones, & U. Bellugi . Laboratory for Cognitive Neuroscience, The Salk Institute, La Jolla, CA 92037.

Williams syndrome (WMS) is a genetic syndrome of neurodevelopmental anomaly that involves mental retardation but presents a remarkable juxtaposition of impaired and intact mental capacities. Most prominently, linguistic functioning is preserved while problem solving ability and visual based cognition are impaired.

Good face processing ability is also characteristic of WMS, providing evidence of asymmetry in cognitive functioning within visual-based cognition. We report here on performance of WMS adolescents on three paradigms involving distinct aspects of face processing: Benton Face Recognition (Discrimination of unfamiliar faces); Warrington Recognition Memory for Faces (immediate recall of unfamiliar faces); and Mooney Face Classification (Perception of faces from unclosed contours). WMS subjects performed significantly better than age- and IQ-matched DNS controls on all three of these measures. Moreover, the WMS subjects were indistinguishable from normal chronological age-matched subjects on the Benton Faces task. Strong, significant inter-task associations exist among the face processing tasks; in contrast, no significant inter-task associations exist between the face processing tasks and WISC-R IQ, or between face processing and other visual-based processing tasks such as a non-faces closure task (KABC Gestalt Closure), or between face processing and indices of language ability such as comprehension of grammatical forms.

Brain morphology shows an intriguing link with face processing in WMS (Jones, Rossen, Hickok, Jernigan, & Bellugi, Neurosciences Abstracts, this issue). *In vivo* MRI data from nine WMS adolescents reveal a strong correlation between performance on Benton Faces and volume of gray matter in inferior posterior medial cortex, normalized by total supratentorial volume ($r=.89$, $p < .001$). Warrington Recognition Memory for Faces and Mooney Face Classification also correlate strongly with normalized IPMCG volume. These results are consistent with data from prosopagnosics on brain loci important for face processing and provide new data relevant to the neural systems underlying specific aspects of behavior.

757.18

BRAIN-BEHAVIOR LINKS: BRAIN MORPHOLOGICAL CORRELATES OF LANGUAGE, FACE, AND AUDITORY PROCESSING IN WILLIAMS SYNDROME W. Jones, M. Rossen, G. Hickok, T. Jernigan†, & U. Bellugi.* Lab For Cognitive Neuroscience, The Salk Institute, La Jolla, CA 92037. †Veterans Affairs Medical Center and Univ. of California at San Diego, La Jolla, CA, 92037.

Williams syndrome (WMS) is a genetic disorder involving an asymmetric profile of mental retardation, with relative sparing of language and face processing, extreme impairment in spatial cognition, and hyperacusis: an abnormal sensitivity to sound. Distinctive patterns of abnormal brain morphology in WMS have also been reported.

We report evidence of relationships between regional brain volumes and specific behavioral abilities in WMS. Using in vivo MRI data from 9 adolescents with WMS, brain regions were delineated by stereotactic parcellation of cortex into eight areas using three orthogonal planes. **Faces.** A strong correlation was found between performance on Benton Facial Recognition and volume of cortical gray matter in inferior posterior medial cortex (IPMCG) normalized by total supratentorial volume ($r=.89$, $p<.001$). IPMCG predominantly includes hippocampus, posterior parahippocampal gyrus and some retrosplenial cortex. Normalized IPMCG also correlated with two other tasks involving face processing: Warrington Recognition Memory for Faces ($r=.87$, $p<.01$) and Mooney Face Classification Test ($r=.72$, $p<.07$). None of the other seven cortical regions showed significant correlations with these three face processing measures. **Language.** A significant correlation was found between pooled performance on standardized language measures and a measure of volume of inferior frontal cerebrum normalized by total supratentorial volume ($r=.73$, $p<.025$). Other regions did not show significant correlations with language performance. **Hyperacusis.** Volume of Heschl's gyrus (A1), normalized by superior temporal gyrus volume, was examined in a separate study using three WMS subjects. An abnormally large A1 volume (relative to normals and matched Down syndrome subjects) was observed. These apparent WMS brain-behavior relations are consistent with existing evidence on localization of language, face, and auditory processing, and suggest that analyses in WMS may provide clues to the brain bases of behavior.

PRINT EXPOSURE IN DYSLEXIC ADULTS: EVIDENCE FOR AN INDEPENDENT PREDICTOR OF KNOWLEDGE. J.G. Foy*. Department of Psychology, Loyola Marymount University, Los Angeles CA 90045.

The clinical neuropsychological literature defines dyslexia as an impaired ability to read and comprehend written or printed words, but the etiological role of language deficits in this disorder has been a matter of considerable debate. Dyslexic children frequently have difficulties with phonological processing (e.g., Mann, 1993), but linguistic deficits are not always found in dyslexics (e.g., Aaron, Olsen, & Baker, 1985, Coltheart, 1983). Stanovich and his colleagues have shown that print exposure may be an independent predictor of knowledge in normal readers with varying degrees of reading comprehension ability (e.g., Stanovich & Cunningham, 1993). Since knowledge bases play an integral role in skilled reading (Kintsch, 1983), print exposure may be an important variable to control when studying populations with reading impairments. In order to investigate these issues, dyslexic adults (18-25 years) who had graduated from high school and were attending college were matched by age, gender, and cognitive ability with normal readers. Linguistic, cognitive and reading skills, including phonological awareness and print exposure, were tested in the subjects. Dyslexics did not differ in phonological skills from normal readers. However, dyslexics differed significantly from normal readers in print exposure. Multivariate statistical analyses revealed that print exposure was a significant predictor of knowledge, independent of cognitive ability. These results suggest that print exposure may play an important role in cognitive processing and should be controlled in studies of dyslexic subjects. Supported by a Loyola Marymount University Faculty Research Grant.

MATCHING PURSUIT ON ERP ANALYSIS J.J. Allen, B. Shen, J.G. Williams and J.B. Angevine* Dept. of Psychology, University of Arizona, Tucson, AZ 85721

Obtaining averaged event-related potentials (ERPs) requires many repeated presentations of stimuli or the use of single trial methods that are heuristic and thus imperfect. For single trial events, traditional analysis techniques (e.g., Fourier analysis) often fail to extract information from noisy signals reliably. By averaging a large number of trials, the signal-to-noise ratio of temporal patterns in ERPs may be enhanced, but at the price of losing frequency information. A recently developed technique, matching pursuit analysis, offers flexible decompositions of signal components localized in both time and frequency domains (Mallat and Zhang, 1993). We found that this technique could extract both temporal and frequency information from noisy single trial ERPs. Averaging as few as several ERPs over the transformed domain provided distinct temporal frequency patterns that corresponded to the classic P3 component of the ERP in a memory-assessment task. Random noise and systematic artifacts of ERPs could be rejected by simply subtracting appropriate time-frequency atoms. For us, this technique not only provided a more efficient and precise tool for analyzing averaged ERPs, but also suggested a new approach to the analysis of single trial events.

758.2

POSSIBLE FRONTAL LOBE CONTRIBUTION TO NEGATIVE REPETITION PRIMING S. Yamagata, S. Yamaguchi* and S. Kobayashi. Dep. of Internal Medicine III, Shimane Med. Univ., Izumo, 693, Japan.

Several lines of evidence have shown that the repetition priming effect is sensitive to the direction of attention. On the other hand, one recent study confirmed an inverse repetition effect to words at the unattended location. We studied the positive and negative repetition priming effects on attended and unattended words during a lexical decision task and hemispheric contributions on those effects using topographic analysis of event-related evoked potentials (ERPs). Subjects were asked to focus their attention to a word (vertically oriented Kanji letters) presented in one visual field and ignore the word in the opposite field during a task of detecting a non-word in the attended field. The field attended was informed by an arrow precue and word color. The identical word appeared sequentially 56 times at the attended and unattended visual field respectively at random. A positive ERP deflection to repeated words developed when the sequential words were presented in the attended location. This repetition effect was greater over the posterior scalp sites contralateral to the attended field. Non-attended repeated words generated a negative-going shift over the left frontal scalp sites regardless of the field of word presentation. These results suggest that the frontal lobe may contribute to the active inhibition of implicit word processing within the unattended channel.

FUNCTIONAL TOPOGRAPHY DURING PROCEDURAL LEARNING STUDIED WITH EVENT-RELATED DESYNCHRONIZATION MAPPING (PRELIMINARY FINDING) P. Zhuang, C. Toro, J. Grafman, P. Manganotti, L. Leocani, M.-P Deiber, J.Walters*, M. Hallett, National Institute of Health, NINDS, Human Motor Control Section, Medical Neurology Branch, Bethesda, MD 20892, USA.

To explore the role of the human motor cortex associated with the development of implicit and explicit knowledge, we studied event-related desynchronization (ERD) as an indicator of localized brain activation during a visual motor task. EEG-signals were recorded from 3 right-handed subjects as they performed a variation of the serial reaction time task (SRTT). ERD was calculated within the alpha (8-12 Hz) band from EEG recording of 29 scalp locations from -1 to 1 sec around to the correct keypresses. During the data collection, all subjects developed implicit knowledge of the test sequence, which was reflected by diminishing response time and generation of explicit knowledge. ERD maps revealed localized alpha power reactivity overlying the contralateral sensorimotor hand area. The area of power reactivity became progressively larger until explicit knowledge was reached, after which the power spectra showed a declining power. These electrophysiological findings are in support of our previous results demonstrating the rapid functional plasticity of cortical motor outputs associated with procedural learning and with transfer of knowledge from an implicit to explicit state.

758.4

EVENT-RELATED POTENTIAL (ERP) CORRELATES OF TARGET DETECTION: EFFECTS OF TASK DIFFERENCES. I.Kiss* and A.W.Fazikas. Toupin Psychophysiology Lab, Northern Alberta Regional Geriatric Program and Division of Neuroscience, Univ. of Alberta, Edmonton, Alberta.

Ten subjects completed two visual "oddball" tasks involving identical stimuli; random length series of 3 to 9 individually presented digits. Target sets (3 digits or 3 item letter-digit sets) were presented between series in the *detect* condition. Subjects were asked to selectively respond to the 3 digit sets. In the *detect + compare* condition, subjects selectively responded to 3 number targets that matched the last 3 individual numbers presented. Error rates were similar across conditions.

ERPs elicited by target stimuli recorded from 4 midline scalp sites (Fz, Cz, Pz, Oz) included two major positive-going peaks (approximately 200 and 375 msec latency) in both conditions (Fig.1). Analyses of variance failed to support main effects of condition upon latencies. The effect of condition on amplitude just reached significance ($p = 0.049$) for the earlier but not the later peak (P300). This lack of amplitude and latency differences of the P300-like peak suggest insensitivity to considerable differences in task requirements. P300 may reflect the time course and effort involved in more general processes that proceed in parallel with, but independent of, divergent processes in distinct tasks. Digital ERP subtraction *[detect-(detect + compare)]* revealed ERP features (Fig.1) associable with comparison of working memory contents to external stimuli.

HEBBIAN INDUCTION OF AUDITORY CORTICAL RECEPTIVE FIELD PLASTICITY: EFFECT OF NUMBER OF TRIALS & CORTICAL STATE

Scott J. Cruikshank* and Norman M. Weinberger, CNLM and Dept. Psychobiology, UC Irvine, CA

Receptive field (RF) plasticity in the adult auditory cortex (Aud Cx) has been observed following learning (Weinberger et. al., 1990, *CINS*). We are investigating induction mechanisms of such plasticity, and have focused on Hebbian rules, because they have been implicated previously in neocortex (e.g., Shulz & Fregnac, 1992, *J Neurosci*; Ahissar et al, 1992, *Sci*). However, a preliminary report from our lab indicated that for most cells in Aud Cx, a "Hebbian" treatment (below) was insufficient to induce RF plasticity (*Soc Neuro Abs*, 1993). Since that report, we've investigated several factors that seem to affect the probability of observing RF plasticity following a "Hebbian" treatment. These include number of pairing trials and cortical EEG state.

Procedure: In Urethane anesthetized Guinea pigs, first, a single postsynaptic (postsyn) Aud Cx cell was isolated with a KCl-filled juxtacellular micropipette. During a baseline period, two Aud stimuli of differing frequency were presented, to activate different sets of presynaptic afferents for the recorded cell. The response of the postsyn cell to these two stimuli were recorded, to assess their synaptic strength. Next a "Hebbian" treatment was imposed in which one of the Aud stimuli (CS+) was paired with excitatory current to the postsyn cell, to enhance the pre/postsyn covariance. The other Aud stimulus (CS-) was paired with inhibitory postsyn current. After 60 pairings, the synaptic strengths were re-determined. For most cells another block of 60 pairings was imposed, to test the effect of number of trials on plasticity. EEG was also recorded.

Results: We calculated the relative response of the postsyn cell to the two Aud stimuli (CS+)/[(CS+)+(CS-)] for each trial in each period. The distributions of these relative scores were compared between periods (t-test, $p<.05$). All cells (n=28) were significantly controlled *during* the treatments. Only 3/28 (=11%) cells had significant relative increases for the CS+ *after the first* treatment block compared to baseline. However, there were much larger effects *after the 2nd* treatment block, with 7/22 (=32%) cells showing significant relative increases for the CS+. No cells had significant decreases. In addition, the probability of significant effects was greatest if the cortical EEG was "activated" during the treatment: only 2/13 cells that underwent treatment during EEG synchrony were affected, while 5/9 that underwent treatment during EEG activation (i.e., desynchrony or shift between synchrony and desynchrony) were affected. Other factors that might affect the probability of observing RF plasticity following a Hebbian treatment are being investigated.

THE P3-LIKE LONG-LATENCY COMPONENT IN RATS: IS IT A HIPPOCAMPAL THETA WAVE? J. Brankack* and T. Seidenbecher, Inst. of Physiology II, Heinrich-Heine-University, Düsseldorf and Institut of Neurobiology, Magdeburg, Germany

Long-latency components of event-related potentials (P3 or P300) correlate with the ability of subjects to detect and process unexpected, novel or task relevant events. P3-like components were recorded in the neocortex and hippocampus of rats performing an auditory discrimination task, similar to the oddball paradigm used in human psychophysiological experiments. In anaesthetized rats surface and depth electrodes were implanted at several neocortical regions and the hippocampus. After recovery from surgery rats were trained to discriminate two auditory signals, a frequent irrelevant tone (T1) and a rare tone (T2) related to water reward. In response to T2 but not T1, P3-like components with a mean latency of 274 ms (range: 244 to 305) and a mean amplitude of 67 μV (range: 24 to 158) were recorded from the surface of the neocortex. The largest amplitudes were found in the anterior part of area Oc2MM situated above the hippocampal CA1 region. Powerspectra of differences between responses to T2 and T1 revealed peaks in the theta range (4-12 Hz) maximal at area Oc2MM. The amplitude increased with depth to a maximum of 298 μV in stratum oriens of the CA1. A polarity reversal occured at the pyramidal cell layer (-175 μV). The largest negative amplitude was found in stratum radiatum (-304 μV). It is suggested that the P3-like component in rats corresponds to a theta wave out of a burst of hippocampal theta cycles. This work was supported by the Deutsche Forschungsgemeinschaft grant Br1289/1-1.

N400-LIKE EVOKED POTENTIALS IN THE MACAQUE HIPPOCAMPUS

J O'Neill*[1,3],E Halgren[1,3-5],K Marinkovic[3,5],LJ Fitten[2-4],and KM Perryman[1-4]
[1]VA West LA &[2]VA Sepulveda Medical Centers,Los Angeles,CA
[3]Brain Research Institute,[4]Dept. of Psychiatry,UCLA School of Medicine
[5]INSERM CJF90-12,CHU Pontchaillou,Rennes,France

Several animal models of the P300 exist,but non-human correlates of cognitive EPs of the N400-family have received scant attention. We recorded intracranial VEPs (peri-inial skull screw reference) from stereotaxic probes implanted in an adult female bonnet monkey (*M. radiata*). The task required her to distinguish familiar from unfamiliar human faces. Major components from a right hippocampal contact (coordinates A12.1,R11,D27: atlas of Szabo & Cowan,verified by MRI) were: Positive at 112±2.6 ms to peak,N156(12.9), N194(5.3),N266(14.0). Here amplitudes (μV) of the two largest components in the interior hippocampus *vs.* values at immediately superior and inferior sites:

Contact	N194		N266	
superficial (D25)	+ 90.7 ± 10.8	p<0.05	- 32.3 ± 18.4	p<0.05
interior (D27)	-110.6 ± 74.9		-115.5 ± 19.4	
deep (D29)	+ 78.7 ± 15.3	p<0.05	- 23.7 ± 24.6	p<0.05

The inversion of the N194 and the steep voltage gradients of both components suggest that the two are generated locally in the hippocampus. Thus large focal negativities occur in the monkey hippocampus in response to the same stimuli and in the same task that evoke large focal N310 and N430 components in the human hippocampus. While precise component homologies will require further work with additional tasks and in other subjects,monkey components appear generally to be earlier than in humans.

NEURONAL ACTIVITIES IN MEDIAL PREMOTOR AREA OF MONKEY DURING LEARNING OF SEQUENTIAL MOVEMENTS.

K. Miyashita, O. Hikosaka*, X.Lu, and S. Miyachi, Dept. of Physiology, Juntendo Univ. Sch. of Med, Tokyo, 113. Japan

To investigate where and how the memory for sequential movements might be represented in the brain, we trained a Japanese monkey to perform a sequential button press task, "2x5 task". On pressing a home key, two of 16 (4 x 4) LED buttons (called 'set') were illuminated simultaneously. The monkey had to press them in a predetermined order which he had to find out by trial-and-error. A total of 5 sets ('hyperset') was presented in a fixed order for completion of a trial. A hyperset was repeated as a block of experiment until 20 successful trials were performed. The monkey experienced 965 newly generated hypersets. Short-term and sequence-selective learning occurred by repeating a particular new hyperset during a block of experiment. 14 hypersets were assigned to 'learned hypersets' which had been learned daily so that the animal could perform them with few errors.

We recorded spike activities of 154 single neurons in the medial premotor area as the monkey was performing 'learned' or 'new' hypersets. 68 cells (44%) showed differential activities between learned hypersets and new hypersets. Among them, 51 cells showed learning dependent changes within a block of experiment during which the monkey repeated a new hyperset. (1) 30 cells initially did not show task-related activities, but as learning proceeded, activities appeared that were related to hand movements of particular transitions or combinations of sequences. (2) 11 cells showed strong activities for new hypersets which became weaker as learning took place. These changes of activation pattern occurred for each new sequence repeatedly. These results suggest that medial premotor area participates in short-term and long-term learning of sequential movements.

758.9

REWARD-DEPENDENT ACTIVITY OF "DIFFERENTIAL DELAY NEURONS" IN THE PRIMATE PREFRONTAL CORTEX.

M. Watanabe*, M. Odagiri, K. Hikosaka, T. Kodama, and S. Shirakawa. Dept. Psychol., Tokyo Metropol. Inst. for Neurosci., Musashidai 2-6, Fuchu, Tokyo 183 JAPAN

In the delayed response task (DR), "Differential Delay Neurons" (DDN) are observed in the primate prefrontal cortex (PFC), which show differential activity between right and left trials during the delay period. They are considered to be related to the spatial working memory. In the last year's meeting, we reported reward-dependent delay-related activity in the PFC neurons. Here we report the activity of DDN in various reward situations.

Three monkeys were trained on the DR using several kinds of food and liquid reward (usually using the same reward for a block of 30 – 50 trials). On the 'Indirect method situation' position of a red light, and on the 'Direct method situation' position of reward itself (food reward only), indicated the correct side.

Many DDN were found to behave in different ways between Direct and Indirect and/or between food and liquid reward and/or among different food (or liquid) reward situations, showing different patterns of spatial specificity during the delay period. Among them there were such DDN which showed the spatial specificity either on Direct or on Indirect method situation, or either on liquid or on food reward situation.

The results indicate that DDN could be involved in retaining the difference of reward situation during the delay period besides being related to retaining spatial information and that the single PFC neuron could be involved in retaining more than one kind of information at the same time.

758.10

DISSOCIATION OF MOVEMENT RELATED NEURONAL ACTIVITY IN POSTERIOR CINGULATE CORTEX IN MONKEYS PERFORMING OCULOMOTOR AND MANUAL DELAYED RESPONSE TASKS.

S. Carlson*, P. Goldman-Rakic. Sect. Neurobiol., Sch. of Med., Yale Univ..

Single neurons in the posterior cingulate cortex (pCC) exhibit nonspecific delay period activity in monkeys doing oculomotor delayed response task (Carlson et al. 1993). In the present study we recorded single neuronal activity in the posterior cingulate cortex in monkeys performing both oculomotor and manual delayed response tasks (ODR and MDR resp.). The aim was to determine whether single neurons show task related activity also in the MDR task and whether the same or different neurons are engaged in the oculomotor and skeletomotor movements. As in the ODR task delay period activity was recorded also during the MDR task, and was not spatially tuned. The pCC neurons were "omnidirectional", i.e. active in the delay for all taget directions. Movement related neurons fired either during eye- or hand movements in pCC and were broadly tuned. The results indicate that neurons in pCC are nonspecific with respect to spatial mnemonic information; rather, their activity is related to preparation and execution of movements.

758.11

FUNCTIONAL ORGANIZATION OF THE ANTERIOR CINGULATE CORTEX IN MONKEYS.

T.Ono*, Y.Yamamoto, H. Nishijo, T.Uwano, and T.Yamashima Dept. Physiol., Fac. Med., Toyama Med. & Pharmaceu. Univ., Toyama 930-01, Dept. Neurosurg., Fac. Med., Kanazawa Univ., Ishikawa 920, Japan.

It has been suggested that the anterior cingulate (AC) cortex is involved not only in learning, but also in behavioral manifestation. In the present study, single neuron activity was recorded from the monkey AC during operant behavior based on discrimination of rewarding, aversive, and neutral objects. Of 303 neurons recorded from the AC, 63 responded in one or more phases of the task. Of these 63, 23 responded to visual stimuli (differentiating, 19; nondifferentiating, 7). These 19 responded to rewarding (5), aversive (6), or rewarding and aversive but not to neutral objects (8). Responses of 5 neurons that responded to aversive objects were readily suppressed by associating the aversive objects with reward (reversal). Of 15 neurons that responded mainly in the bar press phase, 5 differentiated bar pressing to avoid shock from bar pressing to obtain reward. Responses of 4 neurons were anticipatory, with gradually increasing activity between the start tone and a visual stimulus (object). There were topographic distributions of these responsive neurons in the AC; differential vision-related, differential bar press-related, and nondifferential bar press-related neurons were located from the anterior to posterior portion of the AC, respectively. The results suggest that sensory information is processed and transformed to motor command from the anterior to the posterior portions of the AC.

PARIETAL UNIT RESPONSES IN A CROSS-MODAL (VISUO-HAPTIC) DELAY TASK.

Yong-Di Zhou and Joaquín M. Fuster*. Department of Psychiatry and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The purpose of this research is to explore the reactivity of somatosensory cortical cells to visual stimuli and their role in the mnemonic retention of those stimuli for a prospective haptic choice. Monkeys were trained to perform a visuo-haptic task with a forced delay between a visual stimulus and a tactile choice appropriate to it. Each trial consisted of the following: (1) 3-sec visual *icon*--i.e., black and white pattern of vertical or horizontal stripes; (2) delay of 10-20 sec; (3) click signalling accessibility of two parallel rods, one with horizontal and the other with vertical ridges on the surface; (4) tactile comparison of the two rods; (5) choice (pull) of rod with ridges in the same direction as the stripes of the icon. Correct choice was rewarded with liquid reinforcement. Icon and relative rod position were changed at random from trial to trial. Units in cortical area S1 showed excitatory responses to the icon initiating the trial. The latency of the responses was about 200 ms. In some units ("memory cells"), the excitatory response persisted during the delay (retention period) in the form of sustained elevated firing. Some cells reacted differentially to the icons, i.e., more to stripes in one direction than in the other, and direction-differential firing continued during the subsequent memory period. In some instances, the preferred visual directionality of a cell was reflected by comparable preferred directionality in touch. These findings suggest that somatosensory units are accessible to visual information behaviorally associated with tactile information. Further, the results suggest that S1 neurons can be part of cross-modal memory networks.

INHIBITION OF LOCUS COERULEUS NEURONS BY SPONTANEOUS AND INDUCED FRONTAL CORTEX ACTIVITY D.A. Wilson*[1], A. Hervé-Minvielle, D. Robinson and S.J. Sara, Institute des Neurosciences, Univ Paris VI, Paris, 75005, France and [1]Dept. Zoology, Univ. Oklahoma, Norman, OK, USA

Given the neuromodulatory action of norepinephrine throughout the forebrain, identification of central structures influencing locus coeruleus (LC) activity can have important implications for our understanding of the role of this system in many aspects of information processing Recent evidence has shown that a small population of neurons in the medial precentral region of frontal cortex (FC) of the rat can be antidromically driven by LC stimulation; suppression of activity in these cells results in an enhancement of tonic LC activity (Sara & Hervé-Minvielle, *PNAS*, in press). The present study further examined the influence of FC activity on LC neurons in ketamine-anesthetized rats. Phasic LC unit responses to FC activity were examined using two methods. 1) Spontaneously active, multiple single-units were recorded simultaneously from FC and LC. Cross-correlation analysis examining LC unit activity as a function of FC unit activity, frequently showed a transient suppression of LC firing 25-50 ms after the FC unit discharge. 2) Patterned electrical stimulation of the FC produced a transient supression of LC activity, often followed by enhanced discharge at stimulus offset. Stimulation of the FC outside of the medial precentral region produced no, or much less, suppression. Together these data show, in addition to the previously demonstrated tonic influence, a phasic influence of a circumscribed region of FC on LC activity.

The effect of Δ^9-THC on neuronal activity in the frontal cortical-basal ganglia system during a delayed match to sample task in rats. *J-Y. Chang*, M.G. Laubach, A.B. Kirillov and D.J. Woodward, Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University. Winston-Salem, NC 27157.*

Marihuana is currently one of the most prevalent substances of abuse. Its aversive effects include a disruption of motoric and cognitive abilities. Cannabinoid receptors are densely concentrated in the frontal cortical and basal ganglia of rats, suggesting that behaviors that are dependent on the cortical-thalamic system should be sensitive to the effects of the cannabinoids. The present study employed ensemble recording to examine the effects of Δ^9-tetrahydrocannabinol (Δ^9-THC) on neuronal activities in medial frontal cortex (mPFC), striatum (STR) and substantia nigra pars reticulata (SNr) during performance of a delayed-match-to-sample-task. Rats were instructed to press a right or left sample lever and to then execute nose-poke responses a delay period (~15 seconds). The first nose poke after the delay period resulted in the presentation of both levers. Pressing the same lever as in the sample phase resulted in a reward, whereas pressing the lever opposite to that presented in the sample phase resulted in a time-out period. Single neuron and ensemble activities were analyzed by using peri-event histograms, joint peri-event time histograms and classification trees (CART). Alterations in spike activity associated with behavioral events in the sample, delay, and match phases were observed in mPFC, STR, and SNr. Δ^9-THC at doses of 0.5-1.0 mg/kg (i.p.) increased the occurrence of errors in the task in parallel with alterations in neuronal activity during the sample, delay and match phases. The data suggests that the frontal cortical-basal ganglionic system is part of neuronal circuitry through which the cannabinoids may influence attentional and memory process. *Supported by DA2338 W.W.W .server: http://biogfx.bgsm.wfu.edu.*

INVOLVEMENT OF GABAERGIC PROJECTIONS IN SYNCHRONOUS OSCILLATIONS IN CULTURED CORTICAL NEURON NETWORKS FIRING; BICUCULLINE EFFECTS FREQUENCY OF OSCILLATION. K.Kobayashi[1]*, K. Umezawa[1], A. Nozawa[1], K.Muramoto[1], M.Kawahara[1], E. Maeda[2], A.Kawana[2], Y. Kuroda[1]
[1]Department of Molecular and Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, Fuchu-shi, Tokyo183; [2]NTT Basic Research Institute, Atsugi, Kanagawa, Japan.

Synchronous oscillation of neuronal activities has been suggested to be important for sustaining firing to reinforce activity-dependent changes of synaptic plasticity in memory circuits (Kuroda et al Soc.Neurosci.Abstr. 20, 801, 1994). We have found that dissociated rat cortical neurons make networks with high synaptic convergence in culture and that the networks fire spontaneously in synchronous oscillation (Kuroda et al. Neurosci.Let.,135, 255,1992,). The existence of GABAergic neurons and synapses in the culture was investigated by immunocytochemistry. After fixation, approximate 10-15% of neurons were stained with both anti-GABA antibody and with Anti-GAD antibody. The proportion of GABAergic neurons in the primary culture is thus very similar to that of rat visual cortex in vivo. Anti-GAD also stained many small dots around neurons and their dendrites. When double-staining with anti-synaptotagmin antibody was carried out, many small dots of synaptotagmin staining were also stained by GAD antibody, indicating existence of abundant GABAergic terminals. Since inhibitory postsynaptic currents are also found in some neurons in the network (Robinson et al. J. Neurophysiol. 70, 1606,1993), the effects of a GABA antagonist on the synchronous oscillation of burstings were observed using fura-2 multi-site Ca fluorometry. Application of bicuculline decreased the frequency of synchronous oscillations suggesting a contribution of GABAergic input to the network activity.

THE GABAB RECEPTOR, INPUT SELECTIVE PRESYNAPTIC INHIBITION AND THE REPRESENTATION OF FAMILIARITY A.C. Tang* and M.E. Hasselmo Department of Psychology and Program in Neurosciences, Harvard University, Cambridge MA 02138.

Recent physiological studies in brain slice preparations of the piriform cortex (Tang and Hasselmo, *Brain Res.* 659: 75-81) demonstrate that the suppression of synaptic transmission (presynaptic inhibition) elicited by activation of GABAB receptors is selective for excitatory synapses between pyramidal cells, but not for afferent input to the cortex. We have used computational models of cortical function to study how this differential influence on afferent versus intrinsic inputs to principal neurons plays a role in the judgement of the novelty or familiarity of stimuli. The model contained coupled pairs of excitatory and inhibitory neurons, with full connectivity among the excitatory neurons. We focused on the transient responses of individual neurons, showing that the perceived familiarity of a pattern of afferent input can be represented by a quantity S -- the first derivative of the second inflection point of the neuronal response profile. Activity dependent presynaptic inhibition was crucial for an adequate representation of perceived familiarity in this model. Modeling allowed manipulation of network parameters corresponding to the presynaptic GABAB receptor density and the concentration of exogenous GABAB agonist (baclofen, used clinically to treat spasticity). Results show that either decreased GABAB receptor concentration on the presynaptic terminals, or increased exogenous GABAB agonist concentration, reduces perceived familiarity within the model. These results are consistent with the effect of chronic baclofen administration on rat behavior in an odor habituation task (Tang and Hasselmo, *Behav. Brain Res.* in press), the loss of recognition memory as a result of baclofen overdose, and the loss of GABAB receptors in Alzheimer's patients.

Basolateral amygdaloid neuron responses in rats performing a spatial maze task. W.E. Pratt* & S. J. Y. Mizumori, Dept. Psychol., University of Utah, Salt Lake City, UT 84112

Much research involving the nucleus accumbens (NA) has suggested that it is a crucial site for the modulation of reward and spatial learning. Previously, we have reported the presence of cells with reward and spatial correlates within the NA (Lavoie & Mizumori, 1994). The pathway from the basolateral nuclei of the amygdala (BLA) to the NA may be important in the conduction of reward information. The present study investigated information encoding within the BLA which could then pass to NA neurons.

Single units in the BLA were recorded while animals performed a spatial memory task on an eight arm radial maze. Four arms consistently had low reward (1 drop chocolate milk) and four consistently had high reward (5 drops chocolate milk). Initial results (n= 43 cells, 1 rat, 2 passes in each of 2 hemispheres) indicate a variety of behavioral correlates. 14% of cells displayed location specificity. 30% showed an increase in firing rate of at least 20% (range:22-77%)when traveling outbound from the center of the maze relative to traveling inbound, and 14% increased inbound relative to the outbound rate (24-62% increase). 9% of cells decreased their rate 50% at the end of arms, with a corresponding increase once movement resumed. Three cells showed possible reward correlates; one fired only at the end of arms during trials, and the other two either showed a 50% increase or decrease which did not appear movement related.

These data, while not proving or disproving a role for the BLA in reward-related processes, suggest that the amygdala may encode more spatially-related forms of information than was previously imagined. These data illustrate for the first time the heterogenous nature of information coded in the BLA during performance of this spatial task. Consistent with lesion studies on conditioned place preference, the BLA may code reward associations within the spatial context in which learning occurs. [Supported by AG09299 and BNS 9120784]

SPATIAL REPRESENTATIONS OF DORSAL CAUDATE NEURONS OF FREELY-BEHAVING RATS. S. J. Y. Mizumori* & B. G. Cooper, Dept. Psychol., University of Utah, Salt Lake City, UT 84112

Experience-dependent visuospatial navigation requires not only continual update and modification of representations of our sensory surround as animals move through their environment, but also continual refinement of movement patterns. With respect to the latter process, ventral striatal neurons show dynamic spatial and reward properties that may be used to direct navigational behavior (Lavoie & Mizumori, 1994). This study extends our striatal analysis by assessing the contribution of the caudate nucleus to control of navigational behaviors.

Rats (9-12 mo old) performed multiple spatial memory trials on a radial maze. 192 neurons were recorded in dorso-rostral caudate nucleus of 7 rats. Consistent with Wiener (1993), a variety of spatial correlates were observed. Some spatial cells (n=8) showed clear directionally-specific, spatially-localized firing. Another type of spatial coding was shown by 1 cell which exhibited mnemonic, directional heading properties: it fired when the animal's head was oriented in a preferred direction in space, regardless of the animal's location. Such directional firing could be maintained in the absence of visual cues or voluntary movement. 10 other cells also showed directionally-specific firing, but the firing occurred relative to the maze configuration. Additional spatial cells selectively fired when animals made right and/or left turns (n=12); 3 of these displayed turn correlates only when animals occupied certain locations. Thus, caudate spatial messages are coded within multiple reference frames. Also, these data are consistent with primate studies which show that caudate neurons code contextually-dependent, nonmotor information relevant to spatially-guided learned behaviors. Intra-amygdala infusion of APV blocks auditory evoked potentials in the lateral amygdala and thalamo-amygdala transmission, but spares cortico-amygdala transmission. M. T. Rogan* and J.E. LeDoux, Center for Neural Science, New York University, NY, NY 10003.

Thalamic and cortical amygdala-fugal pathways have been implicated in fear conditioning with an acoustic conditioned stimulus. Since infusion of NMDA-antagonist APV in the amygdala disrupts fear conditioning, we studied the effect of APV infusion on neural transmission in the thalamo-amygdala and cortico-amygdala pathways, and on auditory evoked potentials in the lateral amygdala (LA). Urethane anesthetized rats were fitted with an auditory speaker for the delivery of a calibrated acoustic stimulus, and two stimulating electrodes: one in the medial division of the medial geniculate body and posterior intralaminal nucleus (MGm/PIN), and one in the TE3 region of auditory cortex. Averaged evoked potentials (EPs) elicited by these 3 stimuli (auditory-EPs, MGm/PIN-EPs, and TE3-EPs) were measured in the lateral amygdala with a steel recording electrode equipped with an attached micropipet (50μ OD) loaded with APV (50μM). After stable baseline measurements were obtained, .5μl of APV was infused, and all EP measurements were monitored at 15 min intervals. APV infusion reduced the slope of the auditory-EP and MGm/PIN-EP at least 75% from baseline levels, and these responses showed recovery with time. APV infusion had no effect on TE3-EP, which remained stable throughout the measurement period. These results indicate that auditory-evoked activity in LA and transmission through thalamo-lateral amygdala synapses are both largely dependent upon NMDA-receptor function. In contrast, transmission through cortico-amygdala synapses is not dependent on NMDA-receptor function. Supported by MH38774, MH46516, MH00956, MH10919.

THE AMYGDALA IS NECESSARY FOR THE INITIAL ACQUISITION BUT NOT FOR MAINTAINENCE OF DISCRIMINATIVE AVOIDANCE BEHAVIOR IN RABBITS. **A. Poremba* and M. Gabriel. Dept. of Psych. and Beckman Institute, Univ. of Illinois, Urbana, IL 61801.**

Bilateral electrolytic amygdala lesions block acquisition of discriminative avoidance conditioning wherein rabbits learn to step in a large activity wheel upon hearing a footshock-predictive tone conditional stimulus (CS+, 1 or 8 kHz) and to ignore a different tone (CS-, 1 or 8 kHz), not predictive of shock (Poremba and Gabriel, Soc. Neurosci. Abstr., 17:325, 1991). Here we asked whether the circuit necessary for the initial acquisition of the avoidance behavior is also involved in maintaining performance of the well-learned behavior. Rabbits (n=6) given bilateral intra-amygdaloid microinjections (.5 μl) of the $GABA_A$ agonist, muscimol (1 μmol), showed no signs of learning, either in terms of discrimination between CS+ and CS- or in terms of response incidence relative to a preliminary training session in which the CSs and the footshock were explicitly unpaired (p<.02). Rabbits given saline (vehicle) microinjections did develop discrimination (p<.02). Next, all rabbits (n=11) were trained to asymptotic performance and received 3 additional training sessions (overtraining). After this training, muscimol microinjections then significantly reduced performance relative to saline microinjections (p<.05). Finally, the rabbits received an additional seven days of training (n=4) or seven days of rest (n=5) followed by a muscimol and a saline session. In contrast to the findings after three days of overtraining, no significant reduction of avoidance responding was found. These results suggest that the amygdala is necessary for the initial acquisition of the discriminative avoidance behavior. Merely the passage of time after overtraining renders the amygdala unnecessary for maintenance of the avoidance behavior. (Support: NINDS grant NS26736 to MG).

758.21

PREDICTION OF LEARNED BEHAVIOR FROM ELECTRO-PHYSIOLOGY: DIMINISHED CONTRIBUTION OF LIMBIC THALAMUS TO AVOIDANCE RESPONDING AFTER EXTENSIVE OVERTRAINING IN RABBITS. **M. Gabriel*, M. Hart, A. Poremba. Dept. of Psych. and Beckman Institute, Univ. of Illinois., Urbana, IL 61801.**

Neurons in the limbic (anterior and medial dorsal) thalamic nuclei exhibit training-induced multi-unit activity (TIA), as rabbits learn to avoid a foot-shock by stepping in an activity wheel upon hearing a shock-predictive tone (CS+, 1 or 8 kHz), and to ignore a different tone (CS-, 1 or 8 kHz) not predictive of shock. The TIA, increased tone-elicited discharges (excitation), which are greater in response to the CS+ than to the CS- (discrimination), reaches maximal levels in the limbic nuclei as behavioral learning reaches asymptote (see Gabriel, M., in Neurobiology of Cingulate Cortex and Limbic Thalamus, 1993, Birkhauser: Toronto, 478-523). Bilateral electrolytic limbic thalamic lesions block learning (op. cit, 1993). The fact that TIA amplitude declines gradually during post-criterial training (overtraining) suggested that the contribution of limbic thalamus to the learned behavior may diminish during overtraining. Here rabbits (n=5) given training to behavioral asymptote followed by limbic thalamic lesions showed significantly impaired post-lesion retention, relative to sham lesion controls (n=4), as measured by avoidance response performance during extinction testing (p< .04) and re-acquisition to criterion (p< .04). Ample retention was exhibited by other rabbits (n=5) given lesions after receiving training to criterion plus ten days of overtraining. This performance did not differ from that of similarly trained sham lesion controls (n=5). Thus, the limbic thalamic nuclei are involved in original learning and maintained performance of discriminative avoidance behavior, but are not critical for the behavior in highly overtrained rabbits. (Supported by NINDS grant NS26736 to MG).

LEARNING AND MEMORY: PHYSIOLOGY IV

759.1

MUTUAL INHIBITION OF NEURAL PATHWAY SYSTEMS DURING FORWARD AND BACKWARD CONDITIONING SUGGESTS SYMMETRICAL ATTENUATING MECHANISM DURING ASSOCIATIVE LEARNING. T.Korhonen*, T.Ruusuvirta and J.Arikoski, Dept.of Psychol.,Univ.of Jyvaskyla, P.O. Box 35, 40351 Jyvaskyla, Finland.

Forward and backward conditioning procedures were used for an evaluation of the order effect of the conditioned (CS) and unconditioned stimulus (UCS) presentation. Six cats were first classically conditioned using tone-CS (1500 ms) delay paradigm in which a rewarding electrical stimulation train (500 ms) of the lateral hypothalamus served as the UCS. Both behavioral (head movements) and evoked neural responses were recorded in hippocampal areas (CA1, dendate fascia and subiculum) in freely moving cats. The result showed that during the forward pairing both the head movements and unconditioned evoked responses were significantly attenuated compared to to the UCS-alone presentations. Correspondingly, the responses to the CS (short latency, alpha responses) were significantly attenuated during the backward sessions compared to the CS-alone presentations. These findings suggest that the preceding stimulus leaves a temporal trace the effect of which temporally overlaps the subsequent stimulus. An assumption of the local postsynaptic interaction might explain the mutual inhibition effect of the converging CS and UCS pathways found in the present study. This conclusion was also supported by an observation of the specific modifying effect the UCS pathway on the CS pathway and vice versa.

759.2

PRESYNAPTIC INHIBITION: A TEST OF ITS POTENTIAL ROLE IN BLOCKING CLASSICALLY CONDITIONED REFLEX POTENTIATION AT CERTAIN INTERSTIMULUS INTERVALS. R.G. Durkovic*. Dept.Physiol., SUNY Health Sci. Ctr., Syracuse, NY 13210.

In spinal cat classically conditioned flexion reflex potentiation over spinal circuits activated by large myelinated (A-beta) cutaneous fibers occurs when the unconditioned stimulus (US) onset slightly precedes conditioned stimulus (CS) onset, but not when the CS and US completely overlap in time. Presynaptic inhibition of A-beta afferents of the US by CS inputs has been hypothesized as a mechanism responsible for blocking A-beta conditioned potentiation in paradigms with complete overlap of CS and US (Onifer and Durkovic, J. Neurosci. 8:502). The present study tested for evidence of presynaptic inhibition of the US (superficial peroneal (SP) nerve terminals) by saphenous (S) nerve inputs (the CS) by examining changes in SP primary afferent terminal thresholds following S stimuli (i.e., tests of primary afferent depolarization, PAD, which parallels presynaptic inhibition: J.Physiol. 161:258).

In unanesthetized decerebrate T-10 spinal cats stimulation of the L-6 dorsal root entry zone with single pulses elicited antidromic potentials recorded from the SP nerve. Single S nerve pulses preceding spinal cord stimuli potentiated initial and depressed secondary (dorsal root reflex) potentials recorded from the SP nerve for at least 70 ms with maximum effects at 25-50 ms after the S pulse. Similar results followed each one of the 10 Hz pulses of the S nerve train employed as the CS.

These results supply evidence for presynaptic inhibition of US primary afferent terminals by CS inputs. This phenomenon may prevent the necessary A-beta associative inputs from reaching first order interneurons when CS and US completely overlap, thus preventing A-beta associative reflex potentiation. Supported by NSF grant IBN 9220206.

BEHAVIOURAL, NEUROCHEMICAL AND MORPHOLOGICAL CHANGES IN AGED RATS: COMPARISON WITH BASAL FOREBRAIN AND ENTORHINAL CORTEX LESIONS. G.A. Higgins*, J. Clapham, J. Murray, D.L Kirkby, H.T.R. Rupniak, H. McCleave, J.C. Barnes Pharmacology 2, Glaxo Research & Development Ltd, Ware, Herts, UK.

In Alzheimer's disease (AD) some of the earliest neurodegenerative changes include synapse loss in the molecular layer of the dentate gyrus, as measured by synaptophysin immunoreactivity (SI; Masliah et al (1994) Neurosci. Lett. 174: 67) and reductions in forebrain choline acetyltransferase (ChAT; Perry (1986) Brit. Med. Bull. 42: 63). We and others have found similar changes in rats following electrolytic lesions of the entorhinal cortex (EC) or AMPA neurotoxin lesions of the basal forebrain (BF). In the present series of studies we have characterised 3 groups of male, Lister hooded rats (young (Y) 3 months; middle aged (MA) 15 months; aged (A) 22 months) for behavioural, neurochemical or morphological differences to compare with those produced by BF or EC lesions.

Water maze testing revealed clear age-associated deficits in acquisition to find a submerged platform, which could be dissociated from changes in motivation /sensorimotor function. A subpopulation of A rats showed particularly poor acquisition e.g day 4: path lengths Y=282±44cm, A unimpaired (AU)=331±43cm, A impaired (AI)=653±14cm; $p<0.01$ vs. Y and AU groups. Unlike EC lesioned rats, A rats (including AI) showed no significant change in SI in the molecular region of dentate gyrus compared to Y rats. Furthermore reductions in ChAT activity were much smaller then those produced by BF lesions, and were more prominent in the striatum, rather than hippocampus/cortex. Thus in the present studies we have failed to find a simple correlation between age associated changes in cognitive performance with SI/ChAT, perhaps indicating that multiple factors are likely to contribute.

TOPOGRAPHIC DISTRIBUTIONS OF THE MEDIODORSAL THALAMIC NEURONS DURING ASSOCIATIVE LEARNING IN RATS. T.Oyoshi, H.Nishijo, T.Asakura, T.Kobayashi* and T.Ono. Dept. Physiol., Fac. Med., Toyama Med. & Pharmaceu. Univ., Toyama 930-01, and Dept. Neurosurg., Fac. Med., Kagoshima Univ., Kagoshima 890, Japan.

Neuronal activities were recorded from the mediodorsal thalamic nucleus (MD) of behaving rats during discrimination and learning of conditioned stimuli associated with or without reinforcements: sucrose solution, intracranial self-stimulation, and aversion (electric shock). The rats were trained to lick a protruding spout just after a conditioned stimulus to obtain reward or to avoid aversion. Of 122 MD neurons responding during the task, the activity of 13 correlated to licking (behavior-related), and that of 109 did not (behavior-nonrelated). Activity of behavior-related neurons increased just before licking only during the task, but not before spontaneous licking during the intertrial interval. These behavior-related neurons were mainly located in the lateral segment of MD, which has intimate anatomical connections with motor-related areas such as anterior cingulate and striatum. Of 109 behavior-nonrelated neurons, 97 responded differentially to conditioned sensory stimuli and the remaining 12 responded nondifferentially. These differential behavior-nonrelated neurons had the following characteristics: First, most neurons (90/97) responded to both auditory and visually conditioned stimuli. Second, most neurons (37/39) changed their responses plastically along with learning during the extinction and relearning trials. Third, most neurons (8/14) responded during the delay period, as well as during the conditioned stimulation period in the reward task with delay, in which delay was imposed between the conditioned auditory stimuli and the protrusion of a spout. These differential behavior-nonrelated neurons that had short latencies less than 300 ms were mainly located in the rostro-medial portion of the MD, which receives afferents from the basolateral nucleus of the amygdala, where various sensory information converges. The present results, along with previous anatomical studies, suggest the evidence of two limbic circuits; anterior cingulate-striatum-lateral MD (motor), and amygdala-medial MD-orbital cortex (emotional/motivational) circuits.

THE INVOLVEMENT OF NUCLEUS ACCUMBENS IN LATENT INHIBITION. I. Weiner√#, G. Gilad√, J. Feldon√#, √Dept. Psychology, Tel-Aviv University, Tel-Aviv, **Israel**. #Lab. Behav. Biol. Funct. Toxicol., Instit. Toxicol., Schorenstrasse 16, Schwerzenbach 8603, **Switzerland.** (ENA)

When an organism receives repeated presentation of a stimulus without any other consequences, it subsequently disregards this stimulus when it is followed by significant consequences, e.g., reinforcement. This is reflected in slower conditioning to this stimulus as compared to a novel stimulus and constitutes the phenomenon of latent inhibition (LI). LI is absent in rats and humans receiving the psychotomimetic, amphetamine, as well as in acute schizophrenic patients. Neuroleptic treatment restores LI in amphetamine-treated rats and schizophrenics. These results have led to the proposition that LI disruption models a cardinal cognitive deficit in schizophrenia, namely, an inability to ignore irrelevant stimuli. This proposition is strengthened by the fact that the neural substrates of LI parallel those implicated in the pathophysiology of schizophrenia, namely, the retrohippocampal region and the ventral striatum. The present experiments investigated the involvement of the two subterritories of the nucleus accumbens (NAC), shell and core, in LI. Electrolytic lesions of shell and core produced distinct effects on LI: shell lesion led to total disappearance of LI whereas core lesion only attenuated conditioning to a novel stimulus. Only shell lesion increased amphetamine-induced activity, suggesting that it produced increased dopamine (DA) transmission. This was further substantiated by the fact that the administration of a DA blocker, haloperidol, restored LI in shell lesioned animals. Thus, the capacity to ignore irrelevant stimuli critically depends on the integrity of the shell subterritory of the NAC (and therefore probably on the inputs received by this region from retrohippocampal structures), and an impairment of such capacity is subserved by increased mesolimbic DA transmission. In addition, these results provide the first behavioural demonstration for the functional specialization of the shell and core subterritories of the NAC.

DIFFERENTIAL LEARNING-RELATED ACTIVITY OF HIPPOCAMPAL SINGLE UNITS DURING CLASSICAL CONDITIONING IN THE RABBIT. R.L. Borgnis*, M.A. Seager and S.D. Berry. Center for Neuroscience Research and Department of Psychology, Miami University, Oxford OH 45056.

While it is generally accepted that hippocampal cells show plasticity during behavioral classical conditioning, unit/behavior analyses from several laboratories have indicated a surprising heterogeneity of responses among similar cell types both within and across hippocampal subfields (e.g., Berger *et al.* 1983; Ranck 1973; Weiss *et al.* 1993). However, much of the research has been done in a single aversive paradigm (rabbit NM conditioning). To expand these findings, we recently showed that multiple unit activity recorded from CA1 corresponded to the behavioral response in the appetitive conditioned jaw movement paradigm (CJM; Oliver, Swain & Berry 1993). Given the variety of potential single unit response profiles (as in NM conditioning), we decided to undertake single unit analyses of various hippocampal cell types during CJM.

New Zealand White rabbits were anesthetized (ketamine 50mg/kg and xylazine 10mg/kg) and unilaterally implanted with a stainless steel microelectrode. A capped metal cylinder was cemented into place over the contralateral hemisphere that would later hold a microdrive unit containing both single and multiple unit electrodes. Rabbits were trained for two days (54 trails per day) in CJM prior to attachment of the microdrive on the third day. Hippocampal unit responses and field potentials were recorded from both hemispheres. Some rabbits were trained in NM/CJM concurrent discrimination.

Our results show that cells within the same electrophysiological classification (e.g., spike widths >0.5 ms) respond differently during CJM, some showing diffuse increases in firing rate to the tone, others showing periodicities similar to the rhythmic jaw movement response. Some units are from animals that were trained in a concurrent NM and CJM discrimination task to assess whether the same cell responds differently during performance of the two distinct behavioral responses.

Hippocampal CA1 Single Neuron Activity During Trace Eyeblink Conditioning C. Weiss,* M.A. Kronforst, and J.F. Disterhoft, Dept. of Cell and Molecular Biology, Northwestern University Medical School, Chicago, Il. 60611

Multichannel recordings were used to monitor the activity of several hippocampal CA1 pyramidal cells simultaneously during trace eyeblink conditioning in the rabbit (100 ms tone, 500ms trace, 150 ms airpuff). Control rabbits were presented with unpaired tones and airpuffs. The Datawave software package was used to separate the activity of single neurons from each electrode. Pyramidal cells were separated from interneurons according to spike width, spike rate and the presence of complex spikes. Activity during the tone, trace, UR (500ms after airpuff onset), and post trial (PT) periods (2s after the UR period) was compared with activity from an equal time window prior to tone onset using either one sample t-tests or the binomial test (for slowly firing cells). Changes were considered significant if $p \leq 0.01$.

Recordings were made from 113 CA1 pyramidal neurons from 11 rabbits during trace conditioning and from 23 neurons from 5 rabbits during unpaired stimulation. Many of the neurons (40%) had baseline firing rates ≤ 0.5Hz. During sessions with >60% CRs, 46% of the neurons exhibited a statistically significant change in firing rate during the trial period. Another 18% changed only during the PT period. In comparison to control rabbits, the conditioned rabbits were found to have a greater percentage of significantly affected neurons during the CS, trace and PT periods. The percentage of cells from conditioned and control rabbits that changed during the UR period was similar. Both excitation and inhibition occurred during the trial period, but inhibition predominated during the PT period.

The low number of significantly related cells, the great diversity of responses, and the large number of neurons with significant inhibition during the trial period suggest that information processing by the hippocampus is more complex during hippocampally-dependent conditioning than during hippocampally-independent conditioning (cf. Berger et al., 1983).

INCREASED SYNAPTIC RESPONSIVENESS BETWEEN CA3 AND CA1 AFTER TRACE EYEBLINK CONDITIONING RECORDED *IN VITRO*. J.M. Power*, L.T. Thompson, J.R. Moyer, Jr., and J.F. Disterhoft, CM Biology, Northwestern University Medical School, Chicago, IL 60611.

Thirty-four young (2 mo) female NZW rabbits received either trace conditioning (80 trials daily: 100 ms tone CS; 500 ms trace ISI; 150 ms corneal airpuff), pseudoconditioning, or were naive. Conditioned animals were trained daily until reaching a criterion of 80% CRs in a given session. Hippocampal slices were prepared 1 h or 24 h following the final training session. Field potentials were evoked by stimulation of the Schaffer collaterals, using a stainless steel bipolar electrode. Somatic and dendritic field potentials were recorded in CA1, 750 µm from the stimulating electrode. An input-output function for each slice was generated using a 100 µA current and a range of stimulus durations (20 - 600 µs) encompassing subthreshold to maximal population spike responses.

The maximal population spike amplitude was 39% greater in slices from conditioned animals sacrificed 1 h after acquisition and 24% greater in slices from conditioned animals prepared 24 h after acquisition relative to naive controls. Additionally, the EPSP slope was found to be greater in slices prepared from conditioned animals 1 h post acquisition. Field potentials from naive and pseudoconditioned animals were indistinguishable. All recording and data reduction was performed **blind** to the conditioning task. Further analysis and experimentation are being done to decipher whether the enhanced population spike amplitudes result from altered synaptic efficacy, increased postsynaptic excitability, or both.

CLASSICAL CONDITIONING USING NUCLEUS BASALIS STIMULATION PRODUCES ASSOCIATIVE CS-SPECIFIC DESYNCHRONIZATION OF AUDITORY CORTEX EEG. JS Bakin*, TS Bjordahl, and NM Weinberger, Center for the Neurobiology of Learning and Memory, and Department of Psychobiology, University of California, Irvine, CA 92717

Cholinergic system activity plays a critical role in learning and memory, cortical processing, and cortical plasticity (cf Weinberger 1993 *Current Opinion Neurobio*). Classical conditioning using an auditory conditioned stimulus (CS) produces specific long lasting plasticity in primary auditory cortex (ACx) receptive fields (RFs), resulting in retuning RFs to or towards the CS frequency (Bakin and Weinberger, 1990 *Br Res*). We hypothesized that this plasticity requires the convergent activation of acoustic thalamocortical and cholinergic modulatory inputs to the ACx (Weinberger et al, 1990 *CINS*). As an initial test of this model, we classically conditioned urethane anesthetized adult male rats, substituting electrical stimulation of the NB for footshock, as the unconditioned stimulus. Neuronal RFs and cortical EEG were simultaneously obtained from ACx ipsilateral to the NB stimulating electrode, and contralateral to the CS speaker. Here we report the effect of classical conditioning with NB stimulation on ACx EEG.

NB stimulation alone (500ms, 200Hz, 100-300μA) produced EEG desynchronization (14/14 subjects, $p<.0003$) that could be blocked by atropine (5/5, $p<.05$). Auditory tones alone did not (5/5, $p>.43$). During RF characterization following tone/NB conditioning (40 trials), the CS frequency ($p<.03$), but not non-CS frequencies ($p>.61$) produced EEG desynchronization. Sensitization controls did not develop CS-induced EEG desynchronization ($p>.26$), indicating that this effect is associative. This CS-specific EEG desynchronization could be detected 30 minutes post training, the longest interval tested.

These results demonstrate that convergent activation of acoustic and cholinergic inputs to ACx can support cortical plasticity, and might provide the basis for ACx RF plasticity during learning. Supported by NIDCD #DC02346 (NMW).

MULTIPLE-UNIT RECORDING OF THE INTERPOSITUS NUCLEUS DURING CLASSICAL CONDITIONING OF THE RABBIT EYEBLINK RESPONSE TO INTERMODAL (LIGHT AND TONE) STIMULI. J. A. Huska* and J. E. Steinmetz. Program in Neural Science and Department of Psychology, Indiana University, Bloomington, IN, 47405.

The interpositus nucleus (INP) is believed to be essential for the acquisition of a classically conditioned eyeblink response (CR) following pairings of either light or tone conditioned stimuli (CS), and an airpuff (US) to the cornea. Previous single-unit and multiple-unit recordings from the INP have revealed neuronal activity that precedes and models the CR. Allen and Steinmetz, 1994 found sites in cerebellar cortex that modeled CRs to two different tone frequencies, one of the tones signalling a long interstimulus interval (ISI), the other signalling a short ISI. The present study sought to determine whether recording sites in the INP could be found that would model CRs to stimuli from two distinct sensory modalities.

Rabbits were surgically implanted with multiple-unit electrodes in both the left and right INP and trained on each side with both tone and light CSs until reaching a criterion of 75% or more CRs for two consecutive days. In each session the rabbit received 120 CS-US pairings of a 350 ms CS that co-terminated with a 100 ms airpuff in a standard delay conditioning paradigm. Activity was recorded from the INP throughout training.

Preliminary findings indicate tone-related CR activity at sites within the INP, but no recording sites have modeled CRs to both tone and light CSs. Examination of the histological data reveals that thus far the sites sampled have been from lateral sections of the INP. These results would suggest that separate pathways exist through the INP for encoding the light versus tone CS-US association. We are currently recording from other deep nuclear areas in an attempt to localize sites where light CS-related activity can be found. Supported by NIMH grant # MH51178.

IMMUNOHISTOCHEMICAL EXPRESSION OF THE c-FOS PROTEIN IN THE SPINAL TRIGEMINAL NUCLEUS FOLLOWING PRESENTATION OF A CORNEAL AIRPUFF UNCONDITIONED STIMULUS. M.D. McEchron*, P. M. McCabe, T. J. Webber, E. J. Green, Janice M. Hitchcock, and N. Schneiderman, Behavioral Neuroscience Program, Dept. of Psychology, University of Miami, Coral Gables, FL 33124.

Previous work has shown that pairing a tone-conditioned stimulus (CS) with a corneal airpuff-unconditioned stimulus (US) produces reliable heart rate (HR) conditioning. A major goal in the neurobiological study of this HR conditioning paradigm is to localize potential sites of plasticity in the central nervous system (CNS) where CS and US information converge. The circuitry involved in the processing of the tone-CS has been examined in some detail, however, less is known about how airpuff-US information reaches critical sites of plasticity in the CNS. Therefore, the present study examined the expression of the c-Fos protein in the rabbit's CNS to determine which areas are activated by the presentation of the corneal airpuff US. In this study restrained awake rabbits received 100 presentations of a corneal airpuff. Brains were then removed and processed immunohistochemically for the c-Fos protein. In animals that received the airpuff, the ventral portion of the ipsilateral spinal trigeminal subnucleus caudalis (SVc) and interpolaris (SVi), and the dorsal raphe nucleus exhibited a greater number of c-Fos labeled cells per coronal section compared to control animals. Another group of animals was given microinjections of WGA-HRP in the medial nucleus of the medial geniculate (mMG) to determine if this critical area of the HR conditioning circuitry receives projections from SVc and SVi. These injections produced retrograde labeling in the same areas of SVc and SVi activated by the airpuff. Thus, a corneal airpuff US activates neurons in SVc and SVi which could then activate neurons in mMG. This provides additional evidence that CS and US information converge in mMG, an area believed to be a site of plasticity in the HR conditioning pathway. Supported by NSF IBN9222194 and NIH HL07426.

NEURAL EXCITABILITY MEASURED INTRACELLULARLY IN VIVO IN VENTRAL COCHLEAR NUCLEUS (VCN) AFTER BEHAVIORAL SENSITIZATION AND CONDITIONING. C. Woody*, X.F. Wang and E. Gruen. UCLA Med. Ctr., MRRC, BRI, Los Angeles, CA 90024.

Cats were studied before and after pairing 70 db click as CS with glabella tap and hypothalamic electrical stimulation (HS) followed 2.4 s by 70 db hiss as a DS. This order of presentation produced blink conditioning to the CS. When HS preceded the CS, tap and DS, sensitized responses to click and hiss were observed. An earlier study (Woody et al. NeuroReport 1994) showed greater activity increases to the stimuli after sensitization than conditioning. Further studies have tested unit excitability by measuring threshold currents for intracellular depolarizing pulses to initiate spiking. Percentages of neurons responding with increased activity 4-8 ms after click and 20-32 ms after the more slowly rising onset of hiss were also compared.

nA	ADAPTATION	SENSITIZATION	CONDITIONING
to fire	0.97±.36	0.57±.33	0.79±.33
response	n / %	n / %	n / %
to click	8 / 7	20 / 24	20 / 12
to hiss	3 / 3	13 / 16	12 / 7

The results suggest that the facilitation of activity in VCN cells is mediated by increases in excitability that are expressed postsynaptically in the neurons and potentiate their ability to respond. (Supported by Deafness Research Foundation.)

DIFFERENT NEURONAL ACTIVITIES IN ASSOCIATIVE FOREBRAIN REGIONS OF IMPRINTED AND NAIVE CHICKS. M. Bredenkötter* and K. Braun. Institute for Neurobiology, Magdeburg, Germany.

The medial part of the rostral neostriatum/hyperstriatum ventrale (MNH) in chicks is involved in auditory filial imprinting. 2-DG studies show that in imprinted chicks the MNH is strongly activated upon playback of the acoustic imprinting tone. Thus, we compared the activity of MNH neurons in imprinted and naive chicks evoked by either the imprinting tone or an unknown discrimination tone using freely moving or urethane anesthetized chicks.

In imprinted chicks the FFT-power of slow field potentials is increased during playback of the imprinting tone compared to the discrimination tone, whereas no differences are detectable between both stimuli in naive chicks. Single unit activity in imprinted chicks is drastically enhanced during playback of the imprinting tone in comparison to spontaneous activity ($p\leq0.002$) and during playback of the discrimination tone ($p\leq0.07$). The spike rate during playback of the imprinting tone is significantly higher than the spike rate during playback of the discrimination tone ($p\leq0.004$). In naive chicks no significant differences in neuronal activity could be observed between both tones and spontaneous activity.

Our results lead to the assumption that the MNH is also involved in memory recall. The single unit recordings in anesthetized chicks are in good agreement with the results from freely moving animals: there is an increase of neuronal activity in imprinted chicks but not in naive animals during playback of the imprinting tone in relation to spontaneous activity. While the discrimination tone evokes an increase of spike rate in the MNH of imprinted chicks, activity does not change significantly in naive controls. These results suggest that early acoustic experience during filial imprinting changes the neuronal responsiveness towards meaningful acoustic stimuli in the MNH.

EXCITATORY SYNAPTIC TRANSMISSION IN TELENCEPHALIC *IMHV* SHOWS A HEBBIAN POTENTIATION ONLY IN EARLY NEONATAL CHICKS: A SLICE PATCH EXPERIMENT.

T. Matsushima*[1,2] and K. Aoki[1],

1. Life Science Institute, Sophia Univ., Tokyo 102, and 2. School of Agricultural Sciences, Univ. of Nagoya, Nagoya 464-01, JAPAN.

Properties of local synaptic transmission were examined by whole-cell patch recording in slices of telencephalic hyperstriatum ventrale (the *IMHV* region) of neonatal quail chicks at 1-3 days (young) and 7-10 days (old) post-hatch. Postsynaptic current responses to local electrical stimuli were composed of an early excitatory and a late inhibitory components. The early EPSC proved to be mediated by monosynaptic activation of DNQX-sensitive glutamate receptors, while the late IPSC was mostly due to polysynaptic activation of bicuculline-sensitive GABA receptors. Upon depolarization of the postsynaptic neuron at -45 mV or above, a tetanic stimulation of low frequency (5 Hz x 100-300 pulses) induced a transient slow inward current. The slow inward current was strongly depressed at -70mV and AP5-sensitive, thus proved to be NMDA-ergic. The tetanic stimulation also induced a long-term potentiation of the DNQX-sensitive fast EPSC only in young chicks below 3 days. In older chicks, however, tetanus similarly induced the NMDA-ergic slow inward, though failed to initiate LTP. Such a temporal window of synaptic plasticity in the *IMHV* could represent **sensitive period** of early learning processes such as filial imprinting and passive avoidance learning. A change in mechanisms downstream to the Ca^{2+} influx via NMDA receptors could be responsible for terminating the sensitive period.

RESPONSE CHARACTERISTICS OF VENTRAL TEGMENTAL NEURONS IN THE AWAKE RABBIT. F.A.Guarraci* and B.S.Kapp, Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405.

A great deal of research has indicated that the mesotelencephalic dopamine (DA) system plays an important role in reward and aversive processes. Nevertheless, there has been a paucity of research describing in detail the sensory response characteristics of single DA neurons within the ventral tegmental area (VTA) of awake animals, particularly in response to stimuli predictive of aversive events. The present experiment is one of a series designed to investigate the response characteristics of VTA neurons to a variety of novel auditory stimuli (e.g., pure tones, white noise) and to auditory stimuli which predict aversive events in the awake rabbit. Single DA neurons within the VTA were isolated and identified according to established criteria: spontaneous rate of 0.8-10Hz and >2.0msec spike duration. In the absence of stimulus presentations, the spontaneous activity of these neurons was characterized by single spikes interspersed with bursts of 2-6 spikes with a mean burst interspike frequency of approximately 50msec. In response to auditory stimuli, three distinct response patterns were observed among different VTA neurons. The first was an increase in activity within 100msec of stimulus onset which was often characterized by a spike burst. The second response pattern was characterized by a marked inhibition to stimulus onset which outlasted the duration of the stimulus. The third pattern was characterized by a lack of response to auditory stimuli. Additional, preliminary data suggest that these three response patterns also occur in response to Pavlovian aversively-conditioned auditory stimuli. These results suggest that DA neurons within the VTA of the rabbit are responsive to novel auditory stimuli as well as to auditory stimuli predictive of aversive events.

ANALYSIS OF GENE EXPRESSION ASSOCIATED WITH MEMORY CONSOLIDATION IN RATS USING THE DIFFERENTIAL DISPLAY METHOD. A-Min Huang*[1] and Eminy H. Y. Lee[2]. Graduate Institute of Life Sciences, National Defense Medical Center[1] and Institute of Biomedical Sciences, Academia Sinica[2], Taipei, Taiwan, R. O. C.

Involvement of gene expressions associated with memory formation has been examined in learning paradigms for some invertebrates and vertebrates. However, little is known in the paradigm of inhibitory avoidance learning in rats. In this study, a PCR-related procedure based on the method of mRNA differential display was used to analyze differential gene expressions related to memory consolidation. Total hippocampal RNAs isolated from animals showing poor and good retention scores were used for comparison. Three 3'-end primers ($T_{12}AG$, $T_{12}GC$, and $T_{11}CA$) and four 5'-end arbitrary 10-mers were used. Each primer pair generates an average of 50-70 cDNA bands and most of the bands between individuals are identical. Several bands were found to be differentially expressed between poor and good memory rats. In one particular case, only a 3'-end primer ($T_{12}AG$) was used for PCR amplification. Two cDNA bands, designated as upper and lower band, showed differential expression between individuals of poor and good memory. These two bands were separately recovered from the gels, cloned into a TA vector, and sequenced. Both of them showed 90% homology with the 3'-end cDNA sequence of the glial fibrillary acid protein (GFAP). For further examination, 13 poor and 13 good memory individuals were compared. In the poor memory group, the lower cDNA band was found in 12 individuals. However, only 5 individuals in the good memory group showed this band. These results suggest that two different GFAP-like transcripts exist in the population and one of them may be associated with memory consolidation. cDNA clones of these two different transcripts will be isolated from the individual hippocampal cDNA library and the differences will be characterized.

ENHANCED HIPPOCAMPAL CRF GENE EXPRESSION ASSOCIATED WITH MEMORY CONSOLIDATION IN RATS. E.H.Y. Lee*, A.M. Huang and K.S. Tsuei Inst. Biomed. Sci., Academia Sinica, Taipei 115, Taiwan, R.O.C.

Corticotropin-releasing factor (CRF) was found to produce various behavioral changes other than its neuro-endocrine function. We have previously found that intra-hippocampal injections of CRF significantly improve memory retention of an inhibitory avoidance learning task in rats and CRF antagonist prevents this effect. Other laboratories have also found that i.c.v. injections of CRF enhance acquisition/learning in different learning paradigms in rats and mice. CRF gene expression was demonstrated in various brain regions including the hippocampus. The present study used the quantitative RT-PCR method to examine CRF gene expression in the memory consolidation process. One-way inhibitory avoidance learning paradigm was adopted. Results indicated that during the early phase of memory consolidation, which is 1 hr and 3 hr after the training procedure, there was a marked increase of CRF mRNA level in the hippocampus in animals showing good memory when compared with those showing poor memory. These results suggest that CRF gene expression is enhanced during the memory consolidation process.

759.18

ALTERATION IN THE ACTIVITY OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II ASSOCIATED WITH SPATIAL LEARNING IN RATS. S.E. Tan* and K.C. Liang+. *Dept. Psychology, Kaohsiung Med. Coll., and +Dept. Psychology, Natl. Taiwan Univ., Taiwan, R.O.C.

Protein phosphorylation plays a major role in neuronal plasticity as well as in behavioral learning processes. CaM-kinase II (Calcium/calmodulin-dependent protein kinase II) is one of the major brain protein kinases involve in learning and memory processes. The present study examined the role of CaM-kinase II in spatial behavioral learning.

Sprague-Dawley rats were trained in the Morris Water Maze. Three experimental groups recieved 5-, 2-, or 1-day training; and a control group. The hippocampal CaM-kinase II activities were analysed. The results showed that the activation of hippocampal CaM-kinase II (measured in term of the percentage of Ca^{++}-independent activity) was proportional to the extensiveness of behavioral training. There was a significant difference between the control and 5-day training groups in the percentage of Ca^{++}-independent activity ($p<.05$). There were no differences in the Ca^{++}-independent activity between the control and 1-day training groups, as well as in the total CaM-kinase II activity across the groups. Intra-hippocampal injection of a specific CaM-kinase II inhibitor, KN-62 (1-[N,O-bis(5-isoquinolinesulfonyl)-N-methyl-L-tyrosine]-4-phenyl-piperazine), hindered the spatial learning significantly ($p<.01$). The Ca^{++}-independent activity of CaM-kinase II in the KN-62 treated group was significantly lower than that in the vehicle control ($p<.01$). Our results indicate that the activation of CaM-kinase II is correlated with spatial learning.

BEHAVIORAL STRESS IMPAIRS HIPPOCAMPAL LONG-TERM POTENTIATION (LTP) THROUGH ACTIVATION OF N-METHYL-D-ASPARTATE (NMDA) RECEPTORS. J. J. Kim*[1], M. R. Foy[2] and R. F. Thompson[1], [1]Neurosciences Program, Univ. of Southern Calif., Los Angeles, CA 90089-2520 and [2]Psychology Dept., Loyola Marymount Univ., Los Angeles, CA 90045-2669.

Behavioral stress is known to impair various learning and memory tasks, and also to impair hippocampal LTP. Our previous work suggested that stress may occlude subsequent LTP development by elevating the basal synaptic transmission level. Since the induction of LTP in the hippocampus (e.g., area CA1) is known to require activation of NMDA receptors, we tested whether NMDA antagonists can block the stress effect on subsequent LTP.

Adult Long-Evans male rats (290-350 g) were administered intraperitoneally (i.p.) with either CGP39551 (30 mg/kg), a competitive NMDA receptor antagonist which crosses blood brain barrier, or saline 2 hours prior to stress. The stress consisted of 60 tailshocks (1mA, 1-s, 30-90-s apart) while restrained. Following stress, hippocampal slices were prepared in a standard manner. When initial slopes of field-EPSPs were examined in stratum radiatum in CA1 following stimulation of Schaffer collateral/commissural fibers, we found that slices from saline-stressed animals exhibited significantly impaired LTP ($107.9\pm4.9\%$; mean $\pm$ sem) after tetanus in comparison to slices from saline-control ($141\pm6.4\%$), CGP39551-control ($140.4\pm 8.0\%$) and CGP39551-stressed ($151.1\pm9.8\%$) animals. The CGP39551 effect appears not to be due to anxiolytic properties since slices obtained from animals injected with the anxiolytic drug diazepam (5 mg/kg i.p.) and then stressed were still impaired in LTP. Thus, our results suggest that the process by which stress impairs LTP appears to be mediated through NMDA receptor activation. PRENATALLY-INITIATED LEAD (Pb) EXPOSURE IMPAIRS HIPPOCAMPAL LTP IN THE AWAKE RAT. M.E. Gilbert*[1,2], C.M. Mack[2], and S.M. Lasley[1], U. North Carolina, Chapel Hill, NC 27599, US EPA, RTP, NC 27711, and U.Ill. Coll. Medicine, Peoria, IL 61656.

Childhood lead (Pb) exposure has been associated with impaired cognitive function. Previously, we employed the hippocampal long-term potentiation (LTP) memory model system and demonstrated an increase in the threshold for LTP induction in the urethanized Pb-exposed rat. The present study examined the induction and time course of decay of LTP in the dentate gyrus of the conscious rat chronically exposed to Pb. Prior to mating, female rats received 0.2% Pb-acetate in the drinking water and male offspring were maintained on this solution. As adults, animals were prepared with chronic stimulating/recording electrodes in the hippocampus. Following recovery from surgery and the establishment of stable field potentials evoked by single pulse stimulation (0.1 ms) of the perforant path, a pretrain input/output (I/O) function was collected. LTP was then induced by delivering 10 train pairs (4 pulses/pair at 400 Hz), 200 ms apart, with an intertrain interval of 10 s at 6 stimulus intensities (200-1000μA). Three additional I/O functions, 1 hr, 1 day, and 1 wk following tetanization were obtained to monitor induction and decay of LTP. Comparison of pre- and post-train I/O functions revealed a significant enhancement of PS amplitude in the control group, but no difference from pretrain levels in the Pb-exposed group at any timepoint. These data suggest that the detrimental effects of developmental Pb exposure on cognitive function may be due to its interference with the synaptic processes underlying LTP. Hippocampal LTP and Spatial Learning are Attenuated by $GABA_B$ Receptor Blockade in the Rat

F.H. Brucato[1], E.D. Levin[3], D.D. Mott[2], D.V. Lewis[1,2]*, W.A. Wilson[4,5] and H.S. Swartzwelder[1,3,5] Departments of Medicine[1], Pediatrics[2], Psychiatry[3], and Pharmacology[4] Duke University Medical Center and Neurobiology Research Laboratory, V.A. Medical Center[5], Durham, N.C. 27705.

This series of experiments assessed the role of $GABA_B$ receptors in the induction of long-term potentiation (LTP), and spatial learning and memory using three different tasks. In urethane-anaesthetized rats, theta burst stimulus trains were applied to the angular bundle and recorded in the dentate gyrus. Control LTP was attenuated from a mean of 145% to 57% in CGP 46381 treated rats ($t_{(13)}$=2.502,p=0.028,n=14).

We assessed the performance of rats on several spatial learning and memory tasks in CGP 46381 and saline treated rats. We found that the working memory performance of highly trained rats on the eight arm radial maze was unaffected by CGP 46381. There was also no effect of $GABA_B$ receptor blockade on learning in the eight-arm maze using a repeated acquisition paradigm. However, when we tested spatial learning in naive rats using the Morris water maze, we found that CGP 46381 treated rats (n=12) took significantly longer ($p<0.025$) to learn the location of the escape platform than controls(n=11). In addition, CGP 46381 treated rats travelled a greater distance over the acquisition and probe trials than did control rats. These data support our hypothesis that $GABA_B$ receptor blockade suppresses hippocampal LTP *in vivo* and impairs spatial learning in a task where stress may be important.

LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS XI

760.1

THE CONTRIBUTION OF THE MEDIAL SEPTUM TO THE FUNCTIONS OF THE HIPPOCAMPAL SYSTEM IN RATS. R. NUMAN.* Psychology Department, Santa Clara University, Santa Clara, CA 95053.

In people, consensus now favors the view that the septohippocampal system regulates declarative memories. However, as non-human animals do not have language ability, it has been difficult to identify the analogue of declarative memory in these species. We review experiments from our laboratory on the effects of medial septal lesions on the behavior of male Long-Evans hooded rats, and conclude that rats may 'declare' what they know in terms of their volitional behavior, and that the working memory for such voluntary goal directed behavior is disrupted by medial septal lesions.

In one experiment (Numan and Quaranta, 1990), medial septal lesions impaired a left-right operant delayed alternation task which appeared to be caused by a deficit in working memory. In a second experiment (Numan and Klis, 1992) we found that medial septal lesions facilitated performance on a delayed but cued go/no-go stimulus working memory task, suggesting that the lesions do not produce a general working memory impairment. In a final experiment (Numan, 1994) we found that medial septal lesions impaired performance on a delayed go/no-go response alternation task suggesting that the deficit is specific to response working memory, and that spatial task requirements are not necessary for the expression of such a deficit.

We suggest that the septohippocampal system functions as a response intention--response outcome working memory comparator and that while damage to the system impairs the working memory for voluntary behavior, it may also lead to a compensatory reliance on, and hence a potential enhancement of the functions of, exteroceptive cue based memory systems.

760.2

LOSS OF NUCLEUS BASALIS MAGNOCELLULARIS, BUT NOT SEPTAL, CHOLINERGIC NEURONS CORRELATES WITH PASSIVE AVOIDANCE IMPAIRMENT IN RATS TREATED WITH 192-SAPORIN. R.G. Wiley*, Z.-J. Zhang, T.G. Berbos and C. Wrenn, Lab of Experimental Neurology, VAMC, and Vanderbilt University, Nashville, TN 37212-2637.

Intraventricular injection of the immunotoxin, 192-sap, that selectively destroys neurons expressing the low affinity neurotrophin receptor, $p75^{NGFr}$, efficiently and selectively destroys the cholinergic neurons of the basal forebrain (CBF). In the present study, we sought to determine if there was a correlation between the degree of CBF neuron loss and alteration in passive avoidance behavior. Anesthetized, adult, male Sprague-Dawley rats were stereotactically injected with 4 μg of either 192-sap or OX7-sap, a control immunotoxin that recognizes the Thy 1 surface antigen and destroys cerebellar Purkinje neurons. 6-8 weeks later, immunotoxin and naive control rats were tested on a step-through passive avoidance paradigm. After behavior testing, all rats were sacrificed and brain sections processed for histochemical demonstration of AChE and immunohistochemical demonstration of $p75^{NGFr}$. The numbers of neurons in specific regions of the CBF were counted from the $p75^{NGFr}$ staining and the intensity of dorsolateral neocortical staining for AChE were assessed using image analysis. The magnitude of cell loss was similar (67-70%) for the entire CBF , the Nbm and septum/DBB. The severity of passive avoidance impairment was significantly correlated to cell loss in the entire CBF (r=0.748, 23 df, $p<0.001$) and in the Nbm (r=0.778, 23 df, $p<0.001$) but not the septum/DBB (r=0.419, 23 df, $p>0.05$). Behavioral impairment also correlated significantly to loss of cortical AChE staining intensity ipsilateral to the intraventricular injections (r=0.796, 15 df, $p.<0.001$). These findings show that loss of Nbm, but not of septum/DBB, cholinergic neurons is proportional to impairment in passive avoidance behavior suggesting a role for Nbm-neocortex cholinergic innervation in this type of learning. (Supported by the Department of Veterans Affairs.)

760.3

INTRASEPTAL INJECTION OF 192 IgG SAPORIN, AN IMMUNOTOXIN, REDUCES LATENT INHIBITION IN A CONDITIONED TASTE AVERSION PARADIGM. K.D. Dougherty*, Salat, D.H., Walsh, T.J. Rutgers University, New Brunswick,NJ, 08903,

When animals are pre-exposed to a CS prior to its pairing with a US, the acquisition of the conditioned response is impaired. This phenomenon is called latent inhibition (LI) and is often used as a measure of selective attention. The role of cholinergic mechanisms in selective attention was assessed using a conditioned taste aversion/ LI paradigm. 192 IgG saporin (SAP) (375 or 100 ng/0.45 ul) or artificial cerbrospinal fluid (aCSF) (0.45ul) was injected into the medial septal area of male Sprague Dawley rats. aCSF subjects given 4 pre-exposures to a novel saccarhin (0.2%) solution prior to its pairing with lithium chloride (0.15M) later displayed robust LI during a two bottle choice test. In contrast, subjects treated with either 100 or 375 ng SAP displayed significantly attentuated LI. Nonpre-exposed SAP treated rats displayed aversions to saccarhin rates of extinction comparable to those of controls. Both 100 and 375 ng SAP significantly decreased high affinity choline uptake (HAChU) in the hippocampus and cingulate cortex. Only the 375 ng dose caused significant HAChU decreases in entorhinal cortex. HAChU was not altered in striatum. HPLC analysis performed in a subset of subjects revealed no effect of SAP on regional concentrations of norepinephrine, serotonin, dopamine or their metabolites in hippocampus. The results indicate that there may be considerable overlap between the cholinergic systems that mediate working memory and those that are critical to selective attention.

760.4

Effects of 192 IgG Saporin Induced Lesions of the Medial Septum on Two Allocentric Spatial Memory Tasks. **L.S. Janis*, Z. Fülöp, and D.G. Stein. Brain Research Lab, Inst of Animal Behav, Dept of Psychology, Rutgers University, Newark, New Jersey, 07102.**

Previous studies have suggested that the hippocampal system is important for processing allocentric spatial information and that damage to the medial septum (MS) impairs an animal from using allocentric information to solve a spatial task. Because the cholinergic input to the hippocampus via the MS is necessary to maintain normal electrical activity and normal physiological functions of the hippocampus, we sought to determine whether hippocampal allocentric spatial ability was dependent upon this input. Twenty male rats were initially trained on a win-shift radial arm maze (RAM) task and then given either sham or cholinergic induced (192 saporin) lesions of the MS. Rats were then tested postoperatively on the RAM to assess their allocentric spatial ability. The results indicated that while rats with cholinergic MS lesions were significantly impaired in resolving the task, they did not exhibit deficits in allocentric spatial ability. In addition to RAM testing, rats were also tested on a modified water maze task designed specifically to test allocentric spatial ability. In this task, rats with cholinergic MS lesions performed as well as sham rats. Taken together these results suggest that the cholinergic projection from the MS is not critical for normal allocentric spatial ability and that such ability can be maintained by the remaining septohippocampal input.

760.5

LATERAL ENTORHINAL CORTEX ASPIRATION IMPAIRS ASSOCIATIVE "ODOR-PLACE" LEARNING IN RATS. T. Otto*, K.M. Schiller, G. Cousens, & C. Ding. Program in Biopsychology and Behavioral Neuroscience, Dept.of Psychology, Rutgers University, New Brunswick, NJ 08903.

Neuropsychological, anatomical, and electrophysiological data indicate that the lateral entorhinal cortex (LEC) is an important area of convergence of olfactory information and hippocampal processing during learning. In an attempt to explore the potential functional role of the LEC in the acquisition of the relations between olfactory and spatial stimuli, we have recently developed an "odor-place" task in which rats are required to learn to go to one location in the presence of a particular odor and to a second location in the presence of a different odor in order to obtain water reinforcers. Thus, accurate performance in this task requires learning the relationship between a specific odorant and a discrete spatial location. Bilateral aspiration of the LEC resulted in a marked deficit in acquisition of this task relative to sham-operated subjects; control experiments indicate that this impairment is not due to a sensory deficit. These data are consistent with the notion that the LEC participates critically in the acquisition of associations between multiple, discrete stimuli.

760.6

THE ROLE OF THE MEDIAL SEPTAL AREA AND THE PRELIMBIC CORTEX IN MEDIATING PERFORMANCE IN AN OPERANT WORKING MEMORY TASK. J.M. Williams*, E. Mohler, A. Canacci & B.S. Givens. Dept. of Psych.., The Ohio State Univ., Columbus, OH 43210.

Both the medial septal area and the prelimbic area of the prefrontal cortex have been implicated in working memory. However, it is not clear whether deficits following damage to the medial septal area and prelimbic cortex are due to memory per se or to attentional/encoding processes. To examine the nature of septal and prelimbic deficits, rats were trained on an operant task that allowed for separate analysis of the attentional and working memory components. Rats (divided into DMTS and DNMTS groups) were tested in an operant chamber with three lights located on the front panel. Levers were located beneath each light. A tone signalled the start of the sample phase of each trial. In the sample phase, rats were presented with either a signal in which the center light was illuminated or no signal. To assess the attentional components of the task, signal length was varied (one or two seconds). After the sample stimulus, a delay of 0 or 2 seconds was introduced. This delay constituted the working memory component of the task. During the choice phase, a light appeared randomly over either the right or left lever. The opposite side remained unlit. In order to obtain a subsequent reward rats were required to press the lever that either matched (DMTS) or did not match (DNMTS) the sample phase stimulus.

After reaching criterion, reversible inactivation (tetracaine infusions) and reversible manipulations of the GABAergic and cholinergic systems (muscimol, scopolamine and carbachol infusions) of each of these areas were performed to determine the extent and nature of medial septal and prelimbic involvement in attention and working memory. Preliminary results suggest that infusions into both the medial septal area and the prelimbic cortex produce delay-dependent deficits in performance of this visual working memory task.

760.7

EFFECTS OF PERIRHINAL OR RHINAL CORTEX LESIONS ON OBJECT-MEMORY TASKS IN THE RAT. T.J. Kornecook*, M. Liu, C.A. Duva, A. Anzarut, and J.P.J. Pinel. Dept. Psychol., University of British Columbia, Vancouver, B.C., Canada. V6T 1Z4.

Work with both monkeys and rats has shown that damage limited to the rhinal cortical region (entorhinal cortex + perirhinal cortex) is sufficient to produce severe impairments in object-recognition memory (Murray et al, 1989; Mumby et al., 1994). In primates, this impairment is largely due to the perirhinal component of the lesion, as ablations of the perirhinal cortex alone produces DNMS deficits nearly as severe as those seen after complete rhinal cortex lesions, whereas ablations of the entorhinal cortex produce only a mild deficit (Meunier et al., 1993). To assess the contribution of the perirhinal cortex to object memory in rats, we compared the performance of animals with lesions limited to this area to that of animals with combined perirhinal and entorhinal cortex ablation on a rodent version of DNMS, as well as on three different object-memory tasks which resemble those used to study amnesia in humans and monkeys: (1) object discrimination, (2) discrimination reversal, and (3) 8-pair concurrent object discrimination learning.

Male Long-Evans rats received either bilateral aspiration lesions of the perirhinal cortex alone (Per), perirhinal + entorhinal cortex aspirations (Rh), or sham sugery (Cont). The Rh group was significantly impaired with respect to the Cont group on postsurgery DNMS testing at delays of 60 sec($p<0.05$), and impaired with respect to both control and perirhinal-lesioned rats at delays of 120 sec ($p<0.01$). Although the DNMS scores of the Per group were lower than the controls at almost all delays, no statistical differences were found. On the simple object discrimination task, both the Per and Rh groups were equally impaired relative to the control rats ($p<0.02$). There were no statistical differences, however, in the rate at which all three groups acquired the discrimination reversal. With respect to the concurrent object discrimination task, a significant impairment arose only when the Per and Rh animals were combined into a single, uniform group ($p<0.03$). These results provide further evidence for the importance of the rhinal cortex in object-memory processes in the rat.

760.8

THE EFFECTS OF SEPARATE AND COMBINED LESIONS OF THE PERIRHINAL CORTEX, FORNIX AND SEPTUM ON MEMORY IN THE RAT. K. A. Wiig, S. J. Booth, P. Liu, L. Cooper*, and D. K. Bilkey. Department of Psychology, University of Otago, Dunedin, New Zealand.

Sham operated control rats and rats with bilateral lesions of either the perirhinal cortex, fimbria-fornix, or both these structures, were tested on a two choice discrimination task and an object-guided DNMS task (Mumby et al, 1990). All lesioned rats were able to learn the discrimination task at a rate comparable to control animals. In contrast, animals with lesions of the perirhinal cortex or fimbria-fornix exhibited a moderate, delay dependent memory deficit on the DNMS task, as they performed normally at short delay intervals, but were impaired relative to control rats at delay intervals of 30 seconds or more. Animals with combined lesions displayed a significantly greater impairment on the DNMS task than animals with lesions of either structure alone. The combined lesioned rats were severely impaired in acquisition of the task, and displayed a profound memory deficit at delay intervals of 15 seconds or more. We are currently investigating the effects of transient lesions of either the perirhinal cortex, medial septum or combined lesions of both these regions on watermaze performance. Preliminary data suggests that combined but not separate lesions produce a marked disruption in spatial memory. Overall, these results suggest that the perirhinal cortex and septohippocampal system may function synergistically in both spatial and nonspatial memory processes.

760.9

PERIRHINAL CORTEX DAMAGE: EFFECTS ON ACQUISITION AND RETENTION OF OBJECT AND PLACE DISCRIMINATIONS IN RATS. R.S. Astur*, D.G. Mumby, and R.J. Sutherland. Depts. of Psychology and Physiology, Univ. of New Mexico, Albuquerque, NM 87131.

In order to examine the effects of perirhinal cortex lesions on object memory, 12 rats were trained on 5 object discriminations 1, 4, 7, 10, and 13 week(s) prior to surgery. To examine place memory, each rat was trained in 3 different water task problems 2, 8, and 14 weeks prior to surgery. Six rats then received bilateral aspiration lesions of perirhinal cortex, and 6 rats received sham lesions. Retrograde effects were assessed by testing all rats on the five object discriminations and the three pool problems that they had learned previously. Anterograde effects were assessed by teaching the rats two new object discriminations and one new pool problem. For the old object discriminations, there were no differences between the groups in relearning the discriminations nor in their accuracy in the first five trials of testing. For the new object discriminations, there were no significant differences between the groups in learning the new object discriminations. For the old pool problems, there were no differences between groups in percent of time spent in the correct quadrant during probe trials or first-trial escape latency, although there was a trend for the perirhinal group to be impaired on these measures. These data suggest that perirhinal cortex plays a nonessential role in the acquisition and retention of object and place discriminations.

760.10

POSTTRAINING LESIONS OF PERIRHINAL CORTEX DECREASE PASSIVE AVOIDANCE OF PUNISHED DRINKING BUT NOT ITS REINSTATEMENT. G.D. Coover* and S.J. Mertes. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Lesions of the rostral perirhinal cortex (rPRh) of the rat disrupt fear conditioned to discrete stimuli (Rosen et al., J. Neurosci. 12:4624-4633, 1992) and also contextual stimuli (Corodimas and LeDoux, Soc. Neurosci. Abstr. 20:1007, 1994). The present study examined whether rPRh lesions would disrupt the context-dependent memories of previously-learned passive avoidance of drinking (dPA).

Male Long-Evans rats were water-deprived and trained to a criterion of 5 min avoidance of drinking by punishing drinking with .5-sec footshocks (FS) that increased in intensity over trials. They learned within 11 - 20 FS (Mdn = 16, M = 15.9, SD = 2.6). Five days later they received either control surgery or 1-mA/15-sec anodal lesions of rPRh or the rostral central nucleus of the amygdala (rACe). Two weeks later latency to drink without further FS was assessed in the testing chamber. They were allowed to drink for 30 sec. Rats not returning to drink within 5 min were given another session the next day. All rats were given two additional, daily sessions of 1-min cumulative drinking and then tested for reacquisition of dPA.

When tested two weeks after surgery, the 8 control rats took at least 168 sec to drink (Max = 788, M±SE = 373±90). All 9 rPRh rats drank in less than 95 sec (Min = 34, M±SE = 61±7). The rACe group also returned sooner than the control group (Range 50 - 220, M±SE = 114±27). Despite the apparently greater retention of dPA by controls, they did not reacquire dPA with fewer FS trials (M±SE = 3.25±0.49) than the rPRh group (M±SE = 3.67±0.24). The rACe group exhibited a major deficit in dPA by requiring 32.0±3.6 FS to avoid for 5 min.

In reacquisition, the rPRh rats actively avoided the spout after the 1st FS (3 rats) or 2nd FS (the other 6) and they exhibited approach/avoidance of the spout on that trial (6 rats) or after one more FS (the other 3). The lesions appeared to alter the "state" in which memory of the punishment contingency was being retrieved.

760.11

AMYGDALA $GABA_A$ RECEPTORS MODULATE RETENTION OF CHANGES IN REWARD MAGNITUDE. J.A. Salinas* & J.L. McGaugh. Center for the Neurobio. of Learning & Memory and Dept. of Psychobio., U. of Calif., Irvine, CA 92717-3800.

We have previously shown that post-training amygdala inactivation impairs memory for reward reduction. In the present study we infused a $GABA_A$ agonist (muscimol, MUS) or antagonist (bicuculline methiodide, BMI) into the amygdala immediately after a reward shift. Rats with bilateral amygdala cannulae were trained to run a straight alley for a large or small food reward. In Experiment 1 rats in the large-reward group were shifted to the small reward and received an infusion of vehicle or MUS bilaterally into the amygdala immediately after. Shifted vehicle animals displayed an increase in runway latencies compared to unshifted controls. In contrast, shifted MUS animals displayed latencies comparable to unshifted animals by the second postshift day. These findings suggest that muscimol attenuated the memory of the reward reduction. In Experiment 2 rats were trained as before except they received BMI immediately after reward reduction. Shifted BMI animals displayed elevated runway latencies compared to shifted vehicle animals by the second postshift day. These findings suggest that BMI enhanced memory of the reward reduction. In Experiment 3, animals were trained as before except they first experienced a reward increase before receiving post-training injections of vehicle, MUS or BMI. On the next day the reward was reduced. Despite reward reduction, shifted BMI animals persisted displaying low latencies for more trials than shifted MUS animals. These findings suggest that BMI enhanced memory for the reward increase. Further, the findings suggest that the amygdala and its GABAergic system is involved in memory consolidation for both positive and negative affective experiences.

760.12

BASOLATERAL AMYGDALA LESIONS BLOCK GLUCOCORTICOID-INDUCED MODULATION OF MEMORY FOR SPATIAL LEARNING. B. Roozendaal*, G. Portillo-Marquez and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Dept. of Psychobiology, Univ. of California, Irvine CA 92717-3800.

This study examined the involvement of the amygdala in the effects of glucocorticoids on the formation of memory for spatial learning in a water maze. Male Spraque-Dawley rats were given five training trials of spatial orientation learning in a water maze, and retention was tested 48 h later. Removal of the adrenal glands (adrenalectomy; ADX) 4-5 days prior to training significantly impaired memory for this task, and immediate posttraining systemic (s.c.) injections of dexamethasone (0.3 mg/kg), a potent synthetic glucocorticoid, attenuated the memory impairment. In contrast, injections of corticosterone (0.3 mg/kg) were ineffective. Neurochemically-induced lesions of the basolateral (BLA), but not of the central (CEA) or medial (MEA) nucleus of the amygdala blocked the modulatory effects of short-term ADX and dexamethasone administration on spatial memory. These findings are consistent with previous evidence that the dexamethasone-induced enhancement of memory for inhibitory avoidance training was also selectively blocked by lesions of the BLA. ADX also impaired acquisition performance in the water maze. Lesions of the CEA, MEA, as well as lesions of the BLA, appeared to block the impairing effects of ADX on acquisition performance in the water maze. Acquisition and retention performance were not significantly affected by BLA lesions in otherwise untreated animals. In contrast, lesions of the CEA resulted in both deficient acquisition and retention performances, and lesions of the MEA resulted in an impaired retention. These experiments further provide evidence that the BLA is a critical area involved in integrating hormonal influences on learning and memory.

STRIA TERMINALIS LESIONS DO NOT BLOCK BENZODIAZEPINE-INDUCED ANTEROGRADE AMNESIA. O. Carmi* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Department of Psychobiology, University of California, Irvine, CA 92717-3800.

Extensive evidence indicates that benzodiazepines (BZ) induce anterograde amnesia when administered systemically or directly into the amygdala before training. Furthermore, lesions of the amygdala block the BZ-induced anterograde amnesia. The stria terminalis (ST) is a major input/output pathway of the amygdala. ST lesions, similar to amygdala lesions, have been shown to block the memory enhancement produced by hormonal and neurotransmitters systems, including adrenergic, cholinergic, opioid peptidergic and glucocorticoid systems. Such findings imply that ST lesions should also block BZ effects on memory. The present study examined this hypothesis in experiments using two tasks, inhibitory avoidance and spatial orientation water maze tasks. Bilateral ST lesions were produced by radio-frequency current in male Sprague-Dawley rats and one week later, ten minutes prior to inhibitory avoidance training (0.45mA, 1s), rats received injections of saline or the BZ agonist midazolam (MDL, 1 mg/kg, i.p.). On a 48-h retention test, the retention latencies of MDL-treated rats were lower than those of saline-treated rats. This BZ-induced retention impairment was not blocked by ST lesions. For the water maze experiment, rats pretreated with MDL, received five training trials to find the hidden platform. The MDL impaired acquisition. Furthermore, this BZ-induced acquisition effect was not blocked by ST lesions. On a 48-h retention test, MDL-treated rats were still impaired relative to their control group. These data suggest that the BZ-induced memory effects are not dependent upon intact ST. These data conflict with those of many previous studies examining drug effects on learning and memory on animals with ST lesions. A possible explanation for this discrepancy is that BZ-induced amnesia is may be due to an impairment in acquisition rather than modulation of memory storage.

LARGE UNILATERAL LESIONS OF THE AMYGDALA AND MEDIAL PREFRONTAL CORTEX ON OPPOSITE SIDES OF THE BRAIN DO NOT PREVENT ACQUISITION OF CONDITIONED BRADYCARDIA. Mark Chachich*, D.A. Powell, James Penney, Saera Saleem & Mike Kaczmarek. VA Medical Center and University of South Carolina, Columbia, SC 29208.

We reported at last year's meeting that unilateral lesions of the central nucleus of the amygdala (ACN) and medial prefrontal cortex (mPFC) on opposite sides of the brain diminished but did not prevent acquisition of conditioned bradycardia. These data seemed to suggest separate and parallel control of conditioned bradycardia by the amygdala and mPFC. However, connections between mPFC and the amygdala originate not in the ACN (except for its most ventral aspects) but in the basolateral (BL) and lateral (L) nuclei. Thus, in the present experiment unilateral lesions were made on opposite sides of the brain centered on the mPFC and the BL and L nuclei of the amygdala. One session of differential heart rate (HR) conditioning was administered, in which tones served as CSs and paraorbital shock served as USs. Although large bilateral lesions of the amygdala completely abolished conditioned bradycardia, unilateral lesions of the mPFC and amygdala on opposite sides of the brain again diminished but did not prevent occurrence of the decelerative HR conditioned response.

EXCITOTOXIC LESIONS IN THE BASOLATERAL AMYGDALA SELECTIVELY ABOLISH DELAYED CONDITIONED TASTE AVERSIONS IN RATS. M. Foy[1]*, S. Maren[2] and D. Mitchell[3]. [1]Dept. of Psychol., Loyola Marymount Univ., Los Angeles, CA 90045, [2]Dept. of Psychol., Univ. of California, Los Angeles, CA 90024, [3]Dept. of Psychol., Univ. of Southern California, Los Angeles, CA 90089.

The amygdala mediates a variety of associative and nonassociative learning processes, including conditioned taste aversions (CTAs) and taste neophobia. Previous research has shown that electrolytic lesions in the amygdala disrupt immediate CTAs in which illness immediately follows consumption of a novel solution, but that excitotoxic lesions do not. However, the effects of amygdala lesions on delayed CTAs in which illness follows consumption of a novel solution by several hours have not been investigated. Given that long delay learning is a salient characteristic of CTAs and theoretical assertions that delayed CTAs are mediated by nonassociative processes (Mitchell, Scott & Mitchell, 1977), we reasoned that delayed CTAs would be especially susceptible to amygdala damage. Accordingly, excitotoxic lesions were made in the basolateral amygdala of pentobarbital-anesthetized male rats using *N*-methyl-D-aspartate; control rats received sham surgery with no drug infusion. One week following recovery from surgery, half of the rats from each group were made ill with LiCl injections administered either immediately or 4 hours after consumption of a novel saccharin solution. Neophobia controls were surgically treated as above, but received no saccharin or LiCl treatment. All groups were subsequently administered a two-bottle preference test (water vs. saccharin) during a 20 day period. The results showed that basolateral amygdala lesions blocked both taste neophobia and delayed CTAs, but had no effect on immediate CTAs. These data demonstrate that taste neophobia and delayed CTAs share a common nonassociative process that requires neurons in the basolateral amygdala, and support the theory that immediate and delayed CTAs are differentially mediated by associative and nonassociative learning processes.

INVOLVEMENT OF THE PERIAQUEDUCTAL GRAY IN FEAR-POTENTIATED STARTLE. **D.L. Walker* and M. Davis. Dept. of Psychiatry, Yale University Sch. of Med., New Haven, CT 06508.**

The acoustic startle response is reliably enhanced when elicited in the presence of a cue previously paired with moderately intense footshock (i.e., fear-potentiated startle). Interestingly, training with higher intensity footshocks produces relatively poor potentiated-startle. Because recent evidence suggests that particularly aversive stimuli may activate the dorsolateral periaqueductal gray (dl-PAG) and that behaviors associated with dl-PAG activation may be incompatible with startle, we hypothesized that stimuli paired with high-intensity footshock might also activate this system and interfere with the expression of fear-potentiated startle. To test this hypothesis, two experiments were conducted.

In Experiment I, rats received 30 light-shock pairings using either moderate (0.6 mA) or high (1.6 mA) footshocks, followed by excitotoxic lesions of the dl-PAG or sham lesions. When trained at 0.6 mA, fear-potentiated startle was comparable in both sham and lesioned animals. When trained at 1.6 mA, however, potentiated startle was reliable only in lesioned rats. Baseline startle was unaffected. In Experiment II, rats trained at 0.6 mA were tested immediately after intra-PAG infusion of either distilled water or an excitatory non-toxic dose of kainic acid. Kainic acid infusions significantly disrupted fear-potentiated startle but did not affect baseline startle.

Together, these results suggest that the dl-PAG may be activated by stimuli associated with particularly aversive events and that this activation may interfere with the expression of fear-potentiated startle.

760.17

THE EFFECTS OF OLFACTORY BULBECTOMY ON THE ACOUSTIC STARTLE REFLEX AND ITS MODULATION BY STRESS. K.A. McNish* and M. Davis. Depts. of Psychiatry and Psychology, Yale Univ. Sch. of Med., New Haven, CT 06508.

The effects of olfactory bulbectomy on the acoustic startle reflex, fear-potentiated startle, and shock-induced sensitization of the acoustic startle reflex were examined in a series of three experiments. In Experiment 1, bilateral olfactory bulbectomy resulted in an increase in the acoustically elicited startle reflex relative to sham operated controls. The increase in baseline startle was persistent for up to five weeks following the lesion. Bulbectomized animals showed normal acquisition of fear-potentiated startle but enhanced context conditioning relative to sham operated controls. In Experiment 2, olfactory bulbectomy resulted in an increased sensitivity to footshock-induced sensitization (0.6 mA and 1.0 mA) of the acoustic startle reflex relative to sham and unoperated controls. In Experiment 3, bulbectomized animals showed shock sensitization to a shock level (0.3 mA) which did not produce sensitization in sham and unoperated controls. Taken together, these data suggest that olfactory bulbectomy results in an increased vulnerability to stressors, perhaps because of a disinhibition of the amygdala. Thus, the olfactory bulbectomy model of depression may share some similarities with other stress-induced models of depression.

MEDIAL PREFRONTAL CORTEX (mPFC) LESIONS FOLLOWING FEAR CONDITIONING DO NOT RETARD EXTINCTION OF THE FEAR-POTENTIATED STARTLE RESPONSE. J.C. Gewirtz* & M. Davis, Depts. of Psychiatry and Psychology, Yale University Sch. of Med., New Haven, CT 06508.

Although the neural systems involved in fear conditioning are relatively well elucidated, much less is known about the neural systems involved in extinction of conditioned fear. Recently, it was shown that mPFC lesions made before acquisition of conditioned fear retarded subsequent extinction of conditioned freezing (Morgan, Romanski & LeDoux, 1993). The present study examined the effects of lesions of mPFC on extinction of another conditioned response, fear-potentiated startle, when the lesions were made after acquisition of conditioned fear.

In each of 12 acquisition sessions, rats were given two presentations of a 3.7-s light CS which terminated with a 0.5-s, 0.6-mA footshock US. To assess fear-potentiated startle, each session also included presentations of a 50-ms, 95-dB startle-eliciting stimulus alone, and of the same stimulus in the presence of the visual CS. Rats showed a gradual increase in startle to the startle-eliciting stimulus alone (contextual conditioning) and an additional gradual increase in startle to the same stimulus presented in the presence of the light (explicit cue conditioning). On the basis of their terminal levels of fear-potentiated startle, rats were matched into two groups. One group received electrolytic lesions of mPFC (n=24) and the other group received sham lesions (n=20). Both groups received 18 extinction sessions, starting one week after surgery. These were identical to acquisition sessions, except that the US was no longer presented. Both groups showed gradual extinction of fear-potentiated startle to the explicit cue and to the experimental context. In addition, they showed equivalent "reinstatement" of fear-potentiated startle when retested one day after receiving 5 presentations of the US alone. Hence, under these conditions, lesions of the mPFC did not have any effect on extinction or reinstatement of conditioned fear.

Experiments are currently under way to evaluate the degree to which the role of the mPFC in extinction depends upon the level of initial excitatory conditioning, the modality of the CS, the nature of the conditioned response, and when lesions are made relative to the time of excitatory conditioning.

760.19

LESIONS OF THE PERIRHINAL CORTEX BLOCK CONDITIONED EXCITATION BUT NOT CONDITIONED INHIBITION OF FEAR MEASURED WITH FEAR-POTENTIATED STARTLE. W.A. Falls* , K. Bakken, S. Webster & M. Davis, Dept. Psychology, Northern Illinois University, DeKalb, IL 60115 and Dept. of Psychiatry, Yale Univ., Med. Sch., New Haven, CT 06508.

Although much is known about the neural systems responsible for the acquisition and expression of conditioned fear, little is known about the neural systems responsible for the inhibition of fear. Following a conditioned inhibition procedure in which a light is repeatedly paired with shock (i.e., light+) and a light-noise compound is presented without shock (i.e., noise→light-), the noise acquires the ability to inhibit fear-potentiated startle to the light in a noise→light summation test (Falls & Davis, 1993; *Neurosci. Abs.* vol. 19, p.372, #155.6).

Perirhinal cortex lesions performed after light+shock training block fear-potentiated startle. However, fear-potentiated startle to the light can be re-acquired. Because of this, it is possible to use a summation test to assess whether lesions of the perirhinal cortex will disrupt previously acquired conditioned inhibition. Rats were given 15 light+shock pairings on each of 2 days followed by conditioned inhibition training consisting of 5 light+ trials intermixed with 15 noise→light- trials on each of 5 days. Testing occurred 1 day later. All rats showed conditioned fear to the light as defined by greater startle amplitude in the presence of the light than in its absence. All rats showed conditioned inhibition of fear, defined as a reduction in fear-potentiated startle to the light when accompanied by the noise. Next, half of the rats were given perirhinal cortex lesions and half were sham operated. All rats were tested 1 week later. As expected, lesions of the perirhinal cortex blocked fear-potentiated startle to the light. On each of the next 5 days, the rats were retrained with light+ trials with no further conditioned inhibition training. Testing occurred 1 day later. Perirhinal cortex lesioned rats re-acquired fear-potentiated startle to the light. Importantly, the noise conditioned inhibitor retained its ability to inhibit fear-potentiated startle to the retrained light.

Although the perirhinal cortex is critical for initial performance of fear-potentiated startle, it is not critical for the expression of conditioned inhibition. We have reported that lesions of the central nucleus of the amygdala also fail to prevent the expression of conditioned inhibition to a retrained light (Falls & Davis, *Behav. Neurosci*, 109(3), 379-387). Hence, inhibition of fear-potentiated startle is likely to occur elsewhere in the fear-potentiated startle pathway.

760.20

THE EFFECTS OF EXCITOTOXIC LESIONS OF PIRIFORM CORTEX, ENTORHINAL CORTEX, AND MEDIAL THALAMUS ON CONTINUOUS OLFACTORY NON-MATCHING TO SAMPLE (CONMTS) AND DISCRIMINATION Y.P. Zhang* and , R. G. Mair. Dept. of Psychology, Univ. of New Hampshire, Durham, NH 03824.

Forty-eight male rats were pre-trained on a go/ no-go CONMTS task. Rats were matched for performance and randomly assigned to one of the following treatment groups (N=8 in each group); excitotoxic lesions of piriform cortex (PIR), entorhinal cortex (ENT), lateral internal medullary lamina of thalamus (LIML), medial dorsal nucleus of thalamus (MDn), nonspecific nuclei of thalamus (NONS), and sham controls (CON). After recovery from surgery, the rats were retrained on CONMTS and then on a go/no go discrimination trained with procedures matched to CONMTS.

Initial analyses indicate that only the PIR and LIML groups were significantly impaired on CONMTS. The ENT and MDn groups showed transient impairments like those found in an earlier study for frontal cortical lesions. All groups learned the discrimination task a normal rates. These results are consistent with the hypothesis that olfactory pathways beyond piriform cortex are necessary for olfactory memory, but not discrimination.

LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS XII

761.1

Disinhibition of reinforcing brain stimulation following lesions in the region of the tuberomammillary nucleus and the CA1 region of the hippocampus

Wagner, U., Zimmermann, P. and Huston, J.P., Institute of Physiological Psychology, University of Düsseldorf, 40225 Düsseldorf, Germany (EBBS)

The subnuclei of the tuberomammillary nucleus (TM) are located in the posterior part of the hypothalamus.The neurons of this nucleus innervate extensive parts of the brain with several transmitters and they represent the only source of histaminergic projections in the brain. Studies are presented dealing with lateral hypothalamic self-stimulation behavior in rats following unilateral lesions in this region and in the hippocampus, which has been described as the only ipsilateral projection area of the TM.

A unilateral electrolytic lesion of the TM led to an ipsilateral increase in self-stimulation behavior beginning with the first post-lesion day. Response rates continued to rise for two weeks post-lesion. In a follow-up study the effects on self-stimulation were replicated by lesioning the TM with ibotenic acid, indicating that the observed disinhibitory effects in both experiments are based on the destruction of intrinsic cells and not on fibers passing through the lesioned area. A projection area possibly involved in the observed lateralized amplification of brain stimulation reward is the CA1 region of the hippocampus. Following a unilateral ibotenic acid lesion in this structure we observed an increase in bar pressing on the contralateral side of the lesion. The lesion did not result in a greater resistence to extinction; thus, it is likely that the increase in response rates can be interpreted in terms of an amplification of the rewarding value of brain stimulation and not in terms of a response perseveration which has been described as a result of hippocampal ablation.

Our results suggest that the TM together with the hippocampus exerts an inhibitory control over lateral hypothalamic self-stimulation. These results are the first to focus on an inhibitory element in the neural substrate of reinforcement.

761.2

MEMORY ENHANCING EFFECTS OF IBOTENIC ACID LESIONS OF THE TUBEROMAMMILLARY NUCLEUS AND EFFECTS ON BRAIN HISTAMINE. J.P. Huston[1]*, Ch. Frisch[1], H.W.M. Steinbusch[2], R.U. Hasenöhrl[1]. European Graduate School for Neuroscience i.f. 'Brain and Behavior'. [1]Inst. Physiol. Psychology, Univ. Düsseldorf, FRG.; [2]Dept. Psychiatry and Neuropsychol., Univ. Limburg, Maastricht, The Netherlands.

The tuberomammillary nuclei (TM) are located in the posterior part of the hypothalamus and provide the main source of neural histamine (HA) in the brain. Our experiments performed with bilateral lesions of the TM region revealed a role of the TM system in learning and memory processes. These lesions facilitated inhibitory avoidance performance and improved long-term retention in a spatial discrimination test in both adult and aged rats. However, since dc-lesions were performed, it was not possible to point at the TM neurons as responsible for the observed effects on learning and memory. Thus, the objectives of a follow-up study were two-fold. In order to determine whether the facilitation of learning was due to the destruction of intrinsic TM neurons a bilateral ibotenic acid lesion of the TM was performed and the rats were tested along with sham-lesioned controls on different versions of the Morris water maze task. In order to determine whether the behavioral effects revealed upon destruction of the TM neurons involve histaminergic mechanisms concentrations of HA and HDC were determined in different brain regions using immunohistochemical methods. The main finding of this study was that rats with neurotoxic lesions of the TM showed an accelerated acquisition rate in the course of place learning and an improved ability to locate the platform site during a spatial probe trial. Furthermore, following destruction of the TM region changes in HA and HDC concentrations were observed in several brain regions, including the site of lesion in the TM, basal forebrain nuclei and hippocampus. These results indicate that the facilitatory effects on learning following TM lesion are based on the destruction of intrinsic TM neurons and suggest that this facilitation may be related to the function of the histamine system.

761.3

SELECTIVITY OF SPATIAL LEARNING IMPAIRMENT IN RATS WITH LESIONS OF THE MAMMILLARY REGION V. Sziklas*, M. Petrides, and P. Jackson. McGill University, Montreal, Quebec, Canada

Rats with lesions of the mammillary region (MB-R), the dorsal hippocampus (H), or a control operation (OC) were trained on a spatial conditional associative learning task in which they had to learn to respond to one of two visual stimuli depending on their location in an open field. In a second study, rats with similar lesions were trained on a place learning task which required them to locate a hidden platform in a pool of opaque water. Rats with damage to the MB-R were able to acquire the conditional associative task at a rate comparable to that of the OC animals. The H group was significantly impaired in comparison with both the MB-R and the OC groups. By contrast, both the MB-R and the H animals were slower to acquire the location of the hidden platform in comparison with the OC group. Taken together with earlier findings from our laboratory, the present results suggest that damage to the MB-R impairs the ability to learn and remember the location of spatial cues but does not affect the capacity to discriminate between particular visual stimuli, depending on the location within which they are embedded.

761.4

ASSESSING THE CONTRIBUTIONS OF DIFFERENT ANTERIOR THALAMIC NUCLEI TO SPATIAL MEMORY J.P. Aggleton*, S. Nagle, N. Neave and P. Hunt. School of Psychology, University of Wales, Cardiff, CF1 3YG .

Rats were prepared with neurotoxic lesions centred in either the anterior medial (AM, n= 8) or the anterior ventral (AV, n=8) thalamic nuclei. These were compared with a further group of rats with neurotoxic lesions in both nuclei (AM+AV, n=7) and a group of surgical controls (SHAM, n=11). The lesions were produced by injecting N methyl-d-aspartate acid (0.12M). Following recovery from surgery the rats received 16 sessions (6 trials/session) of a food rewarded forced-alternation task in a T-maze. The AM+AV group were severely impaired throughout this training, but the AM and the AV groups displayed equivalent, mild impairments. The AM and AV groups were able to match the SHAM animals by the end of training. A series of sessions using a cross-shaped maze then confirmed that the SHAM, AV, and AM animals were able to use allocentric cues. The four groups were then tested in the cross-maze on an egocentric discrimination and single reversal (always turn in one direction, then after reaching criterion always turn the other way). None of the groups were impaired, the AM+AV animals showing a slight advantage. Finally, the animals were tested on the radial arm maze, where only the AM+AV group showed a clear impairment. The results help to confirm the importance of these nuclei for allocentric memory tasks, but indicate that neither nucleus is pre-eminently important.

761.5

AUDITORY DELAYED RESPONSE TASK DEFICITS FOLLOWING MEDIAL THALAMIC AND PREFRONTAL CORTICAL LESIONS IN THE RAT. A.A. Stevens, R. G. Mair*. Dept. of Psychology, Univ. of New Hampshire, Durham, NH 03824.

To study auditory memory in a rodent model of Korsakoff's syndrome, 24 male rats were pre-trained on an auditory conditional discrimination task which required the rat to respond to one location following a 3 kHz tone and a second location following an 11 kHz tone. Retention intervals (RI) were imposed by blocking access to the response locations with a gate. Treatments included sham control (CON, n=8) and lesions of medial wall of frontal cortex (MW, n=8) or the lateral internal medullary lamina of thalamus (LIML, n=8). Throughout extensive post-surgical training, the LIML group showed a chronic and significant deficit even when the tones remained on until a response was made. The MW group also performed worse than the CON group when no RI was instituted but not significantly so. Both lesion groups also performed poorly across retention intervals from 0 - 6.4 sec, although there was no evidence of abnormally rapid forgetting. These results suggest that medial thalamic and frontal cortical lesions can produce a conditional discrimination deficit even when there is no memory requirement. Because the LIML group was also impaired on a simple auditory discrimination, it is not certain whether this deficit is the result of an impaired ability to discriminate pure tone stimuli.

761.6

VALIDATING THE DIRECT METHOD FOR MEASURING THE SUBJECTIVE MAGNITUDE OF BRAIN STIMULATION REWARD. M. I. Leon* & C. R. Gallistel. Dept. of Psychology, UCLA, Los Angeles, CA 90095-1563.

The direct method for scaling subjective reward magnitude as a function of stimulation strength uses a two-lever choice paradigm with concurrent variable interval schedules of reward. The rat allocates its time between a "standard" lever delivering rewards of fixed magnitude, and an "alternate" lever delivering rewards that vary in magnitude over trials. The validity of the procedure rests on the assumption that subjective reward magnitudes and relative rates of reward combine multiplicatively to determine time allocation. If this assumption is correct, a rat will equiprefer a particular reward being delivered every ten seconds to a reward half that size being delivered every five seconds. This experiment was designed to test this assumption. The results in self-stimulating rats (male Sprague-Dawley) with electrodes in the lateral hypothalamus and VTA suggest that subjective reward magnitude and rate of reward combine multiplicatively when the net value of either lever does not cause the rat's time allocation between levers to differ by more than approximately 6:1. When the ratio of time distributions surpasses this limit, the necessary assumption for scaling subjective reward appears to break down. This suggests that the optimal procedure for scaling reward is to program the standard lever to deliver rewards one quarter as often as the alternate lever, and to set the reward on the standard to its maximal level. The effect of this is to prevent the net value of either lever from becoming so great that the animal's time allocation ratio differs by more than 6 to 1.

761.7

A NOVEL TWO-TRIAL MEMORY TASK WITH AUTOMATED RECORDING. INFLUENCE OF INTER-TRIAL INTERVAL INTERFERENCES AND ENVIRONMENTAL CONTEXT ON PLACE OR OBJECT RECOGNITION. F. Dellu, W. Mayo, M.P. Mano, M. Vallée, J.J. Bouyer, M. Le Moal and H. Simon*. Lab. de Psychobiologie des Comportements Adaptatifs, INSERM U.259, 33077 Bordeaux Cedex, France.

A two-trial memory task, based on place or object exploration in a Y-maze, was developed to study memory in adult and aged rats (Dellu et al., Brain Res., 588, 1992). This paradigm avoids the use of electric shocks or deprivation that may have non-specific effects, and the task does not require learning of a rule. A number of behavioral parameters in several animals could be recorded automatically.

Recognition is differently influenced both by the type of information (place vs. object) and by the inter-trial interval (recognition retention time). For place exploration, recognition was still present at the 6h inter-trial interval whereas recognition in object exploration only appeared to last for about 4h in 2-month-old rats. Memory recognition in old rats (18 months) was clearly affected by increasing the retention time. Recognition also depends on the environmental context as demonstrated by the following results : 1) place recognition remains intact in spite of an interferent exploration (one trial in another Y-maze situated in another environment) between the acquisition and the retrieval trials and 2) object recognition is impaired when the environmental context is changed between the two trials.

This is of particular interest in the light of the dual mechanism suggested to be involved in recognition i.e. determination of stimulus familiarity and stimulus identification which involves retrieval of relevant contextual information processing. It is also noteworthy that contextual information processing alterations are at the heart of age-related cognitive deficits. In conclusion this memory task combines simplicity, rapidity, sensitivity and high specificity and should be useful to neuro- and psychopharmacologists.

761.8

SAME-SESSION ANALYSIS OF WORKING AND REFERENCE MEMORY IN THE RAT: PROCEDURE. W. J. Wilson*, S. A. Bradtmiller, M. L. Felton, G. D. Lyons, L. A. Shaffer, & A. S. Zieles. Dept. of Psychological Sciences, Indiana-Purdue University, Fort Wayne, IN 46805 USA.

Eight female Sprague-Dawley rats were trained successively in two different behavioral tasks: spatial alternation and visual discrimination in a phi-maze. In spatial alternation rats were rewarded for choosing the arm not used on the previous trial. In visual discrimination rats were rewarded for selecting the lighted arm, the position of which varied randomly. Rats next experienced these two tasks on alternate days, then combined in the same session, yielding a behavioral session requiring the use of both reference (visual discrimination) and working (spatial alternation) memory. In this phase in which both tasks were employed, the rat was rewarded first for selecting the lighted arm of the maze, then for selecting the opposite arm, and so on. Thus the contingency in effect changed following each reinforcer. Each daily session lasted until the rat received 41 reinforcers (an initial free reinforcer, and 40 earned via the selection of the appropriate arm of the maze).

Rats acquired the spatial alternation task more readily than they did the visual discrimination task (means: 8.88 vs 13.00 sessions to reach the criterion of 3 successive sessions completed in fewer than 50 trials; $p < .01$), probably reflecting both the tendency to alternate spontaneously, and an initial bias to select the dark arm of the maze in the visual task. When both tasks were combined, rats performed equally well on the working and reference memory tasks in Sessions 1 - 5 (means: 23.33 [working] vs 22.63 [reference] trials to receive 20 reinforcers). Performance on the reference memory task decreased significantly by Sessions 11 - 15 (working: 22.17 vs reference: 25.23 trials, $p < .01$). This procedure will serve in future studies examining the effects of amnestic or nootropic drugs.

TRANSFER OF TEMPORAL DISCRIMINATION TRAINING. S.P. Clarke, R.B. Ivry, S. Roberts*, and N. Shimizu. Dept. of Psychology, University of California, Berkeley, CA 94720.

If separable neural systems exist for the perception and discrimination of different temporal intervals, then experience with one task involving discrimination between stimuli of short duration should have no effect on rate of learning upon transfer to a task requiring discrimination between stimuli of longer duration, and vice-versa. Rates of learning will be assessed for rats trained on temporal discrimination tasks in a standard operant chamber. In the first experiment, rats will be trained to discriminate between white noise stimuli in either a short range (SR; 200 vs. 800 msec) or long range (LR; 20 vs. 80 sec). A sucrose pellet is delivered for a press on one lever corresponding to the shorter stimulus in each task (200 msec or 20 sec) or for a response on the other lever for the long stimulus (800 msec or 80 sec). After training to asymptote, the two groups (SR and LR) will then be trained to asymptote on the opposite task (LR and SR) with lever mapping reversed for half of each group. If separable neural systems mediate the learning of the SR and LR tasks, then the rates of learning for all mapping groups should be the same, indicating that experience with SR timing had no effect on learning a discrimination involving LR timing, and vice-versa. The second experiment will be identical to the first, except that the groups will transferred to a medium range (MR; 2 vs. 8 sec) discrimination task. If the SR cerebellar mediated timing system is limited to perception in the milliseconds range, as our human and animal data suggest, then there should be no difference in rate of learning for the two mapping groups of rats shifted from SR to MR. Facilitation would be expected in rats shifted from LR to MR with the same mapping if a LR timing system, responsible for learning in the seconds-to-minutes range, is involved in both tasks.

761.10

HOW RATS ARE TRANSPORTED TO THE MAZE DETERMINES SUCCESS OR FAILURE OF SPATIAL PROBLEM SOLVING: ENVIRONMENTAL CUES ARE NOT SUFFICIENT TO SUPPORT SPATIAL LEARNING. G.M. Martin, C.W. Harley*, A.R. Smith, E.S. Hoyles, and C.S. Rideout. Psychology Dept., Memorial University, St. John's, NF A1B 3X9

Theories of spatial learning suggest rats possess a map based on distal environmental cues and/or environmental shape. These theories attribute spatial learning to environmental information during maze training and not to events which precede the animal's placement in the training situation.

In the present experiment two procedures were used to bring rats to a four arm elevated maze on which food was in a constant spatial location. Rats in the normal procedure were brought into the training room in their home cage and placed on a storage rack. Rats were carried from the home cage and placed on the maze on each of eight trials. Rats were returned to the home cage after a correct choice or 60 secs.

Rats in the second procedure were placed in closed metal containers, rotated six to ten times over a 60 second period and then brought into the training room and placed on the storage rack. Rats were carried in the containers to the maze, removed and placed on the maze. At the end of each trial rats were replaced in the container, returned to the storage rack and rotated. Two minutes or more intervened between rotation and subsequent maze placement. Criterion was 9 out of 10 correct.

Rats trained with the normal home cage procedure readily solved the maze problem. Rats trained with the closed metal container procedure did not solve the problem.

These data show environmental information is not sufficient to ensure learning. Rats may need to be oriented in order to construct a single spatial representation of a new environment. Hence, multiple representations or map failure could account for impaired performance. Alternatively rats may encode location by dead reckoning, not distal cues. Dead reckoning could be disrupted by the closed container experience.

761.11

THE INVOLVEMENT OF PASSIVE PATH INTEGRATION IN LEARNING THE MORRIS WATER MAZE. S.H. Alyan,^ D.S. Touretzky^* and J.S. Taube,+ Dept. of Computer Science, Carnegie Mellon University, Pittsburgh, PA 15213^ and Dept. of Psychology, Dartmouth College, Hanover, NH 03755.+

Many previous studies have used the Morris water maze as a tool to investigate the cognitive mechanisms underlying successful navigation (e.g., Morris et al., 1982; Sutherland et al., 1987; Keith & McVety, 1988; Whishaw, 1991). Although some of these studies have questioned the extent to which rats rely solely on the learned relationships between various landmarks in solving the task, none of them have explicitly examined the role path integration plays in learning to locate the platform. Path integration is the ability to compute a trajectory by integrating past passive or active displacements. The present study was designed to determine the effect of degrading passive path integration as the animal learned the water maze.

Four groups of 6 Long-evans male rats underwent training in a 1.9 m diameter water tank containing a partially submerged hidden platform. The rats were transported from their cages to the tank, either on a wooden board in a straight path (Groups 1 & 3) or in a black box in a circuitous path (Groups 2 & 4). Groups 1 & 2 were left on the platform for 30 sec each time before being released into the tank. Groups 3 & 4 were given a total of 17 min placement on the platform before the training began, and no placement on the platform before releasing them into the tank. Latency time to arrive at the platform, percent time spent and number of entries into an annulus zone surrounding the platform were recorded to assess the rats' performance. The rats that underwent a disorientation procedure (Groups 2 & 4) scored significantly lower on all three measures than rats not subjected to disorientation (Groups 1 & 3).

The results suggest that in the water maze, rats navigate by employing a variety of mechanisms simultaneously, including integrating their passive transportation from one location to another. It is not clear how, or how much, each mechanism contributes to successful navigation, but attention should be given to the procedures used in transporting the animal from its home cage to the tank, especially when using this paradigm to test for the functional integrity of underlying spatial mechanisms.

761.12

MORRIS WATER TASK: WHICH CUES DEFINE LOCATIONS? M.P. Weisend*, R.L. Klein, J. M. Hoesing, R.S. Astur, A. Koerner, R.J. McDonald, T. Geving, J. Peinado, J. Biela, J. McWhorter, M. Weems, J. Schlegelmilch, R. Yeo, R.J. Sutherland Dept. of Psychol., Univ. of New Mexico, Albuquerque, NM 87131.

We posed two questions: 1) Do rats swim to locations defined by direction and distance to extrapool cues or pool geometry plus compass direction? and 2) Does the blocking phenomenon occur in place learning? In experiment 1, male and female rats were trained to navigate to a hidden platform at cardinal north about 6 inches from the pool wall. Males received 20 training trials and females 24, two other groups, one of each sex, received 80 training trials. All groups reached asymptotic performance by the end of training. A no-platform probe trial was then conducted. On this probe the pool was rotated 225° with the axis at the hidden platform location (i.e. the pool was moved relative to the room). Male rats with 20 trials searched for the platform in the northern region of the pool, not in the location defined by extrapool cues. In contrast, male rats with 80 trials searched the location defined by extrapool cues, not the north. Female rats with 24 trials searched in the north and the location relative to room cues equally. Females with 80 trials searched in the north. The second study examined the phenomenon of blocking for cues used in place navigation. One group of animals was trained to navigate to a hidden platform with cue set A, then cue sets A and B. The second group was trained with A and B only. On a no-platform probe trial conducted with cue set B only, rats trained with cue sets AB alone performed significantly better than rats trained on A then AB. When further training was conducted with cue set B, only animals trained on A then AB showed a significant increase in escape latency. We conclude that male rats can navigate based on compass direction and pool geometry or direction and distance from extrapool cues depending on training. Female rats seem to use only compass direction and pool geometry under these conditions. In addition, the blocking phenomenon can be demonstrated for cues in a place navigation task.

761.13

LANDMARK-BASED NAVIGATION IN GERBILS SUPPORTS VECTOR VOTING. **L.M. Saksida*, A.D. Redish, C. Reiber Milberg†, S.J. Gaulin†, and D.S. Touretzky.** **School of Computer Science, Carnegie Mellon University, Pittsburgh PA 15213. †Department of Anthropology, University of Pittsburgh, Pittsburgh PA 15261.**

Vector voting and vector averaging are competing hypotheses about how animals use landmarks to reach a goal. A related issue is how cues from multiple reference frames interact when the landmark array moves within a larger, stable environment.

Six male and six female gerbils were trained on a navigation task described by Collett, Cartwright, and Smith (*J. Comp. Physiol*, 1986). A sunflower seed was buried at the center of an equilateral triangle defined by three identical cylindrical landmarks. During training this landmark array was translated after every three trials, but never rotated.

Once the animals reached criterion, no-seed probe trials were intermixed with the training trials. The probe conditions were: (a) normal array, (b) one landmark removed, (c) two landmarks removed, (d) one landmark displaced to twice the normal distance from the goal, and (e) entire array rotated by 180°.

Cumulative 2D spatial histograms of search effort closely resembled those of Collett *et al.* except for the (c) probe, where our animals appeared confused. Performance on the (b), (d), and (e) probes was in agreement with the hypothesis that gerbils predict goal locations by tallying votes from individual landmarks, rather than vector averaging.

We developed two statistical measures to quantitatively analyze the animals' search behavior. Histograms from multiple trials are first aligned based on the landmark array, and searching behavior is allocated to discrete bins. Differences between groups of gerbils or trials are then determined by χ^2 tests. By examining the z-scores of specific bins, we can also demonstrate quantitatively the gerbils' preference for certain locations over others, allowing us to compare the predictions of competing hypotheses.

Probes (b)-(e) produced dramatically more exploration behavior than the (a) case, indicating the gerbils were aware of perturbations to the landmark array. The experiment also revealed that most probe results reported by Collett *et al.* can be obtained without any effort to eliminate stable room cues.

TWO DIFFERENT MODES OF INTEGRATION OF OLFACTORY AND VISUAL CUES IN SPATIAL ORIENTATION. P. Lavenex (1), P. Gisquet-Verrier*(2), F. Schenk (1). 1-Institute of Physiology, University of Lausanne, CH-1005 Lausanne; 2-NAM CNRS URA 1491, University of Paris Sud, F-91405 Orsay

The aim of this study was to solve the apparent paradox that although macrosmatic, rats orient preferentially relatively to visuospatial cues and ignore olfactory cues when they are in conflict with visuospatial cues. Rats were trained in an eight-arm radial maze with eight different supplementary olfactory cues, while the access to visuospatial cues was prevented. Training was conducted in darkness (infrared illumination), which precluded any visual stimulation, or in translucent tunnels, which restricted the access to visuospatial information but left the inside of the maze illuminated. Rats trained in darkness relied on the olfactory cues and reached maximal performance. In contrast, rats trained in translucent tunnels did not rely on the olfactory cues and their performance remained poor. Nevertheless, probe trials revealed that rats of both groups had memorised the location of the olfactory cues. A third condition, in which olfactory cues were replaced by intramaze visual cues in the translucent maze, revealed that visual but not olfactory cues allowed maximal efficiency in the translucent condition. Performance of rats trained in darkness when the olfactory cues were dissociated from the external spatial frame of reference revealed that the olfactory cues do not need to be linked to spatial information to allow maximal efficiency. When three of the arms contained the same olfactory cue, only the configuration of the olfactory cues allowed to solve the task. In this case, a good performance was observed on condition that these cues were stable relatively to the external spatial frame of reference. This reference could consist of a directional reference maintained by the integration of vestibular information. Together, these results show that olfactory cues are taken into account when they are coherent with spatial information, but do not allow accurate arms' choice when vision is allowed, even if no visuospatial cues are available. Olfactory cues do, however, allow accurate arms' choice in the absence of vision (darkness). This suggests an implicit use of the olfactory cues when vision is available and an explicit use of these cues in darkness.

SPATIAL ALTERNATION IS NOT FACILITATED BY TRANSECTION OF THE CORPUS CALLOSUM. D.P. Crowne* and S.P.C. Gray. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, CANADA N2L 3G1

In *The Psychology of Left and Right*, Corballis and Beale proposed that mutual sharing of mirror-image information by the cerebral hemispheres confounds the discrimination of left and right stimuli, so that an animal with intact and communicating hemispheres will learn mirror-image tasks more slowly than one with a divided brain. Discriminating mirrored left and right responses should be similarly affected. Noonan and Axelrod examined the latter, comparing splitbrain and intact rats on a conditional spatial discrimination. Their splitbrain animals were markedly better. Here, we studied another, more basic spatial problem that requires mirrored left and right responses: delayed spatial alternation. Splitbrain (n= 11) and control (n = 11) rats were trained on spatial alternation in a water T-maze similar to Noonan and Axelrod's and tested for 800 trials. The mean trials to criterion of controls was 449.09, of splitbrains 692.73, F (1, 18) = 9.74, p = .006. All controls learned; 7 splitbrains failed to learn. It appears that only some mirror-image spatial tasks are better performed by splitbrain animals, perhaps those involving a conditional cue. The more general effect of callosum section on spatial learning is a severe deficit, earlier shown on allocentric tasks and now on an egocentric one.

Thiamine Deficiency in 16 month old rats versus 3 month old rats: Behavioral and pathological differences. L.M. Savage*, R. Castillo, & P.J. Langlais. Department of Psychology, SUNY-Binghamton, San Diego State University, and VA Medical Center San Diego, 92161.

To examine age-dependent differences in the neuropathology and behavioral consequences of Pyrithiamine-Induced Thiamine Deficiency (PTD) a group of older rats (16 months) than those used in previous studies (3 months) were pre-trained on the Morris water maze, exposed to either a bout of PTD or Pair-fed (PF) control treatment, re-trained on the water maze, and then tested on an acoustic startle task. A standard bout of PTD produced a higher mortality rate (60%) in these older rats than previously observed in young rats (20%). Furthermore, after the reversal of PTD treatment, the older rats also took twice as long (4 versus 2 weeks) to regain weight lost during treatment, relative to young PTD treated rats. When re-tested on the Morris water maze, the older PTD rats had longer latencies to reach the platform compared to their last pre-training session or relative to the older PF rats on re-acquisition. This "retrograde loss" was not observed in a previous study using 3 month old PTD treated rats. There were no groups difference observed on the acoustic startle task. The neuropathology produced by PTD treatment in the older rats is different from what has been seen in young PTD-treated rats. Thus, the age at which a rat is exposed to PTD treatment appears to influence both the behavioral and pathological consequences.

EFFECTS OF NEONATAL OXYGEN DEPRIVATION ON DEVELOPMENT OF SPATIAL LEARNING IN RATS. R.E. Hartman* and C.R. Almli. Developmental Neuropsychobiology Lab., Dept. Psych., Washington University, St. Louis, MO 63108.

Human neonatal oxygen deprivation has been related to a wide range of developmental disabilities, including cerebral palsy, mental retardation and behavioral disorders. The present study determines the effects of neonatal oxygen deprivation on the development of spatial learning and memory in the albino rat. At postnatal ages (days) PN 0 to PN 7, pups were subjected to 3 consecutive periods of oxygen deprivation (gasping criteria) separated by 30-min in room air.

Beginning on PN 18, control and oxygen-deprived (OD) rats were tested in a Morris water maze for 10 consecutive days. Three conditions were tested: distal/spatial (invisible escape platform in a fixed location), proximal/cue (visible platform in a fixed location), and random (invisible platform placed in random locations). Each of the 10 testing days consisted of 12, 60-sec acquisition trials (the maze contained an escape platform), and a 60-sec retention trial (the maze did not contain an escape platform). For acquisition trials, latency to enter the maze quadrant containing the platform, and latency to find the platform, were recorded (maximum score = 60-sec). For the retention trials, latency to enter the quadrant that previously contained the platform, and total amount of time spent in that quadrant, were recorded (maximum score = 60-sec).

During acquisition trials, OD rats escaped the maze faster than control rats under the distal/spatial condition. During retention trials, however, control rats in the distal/spatial condition spent more time in the quadrant that previously contained the platform than did OD rats. It appears that neonatal oxygen deprivation may differentially affect acquisition and retention of spatial abilities. Acquisition escape latency may have been faster for OD rats via hyperactivity, whereas retention for the platform's location was adversely affected. These results may be related to the development of glutamate/NMDA receptor excitotoxity.

ALTERED ATTENTION, DECLARATIVE MEMORY, AND REWARD EFFICACY IN RATS EXPOSED TO LEAD DURING EARLY DEVELOPMENT: EVIDENCE FOR DYSFUNCTION OF PREFRONTAL CORTEX, HIPPOCAMPUS, AND NUCLEUS ACCUMBENS. B.J. Strupp*, T. Braga Costa, S. Drazen, C. Hu, H. Raffman, S. Alber, L.E. Bayer, & D. Levitsky. Dept. of Psychology & Div. of Nutritional Sciences, Cornell Univ., Ithaca, NY 14853.

Despite the increasing evidence that low-level lead (Pb) exposure lowers IQ, relatively little is known about the specificity of the impairment. This presen-tation will focus on 3 tasks included in an investigation designed to provide insight into this issue. Pb exposed S's displayed impaired inhibition of prepotent res-ponses in a vigilance task, consistent with prefrontal cortex (PFC) dysfunction. In a win-shift radial maze task, both Pb-exposed groups were significantly impaired relative to controls when tested after an 8-hr retention interval; at shorter delays, they were either unimpaired or superior to controls. This pattern demonstrates a specific impairment in declarative memory, consistent with the evidence that Pb exposure alters hippocampal LTP and NMDA receptor function. This latter task and a matching-to-position task provided evidence that developmental Pb exposure produces a lasting increase in the rewarding value of reinforcers. The increased incentive and impaired response inhibition may both be related to altered dopamine (DA) activity, in nucleus accumbens and in PFC respectively. The evidence that DA activity in PFC inhibits accumbens DA activity suggests that the observed alterations in executive function and incentive motivation may be linked. It is notable that changes in these two functional domains are also seen following prenatal alcohol exposure and in ADHD.

PLACE RETENTION, EXPLORATION, HABITUATION, AND SEROTONIN IN THE RAT. G. Wörtwein, P. Plenge, E. Mellerup and J. Mogensen*. Lab. of Neuropsychiatry, Dept. of Pharmacology, University of Copenhagen and Rigshospitalet-6102, The University Hospital, Copenhagen, Denmark.

A selective lesion of the serotonergic system was made by intracerebroventricular injections of 0.1mg 5,7-dihydroxytryptamine in 10μl 0.1% ascorbic acid per side. Selectivity was assured by pretreatment with normifensine and desimipramine. Postoperatively, habituation of locomotion in an activity cage, habituation of exploration in a vertical holeboard apparatus and retention of a place-learning task in a water-maze were tested.

Quantitative receptorassay of the serotonin reuptake site confirmed the lesion by showing a B_{max} reduction of more than 90%. While habituation of locomation was not affected by this almost complete elimination of the serotonergic system, habituation of exploration was impaired. Furthermore we found place recall to be significantly impaired. Finally, a pharmacological challenge by scopolamine (0.5mg/kg) demonstrated that the place recall of the lesioned animals was hypersensitive to muscarinergic receptor blockade.

These results emphasize the importance of serotonergic and cholinergic interactions for spatial memory - an interaction which may be of importance in Alzheimer's disease.

761.20

EFFECTS OF CHRONIC ANTIDEPRESSANT TREATMENT ON PASSIVE AVOIDANCE BEHAVIOR IN RATS. L.C.Daws*, R.Lopez and A.Frazer. Dept. Pharmacology, Univ. Texas Health Science Center at San Antonio, TX, 78284-7764.

Performance in a passive avoidance (PA) task can be altered by drugs that block ß-adrenergic (BAR) and muscarinic cholinergic receptor systems. The amnesic effect of the muscarinic antagonist, scopolamine, in a PA task can be potentiated by blockade of BARs; blockade of amygdaloid BARs can itself cause an amnesic effect. Chronic antidepressant (AD) treatment of rats results in down-regulation of BARs and this effect occurs robustly in the amygdaloid nuclei, a brain region strongly linked to the regulation of emotionality, particularly fear. Consequently, we determined whether chronic AD treatment in combination with an acute injection of the muscarinic receptor antagonist, scopolamine, would disrupt retention on a PA task. Initial experiments corroborated earlier reports in that: (1) propranolol (34 or 68 nmoles), injected directly into the amygdala complex of rats trained on a PA task, produced dose dependent decreases in retention of the task, and (2) blocking BARs, by systemic administration of propranolol (10 mg/kg, i.p.), potentiated the amnesic effect of scopolamine in a PA task.

Rats were treated with either phenelzine (5 mg/kg, i.p.) daily for 21 days, or desipramine, (10 mg/kg, i.p., bid) for 8 days. Control animals received vehicle at corresponding times. Twenty minutes prior to acquisition training [electric footshock, 0.5 mA for 2 secs (phenelzine group), or for 3 secs (desipramine group)] each of the three treatment groups were randomly divided and given an acute injection of either scopolamine (0.15 or 0.3 mg/kg, i.p.) or saline. Retention (10 min. test) was recorded 24 hours later. All groups showed maximal or near maximal retention on the test day. There was a tendency for rats receiving chronic AD treatment prior to scopolamine to exhibit decreased retention latencies, but these differences were not significant. Chronic treatment of rats with ADs does not alter performance or potentiate the effect of scopolamine on a PA task. Unlike blocking amygdaloid BARs with propranolol, AD-induced down-regulation of such receptors does not produce an amnesic effect in a PA task. (Supported in part by Research Funds from the VA and USPHS Grant MH 29094).

CHALLENGING IBOTENIC ACID LESIONING:
A NEUROANATOMICAL TOOL TO ASSESS THE INTEGRITY OF FIBERS OF PASSAGE IN BEHAVIORAL-LESION STUDIES.
S. Frey*, R. Morris and M. Petrides. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.
In behavioral-lesion studies involving animals, ibotenic acid (IBO) is widely used as a means of damaging brain structures. IBO is considered to be the lesioning method of choice since it destroys cell bodies but leaves fibers of passage intact. If IBO, however, is not used properly, i.e., if the concentration or the volume are too high when injected in a given area, both cell bodies and fibers of passage will be destroyed. The present project evaluates, first, whether ibotenic acid (IBO) is a reliable means of destroying a specific neural structure, and, second, whether it really leaves fibers of passage intact through the lesioned area. In 20 rats, the central nucleus of the amygdala was destroyed with IBO and the fibers that pass through this brain region were evaluated by means of an anatomical tract-tracing technique, namely HRP-WGA histochemistry. The results of this study have shown that IBO could be an ideal means of destroying cell bodies in a given brain area while at the same time sparing fibers running through that area. However, anatomical tract-tracing methods should be considered to assess the success of this technique. In light of the present results, behavioral-lesion studies would benefit from applying this reliable yet simple technique.

IMMUNOTOXIN-INDUCED CHOLINERGIC LESION IN INFANT RATS. B.A. Pappas*, C. Davidson, S. Nallathamby, G.A.S. Park, R.G. Wiley and T. Fortin. Life Sciences Research Centre, Carleton Univ., Ottawa, Ont. K1S 5B6.

Seven day old rat pups received bilateral intraventricular injections of the cholinergic immunotoxin IgG-192 saporin (200 ng/1.5 µl/ventricle). Four to six months later the immunotoxin-injected rats showed profound (88%) reduction of choline acetyltransferase activity in the hippocampus and lesser reductions in cortex (51%) and caudate (30%). Forebrain monoamines were unaffected except for increased NE in cortex and DA turnover in hippocampus. Immunohistochemical labelling of the p75 NGF receptor a marker for basal forebrain cholinergic neurons, indicated reduced immunoreactive neurons which varied among animals. Grossly enlarged immunoreactive varicosities were observed in the dentate gyrus and to a lesser extent in CA2 and CA3. Despite profound reduction and abnormality of hippocampal cholinergic innervation, the IgG treated rats showed neither a spatial memory impairment on the Morris water task, or a short term memory impairment on a delayed spatial alternation task. VISUO-SPATIAL LEARNING IN MICE EXPOSED TO PRENATAL GAMMA RADIATION. R.W.F. Vital* (1), C. Moreira (1), M.L.Dutra (1), R. Linden (2) and S.L. Schmidt (1,3). (1) Departamento de Ciências Fisiológicas, Universidade do Estado do Rio de Janeiro, RJ, 20551030, Brasil. (2) Instituto de Biofísica, Universidade Federal do Rio de Janeiro, Brasil. (3) Department of Psychology, University of Alberta, Edmonton, Canada.

Exposure of pregnant mice to gamma radiation at 16 days of gestation (E16) produces in the progeny extensive shrinkage of the occipital cortex and disruption of the laminar pattern of the hippocampus. This investigation was designed to study visuo-spatial learning in irradiated animals. Pregnant females were exposed to a gamma source at E16 with a total dose of 3Gy. Spatial learning of 58 adult mice (n = 28 irradiated progeny and n = 30 non-irradiated animals) was assessed in the Morris water maze task. This behavioral testing was conducted on two consecutive days, with each mouse receiving 5 trials per day. After 1 week, 20 animals (n=10 irradiated progeny, n=10 non-irradiated) were also tested in the Lashley III Maze. In this test each animal received ten trials, one trial per day, Analysis of the Morris water maze showed that there was not a significant difference between irradiated and non-irradiated animals on the first trial of the first day. On the subsequent trials, the time to reach the hidden platform was consistently greater in the irradiated animals as compared to the normal mice. Similarly, analysis of the Lashley III Maze showed a significant difference between the two groups after the fourth trial. After this trial, normal mice learned the task whereas the irradiated animals never reached the learning criterion. These data show a deficit in the visuo-spatial learning of the irradiated animals and may be a consequence of the early lesion in the hippocampus.

NEONATAL VENTRAL HIPPOCAMPAL LESIONS IMPAIR SPATIAL LEARNING AND MEMORY IN THE RADIAL-ARM MAZE AND ATTENUATE RESPONSE TO THE NICOTINIC ANTAGONIST MECAMYLAMINE. R.A. Chambers, J.P. McEvoy and E.D. Levin*. Neurobehavioral Research Laboratory, Psychiatry Department, Duke University Medical Ctr., Durham, NC 27710 USA.

In a rat model of schizophrenia developed by Lipska et al. (Neuropsychopharmacology 9:67-75, 1993), ibotenic acid lesions are made in the ventral hippocampus on Day 7 after birth, which results in locomotor hyperactivity with an onset during adolescence. We studied the cognitive effects of this lesion by examining spatial learning and working memory in the radial 8-arm maze. Training for 18 sessions began on Day 40 with 6 lesioned and 14 sham operated male and female Sprague-Dawley rats. The lesioned rats had significantly ($p<0.025$) lower accuracy (entries to repeat, Control=6.4±0.1 and Lesioned=5.8±0.2, mean±SEM). The lesion effect became evident with continued training (lesion x session, $p<0.025$). No significant lesion effect was seen on latency. After acquisition, challenges with nicotine (0.1-0.4 mg/kg), mecamylamine (2.5-10 mg/kg) and scopolamine (0.4-1.6 mg/kg) were conducted. Lesioned rats showed a significantly attenuated amnestic response to the nicotinic antagonist mecamylamine ($p<0.025$), suggesting that this system was less critical in lesioned rats than controls for performance of the memory task. These results demonstrate that in addition to hyperactivity, ventral hippocampal lesions on Day 7 cause long-term deficits in spatial learning and working memory function. This may provide a model for the cognitive deficits seen in schizophrenia. (This research was supported by the National Alliance for Research on Schizophrenia and Depression.)

762.5

ACUTE INJECTIONS OF QUINOLINIC ACID CAUSE DOSE -DEPENDENT SPATIAL MEMORY DEFICITS IN RATS.
G.L. Dunbar*, M.C. North, K.L. Haik, and J. Dong. Brain Research Laboratory, Department of Psychology, Central Michigan University, Mt. Pleasant, MI 48859.

Previous work has indicated that acute bilateral injections of quinolinic acid (QA) can mimic some of the neuropathological conditions observed in Huntington's disease and can produce profound learning deficits in a Morris water maze task. However, it was not previously known whether acute bilateral injections of QA could cause memory deficits in a well-learned spatial memory task. The present study investigated this possibility. Six groups of rats were given acute bilateral intrastriatal injections of QA at 0, 100, 125, 150, 175, and 200 nmol concentrations following acquisition of a radial-arm water maze spatial learning task. Although rats with the higher doses of QA took significantly longer to reacquire the task, all rats eventually were able to relearn the task. These results indicate that while acute bilateral intrastriatal injections of QA can disrupt spatial memory in rats, the memory deficits produced are not permanent and are not as profound as those observed in acquisition tasks.

762.6

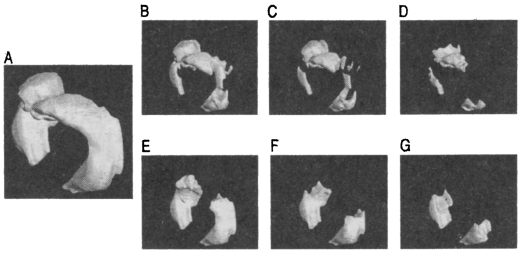
THE HIPPOCAMPUS CONTRIBUTES TO SPATIAL LEARNING AND MEMORY IN RATS WITH FIMBRIA/FORNIX LESIONS. D. K. Hannesson* & R. W. Skelton. Dept. of Psychol., Univ. of Victoria, B.C., Canada, V8W 3P5.

Fimbria/fornix (FF) lesions consistently produce impairments in a variety of spatial paradigms but do not prevent spatial learning entirely since FF-lesioned animals can utilize spatial solutions in such tasks when given extensive training. Though the anatomical substrates of this preserved capacity are unknown, a plausible hypothesis is that the hippocampus continues to subserve some of its normal function since both its internal circuitry and cortical connections remain largely intact after FF lesions. The present study investigated this hypothesis by examining the role of the hippocampus major cortical input/output pathway, the perforant path (PP), in spatial learning and memory after FF lesions in rats (*Rattus rattus*). In Experiment 1, rats subjected to FF lesions (FF), combined FF and PP lesions (FFPP), or sham operations (SH) were tested for acquisition of a constant platform location in the Morris water maze. In agreement with previous findings, FF lesions produced a severe impairment in the rate of acquisition of the platform's location but did not prevent it. Concurrent PP lesions aggravated this impairment but still permitted some spatial learning. In Experiment 2, these same rats received either a PP-lesion or sham-operation (creating groups FF/PP, SH/PP, FF/SH, SH/SH, and FFPP/SH), and were then tested for retention of the platform's location. PP lesions impaired retention in FF-lesioned rats and produced a more modest deficit in sham-operated rats. However, both groups' performance improved to the levels of their respective controls (FF/SH, SH/SH) with further training. No serial lesion effect was observed as both FF/PP and FFPP/SH performed at comparable levels. Our results suggest that the hippocampus does contribute to residual spatial learning and memory abilities after FF lesions. However, since ventral portions of the PP were spared by our lesion procedure, it cannot be determined whether spared hippocampal connections or alternative structures were responsible for residual function following combined FF-PP lesions.

762.7

SPATIAL LEARNING WITH A MINISLAB IN THE DORSAL HIPPOCAMPUS. M.-B. Moser*, E. I. Moser, E. Forrest, P. Andersen and R.G.M. Morris, Centre for Neuroscience, Univ. Edinburgh, Edinburgh EH8 9LE, U.K., and Dept. of Neurophysiology, Univ. Oslo, Norway.

The volume and location of hippocampal (HPC) tissue required for normal spatial learning in rats was investigated. Ibotenic acid was used to make bilateral, symmetric lesions of 20 -100% of HPC volume (Fig1 B-G), with the spared tissue as blocks at either the dorsal or ventral pole of HPC. Spatial watermaze learning was more efficient when the residual tissue was in the dorsal than in the ventral HPC. Even small transverse slabs of HPC [>26 % of total; 1D) could support spatial learning provided they were in the dorsal pole, whereas 60-80 % had to be spared to achieve normal spatial learning with blocks starting from the ventral pole (1E). Acetylcholinesterase staining, population spikes and synaptic plasticity in the remaining dorsal and ventral slabs were inside normal ranges. Thus, HPC-dependent spatial learning only requires the integrity of only a minislab of dorsal HPC tissue.



762.8

PARTIAL HIPPOCAMPAL KINDLING CAN PRODUCE A TEMPORARY DEFICIT IN PLACE LEARNING BY RATS IN THE MORRIS WATER TASK. R. J. Sutherland*, L. S. Leung, R. J. McDonald, & M. P. Weisend. Depts. of Psychol., Univ. of New Mexico, Albuquerque, NM, and Depts. of Physiol. & Clin. Neurol. Sci., Univ. of Western Ontario, London, Canada.

Partial hippocampal (HPC) kindling has been shown to affect performance by rats in the radial arm maze task for about 3 weeks after stimulation (Leung, et al. Behav. Brain Res., 40: 119-129, 1990). We sought to extend these observations in another task, the Morris water task, which is also known to be sensitive to damage in the hippocampal formation. We conducted two experiments to determine if induction of 20 HPC afterdischarges (ADs) affects place navigation in rats.

First, we implanted 12 rats with electrodes bilaterally in the CA1 region. Half of the rats received 21 ADs (1 sec train of 100 µs duration pulses at 100 Hz); the others received only low frequency stimulation. They were trained in the fixed location, hidden platform version of the Morris water task, receiving 8 trials on days 1, 2, 3, 7, 14, and 21 after the last stimulation. Partially-kindled and control rats learned at comparable rates and attained a similar level of performance. Second, we trained 18 rats in the hidden platform, moving location version of the task before delivering stimulation. After the last session we tested their performance in the original pool room and a new room. We found a small, but statistically significant, deficit in place learning set in the old and new rooms, 1 day and 1 wk, but not 3 wks after partial kindling.

These results extend the conclusion that in tasks sensitive to hippocampal damage, including the radial arm maze and place learning in the Morris water task, partial hippocampal kindling can disrupt performance for many days. (Supported by NIH 25383)

762.9

IMPORTANCE OF THE HIPPOCAMPUS DENTATE-HILAR COMPLEX FOR LEARNING AND MEMORY IN THE RAT. W. Samuel#, E. Brush, E. Masliah#, M. Garcia-Munoz, P. Patino, S. Young, P. Groves*. Depts. of Neurosciences# and Psychiatry, Univ. of Calif. Sch. of Med., San Diego, CA 92093-0624.

Prior studies of postmortem tissue from the hippocampal formation (HF) found lesions in the dentate-hilar area to be particularly correlated with Alzheimer's dementia, and prior animal work has suggested that lesions to this area might be particularly disruptive of learning and memory in the rat. As a test of this hypothesis, 30 male rats 50 days of age were trained to press a lever to obtain sucrose pellets on an FR3 schedule only when a stimulus light was off. At 80-82 days of age 10 animals received bilateral injections of 0.2 ul ibotenic acid (20 mM) in the anterior and posterior dentate gyrus/hilar region (DG/H), 10 other animals matched for learning ability were injected with ibotenic acid in the anterior and posterior cornu ammonis (CA2/3), and 10 underwent sham lesions. Eight days after surgery, animals were tested for 30 minutes with the FR3 light discrimination task. On all performance measures, the DG/H group displayed the greatest impairment and the sham controls the least, with the CA2/3 group falling in between: minutes to attain an FR3 criterion performance ($p< .006$), minutes maintaining an FR3 criterion ($p<.04$), ratio of light on to light off bar presses ($p<.004$), and number of reinforcements ($p<.06$). Five to 8 weeks later, rats underwent a one hour trial on an alternating response task involving two response levers, which required the animal to press the left bar (the one previously present) and then the right bar in order to obtain a pellet. The rats exhibited a high rate of bar pressing, but it was nonetheless very difficult for them to learn the alternating sequence. The DG/H group had the most impairment, both in terms of obtaining reinforcements ($p<.005$) and in terms of the ratio of left bar presses to reinforcements, a measure of inappropriate perseveration ($p<.03$). Following perfusion and sacrifice, histology with H&E and immunocytochemistry with glial fibrillary acidic protein confirmed the accuracy of the bilateral lesion placements.

762.10

FIMBRIA/FORNIX LESIONS ENHANCE PERFORMANCE ON A NON-SPATIAL TRAJECTORY TASK IN THE WATER MAZE. A.M. White, D.B. Matthews, P.J. Best*. Dept. of Psychology and Center for Neuroscience, Miami University, Oxford, OH 45056

Lesions of hippocampal connections, such as the fimbria-fornix, impair performance on tasks that require the formation of a spatial-cognitive map, but spare the ability to solve non-spatial tasks. A number of studies on the radial-arm maze have found that rats with fimbria-fornix lesions actually perform better than intact rats on various non-spatial tasks. However such has never been reported in the Morris water maze, perhaps because the non-spatial tasks previously used have been too easy.

The current study compares performance of intact and fimbria-fornix lesioned rats on a spatial task and a relatively difficult non-spatial trajectory task in the Morris water maze. Subjects were started from four different locations on each of seven days of training. In the spatial task, the platform location remained fixed with respect to the training room, regardless of the start location. In the trajectory task, the platform location remained fixed with respect to the start location (i.e. to the left of the start position), regardless of the position in the room. The results show that lesioned animals were impaired on the spatial task ($p<.05$) but performed significantly better than controls on the trajectory task ($p<.05$). The results suggests that the formation of a spatial cognitive map by the intact animals placed them at a disadvantage on the non-spatial trajectory task. The fimbria-fornix lesioned rats could not form such a map, and therefore did not suffer the same disadvantage on the trajectory task.

762.11

SELECTIVE IMPAIRMENTS OF SPATIALLY-MEDIATED BEHAVIORS PRODUCED BY TRANSIENT, LIDOCAINE-INDUCED LESIONS OF THE VENTRAL HIPPOCAMPUS OF THE RAT. A.G. Phillips, S.B. Floresco, J.K. Seamans and R.C. Tees* Dept.of Psychology, University of British Columbia, Vancouver, B.C., V6T 1Z4

The ventral hippocampus (VH) is part of a neural circuit which includes the prelimbic region (PL) of the medial prefrontal cortex and the nucleus accumbens (N.Acc.). Previous reseach has shown that the N.Acc. (Seamans and Phillips, *Behav.Neurosci.*, 1994(108) 456-468) but not the PL (Seamans, Floresco and Phillips, 1994, *Society for Neuroscience abstracts*, 494.4) is essential for spatially-mediated foraging behavior in the rat. The purpose of the present study was to determine the unique contribution of the VH to spatially-mediated behaviors. Well trained rats with lidocaine-induced lesions of the VH made more revisit errors (relative to saline controls) on a radial arm maze task, in which 4 out of 8 arms were baited randomly. Lesions in a separate group of rats produced impairments in the acquisition of a water maze task, but did not effect retention of spatial information on this task at a time when the anesthetic effects of lidocaine had dissipated. Transient lesions of the VH prior to retention of a water maze task produced no impairments in performance. Taken together, these results suggest that 1) the VH is not involved in the retention of spatial information of a water maze task, but 2) the VH is involved in "on-line" processing of spatial information during foraging on a radial arm maze or acquisition of a water maze task. Given the result of our previous studies, it is proposed that the VH specifically interacts with the N.Acc, but not PL, to guide spatially cued foraging behavior.

SELECTIVE IMPAIRMENT ON A DELAYED RADIAL ARM TASK FOLLOWING LOCAL ADMINISTRATION OF A D1 BUT NOT D2 ANTAGONIST INTO THE PREFRONTAL CORTEX. J.K. Seamans*, G.R. Wunderlich, S.B. Floresco & A.G. Phillips Dept.of Psychology, University of British Columbia, Vancouver, B.C., V6T 1Z4

Recently we have demonstrated a preferential involvement of the prelimbic region (PL) of the rat medial prefrontal cortex in delayed but not single phase foraging behavior. Using an in vitro slice preparation we also have shown that neuronal activity in this region is modulated by dopamine, primarily via stimulation of the D1 receptor (Yang & Seamans, *Society for Neuroscience abstracts*, 1995). In order to gain insight into the behavioral consequences of dopaminergic modulation in the PL, D1 or D2 antagonists were delivered locally into this region prior to the performance of a delayed or single phase foraging task on an 8-arm spatially-cued radial maze. The D1 antagonist SCH-23390 (0.05, 0.5, 5ug/ 0.5ul), but not the D2 antagonist sulpiride (0.05, 0.5, 5ug/ 0.5ul), dose-dependently disrupted performance on the delayed spatial win-shift task in which the rats were required to visit 4 open and baited arms during a Training phase and to visit the 4 remaining arms that were baited 30min later during a Test phase. Rats receiving SCH-23390 injections made an equal number of across phase errors(revisits to arms visited during the Training phase) and within-phase errors(revisits to arms visted within the Test phase), indicating disorganization of the effecient foraging strategy. In contrast, similar doses of these drugs had no effect on performance of the random foraging task in which 4 of 8 arms were baited randomly each day. These results compliment data obatined in the primate, and demonstrate that the D1 but not the D2 receptor in the PFC is essential for accurate performance on tasks in which information acquired prior to a delay is used to organize prospective responses.

THE ROLE OF THE HIPPOCAMPUS IN REDUCING SPATIAL INTERFERENCE. W.E. DeCoteau*, R.P. Kesner and P. Gilbert. Dept. of Psychology, University of Utah, Salt Lake City, UT 84112

A delayed-match-to-sample for spatial location task on the dryland version of the Morris water maze was utilized to assess spatial interference in rats. During the task's study phase an object which covered a baited food well was randomly positioned in one of six possible spatial locations. Rats exited a start box and displaced the object in order to receive the food reward and were then returned to the start box. On the ensuing test phase rats were allowed to choose between two objects which were identical to the study phase object. One object was baited and positioned in the previous study phase location (correct choice), the other was unbaited and placed in a different spatial location (incorrect choice). Five distances (min = 15 cm, max = 105 cm) were randomly used to separate the foil from the correct object. Following the establishment of a criterion of 75% correct averaged across all separation distances, rats were given either hippocampal or cortical control lesions. Post-surgery control animals matched their pre-surgery performance for all spatial distances. Hippocampal lesioned animals displayed impairments for short (15 cm - 37.5 cm) and medium (60 cm) spatial separations, but performed as well as controls when the spatial separation was long (82.5 cm - 105 cm). These results suggest that the hippocampus plays a significant role in reducing the interference produced by proximally close spatial locations.

HIPPOCAMPAL LESIONS AND TEMPORAL PROCESSING IN THE PIGEON: THE USE A DURATION MATCHING-TO-SAMPLE PROCEDURE TO EXAMINE HIPPOCAMPAL FUNCTION. J.M. Dose, P.J. Kraemer, C.K. Randall, R.W. Brown & J.F. Zolman*. Depts. of Psychology and Physiology, University of Kentucky, Lexington, KY 40506.

The role of the avian hippocampus in subjective timing and short-term memory of temporal events was studied using a duration matching-to-sample (MTS) procedure. Pigeons were initially trained on two duration MTS problems in succession. Samples consisted of 2- and 10-s durations of a red light presented from the front wall or white light presented from the ceiling. Choice stimuli consisted of red, blue, green and yellow solid colors presented on two side keys. Correct choices were followed by 2-s access to grain before a 15-s ITI commenced; incorrect choices immediately produced the 15-s ITI. Before and after receiving bilateral aspiration lesions of the hippocampus, pigeons were tested with normal (nonprobe) and probe trials in both the subjective timing and short-term memory tasks. Nonprobe trials for both test sessions consisted of red and white samples immediately followed by appropriate choice stimuli. Test sessions of subjective timing included a random presentation of 40 nonprobe and 8 probe trials. These probe trials consisted of red or white samples presented for 3-, 5-, 7-, or 9-s. Compared with pre-lesion performance, pigeons were more likely to respond "long" following hippocampus lesions, but this effect differed as a function of sample color. Test sessions of short-term memory included a random presentation of 24 nonprobe and 24 probe trials. These probe trials also involved 2- or 10-s presentations of red or white light; but, 0-, 1-, 3-, 6-, 9-, or 12-s delays were imposed between signal offset and choice stimuli onset. Pre- and post-lesion accuracy was disrupted on long samples following the retention interval but this effect was not found using short samples. Results will be discussed in terms of changes in temporal processing following a disruption of normal hippocampus functioning.

762.15

THE EFFECTS OF HIPPOCAMPAL LESIONS IN PIGEONS: VISUAL DMS WITH INTERFERENCE AND SPATIAL MEMORY. M. Colombo* and S. Cawley. Department of Psychology, University of Otago, Dunedin, New Zealand.

Previously (SN Abstracts, 20, 1012) we reported that hippocampus and area parahippocampalis (Hp-APH) lesions in pigeons had no effect on the postoperative retention or acquisition of a visual DMS task, or the postoperative acquisition of a concurrent discrimination task. Given that Hp-APH lesions cause deficits in homing behavior, these results suggested that the hippocampus in pigeons functions mainly to support the processing and retention of spatial, rather than visual, information.

A number of primate studies have reported that the effects of hippocampal lesions are exacerbated under conditions of interference. In this current study we explored whether visual DMS behavior in pigeons was impaired by testing with two forms of interference. The same ten subjects that served in the previous report served in the current studies. Five had received bilateral Hp-APH lesions and five served as unoperated controls. In Experiment 1, we examined the effects of proactive interference on visual DMS behavior by testing the pigeons with either a 15 sec or 1 sec intertrial interval (ITI). Confirming previous studies, reducing the ITI led to an impairment in performance. However, both control and Hp-APH pigeons were equally affected. In Experiment 2, we examined the effects of retroactive interference by interjecting visual interference during the delay period. Visual interference reliable impaired performance in both control and Hp-APH pigeons. Again, however, both control and Hp-APH pigeons were equally affected. In Experiment 3, we examined the effects of Hp-APH lesions on the acquisition of a open-field radial maze task. Of the five birds tested to date, three Hp-APH pigeons required 38, 41, and 47 days to learn the task, whereas two control pigeons learned the task in 6 and 14 days. These results provide further evidence that the pigeon hippocampus is important for the processing and retention of spatial rather than visual information.

762.16

SEASONAL DIFFERENCES IN FOOD-STORING, BUT NOT SPATIAL MEMORY OR HIPPOCAMPAL SIZE IN WHITE-BREASTED NUTHATCHES. K. Petersen and D.F. Sherry*. Dept. of Psychology, Univ. of Western Ontario, London, Ontario, Canada, N6A 5C2.

Several recent studies have described seasonal differences in hippocampal size and neurogenesis that are correlated with seasonal changes in food-storing behaviour. In Black-capped chickadees, both the relative size of the hippocampus and the number of [3H] thymidine labelled neurons in the hippocampus were found to be greatest in October, which coincides with the onset of food-storing (Barnea & Nottebohm, *PNAS* 1994 91, 11217; Smulders et al. *J. Neurobiol.* 1995 27, 15). We wished to determine whether seasonal differences in the size of the hippocampus coincided with seasonal changes in food-storing and spatial memory in the food-storing White-breasted nuthatch (*Sitta carolinensis).*

Birds were captured in the wild between October and April. Food-storing behaviour was observed in an outdoor aviary for two days. Accuracy of memory for caches was determined during five days of observation in an indoor aviary. Birds were sacrificed and volume of the hippocampus, telencephalon, and lobus parolfactorius were determined. Behavioural results indicated that birds in the winter months had significantly higher levels of caching and cache retrieval than spring birds. No seasonal differences were found in the accuracy of memory for cache sites. Neuroanatomical results indicated a larger telencephalon in spring than in winter, but no seasonal difference in relative size of the hippocampus, or lobus parolfactorius. Thus, no seasonal difference in spatial memory or relative size of the hippocampus was found to coincide with the observed seasonal change in food-storing activity.

PLACE LEARNING ON THE MORRIS WATER TASK DOES NOT REFLECT CA1 SYNAPTIC DENSITY CHANGES ACROSS THE ESTROUS CYCLE. S.G. Warren* and J.M. Juraska. Dept. of Psychology, University of Illinois, Champaign, IL 61820.

Synaptic density and long term potentiation (LTP) in hippocampal CA1 stratum radiatum vary significantly across the rat estrous cycle. The current study examined the behavioral implications of these rapid neural changes across the estrous cycle. While previous studies have suggested that spatial learning varies between the behavioral estrous and diestrus phases of the cycle no attempts were made to minimize the stressful aspects of the task, even though the stress response varies significantly across the estrous cycle. In the current study females in each phase of the estrous cycle and males were trained on a place version of the Morris water task, with each female's training restricted to one phase of the cycle. To reduce the stress involved with performance on this task all animals received extensive handling and pre-training (in a different room) in a small water maze with a visible platform. Results indicated that performance varied across the estrous cycle. On several measures females in estrus were similar to males, while rats in diestrus were similar to those in proestrus, with females in proestrus performing more poorly than males and females in estrus. The anatomical and LTP changes across the cycle do not correlate with the behavior. Supported by NSFIBN9310945 to JMJ and HD07333 to SGW.

THE ESTRUS CYCLE AFFECTS SPATIAL LEARNING IN ANIMALS WITH HIPPOCAMPAL DAMAGE. B. Therrien*, E. K. Hebda-Bauer, N. J. Bidlack, The University of Michigan, Ann Arbor, MI 48109-0482

Damage to the hippocampus (HPC) produces greater place navigation deficits in females than males. We also find that female animals with HPC damage are more resistant to therapy and more distractible than males. This study examined the influence of the estrus cycle on spatial learning in the presence and absence of HPC damage. We hypothesized that the stage of estrus on the initial test day influences spatial learning on subsequent days as prior work has shown that the majority of learning occurs between the first and second day of behavioral testing. Adult female (N = 32) rats received bilateral HPC lesions or sham surgery (control). Upon recovery, all animals were given 4 days of testing on the Morris water task. Daily vaginal smears determined the stage of estrus cycle. As expected, behavioral testing revealed that animals with bilateral damage were markedly impaired when compared to controls ($p<.05$). Stage of the estrus cycle did not significantly affect performance in controls. In contrast, lesioned animals in proestrus (proestrus and early estrus: high estrogen levels) learned the place navigation task more efficiently than those in diestrus (metestrus and diestrus: low estrogen levels), as evidenced by shorter swim times on the first 2 days (day 1: $X = 71.06 \pm 13.98$ vs $X = 114.09 \pm 19.96$, $p = .10$ and day 2: $X = 39.25 \pm 14.01$ vs $X = 91.03 \pm 14.61$, $p<.05$). The groups continued to differ across all 4 test days. The extent of HPC damage did not differ between the two lesioned groups. Qualitative analyses of swim paths revealed that lesioned animals in proestrus displayed more purposeful psychomotor learning strategies compared to the perseverative patterns of females in diestrus. These results show that animals with HPC damage quickly adopt more efficient learning strategies when estrogen levels are high. We therefore conclude that spatial learning is enhanced by peak estrogen levels.

EXPLORATORY BEHAVIOR IMPROVES SPATIAL LEARNING IN FEMALES WITH UNILATERAL HIPPOCAMPAL LESIONS. T. Briones*, C. Pacini, B. Therrien. The University of Michigan, Ann Arbor, MI 48109-0482

Exploratory behavior is thought to enhance spatial learning; such behaviors are reportedly absent in rats following bilateral hippocampal (HPC) damage. Our prior work revealed gender differences in animals with HPC damage. Specifically, females, unlike males, engage in exploration nearly as much as controls when exposed to a novel environment. Although females with bilateral HPC lesions engage in exploration, they still have spatial learning deficit. The purpose of this study was to determine if the association between exploration and spatial learning is a function of the amount of hippocampal damage. Adult female rats were randomly assigned to either unilateral (n = 29) HPC lesion or sham surgery (n = 12). Following recovery, rats were tested for four days on the Morris water task. Exploratory activities, i.e., rearing and circling were recorded for 30 seconds once the rats reached the platform. Rats with unilateral HPC damage engaged in as much or more exploration as controls. When lesioned animals were categorized as having greater than average exploration ($\bar{X}$ activity >12 epochs) vs average exploration ($\bar{X}$ activity <12 epochs) on test Days 1 and 2, a significant learning effect was found. Those that engaged in more versus average exploratory behavior showed enhanced spatial learning evidenced by improved directional heading on Day 3 ($\bar{X}$ = 17.97 ± 3.3 vs 43.69 ± 5.7 degrees error, p<.001) and Day 4 ($\bar{X}$ = 16.43 ± 3.0 vs 36.65 ± 6.8 degrees error, p = .01, respectively). No differences were noted in swim latency. However, all lesioned animals remained impaired compared to controls (p<.05). In addition, no significant difference were seen in control animals when categorized by degree of exploration. We conclude that female rats with unilateral HPC lesions actively explore new places but that these animals need a greater than average amount of exploratory activity to improve spatial learning performance.

ACUTE CORTICOSTERONE REPLACEMENT THREE-MONTHS AFTER ADRENALECTOMY IMPROVES PERFORMANCE IN A MORRIS WATER MAZE DESPITE DEGENERATION IN THE DENTATE GYRUS. C.M. McCormick, M. McNamara, J.E. Kelsey, & N.W. Kleckner*. Departments of Psychology and Biology, Bates College, Lewiston, ME 04240, USA.

Adrenalectomy (ADX) causes loss of dentate granule cells and impairs spatial memory performance (e.g., Sloviter et al, 1989; Conrad & Roy, 1993). These losses are prevented by *continuous* replacement of corticosterone (CORT). We investigated the effects of *acute* CORT replacement on water maze performance following long-term ADX. Of the 27 ADX, 9 were considered complete ADX on the basis of plasma CORT levels, low body weight, and saline intake. The remaining were considered incomplete ADX (INC). 18 rats had sham surgery. Approximately half of ADX, INC, and SHAM groups were given CORT in their drinking water (20 μg/ml) 5 days prior to, and during the 5 days of testing. Testing consisted of animals learning to find a submerged platform ina water maze from different start locations (6 trial/day for 5 days). There was an effect of group, and an interaction between group and replacement for both latency and distance to reach the platform: ADX showed poorer performance than both INC and SHAM, who did not differ. There was no effect of CORT replacement in INC and SHAM. CORT replacement improved ADX performance compared to ADX w/o replacement, and made their performance similar to that of the other four groups. At the end of behavioural testing, ADX+CORT rats showed significant weight gain compared to all other groups. There was no effect of CORT replacement on plasma glucose levels: both groups of ADX showed lower levels than SHAM and INC. Preliminary analysis indicated a 40% reduction in area of the dentate granule layer in ADX and ADX+CORT compared to INC and SHAM. The means by which acute CORT treatment improved the performance of ADX rats is unknown.

LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS XIV

763.1

INTERACTIONS BETWEEN BENZODIAZEPINE AND DOPAMINE RECEPTORS IN THE MODULATION OF CORTICAL ACETYLCHOLINE RELEASE H. Moore*, M. Sarter and J.P. Bruno, Dept. of Psychology and Neuroscience Program, The Ohio State University, Columbus, OH 43210

Benzodiazepine receptor (BZD-R) inverse agonists have been shown to disinhibit cortical acetylcholine (ACh) efflux via their ability to negatively modulate GABA-mediated chloride flux in the basal forebrain. In the present experiments, the BZD-R partial inverse agonist, FG 7142, was used to test the hypothesis that dopamine (DA) receptors in the nucleus accumbens (NA) interact with $GABA_A$/BZD-R in the regulation of cortical ACh release. Systemic administration of FG 7142 was preceded by systemic or intra-accumbens administration of selective D1 (SCH 23390) and D2 (clebopride) antagonists, and the neuroleptic haloperidol. ACh efflux in the frontal cortex was measured in awake animals using in vivo microdialysis. FG 7142 (8.0 mg/kg) increased cortical ACh efflux. This increase was dose-dependently attenuated by systemic administration of the D1 antagonist (0.1, 0.3 mg/kg) or haloperidol (0.15, 0.9 mg/kg). The D2 antagonist, clebopride (10 mg/kg), however, had no effect on stimulated ACh efflux. Haloperidol administered into the NA (10, 100 μM) appeared to block FG 7142-stimulated cortical ACh efflux, whereas equimolar doses of SCH 23390 into the NA did not. Neither drug administered intracortically, via the microdialysis probe, blocked FG 7142-increased ACh efflux. These results suggest that the well known ability of FG 7142 to stimulate DA release may contribute to the induction of cortical ACh release. This DA-mediated effect does not occur locally within the frontal cortex and the site of action of D1 antagonists (i.e. non-accumbens) and neuroleptics (i.e. accumbens) can be dissociated.

763.2

BIDIRECTIONAL TRANS-SYNAPTIC MODULATION OF CORTICAL ACETYLCHOLINE IN INTACT AND 192 IgG-SAPORIN-LESIONED RATS. J.Fadel*, H. Moore, B. Givens, M. Sarter and J.P. Bruno, Dept. of Psychology and Neuroscience Program, The Ohio State University, Columbus, OH 43210

Loss of cortically-projecting basal forebrain cholinergic neurons correlates with the cognitive decline associated with Alzheimer's disease. Trans-synaptic modulation of the remaining cholinergic neurons may prove therapeutic by augmenting cortical acetylcholine (ACh) release in close temporal contiguity with the activating demands of cognitive processing. Ligands that modulate the $GABA_A$/benzodiazepine receptor (BZD-R) complex represent a putative site for this type of modulation. The present study utilized in vivo microdialysis in awake rats to assess the effects of positive and negative modulators of GABA-mediated chloride flux on cortical ACh efflux in awake intact rats and in rats sustaining cholinergic deafferentation with cortical microinfusions of the immunotoxin 192 IgG-saporin. Lesioned animals exhibited a 50-60% reduction in basal cortical ACh efflux but responded to the GABA negative modulator, BZD-R partial inverse agonist FG 7142 (8.0 mg/kg) with a stimulation of ACh efflux similar in magnitude to that seen in intact rats (100-200% above baseline). These findings were confirmed with another negative modulator of GABA, the BZD-R weak inverse agonist ZK 93 426. Acute systemic administration of the postive GABA modulator ethanol (1.0 g/kg, ip) produced an initial increase, followed by a decrease in cortical ACh efflux in intact animals. The effects of localized perfusions of ethanol and its affect on cortically deafferented rats will also be discussed.

763.3

EFFECTS OF LESIONS OF THE DORSAL NORADRENERGIC BUNDLE ON BEHAVIORAL VIGILANCE. S. Ruland*, V. Ronis, J.P. Bruno and M. Sarter. Department of Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

The different cognitive functions of the major cortical afferent systems have remained unsettled. An operant procedure that required the animals to detect visual signals (presented for 25 - 500 msec) and to discriminate signals from non-signals was used to assess the role of forebrain noradrenergic afferents in behavioral vigilance. Measures of performance include the relative number of hits and misses (correct and incorrect responses to signals), and correct rejections and false alarms (correct and incorrect responses to nonsignals). Performance was characterized by a signal length-dependent ability to detect signals, and by performance decrements over time (vigilance decrement). Following the pretreatment with Pargyline (50 mg/kg), 6-hydroxydopamine was injected into the dorsal noradrenergic bundle (2 μg/μl/hemisphere). The lesion reduced the concentrations of noradrenaline in the cortex by > 90 % and in the hippocampus > 80 %. Postsurgery performance of the lesioned animals was characterized by relatively small and rapidly recovering decreases in both the relative number of hits and correct rejections. This finding contrasts with the persistent, potent, and selective decrease in the relative number of hits following 192 IgG-saporin-induced basal forebrain lesions (McGaughy et al. 1995). Thus, behavioral vigilance as measured by this procedure critically depends on the integrity of forebrain cholinergic, but not noradrenergic inputs.

763.4

FUNCTIONS OF CHOLINERGIC INPUTS TO VISUAL CORTICAL AREAS: EFFECTS OF VISUAL CORTICAL CHOLINERGIC DEAFFERENTATION ON VISUAL ATTENTION IN RATS. L.A. Holley* and M. Sarter. Department of Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

The functions of the cholinergic inputs to visual cortical areas remain largely unknown. Likewise, the extent to which the loss of cholinergic inputs to the visual cortex contributes to the impairments in visual and cognitive functions in senile dementia is not clear. Our previous research on the effects of infusions of 192 IgG-saporin into the visual cortex revealed an impairment in the acquisition, but not performance, of complex visual discriminations of variable difficulty. In the present experiment, 192 IgG-saporin (0.008 μg/0.8 μl) was infused into the primary and secondary visual cortex (two infusion sites per hemisphere) of rats trained in a visual sustained attention task (McGaughy & Sarter; Psychopharmacol. 117:340-357). This task requires the animals to detect visual signals presented for 25, 50 or 500 msec and to discriminate these signals from non-signals. Present data suggest that the partial loss of cholinergic input to visual cortical areas impairs performance, primarily by decreasing the animals' ability to detect longest signals and to correctly reject non-signal trials. These findings contrast with the selective and signal length-dependent decrease in the detection of signals in animals with 192 IgG-saporin lesions of the basal forebrain and suggest a discrete function of visual cortical ACh in visual attention.

763.5

INTERACTIONS BETWEEN THE ATTENTIONAL EFFECTS OF INTRABASALIS INFUSIONS OF BZR AGONISTS AND INVERSE AGONISTS AND SYSTEMIC HALOPERIDOL. J. McGaughy* and M. Sarter. Dept. Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

Previous work demonstrated that infusions of the benzodiazepine receptor (BZR) agonist chlordiazepoxide (CDP) or the BZR inverse agonist β-carboline β-CCM into the substantia innominata of the basal forebrain produced dissociable effects on the performance of animals tested in a behavioral vigilance task. Specifically, CDP selectively decreased the animals' ability to detect signals while their ability to correctly reject non-signal trials remained unaffected. In contrast, infusions of β-CCM selectively increased the relative number of false alarms (i.e., claims for hits in response to non-signal trials; Holley et al., Psychopharmacol., in press.). Because these findings were related to the contrasting effects of BZR agonists and inverse agonists on cortical acetylcholine (ACh) efflux (Moore, Sarter, & Bruno, Neurosci. Lett., in press), and because of the transsynaptic regulation of cortical ACh efflux by accumbens dopamine via its effects on the accumbens GABAergic projection to the basal forebrain neurons, this experiment tested the hypothesis that systemic co-administration of haloperidol (0.001 - 0.01 mg/kg) augments the attentional effects of intrabasalis infusions of the BZR agonist (40 μg/hemisphere) and attenuates the attentional effects of intrabasalis infusions of the BZR inverse agonist (3 μg/hemisphere).

763.6

CORTICAL ACETYLCHOLINE EFFLUX AND SINGLE UNIT ACTIVITY IN RATS PERFORMING OPERANT PROCEDURES ASSESSING BEHAVIORAL VIGILANCE OR SENSORIMOTOR AND MOTIVATIONAL TASK COMPONENTS. A.-M. Himmelheber, H. Moore, J. McGaughy, B. Givens, J.P. Bruno and M. Sarter*. Department of Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

The study of the cognitive functions of cortical acetylcholine (ACh) requires experimental approaches aimed at measuring the activity of cortical cholinergic afferents in relationship to cognitive activities which recruit this system. Animals were trained in an operant vigilance task (McGaughy et al., Psychopharmacol. 117:340-357). Animals were prepared for the measurement of cortical ACh efflux as described in Moore et al. (Brain Res. 627:267-274) or for multiple single unit recording (Givens, Neurosci. in press). Medial prefrontal (i.e., prelimbic) ACh efflux increased as a result of transfer of the animals to the test chamber and task onset. Presentation of "background noise" (houselight flashing at 0.5 Hz) during one of the 4 blocks of trials significantly impaired performance, increased cortical ACh efflux and increased spontaneous prelimbic neuronal activity. Different groups of animals were trained in a series of behavioral control procedures assessing the role of motor performance, response habits, reward loss, and sensory stimuli in ACh efflux and neuronal activity. The results from these experiments provide the basis for a discussion about the procedural and conceptual issues important for studies on the cognitive functions of cortical ACh.

763.7

A CENTRAL CHOLINERGIC LINK IN THE CARDIOVASCULAR EFFECTS OF THE BZR PARTIAL INVERSE AGONIST FG 7142. V. Ronis, S. Ruland, S. Hart, M. Sarter and G.G. Berntson*. Dept. Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

Previous work demonstrated that systemic administration of the benzodiazepine receptor (BZR) partial inverse agonist ß-carboline FG 7142 (FG) augments the cardiovascular response to nonsignal stimuli, and mimics the cardiovascular effects of a conditioned stimulus for an aversive event. Analyses of the parasympathetic and sympathetic contributions to the effects of FG prompted the hypothesis that increases in central cholinergic activity mediates the potentiation of the cardioacceleratory response by FG. Consistent with this hypothesis, the present experiments demonstrate: a) ICV infusion of the muscarinic receptor agonist carbachol mimics the response-potentiating effects of FG; b) this effect of carbachol was blocked by ICV co-administration of the muscarinic antagonist atropine; c) ICV infusions of atropine blocked the potentiation of the cardioacceleratory response by systemically administered FG, but did not alter the basal response to the stimulus; and d) 192 IgG-saporin-induced lesions of basal forebrain cholinergic neurons prevented the FG-induced potentiation of the cardioacceleratory response, without altering the basal cardiac response. These data strongly support the hypothesis that the effects of FG on cardiac reactivity are mediated via an activation of central muscarinic cholinergic mechanisms.

763.8

COMPARISON BETWEEN THE EFFECTS OF INFUSIONS OF 192 IgG-SAPORIN INTO THE BASAL FOREBRAIN OR THE CORTEX ON BEHAVIORAL VIGILANCE. D. Wendelin, J. McGaughy, B.H. Smith* and M. Sarter. Department of Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

Cortical cholinergic deafferentation was produced either by bilateral infusion of 192 IgG-saporin into the basal forebrain (0.42 mg/ml; 0.5 μl/hemisphere) or by infusions of the immunotoxin into the cortex (a total of 5 infusions/hemisphere; 0.01 mg/ml; 0.5 μl/infusion; see Holley et al., Brain Res. 663:277-286). Following surgery, control animals and lesioned animals were retrained in an operant procedure designed to measure the animals' ability to detect visual signals (presented for 25 - 500 msec) and to discriminate signals from non-signals, i.e., behavioral vigilance. Additionally, the hypothesis that administration of the benzodiazepine receptor partial inverse agonist FG 7142 or the cholinesterase inhibitor physostigmine improves the lesioned animals' performance was tested. Basal forebrain infusions resulted in > 90 % loss of frontoparietal cortical AChE-positive fibers. Intracortical infusions decreased fiber counts by less than 50 %. Basal forebrain lesions resulted in a persistent impairment in the animals' ability to detect signals but did not affect their ability to correctly reject non-signal trials. Beneficial drug effects were not found in basal forebrain lesioned animals, possibly because of the almost complete loss of cholinergic neurons. These findings are compared with the data from the intracortically infused animals, and the usefulness of the two models will be discussed.

763.9

CORTICAL ACETYLCHOLINE AND PROCESSING CAPACITY: EFFECTS OF CORTICAL CHOLINERGIC DEAFFERENTATION ON CROSSMODAL DIVIDED ATTENTION IN RATS. J. Turchi, J.P. Bruno* and M. Sarter. Department of Psychology & Neuroscience Program, The Ohio State Univ., Columbus, OH 43210.

Divided attention is a psychological construct that is characterized by assumptions about the fixed finite capacity of subjects to simultaneously process multiple sets of information. While the role of cortical acetylcholine (ACh) in other aspects of attention (e.g., sustained, selective) is intensely studied, the extent to which cortical cholinergic inputs mediate processing capacity has remained unclear. An operant analogue of the crossmodal divided attention paradigm was developed and the potency of scopolamine to augment speed-accuracy tradeoffs was previously demonstrated (McGaughy, Turchi, Sarter, Psychopharmacol. 115:213-220). In the present experiments, local or global cortical cholinergic deafferentation was achieved by infusions of 192 IgG-saporin into the medial prefrontal or frontoparietal cortex (local deafferentation; Holley et al., Brain Res. 663:277-286) or into the basal forebrain (global deafferentation). Performance following these lesions suggests that local, restricted loss of cortical cholinergic inputs does not robustly affect the animals' ability to divide their attention between the processing of auditory and visual response rules, contrasting with the effects of global deafferentation. Cortical cholinergic mediation of processing capacity may follow mass-action rules rather than being critically dependent on single areas.

763.10

EFFECTS OF NERVE GROWTH FACTOR ON RATS GIVEN AN IMMUNOTOXIC LESION OF p75-BEARING CHOLINERGIC BASAL FOREBRAIN NEURONS. J.J. Waite*, J. Winkler, R.G.Wiley, D.A. Lappi, & L.J. Thal Dept. of Neurosciences & Neurology, UCSD & VAMC, San Diego, CA 92161.

Immunotoxic lesion provides a more selective model for testing NGF effects on the cholinergic basal forebrain. Rats received i.c.v. PBS or 192 IgG-saporin to produce either 50% (1μg) or 80% (2.7μg) overall depletions of ChAT activity in four cortical regions, hippocampus and olfactory bulbs. Half of each group was then treated i.c.v. with either 5μg/day NGF or cytochrome c for 7 weeks. Behavioral testing was performed in treatment weeks 5-7. In each brain region examined, NGF produced the greatest increase in ChAT activity in the unlesioned group and the least increase in the highly lesioned group. NGF-treated animals showed a deficit in single-trial passive avoidance retention and an increase in acoustic startle response associated with decreased habituation to startle. No lesion effect was observed in either test. In the water maze, highly lesioned rats had a longer latency to reach a visible platform. There was a significant overall effect of lesion and of NGF treatment, but no interaction. Highly lesioned rats were significantly impaired in finding a hidden platform after learning to escape to a visible platform compared to controls. NGF treatment significantly mitigated this lesion effect. All groups learned to escape to the hidden platform. This study found that NGF affected passive avoidance retention and acoustic startle independent of the cholinergic lesion. Furthermore, NGF partially improved a performance deficit produced by this lesion in the water maze.

CHOLINE EFFECTS ON MAZE PERFORMANCE ARE MODERATED BY SEX, AGE & ACH AVAILABILITY. K. Schultz*, L. Francis & N. Ward, Psychology Department, University of Winnipeg, Winnipeg, MB, Canada R3B 2E9

Allocentric performance in the Morris water maze is known to vary with sex. Males generally are slightly more efficient at this task than are females. Further, performance is also enhanced by pre- and postnatal choline supplementation. This study examined the allocentric performance of 160 Long-Evans rats, 80 of which had been exposed to enhanced choline levels throughout gestation and for 21 days after birth. Equal numbers of choline treated and control male and female rats were tested at four developmental stages: pup, prepuberty, midpuberty and adult. Finally half of the animals in each condition were tested following a scopolamine challenge. Overall, animals exposed to supplemental choline had shorter escape latencies. This enhanced performance was most apparent in male pups and prepubertal females. These differences are related to the structure of the dentate gyrus. Following scopolamine administration, animals previously exposed to choline had longer escape latencies than controls, thus choline availability as well as dentate gyrus structure differ in these groups.

INJECTION OF 192-IgG-SAPORIN INTO THE MEDIAL SEPTAL AREA EXACERBATES A SPATIAL MEMORY DEFICIT IN AGED RATS: A.W. Bannon*, P. Curzon, K.L. Gunther, and M.W. Decker, Neuroscience Research, D47W, 100 Abbott Park Rd., Pharmaceutical Discovery, Abbott Park, IL 60064-3500.

192-IgG-Saporin (IgG-Sap) is an immunotoxin that can be utilized to selectively destroy basal forebrain cholinergic neurons. In this study, IgG-Sap or PBS was injected into the medial septal (MS) area of mature (6 mo old) and aged (24-26 mo old) male Long-Evans rats. Ten days following surgery, testing began in a battery of behavioral tasks including two versions of the Morris water maze (i.e., invisible platform [Inv-P] task and 2-platform [2-p] task), inhibitory avoidance (IA), and pre-pulse inhibition of acoustic startle (PPI). At the termination of the study, tissue from several CNS sites was taken for analysis of ChAT activity.

On the Inv-P water maze task, we observed an age-associated impairment during acquisition, but no effect of IgG-Sap in either age group. Data from a probe trial conducted following 7 days of training (4 trials/day) revealed a significant spatial memory deficit in the aged rats. Interestingly, this deficit was significantly more pronounced in aged rats treated with IgG-Sap, an effect not observed in the 6 mo old rats. In the 2-P water maze task, a minimal age-associated impairment was observed. For the IA task, no significant age or treatment effect was found. In the PPI task, aged rats were significantly less responsive to the acoustic stimulus than the younger animals, but no effect of IgG-Sap was observed for either age. Finally, significant reductions (i.e., 65%) in ChAT activity of the dorsal hippocampus were observed in IgG-Sap treated rats of both ages. In conclusion, although IgG-Sap produced similar reductions in ChAT activity of dorsal hippocampus in both mature and aged rats, a significant effect of the IgG-Sap on spatial memory was only observed in aged rats.

SUBCELLULAR LOCALIZATION OF A LEARNING ASSOCIATED PROTEIN IN RAT ASTROCYTES. A. Favit*, ^M. Grimaldi, T.J. Nelson, ^G. Schettini and D.L. Alkon. Lab. of Adapt. Sys., NINDS, NIH, Bethesda, MD 20892 U.S.A.; and ^Dip. Neurosci., Sez. Farm., Univ. Napoli "Federico II", Via S. Pansini 5, I-80131 Napoli, Italy.

In this study we have analyzed the subcellular localization of cp20, a small GTP-binding protein, whose phosphorylation by PKC has been implicated in associative learning of several species. Cp20 subcellular distribution was studied in purified rat cortical type I astrocytes by indirect immunofluorescence using a polyclonal primary antibody affinity purified. Western blot analysis showed that this antibody specifically reacted with cp20 in the rat astrocytes. Immunofluorescence studies demonstrated that cultured astrocytes exhibited high cp20 immunoreactivity within the nucleus. In addition, optical sections of astrocyte nuclei studied with a confocal microscope, confirmed the nuclear localization of cp20 immunoreactivity in the astrocytes. Although cp20 has been shown to be closely related to ARF-class GTP-binding proteins, such as Sar1p, we tested whether other small GTP-binding proteins have the same subcellular localization. Surprisingly, no immunoreactivity was observed in the nuclei of rat astrocytes following immunostaining with an antibody recognizing Sar1p protein, suggesting a peculiar role for cp20 in rat cortical astrocytes. Since cp20 is specifically phosphorylated by PKC we tested the effects of phorbol esters upon subcellular localization of cp20. In serum-deprived astrocytes treated with 100 nM phorbol mystrate acetate (PMA) for a period of time ranging between 15 and 180 min, cp20 nuclear immunoreactivity was no longer detectable from the nuclei of the astrocytes. However, in the presence of serum, time-dependent treatments with PMA did not affect the immunostaining for cp20. Accordingly with our previous observations, these findings suggests that cp20 may play a role in the control of gene transcription, and moreover that PKC may exert a thight control of cp20 function in rat cortical astrocytes.

DEVELOPMENTAL INCREASE IN THE BEHAVIORAL INDUCTION OF FOS PROTEIN IMMUNOREACTIVITY IN AREA CA1 OF THE RAT HIPPOCAMPUS. Nicholas S. Waters*, Anna Y. Klintsova, and Thomas C. Foster, Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Juvenile rats are unable to perform a number of learning and memory tasks which, in adults, appear to require an intact hippocampus. This inability appears despite competent sensory-motor systems, and the ability to perform other learning tasks. Hippocampal responsiveness following exposure to a memory task was studied in juvenile rats, using immunocytochemistry to FOS. FOS protein is the product of the immediate early gene *c-fos*, and has been considered a marker of cellular activity. Thirty-three littermate pairs served as experimental and control animals, and were tested at P16, P23, and P30 (birth=P0). Experimental animals were tested for 5 min in a water-motivated alternation (Y-maze) task, placed into a novel environment for 55 min, then perfused. Controls were sacrificed immediately after removal from the home cage. Immunocytochemistry for FOS protein was performed on free floating, 35 μm sections of the dorsal hippocampus. Stained sections were digitized using an Olympus Cue-2 densitometry system, and cell counts were performed in 5 regions in the hippocampus and dentate gyrus. There was no effect of age on baseline FOS expression in any region. The behavioral manipulation resulted in a significant increase in FOS immunoreactivity only in P30 subjects, and this effect was restricted to area CA1. This increase coincided with a significant increase in alternation behavior at the same age. These findings suggest that developmental changes in CA1 are related to the emergence of spatial alternation behavior, and are consistent with previous findings of presynaptic changes in the CA3-CA1 synapse at this age. This work was supported, in part, by NIH Grants NS31830 to TCF, and HD07323.

STIMULUS NOVELTY EFFECTS NACL TASTE-INDUCED EXPRESSION OF C-*FOS* IN THE CNS OF GOLDEN HAMSTERS. M. A. Barry*, E. J. Chesler, Dept. of BioStructure and Function, University of Connecticut Health Center, Farmington, CT 06030-3705.

We are using the expression of the immediate early gene, c-*fos*, as a marker for neuronal activity and protein synthesis induced by gustatory stimulation. We first showed that a series of presentations of 0.1 M sucrose or 0.15 M NaCl resulted in stimulus familiarity in golden hamsters by utilizing the phenomenon of learned harmlessness in a conditioned taste aversion (CTA) paradigm. Hamsters with preexposure to the unconditioned stimulus showed a significantly reduced aversion to the stimulus following a CTA relative to those preexposed to water. Learned harmlessness had not been previously demonstrated in hamsters. For studies of c-*fos* expression, animals were either preexposed to NaCl (familiar group), or water (novel group). The hamsters were then water deprived and given a drink of 0.15 M NaCl. After two hours the animals were sacrificed, and their brains were processed to reveal c-*fos* protein with immunohistochemistry. There was greater c-*fos* expression in the novel than the familiar group in many (but not all) areas of the brain including gustatory parts of the parabrachial nucleus and insular cortex. Thus a formed memory for familiar stimuli effects c-*fos* expression associated with gustatory stimuli even in brainstem gustatory nuclei. **Supported by 5P01-DC00168**

IMMEDIATE EARLY GENE (IEG) EXPRESSION DURING A DISCRIMINATION TASK IN ADULT CAT VISUAL CORTEX : AN IMMUNOCYTOCHEMICAL STUDY. E. Van der Gucht[1,2], L. Arckens[1,2], E. Vandenbussche[2], G.A. Orban[2] and F. Vandesande*[1]. [1]Lab. Neuroendocrin. & Immunol. Biotechnol., [2]Lab. Neuro- & Psychofysiol., K.U.Leuven, B-3000 Leuven, Belgium.

Using immunocytochemical methods we investigated the influence of a visual learning process on the expression of two IEGs, c-fos and zif-268, in the primary visual cortex of the adult cat. We compared the expression levels of both IEGs in the visual cortex and somatosensory cortex (SII) from different cats before and after being trained in a bar orientation discrimination task at different performance levels.

In the visual areas 17 and 18, but not in SII, we detected different degrees of c-fos and zif-268 labeling depending on the experimental conditions. The expression level of c-fos and zif-268 was elevated in the bar orientation discrimination cat after five days of training, during which the cat really learns to distinguish between two bars of different orientation. In contrast the expression levels of both IEGs in the brains, i.e. before orientation discrimination training, or after completion of the training (75% correct for an orientation difference of 5°) in bar orientation discrimination revealed a basal level of c-fos positive nuclei in the supra- and infragranular layers, while the expression of zif-268 immunoreactive neurons even was below basal level in layers II, III, IVc and VI of area 17 and 18 in a full-trained cat.

Our results show that a discriminative learning process induces c-fos and zif-268 expression in areas 17 and 18 of the cat visual cortex.

EFFECTS OF MATERNAL EXPERIENCE ON FOS-LIR IN MPOA, AMYGDALA AND CORTEX. A.S. Fleming* and M. Korsmit. Erindale College, University of Toronto, Mississauga, Ontario L5L 1C6.

In order to determine what brain sites are activated during the acquisition and retention of a maternal experience in postpartum rats, two studies examined the number of cells showing Fos-like immunoreactivity (Fos-lir) in brains following re-exposure to pups (USs and CSs) and pup-associated cues (CSs) in maternally-experienced and inexperienced rats. In the first study, day 1 postpartum rats were given a 2 hour interactive experience with pups and then re-exposed to pups or to a neutral stimulus (perforated box) 4 days later. In the second study, day 1 postpartum rats were given a 4 hour interactive experience with pups and a neutral box in a new cage or were left undisturbed. On day 10 postpartum animals were exposed either to pups in the perforated box in the new cage (USs and CSs), to the box and cage without pups (CSs alone), or left in the home cage. For both studies, at the end of the test phase animals were sacrificed and brains were prepared for immunohistochemical detection of Fos-lir.

In both studies the brain site showing the most consistent difference between experienced and inexperienced animals was the medial preoptic area (mpoa), an area of the brain known to be important for the expression of maternal behavior. Fos-lir was higher in the mpoa of the experienced groups. Marginal experience effects were also found in the basolateral amygdala, an amygdaloid structure involved in the formation of associations within biologically-relevant contexts. The third site showing experience effects (in the first study only, where animals actually physically interacted with pups on re-exposure) was the parietal cortex. In a fourth site, the prefrontal cortex, experienced animals showed lower Fos-lir than did inexperienced animals, an effect that may reflect exposure-based habituation to novelty of the pup stimuli.

REF-1 PROTEIN EXPRESSION FOLLOWING FEAR CONDITIONING. O. Stiedl*[1], S. Milanovic[1,2], O. Laban[1], and J. Spiess[1]. [1] Dept. of Molecular Neuroendocrinology, Max-Planck-Institute for Experimental Medicine, Hermann-Rein-Str. 3, D-37075 Goettingen, Germany; [2] Central Institute for Mental Health, J5, D-68159 Mannheim, Germany

Male mice (C57/BL6J) were subjected to fear conditioning in order to investigate specific changes in the expression of *ref-1* protein. Freezing frequency and locomotor activity were evaluated as behavioral parameters. Heart rate was monitored to assess stress levels. In the training phase animals were placed for 3 min into a conditioning box, then presented with a pulsed (5 Hz) tone stimulus (1 kHz, 80 dB, 30 s) before a foot shock (2 s, 0.7 mA) was applied. Animals were tested the day after training either for contextual retention by placing them into the same box for 6 min without auditory or foot shock stimulation or for tone-dependent retention in an altered context. In addition, unpaired conditioning was performed to determine the retention-specificity of *ref-1* protein expression.

Ref-1 is a nuclear protein controlling the activity of homo- and heterodimers of immediate early genes (*c-fos, c-jun*) by redox activation and also functions as a apurinic/apyrimidinic DNA repair enzyme. *Ref-1* protein could be an important molecular signal in the proposed cascade from ion channel activation to learning and memory.

In brains of control mice, *ref-1* protein was highly expressed in the hippocampus (CA1, DG), frontal and parietal cortical areas, and in nc. septalis lateralis and medialis. A time-dependent differential expression of *ref-1* protein was observed in the time range from 0-180 min following the training phase with a peak difference at 60 min. At that point *ref-1* protein expression was absent in the hippocampus and strongly increased in the 2. and 3. layer of the parietal cortex. After 180 min the *ref-1* protein expression pattern was identical with the one in control animals. Differential expression pattern of *ref-1* protein following contextual and tone-dependent retention will be discussed.

ANALYSIS OF MEMORY CONSOLIDATION USING INTRACEREBRAL INFUSIONS OF ANTISENSE OLIGONUCLEOTIDES TO THE TRANSCRIPTION FACTOR CREB. J.F. Guzowski, B. Setlow, G.D. Novack* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Department of Psychobiology, University of California, Irvine, CA 92717-3800.

The regulatory transcription factor CREB is constituitively expressed in the brain and can be phosphorylated both by PKA and CaMK, which are activated by cAMP and Ca^{2+}, respectively. Phosphorylated CREB activates transcription of genes containing cyclic AMP response elements (CREs) in their promoters. Thus, CREB and related transcription factors provide the link between changes in second messenger levels to changes in the cell's transcriptional program. Recent publications have shown a role for CREB in long-term memory consolidation. The transgenic approaches used in these studies, however, do not allow anatomical localization of the observed effects to defined structures. To gain a greater understanding of the role of CREB in the consolidation of different tasks in the mammalian brain, we have initiated studies in which antisense CREB oligonucleotides are stereotactically infused into defined regions of the rat brain and the effect on learning and memory are compared to buffer and mismatch oligonucleotide control groups. The hippocampus and the amygdaloid complex have been chosen for study because of their well documented role in the learning and memory of different tasks. Tasks chosen for study are the hidden platform water maze and continuous multiple trial inhibitory avoidance (CMIA). Preliminary results indicate that CREB antisense oligonucleotides infused into the hippocampus impair memory consolidation but not acquisition in both tasks. Additional preliminary evidence suggests that CREB antisense oligonucleotides infused into the amygdala do not affect memory consolidation in CMIA. These results suggest that hippocampal, but not amygdaloid, CREB mediates changes in transcription important for memory consolidation.

CREB LEVELS ARE REDUCED IN THE RAT HIPPOCAMPUS FOLLOWING OVARIECTOMY AND HYPOGLYCEMIA-INDUCED SEIZURE. K. S. Panickar[1,3,*], K. R. Purushotham[2], G .Rajakumar[3], M. A. King[4] and J .W. Simpkins[3]. [1]Dept. of Pharmacology & Experimental Therapeutics, [2]Dept. of Oral Biology, [3]Center for Neurobiology of Aging and Dept. of Pharmacodynamics, [4]Dept. of Neuroscience. University of Florida, Gainesville, FL 32610..

cAMP response-element binding protein (CREB) is a transcription factor which has been implicated in the activation of protein synthesis required for long-term memory. Previous research from our laboratory has shown that memory is compromised following ovariectomy and that some of these memory deficits can be ameliorated with estrogen replacement. We have also reported cognitive deficits following severe hypoglycemic episodes in rats. Given that CREB is critical for memory, we investigated the levels of CREB in rat hippocampus in these two models of memory dysfunction. In Experiment 1, immunoblot analysis of proteins (SDS-PAGE) using polyclonal antibody to CREB revealed that CREB had decreased by 23% in the hippocampus following one week of ovariectomy while the estrogen-replaced animals showed a recovery in CREB levels compared to ovariectomized animals. This suggests that estrogen treatment may be beneficial in preventing the decrease of CREB in rats, thereby playing a role in memory consolidation. In Experiment 2, we found that insulin-induced seizure reduced CREB by 55% compared to controls in the hippocampus. Immunohistochemistry also revealed a decrease number of CREB positive cells in CA1, CA3, dentate gyrus, and the entorhinal cortex. Taken together these results suggest that CREB is an important mediating factor in memory loss following ovariectomy and severe hypoglycemic episodes. (Supported by NIA AG 10 485 to JWS).

GLUCOSE PREFERENCE AND RECOGNITION OF PERIPHERAL GLUCOSE UTILIZATION IN THE BRAIN OF RATS WITH INSULIN DEPENDENT DIABETES MELLITUS BY A FUNCTIONAL MRI AFTER INSULIN TREATMENT. K.Torii*[1,2], M. Mori[1], T.Yokawa[1], T.Murata[1], K.Tajima[1], M.Takezawa[1] and T.Ono[3]. [1]Torii Nutrient-stasis Project, ERATO, R&D Corp. of Japan, Yokohama 221, [2]Ajinomoto Co. Inc., Central Res. Lab., Yokohama 244, and Toyama Med.&Pharmaceu.Univ., Toyama, 930-01, Japan.

The patients with diabetes mellitus generally display a strong preference for sweets as energy sources to compensate for disorder of peripheral glucose utilization by failure of insulin function. Either preference for glucose or change of the brain function treated with insulin was examined before and after Streptozotocin (STZ) administration to Sprague-Dawley male adult rats. Preference for glucose in rats was evoked several hours after STZ treatment (50 mg/kg BW, i.p.) and reached a plateau level for a week. Histological findings of the pancreas also supported these behavioral changes as an insulin dependent diabetes mellitus (IDDM). Each anesthetized similar rat was settled in the 40 cm bore of a 4.7 tesla MRI. Fasted glucose in plasma was above 400 mg / dl and normalized below 80 mg/dl at 100 min after insulin injection (20 U/kgBW, i.p.). The brain O_2 consumption was monitored by T2* weighted intensity and visualized chronologically by rapid gradient echo pulse sequence method. The intensity changed in the hippocampus at 20-30 min, the paraventricular nucleus at 30 min, the thalamus and the dorsomedial hypothalamus at 40-50 min and then the ventromedial hypothalamus at 100 min after insulin injection. These changes were recovered at 120 min by normal glucose utilization with insulin treatment. Saline treatment in IDDM rats as control never caused any intensity change in the brain. The degree of glucose preference and chronological brain functional changes by MRI can be a useful diagnosis for status of diabetes mellitus.

DISHABITUATION OF TAIL PINCH-INDUCED GLUTAMATE AND LACTATE RELEASE BY LOCAL PERFUSION OF RECEPTOR AGONISTS IN RAT PREFRONTAL CORTEX. M.Takita*. Nervous Informatics Lab., Biosignalling Dept., Natnl. Inst. of Biosci. and Human-Technol., Ibaraki 305, Japan.

To clarify the roles of rat medial frontal cortex (mpFC) responding to stressful stimuli, we have been studying the habituation of stressful stimuli-induced glutamate (GLU) and lactate (LAC) release by using continuous *in vivo* brain microdialysis with less than 1 min-resolution. In brief, the dialysate was mixed directly with an assay solution in a T-tube and GLU or LAC was measured in a flow cell under the freely moving condition. We have reported the following. 1) The mpFC GR was increase immediately and transiently from its steady state level after1min tail pinch (TP). The mpFC LR was also increased by various stimuli (TP, 5min 100dB white noise, and 5min immobilization). 2) The 2nd response to the same stimuli given 1 hour later was smaller than the 1st response (about 35% decrease). 3) GR and LR both showed a decreasing response in septum. 4) The mpFC GR response occurred under reserpinization while the LR was completely abolished. In addition, we found that the habituation of TP-induced GLU or LAC release disappeared by perfusion of DA (10^{-4}M) or NMDA (10^{-4}M) into the probe for 5min between the two trials in a manner of dis-habituation. These treatments increased the 2nd TP-induced response of GLU or LAC compared with the 1st one {GLU: 133.4±11.4% (n=7), LAC: 360±255% (n=3)}. These results suggest that there are at least two different systems for information storage processing specialized in rat mpFC.

AMINO-ACID REGULATION OF STRESS-INDUCED PROENKEPHALIN GENE EXPRESSION IN THE PVN

D. Borsook*, O. Falkowski, O. Smirnova, S.E. Hyman. Molecular and Developmental Neurobiology Laboratory, Mass. Gen. Hospital, Boston MA 02114

Proenkephalin (ENK) is expressed in the paraventricular nucleus (PVN) of the hypothalamus where it is regulated by a number of physiological stimuli. Excitatory and inhibitory amino acid neurotransmitters are present at high levels within the PVN and have putative roles in hypothalamic neuroendocrine regulation. Using a hypertonic stress paradigm in a transgenic mouse model expressing a proenkephalin-ß-galactosidase fusion gene, we have studied the effects of excitatory and inhibitory amino acids on the expression of the proenkephalin gene in the PVN under basal conditions or in response to a 1.5M saline stress. The GABA-ergic drugs aminoxoyacetic acid (AOAA, a GABA-transaminase inhibitor), GABA, or baclofen (a GABA-B agonist) all induced expression of the transgene at 6hrs following i.p. administration. Chronic (4 day) administration of AOAA inhibits both basal and stress-induced expression of the transgene. Muscimol (a GABA-A agonist) inhibits both basal and stress-induced expression of the transgene. MK-801 (a non-competitive NMDA antagonist) inhibits both basal expression and 1.5M saline stress-induced expression of the transgene. The excitatory amino acids, NMDA and kainate, do not induce proenkephalin gene expression in the PVN after acute or chronic (4 day) or administration. Alterations in transgene expression were compared with alterations in c-Fos expression in the PVN using the same paradigms *in vivo* and in hypothalamic cultures. A dissociation between transgene and c-Fos expression was seen following administration of some of these drugs. These results show that excitatory and inhibitory aminoacids can modulate basal and stress induced proenkephalin gene expression in the PVN and may be used to probe positive and negative transcriptional regulation of the proenkephalin gene in this model.

ACUTE STRESS ALTERS EXPRESSION OF IMMUNOREACTIVE INTERLEUKIN-1β IN THE MALE RAT HIPPOCAMPUS AND PARAVENTRICULAR HYPOTHALAMUS. **A. P. Ray*, N. Quan, J. M. Weiss and A. N. Clancy. Department of Psychiatry and Behavioral Sciences, Emory University Medical School, Georgia Mental Health Institute, 1256 Briarcliff Rd., Atlanta, GA 30306.**

The presence of interleukin-1β (IL-1β) in brain has been demonstrated in several recent studies. Other studies have suggested that brain IL-1β may mediate various responses to stress. This study examined stress-induced changes in IL-1β immunoreactivity in two brain areas implicated in stress response modulation: the hippocampus (HIP) and paraventricular hypothalamic nucleus (PVN). Rats, processed as matched pairs, were given either one hour of footshocks (experiment) or taken directly from their home cages (control). Brains were removed, sectioned and incubated in anti-rat IL-1β antibodies (RIL-1β Ab), anti-human IL-1β antibodies (HIL-1β Ab), or no primary antibodies (zero Ab control); sections were processed by the avidin-biotin-immunoperoxidase method. Optical density (OD) of labeling for IL-1β was measured by computer-assisted video densitometry. In the HIP pyramidal cell layer (CA1 and CA3), the OD of nonstressed rats (16.1 ± 1.93) was significantly greater (p<.04, n=9) than the OD of stressed rats (9.96 ± 1.99), while in the PVN the OD of nonstressed rats (5.58 ± 1.67) was significantly lower (p<.03, n=9) than the OD of stressed rats (12.5 ± 3.14). We conclude that, following exposure to acute stress, IL-1β was reduced in HIP pyramidal cells and increased in the PVN. This suggests that IL-1β is released in the hippocampus and is accumulated (possibly synthesized?) in PVN cells following acute stress. (Supported by NIMH Grant MH-50420).

NEUROPEPTIDE Y (NPY) GENE EXPRESSION DURING STRESS. S.P. Han*, X.L. Chen, Y.M. Wu, L. Naes and T.C. Westfall. Dept. Pharmacol. and Physiol. Sci., Saint Louis Univ. Health Sci. Ctr., St. Louis, MO 63104.

Hypertension is a multifactorial disease involving both environmental and genetic factors. A major environmental factor that has often been associated with hypertension is stress. Neuropeptide Y (NPY) is a vasoactive peptide that is co-synthesized and co-released together with catecholamines from sympathetic nerves and the adrenal medulla. Both NPY and catecholamines may be involved in mediating stress-induced increases in blood pressure and are potential links to hypertension, itself. In the present studies we have investigated changes in NPY gene expression resulting from insulin-induced hypoglycemic stress. Northern hybridization techniques were employed to detect changes in NPY mRNA abundance in the superior cervical ganglia (SCG) and the adrenal medulla. Subcutaneous injection of insulin produced dose-dependent increases in NPY mRNA abundance both in the SCG and the adrenal medulla. The hypoglycemia-induced increase in NPY gene expression in the SCG was attenuated by denervation of the ganglion. The hypoglycemia-induced increase in NPY gene expression was mimicked by direct activation of acetylcholine-nicotinic receptors produced by nicotine in a dose-dependent manner. NPY immunoreactivity (NPY-ir) was determined by radioimmunoassay. NPY-ir in the adrenal medulla was also increased following subcutaneous administration of nicotine. These results suggest that increased NPY mRNA levels during stress appear to be due to trans-synaptic activation of the post-ganglionic neurons. Increased synthesis and subsequent release of NPY may be partially responsible for the increased vascular observed during stress. (Supported by HL-26319 and HL35202)

ORAL ADMINISTRATION OF CORTICOSTERONE MIMICS EFFECTS OF STRESS ON HIPPOCAMPAL CA3c DENDRITIC STRUCTURE. A.M. Magariños*, M. Orchinik and B.S. McEwen. Lab. of Neuroendocrinology, Rockefeller University, New York, NY 10021.

The hippocampus undergoes plastic changes in response to stress. Following repeated stress, rats display deficits in spatial memory tasks and a corresponding atrophy in apical dendrites of CA3c neurons. One mediator of this structural change is corticosterone (CORT); injection of supraphysiological doses of CORT mimics the stress effect, and blockade of stress levels of CORT prevents stress-induced dendritic atrophy. In this study, we administered CORT in a non-stressful manner to isolate CORT effects from more generalized stress effects. Adrenally-intact male rats were administered either CORT (400 mg/ml) or vehicle (VEH; 2.4% EtOH) in the drinking water for 3 weeks. This protocol produced plasma CORT levels similar to that seen in stressed rats, although the normal diurnal rhythm of CORT release was disturbed. During this period, rats were either subjected to daily restraint stress (6 hrs/day) or undisturbed. At the termination of treatment, brains were processed for Golgi impregnation.The number of apical dendritic branch points in CA3c was significantly reduced in both stress/VEH- and nonstress/CORT-treated animals, relative to nonstress/VEH controls. The total apical dendritic length was also decreased, but not significantly, in both stress/VEH- and nonstress/CORT-treated animals. Interestingly, there was no tendency for a reduction in dendritic branch points or dendritic length in stress/CORT-treated rats. These data support the conclusion that physiological levels of CORT alone can induce dendritic atrophy, but also suggest that sustained exogenous CORT may modulate stress effects on hippocampal neuronal structure. Supported by MH41256 and NS07080 (B.S.M.).

VIP AND AVP mRNA EXPRESSION IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF THE RAT BRAIN FOLLOWING SHOCK STRESS. L. Zhou and R. F. McGivern*. Dept. of Psychology, San Diego State Univ., San Diego, CA 91920.

Vasoactive intestinal peptide (VIP) and arginine vasopressin (AVP) are expressed differentially in the SCN. VIP in the brain can be regulated by adrenal steroids (Rotsztejn et al, 1980) and VIP in the SCN has been suggested to regulate phase shifts in the circadian rhythm of locomotor activity of free-running rats (Albers et al, 1991). Therefore, we examined the level of AVP and VIP mRNA expression in the SCN, as well as the SON and PVN, in response to 30 minutes of stress. During the 3-4th hour of the light cycle (12:12), two or six month old male Sprague-Dawley rats were administered 15 seconds of intermittent shock (0.5 mA) every 5 minutes for 30 minutes. They were decapitated at 75 or 135 minutes after the onset of the shock-stress session. Control animals were placed in similar cages with no shock and sacrificed at the 75 minutes time point. Brains were removed and subsequently probed for AVP and VIP mRNA using *in situ* hybridization. The exonic probes were labeled with ^{35}S deoxyadenosine-5'- (-thio) triphosphate by terminal transferase enzyme. After hybridization with the probe (~1.10 x 10^6 cpm/µl), sections (16 µm) were dried and exposed to Hyperfilm B_{max} for 1 1/2 days for AVP, and for 2 1/2 days for VIP. Sections were dipped in nuclear emulsion and exposed for five and three days respectively. Results revealed a significant decrease in optical density of VIP mRNA expression in SCN at 75 and 135 min in response to the stress at both ages. In addition, there was a significant decrease in VIP with age. Analyses employing grain counts over single cells, revealed a significant decrease in the number of SCN cells expressing VIP mRNA following stress. However, no significant differences following stress were observed in AVP mRNA expression in the SCN, the SON and the PVN. Further studies have shown this stress will significantly phase advance the activity of free running animals under constant light conditions. Overall, these results indicate that stress can alter SCN gene expression and provide indirect support for the hypothesized role of VIP in regulation of phase shifts in circadian rhythms. RESTRAINT STRESS AND ACUTE ETHANOL ADMINISTRATION ALTER ENDOGENOUS LEVELS OF A NEUROACTIVE STEROID. D.A. Finn*, A.J. Roberts and J.C. Crabbe. VA Medical Center and Dept. Medical Psychology, Oregon Health Sciences University, Portland, OR 97201.

The GABA-agonist neuroactive steroid 3α-hydroxy-5α-pregnan-20-one (3α,5α-P) can reach endogenous levels which potentiate the action of GABA *in vitro*, suggesting that it may be a physiologically relevant neuromodulator. With the single exception of the report that 10 min. swim stress significantly increased brain and plasma 3α,5α-P, there are no available data regarding the influence of stressors on endogenous 3α,5α-P. Therefore, we measured the time course for changes in plasma 3α,5α-P and corticosterone (CORT) following 30 min. restraint stress and ethanol injection (4 g/kg) in genetically heterogeneous male mice. Restraint stress significantly increased plasma 3α,5α-P and CORT, which was evident immediately post-restraint (t = 30 min). Plasma 3α,5α-P remained significantly elevated at 60 min, while plasma CORT remained elevated at 60 and 90 min. Both steroids had returned to basal levels at the later time points (150 and 210 min). This result contrasts with the report that swim stress-induced increase in plasma 3α,5α-P did not occur until 60 min post-stress. Acute administration of ethanol produced a significant increase in plasma CORT at 0.5, 2 and 7 hrs post-injection and a significant decrease in plasma 3α,5α-P at 7 hrs post-injection. Withdrawal severity, measured by an increase in handling-induced convulsion scores peaked at 6 hrs and remained elevated at 12 hrs post ethanol. Collectively, these findings suggest that there are differences in the stress response, measured by plasma 3α,5α-P and CORT, depending on whether swim, restraint or alcohol withdrawal was the stressor. THE EFFECTS OF MICROGRAVITY ON GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) and BRAIN DERIVED NEUROTROPHIC FACTOR (BDNF) mRNA EXPRESSION IN THE RAT BRAIN. B. W. Prahl,* J. R. Day. Dept. of Biology, The Pennsylvania State University, University

The objective of this study was to examine the effects of microgravity on neurodegeneration in rats using GFAP and (BDNF) as markers. GFAP mRNA is a useful astrocytic marker that increases in response to injury, neurodegenerative disease, and aging. BDNF plays an important role as a growth factor in several neuronal populations. The rats in this study were also treated with Bone Morphogenic Factor (BMF) as part of an experiment to test this growth factor's actions on bone density loss in microgravity. Twenty-four ovariectomized adult female Fisher 344 rats obtained from NASA through the Penn State Center for Cell Research, were housed individually and divided into four groups:1) flight/vehicle-injected, 2) flight/BMF-injected, 3) ground/vehicle-injected controls, 4) ground/BMF-injected controls. The flight animals were exposed to microgravity (PSE4) for 14 days, and at the conclusion of the flight, brains were removed and frozen for *in situ* hybridization. Grain densities per cell were determined on emulsion coated slides via computer-assisted videodensitometry for different hippocampal strata. All flight animals showed a 40% decrease in GFAP mRNA compared to ground controls. There was no significant difference in GFAP mRNA expression between flight/BMF group and ground/BMF controls. BDNF mRNA levels were not significantly different in the flight group compared to the controls. The decreased GFAP mRNA expression might be due to elevated glucocorticoid levels induced by reentry stress and/or by microgravity itself. The altered GFAP expression suggests that exposure to microgravity might alter gene expression in the brain, particularly in astrocytes.

INHIBITION OF STRESS-INDUCED C-*fos* EXPRESSION IN THE RAT FOREBRAIN BY TRANSCRANIAL ELECTROSTIMULATION (TCES). G.P. Kozlowski and V.P. Lebedev*. Dept. Physiology, Univ. of Tex. Southwestern Med. Cen., Dallas, TX 75235 and Cen. for Research, Parker College, Dallas, TX 75229.

The effect of TCES on stress-related c-*fos* expression was determined using cranial subcutaneous needle electrodes in rat brains from animals that were either restrained (intensive stress-IS) or unrestrained (mild stress-MS). Control animals were untreated with TCES. MS and IS animals were stimulated for one hour with the Neurotrans unit using parameters of stimulation (70Hz, 3.5msec, 1.2ma) previously shown to ameliorate pain in rats (Fiziol Zhurn SSSR, 74:1094, 1988). c-*fos* immunopositive nuclei in several brain regions from all animals were manually counted in a systematic, reproducible fashion using stringent criteria established by one operator and confirmed by another. The brain regions studied were: 9 areas of the cortex (layers I-IV, V, VI), hippocampus, dentate gyrus, thalamus (6 nuc), habenula, hypothalamus (7 nuclei including the supraoptic-SO & paraventricular-PA) and 2 basal ganglia. Administration of TCES significantly inhibited stress-induced c-*fos* expression in most of the areas studied except for the centromedial thalamic and perifornical nuclei which had an insignificant increase in the number of c-*fos* neuronal nuclei. For example, c-*fos* neurons decreased ≈72.3% in magnocelluar cells of PA and ≈75.0% for SO. These results in experimental animals correlate with our previous data on antistress activity of TCES in human and other animals treated for gastric ulcer repair or alcohol withdrawal (Biogenic Amines 5:427, 1988). Supported by NIAAA AA-06014.

DIFFERENTIAL INDUCTION OF FOS PROTEIN FOLLOWING TAILPINCH OF YOUNG AND OLD MALE RATS. W.J. Smith, J. Stewart, and J.G. Pfaus*. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montréal, QC, Canada.

Tailpinch is a short-term stressor that induces a general arousal in the rat. This stimulation increases sensitivity to incentive cues, for example, making sated rats eat more, sexually sluggish male rats copulate, and can increase dopamine release in the nucleus accumbens. However, tailpinch becomes less effective with age. We were interested in examining where in the brain tailpinch might induce neural activation. Young (2 to 3 months) or old (one year) male rats were administered either 5 tailpinches (one every 2 min), 1 tailpinch, or sham treatment (n=4 per stimulation condition). Rats were sacrificed 1 hr following the onset of stimulation for histological analysis of Fos immunoreactivity. Serial coronal sections were taken from the area of the nucleus accumbens back to the central grey in each rat. Tailpinch produced a monotonic increase in Fos in a variety of brain regions, including the nucleus accumbens, striatum, lateral septum, lateral preoptic area, paraventricular hypothalamus (PVN), medial amygdala, ventral tegmental area (VTA), and central grey. A significant difference in Fos induction by age was found in the PVN and VTA, in that older rats had less Fos within these regions following both 1 and 5 tailpinches. The other areas are currently being counted and will be presented. These data indicate that tailpinch activates regions of the brain known to be involved in behavioral responses to different types of incentive cues. These data also suggest that the decrease in sensitivity to tailpinch in older animals may reflect a decrease in the ability ot this sitmulus to activate these different brain regions.

DIFFERENTIAL EXPRESSION OF FOS PROTEIN IN THE VENTRAL TEGMENTAL AREA OF COPING AND NON-COPING RATS. M.L. Coco* and J.M. Weiss. Dept. of Pharmacology, Duke Univ., Sch. of Med., Durham, NC 27710 and Dept. of Psychiatry & Behavioral Sciences, Emory Univ. Sch. of Med., Atlanta GA 30306.

We are interested in establishing the central pathways that underlie effective coping behavior. Previous studies have demonstrated the ability of Fos immunocytochemistry to detect neuronal areas of activation under a variety of conditions. Since rats able to perform a coping response in a stressful situation show different behavioral, neurochemical, and hormonal responses from rats unable to perform a coping response, we examined expression of Fos protein in the brains of coping and non-coping rats using immunocytochemical techniques. Feedback stimuli following performance of a coping response have been shown to be an important factor in establishing effective coping behavior, i.e., responses that in addition to removing a stressor also remove the negative physiological and/or behavioral effects of being exposed to the stressor. Quartets of Sprague-Dawley rats consisting of an Avoidance-escape animal able to control its shock and receiving a feedback stimulus following performance of the coping response (AE-FB), a Yoked animal receiving the same shocks and feedback but without control over them (Y-FB), a Yoked animal similar to Y-FB but without feedback (Y-NFB), and a Box-control animal placed in the same apparatus and receiving feedback but no shock (BC-FB), were given several training sessions over a period of weeks and then were exposed to a 1.5 h test session. The feedback stimulus was an 8 s compound stimulus consisting of lights off and a tone. Immediately after the test session, the rats were returned to their home cages. They were anesthetized 1 h later, followed by perfusion and fixation of their brains. A fifth, Home-cage control, rat was used to determine basal levels of Fos expression. Fos was visualized in 40 μm sections by the ABC immunoperoxidase method. Preliminary results indicate that Fos protein expression was increased in the ventral tegmental area of AE-FB rats compared to all other groups. Numbers of Fos-positive cells did not differ between AE-FB, Y-FB, and Y-NFB rats in the caudate-putamen or locus coeruleus.

EXPRESSION OF NEURONAL PLASTICITY-RELATED MARKERS IN HIPPOCAMPUS OF CONGENITAL LEARNED HELPLESS AND RESISTANT RATS UNDER CONDITIONS OF INESCAPABLE STRESS. G. A. Laforet†, E. Edwards⌖, J. A. King†, and D. T. Rivera.†* †Department of Psychiatry, Behavioral Neuroscience Division, University of Massachusetts Medical School, Worcester, MA 01655. ⌖Department of Pharmacology and Toxicology, University of Maryland, Baltimore, MD 21201.

Environmental stress requires adaptations in behavior and homeostasis to optimize survival. The central nervous system mediates stress responses not only by neurophysiological changes but also potentially by alterations in neuronal connectivity. Such changes may be particularly prominent in the hippocampus, a brain region implicated in learning and memory, and one which retains a high degree of plasticity into adulthood. This study investigates stress-related hippocampal plasticity in rats with learned helplessness, a well-studied paradigm which may model human stress-induced neuropsychiatric illness. Learned helpless rats fail to escape from avoidable shock after having been subjected first to inescapable shock. Strains of rats have been bred to foster either increased susceptibility (cLH) or resistance (cNLH) to development of learned helplessness. Hippocampal mRNA expression of plasticity markers F1/GAP 43 and SCG 10 was assessed in these animals using Northern blot analysis. A time course study of F1/GAP 43 and SCG 10 expression revealed differences in marker message levels between cLH and cNLH rats. In particular, F1/GAP 43 and SCG 10 mRNA levels were diminished 24 hours after two shock stress sessions in congenital learned helpless rats, but not in resistant animals. These results suggest that there may be genetically-based differences in patterns of central nervous system plasticity that underlie inherent vulnerability or adaptability to stress.

STRESS-INDUCED INCREASES IN REGIONAL BRAIN CONCENTRATIONS OF NEUROPEPTIDE Y-LIKE IMMUNOREATIVITY. F.B. JOLICOEUR*, P. C. SIMARD, R. LEDUC, J.P. BOULENGER, AND A. CADIEUX. Depts. of Psychiatry and Pharmacology, University of Sherbrooke, Sherbrooke, Qué., Canada, J1H 5N4.

Experimental evidence suggests an important implication of neuropeptide Y (NPY) in anxiety. For example, we have recently shown that NPY plasma concentrations were significantly higher in panic disorder patients (Society for Neuroscience abstr. 1994). To better understand the relationship between NPY and anxiety, we examined the effects of experimental stress on NPY concentrations in several brain regions in rats. Animals (male Long Evan rats, 250-275g) were separated into two groups (n=8): one control and one experimental stress. Animals were handled for 10 min. every day for four days prior to the experiment. On the fifth day, a standard restraint stress was imposed on experimental animals for one hour. Immediately after, dissection of the following regions was performed: nucleus accumbens, striatum, septum, hypothalamus, hippocampus, amygdala, frontal cortex and prefrontal cortex. NPY concentrations were measured by radioimmunoassay. Results revealed that, in comparison to control animals, NPY levels in stressed rats significantly ($p<0.05$) increased in septum (5.4 pmol/g vs 10.2 pmol/g), hippocampus (3.9 pmol/g vs 6.6 pmol/g), frontal cortex (5.9 pmol/g vs 7.8pmol/g), prefrontal cortex (5.8 pmol/g vs 10.8 pmol/g) and amygdala (4.5 pmol/g vs 15.4 pmol/g). The marked increase in the amygdala is interesting because of the well known involvement of this limbic region in anxiety. There were no significant differences between control and stressed animals in the other regions studied. The results of the present study support the hypothesis that NPY plays a functional role in anxiety. (Supported by le Reseau en Santé Mentale du Fonds de la Recherche en Santé du Québec).

THE STRESS-INDUCED POLYAMINE RESPONSE; ADAPTATION AND INHIBITION BY LITHIUM. **V.H. Gilad*, J.M. Rabey and G.M. Gilad.** Lab. of Neuroscience, Dept. of Neurology, Tel Aviv-Elias Souraski Medical Center, Tel-Aviv 64239, Israel.

As a transient increase in polyamine (PA) metabolism is a common response to stressful stimuli, our hypothesis is that a maladaptive PA response is involved in the pathophysiology of affective disorders. Previously, we found that, unlike peripheral tissues, the *acute* stress-induced PA response in the brain can be prevented by long-term (days), but not by short-term treatment with lithium. Based on the premise that *chronic* stress may best approximate stressful life events which can exacerbate affective disorders, our present findings demonstrate that in the rat brain, inescapable chronic intermittent stressor results in a recurring PA response. In contrast, in the periphery (liver), a similar stressor causes habituation of the PA response. The recurring brain PA response can also be blocked by long-term lithium treatment. Interestingly, immature rats do not show the characteristic brain PA-response. The ontogenesis of this effect is brain region-dependent. In general, the developmental switch to a mature PA response corresponds in time to the cessation of the "stress non-responsive period" in the pituitary-adrenocortical system. Our findings implicate an over-reactive PA response as a component of the adaptive, or maladaptive, brain response to stressful events, and as a novel molecular target for lithium action.

MOTOR ACTIVITY AND QUANTITATIVE AUTORADIOGRAPHIC STUDIES OF MUSCARINIC RECEPTORS IN THE BRAIN OF RATS SUBJECTED TO THE FORCED SWIMMING TEST. E. Carrizo[1], G. Cano[2], H. Suárez-Roca[1,2], E. Bonilla[1,2]*. [1]Instituto Investigaciones Clínicas, Universidad del Zulia and [2]Fundacite-Zulia, Maracaibo, Venezuela.

A cholinergic dysfunction has been involved in the neurobiological mechanisms of stress and depression. In addition, the Forced Swimming Test (FST) has been extensively used as an animal model of depression. In the present study, the distribution of muscarinic cholinergic receptors in the brain of rats subjected to the FST was determined to evaluate the cholinergic hypothesis of depression. Male Sprague-Dawley rats were subjected to the FST for 30 min daily during 15 days. The sham group was placed in the same conditions without swimming. Motor activity was automatically analyzed daily before swimming. Saturation studies were carried out in the presence of 8 increasing [^{3}H]-Quinuclidinyl benzilate ([^{3}H]-QNB) concentrations (0.0625-10 nM) in 0.05M PBS. Regional distribution of cholinergic muscarinic receptors was analyzed by autoradiographic methods, using 1 nM [^{3}H]-QNB. Non-specific binding was determined in the presence of 1μM atropine.

In the FST group, both total horizontal activity and ambulatory movements exhibited a significant decrease (34% and 46% respectively) when the data from 1st and 15th days were compared. [^{3}H]-QNB binding parameters were examined in the caudate-putamen, cortex and hippocampus. The Kd and Bmax values were very similar for both groups in the three analyzed areas, suggesting that neither the affinity of the [^{3}H]-QNB nor the maximal number of receptors were affected by the FST. The distribution of [^{3}H]-QNB binding sites did not show significant differences between both groups in the 30 studied areas. To rule out any cholinergic involvement, further analysis of muscarinic receptor subtypes after FST would be of interest since an alteration of one receptor subtype could be masked by [^{3}H]-QNB binding.

DRUGS OF ABUSE: COCAINE V

765.1

REPEATED ADMINISTRATION OF COCAETHYLENE PRODUCES SENSITIZATION TO ITS LOCOMOTOR EFFECTS

E. P. M. Prinssen*, M. S. Kleven and W. Koek. Centre de Recherche Pierre Fabre, Castres, France.

Cocaethylene, a metabolite resulting from combined ethanol and cocaine consumption, is a dopamine reuptake blocker and psychostimulant. That its effects, although similar, may not be identical to those of cocaine is suggested by the finding that, in rats, cocaethylene did not induce sensitization following repeated administration, nor did it induce cross-sensitization to cocaine, while the reverse was true for cocaine (Elsworth et al., Drug Dev Res 30, 189, 1993). To compare further the behavioral effects of repeated administration of cocaethylene, male C57BL/6J mice (n=5/group) were injected with cocaethylene (0, 10, 20, or 40 mg/kg, i.p.) for 3 consecutive days. On the 4th day, cocaethylene (0, 2.5, 10, 20, or 40 mg/kg, i.p.) was administered to all pretreatment groups. During daily sessions, mice were removed from their individual home cages and placed in an observation cage where locomotion was recorded for 30 min before and after injection using an automated activity monitor. Repeated injection of cocaethylene (10, 20, and 40 mg/kg/day x 3 days) produced apparent shifts of the cocaethylene dose-response function to the left, relative to that obtained in chronic saline treated animals. Cocaethylene pretreatment also induced an increase in the maximal effect compared to saline pretreatment (maximal beam breaks of 446 $\pm$ 53 and 205 $\pm$ 45, mean $\pm$ SEM, cocaethylene vs saline, respectively). These results demonstrate that cocaethylene produces a dose-dependent sensitization to its locomotor effects and, in this respect, is similar to cocaine which also showed sensitization under the present conditions. Therefore, together with the reported substitution of cocaethylene for cocaine in drug discrimination, the finding that cocaethylene, like cocaine, induces sensitization to its locomotor effects, suggests that both drugs share effects not only after acute, but also after chronic administration.

765.2

DIFFERENCES IN OPERANT BEHAVIOR OF RATS RUNNING FOR COCAINE VS COCAETHYLENE.

M. A. Raven*, B. D. Necessary, D. A. Danluck and A. Ettenberg. Behavioral Pharmacology Lab, Department of Psychology, University of California, Santa Barbara, CA 93106

The effects of cocaethylene, a psychoactive metabolite of cocaine produced in the presence of ethanol, were compared to cocaine using an operant runway self-administration paradigm. Rats were trained to traverse a straight-arm alleyway one trial per day for a single iv injection of cocaine or cocaethylene (0.5, 0.75, 1.0 or 2.0 mg/kg/inj). Infrared sensors located throughout the length of the runway were used to record the latency to initiate running (start latency), the time to enter the goal box (run time) as well as the intra-alley behavior of the animals. Although start times remained stable and fast, both drug groups demonstrated some ambivalence (approach-avoidance behavior) about entering the goal box. The incidence of this behavior, however, tended to increase with dose for cocaine and decrease with dose for cocaethylene. It is hypothesized that the strength of the positive relative to negative drug effects may be greater for cocaethylene than for cocaine, especially at higher doses.

765.3

COCAETHYLENE EXPOSURE DURING THE BRAIN GROWTH SPURT INDUCES BRAIN WEIGHT DEFICITS. W.-J.A. Chen*, R.L. Hernandez and J.R. West. Human Anatomy & Medical Neurobiology, Texas A&M University Health Science Center, College Station, TX 77843-1114

The increased prevalence of alcohol and cocaine abuse among women of reproductive age has received considerable attention since the concurrent use of these two substances results in the exclusive formation of a pharmacological active substance, cocaethylene (CE). Presently, it is unclear whether and, under what conditions, fetal/neonatal hepatic microsomal carboxylesterase activity is capable of transesterifying cocaine to CE in the presence of alcohol. Therefore, in this study we examined the direct action of CE, rather than the co-administration of alcohol and cocaine, on brain growth restrictions (microencephaly) during the major portion of the brain growth spurt. Three groups of artificially reared pups were given one injection of either 0, 10 or 20 mg CE (s.c.) daily, from postnatal days (PDs) 4 through 9. One group of normally reared pups (suckle control; SC) was included. All pups were perfused on PD 10 and the brains were removed and dissected into forebrain, cerebellum and brainstem. The analyses indicated that daily administration of either 10 or 20 mg CE produced a statistically significant restriction on brain growth in all three brain regions compared with the 0 mg CE group. However, no difference in brain weight deficits was found between two CE groups. Separate analyses between 0 mg CE and SC groups revealed no difference in brain measures. These results suggest that cocaethylene is teratogenic to the developing fetus and the concurrent use of alcohol and cocaine during pregnancy may be more harmful due to the unique formation of cocaethylene in addition to the intrinsic teratogenic effect of cocaine and alcohol individually. Supported by NIH grant DA07364.

PARTIAL DOPAMINE AGONISTS REDUCE ETHANOL INTAKE IN THE RAT L. Pulvirenti[1,2]*, C. Balducci[3], G. Bono[3], P. Richelmi[3] and G.F. Koob[1] [1]Dept. of Neuropharmacol., Scripps Res. Inst., La Jolla, Calif., [2]"Mondino-Tor Vergata" Ctr for Exp Neurobiol, Un. of Rome "Tor Vergata", Rome, [3]"C. Mondino" Fndtn., Pavia, Italy.

Ethanol is known to activate brain dopamine neurotransmission and the acute reinforcing properties of ethanol appear to be modulated by administration of drugs acting at the dopamine receptor site. Partial dopamine agonists are a recently characterized group of compounds which bind to dopamine receptors with high affinity and low intrinsic activity. These drugs act as functional antagonists in conditions of high dopamine tone, while they show an agonistic profile in conditions of dopamine depletion (e.g. denervation). The aim of the present study was to evaluate the effects of acute and chronic pretreatment with terguride and SDZ 208-911, two prototype partial dopamine agonists, in non-fluid deprived rats trained to drink alcohol (10 v:v) in a free-choice procedure. Acute treatment with both SDZ 208-911 (0.025-1.6 mg/kg) and terguride (0.025-4.0 mg/kg) dose-dependently reduced the reinforcing properties of ethanol as measured by lower intake. Similarly, chronic (10-day) treatment with both SDZ 208-911 or terguride (0.2 mg/kg) induced a significant reduction of ethanol intake. In no case was water intake affected thus ruling out possible nonspecific effects of these drugs on motor performance of consummatory behavior. Therefore, the unique pharmacological profile of partial dopamine agonists supports the hypothesis that these drugs may represent a novel potential therapeutic strategy for normalizing dopamine tone during the various phases of the natural history of drug dependence including alcoholism.

Effects of chronic alcohol and cocaine administration on brain gene expression. **German Torres* and Judith Pielecha. Behavioral Neuroscience Program. Department of Psychology. State University of New York at Buffalo. Buffalo, New York 14260.**

The concomitant use of alcohol and cocaine is the most common abuse pattern found in the addictive population. We have recently shown that this combination produces an antagonistic effect at the gene level, with alcohol blocking the transcription of *c-fos* by cocaine in brain neurons (G Torres, Synapse 18, October 1994). To explore this effect further, we investigated the long-term effects of combined alcohol and cocaine exposure on *c-fos* in discrete areas of the rat brain. Male rats were given a liquid diet containing alcohol (8.7%) for 15 days. Each night, two hr after the onset of darkness, the same rats were injected (ip) with cocaine (20 mg/kg). In addition, we determined the effects of cocaethylene (a psychoactive metabolite of cocaine produced by a liver carboxylesterase when alcohol is administered in conjunction with cocaine) on gene expression in order to compare its relative effects to those of alcohol and cocaine. Administration of alcohol and cocaine produced significant levels of plasma cocaethylene as detected by capillary gas chromatography and mass spectrometry. Further, chronic alcohol exposure markedly altered the induction of gene expression by cocaine in caudate putamen perikarya. The systemic injection of cocaethylene (20 mg/kg) also produced changes in *c-fos* in various regions of the rat brain including the caudate putamen, nucleus accumbens and cerebellum. Alcohol alone, in contrast, had no effect on gene transcription. Taken together, our data suggest that alcohol exerts a powerful inhibitory effect on cocaine actions, and that cocaethylene alone produces genomic effects similar to those seen after cocaine exposure.

HUMAN COCAINE SELF-ADMINISTRATION: USE OF AN ALTERNATIVE REINFORCEMENT PROCEDURE TO EXAMINE POLYDRUG EFFECTS. John M. Roll*, Stephen T. Higgins, and Angela J. Desranleau. Dept. of Psychiatry, Human Behavioral Pharmacology Laboratory, University of Vermont, Burlington, VT 05401-1419.

A choice pardigm in which volunteers select from cocaine, placebo, alternative reinforcers (money) or elect not to respond will be described (See Higgins, et al., 1994 Life Sciences). This sensitive procedure demonstrates that cocaine self-administration varies as an orderly function of the magnitude of an alternative reinforcer (i.e., money). Said another way, as the magnitude of alternative reinforcer increases, cocaine self-administration decreases. This relationship provides a sensitive baseline to examine whether the effects of pretreatment with other drugs alters the behavioral control exerted by cocaine. Such an assessment is important because cocaine is frequently used in combination with other drugs of dependence. To date we have assessed the effects of ethanol pretreatment and have begun to assess the effects of caffeine pretreatment. Results indicate that both drugs alter preference for cocaine self-administration.

Characterization of a Novel Cocaine and Amphetamine Regulated Transcript (CART) P. Couceyro*†, M. Shoaib^, M. McCoy†, S. Goldberg^, M.J. Kuhar† Intramural Research Program, Neuroscience Branch†, Preclinical Pharmacology Lab^, Natl. Inst. Drug Abuse, NIH, Baltimore, MD 21224

Psychostimulant drugs such as cocaine and amphetamine can alter patterns of gene expression within neuroanatomical sites known to mediate drug reinforcement. Using PCR differential display, we previously identified a novel transcript (CART) rapidly induced only within the striatum by acute cocaine and amphetamine administration. In these studies, transcriptional regulation of CART was first assessed in the cocaine self-administration model. In limited daily access, Sprague-Dawley rats were trained to self-administer cocaine (0.66 mg/kg/infusion, i.v.) under a fixed ratio 3 schedule of reinforcement. Once behavior was maintained and response rates were stable for 5 consecutive days (less than 10% variability), animals were sacrificed 1 hr. after the last session. In 4 of 6 groups of animals, there was approximately a 50% reduction in CART mRNA levels in the nucleus accumbens (determined by Northern blot analysis) of rats self-administering cocaine compared with their saline-yoked controls. These data suggest a possible role for CART gene products in mediating the reinforcing properties of cocaine. Secondly, we now have evidence that passive acute cocaine and amphetamine administration increase CART mRNA levels within the nucleus accumbens and not in the caudate putamen.. The induction of CART by acute cocaine and amphetamine administration has been inconsistent, however. Future work will address this issue. Third, stress is known to alter the behavioral effects of drugs of abuse in animal models. We have begun to assess the effects of acute stress on CART expression. Within the nucleus accumbens, CART expression was decreased 1 hr. after either an i.p. saline injection, a 10 min. cold water swim and after 10 min. restraint. However, within the hypothalamus, CART mRNA levels were elevated by an i.p. saline injection, decreased after the cold water swim and unchanged by restraint. These studies strengthen the notion that CART may be involved in mediating the rewarding affects of cocaine and also indicate a role in response to stress.

765.8

DIFFERENTIAL EXPRESSION OF C-FOS FOLLOWING EXPOSURE TO A COCAINE- OR d-AMPHETAMINE-PAIRED ENVIRONMENT. **M.A. Klitenick*, C.-S. Tham and H.C. Fibiger. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1Z3**

The attribution of incentive salience to a drug-paired environment is of considerable clinical interest as drug craving can result from the presentation of stimuli previously associated with the effects of cocaine or d-amphetamine. In the present study regional expression of *c-fos* was examined immunohistochemically in rats exposed to an environment previously paired with either cocaine (10 mg/kg, i.p. X 10 days) or d-amphetamine (1.5 mg/kg, i.p. X 10 days). In addition to the conditioned motor-stimulant response elicited in animals exposed to the cocaine- or d-amphetamine-paired environment, *c-fos* expression was significantly increased in the cingulate and piriform cortices, claustrum, dorsomedial striatum, lateral septum, paraventricular nucleus of the thalamus and amygdala in those animals in which cocaine was previously paired with the environment. In addition, *c-fos* expression was significantly increased in the piriform cortex, dentate gryus and amygdala only in animals that were placed in an environment previously paired with d-amphetamine. These results indicate that the pattern of neuronal activation elicited by conditioned stimuli previously paired with d-amphetamine differs somewhat from that produced by a cocaine-paired environment. In contrast, acute administration of cocaine and d-amphetamine produce similar patterns of *c-fos* expression. Interestingly, although the nucleus accumbens is necessary for the unconditioned locomotor effects of cocaine and d-amphetamine, *c-fos* expression in this structure was not significantly altered by the contextual conditioned stimuli associated with either drug, thus indicating that different circuits may be involved in the conditioned and unconditioned effects of cocaine and d-amphetamine.

PLASMA CONCENTRATIONS OF COCAINE AND BENZOYLECGONINE FOLLOWING INTRAVENOUS COCAINE ADMINISTRATION. A.E. McCrea*, A.F. Lehner, R.M. Booze and C.F. Mactutus, Univ. of Kentucky College of Medicine, Dept. of Pharmacology, College of Pharmacy, THRI and Graduate Center for Toxicology, Lexington, KY 40536.

Following either s.c. or i.p. injection, plasma cocaine concentration is characterized by slow first order kinetics and prolonged elevation. The present study examined the plasma concentrations of cocaine and benzoylecgonine (BE) following a single i.v. injection of 0.5 mg/kg, 1.0 mg/kg or 3.0 mg/kg cocaine. Male Sprague-Dawley rats (N=32) were fitted with a subcutaneous vascular access port (Mactutus et al., 1994) and allowed to recover for at least 3 days. Plasma samples (200 µl) were obtained at 8 time points (30, 60, 90, 120 seconds and 5, 10, 20, 30 minutes) following injection and analyzed by single ion monitoring using GC/MS. Derivatization of BE to the trimethylsilyl ester (TMS) was performed prior to analysis and the 240/243 m/e ion pair ratio was interpolated to a 9 concentration (0-10,000 ng/ml) standard curve. Identical SIM procedures were established utilizing the cocaine 182, 198, 272 and 303 m/e ion pairs and the plasma concentration of cocaine was determined by the interpolation to the 185 m/e peak of cocaine-d_3. Peak plasma concentrations of cocaine occurred at 30 seconds in a dose-dependent manner (3.0>1.0>0.5 mg/kg). In both 0.5 and 1.0 mg/kg cocaine groups, plasma concentrations decreased to <200 ng/ml by 10 minutes, yet the 3.0 mg/kg group remained elevated (>500 ng/ml) for longer than 20 minutes. Plasma concentrations of BE reached a plateau in the 0.5 mg/kg (80-90 ng/ml) and the 1.0 mg/kg group (160-170 ng/ml) within 10-20 minutes whereas the concentration of BE in the 3.0 mg/kg group was increasing at 30 minutes (>500 ng/ml). The close parallel of the present data to human cocaine kinetics (Evans et al., 1994) indicates the s.c. vascular access port model of i.v. cocaine administration offers a viable alternative to i.p. or s.c. routes for the study of behavioral modifications and neuropharmacology following cocaine administration. DIFFERENTIAL ACTIONS OF COCAINE AND AMPHETAMINE ON SOMATOSENSORY CORTICAL NEURONS. F.M. Sessler*, T.N. Felder, J. Zhai, F.-C. Hsu, R.C.-S. Lin, B.D. Waterhouse, and J. Lehmann. Depts. Of Anat. & Neurobiol., and Neurosurg., Med. Col. Of Pennsylvania and Hahnemann Univ., Philadelphia, PA 19102

Cocaine and amphetamine have both psychostimulant properties. Some of their effects have been related to an enhancement of monoaminergic transmission by blockade of reuptake and/or direct release of monoamines. The question whether these two compounds produce similar or differential actions on sensory cortical circuits and pyramidal neurons membrane was investigated here. Experiments were conducted using an in vitro brain slice preparation from rat somatosensory cortex. Intracellular recordings of cortical neurons were made before, during and after bath application of cocaine or amphetamine (0.1-100µM). EPSPs were evoked by electrical stimulation of the underlying white matter. At low concentration (0.1-1µM), both cocaine an amphetamine increased spike firing probability and EPSP amplitude of cortical neurons. At higher concentrations (10-100µM), bath application of cocaine was predominantly inhibitory whereas amphetamine produced both excitatory and inhibitory effects over these same parameters depending on the cell tested. These results suggest that different monoamines system may be involved with higher concentrations of amphetamine. Also, cocaine-induced local anesthetic action may interact and cancel psychostimulant effects of the drug on cortical circuits. Furthermore, identification of vulnerable cell types may be a necessary step in predicting the impact of these drugs on somatosensory cortical circuits. (Supported by NIDA DA08405 to FMS and DA05117 to BDW).

PRECLINICAL ASSESSMENT OF THE POTENTIAL USE OF METHYLPHENIDATE AS A TREATMENT FOR COCAINE ABUSE C. McNamara* and S. Schenk, Texas A&M University, Dept. Psychology, College Station, TX 77843

Three different self-administration paradigms were used in an assessment of the potential use of methylphenidate as a substitution pharmacotherapy for the treatment of cocaine abuse. In the first, rats were trained to self-administer cocaine and then were treated with methylphenidate (0.0 or 20.0 mg/kg) immediately prior to daily 2 hr sessions. Methylphenidate reduced cocaine-reinforced responding across a wide range of cocaine doses (0.03-0.50 mg/kg/infusion) to control levels suggesting that the reinforcing effects of cocaine were completely blocked by pretreatment with methylphenidate. However, methylphenidate was reliably self-administered and, in a model of drug seeking behavior, it dose-dependently reinstated extinguished cocaine-taking. Taken together, these data suggest that methylphenidate can effectively block cocaine self-administration. However, the drug has potential for abuse, as indicated by its self-administration and may serve as a cue to reinstate drug-seeking behaviors.

rGβ: A NOVEL RAT G PROTEIN β SUBUNIT WHOSE EXPRESSION ALTERS PROCESS FORMATION IN SHY5Y CELLS **@#G.R.Uhl,* X.B.Wang@.. Mol. Neurobiol. Br.@, IRP, NIDA, NIH; Dept. #Neurol. & Neurosci., JHUSM, Balto., MD 21224.**

βγ dimers resulting from G protein activation may transduce cellular signals from a variety of extracellular stimuli, including abused drugs. During searches for drug-regulated genes, we identified a partial cDNA clone that demonstrated striking regulation by psychostimulants and morphine as 80% homologous to 3' sequences of the human G protein β_1 subunit. Screening produced a 2.9 kb cDNA that contained an open reading frame of 1020 bp sequence and a predicted amino acid sequence 98% identical to the hGβ_1 sequence but only 72% or less identical to previously-reported rat Gβ sequences. This apparent rat G protein β_1 subunit was expressed most strongly in brain, with different levels noted in different brain regions. Striking morphological changes were observed when mRNA sense and antisense rGβ_1 constructions were expressed in SY5Y neuroblastoma cells. Transfection with mRNA sense rGβ_1 resulted in slow growth and loss of neuronal-like processes from these cells. In contrast, cells transfected with the antisense construction displayed more vigorously extended neural process and expanded growth cones. If these *in vitro* findings are reproduced in neurons, rGβ_1 may play a significant role in drug-induced synaptic plasticities.

GENES REGULATED BY PSYCHOSTIMULANTS AND MORPHINE IN BRAIN *X.B.Wang*@, H. Ujike@, J.T.You@ and G.R.Uhl#@*. @Mol. Neurobiol. Br., IRP, NIDA, NIH; #Dept. Neurol. & Neurosci., JHUSM, Balto., MD 21224

Although molecular mechanisms establishing or maintaining long-term behavioral changes induced by abused drugs are largely unknown, drug-induced alterations in neuronal gene expression could play significant roles in these manifestations of neuronal plasticity. We have used subtracted differential display PCR to identify an initial set of 20 genes characterized by altered expression following psychostimulants or morphine. Differentially-expressed cDNAs hybridize to mRNAs ranging in size from 0.5 to 12kb. Six display brain-specific expression. Sequence analyses reveals several with homologies to neurotransmitter receptor, intracellular signal transducing factor, and stress responsive enzyme gene families. These and other drug-regulated cDNAs encode candidate genes for involvement in long term CNS changes induced by abused drugs.

FACILITATION OF BRAIN STIMULATION REWARD BY MILDLY PSYCHOACTIVE SUBSTANCES: A QUANTITATIVE COMPARISON WITH PROTOTYPIC ADDICTIVE DRUGS. M.A. Bozarth*, C.M. Pudiak, & R. KuoLee. *Department of Psychology, University at Buffalo, Buffalo, NY 14260-4110.*

Considerable evidence suggests that a compound's effect on brain stimulation reward (BSR) provides a useful assessment of its potential addiction liability. Drugs that enhance BSR are generally highly addictive, and drugs that are not addictive usually fail to enhance BSR. Most investigators consider this a qualitative indicator: BSR facilitation suggests the drug has addictive properties. However, earlier work (M.A. Bozarth, *Intracranial self-stimulation as an index of opioid addiction liability* . . . . Unpublished M.A. thesis: RPI, 1978) suggested that quantitative aspects of facilitation may be important in distinguishing compounds with high and low addiction liabilities. The present study examined the facilitatory effects of three compounds: the prototypic addictive drug cocaine, the nonaddictive decongestant pseudoephedrine, and nicotine.

Male, Long-Evan rats with lateral hypothalamic stimulating electrodes were tested using a threshold tracking procedure. Daily 30-min test sessions determined the minimum stimulation frequency necessary to maintain responding at ≥30 presses/min. Cocaine hydrochloride (1 to 30 mg/kg, i.p.), pseudoephedrine hydrochloride (3 to 100 mg/kg, i.p.), or nicotine bitartrate (0.125 to 1 mg/kg, s.c.) were injected immediately before threshold tracking. All drug injections were separated by a minimum of 72 hrs. Peak threshold-lowering effects were determined using 180-min test sessions.

Cocaine produced robust threshold lowering. Pseudoephedrine also lowered BSR thresholds, but this effect was much less than that seen with cocaine (i.e., <25% vs. >50% threshold reduction, respectively). Nicotine produced facilitation quantitatively similar to that seen with pseudoephedrine and distinct from the effect seen following cocaine. These data suggest that quantitative aspects of facilitation must be considered to distinguish compounds with a high addiction liability (e.g., cocaine) from substances with a low addiction liability (e.g., pseudoephedrine). These data further suggest that nicotine's profile in this animal model is that of a nonaddictive substance.

765.15

THE EFFECTS OF MEDIAL PREFRONTAL CORTEX LESIONS ON COCAINE SELF-ADMINISTRATION AND CONDITIONED COCAINE-SEEKING BEHAVIOUR IN RATS. R. Weissenborn*, T.W. Robbins and B.J. Everitt
Department of Experimental Psychology, University of Cambridge, Cambridge CB2 3EB, UK

The medial prefrontal cortex (mPFC) may have an important function in mediating the reinforcing effects of psychostimulant drugs - most likely through its role within corticostriatopallidal feedback loops and specifically through its afferent connections with the ventral striatum. The present series of experiments was designed to examine in detail the involvement of the mPFC in different aspects of conditioned and unconditioned cocaine-seeking behaviour in rats. Quinolinic acid-induced excitotoxic lesions of the mPFC resulted in significantly shorter inter-injection intervals and higher response rates during the acquisition and maintenance of i.v. cocaine self-administration, compared to sham-lesioned controls ($p<0.05$). This lesion effect was specific to cocaine-reinforced responding, since both groups extinguished responding on a control lever at the same rate. Within- and between-session dose-effect curves to cocaine were also determined. Medial PFC lesions produced significant increases in response rates both on the ascending limb and at the top of the descending limb of the inverted U-shaped dose-effect curve, but no shift to the left of the entire function was observed. When responding resulted in saline infusions only, lesioned rats continued to discriminate between active and inactive levers, while control rats responded on both levers at equal rates. Together, these observations support the hypothesis that excitotoxic lesions of the mPFC may enhance the propensity for perseverative responding rather than alter cocaine's ability to maintain operant responding. Preliminary data further suggest that mPFC lesions may impair responding maintained by conditioned reinforcers under second-order schedules of cocaine reinforcement, indicating a deficit in the extent to which cocaine-seeking behaviour is controlled by drug-associated cues. This work was supported by MRC Grant G9407194N.

OPENFIELD AND PASSIVE AVOIDANCE BEHAVIOR OF YOUNG ADULT RATS PRENATALLY EXPOSED TO COCAINE, ETHANOL OR BOTH DRUGS OF ABUSE. K. Foley* and C. Ulibarri, Dept of VCAPP, Washington State University, Pullman WA 99164-6520.

Drugs of abuse such as cocaine and alcohol are known to cause behavioral deficits. When cocaine and alcohol are abused simultaneously, the transesterification product, cocaethylene, is formed. Cocaethylene is more potent than cocaine in some systems, and is known to cross the placenta barrier. Few studies have characterized the effects of alcohol and cocaine used concurrently in an animal model. In this study, the effects of prenatal exposure to cocaine, alcohol, or both drugs of abuse on activity in an openfield as well as memory retention in a passive avoidance paradigm were studied. Timed-pregnant Sprague-Dawley dams were treated on gestational days 11-21 with one of the following: 1) free-fed 2) nutritionally matched to drug-treated dams (pair-fed) 3) cocaine (20 mg/kg) 4) low dose of alcohol (EtOH-lo; 30% of calories as alcohol) 5) high dose of alcohol (EtOH-hi; 60% of calories as alcohol), 6) EtOH-lo and cocaine, 7) EtOH-hi and cocaine. At birth, pups were fostered to surrogate dams to avoid possible maternal postnatal effects of the drugs. As adults, rats were tested in four weekly openfield behavior tests followed by training on a standard dark-light passive avoidance paradigm.

In openfield behavior tests males from the EtOH treatment groups demonstrated significantly reduced margin time as compared to pair-fed controls. These males also had a significantly increased level of horizontal activity and a significantly decreased level of vertical activity. In a passive avoidance paradigm, males showed a significantly greater latency to enter after shock conditioning than females. Alcohol treatment significantly increased the latency to enter in the passive avoidance paradigm. THE RELATIONSHIP BETWEEN COCAINE SELF-ADMINISTRATION AND SACCHARIN PREFERENCE. B.A. Gosnell*, D.D. Krahn and J.M. Yracheta.
Department of Psychiatry, University of Wisconsin-Madison, Madison, WI 53792.

Previous research suggests a positive relationship between saccharin preference and the self-administration of ethanol (orally) and morphine (i.v.) in rats. This experiment was performed to determine whether a similar relationship exists between saccharin preference and cocaine self-administration. Male rats (n=32) were given *ad lib* access to saccharin and water for 4 days. Total daily fluid intake over days 3-4 was then expressed as a percentage of intake when only water was available. Rats varied in the degree to which saccharin increased total intake, with values ranging from 99 - 237% of baseline water intake. Jugular catheters were then implanted in all rats. After recovery, cocaine self-administration was measured in an overnight session (18 hr, FR 1 schedule, 0.4 mg/kg/infusion with a cutoff of 80 mg/kg). Some rats (n=8) across the entire range of saccharin preferences obtained the maximum number of infusions. Interestingly, of the remaining 24 rats, those with intermediate saccharin preferences self-administered more cocaine than rats with low or high preferences; in these rats, the difference between low and intermediate rats was significant ($p<0.05$). Following the overnight session, all rats were tested in daily 1 hr sessions at doses of 0.125 - 1.0 mg/kg/infusion and with reinforcement schedules of FR1 - FR6. A significant relationship between saccharin preference and cocaine self-administration was observed only under conditions of a FR 6 schedule combined with a low dose (0.125 mg/kg/infusion). Under these conditions, rats from the middle third of the distribution of saccharin preferences self-administered more cocaine than rats in the upper or lower thirds. This "inverted U"-shaped relationship between saccharin preference and cocaine self-administration differs from that observed with ethanol and morphine. These results may be related to the observation by Glick et al. (Brain Res. 653:148-154, 1994) of a curvilinear relationship between baseline levels of dopamine in the nucleus accumbens and cocaine self-administration.

PREEXPOSURE TO COCAINE ATTENUATES COCAINE-INDUCED TASTE AVERSIONS. H.F. Diamond* and A.L. Riley.
Psychopharmacology Laboratory, Department of Psychology, The American University, Washington, DC 20016.

Animals exposed to one of a number of compounds prior to taste aversion conditioning with those compounds display attenuated aversions relative to nonpreexposed subjects. In the present experiment, the effect of exposure to cocaine on cocaine-induced aversions was assessed. Cocaine was examined within this preparation because in other designs chronic exposure to cocaine potentiates (or sensitizes) subsequent responsivity to cocaine. In the present design, rats were administered cocaine (32 mg/kg, SC) or vehicle every fourth day for a total of five drug exposures. Animals were then given a novel saccharin solution to drink and immediately injected with cocaine (32 mg/kg, SC) or the distilled water vehicle. Animals preexposed to vehicle and injected with cocaine during conditioning rapidly acquired a taste aversion to cocaine. Animals preexposed to cocaine and injected with cocaine during conditioning failed to acquire a taste aversion, drinking at levels comparable to controls (i.e., subjects preexposed to cocaine but injected with vehicle and subjects preexposed to the vehicle and injected with vehicle). Similar to other drugs within this preparation (both abused and nonabused), cocaine preexposure weakens (and does not potentiate) subsequent cocaine-induced taste aversions.

766.3

THE INTERACTION OF ALCOHOL AND COCAINE IN TASTE AVERSION CONDITIONING. B.-F. X. Sobel*, S. A. Etkind, W. E. Fantegrossi and A. L. Riley. Psychopharmacology Laboratory, Department of Psychology, The American University, Washington, DC 20016.

In prior work (Sobel & Riley, Coll. Prob. Drug Dep., 1994), we have demonstrated that doses of alcohol and cocaine without effect on schedule-controlled behavior markedly suppressed responding when given in combination, an effect consistent with work from a number of other behavioral and physiological preparations in which alcohol has been reported to potentiate the effects of cocaine. In the present experiments, the interaction of these compounds was assessed within the taste aversion preparation, a behavioral index of toxicity. In Experiment 1, different groups of rats were given 20-min access to a novel saccharin solution followed immediately by an injection of either alcohol (0.56 g/kg, ip), cocaine (25 mg/kg, sc), the distilled water vehicles or the alcohol/cocaine combination. Although neither drug alone (nor the vehicle injections) induced a taste aversion, animals injected with the combination markedly decreased saccharin consumption, acquiring an aversion to saccharin after only two saccharin-alcohol/cocaine pairings. Interestingly, alcohol did not potentiate cocaine-induced aversions when cocaine was given ip, although the same combination dramatically affected schedule-controlled behaviors (Experiment 2). These data indicate that the interaction of alcohol and cocaine (when administered subcutaneously) extends to indices of toxicity.

COCAINE HAS DIRECT EFFECTS ON THE CORTICOTROPHS (AtT-20) L.M. Konopka*, R.J. Wong, S.M. Delisi and J.W. Crayton. Biological Psychiatry Section,
Hines VA /Loyola Strich Sch. of Med., Hines, Il 60141.

Cocaine abuse is a major public health problem. Cocaine addicts frequently present with psychiatric as well as neuroendocrine abnormalities. Cocaine's influence on the neuroendocrine system has been investigated. Primary research efforts have been directed towards elucidating the hypothalamic mechanisms of cocaine's action. To date however, no studies addressed direct effects of cocaine on the pituitary cells. We have selected a well-characterized model of anterior pituitary corticotrophs, the AtT-20/D16v cell line, to elucidate the direct effects of cocaine on a single component of the neuroendocrine system. Whole cell recordings utilizing current and voltage clamp techniques was employed. In addition, intracellular calcium was measured by means of Fura-2 imaging techniques. Images of both cell populations and single cell recordings were acquired. Application of cocaine (300 nM - 3 micM) resulted in inhibition of spontaneous firing. This inhibition was associated with significantly increased outward and to lesser extant inward currents. Results from the population based calcium recordings indicated cocaine induced increase in the resting calcium levels. Single cell recordings support the population studies. The results of this study point to a complex mode of cocaine's action on the pituitary corticotrophs and its possible role in the modulation of the excitation secretion processes.

766.5

THE EFFECTS OF REPEATED COCAINE ADMINISTRATION ON PERGOLIDE-INDUCED ENDOCRINE RESPONSES IN HUMAN DRUG USERS. M.H.Baumann*, K.M.Becketts, T.M.Gendron, J.E.Henningfield, D.A.Gorelick and R.B.Rothman. Clinical Pharmacology Lab., IRP, NIDA, NIH Baltimore, MD 21224.

Preclinical evidence indicates that chronic cocaine exposure alters dopamine (DA) neurotransmission. In the present study, we examined the effects of repeated intranasal cocaine administration on DA function in human subjects in an in-patient research study. Male polydrug abusers (N=11) participated in 2 daily self-administration sessions (AM & PM) for 5 consecutive days. Subjects snorted both placebo and cocaine (96 mg) each day, with cocaine being presented in a randomized, double-blind fashion at 1 of the daily sessions. Neuroendocrine challenge tests were performed using the DA receptor agonist pergolide (0.1 mg, p.o.) 5 days before and 3 days after the repeated cocaine dosing regimen. Repeated blood samples were drawn at 30 min intervals from 1 hr before until 6 hr after pergolide challenge. Plasma prolactin (PRL) and growth hormone (GH) concentrations were determined by RIA. Pergolide decreased circulating PRL and increased GH. No significant differences in responsiveness to pergolide were found between the pre- and post-cocaine condition. Our data suggest that repeated doses of intranasal cocaine do not modify DA receptor sensitivity in human drug users.

766.6

INFLUENCE OF CORTICOSTERONE ON THE PSYCHOMOTOR EFFECTS OF COCAINE: A DOSE-RESPONSE STUDY. M. Marinelli, F. Rougé-Pont, M. Le Moal and P.V. Piazza*. INSERM U. 259, Université de Bordeaux II. 33077 Bordeaux Cedex, France.

Adrenalectomy (ADX) is known to reduce the behavioral effects of cocaine whereas replacement of corticosterone in the range of basal diurnal levels reverses these effects. This study further investigated the relationship between corticosterone (CORT) and sensitivity to psychostimulants. For this purpose, in a first experiment we studied the effects of ADX on the locomotor response to different doses of cocaine (0, 3.25, 7.5, 15, 30, 60 mg/kg). Locomotor activity increased with the increase in drug concentration reaching the maximal locomotor activation at the dose of 30 mg/kg in all animals, however the maximal effect of the drug was reduced by 60% by removal of circulating of CORT. Thus, ADX rats did not differ from controls either for the response to a saline injection or for the psychomotor activation induced by the lower doses of cocaine (3.125 and 7.5 mg/kg), but at all of the higher doses ADX rats showed a lower locomotor response than sham rats. In a second experiment we investigated the dose-response effects of replacing circulating CORT in ADX rats on the locomotor response to cocaine (20 mg/kg). In this study ADX animals were implanted with subcutaneous pellets containing different concentrations of the hormone (0, 3.125, 12.5 or 50 mg) so as to progressively increase circulating CORT to levels observed in diurnal conditions. Again, the absence of CORT reduced the locomotor response to cocaine and there was a progressive increase in drug effect with increasing doses of CORT. The effects of ADX were completely abolished by the higher dose of CORT which gave diurnal levels of the hormone. The differences observed in response to cocaine cannot be explained by a difference in drug availability since neither ADX nor CORT replacement had any effects on brain levels of cocaine. These results indicate that stimulant effects of cocaine depend on CORT concentrations and that this hormone facilitates the psychomotor properties of this drug. This study suggests that individual differences observed in sensitivity to drugs of abuse may depend on circulating CORT levels and may open new therapeutic strategies for drug addiction.

CHRONIC COCAINE TREATMENT DECREASES OXYTOCIN LEVELS IN THE AMYGDALA AND INCREASES MATERNAL AGGRESSION IN SPRAGUE DAWLEY RATS. **J.M.Johns*, B.M.Faggin, L.R.Noonan, L.Li, L.I.Zimmerman and C.A. Pedersen. Dept. of Psychiatry, Univ. of North Carolina, Chapel Hill, N.C. 27599.**

Gravid Sprague-Dawley rats (250-275g) received one of three treatments throughout gestation; s.c. injections b.i.d. of saline (Sal) or 15 mg/kg of cocaine HCL or 1.5 mg/kg amfonelic acid (AFA) once daily. Females were tested on postpartum day 6 for maternal aggression towards a male intruder during a 10 min. period. Cocaine treated dams threatened intruders more than AFA dams (p<.04) and attacked intruders more than AFA (p<.05) or Sal (p<.04) treated dams. Dams were sacrificed for oxytocin RIA's using the whole ventral tegmental area and amygdala. Mean picograms per area and per mg protein were compared for the groups. Chronic cocaine treatment significantly reduced oxytocin levels in the amygdala as compared to Sal-treated (p<.05) and AFA-treated dams (p<.01). **(Supported by NIH grant DA08456 and a UNC Medical Faculty Grant).**

NEUROENDOCRINE AND BEHAVIORAL RESPONSES TO COCAINE iN FISCHER AND LEWIS RATS M. Renee Simar* and Nick E. Goeders. Dept. of Pharmacology and Therapeutics. Louisiana State University Medical Center, Shreveport, LA 71132.

Differences in the vulnerability to self-administer drugs of abuse have been observed in laboratory rats. Reports suggest that differences in adrenocortical activity may be a factor in the variability to acquire drug self-administration. These studies compared the cocaine-induced neuroendocrine and behavioral responses in strains of rats previously shown to self-administer drugs differently. Lewis (LEW) and Fischer (F344) rats were chosen for their pattern of self-administration as well as for differences in the responsiveness of the hypothalamic-pituitary-adrenocortical (HPA) axis to various stimuli. The acute neuroendocrine responses to cocaine were characterized by the effect of cocaine (1-60 mg/kg, i.p.) on hypothalamic corticotropin-releasing factor (CRF), corticosterone (CS), and adrenocorticotropin hormone (ACTH). Although both LEW and F344 rats displayed a decrease in brain CRF and an increase in plasma CS and ACTH, the percent response in LEW rats was greater than in F344 rats. This suggests that acute injections of cocaine can stimulate HPA axis activity, and that LEW rats, the drug-preferring strain compared to F344 rats, are more sensitive to the neuroendocrine activating effects of cocaine. Studies on the reinforcing effects of cocaine using an operant model of intravenous (i.v.) administration have also been performed. Rats were tested for acquisition of cocaine self-administration at increasing doses (0, .031, .062, .125, .250, .500, and 1.00 mg/kg/infusion). Our data indicate that LEW rats will self-administer i.v. cocaine more readily than F344 rats. Although basal plasma CS is higher in F344 rats, a greater CS response to i.v. cocaine was observed in the LEW strain. These studies suggest that neuroendocrine and behavioral responses to cocaine are markedly different in LEW and F344 rats , and these differences may be a factor in the variability in drug preference observed in these strains. This work was supported by USPHS Grant DA06013.

INCREASED COCAINE SELF-ADMINISTRATION AFTER SOCIAL STRESS. K.A. Miczek*, N. Hubbard and I. Cantuti-Castelvetri. Dept. Psychology, Tufts Univ., Medford MA 02155.

Cocaine and many kinds of stress lead to increased release of mesocorticolimbic dopamine. How specific is the activational effect of social stress to cocaine self-administration? We assessed the impact of social stress on behavior that was reinforced either by i.v. cocaine or by food, each at similar rates. Social stress was engendered by exposing the experimental rat solely to the threats of an aggressive resident rat behind a protective screen without potentially injurious attacks. Initially, we determined the characteristic inverted U-shaped concentration-response rate curve for cocaine self-administration (0.016-0.25 mg/infusion), maintained by an FR 10 schedule. Each cocaine dose was assessed for 3-5 days. In a second phase, animals were exposed to social stress for 60 min immediately before the daily session, and the cocaine concentration-response rate curve was re-determined. In a parallel group, the rate of food-reinforced behavior, maintained by a joint FR 10 FI 3 min schedule, was determined before, during, and after daily exposure to social stress. The rate of i.v. cocaine self-administration, but not of food-reinforced responding, was increased in rats that were socially stressed prior to the daily session. Other stressors like pair housing or exposure to a novel environment did not affect cocaine self administration. This increase was largely due to a high rate of responding immediately after the cocaine infusion pointing to activational effects of the self-administered cocaine in animals whose mesocorticolimbic dopamine is already released due to social stress.

766.10

SOCIAL STRESS MODULATES FOS EXPRESSION AFTER COCAINE AND MORPHINE TREATMENT IN MICE. E.M. Nikulina*, J.E. Marchand, K.A. Miczek and R. Kream. Department of Anesthesiology and Department of Psychology, Tufts University, Medford, MA 02155

Previous stress may change vulnerability to drugs of abuse, however neither the neural mechanisms underlying such effects nor the nature of the stress are well understood. The objective was to study whether social stress, either one week or immediately before administration of morphine or cocaine can influence c-fos expression in brain stem of mice. "Social stress" was defined as defeat in a brief confrontation with aggressive resident mouse and subsequent exposure to the resident's threats behind a protective screen. Mice were injected i.p. with morphine (7.5 mg/kg) or cocaine (40 mg/kg) and perfused 1 hour after injections. c-Fos immunoreactivity protein was investigated in periaqueductal gray (PAG) and locus coeruleus (LC). Social (defeat) stress in naive mice increased Fos-positive cells in PAG and LC in comparison to saline or untreated mice. Administration of morphine enhanced c-fos expression in PAG and LC. Social stress immediately before morphine injection appeared to have additive effects on c-fos expression in PAG and LC, whereas social stress one week before morphine challenge attenuated c-fos expression in PAG. Cocaine produced large c-fos expression 1 hour after injection in PAG and LC. A single defeat immediately before cocaine significantly attenuated c-fos expression in PAG and LC, whereas social stress 1 week before cocaine administration diminished c-fos expression in LC, resulting in ca. 50% lower count than after acute cocaine. These results suggest that development of stress-induced tolerance or sensitization to morphine or cocaine, respectively, is related with c-fos expression in brain stem.

766.11

VARIABLE HEMODYNAMIC RESPONSIVENESS TO BEHAVIORAL STRESS AND COCAINE IS RELATED TO DIFFERENTIAL CNS RESPONSIVITY. M.M. Knuepfer*, D. Hoang, P.J. Mueller, Q. Gan, L. Vickery and T.C. Westfall. Pharm. & Physiol. Sci., St. Louis Univ., St. Louis MO 63104.

We have noted highly variable hemodynamic responsiveness to cocaine and air jet stress in a population of rats (AJP, 265:H779-H782, 1993). In the present study, we examined the relationship between cardiovascular responsiveness to cocaine and to air jet with release of dopamine (DA) and norepinephrine (NE) in the nucleus accumbens (NA) and striatum (Str) as measured by HPLC. Conscious rats instrumented for determination of changes in cardiac output (CO) using pulsed Doppler velocitometry were tested for hemodynamic responsiveness to cocaine (5 mg/kg, *i.v.*) and air jet stress. Subsequently, rats were prepared with microdialysis probes in the NA and Str. On the following morning, rats were acclimated then physically restrained for 20 minutes while collecting dialysates. In the afternoon, cocaine was administered as before. As previously reported, stress or cocaine elicited pressor responses by increasing systemic vascular resistance only (vascular responders) or by increasing both CO and vascular resistance (mixed responders). The mixed responders had higher resting NE levels in Str. Restraint stress elicited increases in Str NE only in mixed responders whereas cocaine elevated Str DA levels more in vascular responders. These data suggest that differential hemodynamic responses to cocaine or stress are related to variable levels and release of catecholamines in the striatum. (Supported by DA05180).

DIFFERENTIAL EFFECTS OF ACUTE RESTRAINT STRESS ON THE BEHAVIORAL EFFECTS OF COCAINE. J.B. Acri and J.M. Witkin* Drug Development Group, Psychobiology Section, NIDA-DIR-ARC, NIH, Baltimore, MD 21224.

Acute laboratory stressors result in a number of neurochemical and behavioral effects. Stress has been reported to increase dopamine levels in brain regions associated with subjective and reinforcing effects of abused drugs, and has been reported to produce cross sensitization to psychomotor stimulants. The present experiments were undertaken to determine if acute restraint stress could modify the discriminative stimulus effects and the locomotor stimulatory effects of cocaine. Six rats trained to discriminate 10 mg/kg of cocaine were restrained for 15-20 minutes, and the dose-effect curve of cocaine was significantly shifted to the left, suggesting a potentiation of subjective effects. Subsequent re-establishment of the dose-effect curve indicated that the stress effect was transient, by a return to baseline values. A second series of experiments evaluated the effects of 15-20 minutes of restraint stress on the locomotor stimulant effects of cocaine in mice. Naive mice were either restrained for 15-20 minutes or remained in home cages prior to administration of saline or one of several doses of cocaine. Stress significantly decreased locomotor activity, measured as horizontal activity or number of movements, and significantly reduced cocaine-induced increases. When this experiment was repeated with mice that had been previously habituated to the locomotor arena, stress reduced locomotor activity in saline-treated, but not in cocaine-treated mice. These results suggest that stress effects on cocaine-mediated behaviors are complex, are dependent upon the behaviors being measured, and can be further modulated by behavioral history.

CHRONIC EXPOSURE TO CADMIUM ALTERS THE INITIATION OF BEHAVIORAL SENSITIZATION TO COCAINE. J.R. Nation*, C.L. Livermore, and G.R. Bratton. Texas A&M University, College Station, TX 77843

Cadmium selectively accrues in tobacco plants and poses a significant health hazard to heavy users of tobacco products. Recent findings indicate that risks may extend to include altered sensitivity to drugs that have substantial abuse liability. Continuing this line of research, the present investigation examined the effects of recurrent cadmium exposure on behavioral sensitization to cocaine. While monitoring motor activity, control and cadmium-treated adult male rats [60 days exposure to 100 ppm cadmium chloride via water supply], received single daily IP injections of 10 mg/kg cocaine HCL or saline for 14 successive days. On Day 15 all rats received saline injections, followed on Day 16-18 with incremental challenges of 10, 20, and 40 mg/kg cocaine. The findings showed that cadmium exposure retarded the initiation of sensitization. These data suggests that xenobiotic contamination may alter drug responsiveness and therein may influence patterns of drug selection and use.

NEUROBIOLOGICAL RELATIONSHIP BETWEEN VULNERABILITY TO DEPRESSION AND TO DRUG ABUSE: *IN VIVO* MICRODIALYSIS STUDIES. Marino Lepore* and Eliot L. Gardner. Department of Psychiatry, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, NY 10461-1602.

Clinical studies have shown a marked association between co-vulnerability to depression and to drug abuse. In agreement with theories that depression is reflected in a reduced capacity to experience pleasure, animal experiments demonstrate that manipulations that predispose towards depression also influence reward processes. Changes in neurotransmission in the mesolimbic dopamine (DA) system may underlie this effect. Stress has been shown to increase DA turnover in this system and mild /severe stress can induce abnormalities in DA transmission specific to the nucleus accumbens (NAcc). The following experiment examined the relationship between the co-vulnerability to depression and to drug abuse. The effect of cocaine on the development of learned helplessness (LH) was studied in animals genetically susceptible (Lewis-L)/non-susceptible (Fischer 344-F344) to drug abuse. Following exposure to LH, animals were implanted with dialysis probes in the NAcc, and the effect of cocaine challenge (10 mg/kg) on DA transmission was examined. Although L rats are more susceptible to drug abuse than F344, neither strain demonstrated any predisposition towards LH. When cocaine was administered prior to LH training, 40% of L and 70% of F344 rats became non-LH. Cocaine, therefore, had a protective effect on the development of LH, and was more pronounced in F344 rats. Following cocaine challenge, dialysate DA levels were heavily influenced by previous LH exposure. For controls, dialysate DA was higher in L rats than F344. Following LH training, dialysate DA levels did not increase significantly in F344 rats compared to controls. However, F344 rats that received cocaine during LH training (and who later became non-LH) showed a greater than 300% increase in dialysate DA levels. The effects of cocaine on dialysate DA in the L rat are currently under investigation. Thus, when cocaine is administered during LH training, the effect on dialysate DA levels in F344 rats is dramatic, and suggests that a potentially significant and long-lasting change in the mesolimbic DA system following cocaine+stress could reverse a genetic non-susceptibility to drug abuse.

EFFECT OF ADRENALECTOMY ON INITIATION AND EXPRESSION OF COCAINE- INDUCED SENSITIZATION AND STRESS- INDUCED CROSS SENSITIZATION. B. M. Prasad , C. Ulibarri, P. Duffy,*P. W. Kalivas and B. A. Sorg. Dept. of VCAPP, Washington State University, Pullman, WA 99164.

Activation of the hypothalamo-pituitary-adrenal (HPA) axis has been implicated in the development of psychostimulant- and stress- induced behavioral sensitization. In an attempt to further characterize the role of the HPA axis in sensitization, the effect of adrenalectomy (ADX) on the initiation and expression phases of cocaine- induced behavioral sensitization and stress- induced cross sensitization was evaluated. To determine the role of HPA axis in the initiation of behavioral sensitization, male Sprague-Dawley rats were subjected to sham surgery or ADX. A week later, rats were subjected to a sensitization paradigm with intraperitoneal injection of cocaine(Day 1- 15 mg/kg; Day 2 to 6 - 30 mg/kg). On day 7 (early withdrawal) the behavioral response to cocaine challenge (15 mg/kg) was tested. Three days later, one half of ADX rats were given corticosterone pellets and corticosterone in the night drinking water to mimic the circadian variation of corticosterone levels. After one week, rats were given a saline challenge followed by a cocaine challenge (15 mg/kg) the next day (late withdrawal). Sham controls demonstrated a sensitized locomotor response to the cocaine challenge at both early and late withdrawal times compared to the response on day 1. In contrast, sensitization was completely blocked in ADX rats at the early withdrawal time but not at late withdrawal. The effect of ADX on the expression phase of sensitization was examined by administering daily cocaine as before followed by surgery one or two days later. No effect of adrenalectomy was found on the expression of behavioral sensitization. These results suggest that corticosterone is necessary during the initiation of behavioral sensitization for the manifestation of sensitized response at the early withdrawal time but not at late withdrawal time. Similar experiments were done to examine the effect of adrenalectomy on stress- induced cross sensitization. A stress paradigm that included mild foot shock stress and restraint stress was used in place of daily cocaine injections. Preliminary results from these experiments suggest that ADX had similar effects on both cocaine- and stress induced sensitization.

ANXIOGENIC EFFECTS OF COCAINE ORAL SELF-ADMINISTRATION AND OF COCAINE WITHDRAWAL. H.M.T. Barros *, V.B. Lanziotti, S.L.Tannhauser, M.Tannhauser. Division of Pharmacology and Toxicology, Fundação Faculdade Federal de Ciências Médicas, Porto Alegre, RS, Brazil, 90050-170.

Different studies show that cocaine administration and cocaine withdrawal produce anxiogenic states in animals. This study was done to examine the behavior of rats in the elevated plus-maze during acute and prolonged cocaine self-administration and after cocaine withdrawal. Adult male rats were allowed to administer cocaine solutions (0.1 - 0.5 mg/kg) using the two-bottle choice technique during different periods of time (30 or 60 days). The amount of cocaine self-administered was in the range of 10 to 30 mg/kg/day. The animals were introduced into the elevated plus maze during the first, 15th and 30th day of cocaine administration and for 5 days after withdrawal. Ethological evaluation of frequency and duration of entrance to open and closed arms was further conducted using videotape recordings. Behavioral effects were not detected after acute oral self-administration of lower doses of cocaine. Decreased entries into the open arms was seen on the third day of treatment withdrawal. Decreased entries to the open arms was verified after acute self-administration of higher doses of cocaine . These animals also showed this behavior during the five days of testing after cocaine withdrawal.

LIMBIC ACTIVATION DURING CUE-INDUCED COCAINE CRAVING
A.R. Childress, D. Mozley, J. Fitzgerald, M. Reivich, J. Jaggi, and C.P. O'Brien*. Depts. of Psychiatry and Radiology, Univ. of Penn. School of Medicine, and Philadelphia VA Medical Center, Philadelphia, PA 19104

Cocaine-related cues (e.g., drug users, drug talk, drug locations, drug paraphernalia, etc.) can trigger profound cocaine desire in users of the drug, but the brain correlates of this state are just beginning to be studied. The similarity of responses during cocaine craving (arousal, heart palpitations, light-headedness, ear-ringing, chest-tightness, a cocaine 'taste' in back of the throat, and even mild euphoria) to the effects of actual cocaine suggests a possible overlap of brain substrates. As many of cocaine's direct effects are mediated through the mesolimbic dopamine system, we have hypothesized activation of the same system during cue-induced craving.

To test the hypothesis of limbic activation during cue-induced craving, rCBF (regional cerebral blood flow) was imaged in abstinent cocaine patients and in matched controls without a cocaine use history during exposure to videos of both non-drug and cocaine-related scenes. Imaging of rCBF was accomplished with PET (Positron Emission Tomography) scans, using radioactively-labeled (O-15) water as the flow tracer. PET scans for each subject were co-registered with an MRI (magnetic resonance image) to permit anatomical localization of radioactivity. Cocaine patients (n=9 thus far) experienced craving to the cocaine video, and several showed rCBF increases in amygdala and in temporal pole during the cocaine video (as compared to resting baseline). Systematic activation did not occur in non-limbic comparison regions, nor in response to the non-drug cues. Control subjects (n=6) did not experience craving during the cocaine video, and did not show systematic rCBF increases to either video type. These results suggest limbic activation may be one component of cue-induced drug craving.

COCAINE-INDUCED ALTERATIONS OF BRAIN ACTIVITY IN HUMANS: AN FMRI STUDY. E.A.Stein*, J.Pankiewicz, H.H. Harsch, M. Rossing, J-K.Cho, S.A.Fuller, S.M. Rao and A.S. Bloom. Departments of Psychiatry, Pharmacology and Neurology, Medical College of Wisconsin, Milwaukee, WI 53226

Cocaine is a powerful psychostimulant agent with high abuse potential in humans. While considerable progress has been made in understanding cocaine's mechanisms of action using in vitro and animal model systems, very limited information is available on the pharmacokinetics and localization of action of cocaine in the human brain. Functional MRI is a non-invasive imaging technique that permits the visualization of functional brain activity with excellent temporal and spatial resolution without the use of ionizing radiation. Single shot echo planar imaging was obtained on a 1.5 Tesla GE Signa scanner using an insertable, balanced torque, 3-axis head gradient coil designed for rapid gradient switching. To obtain images throughout the entire brain volume, a shielded quadrature elliptical endcapped transmit/receive birdcage radio frequency coil was used. Four experienced crack/IV cocaine users received doses of cocaine IV (10, 20 and 40 mg over 60 sec) while FMR data were acquired (TR=6 sec; TE=40 msec; 8 mm slice thickness). Subjects all displayed consistent increases in heart rate, arterial blood pressure and generally reported positive subjective effects to the drug. Heterogenous activation patterns included consistent cerebral activation in the dorsolateral frontal, anterior cingulate, temporal and insular cortex. Prominant inhibitory responses were evident in several frontal fields. Signal activation latency generally varied between 1-2 min with duration of effect between 8-20 min depending upon region. These data demonstrate the ability of FMRI to map drug effects in the human brain. (Support by USPHS grant DA09465)

CEREBRAL GLUCOSE METABOLISM DURING COCAINE CRAVING: A PET FDG STUDY. Steven Grant*[1], David Newlin[1], Victor Villemagne[2], Robert L. Phillips[1], Xiang Liu[1], Alane S. Kimes[1], Carlo Contoreggi[1,3], Edythe D. London[1,4,5]. [1]Neuroimaging and Drug Action Section, Addiction Research Center, NIDA, NIH, Balto., MD 21224; [2]Dept. Pharmacol. Exp. Ther., School of Medicine, University of Maryland, Balto., MD 21201; and [3]Dept. Radiology, The Johns Hopkins School of Medicine, Balto., MD 21205.

Stimuli that are regularly associated with drug use are thought to elicit behavioral and physiological responses that contribute to addiction. In particular, relapse after abstinence may be due, in part, to cue-elicited responses. In the present study measurements of regional cerebral metabolic rates for glucose (rCMRglc) using the [F-18] fluorodeoxyglucose (FDG) method and positron emission tomography were paired with psychophysiological and self-report assessments in cocaine abusers during two experimental sessions. During the FDG uptake period, subjects were exposed to either a neutral videotape on arts and crafts or a cocaine-related stimulus complex (videotape of cocaine-related activity and paraphernalia; presence of paraphernalia and a small amount of cocaine). Analysis of data from the first 9 subjects reveals increases in self-reports of craving and overall EEG arousal during presentation of the cocaine-related stimuli. Changes in rCRMglc in response to cocaine-related stimuli differed from those observed previously in response to acute administration of cocaine. The changes in response to cocaine-related stimuli were "drug-opposite", as the stimuli caused selectively increased rCMRglc, whereas acute cocaine administration reduces glucose metabolism globally. Increases in rCMRglc occurred in regions of the prefrontal cortex, occipital cortex, the middle temporal gyrus, and the parahippocampal gyrus. The metabolic changes may reflect a distributed neuroanatomical network that mediates reactivity to cocaine-related stimuli.

DECREASED FDOPA UPTAKE IN RIGHT PUTAMEN IN PET STUDY OF COCAINE ADDICTS DURING ACUTE WITHDRAWAL. J.C. Wu*, K. Bell, E. Klein, C. Widmark, A. Najafi, C. Tang, L. LaCasse, B. Bunney, W.E. Bunney. Brain Imaging Center, UCI-CCM Psychiatry Dept., Irvine, CA 92717.

A persistent decrease in dopamine presynaptic activity has been hypothesized to be a key reason why so many cocaine addicts relapse. This study measured F-Dopa uptake, a measure of dopamine presynaptic activity, using positron emission tomography (PET) scans in nine cocaine addicts who had been drug free (off cocaine) for a minimum of one week compared with ten normal controls. Nine cocaine dependent subjects in acute withdrawal (< 30 days since last use) were studied. The cocaine dependent subjects had a mean age of 32.2 $\pm$ 14.4 years. Their mean useage of cocaine was 14.1 $\pm$ 5.2 years. The mean quantity of cocaine consumed was 1.2 $\pm$ 0.81 grams/day. The mean days off cocaine was 21.1 $\pm$ 9.5 days. All cocaine dependent subjects were male. The ten control subjects had a mean age of 36.3 $\pm$ 19.0 years. Seven control subjects were male and three were female. All control subjects had a negative urine drug screen and had a negative history of personal psychiatric illness. PET studies were performed with the University of California, Irvine (UCI) Brain Imaging Center (BIC) single ring Neuroecat IV system from CTI. Each subject received 2.0-4.0 mCi of 6-FD. FDOPA uptake was determined graphically using the method of Martin et al. (1989). FDOPA uptake was graphically represented pixel by pixel using in-house software. Images were analyzed using a method which involved dividing the striatum into a grid of 3x3 pixels. The striatal grid was subdivided into three structures (caudate, anterior putamen, and posterior putamen). Controls were significantly higher than cocaine addicts for FDOPA uptake in the right putamen. A significant structure by hemisphere by group interaction was found for FDOPA uptake activity ($F=3.53$, $d.f = 1.76, 31.59$, $p = .0466$). This finding is partly compatible with the theory presented by Dackis and Gold (1985) and Weiss et al. (1992) that there may be a chronic suppression of presynaptic dopamine activity as an adaptation to chronic dopamine exposure induced by habitual cocaine useage.

PHARMACOLOGIC MODULATION OF COCAINE-INDUCED DOPAMINE RELEASE AND LOCOMOTOR ACTIVITY: A POTENTIAL THERAPEUTIC STRATEGY FOR COCAINE ABUSE. C.-E. Chen, R. M. Straughter-Moore, D. L. Tedeschi, N. B. Russo, D. L. Alexoff, N. D. Volkow, J. S. Fowler, C. S. Chaurasia, and S. L. Dewey*. Chem and Med Dep'ts, BNL, Upton, NY 11973 & College of Pharm and Allied Health Prof, St. Johns Univ, NY 11439.

We have demonstrated that PET is a suitable imaging technique for non-invasively measuring changes in neurotransmitter concentrations following pharmacologic challenge (Dewey, et al., J. Neuroscience, 1992; 1995). Utilizing a variety of neurotransmitter-specific radiotracers, we have measured drug-induced changes in DA, 5-HT, and ACh in the primate and human brain. With our findings that certain neurotransmitters inhibit striatal DA release, combined with cocaine's ability to increase extracellular striatal DA levels, we have applied this novel strategy to an investigation of the effects of GVG (gamma vinyl-GABA, a selective suicide inhibitor of GABA-transaminase), lorazepam, and ethanol on coc-induced increases in striatal DA levels and locomotor activity using *in vivo* microdialysis in freely moving rats. In control studies, coc (20 mg/kg) increased extracellular DA levels to approximately 250 % of baseline values. GVG (100 - 300 mg/kg), lorazepam (0.1 - 0.68 mg/kg), and ethanol (1 - 3 g/kg) however, dose-dependently attenuated both this and the locomotor response. Furthermore, GVG and lorazepam produced a decrease in extracellular striatal DA levels. These findings are consistent with earlier primate PET studies using ^{11}C-raclopride and a similar challenge. Ethanol, however, had no effect on baseline striatal DA levels. Interestingly, while ethanol dose-dependently attenuated coc-induced increases in striatal DA levels similar to GVG and lorazepam, DA concentrations fell below previously established baseline levels following challenge. These studies suggest that therapeutic strategies targeted at potentiating GABAergic neurotransmission may be beneficial for the treatment of coc addiction. SELF-ADMINISTRATION OF INTRAVENOUS COCAINE UNDER A SECOND-ORDER SCHEDULE OF REINFORCEMENT: EFFECTS OF LESIONS OF THE BASOLATERAL AMYGDALA R.B. Whitelaw, A. Markou[1], T.W. Robbins, B.J. Everitt.* Dept. of Exp. Psychology University of Cambridge, UK. CB2 3EB.[1]Scripps Res. Inst., Torrey Pines Rd, La Jolla, San Diego, CA. 92037.

In these experiments we sought to establish the intravenous (IV) self-administration (S-A) of cocaine under a second-order schedule of reinforcement in order: (i) to obtain reliable, drug-free responding for a psychomotor stimulant, and (ii) to enable investigation of the neural mechanisms by which arbitrary cues gain motivational salience and, as conditioned reinforcers, control over drug-seeking behaviour. Initially, each infusion of cocaine (1.5mg/kg IV over 4sec) was made contingent on a response on one of two identical levers and was paired with a 20s light CS. Responses on the second lever were recorded, but had no programmed consequence. When rats acquired stable rates of S-A (5 daily 2h sessions), a second-order schedule of the type FRx(FRy:S) was introduced. Priming (ie. non-contingent) infusions of cocaine were not given. Once the first infusion was obtained under the second-order schedule, further infusions were made contingent on each response (max.10 infusions /day). Each stage was repeated daily until the first infusion of each session was achieved within a 5 min criterion. Rats with bilateral, excitotoxic lesions of the basolateral amygdala (BLA) readily acquired the S-A of cocaine under a continuous reinforcement schedule, initially administering more infusions and maintaining a slightly elevated level of S-A than controls. Despite increased CS /drug pairings, BLA lesioned rats were significantly slower than controls to achieve the more demanding response requirements of the second-order schedule. Lesioned rats showed a slightly elevated dose-response curve compared to controls, but no overall shift in the inverted U-shaped function. There was also no significant difference in the locomotor response to IP cocaine (10, 20, 30 mg/kg), in drug naïve lesioned or control animals. These experiments indicate the feasibility and utility of second-order schedules in studying the neurobehavioural basis of drug S-A, and the potential importance of the BLA in the process by which previously neutral stimuli gain control over drug-seeking behaviour.

767.7

RESPONSE TO NOVELTY PREDICTS COCAINE SELF-ADMINISTRATION IN RATS. J. W. Grimm* and R. E. See. Department of Psychology, Washington State University, Pullman, WA 99164-4820.

Rats displaying a higher locomotor response to novelty than rats with a lower response have been shown to more readily acquire amphetamine self-administration. The present study sought to establish that response to novelty predicts cocaine self-administration as well. Subjects were female Sprague Dawley rats (N=10) weighing 220-280g. Response to novelty was recorded as the locomotor response of a rat in a photobeam activity chamber. The animals were then ovariectomized, implanted with subcutaneous estrogen (17-β estradiol) capsules, and fitted with intra-jugular catheters. Rats then self-administered intravenous cocaine for four days on a fixed interval schedule of reinforcement (0.219 mg/inj) and then for six days on a progressive ratio schedule of reinforcement (0.263 mg/inj). Response to novelty and responding for cocaine on both schedules was found to be highly correlated and statistically significant: response to novelty vs. 4 days FI, Pearson r=0.643, p=0.045; response to novelty vs. 6 days PR, Pearson r=0.720, p=0.019. In addition, responding for cocaine on the FI predicted responding on the PR, Pearson r=0.770, p=0.009. Thus, individual differences in cocaine self-administration can be predicted by individual differences in response to novelty in the female rat. Moreover, response to novelty predicts cocaine self-administration on a progressive ratio schedule of reinforcement, argued to be a measure of motivation to acquire a reinforcer. The relationship between response to novelty and steady state responding for cocaine and the effects of 17-β estradiol on cocaine self-administration and vaginal epithelial status will also be discussed.

767.8

CONDITIONED SUPPRESSION AS A MODEL FOR THE CLASSICALLY CONDITIONED EFFECTS OF COCAINE. C. W. Schindler*, E. B. Thorndike, M. Shoaib and S. R. Goldberg. Preclinical Pharmacol. Lab., NIH/NIDA DIR, Baltimore, MD 21224

While it is often acknowledged that the effects of drugs conditioned to environmental stimuli are important to the behavioral process of drug abuse, these processes have not been extensively studied. Further, most studies which have addressed this issue have used an environmental context as the conditioned stimuli rather that a discrete stimulus. However, this limits the types of behavioral manipulations that can be performed because of the practical issues related to the use of a diffuse stimulus. As such, our ability to study the behavioral processes involved in drug conditioning is also limited. The conditioned suppression procedure holds promise in overcoming some of these difficulties. Conditioned suppression involves the pairing of a drug injection with a discrete environmental stimulus. That stimulus-drug pairing is presented on an ongoing operant baseline and conditioning is measured as a disruption in operant performance. In the current study, rats were trained to nose-poke on a food reinforcement schedule. A 5-min tone-light compound stimulus was then presented 30 min into the session. Two min after the onset of the compound stimulus, a 3 mg/kg dose of cocaine (i.v.) was given. This dose had previously been shown to suppress food-reinforced operant behavior. After four training days, the stimulus was presented alone and shown to disrupt behavior similarly to the unconditioned drug stimulus. The tone-light compound stimulus alone did not disrupt responding. While more studies are needed to confirm the nature of the conditioned response, this preliminary data suggests that the conditioned suppression procedure may be useful in studying the behavioral procesess involved in the classically conditioned effects of cocaine.

INDIVIDUAL DIFFERENCES IN COCAINE SELF-ADMINISTRATION: DOSE-RESPONSE AND RATIO-RESPONSE STUDY. V. Deroche, F. Rougé-Pont, M. Le Moal* and P.V. Piazza., INSERM U259, Univ. de Bordeaux II, 33077 Bordeaux, France.

There are considerable individual differences among humans in drug taking behavior. Individual differences in the propensity to develop drug intake have also been evidenced in rats. When intravenous self-administration is studied with a low dose of psychostimulants, all rats self-administer the drug during the first days of testing, but in some individuals the behavior rapidly extinguishes whereas it is maintained in the others and this can be predicted by the reactivity to stressful situations: individuals with a high locomotor response to novelty (High Responders or HRs) maintain psychostimulants self-administration whereas subjects with a low response do not (Low Responders or LRs). In this report, we studied individual differences in cocaine intravenous self-administration: i) as a function of the dose of drug (1, 0.5, 0.25, 0.125, 0.06, 0.03 mg/kg/inj), ii) as a function of the ratio required to obtain an injection (1, 6, 12, 24, 36, 54, 78) at 1 mg/kg/inj. of cocaine. First rats were trained to self-administer the higher dose (7 days). The other 5 doses were consecutively tested (at least 3 days). At the training dose both LRs and HRs developed cocaine self-administration; the number of nose-pokes was significantly higher in the active hole (delivering the drug) than in the inactive one (without effect). HRs and LRs presented the classical bell-shaped dose-response curve. However for all doses, rate of responding was significantly higher in HRs than in LRs. Similar results were found when the ratio was increased. The increase of the addictive properties of cocaine in HRs can not be explained by a difference in drug pharmacokinetics, since brain levels of cocaine were not statistically different in HRs and LRs either 2, 10 or 20 minutes after an i.v. injection of 2 mg/kg of cocaine. In conclusion, individual differences in drug taking behavior can be observed in rats also when high training doses are used and do not result from a difference in drug catabolism. These data demonstrate that psychostimulant abuse results from an interaction between the drug and a specific individual substrate, inherent or acquired.

SELF-ADMINISTRATION OF COCAINE ON SECOND-ORDER SCHEDULES OF REINFORCEMENT IN RATS. **[1]R. Ranaldi*, [2]R.A. Wise and [1]D.C.S. Roberts. [1]Dept. of Psychology, Carleton Univ., Ottawa, Canada [2]CSBN, Concordia Univ., Montreal, Quebec, Canada**

Drug craving, which can trigger relapse to drug use, may be elicited by interoceptive and exteroceptive events. A rat model of cocaine addiction was used that focused on cocaine-seeking behaviour elicited interoceptively and by conditioned stimuli. Rats were housed in test chambers and had access, by pressing a lever, to a maximum of 20 intravenous cocaine injections (1.5 mg/kg/injection) beginning every morning. The rats were never primed. Although the availability of cocaine was present every morning the rats showed a self-imposed period of abstinence followed by a period of rapid consumption. Using second-order (SO) schedules of reinforcement we evaluated the role of a CS+ (a light and lever retraction) in cocaine-seeking behaviour. In a SO schedule rats must emit a number of responses to obtain a CS+ only and accumulate a number of CS+ presentations to receive a CS+-cocaine injection pairing. We compared the total number of responses that rats would emit to obtain their first and subsequent injections of the day between a group responding on a fixed-ratio (FR) schedule and a group responding on a SO schedule of reinforcement. The number of responses required per injection was incremented daily until the rats failed to consume more than 4 injections. The SO group was able to emit approximately 4 times as many responses as the FR group to obtain their first and subsequent injections. Subsequently, the effect of the CS+ on the initiation of cocaine-seeking behaviour was evaluated by comparing responding in extinction with and without the CS+. Responding in extinction was significantly greater in the presence of the CS+. The results suggest that cocaine-seeking behaviour follows a cyclical pattern and is enhanced by conditioned stimuli. Treatments for cocaine addiction may thus benefit from attempts at reducing craving elicited interoceptively and by conditioned stimuli during periods of abstinence. Funded by NIDA.

CONDITIONED PLACE PREFERENCE AND LOCOMOTION, BUT NO CONDITIONED DOPAMINE RELEASE AFTER EXPOSURE TO A COCAINE-PAIRED ENVIRONMENT. C.L. Duvauchelle*, K. Kressin, J.L. Neisewander and E. Castaneda. Lab. of Behavioral Neuroscience, Arizona State University, Tempe, AZ 85287-1104.

In order to investigate underlying biochemical correlates of cocaine-conditioned behaviors, animals implanted with chronic microdialysis guides above the nucleus accumbens were given I.V. cocaine (4.2 mg/kg) and saline in distinctly different environments. After 12 days (i.e., 6 cocaine and 6 saline injections) removeable microdialysis probes were implanted through the guides. The following day, animals were confined for 50 min to each of 3 environments: cocaine-paired, saline-paired and neutral. Dialysis samples were taken every 10 min and the session was videotaped for analysis of conditioned behaviors. Forty-eight hrs later, animals were tested for conditioned place preference (CPP). Animals exhibited CPP, conditioned locomotion and stereotyped sniffing in the cocaine-paired environment. However, there was no clear evidence for conditioned dopamine release preferential to the drug-paired compartment. These results suggest that although increased dopaminergic activity may be the driving force behind many motivated and stimulant-induced behaviors, it may not be required for the subsequent demonstration of homologous conditioned behaviors. (Supported by DA07730, DA05606 and HHMI).

767.12

A COMPARISON OF THE EFFECTS OF CONTINUOUS COCAINE INFUSIONS ON LOCOMOTOR ACTIVITY AND ON BRAIN STIMULATION REWARD. C.M. Pudiak*, R. KuoLee, & M.A. Bozarth. *Department of Psychology, University at Buffalo, Buffalo, NY 14260-4110.*

Many of the behavioral effects of cocaine show sensitization with repeated cocaine administration. This is usually demonstrated by increased behavioral responses to daily cocaine injections. However, continuous cocaine infusions have been reported to produce tolerance to some effects that show sensitization during intermittent cocaine injections. The present studies examined the effects of continuous cocaine infusions on two behaviors—locomotor activity (LMA) and brain stimulation reward (BSR).

Male, Long-Evans rats were used to examine the effects of continuously delivered cocaine infusions across 14 days of drug administration. The first study measured LMA during daily 30-min sessions. The second study determined BSR thresholds using a threshold tracking procedure: The minimum stimulation frequency necessary to maintain responding at ≥30 presses/min was determined during daily 30-min sessions in rats with lateral hypothalamic stimulating electrodes. Cocaine was continuously infused (≅30 mg/kg/day, s.c.) using osmotic minipumps (Alzet, model 2ML2). After 14 days of continuous cocaine infusions, the minipumps were removed. The development of tolerance or sensitization was further assessed by comparing responding following a cocaine injection (10 mg/kg, i.p.) 72 hrs and again 10 days after minipump removal. Responses were compared with sham operated and with unoperated control animals.

Continuous cocaine infusions increased LMA and lowered BSR thresholds across the 14-day infusion period. Both behavioral responses, however, showed tolerance with Day-1 response levels exceeding those seen on Day-14. Tolerance to the threshold-lowering effect of cocaine was much more pronounced than tolerance to cocaine's stimulation of LMA. Surprising, cocaine challenge 72 hrs and 10 days after termination of the continuous cocaine infusions failed to reveal tolerance. This suggests that unlike sensitization, tolerance seen during continuous cocaine infusions dissipates rapidly following termination of chronic cocaine administration.

ENHANCEMENT INDUCED BY TRIMETHADIONE AND PHENOBARBITAL IN COCAINE HYPERLOCOMOTOR ACTIVITY IN MICE. N. Ono*, M. Hiraki Y. Ono and T. Kuroda. Pharmacoinformatics and Medicinal Research Unit, Fac. of Pharmaceut. Sci., Fukuoka Univ., Fukuoka, 814-01, Japan.

We are investigating the influence of trimethadione, phenobarbital and diazepam on the hyperlocomortor activity produced by cocaine and methamphetamine (MAPT) in mice. Both cocaine and MAPT elicited dose-dependent hyperactivity in open field apparatus at dosages of 1-5 mg/kg and 5-10 mg/kg respectively. The hyperactivity of cocaine (10 mg/kg) and MAPT (2 mg/kg) were augmented dose-dependently by the pretreatment with phenobarbital and diazepam (1-5 mg/kg). While the hyperactivity of cocaine also was augmented by the pretreatment with trimethadione (250-500 mg/kg), but not that of MAPT. The hyperactivities of both psycho stimulants and reinforcing effects by phenobarbital were inhibited by picrotoxin, Cl^- channel blocker (0.5-1 mg/kg). In the experiment of measurement of brain biogenic amines, norepinephrine, dopamine, DOPAC, HVA, 5-HT and 5-HIAA levels were measured 30 min after cocaine by HPLC-ECD. cocaine reduced DOPAC levels in frontal cortex, but not in striatum. The reduction of DOPAC was inhibited dose-dependently by diazepam. Our data suggest that cocaine may participate in a modification of central Cl^- channel and monoaminergic system.

COCAINE-INDUCED PLACE PREFERENCES & AVERSIONS: EVIDENCE FOR AN OPPONENT-PROCESS MECHANISM OF ACTION. A. Ettenberg*, M. Raven, D. Danluck and B. Necessary. Behavioral Pharmacology Laboratory, Department of Psychology, University of California, Santa Barbara, CA 93106

Rats running an alley for IV cocaine have been reported to show a unique approach-avoidance behavior with respect to the goalbox. This ambivalence occurs even though the animals initiate runway trials normally, operantly self-administer the same dose of cocaine that they receive in the goalbox, and demonstrate place preferences for environments paired with the same dose of cocaine. To account for these paradoxical results, an opponent-process model was hypothesized in which an initial positive response to cocaine was thought to diminish in strength followed by, or concurrently with, an insurgence of an negative affective state. The present experiment tested this notion using the Conditioned Place Test in which the effects of a 0.75 mg/kg IV injection of cocaine was paired with a distinctive environment for 5 min either immediately post-injection, after a 5 min delay, or after a 15 min delay. Reliable preferences were demonstrated for the cocaine-paired environment in the no-delay condition, weaker preferences were observed in the 5 min delay condition, and significant aversions in the 15 min delay condition. These results support the notion of an opponent-process mechanism of action for IV cocaine.

DO CALCIUM CHANNELS IN THE A10 DOPAMINE REGION PLAY A ROLE IN THE DEVELOPMENT OF COCAINE-INDUCED BEHAVIORAL SENSITIZATION?. J.D. Steketee* and B.C. Braswell. Department of Pharmacology and Therapeutics, Louisiana State University Medical Center, Shreveport, LA 71130-3932.

Previous studies have suggested that L-type Ca^{2+} channels may be involved in the development of psychostimulant-induced behavioral sensitization. In particular, pretreatment with dihydropyridine Ca^{2+} channel blockers, such as nifedipine or nimodipine, blocked the development of behavioral sensitization. The mesolimbic dopamine system has been proposed to play a critical role in the development of sensitization. The mesolimbic system arises from dopamine cell bodies located in the ventral tegmental area (A10 region) to innervate numerous limbic structures, including the nucleus accumbens. The A10 region is thought to be involved in the initiation of sensitization. Thus, in these studies we examined the role of L-type Ca^{2+} channels in the A10 region on the development of sensitization to cocaine. In one set of studies, animals received daily intra-A10 pretreatment with nimodipine (10 or 30 nmol/µl, 0.5 µl/side), a Ca^{2+} channel blocker, 5 min before a peripheral cocaine injection (15 mg/kg, ip). In a second set of studies, animals received daily intra-A10 injections of Bay K 8644 (10 or 30 nmol/side), a Ca^{2+} channel opener. In both cases, animals received a challenge injection of cocaine 1 week after the last of 4 daily injections. Motor activity was monitored for 2 hr following the first daily injection and on the day of the cocaine challenge. Bay K 8644 did not induce motor activity, nor did daily injections induce behavioral sensitization to cocaine. Nimodipine did not block the acute, nor the development of the sensitized, responses to cocaine. These data suggest that the dihydropyridine sensitive Ca^{2+} channels in the A10 region do not play a role in the development of cocaine-induced behavioral sensitization.

NOCTURNAL HYPOACTIVITY DURING WITHDRAWAL FROM AN ESCALATING DOSE, BINGE-LIKE ADMINISTRATION OF REPEATED COCAINE. F.J. White*, A.J. Vartanian and D.C. Cooper. Neuropsychopharmacology Lab., Dept. of Neuroscience, Finch Univ. Health Sciences/The Chicago Medical School, North Chicago, IL 60064.

During withdrawal from repeated cocaine binge administrations, human addicts experience a syndrome that includes anhedonia, anergia, depression, anxiety and cocaine craving. Both anhedonia and anxiety have been successfully induced in animal models, but there is little evidence for anergia/depression. We have tested for the presence of nocturnal hypoactivity in rats during withdrawal from an escalating dose, binge-like cocaine administration regimen. Rats received 3 injections (1 hr apart) of cocaine or saline during the light cycle for each of 5 days. Cocaine doses were as follows: days 1-2, 10 mg/kg/injection, days 3- 4, 20 mg/kg/injection and day 5, 30 mg/kg/injection. On day 6, all rats received 10 mg/kg in the early afternoon. Home-cage locomotion detectors were then used to monitor activity. In the first two experiments, cocaine treated rats (n=6/exp) were highly sensitized to the locomotor stimulating effects of cocaine as compared to age-matched saline-pretreated controls and also showed marked decreases in nocturnal locomotion during the two dark phases (12 hr cycle) of a 48 hr test. There were no differences in activity during the lights-on portion of the light cycle. In the third experiment, a third day was added to test for longevity of the effect. In this experiment, sensitization was again observed as was nocturnal hypoactivity during the first two dark periods. During the third dark period, nocturnal activity was reduced but to a lesser extent. We also noted that the cocaine treated rats exhibited significantly lower body weights at the beginning of the tests, but gained significantly more weight during the testing period. Thus, there was an apparent rebound hyperphagia along with the nocturnal hypoactivity. Supported by DA 04093 and DA 00207 to FJW.

EXCITOTOXIC LESIONS OF THE BASOLATERAL AMYGDALA ATTENUATE THE ABILITY OF DRUG ASSOCIATED CUES TO REINSTATE RESPONDING DURING WITHDRAWAL FROM SELF-ADMINISTERED COCAINE. W. M. Meil* and R. E. See. Department of Psychology, Washington State University, Pullman, WA, 99164-4820.

Environmental cues previously associated with cocaine abuse have been shown to elicit drug craving and the resumption of drug use in abstinent individuals. Despite the importance of drug associated cues in relapse, few attempts have been made to model this behavior in animals. In the present study, rats exposed to noncontingent presentation of drug paired stimuli following 14 days of 3 hr. daily cocaine self-administration sessions (0.33 mg/infusion), and 20 days of 3 hr. extinction trials showed significant reinstatement of responding. Rats placed back in the experimental chamber following 43 days of withdrawal and exposed to noncontingent presentation of drug paired cues showed higher responding than animals placed back in the chamber under extinction conditions. In addition, bilateral lesions of the basolateral amygdala (BLA), via N-Methyl-D-Aspartic acid (NMDA) microinjection (0.2 mg in 500 ul vehicle), either in the middle of or following chronic cocaine self-administration increased the rate of extinction and attenuated the ability of drug paired stimuli to reinstate responding. Lesions of the BLA following 7 days of cocaine self-administration failed to alter subsequent responding for cocaine. These results are consistent with the hypothesis that the BLA is important for the association of reinforcers with neutral stimuli, but not the reinforcing effects of cocaine itself. Furthermore, this paradigm represents a model for investigating the role of conditioned stimuli in drug craving and relapse.

MODULATION OF mRNAS FOLLOWING WITHDRAWAL FROM COCAINE AS REVEALED BY DIFFERENTIAL DISPLAY. D.J. Ennulat* and B.M. Cohen. McLean Hospital and Harvard Medical School, 115 Mill Street, Belmont, MA 02178.

We are currently using differential display reverse transcriptase PCR (DDRT-PCR) to identify genes which are regulated following withdrawal from multiple doses of cocaine. Initially the ability of DDRT-PCR to accurately and consistently reveal the regulation of known genes was investigated. Total RNA samples were isolated from the striatum of rats that had received repeated IV injections of either vehicle (0.9% saline pH 7.0) or 6 mg/kg cocaine-HCl and subjected to DDRT-PCR with primer pair 8G which is designed to amplify a 240 bp segment (8G240) of cDNA derived from *c-fos* mRNA. Independent DDRT-PCR reactions consistently indicate that the relative amount of 8G240 accurately reflects the level of expression of *c-fos* mRNA that was previously measured by Northern blot analysis [Ennulat *et al.*, (1994), Mol. Brain Res. 26:106-112.]. Here DDRT-PCR mediated amplification of known genes has the advantage of providing an internal control to confirm the validity of the DDRT-PCR reactions. An anonymous PCR product (8G168) was recently observed to be induced at 1 day following the last cocaine treatment, but not at 1 hr. Two other PCR products (8G132 and 8G127) are reproducibly repressed in cocaine treated animals both 1 hr. and 1 day after the last exposure to cocaine. Further characterization of these PCR products is ongoing and additional screening with other selected primer pairs is expected to reveal additional candidate genes. This work is supported by grants from NIMH and NARSAD.

767.19

CHANGES IN Na+ CHANNEL FUNCTION DURING WITHDRAWAL FROM CONTINUOUS OR INTERMITTENT COCAINE ADMINISTRATION. G.R. King, and E.H. Ellinwood Jr.*, Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710

Previous research clearly indicates that intermittent cocaine administration induces sensitization, while continuous cocaine administration induces tolerance, to some of the effects of subsequent cocaine administration. Much research has focussed on the uptake inhibiting properties of cocaine, in spite of the fact that cocaine is a potent local anesthetic. The present experiments evaluated whether sensitization and tolerance are related to functional changes in Na+ channels. Rats were pre-treated with 40 mg/kg/day cocaine for 14 days by either subcutaneous injections or osmotic minipumps. On day 7 of withdrawal the rats were sacrificed, and striatal slices obtained. The slices were perfused with 35 mM K+, to induce DA release, in the absence and presence of 0, 5, 10 or 20 μM procaine, a local anesthetic and Na+ channel blocker. The results indicated that in slices from the intermittent administration rats, the ability of procaine to inhibit K+ induced release was attenuated. In contrast, in slices from the continuous administration rats, the ability of procaine to inhibit K+ induced release was enhanced.

EPILEPSY: ANIMAL MODELS III

768.1

SEIZURE SUSCEPTIBILITY IN AN ANIMAL MODEL OF NEURONAL MIGRATION DISORDERS. S.C. Baraban* and P.A. Schwartzkroin, Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

We investigated the effect of prenatal (E15) methylazoxymethanol acetate (MAMac), a teratogenic agent, on seizure susceptibility of the offspring Cresyl violet-stained sections of hippocampus confirmed the presence of ectopic pyramidal cells in s.radiatum and s.oriens of region CA1/CA2. In awake, freely-behaving animals (P60) from MAMac-injected dams, the latencies to flurothyl-induced seizure activity (myoclonic jerk: 173 ± 2.3 s; forelimb clonus: 215 ± 4.6 s) were significantly shorter than those of age-, weight- and sex-matched controls (200 ± 6.9 s and 238 ± 8.8 s, respectively). Shorter seizure latencies were associated with larger numbers of ectopic pyramidal cells. *In vitro* intracellular recordings from CA1 pyramidal cells in MAMac-treated tissue (P25-P35) were similar in many of their intrinsic properties (e.g., RMP, AP amplitude, R_{in}) to cells from control tissue. The synaptic responses of CA1 cells in MAMac and control hippocampus were also comparable. However, MAMac-treated tissue could be distinguished as having an unusually high proportion of CA1 cells (>60%) which fired a burst of action potentials in response to suprathreshold current injection. Further, elevation of extracellular $[K^+]_o$ from 3, to 6 mM resulted in evoked epileptiform discharge activity (10/10) and spontaneous epileptiform activity (8/13) in slices from MAMac-treated rats; such epileptiform activity was rarely observed in controls (evoked: 3/9; spontaneous: 0/8). These data suggest that prenatal MAMac administration results in functional epileptogenic abnormalities characterized by reduced seizure thresholds. As such, the MAMac model may serve as a useful model for studying early onset epilepsies resulting from abnormal neuronal migration. This work was supported by NIH grant NS15317.

768.2

FUNCTIONAL CHARACTERIZATION OF THE *JERKY* PROTEIN IN MICE. G.P. Donovan* and M. Toth. Department of Pharmacology, Cornell University Medical College, New York, NY 10021.

We have identified a mouse gene named *jerky* that, when disrupted by insertional mutation, causes an epileptic phenotype and EEG. In order to characterize the mechanism by which epileptogenesis occurs, it is necessary to do both localization studies as well as functional analysis of the *jerky* protein. Computer database searches have revealed significant homology to sequences represented in centromere binding protein-B (CENP-B), Drosophila transposable element POGO-R11, and yeast regulatory proteins RAG3 and PDC2. The pairwise alignments were most significant with CENP-B and POGO-R11 (P-values < 10^{-16}). The order of the domains was identical in all sequences, further suggesting the relationship between them. In addition to these homologies, all four of these proteins have DNA binding characteristics. In order to determine if the *jerky* protein also has this function, we have purified the 41.7 kD *jerky* protein using a 6-His fusion vector system. We have also epitope tagged the *jerky* protein at the N-terminus and transfected this construct into mammalian cells for immunohistochemical analysis and further functional studies.

DISSECTING THE COMPLEX GENETICS OF EPILEPSY IN THE EL INBRED MOUSE STRAIN W.N. Frankel*, C.M. Lutz, E.W. Johnson, A. Valenzuela The Jackson Laboratory, Bar Harbor, ME

In the EL mouse strain, several genetic loci combine to produce recurrent, tonic-clonic and generalized seizures like common epilepsies in humans. In the mice, seizures occur naturally at ~90 days of age, although for genetic studies we induce at ~30 d. by gentle rhythmic stimulation to measure seizures quantitatively. Genetic crosses to date reveal several loci: *El5* (Chr 14), *El2* (Chr 2) *El1* (Chr 9), *El3* (Chr 10) and two provisional loci *El4* (Chr 9) and *El6* (Chr 11). Effects of these loci depend not only on strain background but also on the *kind* of cross. In a backcross with ABP, *El2*, *El1* and *El3* account for most of the trait. But only the minor *El3* had an effect in the corresponding intercross. In an intercross with the DDY strain, a close relative to EL, *none* of these loci had major effects. The big difference between this pair, *El5*, maps to Chr 14 accounting for ~35% of the genetic variance. Several minor players were found, including possibly *El1*, and only these were seen in a corresponding backcross to DDY. Finally, in (EL x C3H)F2 intercross progeny, *no* known *El* locus was detectable.

Such complexities are enlightening and disturbing. First, they imply there is no single *El* locus 'essential' for high seizure frequency. Second, although many loci can influence seizures, to explain strain-*independent* effects these loci must exhibit epistatic interactions. While complex, however, the results are still reproducible within a genetic context. Thus it is possible to not only identify candidates, but to *de novo* positionally clone loci with large effects by using special mouse strains. For example, we constructed and tested ABP.EL-*El1*, *El2* and *El3 congenic* strains. Compared to ABP, ABP.EL-$El2^e$ strain seizes much more, ABP.EL-$El1^e$ seizes slightly more, and ABP.EL-$El3^e$ no more than ABP. These results are consistent with the relative effects of these loci in prior crosses. We are now testing derivative recombinant strains to find *El2*, and in similar studies, *El5*.

768.4

EPILEPTIC MICE SHOW DEVELOPMENTAL DIFFERENCES FOR VSCC SUBTYPES. M.J. Litzinger*, R. Hardy, J. Speakman, J.R. Abbott & S.K. Jensen. Lab. of Applied Neurobiology, Depts. of Pediatrics and Physiology, University of Utah. Salt Lake City, Utah 84132.

Developmental differences in voltage sensitive calcium channel (VSCC) subtypes have been discovered in Swiss Webster mouse brain cortical preparations using displacement binding of ω-conotixin(CgTx) GVIA by ω-CgTx MVIIA (Abbott & Litzinger, 1994). Abbott and Litzinger suggest the presence of a juvenile form of the N-type calcium channel in the developing mouse brain. This juvenile form seems to disappear after dendro-axonal synapse formation during the "critical period". Esplin, et al (1994) showed that the DBA epileptic mouse whole brain had a different developmental sequence of ω-CgTxGVIA binding. DBA mouse cortex showed the same unusual binding pattern(Jensen, et al, submitted,1995). The potential for abberant synapse formation in in the DBA mouse brain was proposed.

The present study compares displacement data from the developing DBA mouse whole brain to Swiss Webster mouse whole brain. At postnatal days 4, 8 and 16, ω CgTx GVIA was displaced by ω-CgTx M VIIA. Unlike the Swiss Webster data, the DBA mouse showed no juvenile subclasses of the N-type channel at day 8 or day 16. However, preliminary data suggest that thef juvenile subtype channel is seen earlier on day 4 and is consistant with the different developmetal profile shown in the DBA mouse whole brain ω-CgTx GVIA binding!

Neurodevelopment of epileptic DBA mice is clearly different compared to Swiss Webster mice when following markers of presynaptic calcium channels. Perhaps these developmental differences in the presynaptic calcium channels affect the release of neurotransmitter in the DBA mouse.

768.5

DISINHIBITION OF THE DENTATE GYRUS FROM THE EPILEPSY PRONE EL MOUSE REVEALS PAROXYSMAL FIELD DISCHARGES. H. Wang*, W. Frankel and L.M. Masukawa, Dept. of Neurology, University of Pennsylvania Medical School and The Graduate Hospital Research Center, Philadelphia, PA 19146 and The Jackson Laboratory, Bar Harbor, ME 04609.

A genetic model of epilepsy, the epilepsy prone EL mouse, develops spontaneous seizures after approximately 90 days of life. Hippocampal brain slices from EL mice were examined during a period of 8-14 weeks of age. Field responses from the granule cell layer of the dentate gyrus during perforant path stimulation were compared with those from the genetic control, the DDY mouse strain. In control solution, the orthodromic and antidromic responses were similar for the two mouse strains, each response type was characterized by a single population spike, and the presence of a positive field PSP (duration: 10-20 ms) or an absence of a field PSP, respectively. Paired pulse depression recorded at 10, 20 and 70 ms interstimulus interval was significantly less in the EL than the DDY mouse. After exposure to bicuculline (10 μM) for a period of 40 minutes or more, the orthodromic response was distinctly different in the two strains. The response in the DDY mouse (6/6) exhibited multiple population spikes (2-6) superimposed on a more prolonged monophasic PSP (duration: 30 ms), whereas, the response in the EL mouse (9/9) was greatly prolonged (> 400 ms) and was often biphasic with a large, protracted negative component following an initial positive potential (6/9). During the initial 150 ms of the paroxysmal-like response, a rapid population spike discharge (10-50 spikes) occurred. Therefore, the orthodromic response of the dentate gyrus examined in EL mice during a period somewhat before the period of spontaneous seizures was normal in appearance but exhibited reduced feedback inhibition. During disinhibition an underlying paroxysmal excitatory response was revealed which might function later in life during spontaneous seizure generation. Supported by NIH grant # NS23077 to LMM.

SELF - SUSTAINING STATUS EPILEPTICUS RESULTING FROM BRIEF PERFORANT PATH STIMULATION IN FREE MOVING RATS. A.Mazarati, Y.Shirasaka*, C.G.Wasterlain, VA Medical Center Sepulveda CA 91343-2099, Dept. of Neurology and Brain Research Institute, UCLA School of Medicine.

We studied the effects of perforant path stimulation (PPS) of various durations on the induction of self- sustaining status epilepticus (SSSE), changes in paired- pulse inhibition and brain damage.

Male Wistar rats (13 -14 weeks old) were implanted with a stimulating electrode into the perforant path and a recording electrode into the dentate gyrus and stimulated in the awake state four weeks after surgery (one per minute 10 s trains of single stimuli at 20 Hz, 20 V, 0.1 ms).

After 30 min of PPS, 9 of 10 rats had SSSE lasting at least 3 h and the last rat displayed seizures by EEG without overt behavioral convulsions. 4 rats died within 24 h after PPS. The 5 animals recorded displayed paroxysmal EEG activity and some decrease of paired- pulse inhibition 3 days after PPS. 7 rats had severe bilateral hippocampal damage and lesions in amygdala, pyriform, entorhinal and neocortex, 3 had mild or minimal injury. The degree of brain damage correlated with the severity of SSSE. 15 min of stimulation induced motor SSSE in two of 3 rats and interictal spikes in 1 animal. 1 animal died 24 h after PPS, 1 rat displayed paired- pulse disinhibition 3 days after PPS and in 1 animal paired- pulse inhibition recovered at this time. Neuronal injury was observed bilaterally in hilus, CA1 and CA3. 7 min of PPS did not cause SSSE, loss of paired- pulse inhibition or significant cell loss in any of 4 rats. These results demonstrate that brief PPS is sufficient to trigger SSSE, loss of inhibition and hippocampal damage.

THE ROLE OF $GABA_A$ LOW-AFFINITY RECEPTORS IN CONTROL OF SEIZURES. J. Velíšková, L. Velíšek, M.L. Nunes and S.L. Moshé*, Departments of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461

GABAergic transmission in the substantia nigra pars reticulata (SNR) controls seizure propagation. In adult rats there are two discrete regions which mediate opposing effects on seizures. Bilateral microinfusions of muscimol (both high- and low-affinity $GABA_A$ receptor agonist) into anterior part of SNR are anticonvulsant, while the infusions into the posterior-lateral part are proconvulsant. In contrast, in 15-day-old rat pups, only the proconvulsant muscimol-sensitive network is present.

In this study, we determined the role of low-affinity $GABA_A$ receptors in the SNR in the control of seizures. In 15 day old rats, bilateral intranigral infusions of ZAPA (a low-affinity $GABA_A$ receptor agonist; 2 μg/0.25 μl) significantly increased the latency to onset of both clonic and tonic-clonic flurothyl-induced seizures. In the adult rats, the same doses of ZAPA had no significant effects on either clonic or tonic-clonic flurothyl-induced seizures in either anterior or posterior part of the SNR compared to the saline-infused controls.

The data suggest that the low-affinity $GABA_A$ receptors in SNR are involved in control of clonic and tonic-clonic seizures in 15-day-old rats, but not in adults.

SELECTIVE CHANGES IN GENE EXPRESSION ASSOCIATED WITH EPILEPTOGENESIS IN HIPPOCAMPAL/ENTORHINAL CORTICAL SLICES RS Vick, A Rafiq, DA Coulter, ER Jakoi, and RJ DeLorenzo* Department of Neurology, Medical College of Virginia/Virginia Commonwealth University, Richmond, VA 23298

Long term exposure of hippocampal slice preparations to extracelular 0 Mg^{2+} has been shown to produce recurrent seizures. This study investigated changes in specific mRNA levels that occur in association with these recurrent seizures. Hippocampal/entorhinal cortices (HEC) from male 21-30 d rats were removed, sliced, and placed in oxygenated artificial cerebrospinal fluid (ACSF) in the presence or absence of Mg^{2+} for 2 h. The slices were returned to ACSF containing Mg^{2+} for 3 h. Epileptogenic activity was was elicited throughout representative HEC preparations by a single electrical stimulation. Corresponding slices were frozen, blocked, and cryosectioned for in situ hybridization (Perlin et al., *PNAS*, 90:1741, 1992). Complementary oligonucleotide probes to the $GABA_A$ α1 and α2 subunit, ligatin, α CAMKinase II, and the NMDA receptor subunits NR1, NR2a-c were 3' end-labeled with [a-[^{35}S]thio]dCTP. Autoradiography was analyzed by a Jandel-Mocha image analysis system. In situ hybridization demonstrated that levels of $GABA_A$ α2 and ligatin mRNA decreased in the CA1-2, CA3-4, and DG regions. Levels of $GABA_A$ α1 and α CAMKinase II mRNA did not change throughout the HEC while levels of the NMDA subunits (NR1, NR2a-c) mRNA increased. Decreases in the levels of mRNA for $GABA_A$ α2 and ligatin and increases in the levels of mRNA of the NMDA subunits for at least 3 h post 0 Mg^{2+} exposure are consistent with the hypothesis that long term gene changes are induced during epileptogenesis and may contribute to altered neuronal excitability.

DECREASED CALCIUM-CALMODULIN KINASE II IMMUNOREACTIVITY IN HIPPOCAMPAL CA1 NEURONS IN AN ELECTRICAL STIMULATION MODEL OF STATUS EPILEPTICUS. A.C. Rice*[1], S.B. Churn[1], V.J. Obias[2], and R.J. DeLorenzo[1], [1]Department of Neurology, [2]Department of Physiology, Virginia Commonwealth University, Richmond, Virginia 23298-0599

The well characterized hippocampal damage observed following status epilepticus (SE) involves cell loss in the dentate hilar region, and the CA1 and CA3 pyramidal cell layers. The biochemical mechanisms underlying the cell death are hypothesized to be related to alterations in calcium homeostasis. Calcium-calmodulin kinase II(CaM kinase II) is a calcium dependent kinase involved in many cellular processes such as neurotransmitter release and cytoarchitecture formation. Using an ischemia model, this lab has demonstrated a decrease in CaM kinase II activity which corresponded to a decrease in CaM kinase II-β (60 kDa subunit) immunoreactivity in hippocampal regions with subsequent cell death. Since CaM kinase II activity also decreased in the continuous hippocampal stimulation(CHS) model of SE, we examined the localization of CaM kinase II-β immunoreactivity in CHS treated animals. The CHS paradigm involves 90 min of electrical stimulation (400μAmps, 50Hz in 10s trains every 11s). At 4 hr ,and 3 and 7 days post-CHS the animals were paraformaldehyde perfused and brain sections were paraffin embedded. Ten micron sections were incubated with anti-CaM kinase II-β monoclonal antibodies (1:500 dilution), followed by an ABC elite kit (Vector Labs) protocol and developed using diaminobenzamidine and hydrogen peroxide. Positively staining cells were counted per unit length in the CA1 region. Compared to surgical controls the CHS treated animals had decreased (approximately 40%) immunoreactive cells at all time points examined. Loss of immunoreactivity at the early time points without cell loss indicates that the loss of CaM kinase II predicts cells undergoing delayed neuronal cell death.

Novel Populations of Calbindin-D28k Immunoreactive Neurons in the Hippocampus Following Tetanus Toxin Induced Seizures In Early-Life. Chong L. Lee*, and John W. Swann, The Cain Foundation Laboratories, Dept. of Pediatrics, Baylor College of Medicine, Houston, TX.

Early-life seizures induced by tetanus toxin (TT), produce novel populations of calbindin-D28k immunoreactive (CAL-ir) neurons in the hippocampus. While CAL staining is reduced in CA2 and the dentate granule cell (GCL), novel populations of CAL-ir neurons are observed in the alveus-stratum oriens (A-SO) of CA1 and the hilus. To better under-stand the origin of these CAL-ir neurons, rat pups (PND 3-20) were given daily IP injection of bromodeoxyuridine (BrdU - 50 mg/kg), for 1-20 days. On PND 10, TT (2.5 ng) was injected into the right CA3 subfield and animals monitored daily for 1 hr for occurrence of behavioral seizures. On PND 54-60, animals were processed for double immunohistochemistry to reveal colocalization of BrdU, CAL and somatostatin (SRIF) in the dentate gyrus. Double labeled neurons were not observed in CA1. Dense BrdU-ir granule cells (GC), double labeled with CAL were observed in the GCL. Many (but not all) of the novel hilar CAL-ir neurons were double labeled with BrdU and had soma size similar to double labeled GC in the GCL. BrdU and SRIF double labeled neurons was rarely observed in the DG. No CAL and SRIF double labeled neurons were encountered. In summary, the population of CAL-ir interneurons in the A-SO of CA1 may represent novel expression of CAL by these intrinsic neurons. However, the new population of CAL-ir neurons in the hilus are born postnatally (BrdU-ir) and may represent displaced GC. Both populations could contribute to the change in the excitability recorded in the hippocampus. (Supported by NIH Grant NS18309)

HYPOXIA-INDUCED SEIZURE ACTIVITY PRODUCES MORPHOLOGICAL AND FUNCTIONAL CHANGES IN THE DEVELOPING HIPPOCAMPUS. J. Owens, Jr., C.A. Robbins, H.J. Wenzel, and P.A. Schwartzkroin*. Depts. of Physiology/Biophysics and Neurosurgery, Univ. of Washington, Seattle, WA 98195.

Adults with temporal lobe epilepsy are more likely to have experienced seizures in childhood than are adults without epilepsy. Yet it remains unclear whether the primary pathogenetic factor underlying subsequent epilepsy in adulthood is: a) the event or condition which provoked the childhood seizures; b) the seizures themselves; or c) an interaction between the two. Perinatal hypoxia-ischemia is a frequent antecedent of pediatric seizures and a not uncommon obstetrical complication. In order to separate the effects of hypoxia-induced seizures from hypoxia alone, we exposed 10 day old rats to one of two hypoxia protocols: 1) 60 minutes of approximately 5% oxygen followed by one hypoxia-induced seizure or 2) 60 minutes of hypoxia during which the oxygen concentration was manipulated to produce 8 to 12 seizures. Immediate mortality was higher in the single seizure group (8%) than in the multiple seizure group (<1%). Extracellular recordings from hippocampal slices prepared 3 days post-hypoxia showed an increased gain (relative to controls) in the input-output curve only for animals from the multiple seizure group. Analysis of cresyl violet stained sections through the dorsal hippocampus revealed a significant increase, relative to littermate controls, in both the number and the density of pyknotic cells in the stratum granulosum and hilus of the dentate gyrus in animals from the multiple seizure group but not from the single seizure group. Flurothyl testing 60 to 80 days after the hypoxic exposure demonstrated a significant decrease in latency to the first myoclonic jerk and to forelimb clonus in animals from the multiple seizure group, while a lesser reduction was evident in animals from the single seizure group. These results suggest that the seizure episodes contribute significantly to the morphological and functional changes seen in post-hypoxic hippocampus. (Supported by NIH, NINDS grant# 15317)

THALAMIC CONTROL OF HIGH VOLTAGE SPIKE-AND-WAVE SPINDLES IN RATS. G. Marini*, G.Macchi, M.Mancia (SPON: European Neuroscience Association) Istituto di Fisiologia Umana II, Università degli Studi; *INB-CNR, Milano; Clinica Neurologica, Università Cattolica, Roma (Italy).

It has been shown that the thalamic reticular nucleus (NRT) exerts a control over neocortical paroxysmal activity. Unilateral electrolytical and chemical lesions of the NRT released spike-and-wave complexes on both cerebral hemispheres, but primarily on the contralateral one, in freely moving Sprague Dawley rats. Our working hypothesis is that these paroxysms may be induced by the disinhibition of the contralateral NRT and then transferred via the corpus callosum to the other hemisphere. Four rats, previously implanted for chronical recording of EEG and nuchal EMG, were ketamine-sedated and received ibotenic acid injections stereotaxically placed in the left NRT. The corpus callosum was then transected with a small surgical blade mounted on a stereotaxic holder.The day after the injection high-voltage spike-wave spindles (HVS) at 6-9Hz occurred associated with awake immobility on the right hemisphere. The discharges arose from a desynchronized EEG activity and were not apparent during sleep. The duration ranged from 2 to 6.5s. The intraepisodic frequency of these HVS was 5-10 s. Pinching of the tail interrupted the ongoing HVS. The asymmetry in the two hemispheres was also corroborated by the spectral analysis. The ipsilateral EEG displayed oscillations within a frequency band of 0.5-7Hz while the contralateral one showed the burst of activity in the bands 4-7 and 7-14 Hz. HVS are not present spontaneously in this strain of rodent species. Since in rats HVS patterns are viewed as epileptic phenomena because of their spontaneous, episodic, recurrent, and paroxysmal nature, their appearance after callosotomy only on the contralesioned hemisphere support the idea that the bilaterality of the paroxysm is due to callosal projections and that the disinhibition of the NRT contralateral to the lesion may underlie epileptiform patterns.

DEXTRAN PRESERVATION OF CA3, CA4 AND DENTATE IN HIPPOCAMPAL BRAIN SLICES. **H.Qi*, F.E.Hospod, S.Motwani, S.Trowbridge, C.S.Patlak , G.C.Newman. Depts. of Neurology and Surgery , SUNY at Stony Brook, NY and VAMC at Northport, NY.**

Brain slice models of epilepsy often focus on CA3 and dentate neurons yet hippocampal slices from adult rats show severe neuronal injury in both areas if incubated submerged in Krebs-Ringer (K-R) at 37°C. In an effort to reduce brain slice swelling during incubations, we have re-considered the use of dextran which was shown over 20 years ago to eliminate swelling. We have found that modifying K-R by adding 3% dextran and reducing NaCl by 16 mM significantly improves both histology and water gain.

Slices were incubated for 4 h *in vitro*, submerged 1 mm at 37°C with 95%O_2-5%CO_2. Dextran improves histologic score (1 - 5; lower is better) in all slice regions, but especially in CA3 (1.9±0.2 *v.* 3.3±1.2) and dentate (1.3±0.7 *v.* 2.8±0.6). Wet weight / protein falls from 14.4±3.0 in K-R to 11.9±1.8 with dextran. Water gain over 4 h falls from 33% to 9%. There is no change in tissue ATP, ADP, AMP or energy charge, in the relative size of the extracellular space (0.25) or the diffusion coefficients for either ^{14}C-PEG(4000) (3.8x10^{-7} cm^2 sec^{-1}) or ^3H_2O (1.2x10^{-5}). Dextran increases glucose utilization from 39.7±11.3 to 78.3±19.5 μmole/100g/min.

Thus, dextran markedly improves histology and reduces water gain of adult rat hippocampal brain slices incubated slightly submerged at 37°C. This is not due to improved adenylates or changes in diffusion but is associated with increased glucose utilization. Dextran should be considered when neuronal instability or obvious water gain is encountered in brain slices.

Support of VA Merit Review and NIH #NS28429 are greatly appreciated.

SEIZURE TESTING AFTER GLOBAL ISCHEMIA DOES NOT INDUCE HEARING LOSS IN POST-ISCHEMIC AUDIOGENIC SEIZURE-PRONE (PIAS) RATS. K. H. Reid*, C. Young and V. Iyer Depts. of Anat. Sci. Neurobiol. and Neurology, Univ. of Louisville, Louisville KY 40292.

PIAS rats show some reduction of seizure susceptibility with time; this varies greatly between rats (Kawai et al., Epilepsia 33:38,1992; Reid et al., FASEB J. 8:A660,1994). It has been suggested (Naritoku et al., Exp. Neurol. 115:317,1992) that the repetition of intense auditory stimulation could induce a hearing loss which would appear as a loss of sensitivity to sound-triggered seizures. Hearing impairment has been shown to contribute to the difference in seizure sensitivity between GEPR3 and GEPR9 rats (Faingold et al., Exp. Neurol. 99:678,1988). We used auditory evoked potentials to evaluate hearing in 7 post-ischemic rats repeatedly during seizure testing with a 110 dB alarm bell, and found no hearing loss as measured by threshold to click stimuli at 10/sec. (BAEPs, average of 1024 responses). We conclude that some other process - possibly a return of GABAergic inhibition (Penix et al., Neurol. 43:A312,1993), neuronal regrowth or CNS reorganization - underlies recovery from seizure susceptibility in PIAS rats.

ABERRANT NEURONAL FIRING PATTERNS IN DEEP LAYERS OF SUPERIOR COLLICULUS SUBSERVE AUDIOGENIC SEIZURE EXPRESSION IN GENETICALLY EPILEPSY-PRONE RATS

M.E. Randall and C.L. Faingold*. Dept. Pharmacology, Southern Illinois Univ. School of Medicine, Springfield, IL 62794.

The deep layers of superior colliculus (DLSC) have previously been implicated in the neuronal network for audiogenic seizures (AGS) in the genetically epilepsy-prone rat (GEPR-9). The present study examined DLSC neuronal responses using chronically implanted microelectrodes. Normal Sprague-Dawley rats and the GEPR-9 were anesthetized with ketamine/xylazine (85/3 mg/kg), and microwire electrodes were implanted into DLSC. Unit activity was recorded at least one week later in freely-moving rats. Responses were evaluated to step-wise acoustic intensity increments up to 100 dB SPL (12 kHz tone bursts, 100 msec, 1/2sec), effective in inducing AGS at high intensities. DLSC neurons in the GEPR-9 exhibited a precipitous onset of acoustically-evoked firing at 80-90 dB, N=16), which was a considerably higher intensity than that observed for the more gradual onset of neuronal responses in normals (at 65-75 dB). In most DLSC neurons rapid tonic firing began 1-2 sec before the onset of wild running, and it continued unchanged during AGS. DLSC firing ceased as the post-ictal period began. The DLSC is proposed to be a major nucleus in the trajectory of the AGS network from inferior colliculus (IC) to brainstem reticular formation (RF). The aberrant response patterns in GEPR-9 DLSC neurons share certain similarities with IC (threshold elevation, post-ictal silence) and others with RF neurons (precipitous onset). The aberrant pattern of firing changes in DLSC is unique and suggests that the DLSC may be critical in AGS, particularly in generation of the wild running component.

STIMULUS INTENSITY AND GENDER DEPENDENT CHARACTERISTICS OF AUDIOGENIC SEIZURE ACTIVITY IN RAT. K.C. Ross[1], M.H. Durkin[1], L.A. Abercrombie[1] and J.R. Coleman[1,2]*. Depts. of Psychology[1] and Physiology[2], Univ. of South Carolina, Columbia, SC 29208.

Audiogenic seizure (AGS) activity in rats results from priming to a high intensity sound during an early sensitive period. One goal of this study was to assess later seizure activity patterns associated with exposure to different sound intensity levels. Previous AGS research has utilized dB levels ranging from 98 dB SPL (Frye et al., 1986) to over 120 dB SPL (Snyder-Keller and Pierson, 1992), which may elicit differential AGS activity. L-E rats at postnatal day 14 (PND 14) were exposed to 10 KHz tone bursts for 8 m. at 120 dB SPL. Beginning at PND 24, subjects (n=16) were tested for AGS using continuous white noise at four intensity levels: 90 dB, 100 dB, 110 dB, and 120 dB, and were recorded as displaying no seizure activity, wild running only, or wild running followed by clonus. There was a significant main effect of intensity ($p<.000$). Post-hoc analysis revealed significant pairwise differences in AGS activity between 100 dB and 110 dB ($p<.000$) and between 110 dB and 120 dB ($p<.000$). The main effect of gender and the interaction of intensity by gender was not significant.

Another goal of this study was to explore gender differences with regard to seizure onset latency and onset duration. Onset latency for males (M=36.73 s, SD=12.09) was longer than that for females (M=31.81 s, SD=14.36; $p<.06$). The difference in onset duration for males (M=23.70 s, SD=9.50) and females (M=24.33 s, SD=6.86) was not significant. These data suggest first that AGS activity is intensity-dependent, with 120 dB always eliciting clonus. Secondly, there appear to be some gender differences in AGS characteristics.

COMPARISON OF ELECTROPHYSIOLOGICAL PROPERTIES OF NEURONS IN SUBNUCLEI OF RAT INFERIOR COLLICULUS (IC) IN VITRO. Y. Li*, M.S. Evans, D.N. Chakravarty, and C.L. Faingold, Depts. Pharmacol. Neurol. Southern Illinois University School of Medicine, Springfield, IL 62794.

The major subnuclei of IC play disparate roles in processing of acoustic stimuli and differential roles in audiogenic seizures. The basis for the differing roles of these subnuclei may involve differences in synaptic responses and/or differences in membrane properties of the neurons. The present study examined this issue using intracellular recordings from neurons from external cortex (ICx, N=11), dorsal cortex (ICd, N=32) and central nucleus of IC (ICc, N=12). The locations of the IC subnuclei were determined according to a standard stereotaxic atlas (Paxinos and Watson, 1986). Coronal slices (400 μm) of IC were prepared using a vibratome. Mean resting membrane potential was similar in all subdivisions [61±12mV, SD (ICx), 67±8mV (ICd) and 66±8 (ICc)]. Input resistance measured in each subdivision differed [66±29 MΩ (ICx), 49±21 (ICd) and 33±14 (ICc)]. The mean amplitudes of the action potentials (APs) of cells within the nuclei was similar but the mean AP widths differed. Thus, AP amplitude in ICx cells was 67±9mV, width at ½ height of 0.94±0.37ms. The mean AP amplitude of ICd cells was 68±21mV, width at ½ height of 0.71±0.4ms. The mean amplitude of APs of ICc cells was 70±12mV, width at ½ height of 0.37±0.14ms. Depolarization revealed a calcium mediated "hump" at the onset of the I-V curve deflection in ICd cells that was not seen in ICx or ICc cells. Spontaneous action potentials at resting membrane potential were seen more frequently in ICx cells than in ICd and ICc cells. Afterhyperpolarization was also less common in ICx neurons. Stimulation in CoIC elicited a single AP followed by a late depolarization (N=9 of 12). CoIC stimulation did not elicit a response in ICc neurons. However, stimulation of the lateral lemniscus elicited an action potential followed by a hyperpolarization and a slow return to resting potential in ICc and ICd cells. The present study supports the concept that differences in membrane physiology and responses to synaptic input of neurons in these IC subdivisions may make significant contributions to the different roles in acoustic processing and in the network for audiogenic seizures. INDUCTION OF INTERLEUKIN-1α IN THE HYPOTHALAMUS OF THE FRINGS AUDIOGENIC SEIZURE SUSCEPTIBLE MOUSE . S.L. Skradski[1], L.K. Jackson[2], H.H. Wolf*[1], H.S. White[1] and L.C. Gahring[2], Anticonvulsant Drug Development Program; Depts. Pharmacology and Toxicology[1] and Medicine[2], Univ. Utah, and S.L.C. VA-GRECC[2], S.L.C., UT.

The cytokine interleukin-1α (IL-1α) is a mediator of inflammation and immunity in the peripheral immune system and also a mediator of CNS function such as slow wave sleep and fever. IL-1α can be induced in the CNS by stimulation of the periphery with inflammatory agents such as bacterial lipopolysaccharide and also by seizure inducing convulsants such as kainic acid. Kainic acid induces lesions and immune cell infiltration, which complicate the interpretation of these results. Therefore, we chose to determine the effects of seizures on CNS cytokine production following sound stimulation. The Frings mouse displays generalized tonic-clonic seizures upon exposure to high intensity sound stimulus (110 db, 11kHz). To determine if transcription of IL-1α mRNA is altered by seizure induction, Frings mice were exposed to sound stimuli, observed to undergo tonic extension seizure, sacrificed and perfused with saline (to remove blood contamination) either immediately, 2, 4, 6 or 24 hrs post-seizure. RNA from tissue samples was extracted and RT-PCR performed using IL-1α primers. The results were quantified by measuring EtBr incorporation into the PCR product. IL-1α mRNA levels were elevated in the hypothalamus of 1 of 3 mice sacrificed at 4 hrs and 2 of 3 mice sacrificed at 6 hrs post-seizure. IL-1α mRNA levels returned to normal levels by 24 hrs post-seizure. The induction of IL-1α was blocked completely in mice pre-treated with the anti-inflammatory glucocorticoid, dexamethasone. These results suggest that IL-1α plays a role in post-ictal alterations in the CNS. *Supported by NIH contract NO1-NS-4-2311 and NIH grants AG04418 , NS0990, and the American Federation for Aging Research.*

EPILEPSY: PRIMATE STUDIES

769.1

SPONTANEOUSLY APPEARING SHARP FIELD POTENTIALS IN HUMAN NEOCORTICAL SLICES FROM EPILEPTIC PATIENTS E.-J. Speckmann[1*], R. Köhling[1], A. Lücke[1], H. Straub[1], , I. Tuxhorn[2], P. Wolf[2], H. Pannek[3] and F. Oppel[3]
[1]Institut für Physiologie, Universität, 49149 Münster, [2]Epilepsie-Zentrum Bethel, Klinik Mara I, and [3] Neurochirurgische Klinik, Gilead I, 33617 Bielefeld

Human neocortical slice preparations were obtained from patients undergoing surgical treatment of refractory epilepsy. Repetitive sharp field potentials occurred spontaneously, i.e. without external manipulation (cf. Schwartzkroin and Knowles (1984) Science 223: 709-712; McCormick (1989) J. Neurophysiol. 62: 1018-1027), in these preparations. These potentials resembled epileptiform potentials in the EEG (50-300μV, 0.3-0.6Hz) and were associated with sequences of excitatory and inhibitory potentials of surrounding neurons. In this investigation, these potentials were characterized pharmacologically.

The slice preparations (n=30 of 13 patients) were superfused with artificial cerebrospinal fluid. Field potential (FP) and intracellular recordings (n=10) were done from layer III to V. The following agents were added to the superfusate: DL-2-amino-phosphonovalerate (APV, 100 μM, n=11), 6-cyano-7-nitroquinoxalin-2,3-dion (CNQX, 5μM), bicuculline (10 μM), CGP 55845A (10 μM), verapamil (40 μM), phenytoin and carbamazepine (50-100 μM).

FP and postsynaptic potentials were reversibly blocked by the non-NMDA antagonist CNQX, but not by the NMDA antagonist APV. Likewise, the $GABA_A$ antagonist bicuculline reversibly suppressed spontaneous potentials but not the $GABA_B$ antagonist CGP 55845A. The organic calcium channel blocker verapamil, as well as the standard antiepileptic drugs phenytoin and carbamazepine also reversibly blocked all potentials.

These findings suggest that the spontaneous activity is (1) mediated via non-NMDA receptors, (2) possibly synchronized via gabaergic interneurons, (3) generated involving calcium currents and (4) suppressed by antiepileptic drugs.

769.2

ABNORMAL EXCITABILITY OF DENTATE GRANULE CELLS IN HIPPOCAMPAL SLICES FROM TEMPORAL LOBE EPILEPTIC PATIENTS. K.Uruno*, M.J.O'Connor and L.M.Masukawa. Depts. of Neurology and Surgery, University of Pennsylvania Medical School and The Graduate Hospital Research Center, Philadelphia, PA 19146.

We previously reported that hippocampal tissue taken from some temporal lobe epileptic patients during therapeutic lobectomies exhibited field responses that were more excitable than others, and that those excitable responses were significantly correlated with abnormal Timm staining in the molecular layer of the dentate gyrus, neuronal loss in the hilus (Masukawa et al. 1992) or reduced feedback synaptic inhibition or abnormal synaptic inhibition (Uruno et al. 1994, Uruno et al. in press). Our observations are consistent with an imbalance between overall excitation and inhibition. Since those hippocampi with intact or even strong inhibition were taken from patients with refractory seizures, a decrease in feedback inhibition is unlikely the single cause of epilepsy.

In the present study, in addition to field recordings, we used fine electrode intracellular recording from dentate granule cells to examine responses of individual neurons. We injected cells with biocytin or neurobiotin for identification as granule cells. We observed that when field responses showed increased excitability (i.e., multiple population spikes, prolonged field or, biphasic field PSPs, or multiple antidromic population spikes) individual granule cells showed abnormal excitability such as burst firing to a single afferent stimulus with a prolonged EPSP, less or absences of spike adaptation in response to depolarizing current injection, and spontaneous firing/burst. In a group of neurons, slow membrane depolarization with periodic bursts was observed. Our results suggest increased excitability of granule cells, and possibly a change in synaptic circuitry that leads to periodic bursts. (NIH grant # NS23077 to LMM)

769.3

MODULATION OF SYNAPTIC RESPONSES IN RAT AND HUMAN DENTATE GYRUS. Anne Williamson*, Kunio Kato and Dennis D. Spencer, Section of Neurosurgery, Yale University School of Medicine, New Haven, CT 06520

Adenosine is an endogenous transmitter which is released by tonic electrical stimulation. Activation of presynaptic A1 receptors inhibits transmitter release, presumably by decreasing c-AMP or by blocking channels, which reduces neuronal excitability. This presynaptic regulation could be an important factor in epileptogenesis. We have investigated the modulation of synaptic responses by exogenous and endogenous adenosine in rat and human hippocampal slices. Tissue was obtained from patients diagnosed with mesial temporal sclerosis (MTS) or tumor related temporal lobe epilepsy (TTLE). The synaptic reorganization and cell loss seen in MTS are not seen in the TTLE hippocampi.

Application of the A1 agonist cyclohexyladenosine (CHA) decreased the slope of field EPSPs with an ED50 of 0.076 ± 0.120 μM (N=6). In contrast, in slices from MTS and TTLE hippocampi, the ED50s for CHA were much higher (MTS, 0.386 ± 0.685 μM; TTLE 6.64 ± 1.60 μM). In MTS patients, the ED50 appeared to correlate with the degree of sclerosis. We also applied the A1 antagonist DPCPX at 0.2 μM and monitored the slope of the field EPSPs. The slices obtained from MTS patients showed an increase of 45.3± 10.4 % (N=3) while we observed a 32.6 ± 5.1% μM (N=10) in the rat dentate gyrus. These data suggest that there is a lower sensitivity to adenosine in the human dentate gyrus compared to rats. Adenosine may not, therefore, play a major role in presynaptic modulation in the more normal TTLE tissue, but that purinergic mechanisms are present in the MTS tissue.

769.4

DYNORPHIN IMMUNOREACTIVITY IN THE DENTATE GYRUS IN HUMAN TEMPORAL LOBE EPILEPSY: AN ELECTRON MICROSCOPIC STUDY OF REORGANIZED MOSSY FIBER SYNAPSES. N. Zhang* and C.R. Houser. Brain Research Institute, UCLA, and VA Medical Center, Los Angeles, CA 90095

Ultrastructural studies of dynorphin A localization have been conducted to determine the characteristics of presumptive reorganized axon terminals in the dentate gyrus of humans with temporal lobe epilepsy (TLE). Following immersion fixation, surgical TLE specimens were processed for preembedding immunoperoxidase labeling for dynorphin A(1-17). Dynorphin-labeled axon terminals were numerous in the inner molecular layer, and the immunoreactivity was highly associated with dense core vesicles. The labeled terminals varied greatly in size, but many were relatively large (2μm or greater in major diameter), contained high concentrations of clear round vesicles, had irregular shapes, and thus exhibited many of the ultrastructural features of mossy fiber terminals. The majority of dynorphin-labeled terminals formed distinct asymmetric synapses with dendritic spines and small dendrites. The labeled axonal profiles frequently exhibited two or more synaptic contacts with either the same or different postsynaptic elements. Labeled dense core vesicles were also observed near postsynaptic sites of some dendritic spines and shafts. The findings support the suggestion that reorganized dynorphin-containing mossy fiber terminals form abundant functional synapses in inner molecular layer of the dentate gyrus in humans with TLE. Supported by NS21908 and VA Medical Research Funds.

CHILDHOOD SEIZURES INDUCE HIPPOCAMPAL NEURON LOSSES AND MOSSY FIBER SYNAPTIC REORGANIZATION: GW Mathern *, TL Babb, JK. Pretorius, JP Leite, KM Yeoman, PA Kuhlman, and WJ Peacock. UCLA School of Medicine, Los Angeles, California

This study determined if severe childhood seizures were associated with hippocampal pathology and if hippocampal sclerosis evolved from longer seizure histories. Children with catastrophic epilepsy (n=25) and autopsy (n=23) hippocampal sections were studied for: 1) neuron densities; and 2) gray value density of supragranular neo-Timm's staining. Results showed: 1) Compared to age-matched autopsies, children as young as age 5 years with a history of hippocampal seizures showed markedly decreased granule cell, hilar and regio superior neuron densities in the pattern similar to adult hippocampal sclerosis. By contrast, children with extra-hippocampal pathologies and seizures showed only decreased granule cell densities. 2) The gray value (GV) densities, when compared to autopsies, showed greater supragranular GVs in children with congenital pathologies; however the GVs in children with hippocampal seizures were greatest. 3) Of the children with extra-hippocampal pathologies there were no statistical correlations between longer seizure durations with changes in neuron densities, or mossy fiber sprouting. These results indicate: 1) Extra-hippocampal childhood seizures are associated with moderate fascia dentata and minimal Ammon's horn neuron losses and signs of aberrant mossy fiber sprouting. 2) By contrast, young children with the syndrome of mesial temporal epilepsy show the neuron losses and mossy fiber sprouting typical of hippocampal sclerosis. These findings support the hypothesis that childhood seizures can damage or alter the postnatally developing granule cells of the human hippocampus, and that early neuron losses and aberrant axon circuits may contribute to chronic hippocampal seizures. However, repeated childhood generalized seizures are not necessarily associated with the development of hippocampal sclerosis. Supported by NS 02808, and K08 NS 1603.

NEUROPATHOLOGICAL FINDINGS IN STATUS EPILEPTICUS. M. G. Hadfield*, C. A. Fortner, R.J. DeLorenzo. Div. Neuropathology, Medical College of Virginia/VCU Richmond, VA 23298.

We correlated post mortem brain lesions with clinical findings in 30 patients with status epilepticus (SE) (27 adults and 3 children between 2 months and 80 years of age). Clinical features: survival time ranged from 0 to 59 days post SE. 70% had no prior seizure history; 50% had acute CNS insults; 20% had acute "non CNS" primary causes for SE; 17% had acute hypoxia or anoxia; 17% had preexisting lesions; and 10% were withdrawing from alcohol or antiepileptic drugs.

Pathologic changes identified: 23% old or recent infarcts and an additional 37% acute anoxic changes; 19% CNS infections; 13% hemorrhages; 7% contusions; 7% tumors; 37% edema; 37% astrocytosis in various parts of the brain, including 10% in the hippocampus; neuronal loss in 37%, primarily in the cerebellum.

To our knowledge, this is the most comprehensive study to date concerned with morbid CNS changes seen in SE. In particular it provides novel data on SE patients with no prior seizure history in an adult population and those with nonconvulsive seizures. The range and extent of post mortem lesions was much greater than clinically suspected.

Localization of the glutamate receptor subunit GluR1 in the hippocampus of patients with Temporal Lobe Epilepsy. N.C. de Lanerolle*, G. von Campe, M. Brines, I. Kovacs and D.D. Spencer, Section of Neurosurgery, Yale University School of Medicine, New Haven, CT. 06520.

The GluR1 receptor was localized immunocytochemically in hippocampi surgically removed from patients with intractable temporal lobe epilepsy (TLE). mRNA for the flip and flop splice variants of GluR1 were localized by in situ hybridization with specific oligoprobes. Excised hippocampi fall into two broad categories -- those that show sclerosis and reorganization (MTLE) and are seizure foci, and those that do not show reorganization (MaTLE or PTLE) [Clin. Neurosci., 2, 64-84, 1994]. In the **non-reorganized hippocampus** immunoreactivity was weak in the granule cell bodies, but stronger on the apical dendrites throughout the molecular layer (ML). Hilar interneurons were also stained. Within area CA1 to CA3 immunoreactivity was localized to dendrites and not on pyramidal cell bodies. In stratum oriens cell bodies and dendrites were strongly labeled. The flip variant was weakly expressed on granule cell bodies, but strongly expressed on deep hilar neurons, and throughout the pyramidal cell layer of areas CA1 to CA3. The flop variant was only expressed on granule cell bodies. In the **reorganized (MTLE) hippocampus** the pattern of immunoreactivity showed two differences. (1) Surviving hilar neurons appeared to have punctate clusters of immunoreactivity on them. Many of these neurons resemble mossy cells. The same pattern of punctate staining occurred on the cell bodies of some CA3 neurons. These patterns of staining may represent receptor expression on these cell bodies or on mossy fiber terminals that synapse on these cell bodies. (2) In area CA1 where there is loss of pyramidal neurons, small immunoreactive neurons appear scattered in the shrunken pyramidal layer. These cells were not seen without pyramidal cell loss. The relevance of these distinct changes in GluR1 expression in the hippocampal seizure focus remains unclear at present. [Supported by 27081 to N.C. de L]

MESSENGER RNA AND POSTSYNAPTIC DENSITY PROTEIN ALTERATIONS ARE OBSERVED IN THE EPILEPTIC HUMAN BRAIN.
N. Suzan Nadi*. NINDS, NIH, Bethesda MD 20892.

Temporal lobectomy specimens obtained from surgeries performed for seizures intractable to anticonvulsants and autopsy specimens from neurologically normal individuals were used for the preparation of synaptosomes and postsynaptic densities (PSD) by a modification of the method described by Cohen et al. Synaptosomes and PSD were obtained from the same specimens. The synaptosomes were analyzed for mRNA using Northern Blot techniques. The presence of 14 mRNA molecules were detected. Among these, the mRNA molecules for brain derived nerve growth factor (BDNF), GAP43 the molecule associated with neuronal growth cones, nerve growth factor (NGF), and tubulin were found to be enriched in the synaptosomes relative to the mRNA for the same proteins in the total temporal lobe. Actin was not enriched in the synaptosomes. When the relative mRNA content (defined as the ratio of the mRNA for the protein in question in the synaptosomes to the mRNA of the protein in the total temporal lobe preparation) in the epileptic brain was compared to the synaptosomes prepared from the control specimens a 2.5 fold increase ($p<0.01$) in BDNF mRNA and a 4 fold increase in GAP43 mRNA ($p<0.001$) was observed in the epileptic brain. In the case of tubulin a statistically significant 2 fold increase was observed in the autopsy specimens when compared to the controls. The NGF and tubulin mRNAs were not significantly different. The analysis by polyacrylamide gel electrophoresis, of the PSD proteins revealed a significant increase in the 20, 30 and 60KD bands of the PSD specific proteins in the epileptic brain. The increase in the GAP43 and BDNF mRNA in the epileptic brain suggests a correlation between the growth factor often observed to be increased in seizures and neuronal sprouting. The alterations in a subclass of the PSD proteins suggests a that a structural alteration of PSD may be associated with repeated seizure activity in the human brain.

INCREASED TENASCIN-IMMUNOREACTIVITY IN THE HIPPOCAMPUS OF EPILEPSY PATIENTS WITH AMMON'S HORN SCLEROSIS. B. Scheffler[1], H. Beck[3]*, K. Behle[1], A Faissner[2], O.D. Wiestler[1], I. Blümcke[1]. 1) Dept. of Neuropathology, Univ. Bonn Med. Ctr., 53105 Bonn, F.R.G. 2) Dept. Neurobiology, Univ. Heidelberg, 69120 Heidelberg, F.R.G. 3) Dept. Epileptology, Univ. Bonn Med. Ctr., 53105 Bonn, F.R.G.

Tenascin (TN-C) is an extracellular matrix glycoprotein transiently expressed by primarily astrocytes in the developing CNS. Its expression appears to correlate with key events during neurohistogenesis, e.g. neuronal migration and neurite outgrowth. The adult rat hippocampus contains only low amounts of TN-C. Increased TN-C levels have been detected in the lesioned PNS and, to a lower extent, in stabwounds of the CNS. In this study, we have analyzed the distribution of TN-C in 35 surgical hippocampus specimens from patiens with pharmaco-resistant temporal lobe epilepsy, using a panel of anti-human TN-C monoclonal antibodies.

In normal human autopsy specimens, TN-C antibodies preferentially labeled the borders between principal cell layers and layers harbouring fiber tracts, e.g. the alveus or hippocampal fissure. In addition, TN-C immunoreactivity was found within the polymorphic layer of the dentate gyrus. In hippocampal specimens from patients with severe neuronal cell loss (Ammon's horn sclerosis, AHS) a striking increase in TN-C immunoreactivity was observed in all subfields of the hippocampal formation. This increase was pronounced in the dentate gyrus molecular layer, the pyramidal cell layer and the stratum radiatum of the Ammon's horn. The staining pattern reflects the distribution of reactive fibrillary astrocytes in AHS.

An upregulation of TN-C may be indicative of altered glio-neuronal interactions in the hippocampus of epilepsy patients with Ammon's horn sclerosis and contribute to axonal reorganization and sprouting.

NONLINEAR AUTOREGRESSIVE ANALYSIS OF ICTAL AND INTERICTAL ELECTROCORTICOGRAPHIC RECORDS.
N.D. Schiff, D.R. Labar, J.D. Victor*. New York Hospital - Cornell Medical Center, New York NY 10021.

Electrocorticography (ECoG) permits fine spatial sampling of the electrical fields of the brain. To examine the detailed dynamics of ictal and interictal brain activity, we applied the nonlinear autoregressive (NLAR) fingerprint method (Schiff et al., Biological Cybernetics 1995) to electrocorticographic records obtained from two epilepsy surgery patients with temporal lobe epilepsy. Both patients were chronically implanted with subdural electrodes.

Time series from multiple subdural electrodes were analyzed with a family of NLAR models, each consisting of a single quadratic or bilinear interaction term added to an otherwise linear model. Interictal ECoG segments were best represented by a linear model. Ictal discharges in both patients revealed significant nonlinear signal interactions. Principal components analysis was used to reduce the observed recordings to a minimal set of "generators". This revealed that three or more such "generators" were required. NLAR models of these generators revealed a separate pattern of nonlinear interactions for each generator. In one generator we observed a surprising resemblance to the nonlinear dynamics previously identified in the 3/second spike-wave of petit mal epilepsy, consisting of an interaction of signal values 64 ms in the past with signal values 144 ms in the past. This finding raises the possibility that a common circuit element underlies both types of generalized seizure disorder.

NEOCORTICAL AND HIPPOCAMPAL DEFICITS IN TEMPORAL LOBE EPILEPSY L. Marsh, P.K. Shear*, E.V. Sullivan, M.J. Morrell, H. Freeman, A. Marie, K.O. Lim, A. Pfefferbaum Department of Psychiatry and Behavioral Sciences and Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, CA 94305, and Department of Veterans Affairs Medical Center, Palo Alto, CA 94304

Magnetic resonance imaging (MRI) studies of localization-related epilepsy of temporal lobe origin (TLE) have concentrated on the hippocampus because of the prognostic significance of mesial temporal sclerosis. However, little is known about the extent of volume abnormalities in the neocortex of temporal and extra-temporal brain regions. This MRI study examined whether neocortical volume deficits were present in patients with unilateral TLE, as defined after evaluation for epilepsy surgery. Regions of interest (ROI), measured from 3mm spin-echo coronal images, included the hippocampus as well as gray matter of the temporal lobe, superior temporal gyrus (STG), and a frontal-parietal region (FPR). ROIs were adjusted for normal variation due to head size and age based on 72 controls. Nonparametric tests examined group differences between 7 left-TLE, 7 right-TLE, and an age-matched subsample of 49 controls; all subjects were men. Compared to controls, hippocampal volume deficits were ipsilateral to side of seizure onset in TLE (left-TLE, $p<.002$; right-TLE, $p<.09$). By contrast, relative to controls, both patient groups had smaller gray matter volumes bilaterally in the temporal lobes, STG, and FPR (significant for bilateral FPR and left STG in left-TLE and for bilateral temporal lobe and right FPR in right-TLE). A two-way ANOVA, comparing hippocampal volumes (ipsilateral or contralateral to epilepsy focus) in the two patient groups revealed a significant hemisphere effect ($p<.004$). There were no main effects or interactions in similar ANOVAs for the neocortical ROIs. These data suggest that hippocampal deficits in TLE are related to side of the epileptogenic focus, whereas neocortical tissue volume deficits are bilateral and occur in both temporal and extra-temporal regions.

AN EVENT-RELATED POTENTIAL (ERP) STUDY ON DISTURBANCE OF SEMANTIC PROCESSING IN TEMPORAL LOBE EPILEPSY. T. Miyamoto*, J. Katayama[b], Masako Kohsaka, H. Honma, R. Kobayashi, S. Kohsaka[a], H. Okuhara, and T. Koyama Dept. of Psychiat. and Neurol. and [a]Dept. of Pediat., Sch. of Med. and [b]Fac. of Edc., Hokkaido Univ., Sapporo JAPAN

Several lines of evidence have indicated the disturbance of cognitive function, especially memory and language dysfunction in temporal lobe epilepsy (TLE). We focused the semantic memory which is related to semantic processing in language. We investigated the possible disturbance of semantic processing in TLEs with N400, an event-related potential, related to semantic processing.

The seven TLE patients were right-handed and aged 17-38 years. All had complex partial seizures and were taking 1 to 3 kinds of anti-epileptic drugs. The controls were matched for handedness, gender and age.

We used a category matching paradigm consisting of two conditions; the match-condition in which the target word was the category name for the prime word and the mismatch-condition in which the target was of a different category name from the prime. The subjects were required to press one of two buttons accordingly for matches or mismatches.

Reaction times were significantly longer in TLEs than in the controls. The mean amplitudes of N400 in the mismatch-condition in TLEs were smaller than in the controls.

This suggests that there is a disturbance of the semantic processing in TLEs, especially in the mismatch-condition.

ANTICONVULSANT EFFECTS OF MELATONIN IN HUMANS: TWO CASE STUDIES. TH Champney*, M Sánchez-Forte, A Muñóz-Hoyos, A Molina-Carballo, F Moreno-Madrid and D. Acuña-Castroviejo. Dept Human Anat, Texas A&M Univ, College Station, TX 77843 and Dept Pediat and Dept Fisiol, Univ Granada, Granada, E-18012, Spain.

Melatonin (MEL), a hormone produced by the pineal gland, depresses and/or synchronizes neural activity in numerous species suggesting an anticonvulsive capability. The present case studies describe the effects of MEL administration to two children with untreatable seizures. The first child is a 32 month old female who has had progressive myoclonic epilepsy since one month of age (15 - 20 seizures per day) who was unresponsive to the known anticonvulsants. Ten days after initiating MEL treatment (50 mg, po, at 0900 h and 100 mg at 2100 h) with the anticonvulsants, primidone (125 mg, po, at 0900 h and 250 mg at 2100 h), clonazepam (0.5 mg, po, every 8 h) and phenobarbitone (22.5 mg, po, every 12 h), the seizures disappeared. Presently, she is still receiving the MEL and the anticonvulsants. Clinical tests (EEG, neurologic and psychomotor) all fall within normal ranges and indicate a resumed normal development. The second case involves a 6 year old female with intractable nocturnal seizures that are resistant to the known anticonvulsants. She would experience at least 4 seizures per week shortly after falling to sleep. This produced sleep anxiety and disrupted sleep patterns. After initiating MEL treatment (60 mg daily, po, at 1800 h) and a ketogenic diet, the seizures were reduced to 1 - 2 per week and her sleep pattern improved markedly. She is now receiving 20 - 30 mg of MEL daily which provides good seizure control; reducing the dosage to 10 mg increases seizure production. Both children have been receiving MEL daily for over six months with no apparent adverse side effects. These results suggest that MEL can act as an anticonvulsant in humans, especially in those seizure states that are unresponsive to conventional anticonvulsants. This could be especially important in preventing seizure-dependent neurologic damage in these patients.

ALUMINA GEL INJECTIONS INTO THE AMYGDALA OF MONKEYS CAUSE BEHAVIORAL AND PATHOLOGICAL CHANGES FOUND IN TEMPORAL LOBE EPILEPSY. C.E. Ribak*, L. Seress, P. Weber, and R.A. E. Bakay. Dept. of Anatomy & Neurobiology, Univ. of Calif., Irvine, CA 92717 and Dept. of Neurosurgery, Emory Univ. Clinic, Atlanta, GA 30322.

When alumina gel is injected into the sensorimotor cortex of monkeys, a seizure focus is created that is similar to that observed in posttraumatic epilepsy in humans. Anatomical studies indicate that the focus displays a preferential loss of GABAergic neurons that may underlie the development of seizures. Alumina gel was injected into the temporal lobes of monkeys to determine whether complex partial seizures could be generated. Timm-stained and electron microscopic preparations were analyzed from these monkeys to determine the types of anatomical changes associated with monkeys with these seizures. Non-injected control monkeys and monkeys with injections into the middle and inferior temporal gyri displayed no seizures and did not have any hippocampal pathology. In contrast, complex partial seizures were observed within 2-3 days in monkeys with injections into the amygdala, entorhinal cortex or hippocampus. Hippocampal pathology was limited to the injection site in monkeys with hippocampal injections and was not observed with entorhinal cortex injections. Monkeys with amygdala injections displayed pathology similar to that described in humans with temporal lobe epilepsy. Thus, Timm staining revealed mossy fiber sprouting into the molecular layer of the dentate gyrus, Nissl staining showed degeneration of neurons in the hilus of the dentate gyrus, CA1 of the hippocampus, and layer III of the entorhinal cortex, and electron microscopic preparations demonstrated the hypertrophy of CA3 pyramidal cell dendrites and the formation of complex spines on the dendrites of granule cells by sprouted mossy fibers. These results describe a non-human primate model of temporal lobe epilepsy that displays similar behavioral and pathological findings as those found in humans.

Introduction: The aim of this study was to develop a model of chronic focal epilepsy, in squirrel monkeys. The model was characterized biochemically and electrophysiologically, using intracerebral microdialysis and electroencephalography (EEG) respectively.

Material and methods. Eight squirrel monkeys were used for the experiments. Chronic focal epilepsy was induced by intracortical injection of 25 µl alumina hydroxid. Intracerebral microdialysis (CMA 12 probes, membrane length 2 mm, flow rate of 2 & 5 µl/min) was performed together with the last EEG recording at the end of the observation period (16-18months) and the samples were analyzed in order to obtain basal levels for various amino acids.

Results: All animals devloped chronic focal epilepsy, persisting during the whole period of observation. The seizures started focally, generalized rapidly and lasted for about 1 minute. Interictally, epileptic spikes were recorded in 7/8 animals 3 months after the intracortical injection. The spikes were restricted to the same side as was operated. After 11 months, the interictal epileptogenic activity could also be recorded contralaterally in three animals and ipsilateral in 4 animals. Basal interictal dialysate levels were obtained in 6 animals. The levels of amino acids were (mean ± SEM [µM]) aspartate: 0.34±0.16, glutamate: 1.32±0.87, serine: 1.00±0.22, glycine: 1.41±0.48, taurine: 0.44±0.08.

Conclusion: Intracortical injection of alumina hydroxid induces chronic focal epilepsy with spontanteous seizures in the squirrel monkey. This model may be used for exploring various treatments of epilepsy, e.g. noninvasive methods as radiosurgery.

NMDA RECEPTOR BLOCKERS PARADOXICALLY INCREASE SPIKE-WAVE SYNCHRONIZATION AND NEOCORTICAL EXCITABILITY IN A MUTANT MOUSE MODEL OF SPIKE-WAVE EPILEPSY, STARGAZER. W.K. Nahm*, J.L. Noebels. Developmental Neurogenetics Laboratory, Dept. of Neurology, Div. of Neuroscience, Baylor College of Medicine, Houston, TX 77030

The presence of multiple genetic loci expressing spike-wave (SW) activity and the disparity of pharmacological effects on SW discharges in various models suggest the presence of distinct intervening defects subserving SW epileptogenesis. It is believed that SW activity arises when rhythmic firing in a circuit that includes the neocortex, thalamus and reticular nucleus is converted to abnormal oscillations by enhanced hyperpolarizing GABAergic and depolarizing T-type Ca^{2+} channel conductances. It has been hypothesized that NMDA-R activity is required within this circuit, since NMDA-R blockers suppress SW discharges in several models. To determine whether NMDA-R transmission is an essential component of SW seizures in all models, we employed stargazer (*stg/stg*) mutants (Chr. 15) to examine the effects of competitive (CPP) and noncompetitive (MK-801) NMDA-R blockade on in vivo SW activity and on in vitro neocortical 0 Mg^{2+}-induced epileptiform discharges (EDs). At doses that suppress SW activity in other animal models, CPP (40-60μM/kg) and MK-801 (1.6-2.0μM/kg) paradoxically initiate nearly continuous SW activity in *stg/stg* mice, while they do not affect EEG activity in wild type (+/+) mice. In field recordings from cortical slices bathed in 0 Mg^{2+} aCSF, CPP (10μM) and MK-801 (1-10μM) dramatically increase the frequency [(10μM CPP, 311%) (1μM MK-801, 310%; 3μM MK-801, 375%; 10μM MK-801, 431%)] and decrease the duration [(10μM CPP, 735%) (1μM MK-801, 210%; 3μM MK-801, 424%; 10μM MK-801, 979%)] of spontaneous EDs recorded in layer 4/5 of *stg/stg* slices; while they abolish or greatly attenuate both these parameters in +/+ slices. These data suggest that NMDA-R activation is not an obligatory step in the final pathway of burst generation in all models of SW epilepsy, and point to a specific excitability defect linked to NMDA-R-mediated transmission in *stg/stg* neocortical cells.

770.2

"*slow-wave epilepsy*", A MUTANT MOUSE WITH 3/SEC SPIKE-WAVE SEIZURES. Jeffrey L. Noebels[1]*, Cathleen M. Lutz[2], Audrey Fu[2], Wayne N. Frankel[2]. [1]Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030 and [2]Jackson Laboratory, Bar Harbor, ME 04609.

Electrocorticographic survey of murine neurological mutations has so far revealed 5 recessive loci displaying spontaneous 6-7/sec spike-wave discharges accompanied by behavioral arrest. The seizures are selectively suppressed by ethosuximide, and provide useful gene models of the aberrant thalamocortical oscillations in inherited human generalized absence epilepsies. Here we report a new mutant with a novel epilepsy phenotype that exhibits frequent spike-wave seizures in the 3/sec range. The recessive *swe* mutation arose on the SJL/J inbred background and maps to the distal portion of chr. 4 between D4Nds2 and D4Mit42. Chronic ECoG recordings reveal very frequent (~118/hour) episodes of generalized, bilaterally symmetric wave, and wave-spike activity. The rhythmic periodicity ranges from 3-4.5/sec. Individual durations range from 1-68 secs (mean 3.5 ± 0.7 SEM sec). The seizures are triggered by waves; in some longer discharges, the spike component is absent or buried in the wave. Both the shorter wave-spike bursts and longer wave patterns are associated with behavioral arrest, and are rapidly abolished by ethosuximide (50-100 mg/kg). No 6-7/sec or higher discharges are present. On this inbred background, rare spontaneous generalized tonic-clonic seizure episodes have also been observed in *swe* homozygotes as early as 14-18 days postnatal. By 12-14 days, the mutants develop locomotor ataxia, but no other obvious neurological deficits are evident. The *swe* mutant demonstrates that specific cortical oscillation frequencies are linked to the function of distinct genes, and provides a critical entry point into the molecular dissection of mechanisms regulating spike-wave epileptogenesis.

770.3

CORTICAL HYPEREXCITABILITY IN THE SPIKE-WAVE EPILEPTIC MUTANT MOUSE *STARGAZER*. Eric Di Pasquale, Karl D. Keegan* and Jeffrey L. Noebels, Dept. of Neurology, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030.

Inherited spike-wave epilepsy arises from aberrant bursting in thalamocortical circuits, but the site of gene-linked hyperexcitability is not known. Recordings were performed in brain slices of adult *stargazer* mice (*stg/stg*) and their coisogenic controls (+/+). Field recordings in thalamocortical slices bathed in aCSF revealed the presence of spontaneous low frequency, synchronous network discharges in all layers of *stg*, but not +/+ neocortex. The mutant discharges were not abolished by section of the thalamocortical projection fibers. Intracellular and whole-cell recordings in cortical layer IV-V *stg* neurons showed spontaneous giant depolarizing epsps generating bursts of action potentials with little after burst hyperpolarization. The after burst hyperpolarization seen in +/+ neurons during bursting induced by 0 Mg^{2+} saline was almost absent in *stg* (6.9±1.1 mV vs 1.5±0.5 mV respectively).

In whole-cell configuration, two classes of regular-spiking neurons were identified in similar ratios in both genotypes: RS1 (+/+ 16/20; *stg* 17/22), and RS2 (+/+ 4/20; *stg* 5/22). *Stg* single action potential (AP) half width, rise time and decay time were significantly decreased by 12%, 15% and 13% respectively. The rheobase intensity was significantly decreased by 58% in *stg* (from 80 pA to 25 pA). No differences were observed in single AP overshoot and AHP, afterburst hyperpolarization, resting potential, input resistance, or time constant. The *f-I* slope was significantly increased by 29% in *stg* (*stg* 217.7 Hz/nA; +/+ 154.4 Hz/nA). Anomalous rectification (AR) was observed in both genotypes, but a depolarizing "sag" was strongly enhanced in *stg* (8.6 ±1.2 mV) relative to +/+ (1.6±0.6 mV). These results demonstrate an increase in network and intrinsic excitability in *stargazer* cortical neurons that could lower the threshold for thalamocortical oscillations in this model of inherited spike-wave epilepsy. Supported by NIH NS29709 and PHILIPPE Foundation.

AUDIOGENIC SEIZURES INDUCE EXPRESSION OF FOS IN THE NUCLEUS LOCUS COERULEUS OF GENETICALLY EPILEPSY PRONE RATS. R.W. Clough*[1], J.B. Eells[1], P.C. Jobe[2] and R.A. Browning[1]. [1]Sch. of Med., Southern Illinois Univ., Carbondale, IL 62901 and [2]Sch. of Med., Univ. of Illinois, Peoria, IL 61656.

Genetically epilepsy-prone rats (GEPRs) have an innate and widespread deficiency in the noradrenergic neurotransmitter system which contributes to their propensity for seizures in response to audiogenic stimuli. GEPRs of the mild-seizure substrain (GEPR-3s) display enhancement of seizure severity following depletion of norepinephrine (NE) using 6-hydroxydopamine while augmentation of noradrenergic function in the GEPR brain has an antiepileptic effect in the GEPR. Since epileptic propensity in these animals involves NE hypofunction which may result from failure of activation of NE perikarya, the present study sought to discern whether the nucleus Locus Coeruleus (LC), a major noradrenergic nucleus, exhibits activation of the immediate-early-gene Fos coincident with seizures. Seizures were induced using a 100 db signal. 2.5 hours following seizures, rats were transcardially perfused and prepared for immunohistochemical processing of brain sections for Fos. Quantifiable morphometric results demonstrated a profound activation of Fos immunoreactivity in neurons of the LC subsequent to seizure. These findings suggest that the LC perikarya are highly activated during audiogenic seizures, and perhaps, that deficiencies in other components of the NE system (ie, terminals) may be responsible for the lack of seizure suppression in the GEPR. Supported by Bayer Pharmaceuticals and SIU.

770.5

COINCIDENT MATURATION OF AUDIOGENIC SEIZURE PROPENSITY AND FOS ACTIVATION PATTERNS IN DEVELOPING GENETICALLY EPILEPSY PRONE RATS. J.B. Eells*[1], R.W. Clough[1], P.C. Jobe[2] and R.A. Browning[1]. [1]Sch. of Med., Southern Illinois Univ., Carbondale, IL 62901 and [2]Sch. of Med., Univ. of Illinois, Peoria, IL 61656.

The mild seizure substrain of Genetically epilepsy-prone rats (GEPR-3s) exhibit an interesting developmental pattern of audiogenic seizure (AGS). At 16 days of age, they exhibit a brief run without a seizure in response to an auditory stimulus . At 21 days of age, a brainstem seizure score 3 is followed by facial and forelimb clonus. Seizure severity is increased at 23 days of age to seizure score 9, afterwhich seizure severity decreases again to score 3 by 45 days of age. This study examined possible differences in Fos activation patterns associated with expression of variant seizure types across development in GEPR-3s. Brain sections from rats of 16, 21, 23, and 45 days of age were processed for Fos immunohistochemistry 2.5 hours after AGS. 16 day old GEPR-3s did not exhibit AGS; however, they showed dense Fos immunoreactive (FI) neurons in the pontine nuclei, supraoptic nucleus and the parietal cortex with some Fos labeling in the inferior colliculus and superior olivary nucleus. At 21, 23, and 45 days, rats showed a similar pattern of Fos distribution after AGS; however, seizure severity differed. FI neurons were found in the peripeduncular area, central gray, cuneiform nucleus, paralemniscal area, locus coeruleus and gigantocellular reticular nucleus. Although seizure severity differed, no differences in Fos immunolabeling was observed with different seizure types. Fos immuohistochemistry suggests that these seizure types share a similar neuroanatomical circuitry. Supported by Bayer Pharmaceuticals and SIU.

770.6

ENHANCEMENT OF THE ANTICONVULSANT EFFECTS OF FLUOXETINE BY BLOCKADE OF THE SEROTONIN 5-HT_{1A} RECEPTOR IN GENETICALLY EPILEPSY-PRONE RATS (GEPRs). R. A. Browning[1]*, A. V. Wood[1], M. A. Merrill[1], J.W. Dailey[2] and P.C. Jobe[2]. [1]Dept. Physiol. Southern Illinois Univ, Sch. Med. Carbondale, IL 62901 and [2]Dept. Basic Sciences Univ. Illinois Coll. Med. Peoria IL 61656.

GEPRs are known to have a deficiency in brain serotonin (5-HT). Moreover, pharmacological treatments that increase 5-HT in the synaptic cleft, such as fluoxetine, have been shown to protect these animals against sound-induced (audiogenic) seizures, while treatments that lower the concentration of 5-HT have proconvulsant effects. Inasmuch as recent evidence shows that 5-HT_{1A} antagonists markedly enhance the increase in extracellular 5-HT produced by 5-HT reuptake inhibitors, it was of interest to determine whether such drugs also potentiate the anticonvulsant action of the 5-HT reuptake inhibitor, fluoxetine (FLU), in GEPRs. In the present study female severe-seizure GEPRs (GEPR-9s) received FLU 2 hours before seizure testing and the 5-HT_{1A} antagonist either 30 min or 60 min before testing. The audiogenic seizure response score (ARS), a measure of seizure severity, was significantly ($P<0.05$) reduced when a dose of FLU (15 mg/kg), which alone had no effect on the ARS, was combined with one of the following 5-HT_{1A} antagonists: pindolol (10 mg/kg; ARS reduced from 9 to 4.7); (±) LY 206130 (5 mg/kg, ARS reduced from 9 to 3.9); (-) LY 206130 (2.5 mg/kg, ARS reduced from 9 to 6.0). The mean ARS in GEPR-9s treated with saline or a 5-HT_{1A} inhibitor alone was 9.0, while rats treated with FLU alone had a mean ARS of 8.4 - 9.0. The effect produced by (-) LY 206130 was dose-dependent. Moreover, the anticonvulsant action of FLU in combination with LY 206130 was shown to depend on 5-HT, since it was absent in animals depleted of brain 5-HT by pretreatment with p-chlorophenylalanine ethyl ester (150 mg/kg/day for 3 days). These findings provide further evidence that the anticonvulsant effects of FLU are mediated through 5-HT and that the increase in extracellular 5-HT observed following a 5-HT reuptake inhibitor in combination with a 5-HT_{1A} antagonist is functionally relevant.

770.7

ANTICONVULSANT EFFECT OF ENHANCEMENT OF NORADRENERGIC TRANSMISSION IN THE SUPERIOR COLLICULUS IN GENETICALLY EPILEPSY-PRONE RATS (GEPRS): A MICROINJECTION STUDY. Q.S. Yan*, J. Dickerson, P.C. Jobe and J.W. Dailey. University of Illinois College of Medicine, Peoria, IL. 61656.

An expanding body of data has demonstrated that the seizure prone state in genetically epilepsy-prone rats (GEPRs) is partially caused by deficits in central nervous system noradrenergic transmission. The purpose of this work was to trace etiologically significant noradrenergic terminals to one specific brain area, the superior colliculus (SC). Several drugs with different mechanisms of enhancing noradrenergic transmission were chosen to study. Guide cannulae were implanted just above the SC of female severe seizure GEPRs (GEPR-9s) under anesthesia. Five to seven days later, injection cannulae were bilaterally inserted into the SC while the animal was awake. The drugs or vehicle were administered at a rate of 0.2 μl/min over 5 min. The rats were tested for audiogenic seizure intensity at 0.25, 0.5, 1, 2, and 3 hrs after injection. Bilateral injection of vehicle or prazosin (1 μg/side), or unilateral injection of nisoxetine (8 μg), produced no reduction in the intensity of the audiogenic seizure. Desipramine (2, 4, 8 μg/side), nisoxetine (2, 4, 8 μg/side), and idazoxan (0.25, 1, 4 μg/side) all decreased the seizure intensity in a dose-dependent fashion. Significant decreases in the seizure intensity were also observed after administration of both methoxamine (0.15 μg/side). and phenylephrine (0.15 μg/side). Pretreatment with prazosin (1 μg/side) significantly decreased the anticonvulsant effectiveness of methoxamine (0.15 μg/side) and nisoxetine (8 μg/side). These results suggest that noradrenergic transmission in the SC may be involved in the seizure regulation in the GEPR model, and that this regulation may be mediated, at least in part, by α_1 - receptors. NOREPINEPHRINE AND SEROTONIN RELEASE DURING SEIZURE IN GEPRs AND NON-EPILEPTIC RATS: ANALYSIS OF ONE MINUTE MICRODIALYSIS SAMPLES **P.C. Jobe, V.U. Deoskar, R.L. Burger, J.W. Dailey* K.H. Ko[1] and P.K. Mishra Department of Basic Sciences, Univ. of Illinois College of Medicine, Peoria, IL 61656 and [1]Seoul National University, Seoul, South Korea.**

Forebrain and brainstem seizure predisposition in GEPRs appears to stem partially from noradrenergic deficits in the superior colliculus and ventrally adjacent structures. Accordingly, seizures induced by stimuli such as electroshock are thought to be more severe in GEPRs than in non-epileptic animals partly because of a reduced capacity of the epileptic animals to release norepinephrine (NE) and/or serotonin (5-HT) in response to seizure discharges. The current work was designed to compare seizure-induced release of monoamines in the terminal fields of the superior colliculus of non-epileptic rats with that of the moderate seizure GEPR (GEPR-3).

All-fused silica microdialysis probes (3 mm, loop-type) were inserted in preimplanted guides in the superior colliculus region of GEPR-3s and non-epileptic control animals. Two hours after the probe insertion, three one-min baseline samples were collected. Maximal electroshock seizures (MES) were induced after collecting four more post handling samples. Four additional one-min samples were collected following MES. These one-min microdialysates were analyzed using a high sensitivity microbore-microflow HPLC-EC system (Mishra, et al., Soc. Neurosci. Abstr., Vol. 21). Following seizure induction, a 6-12 fold increase in extracellular NE and 4-9 fold increase in extracellular 5-HT was observed in normal animals. In contrast, in GEPR-3s the release of NE and 5-HT was limited to only 2-4 fold. The highest extracellular concentrations were observed in the one-minute sample collected immediately following the seizure. The levels returned to near baseline levels within 10 minutes. These observations extend earlier indirect evidence by providing direct documentation for seizure-induced increments in NE and 5-HT release. Also, the experiment provides the first direct evidence that deficits in NE and 5-HT levels in the extracellular fluid characterize ictal episodes in GEPRs. (Supported in part by NS32628).

770.9

DIFFERENTIAL SENSITIVITY TO COCAINE-INDUCED SEIZURES IN TWO STRAINS OF THE GENETICALLY EPILEPSY-PRONE RAT (GEPR). C.E.Reigel*, H.Whitehead, A.T.Lovering and B.-K.Lin. Dept. of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Cocaine is a local anesthetic that also blocks the uptake of dopamine (DA), norepinephrine (NE) and serotonin (5-HT). Because local anesthetics induce seizures in high doses, cocaine has long been believed to induce seizures through its local anesthetic effects. We determined the potency of cocaine, bupropion (DA uptake inhibitor), imipramine (NE/5-HT uptake inhibitor) and procaine (similar local anesthetic potency to cocaine) in producing seizures in 3 rat strains. Intravenous seizures thresholds were determined in GEPR-9s (severe seizure strain), GEPR-3s (moderate seizure strain) or Sprague-Dawley (SD) rats, the strain from which the GEPR was derived.

Behaviorally, seizures produced by all 4 drugs were similar. The 4 drugs produced a similar rank order of potency in all 3 strains. Cocaine was the most potent convulsant, followed by bupropion. Imipramine demonstrated intermediate potency. Procaine was by far the least potent in producing seizures. Cocaine seizure threshold was lower in GEPR-9s than SD controls. Imipramine and procaine seizure thresholds were also lower in GEPR-9s. Cocaine seizure threshold was elevated in GEPR-3s over SD controls. Bupropion, imipramine and procaine seizure thresholds were also elevated in GEPR-3s, with the greatest elevation in bupropion seizure threshold (74 percent over SD controls). The resistance of GEPR-3s to the convulsant effects of cocaine as compared to GEPR-9s and SD controls may reflect differences at the level of the DA transporter. The rank order of potency demonstrated by these 4 drugs supports a dopaminergic involvement in cocaine-induced seizures. (Supported by NIH NS 28118.)

EXPRESSION OF NOREPINEPHRINE AND DOPAMINE TRANSPORTER MRNA AND TYROSINE HYDROXYLASE MRNA IN THE GENETICALLY EPILEPSY-PRONE RAT P. Szot*, C.E. Reigel and R.C. Veith GRECC, Seattle VAMC, WA 98108 and Dept. of Psychiatry and Behavioral Sciences, Univ. Washington, Seattle, WA 98195 and Dept. of Pharmacology, Texas Tech Univ., Lubbock, TX 79430.

The genetically epilepsy-prone rat (GEPR) is composed of two independent models of epilepsy; the GEPR-3 which exhibit mild generalized clonus and the GEPR-9 which exhibit more severe tonic extensor convulsions in response to acoustic stimuli. The most striking alteration in neurotransmitter function in these animals occurs in the noradrenergic and sertoninergic systems. The dopaminergic system appears to remain unaltered in both models, however the GEPR-3's have an elevated seizure threshold to cocaine (dopamine re-uptake inhibitor) (Reigel et al. 1995, NS Absts). Since the synaptic level of these neurotransmitters are regulated by specific re-uptake proteins and rate-limiting enzymes, the mRNA expression of these proteins was determined in both GEPR models which were seizure naive, as well as controls using in situ hybridization. Expression of norepinephrine transporter (NET) and tyrosine hydroxylase (TH) mRNA was determined in the locus coeruleus (LC) the major noradrenergic locus. NET mRNA expression was significantly elevated in the GEPR-3's compared to control. GEPR-9 NET mRNA expression was not significantly different compared to control or GEPR-3. However, TH mRNA expression in the LC in GEPR-9 was significantly reduced compared to GEPR-3, but not to control. The expression of dopamine transporter (DAT) and TH mRNA was determined in the ventral tegmentum/substantia nigra compacta region. DAT mRNA expression was significantly reduced in GEPR-3's compared to control and GEPR-9's. Unlike the noradrenergic neurons, TH mRNA expression in the dopaminergic neurons was significantly elevated in both GEPR-3 and GEPR-9's. These data indicate that there are regulatory changes in both the noradrenergic and dopaminergic systems of GEPR-3's and 9's and that the GEPR-3 model of epilepsy demonstrates the greatest changes in both NET and DAT mRNA expression. A QUANTITATIVE COMPARISON OF INHIBITORY SYNAPTIC CURRENTS IN THE HIPPOCAMPUS OF THE LH/LH MOUSE MODEL OF GENERALIZED ABSENCE EPILEPSY. S. J. Caddick* and D. A. Hosford. Neurology Res.,Duke & Durham VA Med.Centers,VAMC Bldg 16, Durham NC 27705.

Absence seizures represent the synchronized burst firing (spike wave discharges) of populations of cortical and thalamic neurons in an oscillatory fashion. Previous work in this laboratory has suggested an upregulation of postsynaptic $GABA_B$ receptor function in the hippocampus of lethargic (lh/lh) mice, a genetic model of absence seizures[1]. In order to look directly at inhibitory transmission, whole cell recordings of locally evoked synaptic currents were obtained from CA1 pyramidal cells in coronal slices (450μm). The peak amplitude of the inhibitory GABAergic currents mediated by $GABA_A$ ($IPSC_A$) and $GABA_B$ ($IPSC_B$) receptors were compared between lh/lh & non-epileptogenic littermates (+/+). IPSC's were isolated using DNQX (20μM) and DL-APV(20μM) and bicuculline (10μM)to isolate $IPSC_B$. We observed no significant differences in the peak amplitude and latency to peak of $IPSC_A$ (lh/lh, 286±41pA, 12±2ms; +/+, 211±28pA, 14±1ms; *P> 0.05*); peak amplitude and latency to peak of $IPSC_B$ (lh/lh, 42±7pA, 148±6ms; +/+, 42±3pA, 161±6ms; *P> 0.05*). These data indicate that there are no changes in the amplitude of the *poststynaptic* IPSC's in pyramidal cells of CA1 taken from lh/lh mice. Further work on comparing the presynaptic $GABA_B$ inhibition of IPSC's and EPSC's is at present underway.

INVOLVEMENT OF THE INDIRECT STRIATO-NIGRAL PATHWAY IN THE CONTROL OF EPILEPTIC SEIZURES. C. Deransart, C. Marescaux and A. Depaulis*, INSERM U. 398, Faculté de Médecine, 11 Rue Humann, 67085 Strasbourg cedex, France.

In order to investigate the involvement of nigral excitatory amino acid transmission in the control of generalized seizures, drugs were bilaterally microinjected in the substantia nigra pars reticulata in two genetic models of epilepsy in the rat. The effects of blockade of the nigral glutamatergic input from the subthalamic nucleus were then examined.

In Wistar rats with spontaneous absence, intranigral injections of dizocilpine, CGP 40116, or 5,7-dichlorokynurenic acid, respectively non competitive and competitive NMDA receptor antagonists and glycine NMDA-associated site antagonist, significantly suppressed spike-and-wave discharges in a time and dose-dependent way (600 and 800; 2 and 4; 500 and 1,000 pmole/side respectively). By contrast, no significant suppressions were observed after intranigral injections of antagonists acting at other glutamatergic receptors. Furthermore, bilateral injections of muscimol (17.5 and 35 pmoles/side) in the subthalamic nucleus suppressed absence seizures in the rat.

In a model of convulsive seizures (audiogenic seizure), bilateral intranigral injections of CGP 40116 (20 and 40 pmoles/side), resulted in a suppression of tonic seizures. No suppressions were observed after bilateral microinjections in the subthalamic nucleus of muscimol at doses up to 700 pmoles/side.

These results show that blockade of NMDA receptors within the substantia nigra pars reticulata suppresses both generalized convulsive and non-convulsive seizures in the rat. Furthermore, the suppression of absence seizures after inhibition of subthalamic neurons suggests the involvement of the indirect striato-nigral pathway in the triggering of the nigral control of epilepsies.

NMDA Antagonists and Glutamate Release-Inhibitors Suppress Seizures in the DBA/2 Mouse. D. Berlove*, O. Amitay, S. Goldin, L. Margolin and W. Holt. Pharmacology Department, Cambridge NeuroScience, Cambridge, MA 02139.

The DBA/2 mouse is known for its extreme susceptibility to audiogenic seizures. These seizures are triggered by intense, high frequency sound and follow a stereotypic course, beginning with a wild running phase that may rapidly progress to clonic seizures, tonic extension and death. Seizures appear to be the result of an imbalance between excitatory and inhibitory transmission in DBA/2 mice. Glutamate is the primary excitatory neurotransmitter in the mammalian central nervous system. Thus a block of glutamate release or receptor binding may prevent or attenuate seizure activity in these mice. We tested the efficacy of the noncompetitive NMDA antagonists MK-801 and CNS 1102 in this assay. Both are highly effective at suppressing audiogenic seizure activity; MK-801 at a dose of 0.25 mg/kg, ip and CNS 1102 at 2.0 mg/kg, ip. The relative *in vivo* potencies of these compounds closely matches their relative *in vitro* potencies at the NMDA receptor, suggesting that blockade at this receptor is responsible for seizure suppression. For pretreatment times up to 4 hours, CNS 1102 significantly reduced seizure severity; no morbidity or mortality was associated with CNS 1102 treatment. We then examined 4 compounds that are believed to block the synaptic release of glutamate: lamotrigine, riluzole, BW619C89, and CNS 1237. All were effective at reducing seizure incidence and severity, although at higher doses than were required for NMDA antagonists. The DBA/2 mouse audiogenic seizure model is a rapid and highly reproducible method of assessing a compound's ability to block glutamatergic neurotransmission. The ability of both NMDA antagonists and inhibitors of glutamate release to prevent audiogenic seizures suggests these seizures may be glutamate-mediated. Drugs selected with this model may have therapeutic value not only for the treatment of epilepsy, but also for other disorders associated with glutamate excitotoxicity including stroke and traumatic brain injury.

LAMOTRIGINE DRAMATICALLY DECREASES CONTENT OF DOPAMINE METABOLITES IN CAUDATE NUCLEUS OF NORMAL AND SEIZURE-PRONE BALB/C MICE. J.P. Vriend* and N.A.M. Alexiuk. Department of Anatomy, University of Manitoba, Winnipeg, Canada R3E 0W3.

Lamotrigine (LTG) is a relatively new anticonvulsive agent. Little is known concerning its neurochemical mechanism of action. In our laboratory we tested LTG for its anticonvulsive effects in an audiogenic seizure-prone strain of Balb/c mice. The initial part of this project was designed to study the neurochemical effects of LTG at clinically relevant doses. A report of its use in Parkinson's disease (Zipp et al., 1993) led us to examine the effects of LTG administration on the content of dopamine (DA) and its metabolites in the striatum. LTG administered ip, 40 minutes prior to bell testing, inhibited tonic-clonic audiogenic seizures in a dose-dependent fashion. Complete inhibition of seizures was observed at doses between 10 and 20 mg/kg. At these doses, LTG had no significant effect on DA content in extracts of caudate nucleus micropunches. However, LTG administration significantly reduced the content of the DA metabolites, DOPAC and HVA, in caudate nucleus of both seizure-prone and seizure-resistant mice. DOPAC concentrations were reduced to 43% ($p<0.001$) of controls in seizure-resistant mice, while a reduction to 34% ($p<0.001$) of controls was observed in the seizure-prone strain. HVA concentrations were reduced to 81% ($p<0.05$) in seizure-resistant mice, while a reduction to 58% ($p<0.01$) was observed in seizure-prone mice. While these data do not provide evidence for a role of DA in the anticonvulsant action of LTG, the dramatic effects of this drug on the content of DA metabolites suggest that LTG is an inhibitor of DA turnover. An alternative explanation is that LTG reduces intracellular levels of metabolites by inhibiting reuptake of DA and its subsequent metabolism to DOPAC and HVA. A question that arises from this work is whether the inhibitory action on DA metabolite content is secondary to an action on glutaminergic or GABAergic neurons.

MIDBRAIN 3D DIPOLE MAPPING OF ACOUSTIC EVOKED POTENTIALS IN AUDIOGENIC SEIZURE RESISTANT ANESTHETIZED RATS. Moraes, M.F.D.*, Barboza, A. Del Vecchio, F. and Garcia-Cairasco, N. Neurophysiology and Experimental Neuroethology Laboratory, Physiology Department, Ribeirão Preto School of Medicine. University of São Paulo, Ribeirão Preto, 14049-900. S. P, Brazil.

The inferior colliculus (IC) is the most critical structure of the auditory midbrain involved in audiogenic seizures (AS), a model of experimental epilepsy. AS are induced in susceptible (S) rats, in contrast to resistant (R) rats, by high intensity acoustic stimulation. Thus, in order to disclose functional differences in S and R rats, we began mapping wave form patterns of midbrain acoustic evoked potentials (AEPs) in R Wistar rats. Data were collected from anesthetized rats (thionembutal 40 mg/kg; 240-280 g b.w), by means of carbon fiber electrodes(Tip=10μm; R=35kohms, developed in our laboratory) in the following coordinates, at 0.5mm intervals: AP(lambda) from +0.5 to -2.0mm; L(midline) from 0.5 to 3.0mm; V(dura mater) from 1.5 to 7.0mm; therefore, the mapping procedure resulted in 360 recorded sites (n=3 per site). Monaural pure tone bursts of 3 kHz (90dB) were applied to the contralateral ear. The collected AEPs were promediated (n=50) by means of an A/D converter interfaced with a computer(BIOPAC) and the data expressed as a percentage of maximum of each lateral sweep. Small electrolytic lesions labeled recording points. The results of AEP mapping are presented as conventional 20 ms recordings and used to calculate instantaneous electrical dipoles in each 0.5mm^3 control volume. The calculated dipoles enabled us to reconstruct a cube of the mesencephalon in which the IC is inserted. Results of 3D reconstruction from 0 to 20 ms on a 1ms time interval suggest the signal coming in at 3 ms through the lateral lemniscus, 5 ms in the IC, in 6 ms the signal splits to the superior colliculus, external and dorsal IC nuclei and also projects to the contralateral IC. At around 8ms, central IC seems to receive feedback information from external nuclei. After 9 ms, no significant dipoles are recorded in the cube. Ongoing studies are highlighting differences and similarities between the dynamic (time dependent) 3D dipole distribution of S and R rats.

EFFECT OF NITRIC OXIDE SYNTHASE INHIBITION IN DIFFERENT EPILEPTIC SEIZURE MODELS. Del Bel E.A., Oliveira P.R., Oliveira J.A.C., Mishra P.K[1]., Jobe P.C.[1], Garcia-Cairasco, N*. Physiology Department, Ribeirão Preto School of Medicine. University of São Paulo, Ribeirão Preto, Brazil. [1]Department of Basic Sciences, College of Medicine at Peoria, University of Illinois, Illinois, USA.

Discrepant results have been found concerning the role of nitric oxide (NO) in epileptic seizures. Inhibition of endogenous NO production is an adequate tool for establishing a role for NO in brain excitability. We evaluated the effect of a NO synthase (NOS) inhibitor (L-NOARG), 25 mg/kg, twice a day, 4 days and 125 mg/kg (i.p.; 30 min before seizure or drug injection), in pilocarpine, pentylenetetrazol (PTZ) and audiogenic seizures (AS) on male Wistar resistant (R) rats or genetic epilepsy-prone rats (GEPR-3s) and Sprague-Dawley controls (SD).

Eighty eight percent of the rats (X^2; $p<0.05$) had seizures elicited by a sub-convulsant dose of pilocarpine (100 mg/kg, i.p., 1 mg/kg methyl scopolamine, n=8 per group), only after NOS inhibition. NOS inhibition had no effect on sub-convulsant doses of PTZ (15 and 30 mg/kg i.p., n=8), but potentiated the severity of limbic seizures induced by PTZ (60 mg/kg i.p.; n=16). However, the L-NOARG treatment protected against tonic seizures and lethality induced by PTZ (80 mg/kg i.p.; n=8). L-NOARG treatment had no effect on eliciting AS (n=8 per group) in Wistar R rats either 30 min or 24 h after L-NOARG injection. Moreover, GEPR-3s and SD did not modify their severity indexes or seizure latencies after similar treatments. In conclusion, these results suggest that the effect of NOS inhibition on seizure activity depends on the seizure inducing agent and in the case of chemical induction (i.e. PTZ) it depends also on the dose.

PROPERTIES OF DEVELOPING RAT HIPPOCAMPUS CA1 NEURONS IN THE GENETICALLY EPILEPSY PRONE RATS (GEPRs) S. Verma-Ahuja, T. L. Pencek* and M.S. Evans, Department of Surgery, Division of Neurosurgery and Department of Neurology, Southern Illinois University, School of Medicine, Springfield, Illinois 62704

The developing GEPRs like normal young rats show a greater propensity for tonic seizure induction during the first two weeks of postnatal development. In the third and fourth weeks, the GEPRs lack the developmental decrease in tonic seizure susceptibility that occurs in normal rats. The adult GEPR hippocampus shows an increased excitability in the CA1 region with paired pulse stimulation, a decreased $GABA_A$ mediated inhibition, reduced spike frequency adaptation with a reduced slow afterhyperpolarization (AHP) in some neurons. We now studied the properties of developing hippocampal CA1 neurons in GEPRs (n=32) and SD rats (n=9). The membrane input resistance was higher in the developing CA1 neurons in GEPRs. The fast AHP was absent in GEPR and the repolarization was slower. The slow AHP was not significantly different in developing GEPR CA1 neurons. All the cells studied in the CA1 region in the SD rats during the first three weeks showed a spike frequency adaptation. In 40% of the GEPR CA1 cells recorded in the 3rd or 4th week of development, the spike frequency adaptation was absent. On single synaptic stimulation, some of the CA1 cells showed burst of action potentials in the 3rd week. Decreased inhibition with repetitive stimulation was seen in developing GEPR rats. Single synaptic stimulation in the presence of 10 μM bicuculline elicited a burst of action potentials lasting about 30 ms in SD rats at three weeks. In GEPRs, however, a prolonged discharge lasting for upto 250 ms was seen in CA1 neurons. These results show an increased excitability with epileptogenic properties in the GEPR CA1 neurons at the time when behavioral seizures are beginning to appear.

771.1

GABA-LIKE IMMUNOREACTIVITY (GABA-LI) IN MOSSY FIBERS OF HIPPOCAMPAL BRAIN SLICES. K.S. Wilcox*, M. Price, B. Johnson, R. Sloviter[2], & M.A. Dichter. Depts. of Neurology and Pharmacology, University of Pennsylvania, Philadelphia, PA, 19104 and [2]Helen Hayes Hospital, W. Haverstraw, NY 10993

Dentate granule cells provide the main excitatory input to the CA3 pyramidal cells of the hippocampus and are thought to utilize glutamate as a transmitter. However, recent work (see Sloviter *et al.*, this meeting) demonstrates that dentate granule cells normally contain both GAD-67 and GABA-LI. When perforant path stimulation is used to induce seizure activity, granule cell GAD and GABA staining increases selectively. We were interested in reproducing this phenomenon in the acute hippocampal slice. Rat hippocampal vibratome slices (400-500 μM) were placed in oxygenated Ringer solution at 32-34° for varying lengths of time. Some slices were incubated in Ringer solution lacking Mg^{2+} to induce seizure-like activity, while others were placed in either standard Ringer or Ringer containing CNQX and APV to block excitatory neurotransmission. Following incubation, sections were fixed with 4% paraformaldehyde and cryoprotected by sucrose. Brain sections (10 μm) were stained with standard protocols for immunoreactivity with a monoclonal GABA antibody (Sigma). Slices that were fixed immediately after dissection showed GABA-LI in the mossy fiber terminals, while brain slices incubated under all other conditions demonstrated more intense GABA-LI in the terminals and throughout the mossy fiber pathway. These findings confirm that GABA-LI is present in the mossy fiber terminals under baseline conditions, and that merely incubating slices in standard Ringer solution, a common protocol in laboratories using hippocampal slices for electrophysiological and biochemical studies, is sufficient to greatly enhance GABA-LI in the mossy fiber pathway.

771.2

IMMUNOCYTOCHEMICAL LOCALIZATION OF 65- and 67kDa GLUTAMIC ACID DECARBOXYLASE (GAD)- AND GABA-LIKE IMMUNOREACTIVITIES (LI) IN THE RAT HIPPOCAMPAL FORMATION; GAD67- AND GABA-LI ARE PRESENT IN NORMAL DENTATE GRANULE CELLS AND ARE RAPIDLY INDUCED BY AFFERENT STIMULATION, KAINIC ACID, OR PILOCARPINE. R.S. Sloviter*, A.L. Sollas, E. Dean, and M.A. Dichter.
Neurology Research Ctr., Helen Hayes Hospital, W. Haverstraw, NY 10993, the Depts. of Pharmacology and Neurology, Columbia University, New York, NY 10032, and the Dept. of Neurology, University of Pennsylvania, Phila., PA 19104

Recent cell culture studies suggest that both excitatory and inhibitory cells contain mRNAs for GAD65 and GAD67. This implies that under certain conditions, excitatory neurons may produce GAD and GABA, and temporarily acquire inhibitory properties. We have tested this hypothesis by inducing seizure discharges **in vivo** and then localizing GAD65-, GAD67-, and GABA-LI. However, we unexpectedly discovered in pilot studies utilizing improved immunocytochemical methods for the detection of GABA-LI that dentate granule cell axon terminals of normal animals contain intense GAD67- and GABA-LI. Stimulation of the perforant path once per minute with 10sec-20Hz stimulus trains evoked population spikes and epileptiform discharges in the granule cell-, CA3-, and CA1 pyramidal layers. Six hours of afferent stimulation induced GAD67- and GABA-LI in granule cells, but not in hilar mossy cells or hippocampal pyramidal cells. Stimulation did not detectably alter GAD65-LI. Granule cell GAD67- and GABA-LI were also induced after kainate or pilocarpine-induced seizures. These results indicate that granule cells normally express GAD67 and GABA and that granule cell excitation increases their expression. These findings suggest that granule cells may normally possess both excitatory and inhibitory characteristics and that excessive excitation may temporarily shift the balance in favor of the inhibitory component, possibly altering hippocampal excitability, seizure frequency, severity, and duration as a result. Supported by NINDS grant NS18201.

771.3

EARLY GONADECTOMY MODULATES LONG-TERM POTENTIATION AT SCHAFFER COLLATERAL-CA1 SYNAPSES IN HIPPOCAMPUS. L. Velisek, J. Veliskova, A.M. Etgen, S. L. Moshé, P.K. Stanton*. Departments of Neurology and Neurosience, Albert Einstein College of Medicine, Bronx, NY 10461

Gonadal steroids play an important role in the development of the nervous system. In this study, we examined the gonadectomy-induced changes in Shaffer collateral-evoked synaptic transmission in CA1 hippocampal neurons in slices from 29-31 day old male rats castrated on day of birth. Sham operated littermates served as controls. In another study, we examined slices from adult females ovariectomized 7 days prior to the experiment, and given estrogen supplement two days prior the experiment and a single progesterone injection at day of the experiment. We observed no difference in the maximal population spike amplitude between naive slices from normal and castrated males. In slices from ovarectomized females given hormone supplement we found significantly larger maximal population spike amplitude than in controls (8.6±1.3 mV versus 4.8±0.7 mV). In both males and females, slices from gonadectomized rats exhibited significantly larger short-term potentiation 1-20 min following tetanization, compared to controls. In contrast, gonadectomy did not cause any difference in the amplitude of LTP measured 30 min after high-frequency stimulation (2x100Hz/0.5sec) in males or females.

The data suggest that gonadectomy causes a selective enhancement of short-term potentiation of synaptic transmission in hippocampal field CA1.

CONTINUOUS HIPPOCAMPAL STIMULATION-INDUCED STATUS EPILEPTICUS RESULTS IN ALTERATIONS IN MICROSOMAL CALCIUM UPTAKE. L. D. Kochan*[2], S.B. Churn[1], R.E. Blair[2], V. J. Obias[3], and R. J. DeLorenzo[1,2].
Department of Neurology[1], Department of Pharmacology and Toxicology[2] and Department of Physiology[3], Medical College of Virginia, Richmond, VA 23298.

Status Epilepticus (SE) is a seizure disorder associated with high mortality and morbidity and neuronal cell loss despite aggressive treatment. Hyperexcitability and neuronal cell death have been well correlated with prolonged increases in intracellular calcium. This has provoked interest in calcium homeostatic mechanisms such as the high affinity, low capacity microsomal Ca^{2+} ATPase. Alterations of this enzyme could contribute to the prolonged increases in intracellular calcium that ultimately accounts for the high morbidity and mortality associated with prolonged seizures. The Continuous Hippocampal Stimulation (CHS) model of SE was employed to study the effects of seizure activity on microsomal calcium uptake. Test animals received 'continuous' hippocampal stimulation consisting of 10-s trains of 50-Hz, 1-ms biphasic square wave pulses (400uA) every 11s for 90 minutes. Implanted/Sham animals were used as controls. Rat brain microsomes were isolated from control and SE animals by differential centrifugation for determination of microsomal calcium uptake. Microsomes prepared from control and SE animals displayed ATP-dependent Ca^{2+} uptake. However, CHS-induced SE resulted in significant inhibition of Ca^{2+} uptake, 47%, compared to control. The data indicate that SE causes alterations in microsomal calcium uptake and thus may play a role in causing elevated intracellular Ca^{2+}. The data support the hypothesis that alterations in microsomal calcium uptake may ultimately account for some of the morbidity and mortality associated with prolonged seizures.

FELBAMATE PREVENTS THE DEVELOPMENT OF KINDLING PRODUCED BY CHRONIC TREATMENT WITH PENTYLENETETRAZOL IN THE RAT. **M. Orlandi, O. Giorgi, F. Marrosu*[1], M. Spiga, V. Valentini and M.G. Corda. Departments of Toxicology and [1]Neurology, University of Cagliari, Italy.**

Chronic treatment with an initially subconvulsant dose of pentylenetetrazol (PTZ), a blocker of the Cl^- channel of $GABA_A$ receptors, determines the progressive development of seizures (i.e., chemical kindling). It has been proposed that an enhancement in NMDA receptor-mediated neurotransmission together with a decrease in GABAergic function play a role in PTZ-induced kindling (J. Pharmacol. Exp. Ther., 262, 792, 1992). Since the anticonvulsant effect of Felbamate (FELB) is probably mediated via interaction with the glycine site of NMDA receptors, it was considered of interest to examine the ability of FELB to antagonize PTZ kindling. Rats were treated with a subconvulsant dose of PTZ (30 mg/kg, i.p., every second day) for up to 8 weeks. Two other groups of rats received FELB (300 or 400 mg/kg, i.p., 90 min before each dose of PTZ) and control rats were treated chronically with saline (2 ml/kg., i.p.). Pretreatment with FELB prevented the development of PTZ kindling partially at the dose of 300 mg/kg and completely at 400 mg/kg (seizure score by the end of the chronic treatment, 0-5 scale: control, 0; PTZ alone, 3.23; PTZ + FELB (300), 1.13; PTZ + FELB (400), 0.21). FELB also prevented the increased sensitivity to the convulsant effect of GABA function inhibitors observed in PTZ-kindled rats. Thus, a challenge dose of isoniazid (120 mg/kg, s.c.) or PTZ (20 mg/kg, i.p.) 15 to 60 days after the end of the chronic treatment induced generalized convulsions in >80 % of PTZ-kindled rats and in <10 % of controls or rats treated with PTZ + FELB (400). The results support the view that NMDA receptor-mediated neurotransmission may be involved in the development of PTZ kindling.

771.6

LIMBIC SEIZURES CAUSE CHRONIC SUSCEPTIBILITY TO STRESS IN RATS. Y. Wang[1], S. Ben-Eliyahu[1], G. Tocco[2], M. Mintz[1]* Psychobiology Research Unit, Department of Psychology, Tel Aviv Univ., Tel Aviv, Israel 69978. [2]Neuroscience program, Univ. of Southern California, CA.

Some patients with temporal lobe epilepsy (TLE) experience psychotic symptoms during the interictal periods of the disorder. The study of such interaction may further our understanding of psychotic behavior. Electrical kindling in animals, a process by which daily sub convulsive stimulation comes to elicit full clonic tonic limbic seizures, is used as a model for TLE. The long term effects of kindling include a decrease in dopamine (DA) reactivity in the prefrontal cortex and increased DA reactivity in the striatum. Such cortical-striatal pattern of DA imbalance may underlie some psychotic behaviors. Such pattern also predicts increased behavioral reactivity to stressful stimuli, a common symptom among psychotics. Therefore, in the present study, rats were electrically or sham stimulated once daily until 5 or 10 full clonic tonic seizures have occurred, and their susceptibility to stress was tested 4 weeks later. Kindled animals, as compared to sham-kindled and naive controls, showed increased locomotion in a novel environment and elevated analgesia on a hot plate test. Naloxone (10mg/kg) did not abolish the effect of kindling on the analgesic response. To further study the relationship between kindling and stress, binding to striatal DA-D1 (SCH-23390) and DA-D2 (YM-09151-2) receptors and to DA-uptake sites (GBR-12935) was assessed using autoradiography following acute restrainment stress. Acute stress caused increased DA-D2 receptor binding in the dorsal striatum in all groups. However, neither kindling nor the interaction of kindling and stress had significant effect on binding to DA receptors or DA uptake sites. In conclusion, the present result suggest that kindling increases susceptibility to stress, and the mechanism underlying this effect is not related to changes in DA receptors or DA uptake sites.

771.7

NMDA RECEPTOR ANTAGONISTS AGGRAVATE HYPERBARIC OXYGEN-INDUCED SEIZURES IN RATS. M. Chavko, A.L. Harabin, J.C. Braisted, S.L. Pocotte*. Naval Medical Research Institute, Bethesda, MD 20889-5607.

Excitatory amino acid receptor antagonists are anticonvulsant in a variety of seizure models. We studied the effect of two non-competitive NMDA receptor antagonists on the latency to electroencephalographic discharges in awake rats (male, Sprague-Dawley, 380-480 g) exposed to 5 atm O_2. MK-801 (0.05 to 4 mg/kg) (n= 12) or ketamine (K) (20 or 100 mg/kg) (n=6) injected ip 30 min before exposure markedly *shortened* latency to seizure when compared to saline-injected controls (C) (n=3) (Fig 1). Because MK-801and ketamine may increase cerebral blood flow (CBF), and increases in CBF may enhance O_2 seizures, we measured the effect of MK-801 on CBF. We chronically implanted a laser-Doppler flow probe over the dura of a separate group (n=4) of rats. MK-801 progressively increased CBF up to 300% between 0.05 and 1 mg/kg. The effect of MK-801 on susceptibility to O_2 seizures correlates with the increased CBF. The proconvulsant effect was slightly attenuated at higher doses (> 0.2 mg/kg) known to be effective in other seizure models. We propose two mechanisms by which MK-801 affects O_2 seizures: (1) A dominant proconvulsant effect mediated by increases in CBF and (2) A less powerful anticonvulsant effect operating at higher doses via a receptor-mediated mechanism.

NEGATIVE SHIFT IN DC-EEG LINKED TO A FALL IN END-TIDAL CO_2 DURING VOLUNTARY HYPERVENTILATION. J. Voipio*, K. Kaila, H. Tolvanen and E. Heinonen. Department of Biosciences, 00014 University of Helsinki, Finland.

We have examined the effects of hyperventilation-induced changes in CO_2 partial pressure (Pco_2) on cortical neuronal excitability in experiments on human volunteers (age 22-44 years, n=9). Bipolar recordings between the vertex (C_z) and the left mastoid were made using a purpose-designed DC-coupled EEG amplifier (bandwidth 0-160 Hz) and sintered Ag/AgCl electrodes. A 3-minute period of hyperventilation led to a mean fall in end-tidal Pco_2 from 38 to 24 mm Hg and to a negative shift of 578 ± 320 μV (± SEM), indicative of an increase in neuronal excitability. The inter-individual variation of the maximum DC shift ranged from 250 to 1250 μV while the individual variation in recordings repeated at intervals of 1-2 weeks was less than 10% (n=3). Voluntary apnea, which leads to a build-up of CO_2, produced a positive shift in the DC-EEG. When breathing a gas mixture of 5% CO_2 + 95% air, a respiratory pattern similar to that employed in air hyperventilation produced only small decreases in end-tidal Pco_2 (from 43 to 38 mm Hg) and a clear-cut inhibition (80-100%) of DC shifts when compared with the responses in air hyperventilation. The present data indicate a strict dependence of the negative shift in the DC-EEG on a decrease in Pco_2, which may be accounted for by the well-known enhancement of neuronal excitability induced by respiratory alkalosis that has been repeatedly documented in work on animal models and on in vitro preparations.

MODIFICATION OF KAINATE-INDUCED BEHAVIORAL AND ELECTROGRAPHIC SEIZURES FOLLOWING INHIBITION OF NITRIC OXIDE SYNTHASE IN MICE. R.D. Kirkby*, R.A. Forbes[1], and S. Subramaniam, Neuronal Excitability Section, Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892-1408 and [1]Department of Anesthesiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20810.

We assessed the effects of N^{ω}-nitro-L-arginine-methyl ester (L-NAME), an inhibitor of nitric oxide synthase, on kainate-induced seizures in adult male NIH Swiss mice. L-NAME dose-dependently shortened latency to convulsions following systemic kainate (44 mg/kg; s.c.) and increased the incidence of convulsive wild running (to the exclusion of the less severe clonic convulsions typically seen in controls); L-NAME did not shorten latency to kainate-induced afterdischarge (AD) in the hippocampus, amygdala, frontal cortex, or midbrain reticular formation. Also, 4 of 6 L-NAME-treated (5 mg/kg; i.p.) mice failed to express AD during initial fits of wild running, suggesting an uncoupling of electrographic and behavioral components of kainate-induced seizures. Finally, L-NAME shortened latency to wild running induced by intraventricular kainate (1 nmol) but altered neither behavioral (clonic) nor electrographic seizures elicited by intrahippocampal kainate (1 nmol). Because L-NAME potentiated seizures following either systemic or intraventricular administration of kainate but not intrahippocampal (focal) administration, the proconvulsant effects of L-NAME may depend on bilateral or extrahippocampal actions of kainate. Moreover, because L-NAME facilitates kainate-induced wild running, which bears striking similarities to motor components of audiogenic seizures in susceptible strains of rodents, it is possible that L-NAME influences tectopontine mechanisms that mediate audiogenic seizures.

•CAPTURE OF NITRIC OXIDE WITH HEMOGLOBIN IN BRAIN MICRODIALYSIS. • Y. Zhang, F.E. Samson, S.R. Nelson*, T.L. Pazdernik, Smith Research Center, Univ. of Kansas Med. Ctr., Kansas City, KS 66160.

• The role of nitric oxide (NO) in many physiological processes including neurotransmission, memory and brain injury is the focal point of many neurobiological studies. There is a need for a reliable method to directly monitor NO. Oxyhemoglobin (Hb) has high affinity for NO and upon binding is converted to MetHb quantitatively. Spectroscopy of Hb conversion to MetHb gives an effective measurement of NO concentration. Although this method is especially promising for microdialysis many factors can influence the reproducibility, sensitivity and stability of this assay, making it difficult to get reliable results at low NO levels. Factors such as protein stability, spectral data processing and temperature control, as well as microdialysis parameters were investigated. Also, direct monitoring of NO in microdialysates from rat brain was assessed. By measuring the difference in the diffusion rates of NO and sodium nitroprusside across the microdialysis membrane, we found that NO readily diffuses through the membrane. An optimal approach to measuring the conversion of Hb to MetHb is to use an integral of the difference spectrum which accounts for both the net increase in MetHb and net decrease in Hb. Another critical step is to take the isobestic point as the reference point to "zero" the spectra. This not only eliminates a serious error source from protein degradation but also compensates for unpredictable reflection effects due to small volumes (50-60 µL). This assay has a practical detection limit of about 10 nM (0.5 pmol/sample) in the microdialysate. We evaluated the method in anesthetized rats by demonstrating that the excitotoxin kainic acid (13 mg/kg, ip) induced NO release (17±7 nM). This study developed a protocol with detailed analytical parameters for No monitoring in neurobiomedical research. Supported by DAMD17-94C-4045.

INCREASED PURINE LEVELS IN THE HIPPOCAMPUS MEASURED BY MICRODIALYSIS FOLLOWING SEIZURES. R. F. Berman* and Bertil B. Fredholm. Wayne State University, Detroit, MI and Karolinska Institutet, Stockholm, Sweden.

There is pharmacological evidence that adenosine is an endogenous anticonvulsant agent. We therefore measured brain levels of purines (e.g., adenosine, inosine, guanosine, xanthine, and hypoxanthine) by microdialysis before and after seizures. Seizures were produced in anesthetized male rats by injection of either bicuculline (0.5 mg/kg, i.v.) or kainic acid (12.0 mg/kg, i.v.), and were monitored electrophysiologically via an electrode implanted, unilaterally, into the hippocampus. A 1.0 mm microdialysis probe was implanted in the other hippocampus. Purine levels were quantified by HPLC. Levels of purines increased substantially during seizures, with the largest increases seen for hypoxanthine and inosine. Smaller increases were seen for adenosine. These effects were observed with both kainate and bicuculline seizures. Addition of the adenosine deaminase inhibitor erythro-9-(2-hydroxy-3-nonyl)adenine (EHNA) to the dialysis media resulted in higher basal levels of adenosine, and larger increases in adenosine during seizures. Basal levels of the adenosine metabolite inosine were correspondingly lower after the addition of EHNA, and increases during seizures were of lower magnitude. These findings indicate that brain levels of adenosine increase during seizures, with concomitant increases in levels of adenosine metabolites. The results support the hypothesis that increased adenosine levels may contribute to modulation of seizure activity, and may play a role in the termination of ongoing seizures and the patterning of subsequent seizures. PATTERN OF DISTANT NEURONAL DAMAGE INDUCED BY AMPA-RECEPTOR MEDIATED STATUS EPILEPTICUS EVOKED FROM AREA TEMPESTAS. A. Easton*, D.Belcher, D. Masco, K. Gale, N. Sahibzada. Georgetown University Medical Center and University of DC, Washington D. C.

Cyclothiazide (1.8 nmol), an agent preventing desensitization of AMPA receptors, when focally applied concurrently with bicuculline methiodide (118 pmol) into the area tempestas (AT) results in a prolonged (1-7 hr) status epilepticus (SE) which can be terminated by application of an AMPA receptor antagonist, NBQX (500 pmol) in AT. To evaluate the pattern of neuronal injury in this model, rats were sacrificed 2-3 days after SE and the brains processed using silver impregnation. With SE lasting 2-3 hr, pronounced neuronal degeneration occurred bilaterally in the anterior olfactory nucleus, endopiriform nucleus, amygdaloid nuclei, insular, piriform and rhinal cortices, hippocampus and several thalamic nuclei. The pattern of degeneration was similar in many respects to that produced by systemic kainic acid. In rats with brief periods of SE (1 hr), neuronal damage was largely restricted to the hemisphere from which the seizures were initiated. Under these conditions, there was a notable absence of degeneration in the hippocampus. Otherwise, the brain regions showing unilateral degeneration closely matched those affected bilaterally in rats with more prolonged SE. It appeared that involvement of the hippocampus was closely associated with, and possibly required for, degeneration of regions in the contralateral hemisphere.

These results show that SE evoked focally from AT leads to a pattern of brain damage resembling that seen with limbic SE evoked by systemic chemoconvulsants. This model of focally-evoked SE is highly controllable, with a clearly defined onset, and has the advantage of having the drug treatment confined to a small area, remote from most of the damaged cell populations. Supported by NIH grants NS28130 and GM08005.

BOTH EXCITOTOXIC AND APOPTOTIC MECHANISMS MAY UNDERLIE BRAIN DAMAGE INDUCED BY INJECTION OF AMINOOXYACETIC ACID INTO THE RAT ENTORHINAL CORTEX. [1]F. Du* and [2]T. Eid, [1]Maryland Psychiatric Research Center, Baltimore, MD 21228 and [2]Department of Anatomy and Cell Biology, University of Bergen, Bergen, Norway.

Injection of aminooxyacetic acid (AOAA), an indirect excitotoxin, into the rat entorhinal cortex (EC) causes a seizure-related neuronal loss in EC layer III (Neurosci Lett. 147:185, 1992). In order to determine whether this distinct neurodegeneration involves apoptosis, we examined AOAA-injected rats using Nissl staining and an *in situ* DNA nick end-labeling technique (TUNEL; J. Cell Biol. 119: 493, 1992) at 24 or 48 hours, or 5 days after the AOAA injection. AOAA treatment resulted in intense nuclear TUNEL labeling in neurons within several limbic regions ipsilateral to the injection. At 24 hours, labeled neuronal nuclei were mainly detected in the most medial region of layer III in the ventro-medial EC and in the lateral amygdaloid nucleus. At 48 hours, many labeled nuclei were observed not only in layer III of the entire medial EC and in the lateral amygdaloid nucleus, but also in the subiculum. This distribution pattern of TUNEL-labeled nuclei remained similar after 5 days. Moreover, morphological characteristics of apoptosis, such as condensation of chromatin and nuclear fragmentation, were noticed in the regions described above. Our results indicate that, in addition to the excitotoxic mechanism previously suggested, a delayed apoptotic cell death is involved in AOAA-induced neurotoxicity in limbic regions. The functional consequences of the dual mechanisms underlying these AOAA-induced lesions are currently under investigation.

INHIBITION OF MICROGLIA ACTIVATION REDUCES CORTICAL NEURONAL CELL LOSS AFTER STATUS EPILEPTICUS. L.S. Chen* and O.C. Snead III. Div. of Neurology, Childrens Hospital Los Angeles, University of Southern California. Los Angeles, CA 90027

Status epilepticus (SE) is associated with acute neuronal injury, which can activate microglia. The activated microglia are capable of killing neurons by releasing neurotoxic factors. Therefore, seizure-induced neuronal cell loss (NCL) may have two components: seizure-induced primary NCL and microglia-induced secondary NCL. To test this hypothesis, we studied the effect of inhibiting microglia activation on NCL after SE. Rats were given intrastriatal injection of 0.1 μmole kainic acid to induce SE or vehicle for control (n=6). Neuronal cell density (NCD) was calculated in deep cortical layers. %NCL was defined as: the difference of mean NCD between experimental and control groups/mean NCD of controls. Microglia were identified by C3 receptor (OX-42) immunohistochemically. SE produced progressive cortical NCL. The %NCL was 49% (n=6) at day 1, 67% (n=6) at day 3 and 90% (n=6) at day 7, despite the cessation of seizures at day 1 or day 2. The progressive NCL was correlated with a progressive increase of microglia in the cortex. Administration of colchicine (0.2 mg/kg/day, i.v.) and chloroquine (2.5 mg/kg/day, i.m.) decreased OX-42 immunoreactivity and reduced NCL ($p < 0.01$). The % NCL was 36% at 7 days after SE in rats (N=5) treated from day 1-4; and was 51% in rats (n=6) treated from day 4-7. These data suggest that microglia activated after SE significantly contribute to NCL. Early intervention to inhibit microglia activation can reduce NCL after SE.

REGENERATION AND HYPEREXCITABILITY IN HIPPOCAMPAL CULTURES AFTER TRANSECTION OF THE SCHAFFER COLLATERAL PATHWAY.

R.A McKinney, B.H. Gähwiler* and S.M. Thompson

Brain Research Institute, University of Zurich, CH-8029 Zurich, Switzerland

Seizures are a common consequence of head trauma, and it has been suggested that axonal reorganization may underlie lasting changes in excitability. Mature organotypic hippocampal cultures (>14 days *in vitro*) were used to investigate the capacity of recurrent axon collaterals of CA3 pyramidal cells to sprout in response to transection of the Schaffer collateral pathway with a razor blade. Cultures were permitted to survive for varying times before either injecting biocytin, to observe axonal arborization, or performing GAP-43 immunohistochemistry to visualize regenerating axons. Quantitative changes in dendritic spines were investigated by injecting CA1 cells with Lucifer Yellow and imaging by confocal microscopy. Axonal sprouting within area CA3 was evident at 3 days post-lesion. By 14 days many axons possessed growth cones and were found to have grown across the cut to the CA1 region. At 3 days post-transection, dendritic spines on CA1 cells were elongated and their number began to diminish 7 days post-lesion. Interestingly, spine number returned to control values by 21 days. Functional synaptic excitation of CA1 cells by stimulation in area CA3 was recorded at <14 days post-lesion. Sprouting axons exhibited more swellings, i.e. putative presynaptic boutons, compared to control axons. Evidence of an increase in the strength of excitation relative to inhibition within area CA3 was apparent, thereby suggesting a possible role for axonal sprouting in post-traumatic epilepsy.

THALAMOCORTICAL RELATIONS DURING TRANSITION FROM SLEEP TO EPILEPTIC PATTERNS IN CATS. N. Dürmüller*, D. Contreras and M. Steriade. Lab. Neurophysiol., Sch. Med., Laval University, Quebec, Canada G1K 7P4.

When spike-wave (SW) paroxysmal activity spontaneously develops from sleep patterns in corticothalamic circuits of anesthetized cats, a surprisingly high number of thalamocortical (TC) neurons are hyperpolarized and remain silent throughout the seizure (Steriade and Contreras, 1995). To shed further light on the behavior of such TC cells, we performed intracellular recordings of thalamic and cortical neurons and simultaneously recorded the surface- and depth-EEG activity from the related cortical areas. During SW seizures, the membrane potential of TC cells repolarized between rhythmic EPSPs, in close temporal relation to the depth-positive EEG wave. This repolarization decreased with depolarizing DC, and was enhanced by hyperpolarizing DC, thus suggesting a non-GABAergic origin. The repolarization was not enough to de-inactivate the Ca^{2+} current underlying spike-bursts and most TC cells remained silent. With slight hyperpolarizing DC injection, cells fired typical spike-bursts at each depth-negative EEG wave (see figure). With depolarizing DC, TC neurons fired short spike-trains that could be easily confounded with spike-bursts in extracellular recordings. We propose that the absence of burst firing in a large proportion of TC cells is due to the lack of a GABAergic component characteristic for other forms of SW seizures. A 4 PROCESSOR PARALLEL COMPUTER USING DIGITAL SIGNAL PROCESSOR CHIPS (DSP). APPLICATIONS IN REAL TIME TOPOGRAPHIC MAPPING OF CORTICAL AREAS DURING AMYGDALOID KINDLING IN THE CAT. R. Fernández Mas and A. Fernández-Guardiola*. Div. Invest. en Neurociencias, Inst. Mexicano de Psiquiatría. México 14370, D.F. México.

We describe the application of a custom designed parallel processor in real time digital signal analysis in experimental epilepsy. Our main goal is to analyze the temporal characteristics of the propagation of afterdischarges induced in the temporal lobe amygdala to the cerebral cortex. This processor is able to generate a "cartoon" of the propagation dynamics in order to characterize the afterdicharge with a very high temporal resolution, and study the evolution of each spike in the cortex. As the Kindling develops, the afterdischarge becomes wider and complex in terms of the dynamics of propagation.

The method generates a series of color maps which shows the temporal evolution of selecte spikes. To satisfy the computational requirements, we design a parallel processor based on 4 DSP (digital signal processor) chips with a total 80 million instruction per second. Thus can be generated one map in one millisecond, allowing the real time tracking of ictal and interictal phenomena. Each processor also has 4 analog input channels. This scheme yields an efficient process distribution among processors resulting in a very fast achievement of the interpolation and map generation algórithms. Partially Supp. by DGAPA-UNAM.

PACING A NEURONAL NETWORK WITH PULSED ELECTRIC FIELDS. T. Netoff, D.H. Duong and S.J. Schiff *. Department of Neurosurgery, Children's National Medical Center and George Washington Univ., Washington, D.C. 20010.

Endogenous electric fields of active neurons are known to participate in neuronal synchronization. In 8.5 mM [KCl], *in vitro* hippocampal brain slices exhibit neuronal population burst-firing that shares physiological similarities with interictal epileptic spikes. We have recently demonstrated that such population activity could be paced with orthodromic and antidromic stimulation of the tissue (*J. Neurophys.* 73: 876-879, 1995).. We sought to determine whether such entrainment could be replicated noninvasively with electric fields.

Transverse slices 400 μm thick were prepared from the hippocampus of 125-150 gm female Sprague-Dawley rats with a tissue chopper, and placed in an interface type perfusion chamber at 32-36.5 ^{o}C. Autonomous burst firing was induced with 8.5 mM [KCl] in the perfusate. Pulsed dipole electric fields were created using 2 platinum plate electrodes placed 1 cm apart within the perfusion bath with a tissue slice in between. Extracellular recordings were performed with micropipette electrodes.

Twenty-two experimental trials were performed on 22 slices from 21 rats. Square wave electric field pulses were delivered in trains, 0.75-1.3 Hz, 0.3-1.0 msec duration, delivering brief steady state fields of 15-83 mV/mm. In each experiment, by increasing the field strength, pulse duration, or both, the response of the neurons could be entrained into a 1:1 relationship with the field pulses. At higher intensities of pulse strength and duration, strict time locking of stimulus and response was seen. At pulse frequencies above the natural interburst interval of the tissue, more complex responses could be observed.

These results demonstrate that a burst-firing autonomous neuronal network can be entrained with relatively small pulsed electric fields. These results may be useful in the control of such systems

772.3

NONLINEAR CHAOTIC AND NON-AUTONOMOUS PERIODS IN HIPPOCAMPAL SEIZURES. J. Csicsvári*, A. Bragin and G. Buzsáki. CMBN, Rutgers University, Newark, NJ 07102

A 16-channel silicon probe array was used to record field potentials during seizures in the hippocampus. Current source density (CSD) analysis was applied to eliminate the effect of volume conduction. In the CSD profiles the wave components (< 50 Hz) were analyzed. An amplitude vs. depth vector was constructed by collecting the peak amplitudes from each CSD channel. Sammon's non-linear projection technique was used to visualize the spatial distribution of the amplitude vectors in their higher dimensional feature space. The multidimensional location of each amplitude vector was projected and plotted in three dimension. This method enabled us to examine the quasi-trajectory of the epileptic afterdischarges. Two different states were observed in these plots: attractor state and a continuously changing state (CCS). In the attractor state the trajectory randomly changed within a subvolume of the feature space while in the CCS the consecutive amplitude vectors usually formed a curve changing toward a definite direction and showing certain linear tendencies. The activation patterns of these states were similar in different animals. Typically, the initial CCS phase was followed by an attractor phase. This first attractor state, representing the main part of the afterdischarge, turned into a complex CCS. This complex state usually contained more than one CCS segment. Seizures were terminated in an elongated attractor phase. Traditional non-linear dynamical analysis methods were also performed (fractal dimension calculations on original and randomized signals and recurrence plots) and they indicated chaotic dynamics during the attractor phase and non-autonomous dynamics during the CCS. These methods are useful for the classification of spatially-temporally distinct patterns.

772.4

HIPPOCAMPAL AFTERDISCHARGES IN THE INTACT RAT: ROLE OF COUPLED OSCILLATORS. A. Bragin*, J. Csicsvári, M. Penttonen and G. Buzsáki. CMBN, Rutgers University, Newark, NJ 07102

Epileptic field patterns and unit activity evoked by perforant path (PP) or commissural (COM) stimulation were monitored in the CA1-dentate axis, CA3 and entorhinal regions using multisite silicon probes in freely moving rats. Both stimulation sites induced 2-6 Hz rhythmic afterdischarges (AD) with superimposed gamma (40-100 Hz) oscillations and 200-400 Hz population discharges. PP-induced seizures were initiated in the entorhinal cortex-dentate gyrus axis and later entrained the CA3-CA1 regions, whereas COM stimulation triggered afterdischarges in CA3-CA1 and entrained the entorhinal-cortex-dentate gyrus. During the main part of the seizure all regions discharged synchronously often without any apparent lead by any of the regions. Following bilateral removal of the entorhinal cortex the basic pattern of AD in the CA3-CA1 axis remained similar. The primary afterdischarge always terminated first in the CA1 region, heralded by a slowly spreading (0.1 mm/sec), low amplitude, 70 Hz oscillation. Population burst initiation migrated within the CA3c-a axis. Non-synaptic population discharges of CA1 pyramidal cells were occasionally observed. Basket cells discharged primarily during the population spikes whereas other interneurons sustained long trains of fast (>200 Hz) spike trains. We suggest that two seizure inducing systems exist in the intact brain: the CA3-CA1 circuitry and the entorhinal-dentate network. These oscillating circuitries are normally coupled, but they may also sustain afterdischarges independently.

772.5

DYE COUPLING OF NEURONS IN THE HIPPOCAMPUS IMPLIES A ROLE FOR GAP JUNCTIONS IN EPILEPSY. M Penttonen*, A Bragin, A Sik, and G Buzsaki. CMBN, Rutgers University, Newark, NJ 07102

In awake rats hippocampal epileptic seizures first terminate in the CA1 region by a slowly spreading (0.1 mm/sec) (60-80 Hz) fast oscillation. A likely mechanism responsible for the oscillation is electrical coupling of pyramidal neurons by gap junctions (Bragin et al.; this meeting). In this experiment we tested this hypotheses by intracellular injection of biocytin or neurobiotin into pyramidal neurons in urethane anesthetized rats. Epileptic afterdischarge was induced by 200 Hz stimulation of commissural pathways or by local micropressure ejection of KCl after dye injection and withdrawal of the pipette from the cell. Commissural stimulation or KCl ejection induced a large intracellular depolarization coupled with extracellular -DC shift. Rhythmic afterdischarges erupted during recovery from depolarization. In intact rats <3% of the injected neurons showed coupling. In rats with afterdischarges >40% of the labeled pyramidal cells were dye coupled with other pyramidal cells, interneurons or astrocytes that were found close to the filled pyramidal neurons. Electronmicroscopic investigation of gap junctions between dye coupled cells is under way. We hypothesize that gap junction-mediated cell coupling and associated decrease of the input resistance may be responsible for the termination of epileptic activity.

772.6

LAMINAR AND TOPOGRAPHICAL ANALYSIS OF PERIRHINAL CORTEX KINDLING IN THE RAT. L.L. Felstead*, M.E. Kelly and D.C. McIntyre. Psychology Dept., Carleton Univ., Ottawa, Ont., Canada, K1S 5B6.

Recently we reported that the rate of kindling in the anterior perirhinal cortex was faster than all other limbic structures. Equally important, the latencies to forelimb clonus from stimulus onset of these perirhinal convulsions were extremely brief (<1 s). These two results suggested that the perirhinal cortex might have direct access to motor systems. Our subsequent anatomical studies confirmed this prediction by showing dense perirhinal projections to the frontal motor cortex, originating principally in the layer V cells. Also, we observed that the entire rostrocaudal extent of the perirhinal cortex projected to the frontal cortex. In the present study, we determined whether the laminar differences we observed in the perirhinofrontal projections were associated with differences in kindling profiles when the kindling electrodes were restricted to different perirhinal laminae. In addition, we assessed whether the entire rostrocaudal extent of the perirhinal cortex shared the previously observed rapid kindling/short latency profile. The results indicated that kindling electrodes located in the perirhinal layers V/VI produced kindling rates of 1-2 trials compared to rates of 4-8 trials when electrodes were located superficially in layers I/III. Further, the rapid genesis of kindling was characteristic of the entire rostrocaudal extent of the perirhinal cortex. This laminar and topographical analysis of the perirhinal cortex provides further support for the view that this cortex might serve as the main conduit for limbic discharges to gain access to the motor structures that support limbic kindled convulsions.

772.7

INTRINSIC RESPONSES AND MORPHOLOGICAL FEATURES OF NEURONS IN THE RAT PERIRHINAL CORTEX. R.A. Battye* and D.C. McIntyre. Psychology Dept., Carleton Univ., Ottawa, Ont., Canada K1S 5B6.

Recent interest in the perirhinal cortex results from its involvement in memory, and its ability to rapidly develop kindled seizures with short latencies. The seizure data suggested direct connections between the perirhinal cortex and motor systems. We confirmed this suggestion in anatomical studies, where layer V cells were shown to project densely to the frontal motor cortex. Although little was known about these cells, Beggs & Kairiss (*Brain Res.*, 665:18-32, 1994) recently described several features of perirhinal cells that we confirm here and extend. In the present study, intracellular recordings were made from over 60 perirhinal cells in a coronal slice preparation (McIntyre & Wong, *J. Neurophysiol.*, 55:1295-1307, 1986). Intrinsic membrane responses were studied with depolarizing and hyperpolaring current steps. Subsequently, most cells were injected with 1-2% biocytin to visualize their morphology. 'Regular spiking' was the most characteristic feature of the small, layer III pyramidal cells. Additionally, these dendritically-slight layer III cells showed no anodal break response after hyperpolarizing current injection. Conversely, the large, layer V pyramidal cells frequently displayed 'intrinsic bursting' to depolarizing current injection at their resting potential, which changed into single spike mode when their membrane was held at more depolarized values. These dendritically-extensive layer V cells always showed a depolarizing anodal break response. It is these intrinsic bursting layer V cells that project extensively to the frontal motor cortex and may be responsible for projecting limbic discharges into their convulsive form.

772.8

LATERALIZATION OF AMYGDALA KINDLED CONVULSIONS BY UNILATERAL CORTICAL SPREADING DEPRESSION. M.E. Kelly *, R.A. Battye and D.C. McIntyre. Psychology Dept., Carleton Univ., Ottawa, Ontario, Canada K1S 5B6.

Kindling in the rat forebrain results in development of motor seizures that involve bilateral forelimb clonus. Several investigators have postulated that the motor substrates that support and drive these clonic responses may reside in the frontal cortex. It is known that all limbic sites have direct or indirect access to the frontal motor regions, and that transection of the anterior half of the corpus callosum is successful in lateralizing kindled motor seizures to the limbs contralateral to the kindled site. In the present study, we determined the involvement of the frontal cortex in the expression of forelimb clonus triggered during amygdala kindling in the rat. One day following the third stage-5 convulsion, spreading depression (SD) was induced in the frontal cortex either ipsilateral or contralateral to the kindled amygdala. SD was achieved via a 2 μl injection of 25% KCl into an intracranial cannula permanently positioned above the dura mater over the frontal cortex. Three min following the infusion of KCL, the amygdala was stimulated at its previous afterdischarge (AD) threshold. It was observed that SD in the frontal cortex contralateral to the stimulated amygdala lateralized the clonic convulsion, similar to split-brain rats, without affecting the AD duration. Conversely, SD in the ipsilateral frontal cortex blocked the convulsion and truncated the amygdala AD. These data strongly implicate the frontal motor regions as (a) critical to the manifestation of the forelimb clonus during limbic kindled seizures and (b) important in the elaboration of the ipsilaterally-triggered amygdala AD.

772.9

RADIAL ARM MAZE PERFORMANCE AFTER PARTIAL HIPPOCAMPAL KINDLING L. Stan Leung*, D. Brzozowki, D. Young and B. Shen Dept. Physiology and Clinical Neurological Sciences, University of Western Ontario, London, N6A 5A5, Canada.

In previous studies (Behav Brain Res 40: 11, 1990; Hippocampus 4: 696, 1994), we found that rats that were previously trained on a radial arm maze (RAM) with external cues showed a 'retention' deficit for up to 25 days after partial kindling of the hippocampal CA1 (15 afterdischarges (ADs) over 3 days). The partially baited 8-arm RAM was used in the following 3 experiments: (1) to find the minimal number of ADs required for RAM deficits; (2) to test if RAM deficits are also found in an internal cue maze; and (3) to test whether acquisition is affected by kindling. For the first two experiments, rats were trained on an external cue RAM with 4 arms baited, and rested for a week before partial kindling. In the 1st experiment, RAM deficits, mainly in reference memory, were found in rats within 1 week after 5 or 10 hippocampal ADs, and at 3 weeks only after 10 ADs. In the 2nd experiment, the rats were trained on an external cue maze and an internal cue maze before kindling. The internal cue maze had minimal extramaze cues, and the 4 baited arms with internal cues (e.g. carpet, sandpaper, etc. on the floor) were shuffled before each trial. After partial kindling (15 ADs), rats showed deficits only on the external but not the internal cue maze, consistent with the literature on hippocampal lesion. In the 3rd experiment, rats were first trained on a RAM in one room, then kindled, and acquisition on the RAM with a different set of baited arms was conducted in a new room. There was no difference in the acquisition rates between kindled and control rats. In conclusion, partial hippocampal kindling disrupted the performance of a previously learned external cue RAM but not that of an internal cue RAM. The acquisition of a new RAM does not seem to depend on whether rats are partially kindled or not. (Supported by NS 25383).

772.10

MOSSY FIBER SPROUTING AND LOW-FREQUENCY (RAPID) KINDLING. L.L. Armitage*, E.M. Jenkins, & M.E. Corcoran. Dept. of Psychology, University of Victoria, POB 3050, Victoria, BC, Canada V8W 3P5.

Anomalous sprouting of mossy fibers has been detected in the supragranular area of the dentate gyrus after kindling or kainic acid-induced seizures and in tissue specimens taken from patients with epilepsy. Recent findings suggest that mossy fiber sprouting is detectable during the early stages of kindling and becomes more prominent with the development of convulsive seizures (Cavazos et al., 1991). Because sprouting and conventional kindling have similar time courses, it is difficult to determine whether sprouting is invariably correlated with kindling. To address this issue, we used a rapid (low-frequency) kindling paradigm to determine whether the time courses of sprouting and kindling could be dissociated.

We implanted bilateral electrodes into the amygdala of rats. Low-frequency (3 Hz) electrical stimulation was administered once daily until the first generalized stage 5 seizure was kindled. Twenty-four hours later, brains were prepared for Timm sulfide-silver staining. Yoked control rats carried electrodes and were handled but did not receive stimulation. Although sparse Timm granules were observed in the supragranular area, the amount of mossy fiber sprouting did not differ between kindled and control rats.

Our results suggest that rapid kindling of one generalized stage 5 seizure can occur in the absence of prominent mossy fiber sprouting.

MOSSY FIBER SPROUTING AND PERFORANT PATH KINDLING IN THE RAT FOLLOWING TRANSECTION OF THE FIMBRIA-FORNIX. P. Mohapel*, D.K. Hannesson, L.L. Armitage & M.E. Corcoran. Dept. of Psychology, University of Victoria, POB 3050, Victoria, BC, Canada V8W 3P5.

The anomalous sprouting of mossy fibers from dentate granule cells has been identified in human epileptics and several seizure models. It is unknown whether mossy fiber sprouting occurs following subcortical denervation of the hippocampus (HPC), via transection of the fimbria-fornix (FF). Previous research has demonstrated permanent changes in epileptic electrical activity, neurochemistry, and morphology in the HPC following FF lesions (Buzsáki et al.,1989; Lahtinen et al.,1993). In our first experiment, we attempted to map out the distribution of Timm granules in the supragranular region of the HPC and to plot the time-course of sprouting development following FF transection in rats. Mossy fiber sprouting was first evident, only in the dorsal aspect of the HPC, at about 14 days post FF lesion. The distribution of Timm granules was of moderate proportions with a continuous yet patchy pattern of granules being observed in the supragranular region between tips and crests of the dentate gyrus. The degree of sprouting did not appear to be greater at 30 days post lesion.

In a second experiment we implanted bilateral electrodes into the perforant path, the primary cortical pathway into the HPC, 30 days following FF lesions. Kindling stimulation was administered daily until generalized seizures were elicited. Afterdischarge thresholds were significantly lower in FF lesioned rats, but we found no significant differences in kindling rates between FF lesioned and non-lesioned rats. FF lesioned kindled rats exhibited a continuous and dense band of Timm granules that spanned into the inner molecular layer and was consistent throughout the entire HPC. Non-lesioned kindled rats demonstrated only moderate sprouting, similar to the degree observed with non-kindled lesioned rats. These results suggest that FF transections and perforant path kindling can independently induce mossy fiber sprouting, and in combination produce additive effects. Supported by MRC.

INHIBITION OF AMYGDALA KINDLING IN THE RAT BY CHRONIC METABOTROPIC GLUTAMATE RECEPTOR (mGluR) BLOCKADE. R.L. Beach*, R.B. Meeker, B.A. Thiede, X.Y. Xiong, and R.S. Greenwood. Department of Neurology, University of North Carolina, Chapel Hill, NC 27599

Although N- methyl-D-aspartate (NMDA) receptor activation appears to play a role in the development of the kindled state, the second messengers involved and the role of mGluRs in the process have not been elucidated. We kindled rats using daily 200 μA biphasic pulse trains, administered via stereotactically implanted amygdala electrodes. The selective mGluR antagonist (+)-alpha methyl-4-carboxyphenyl glycine (+MCPG) was chronically infused intracerebroventricularly via osmotic minipumps. Compared with the stereoisomer and drug free controls, +MCPG rats had a significantly decreased rate of kindling. +MCPG rats required significantly more stimuli to reach stage 5. +MCPG rats also required more stimuli to reach stage 3 seizures. At the time when all but one control animal were fully kindled, 50% of the mGluR animals had not reached stage 5 seizures. Afterdischarge durations (ADs) were shorter in the +MCPG rats at all time points, but were similar when compared by kindling stage. Interestingly, initial afterdischarge thresholds were moderately decreased by mGluR blockade. There was no evidence for adverse effects on the animals, as measured by behavior, water intake and body weights. These studies suggest an important role for mGluRs in mediating the plastic changes required for the development of the kindled state. Recent data suggests that NMDA and mGluR receptors cooperate in mediating neuronal plastic changes. The mechanisms via which NMDA and mGluR activation enhance seizure propogation and kindling, as well as the potential for synergistic effects are under further study.

QUENCHING: INHIBITION OF DEVELOPMENT AND EXPRESSION OF AMYGDALA KINDLED SEIZURES WITH LOW FREQUENCY STIMULATION S.R.B. Weiss*, X.L. Li, J. B. Rosen, H. Li, T. Heynen, R. M. Post Biological Psychiatry Branch, NIMH, Bethesda, Md. 20892

Using low frequency stimulation parameters, similar to those that induce long-term depression (LTD) or depotentiation *in vitro*, we attempted to alter amygdala kindling *in vivo*. Male Sprague Dawley rats were implanted with electrodes in the left amygdala, and kindled once/day with 60Hz, biphasic square wave pulses for 1 sec at their afterdischarge (AD) threshold. Immediately after the cessation of afterdischarge or seizure activity, "quenching" stimulation was administered through the same electrode for 15 minutes at a frequency of 1 Hz, using a 0.1 msec pulsewidth, and an intensity of 100μA over the AD threshold. Controls received either no current (sham-stimulation) or high frequency stimulation (100 Hz, .01 msec pusewidth, 100μA + AD threshold) for 15 minutes. All of the sham- (n=4) and high-frequency-stimulated (n=4) animals kindled, developing increasing afterdischarges and seizures within 10-14 days of stimulation. In contrast, 7 of the 8 rats that received quenching stimulation did not exhibit afterdischarge or seizure progression, although all of these rats exhibited ADs on day 1 of stimulation. The afterdischarge thresholds of the kindled control groups decreased or stayed the same after kindling, while they markedly increased in the animals that were quenched. This effect persisted for several weeks after quenching was discontinued and kindling stimulation resumed. In fully kindled animals, a week of quenching (without concurrent kindling) resulted in an increase in the AD threshold and a long lasting (>1 week and up to 7 weeks in some animals) decrease in the seizure response to the original kindling stimulus. This did not occur in animals given sham stimulation for one week.

These findings demonstrate that stimulation using LTD-like parameters *in vivo* has profound effects on amygdala kindled seizure development, expression and thresholds. Whether quenching is mechanistically related to either LTD or depotentiation requires further study. The marked and long-lasting effects of quenching suggest possible clinical applications not only for epilepsy, but also for other neuropsychiatric disorders where threshold phenomena may be crucial to illness emergence.

ESSENTIAL AMINO ACID (AA) DEFICIENCY LOWERS SEIZURE THRESHOLD IN THE RAT: A NOVEL FORM OF KINDLING? D.W. Gietzen*, K.D. Dixon, B.G. Truong, J.A. Barrett, A.C. Jones and D. Washburn. Dept Vet Anat Physiol & Cell Biol and Food Intake Lab. UC Davis, Davis CA 95616.

Neurotransmitter AAs, including GABA, glu, asp and gly, and disruptions of AA metabolism have been implicated in the neurochemistry of seizures, but nutritionally essential AAs have attracted less attention. The anterior piriform cortex (APC), aka "Area Tempestas" is both highly excitable (Piredda & Gale Nature 317: 623 '85) and activated by acute essential AA deficiency (Gietzen J Nutr 123: 610 '93). Repeated activation of the APC in chronic dietary AA deficiency could cause kindling. Therefore, we tested seizure threshold to pentylenetetrazol (PTZ) given ip, and to bicuculline (BIC) injected into the APC, in essential AA deficient (DEF) rats. In 7 trials, rats were fed defined diets with L-AAs (devoid of a single essential AA) as the sole protein source for at least 2 weeks before testing. The limiting AAs (number of trials) were: his (3), ile (2) and thr (2). Subthreshold doses, PTZ: 25 mg/kg + 5 mg/kg increments or BIC: 56 pmol + 10 pmol increments were given until seizures, stage $\geq$ 2, were observed for at least 5 sec. In the last 2 trials, pair-fed groups were included to control for an energy deficit due to reduced intake of the diets. Over all 7 trials, the AA DEF rats had reduced seizure threshold, as seen in lower doses of PTZ or BIC required to induce seizures, more severe seizures at subthreshold doses, and decreased latency to seizure. In trial 6, Thr DEF rats (N=8/gp) tested with PTZ ip had significantly shorter latency to stage $\geq$ 2 seizure (88$\pm$8 min vs 111$\pm$7 min for the control and 118$\pm$9 min for the pair fed group, $p = 0.05$). In trial 7, ile DEF rats given BIC into the APC reached $\geq$ stage 2 seizures at 72.9$\pm$3.6 pmol, while control and pair fed groups required $\geq$ 90.0$\pm$7.6 pmol to reach the same seizure level ($p \leq 0.05$). Thus, his, ile and thr deficiencies each increased seizure susceptibility in the rat. Supported by the Epilepsy Foundation of America; NIH DK35747 to the Food Intake Lab via UC Davis CNRU.

RGDS TETRAPEPTIDE FACILITATES HIPPOCAMPAL *IN VITRO* KINDLING: EVIDENCE FOR INTEGRIN MEDIATED PHYSIOLOGICAL STABILITY. S.Grooms* and L.S.Jones, Dept. of Developmental Biology & Anatomy, Univ. South Carolina, Sch. of Med., Columbia, SC 29208.

Integrins mediate cell/cell and cell/matrix interactions, and also participate in the transduction of information from the extracellular environment to the intracellular milieu. As many extracellular matrix (ECM) molecules contain the conserved amino acid sequence arg-gly-asp-ser (RGDS) at the integrin recognition site, integrin-ECM binding can be disrupted using RGDS molecules. In this study, we have used the RGDS tetrapeptide to examine a potential role for integrins in an animal model of epileptogenesis termed *in vitro* kindling. 625 μm hippocampal slices were stimulated via the Schaffer collaterals (SCs), and extracellular recordings were made from stratum pyramidale of CA1 and CA3b. All slices were monitored for 15 min via input/output curves in a submersion chamber with constant flow (4-5 ml/min) for 15 min. Slices were then reduced to a recycling submersion chamber (4.5-6 ml/min), monitored for one hour, and then stimulated with a maximum of 6 trains through the SCs delivered at five minute intervals. Experimental groups were washed in 1mM RGDS or the inactive tetrapeptide GGGG for one hour prior to *in vitro* kindling. The control tetrapeptide had no effect on *in vitro* kindling, but in the presence of the RGDS tetrapeptide, there was a statistically significant decrease in the number of stimulus trains required to induce spontaneous bursting. In addition, the RGDS-treated slices displayed a significant increase in the rate of bursts produced spontaneously. The period of spontaneous bursting also increased dramatically in RGDS-treated slices. Our results indicate that in the presence of the competitive peptide, hippocampal slices become hyperexcited over time, indicating that interfering with ECM-integrin binding may alter neuronal stability. Because disruption of the ECM-integrin interaction appears to increase neuronal excitability, these results suggest that integrins may participate in neuronal signaling through an RGDS binding site.

ELECTRICAL KINDLING IS ASSOCIATED WITH A LASTING INCREASE IN THE EXTRACELLULAR LEVELS OF KYNURENIC ACID IN THE RAT HIPPOCAMPUS. **[1]R. Schwarcz*, [1]H.-Q. Wu, [2]A. Monno and [2]A. Vezzani, [1]Maryland Psychiatric Research Center, Baltimore, MD 21228 and [2]Mario Negri Institute for Pharmacological Research Laboratory of Neuropharmacology, Milano, Italy.**

The extracellular levels of kynurenic acid (KYNA), an endogenous broad spectrum excitatory amino acid receptor antagonist with anti-neurotoxic and anticonvulsant activity, were assessed by microdialysis in the hippocampus of kindled rats. One week after the completion of amygdala or hippocampal kindling (stage 5: occurrence of tonic-clonic convulsions), the extracellular concentration of KYNA was 1.7 ± 0.1-fold higher than in sham-operated controls ($P < 0.01$). This effect was observed to the same extent in the hippocampus ipsilateral and contralateral to the electrical stimulation. Moreover, whereas 50 μM veratridine, applied through the probe, reduced extracellular KYNA by 28% within 1 h in control rats ($P < 0.05$), veratridine was ineffective in stage 5 kindled rats. During the initial phases of hippocampal kindling (stage 2: stereotypies, retraction of a forelimb), extracellular KYNA levels and the effect of veratridine were similar to controls. The activity of KYNA's biosynthetic enzyme, kynurenine aminotransferase, which is preferentially localized in astroglia, did not change in the hippocampus one week after stage 5 seizures. These data indicate an enhanced liberation of KYNA from hippocampal astrocytes due to an impairment of its normal regulatory mechanisms in fully kindled animals. This may be of relevance for the control of excitatory amino acid receptor function during epileptogenesis.

ELECTRICAL STIMULATION OF DISCRETE REGIONS IN THE RODENT AMYGDALA ELICITS DIFFERENCES IN SEIZURE DEVELOPMENT AND RESPONSIVITY. M. Sitcoske, J.B. Rosen, S.R.B. Weiss, R.M. Post* Biological Psychiatry Branch, NIMH, Bethesda, Md. 20892

This study examined whether electrically stimulating different nuclei in the amygdala would produce changes in afterdischarge threshold (AD) and seizure development. Male rats were implanted with electrodes aimed at the basolateral (BL) and central (Ce) nuclei and the amygdalostriatal (AmS) zone. The animals were stimulated once/day with 60Hz, biphasic peak to peak square wave current for 1 sec. The AD threshold values were determined prior to kindling to match and divide the animals into 2 groups. Rats were then kindled at threshold or suprathreshold (800μA) current intensities. Data from 52 animals show that the AD thresholds elicited from the three regions differed from one another prior to kindling ($p<.0001$). The mean AD threshold for the BL nucleus was 74μA; the AmS area was 222μA; and the Ce nucleus was 435μA. Once kindled, AD thresholds were redetermined. Kindling at suprathreshold current resulted in an increase in threshold in the BL and Ce nuclei ($p<0.05$) but not in the AmS zone. These findings are consistent with the earlier work of Pinel and associates (1974), and suggest that kindling at threshold vs suprathreshold current intensities elicits different neurophysiological and biochemical actions. In addition, although the AD thresholds in the Ce nucleus were the highest, this area required fewer number of ADs than the BL nucleus to produce three consecutive stage 5 seizures at either stimulation intensity, suggesting the relationship between threshold and kindling susceptibility is complex.

The BL, AmS, and Ce regions contain cells with distinct morphologies and projection pathways. Although Goddard (1969) originally proposed that stimulation of any region within the amygdala produced relatively similar kindled seizure progression, we and others (Le Gal La Salle, 1982; Gilbert, 1981; Cain, 1992) are finding that differences do exist within the amygdala and delineating these may further our understanding of the anatomical progression of seizure development and its biochemical and behavioral consequences.

Repeated subconvulsive electrical stimulation of certain areas of the forebrain leads to kindling, a progressive and permanent amplification of evoked epileptiform activity which is a model for human temporal lobe epilepsy. Kindling induces synthesis of nerve growth factor (NGF) protein and mRNA. In addition, mossy fiber sprouting and functional synaptogenesis have been observed in the hippocampus of kindled animals. We have shown that intraventricular administration of antibodies and peptide antagonists of NGF retard amygdaloid kindling and block kindling-induced mossy fiber sprouting. To determine whether NGF can *enhance* the development of kindling and kindling-associated sprouting, rats receiving intraventricular NGF or saline were kindled in the amygdala by twice-daily stimulations. Rats receiving intraventricular NGF required fewer (6.7± 0.9) stimulations to reach the fully kindled state than rats receiving saline (13.7 ± 0.9). Following kindling, sprouting of the mossy fibers into the stratum oriens of the CA3 region of the hippocampus is measured by Timm staining, and kindling-induced hippocampal damage is assessed by performing total cell counts for the hilus. Timm staining and cell counting analyses are in progress and preliminary data will be reported. Our findings further demonstrate the role of NGF in kindling.

EFFECT OF KINDLING ON CALCIUM CURRENTS IN ADRENALECTOMIZED AND ADRENALLY INTACT RATS. H. Karst[1], A.B. Mulder[2]*, E.R. De Kloet[1] and M. Joëls[2], [1]Med. Pharmacol.,Univ. of Leiden, 2300 RA Leiden; [2]Dept. Exp. Zoology, Univ. of Amsterdam, 1098 SM Amsterdam, The Netherlands.

Stress is known to affect the incidence and nature of seizures in epileptic patients.To study the effect of corticosteroid hormones on epilepsy we used an animal model for temporal lobe epilepsy, i.e. kindling. Via electrodes implanted in the hippocampal Schaffer collaterals, male Wistar rats were tetanized twice daily with 50 Hz stimulation frequency for two seconds with a current intensity of 300 µA. After the tenth class 5 seizure according to the scale of Racine, the rats were fully kindled. Three to four weeks later rats were either adrenalectomized or sham operated. Five to seven days later the animals were sacrificed. Four experimental groups were investigated: non-kindled sham operated, kindled sham operated, non-kindled ADX and kindled ADX rats. Of these groups a number of parameters were studied, including the properties of voltage-gated calcium currents in CA1 neurons, with the in-situ patch-clamp technique in the slice. Kindling and ADX increased the amplitude of low threshold calcium (LTC) currents. Voltage properties and kinetics of (in)activation were not affected. Adrenalectomy of the kindled rats however did not further increase the LTC currents, indicating that ADX is not acting synergistically. In contrast to the LTC-currents, kindling caused a decrease of the high threshold calcium (HTC) currents. Adrenalectomy did not affect these HTC-currents, neither in the non-kindled nor in the kindled rats. The expression of mRNA for voltage gated Ca-channel subunits and corticosteroid receptors in the kindled and ADX rats is presently under investigation. Previously we reported that LTC-channels are mainly located in the dendrites of pyramidal CA1 neurons; HTC-channels can be found near the soma. We tentatively conclude that both kindling and ADX particularly increase calcium influx in the dendritic region, an area where also a considerable part of the synaptically induced Ca-influx takes place.

773.1

CORRELATION BETWEEN THE EXPRESSION OF NICOTINIC ACETYLCHOLINE RECEPTOR α4-SUBUNIT mRNA AND TAU-PROTEIN IN THE CORTEX OF ALZHEIMER PATIENTS. A. Wevers[1*], C. Lobron[2], M. Ghobrial[3], E. Giacobini[4], P. Gass[5], A. Maelicke[2] and H. Schröder[1]. [1]Inst. II für Anatomie, Univ. zu Köln, 50931 Köln, FRG, [2]Inst. für Physiol. Chemie und Pathobiochemie, Univ. Mainz, 55128 Mainz, FRG, Depts. of [3]Pathology and [4]Pharmacology, Southern Illinois Univ. Sch. Med., Springfield, IL, USA, [5]Inst. für Neuropathologie, Univ. Heidelberg, 69120 Heidelberg, FRG

Changes in the expression of nicotinic acetylcholine receptor (nAChR) have been among the first reported neurochemical landmarks of Alzheimer's disease (AD). The availability of nAChR subunit specific nucleic acid probes has allowed to investigate the subunit gene expression and its relation to pathological intracellular changes.

In situ hybridizations were performed on autopsy tissue of the superior frontal gyrus of AD brains (n=6) and age-matched controls (n=5), using a digoxigenin-labeled α4 nAChR subunit-specific riboprobe. Hybrids were visualized by an alkaline phosphatase-coupled digoxigenin antibody. Simultaneous detection of tau-protein or glial fibrillary acidic protein was achieved by subsequent indirect immunoperoxidase technique. As reported earlier, α4 mRNA was detected in many neurons of all cortical layers. We did not observe general changes in the distribution of α4 subunit nAChR expressing neurons in AD as compared to controls. Corresponding to the density of structures expressing tau protein, the number of α4 mRNA-containing apical dendrites was decreased in AD, especially in the pyramidal cells of layer II/III. Neurons that were heavily labeled for the tau-protein expressed little as no α4 mRNA.

The present results underline the importance of the relation between the expression of pathologically modified filaments and nAChR mRNA. Further studies at the EM level on the mRNA distribution of α4 and other subunits will provide additional information on nAChR mRNA transport under normal and pathological conditions.

III.Sumitomo Pharmaceutical Research Center,Konohana-ku,Osaka,554,Japan.

We previously demonstrated that Hippocampal Cholinergic Neurostimulating Peptide (HCNP), a novel peptide purified from 10-12 day old rat hippocampus, specifically enhances acetylcholine synthesis in medial septal nuclei in vitro.The septo-hippocampal system plays an important structural role in memory formation. Moreover, it is well known that certain pathological changes, such as neuron loss, gliosis, plaques and tangles, are found in the hippocampus of patients with Alzheimer type dementia.In this study, we prepared total RNA from hippocampus and frontal lobe of postmortem human brain by the AGCP method. mRNA was quantified by Northern blot analysis using cDNA specific for HCNP precursor protein as a probe.The results suggested that expression of HCNP precursor mRNA in hippocampus decreased in 5 cases with Alzheimer type dementia compared with 5 cases of normal aging, even after correction for the expression of β-actin mRNA.This result surpports our previous findings documenting the lack of neurotrophic substances in brains of patients with Alzheimer's disease. (Ojika,K. et.al., Banbury report 15,Cold spring Harbor,NY.1983;285-295).

FUNCTIONAL REGULATION OF NEOCORTICAL PYRAMIDAL NEURONES BY BOTH MUSCARINIC AND NICOTINIC RECEPTORS. I.P.Chessell, M.A. Simmonds* and P.P.A.Humphrey Glaxo Institute of Applied Pharmacology, Cambridge, CB2 5DH, and *Dept. Pharmacology, School of Pharmacy, London, WC1N 1AX, UK.

A novel cortical brain slice preparation for use with extracellular "grease-gap" recording techniques has been developed, allowing study of both glutamatergic and cholinergic responses of neocortical pyramidal neurones which form the transcallosal-corticocortical pathway. Concentration-effect curves to the muscarinic/nicotinic agonist carbachol and the nicotinic agonist DMPP yielded mean EC_{50} values of 29.5 and 13.2 μM, respectively. Carbachol-induced responses were inhibited by atropine (0.2 μM) and mecamylamine (10 μM). This antagonism was not competitive. Conversely, concentration-effect curves to DMPP were shifted in a parallel rightward manner by mecamylamine, and were unaffected by atropine. Depolarisation responses to glutamate were reversibly antagonised by D-AP5 (30μM) and CNQX (15 μM); these antagonists had no effect on carbachol- or DMPP-induced responses.

This preparation allows reproducible quantification of depolarisation responses of pyramidal neurones whose axons pass through the corpus callosum to contralateral cortex; such studies indicate functional regulation of the activity of these neurones by nicotinic and muscarinic receptors present on their cell bodies and dendrites. These same neurones degenerate in Alzheimer's disease, culminating in marked cortical glutamatergic hypoactivity, which underlies the cognitive deficits observed. We propose, therefore, that therapies aimed at activating nicotinic as well as muscarinic receptors are more likely to succeed in ameliorating the cognitive symptoms of the disease than those aimed at muscarinic activation alone.

773.4

DECREASED BINDING OF THE VESAMICOL ANALOG [^{125}I]-(+)-MIBT TO THE TEMPORAL CORTEX IN ALZHEIMER'S DISEASE. E.M. Garland, I.K. Staley, D.C. Mash, M. Basile* and S.M.N. Efange. Depts. of Neurology & Moll. Cell. Pharmacology, Univ. of Miami School of Medicine, Miami, FL. 33101; Depts. of Radiology, Med. Chem. & Neurosurgery, Univ. of Minnesota, Minneapolis, MN 55455.

The vesamicol binding site on the cholinergic synaptic vesicle is a novel target for development of radiopharmaceuticals for mapping cholinergic innervation. Previous studies using [^{3}H]vesamicol have demonstrated marginal reductions in the densities of vesamicol binding sites in frontal cortex and increased densities in the temporal cortex in Alzheimer's disease (AD). Vesamicol binding site densities correlated poorly with the loss of choline acetyltransferase (ChAT) activity in AD. These conflicting findings suggest that [^{3}H]vesamicol may label also non-cholinergic sites in the cerebral cortex. In the present study, we have evaluated the novel vesamicol analog [^{125}I]-(+)-MIBT as a probe to assess cholinergic synaptic integrity in the temporal cortex of AD and neurologically-normal age matched control subjects. Saturation binding analysis using aminobenzovesamicol (ABV) to define non-specific binding, revealed a high affinity binding site with a K_D value of 3.2 ± 0.2 nM in the temporal cortex in aged control subjects. Similar affinity values were observed for [^{125}I]-(+)-MIBT binding in AD. The density of [^{125}I]-(+)-MIBT binding was reduced significantly in AD temporal cortex (Bmax =11.6 ± 2.8 pmol/g) as compared to control values (Bmax =19.5 ± 3.2 pmol/g). The decrease in [^{125}I]-(+)-MIBT binding was correlated with ChAT activities (r = 0.90) in AD temporal cortex. These results suggest that [^{123}I]-(+)-MIBT may be useful for assessing *in vivo* the loss of cholinergic projections with SPECT in AD and other dementing disorders.

SELECTIVE ACETYLCHOLINE NEUROTOXINS, IN COMBINATION WITH GLUCOCORTICOIDS AS A POTENTIAL MODEL OF ALZHEIMER'S DISEASE: THE EFFECTS OF AF64A AND SAPORIN ON SPATIAL LEARNING IN THE MALE RAT. W.A. Dornan*, A.R.V. McCampbell, G.P.Tinkler, L.J. Hickman, Dept. of Psych., Illinois Wesleyan Univ., Bloomington, IL. 61702.

Alzheimer's disease currently afflicts approximately 4 million people in the United States, with 100,000 new cases being reported each year. This disorder is typified by several cognitive deficits, including memory loss. In our laboratory we have taken several approaches to the generation of a suitable animal model with which to study this disease. Previous work has focused on exploring a possible synergistic effect between a neurotoxic protein (beta amyloid) found in AD patients and stress. In the following series of studies we have expanded on these results in glucocorticoid-treated animals following ICV injections of the ACh neurotoxin, AF64A (1nmol/ventricle), or intracerebral injections of the ACh toxin, saporin (.42ug). In experiment 1, four groups of male rats were used: 1) ICV injections of AF64A in animals treated for 7 days with corticosterone (CORT,7 mg), 2) ICV injection of vehicle + CORT, 3) ICV injections of AF64A + 7 days of sesame oil (CONT), and 4) ICV injections of vehicle + CONT. In experiment 2 the following groups were used: 1) bilateral injections of saporin into the nucleus basalis (NB), 2) bilateral injections of vehicle into the NB (CONT), 3) unilateral injections of saporin into the medial septal area (MSA), and 4) unilateral injections of vehicle into the MSA. Approximately 14 days following surgery, all animals were assessed for spatial learning using a modified version of the Morris Water Maze. Our results reveal a significant impairment on a variety of behavioral parameters associated with spatial learning in the rat following injections of saporin into the NB and the MSA. In support of previous research, a significant recovery was observed in the MSA animals. In addition, a significant potentiation of AF64A on spatial learning was observed in glucocorticoid-treated animals. Our results strongly support the use of selective ACh neurotoxins as a viable model of Alzheimer's disease, and further suggest that chronic stress is involved in the pathogenesis of Alzheimer's disease.

SCOPOLAMINE-INDUCED IMPAIRMENT OF CONTINUOUS PERFORMANCE IN RHESUS MONKEYS IS REVERSED BY TACRINE (COGNEX) AND THE m_1 SELECTIVE MUSCARINIC AGONIST PD 151832. M. J. Callahan*. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.

Pharmacologic blockade of postsynaptic muscarinic receptors impairs cognitive function in animals and man. The muscarinic receptor antagonist scopolamine impairs various aspects of memory including deficits in selective attention. The role of an intrinsic attentional deficit in Alzheimer's disease and the muscarinic cholinergic contribution to these deficits may be important in developing appropriate therapy.

In this study, test experienced rhesus monkeys with established baseline performance were used. Responses on a continuous performance task were measured using a microcomputer-controlled test environment. Animals were rewarded for responding to a target object displayed on the screen of a touch-sensitive color television monitor (CRT). Display of the target object on the CRT was randomized with respect to time and spatial location. Scopolamine (0.003, 0.006 and 0.01 mg/kg, IM) produced a dose-dependent decrease in responses which was seen to persist 2 hrs after dosing. Tacrine (0.03, 0.1, 0.32 and 1.0 mg/kg, IM) given 60 min after scopolamine and 30 min before testing reversed the impaired performance produced by scopolamine in a dose-dependent manner. PD 151832 (0.1, 0.32 and 0.1 mg/kg, IM) given similarly also improved performance in a dose-dependent manner. These data suggest that scopolamine produces a deficit in sustained attention or slowing of information processing that can be attenuated by treatment with tacrine or PD 151832.

773.7

MUSCARINIC AGONISTS INCREASE HIPPOCAMPAL PHOSPHATIDYL INOSITOL TURNOVER *IN VIVO* AND ATTENUATE HEMICHOLINIUM-3-INDUCED AMNESIA IN MICE. K.M. Ward, D.S. Chapin, J.T. Nowakowski, J.T. Forman, D.M. Nason, A. Villalobos and D.R. Liston*, Pfizer Inc., Central Research Division, Deptartment of Neuroscience, Groton, CT 06340.

Alzheimer's disease (AD) results in a loss of the cholinergic projections important in learning and memory. A muscarinic agonist that interacts directly with post-synaptic m1 receptors, which are preserved in AD, may provide effective palliative therapy. We have examined the *in vivo* activity of three potent muscarinic agonists (pilocarpine, LY-246708 and SDZ-ENS-163) using biochemical (*in vivo* phosphatidyl inositol turnover) and behavioral (passive avoidance) models of central muscarinic activation. For *in vivo* PI turnover, ^{3}H-myoinositol was injected i.c.v. (2 µCi/5 µL) 24 hr prior to test compounds to prelabel the hippocampal phospholipid pool. Lithium (10 meq/kg s.c.) was administered 3 hr prior to tissue sampling and the test compounds were administered s.c. 1 hr prior to tissue sampling. The accumulation of inositol phosphates (IP_3) in the hippocampus was determined following extraction and ion exchange chromatography. Significant elevation of hippocampal IP_3 was produced by pilocarpine at 10-32 mg/kg s.c.; by LY-246708 at 3-45 mg/kg s.c.; and by SDZ-ENS-163 at 5-25 mg/kg s.c. A one-trial step-through passive avoidance (PA) procedure was utilized to test the ability of these 3 compounds to reverse hemicholinium-3 (HC-3) induced amnesia. Test step-through latency was reduced by 50-60% following treatment with HC-3 (1.78 µg i.c.v.) two hours prior to the training session. Pilocarpine (1.78-10 mg/kg), LY-246708 (1-10 mg/kg) and SDZ-ENS-163 (1.78-17.8 mg/kg) attenuated HC-3-induced amnesia. Most notably, the effective dose range of LY-246708 and SDZ-ENS-163 in PA spanned a 10-fold range of doses, in contrast to our experience with AChE inhibitors, which show a more narrow range of effective doses in this model. We conclude that selective muscarinic agonists may be useful in treating disease states such as AD where the central cholinergic system is compromised.

COMBINED CHOLINERGIC AND ADRENERGIC CANDIDATES FOR ALZHEIMER'S DISEASE (AD) THERAPY (I): PHARMACOLOGICAL CHARACTERIZATION. H.M. Vargas*, G. Bores, W. Petko, M. Li, D. Selk, D.K. Rush, L. Davis, D. Fink and C.P. Smith. **Hoechst-Roussel Pharmaceuticals, Inc., Neuroscience PGU, Somerville, New Jersey 08876.**

The most widely characterized neurotransmitter deficiencies in AD are of the cholinergic and noradrenergic systems. Clinical studies with acetylcholinesterase inhibitors (AChEI) have shown some symptomatic improvement, but the efficacy of these agents is low. Behavioral literature suggests that norepinephrine (NE) enhances learning and memory in several different animal models. Based on these findings, we developed novel AChE inhibitors which also possess noradrenergic properties. For these studies, all *in vitro* biochemical indicies were derived from rat and dog tissues. In rat brain, the following activities were determined: potency at inhibiting AChE activity, α_2-adrenoceptor affinity as determined by [^{3}H]clonidine displacement, and the functional release of [^{3}H]NE due to presynaptic α_2-adrenoceptor blockade. Antagonism of BHT-920 induced contractions of the dog saphenous vein was used to functionally determine the nature of α_2-adrenoceptor blockade *in vitro*. Our findings indicate that compounds P11467 and P11345 demonstrated pharmacological activity as combined AChE inhibitors with competitive α_2-adrenoceptor antagonist properties. These compounds were inactive as inhibitors of norepinephrine, dopamine and serotonin uptake. In addition, these compounds were inactive as monoamine oxidase inhibitors, nor did they have affinity for muscarinic and dopaminergic receptors. These agents are further discussed in this and accompanying abstracts.

773.9

COMBINED CHOLINOMIMETIC AND ADRENERGIC CANDIDATES FOR ALZHEIMER'S DISEASE (AD) THERAPY (II): *IN VIVO* BIOCHEMICAL ACTIVITY. A. Giovanni*, G. Bores, M. Li, C.P. Smith, L. Zhou, D. Cunningham and H.M. Vargas. **Hoechst-Roussel Pharmaceuticals, Inc., Neuroscience PGU, Somerville, New Jersey 08876.**

Cholinergic deficits appear to correlate with the severity of memory impairment associated with AD. Acetylcholinesterase inhibitors (AChEI) have shown symptomatic improvement although deficits in other neurotransmitters, e.g. norepinephrine (NE), have been implicated in AD. Camacho *et al.* (1995; next abstract) have shown α_2-antagonists potentiate the ability of AChEI's to enhance long-term memory retention. We describe studies in which we examine several *in vivo* parameters to assess the efficacy of a novel AChEI with noradrenergic properties (prior abstract, Vargas *et al.*, 1995). P11467 dose-dependently inhibited rat striatal AChE activity (ID_{50}=3.1 mg/kg, i.p.); this effect was reversible. In microdialysis studies, the compound increased ACh levels in the rat hippocampus 4-fold following a dose of 5 mg/kg i.p., an effect shared with other AChEIs. At 1.25 - 5 mg/kg, i.p., P11467 significantly increased hippocampal NE release (similarly to idazoxan) in a dose-dependent manner, a characteristic not shared with other AChEIs. Doses of P11467 which elevated ACh and NE release also enhanced long-term memory retention in a step-down passive avoidance paradigm in rats. Functional assays showed that P11467 competitively antagonized pre- and postsynaptic α_2-adrenoceptors *in vitro* and *in vivo*. These findings indicate that P11467 elevates central ACh and NE levels via inhibition of AChE activity and antagonism of α_2-adrenoceptor function.

773.10

COMBINED CHOLINERGIC AND ADRENERGIC CANDIDATES FOR ALZHEIMER'S DISEASE (AD) THERAPY (III): *IN VIVO* EFFICACY. F. Camacho, H.M. Vargas, C.P. Smith, J.T. Winslow.* **Hoechst-Roussel Pharmaceuticals Inc., Neuroscience Product Group, Somerville, N.J., 08876**

The cholinergic hypothesis of AD has influenced much of research on learning and memory over the last decade. However, cholinomimetic agents have had limited success in the treatment of AD dementia. The noradrenergic system has also been implicated in cognitive processes and is depleted in AD. This study investigated the effects of enhanced noradrenergic and cholinergic neurotransmission on cognitive measures in rodents. Acetylcholinesterase inhibitors (AChEI) at moderate doses significantly enhanced retention latencies in a step-down passive avoidance (EPA) paradigm. The α_2-adrenoceptor antagonists idazoxan (IDA), yohimbine (YOH), and P7480 had no effect on the retention response in EPA. However, when a sub-threshold dose of heptylphysostigmine (HEP) was administered in combination with IDA, YOH, or P7480 there was a potentiating effect that led to an enhanced retention of the passive avoidance response. This enhanced retention was not evident when HEP was coadministered with either the systemically active, but not centrally active, α_2-adrenoceptor antagonist MK-467 or the postsynaptic α_2-adrenoceptor antagonist SKF 108456. The data indicate that central cholinergic and noradrenergic systems may interact in the formation of a long-term memory trace. Mixed AChEI-α_2-adrenoceptor antagonist compounds P11467 and P11345 were also tested in the EPA and were found to significantly enhance the retention of the passive avoidance response in rats. These results suggest that drugs which enhance cholinergic and noradrenergic activity may be an efficacious in the treatment of AD.

CHANGES IN BRAIN ACETYLCHOLINE OVERFLOW DURING RAT AND MONKEY MICRODIALYSIS FOLLOWING ADMINISTRATION OF THE ACETYLCHOLINESTERASE INHIBITOR, CI-1002. M. Duff Davis* and Leonard W. Cooke, Neurosciences Therapeutics, Parke-Davis Research, Division of Warner-Lambert, 2800 Plymouth Rd., Ann Arbor, MI 48105.

Pathological findings have indicated that cholinergic innervation of the brain in Alzheimer's patients appears to be compromised. In the clinic, some patients have shown improvement or delayed progression of symptoms during treatment with acetylcholinesterase (AChE) inhibitors such as tacrine. Here we report on a new AChE inhibitor and muscarinic antagonist, CI-1002, and its ability to alter neurotransmitter release in two animal species.

Adult male Long-Evans rats had microdialysis probes surgically implanted into the lateral prefrontal cortex and were allowed to recover for 24hrs. Male squirrel monkeys, Saimiri Sciureus, were chair-restrained and a probe placed in the putamen through a previously-implanted guide cannula. CI-1002 was administered at 0.32, 1.0 or 3 mg/kg im with each dose evoking an increase in basal ACH overflow compared to control. This study demonstrates the potential of CI-1002 to elevate cholinergic tone in rodent and non-human primate species.

773.12

DETERMINATION OF BLOOD AND BRAIN ACETYLCHOLINESTERASE (AChE) INHIBITION AFTER ORAL DOSING OF CI-1002. M.R. Emmerling, M.C. Callahan, H. LeVine*, W. Lipinski, & C. Raby. Parke-Davis Pharmaceutical Research, Division of Warner-Lambert, 2800 Plymouth Rd., Ann Arbor, MI 48105.

CI-1002 is a combined AChE inhibitor and muscarinic antagonist (Mol. Neurobiol., 1994, 9, 93). AChE enzyme inhibition in blood and different brain regions produced after oral dosing of 2 and 10 mg/kg doses of CI-1002 was determined by ex vivo radiometric assay. AChE activity in blood after the 2 mg/kg dose was decreased by 40 % compared to control at 0.5 hr and gradually returned to control levels by 4 hours. The 10 mg/kg dose reduced AChE activity in blood by 80% compared to control at 0.5 hr. AChE activity rose over time but remained significantly lower than control over the next 6 hr. In brain, the enzyme activity in hippocampus was significantly reduced by 30% at 1.0 hr at the 2 mg/kg dose of CI-1002 and by 54% at 0.5hr at the 10 mg/kg dose. AChE activity at the 10 mg/kg dose remained significantly less than control for the next 2 hr. The time course of AChE inhibition in hippocampus was similar to that seen in blood at both doses of CI-1002. Significant inhibition of AChE activity was also evident in the frontal cortex at 1 and 2 hr after the 10 mg/kg dose. Although lower levels of AChE activity were detected, no significant changes in the AChE activity of striatum or cerebellum relative to control was detected at any dose or time point tested. These results show that CI-1002 enters the brain in sufficient quantities to cause inhibition of AChE activity. The level of AChE inhibition in brain is dose-dependent and correlates with the level of AChE inhibition detected in the blood. Brain regions are differenetially affected by CI-1002 with the greatest inhibition being detected in the hippocampus. Finally, results will be presented to show that the level of AChE inhibition detected can be used to estimate the concentration of CI-1002 in tissues with reasonable accuracy.

773.13

BUTYRYLCHOLINESTERASE IMMUNOCHEMISTRY IN HUMAN CEREBRAL CORTEX. M.-M. Mesulam*[1], C. Geula[2], S. Brimijoin[3], J.F. Smiley[1]. [1]Northwestern University, Chicago IL; [2]Harvard Medical School, Boston MA; [3]Mayo Foundation, Rochester MN.

Plaques and tangles in Alzheimer's disease (AD) express butyrylcholinestrase (BChE) enzyme activity. This activity could conceivably come from degenerated remnants of premorbidly BCHE-positive neurons. To test this hypothesis, we used monoclonal antibodies to detect BChE- immunopositive neurons in the human cerebral cortex. There were very few BChE-positive perikarya in non-demented young and aged brains. Most were located in the gyral white matter or in layer 6 and were non-pyramidal. Limbic areas, especially the stratum oriens of the hippocampus, contained the highest number. The density of these neurons was 1-2 orders of magnitude less than that of BChE-positive tangles seen in AD. No immunopositive cortical axons were seen to account for the BChE-positivity of neuropil plaques in AD. Concurrent visualization of BChE immunoreactivity with BChE enzyme activity revealed distinctly double-labeled perikarya.

These results support our conclusion that the plaque- and tangle-bound BChE in AD is unlikely to be of neuronal origin. In many of our specimens, neuroglia appeared intensely BChE-immunopositive. Since neuroglia are prone to non-specific immunostaining, this observation needs to be interpreted cautiously. However, the BChE-immunopositivity of neuroglia is consistent with our histochemical experiments and our hypothesis that the plaque- and tangle-bound BChE is of neuroglial rather than neuronal origin. The role of neuronal BChE remains mysterious. Diverse trophic functions have been attributed to BChE and may underlie its role in neuroglia.

773.14

EFFECT OF THE SELECTIVE, REVERSIBLE ACETYLCHOLINESTERASE INHIBITOR E2020, QUANTIFIED BY DFP ANTAGONISM. K. A. Sherman*. Dept. Pharmacol. & Therap., Univ. So. Florida Coll. Med., Tampa, FL 33647

E2020, a piperidine derivative, is a specific, CNS-active, reversible inhibitor of acetylcholinesterase (AChE) that appears to be well-tolerated in humans and animals. Because the drug acts by reversible binding to AChE, its inhibitory effect is reversed by tissue dilution and consequent drug dissociation. Therefore we developed an alternative approach for quantifying E2020's effect on AChE after *in vivo* administration -- measuring the ability of the reversible drug to antagonize diisopropylfluorophosphate (DFP), a hemi-substrate of AChE that produces irreversible phosphorylation, while reacting slowly enough for rate determination at minimal tissue dilution. In this study, we determined the effect of two oral doses of E2020, 5 and 8 mg per day, administered to young male human subjects for up to 14 days, on red blood cell (RBC) AChE by the DFP antagonism technique. Measured in RBC collected 4 hr after drug, at the time of peak plasma concentrations, the effect of 5 mg E2020 on AChE was already nearly maximal by 3 days ($\bar{X} \pm$ S.E.M. at 7 d: 38 ± 1.3%). The degree of DFP antagonism was dose-related. DFP phosphorylation was inhibited nearly 60% after 14 days on the 8 mg dose ($\bar{X}$ ± S.E.M.: 59 ± 1.1%). The effect on RBC AChE was substantially less 72 hr after the last dose, but more than half-maximal effect persisted still in most subjects. As shown in dementia patients treated with 1-2 mg E2020 daily, the degree of DFP antagonism was linearly related to the log of plasma drug concentration; the IC_{50} plasma concentration is about 40 ng/ml E2020. Plasma ChE was unaffected. In companion rat studies, we report that the threshold dose for elevating extracellular ACh in cortex, 0.5 mg/kg, produces about 50% inhibition of DFP phosphorylation at 30 min. Following 2 mg/kg E2020, a dose that elevates microdialysate ACh 20-fold, DFP phosphorylation of cortical AChE is completely blocked at 30 min. Thus, doses of E2020 which are well tolerated in humans produce an effect on AChE of magnitude sufficient to enhance brain cholinergic function.

PHENSERINE, A NEW DRUG FOR ALZHEIMER'S DISEASE: FAVORABLE TOXICITY PROFILE.

N.H. Greig, D.K. Ingram, X-F. Pei, A. Brossi, H.W. Holloway, T.T. Soncrant*. Laboratory of Neurosciences and Molecular Physiology and Genetics Section, NIA, NIH and School of Pharmacy, University of North Carolina, Chapel Hill.

Phenserine, a phenylcarbamate of (-)-physostigmine, is a novel, long acting ($t_{1/2}$=8 h), rapidly cleared ($t_{1/2}$=10 min), brain-targeted (10-fold), and acetyl- selective (>50 fold) cholinesterase inhibitor. In rats, it significantly increases brain acetylcholine and robustly enhances cognition [NeuroReport 6: 481-4, 1995; Med. Res. Rev. 15: 3-31, 1995].

Phenserine is dramatically less toxic than physostigmine (MTD >15 vs. 0.6 mg/kg, ip, rat). In initial toxicological studies, phenserine was administered once daily for 28 consecutive days to rats at doses of 1 and 5 mg/kg ip (cumulative doses of 28 and 140 mg/kg) and was compared to saline-treated animals. Extensive evaluation of blood hematologic and chemical parameters, including markers of renal and hepatic function, together with histological analysis of brain, kidney and liver, demonstrated lack of toxicity at doses more than five times greater than those which maximally enhance cognition. A standard pharmacologic screen revealed no evidence of direct action at neurotransmitter receptors and lack of autonomic activity in mice.

Phenserine's optimal pharmacological properties, combined with its favorable toxicological profile in pre-IND studies, predict efficacy in upcoming clinical trials superior to that of other agents developed for Alzheimer's disease.

773.16

EFFECTS OF THE ACETYLCHOLINE RELEASER LINOPIRDINE ON SPECT RCBF AND COGNITIVE FUNCTION IN ALZHEIMER'S DISEASE. C. H. van Dyck*, C. H. Lin, R. Robinson, J. Cellar, M. Narayan, A.F.T. Arnsten, and P.B. Hoffer. Yale University School of Medicine, New Haven, CT, 06520.

Centrally acting cholinergic drugs have been reported to increase regional cerebral blood flow (rCBF) as measured by single photon emission computed tomography (SPECT) in brain regions affected by Alzheimer's disease (AD). We studied the effects of the acetylcholine releaser linopirdine (LPD) on SPECT rCBF and on cognitive, behavioral, and global variables in patients with probable AD. Twenty-four AD patients (12 M, 12 F; mean age ± SD = 68.9 ± 8.2 years) and 13 healthy controls (8 M, 5 F; 68.4 ± 8.0 years) participated. AD patients were scanned with 20 mCi of Tc-99m-ECD using the CERASPECT at baseline and following 4 weeks of treatment with linopirdine 40 mg TID (n=15) or placebo TID (n=9) in a double-blind trial. Healthy subjects were scanned for comparison with baseline AD scans. A ratio of parietal/cerebellar rCBF (P/C) was derived. The effect of diagnostic group (AD vs. healthy) on P/C was determined by t-test. The effect of treatment condition on P/C and behavioral measures in the AD patients was subsequently examined by t-tests. Significant differences in P/C were found between AD patients (0.70 ± 0.09) and controls (0.88 ± 0.08) ($p<.0000001$). Patients treated with LPD showed an increase in P/C of 4.2% ± 6.0%; whereas those treated with placebo showed a decrease of -1.2% ± 7.5% ($t=2.31$; $df=22$; $p=.03$). Active treatment was also associated with improvement in the Clinical Global Impression of Change ($t=2.14$; $p=.04$) and trends toward improvement in the Alzheimer's Disease Assessment Scale ($t=1.89$; $p=.07$) and the Dementia Behavior Disturbance Scale ($t=1.91$; $p=.07$). These data support the conclusion that rCBF abnormalities in AD are, in part, truly "functional" and can be selectively altered with pharmacological interventions.

773.17

APOLIPOPROTEIN E4 AND CHOLINERGIC DYSFUNCTION IN ALZHEIMER DISEASE: EFFFECT ON TREATMENT OUTCOME. M.-C. Delisle*, J. Poirier, R. Quirion, I. Aubert, M. Farlow, P. Bertrand, D. Dea, S. Gauthier, J. Nalbantoglu and B.G. Gilfix. Douglas Hospital Research Centre, Neuroscience Division, 6875 LaSalle Blvd, Verdun, Québec, Canada. H4H 1R3.

Apolipoprotein E (apoE) is implicated in cholesterol and phospholipid transport, particularly in the central nervous system where other apolipoproteins such as apoA1 and apoB are absent. ApoE is a polymorphic protein of which the major allelic forms are apoE2, apoE3 and apoE4. The latter is associated with familial and sporadic forms of Alzheimer's disease (AD). The number of apoE4 gene copies affects the age of onset, the accumulation of senile plaques and choline acetyltransferase (ChAT) activity in the hippocampus of AD patients (Poirier *et al.*, Lancet, 1993, 342:697-9; Schmechel *et al.*, 1993, PNAS 90:9649-53; Poirier, 1994, TINS 17:525-9). To further characterize the impact of the apoE4 allele(s) on cholinergic deficits in AD, we examined the effect of the number of apoE4 allele copy number on residual ChAT activity, and nicotinic and muscarinic M1 and M2 receptor sub-types in the hippocampus and temporal cortex of post-mortem brains from AD and control patients with different apoE genotypes. The apoE4 allele copy number shows an inverse relationship with residual ChAT and nicotinic binding sites in AD. Such a relationship was not seen in control patients. AD individuals lacking the apoE4 allele show a residual ChAT activity and nicotinic receptor levels rather similar to control values. ApoE4 allele copy number did not correlate with apparent changes in M1 or M2 binding sites in AD. Finally, the effect of apoE4 allele copy number on cholinomimetic drug response was examined in AD patients treated for six months with the esterase inhibitor, Tacrine. Data revealed that over 80% of the patients who do not possess the ApoE4 allele showed significant improvements following this therapy while 60% of the patients with at least one copy of the apoE4 gene did not improve, and even deteriorated, during the treatment These results strongly suggest that apoE4 plays an active role in cholinergic dysfunctions associated with AD. Supported by MRCC.

774.1

SIGNIFICANT CHANGES IN THE HUMAN BRAIN HISTAMINERGIC SYSTEM IN ALZHEIMER'S DISEASE.

P. Panula*, K. Kuokkanen, M. Relja, K.S. Eriksson, T. Sallmen, J.O. Rinne, H. Kalimo. Dept. Biology, Abo Akademi Univ., and Depts. Neurology and Pathology, Univ. Turku, 20520 Abo/Turku, Finland.

Histamine is one of the neuromodulators present in subcortical projection systems. Neurofibrillary tangles are present in histaminergic neurons in Alzheimers disease, but the target areas have not been examined. We combined sensitive immunohistochemical methods with HPLC fluorometry to reveal the changes in brain histamine in Alzheimer's disease.

In normal human brain (n=5, mean age 82 yrs), histamine concentrations were highest in the hypothalamus, followed by substantia nigra, putamen, n. caudatus and different cortical areas. In Alzheimer's disease (n=9, mean age 81.5 yrs) histamine content was significantly reduced only in the hypothalamus (57%), temporal cortex (46%) and hippocampus (56%). Immunohistochemistry revealed only neuronal storage sites of histamine in normal brain and in brain affected by Alzheimer's disease. In normal brains, dense networks of histamine-containing fibers were seen in the entorhinal cortex and subiculum. Moderately dense networks innervated hippocampal fields CA1-4 and dentate gyrus. Long fibers were seen in the fimbriae. The results reveal an extensive histaminergic system in human temporal lobe, and significant changes in this system in Alzheimers disease.

774.2

NEUROFIBRILLARY TANGLES AND TYROSINE HYDOXYLASE IMMUNOREACTIVITY IN THE LOCUS COERULEUS IN ALZHEIMER'S DISEASE.

M.L. Smith* and P.D. Coleman. Department of Neurobiology & Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

The neurofibrillary tangle (NFT) of Alzheimer's disease is composed of insoluble tau isoforms containing multiple phosphorylations. Currently, it is unknown whether the phosphorylation(s) of tau is causal in the aggregation and accumulation of the NFT. However, a phosphorylation at serine 199/202 of tau occurs in the soma and processes of neurons in the absence of detectable NFT. This phosphorylation, identified using monoclonal antibody AT8, also appears to be contained within the NFT proper. Thus, cellular distribution of AT8 staining identifies neurons from a presumptive early stage through the progressive accumulation of pathology within the neurites and neuronal soma.

We hypothesize that as the intracellular NFT accumulates, neuronal function declines. Specifically, as pathology accumulates within the neurites and eventually the cell body, neurotransmitter synthesis declines prior to cell death. The goal of this study is to determine the neurotransmitter synthetic capacity within individual noradrenergic neurons in the locus coeruleus of Alzheimer's' patients as a function of NFT accumulation.

In this study double labeling ICC was performed using antibodies directed against tyrosine hydroxylase (TH; Chemicon Int., Inc.) and phosphorylated serine 199/202 of tau (AT8; Innogenetics Inc.) within the locus coeruleus of AD patients. The degree of intracellular tau pathology in neurons immunoreactive for AT8 was determined according to the criterion of Braak et al., (1994). Noradrenergic neurons were analyzed for tau pathology and TH immunoreactivity was classified as strong, moderate or weak based on staining intensity. Neuromelanin also served to identify noradrenergic neurons containing NFT in the absence of TH immunoreactivity. Preliminary results indicate that as tau pathology accumulates, TH immunoreactivity declines prior to cell death. EFFECTS OF THE RELEASE ENHANCER DuP 996 ON THE IN VIVO RELEASE OF DA AND 5-HT IN RAT STRIATUM.

T. Clarke, D.K. Bryce and H. Rollema*
Department of Neuroscience, Pfizer Central Research, Groton, CT 06340, USA.

DuP 996 (Linopirdine) is a release enhancer which possibly acts via interaction with a K-channel. It is now well established that *in vitro*, DuP 996 increases the K^+ stimulated release of ACh, DA and 5-HT from slices, while microdialysis studies have shown that DuP 996 also inreases *in vivo* ACh release. To determine the effects of DuP 996 on *in vivo* DA and 5-HT release, we measured extracellular DA and 5-HT levels by microdialysis in rat striatum. Of the doses of DuP 996 tested (0.3 - 10 mg/kg s.c.) only 3.2 mg/kg produced a small (20%) increase in extracellular DA and 5-HT levels in rat striatum. High doses of DuP 996 (32 mg/kg) produced a more pronounced elevation (40-60%) in DA and 5-HT release, but extracellular levels of the metabolites DOPAC, HVA and 5-HIAA were increased to the same extent and all animals rapidly developed seizures. The neurochemical effects of high doses of DuP 996 could therefore be related to toxic events.

In view of the marked effects of DuP 996 on evoked DA release *in vitro*, we also studied its effects on extracellular DA levels during K^+ stimulation. To that end, 60 mM KCl was perfused for 60 min and the maximal increase in DA release was measured ("S1"). Three hours later the effects of a second KCl perfusion on DA release were assessed ("S2"), after pretreatment with 10 mg/kg s.c. DuP 996 or vehicle. Comparison of the "S2/S1" ratios for vehicle and DuP 996 treated animals, showed that the K^+ stimulated DA release was slightly, but not significantly, increased by DuP 996.

These *in vivo* results confirm that DuP 996 does not enhance the *basal* release of DA and 5-HT, but do not corroborate the pronounced effects of DuP 996 on *evoked* DA release *in vitro*.

774.4

PRE AND POSTSYNAPTIC SEROTONERGIC MARKERS IN A COMMUNITY ACQUIRED STUDY OF ALZHEIMER'S DISEASE.

J.T Alder[1], C.P.L-H. Chen[1,2], P.T. Francis[1], T. Hope[2], P.R. Heath*[3] and D.M. Bowen[1]. [1]Inst. Neurol. London, WC1N 1PJ. U.K. [2]Univ. Oxford, U.K. [3]Univ. Sheffield, U.K.

20 cases from a prospectively studied, community based sample of demented patients with neuropathologically confirmed Alzheimer's disease (AD) and 20 controls matched for sex, post-mortem delay and storage time were studied.

There was a significant loss of immunoreactive serotonergic dorsal and median raphe neurones in AD compared with controls, however this was not reflected in presynaptic serotonergic markers in the cortex. Thus there was no reduction in the concentration of 5-HT or 5-HIAA, as measured by HPLC, indeed the 5-HIAA/5-HT ratio was increased. Similarly, B_{max} for [^{3}H] paroxetine binding to the 5-HT reuptake site was only reduced in one of the two areas studied. AD cases treated with neuroleptics had reduced concentrations of 5-HT compared to untreated AD patients. Depressed AD patients had significantly lower paroxetine B_{max} compared to non-depressed AD cases. There was no significant difference in the number of 5-HT_{1A} receptors in AD compared with control, but 5-HT_{2A} receptor B_{max} was reduced, the K_D was unchanged in both cases. These data indicate that due to plasticity in the serotonergic system there is little evidence for a pre-synaptic deficit in AD and that reductions reported in previous studies may be due to drug treatment and the presence of non-cognitive behavioural changes such as depression.

An altered balance of postsynaptic receptors and a preservation of the presynaptic system may have implications for the treatment of AD.

774.5

THE DORSAL RAPHE AND DEPRESSION IN ALZHEIMER'S DISEASE.

R.M. Zweig*, T.J. Swiergiel, C. Steele, D.L. Price, C.A. Ross. LSU Med Center, Shreveport, LA 71130 and Johns Hopkins School of Med, Baltimore, MD 21205.

There is considerable evidence supporting a role of serotonergic systems as well as noradrenergic systems in the pathophysiology of major depression. We have previously demonstrated an association between major depression complicating Alzheimer's disease (AD) and disproportionate neuronal loss within the noradrenergic locus coeruleus (Soc Neurosci Abstr 1992;18:206). In order to investigate the possible association of serotonergic pathology and depression, we used an anti-phenylalanine hydroxylase antibody (PH8) (gift from RGH Cotton, Melbourne) to selectively label serotonergic neurons within the dorsal raphe (DR) nucleus of 5 patients with AD complicated by major depression (preliminary assessments based upon prospectively collected psychiatric evaluations) and from 8 age-matched patients without this complication. Sections (12 μm thick) of DR 1.2 mm and 1.68 mm caudal to the oculomotor nucleus were selected from serially sectioned formalin-fixed brainstems (transverse plane). Numbers of PH8-immunoreactive neuronal profiles greater than 12.5 μm in maximum diameter within defined boundaries of the DR were counted manually (400X). Mean profile counts tended to be nonsignificantly higher in depressed than in non-depressed patients at both anatomical levels evaluated: 177.8 ± 57.3 and 204.3 ± 61.4 in depressed patients versus 142.7 ± 51.6 and 179.9 ± 75.1 in patients without depression at rostral and caudal levels. Thus, there does not appear to be a relationship between loss of serotonergic DR neurons and depression in AD.

POLYAMINES IN HUMAN BRAIN: INFLUENCE OF REGIONAL DISTRIBUTION, AGING AND ALZHEIMER'S DISEASE.

L. D. Morrison* and S. J. Kish. Human Neurochemical Pathology Lab., Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

Despite considerable evidence implicating polyamines in brain development and CNS function, little information is available on these substances in normal or diseased human brain. We examined the influence of regional distribution, aging and Alzheimer's Disease (AD) on putrescine, spermidine and spermine levels in autopsied human brain. All three polyamines showed distinct and uneven distribution profiles amongst the 10 examined control brain areas. No statistically significant influence of aging (1 day to 103 years; n=57) on either putrescine or spermine levels in occipital cortex was observed. In contrast, spermidine levels increased markedly from birth, reaching maximal levels at approximately 40 years of age (+228% increase, $p<0.002$, one-way ANOVA, $r=0.71$ Pearson's correlation), which were maintained up to senescence. We also measured polyamine levels in cortical and subcortical areas of 12 patients with AD and carefully matched controls. Mean spermidine levels were markedly and significantly increased (70%) whereas putrescine levels were decreased (28%) in temporal cortex of AD patients compared with controls. No other statistically significant changes were observed. In view of the modulatory effects of polyamines on ion channels and glutamate receptor function, abnormal polyamine levels may contribute to excitotoxic processes occurring in brain of patients with AD. Supported by U.S. NIH NINDS grant NS26034 and the Hospital for Sick Children Foundation.

Vulnerability of pyramidal neurons immunoreactive for an N-acetylated dipeptide in Alzheimer's and Huntington's disease.

L. A. Passani* °, R. Paulsen°° and J. T. Coyle°. Dept. of Psychiatry°, Harvard Medical School/MGH, Charlestown, MA 02129 and Zoologisches Institut I°°, Universitaet Karlsruhe, 76128 Karlsruhe, FRG.

An increasing body of evidence suggests a neurocommunicative role for N-acetyl-aspartyl-glutamate (NAAG), especially in putative glutamatergic pathways. Within glutamatergic pathways in cerebral cortex of primates, NAAG is preferentially localized to a subpopulation of pyramidal neurons. Subsets of pyramidal neurons associated with corticostriatal, corticothalamic and corticopontine projections have previously been described to exhibit NAAG-like immunoreactivity (NAAG-LI) in human brain (Passani et al., 1994). In the present study we investigated the impact of neurodegenerative disease on this type of NAAG-LI neuron. One characteristic feature of Huntington's disease (HD) and Alzheimer's disease (AD) is the selective degeneration of subsets of glutamatergic pyramidal neurons. In HD, losses are most prevalent in layer III and VI of frontal lobe and primary visual cortex and in layer IIIc of the temporal lobe. In AD, losses occur especially in layer III and V of the neocortex, and in the CA1 field and subiculum of the hippocampus. Our preliminary results suggest selective sparing of subpopulations of NAAG-LI pyramidal neurons in frontal cortex and primary visual cortex of HD post mortem brain. In both regions NAAG levels (determined by HPLC) and numbers of NAAG-LI pyramidal neurons (layer III, IVb, VI) are not significantly altered compared to control. Glutamate levels on the other hand are decreased up to 70%, suggesting either loss of glutamatergic neurons or metabolic alterations. In AD, NAAG levels are unaltered in hippocampus and in frontal, primary visual and temporal cortex. These findings suggest different degrees of vulnerablility for glutamatergic pyramidal neurons depending on the presence or absence of NAAG.

NON-PLAQUE DYSTROPHIC DENDRITES IN ALZHEIMER HIPPOCAMPUS: A NEW PATHOLOGICAL STRUCTURE REVEALED BY GLUTAMATE RECEPTOR IMMUNOCYTOCHEMISTRY.

R. Suzanne Zukin, Eleonora Aronica, Linda A. Goodman*, John H. Morrison# and Dennis W. Dickson. *Deparment of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y 10461 #Mount Sinai School of Medicine, New York, N.Y. 10029.*

Alzheimer's disease (AD) is a progressive dementia characterized by a pronounced neurodegeneration in entorhinal cortex, hippocampal CA1 region and subiculum. Excitatory amino acid (EAA) receptor-mediated excitotoxicity is thought to play a role in the neurodegeneration in AD CA1. The present study investigated immunocytochemical localization of EAA receptor subunits in the hippocampus from 10 AD and 10 controls, matched for age, sex and post-mortem interval. Immunocytochemistry with antibodies specific for GluR1, GluR2(4) (AMPA), GluR5/6/7 (kainate) and NR1 (NMDA) receptor subunits demonstrated virtually all projection neurons in all subfields contained subunits from each receptor class. In CA1 GluR1, GluR2 and NR1 labeling was in pyramidal cell somata and dendrites. GluR1, GluR2(4) and NR1 immunolabeling revealed a novel pathological structure in all AD, but none of the control samples.The lesions were juxtacellular clusters of granular immunoreactivity in the neuropil of the pyramidal cell layer. Counterstaining for amyloid indicated lesions were not senile plaques. Neurofibrillary tangles and granulovacuolar degeneration were also not immunolabeled. Ultrastructural analysis revealed the lesions to be dystrophic cellular processes containing dense vesicles and flocculent material with immunolabeling localized to plasma and vesicular membranes. Lesions were not associated with amyloid fibrils. One lesion also contained Hirano body filaments indicating that the dystrophic processes were dendritic in origin. Additional studies are needed to determine the pathogenesis of these novel, non-plaque dystrophic dendrites.

REGIONAL VARIATIONS IN THE NEURONAL GLUTAMATE TRANSPORTER PROTEIN IN ALZHEIMER DISEASE.

H. L. Scott, P. R. Dodd and R. I. Westphalen* *Clinical Research Laboratory, Royal Brisbane Hospital Research Foundation, Brisbane Q4029, AUSTRALIA.*

The pathological features of Alzheimer disease (AD) are area-specific. Pharmacological and molecular biological studies have described several forms of the glutamate transporter protein. If the glutamate uptake system were altered in AD cases, this could enhance excitotoxicity, particularly if the variant transporter protein was inefficient at removing glutamate from the synaptic cleft. Several damaged areas (showing neuronal loss and neurofibrillary tangles) were compared with relatively spared areas to determine how glutamate transporter protein sites vary between control and pathologically confirmed AD cases. We looked at the high-affinity uptake site using binding profiles for D-[^{3}H]aspartate and a range of transport inhibitors (unlabelled D-aspartate, L-glutamate, dihydrokainate, L-cysteate, *threo*-3-hydroxy-D,L-aspartate, L-α-aminoadipate, *cis*-1-aminocyclobutane-1,3-dicarboxylate and α-methyl-D,L-glutamate). Synaptosomal plasma membranes were prepared from human brain tissue obtained post mortem. Data from the homogenate binding studies were processed by the LIGAND program, and analyses of variance performed on logarithmic transforms of the affinity constants. Control and AD cases showed significant differences in transporter binding profile in motor ($P = 0.025$), occipital ($P < 0.001$), mid-temporal ($P = 0.035$), and cingulate regions ($P < 0.01$). The inferior temporal, parietal, hippocampal, and superior and inferior frontal areas did not differ significantly between controls and AD cases. Thus, different forms of the neuronal glutamate transporter may occur in AD cortex, in regions showing variable susceptibility to pathological change. Areas most resistant to damage tended to show greater variations in profile, and all showed a markedly enhanced affinity for glutamate in the AD cases.

NITRIC OXIDE SYNTHASE (NOS) IN POSTSYNAPTIC DENSITY FRACTIONS FROM CEREBRAL CORTEX OF RAT, NORMAL HUMAN AND ALZHEIMER'S DISEASE BRAINS.

J.L. Xu*, K. Wu, H.T.J. Mount, S. Zhong, Y.Y. Huang[1,2] and I.B. Black. Dept. Neuroscience & Cell Biology, Robert Wood Johnson Medical School-UMDNJ, Piscataway, NJ 08854, [1]Div. Neurosci., NY State Psychiat. Inst. and [2]Dept. Biochemistry, Columbia Univ. Medical College of Physicians & Surgeons, NYC, NY 10032.

Nitric oxide synthase (NOS) catalyzes formation of the gaseous transmitter, nitric oxde (NO). Electron microscopic studies have revealed that neuronal NOS (nNOS) is an intrinsic component of the postsynaptic density (PSD), a disc-shaped specialization of the postsynaptic membrane. We now present biochemical evidence for nNOS expression within the PSD. We also show that nNOS levels in the PSD exhibit regional variation and may be elevated in Alzheimer's disease (AD).

We examined expression of nNOS in PSD fractions from adult rat and human brains. Western blot analyses, with a monoclonal antibody against nNOS, revealed higher levels of expression in PSD than in whole synaptic membrane fractions. nNOS levels in PSD samples from rat brain exhibited regional variation. These differences (Cerebellum > Olfactory Bulb > Hippocampus > Cerebral Cortex) reflect the reported distribution of nNOS in whole brain sections (Dinerman et al.,1994, PNAS *91*:4214).

Recent evidence suggests that Alzheimer's disease (AD) may be associated with biochemical changes in the PSD. We examined whether synaptic NOS might be affected in AD brains. In cortical PSD samples from two AD brains, PSD nNOS levels were elevated relative to controls. The pathophysiologic significance of elevated nNOS remains unclear.

Our findings indicate that nNOS is an intrinsic component of the isolated PSD. Regional variation in nNOS levels within PSD fractions may have consequences with respect to synaptic transmission in these areas.

IMPAIRMENT OF THE PHOSPHOINOSITIDE SIGNAL TRANSDUCTION SYSTEM IN ALZHEIMER'S DISEASE BRAIN.

R.S. Jope*, L. Song, X. Li, A. Greenwood, R. Powers. Dept. of Psychiatry and Behavioral Neurobiology, University of Alabama at Birmingham, Birmingham, AL 35294.

Degeneration of cholinergic neurons with retention of postsynaptic muscarinic receptors in Alzheimer's disease (AD) has led to the widespread therapeutic use of cholinomimetics. The purpose of this study was to determine the functional capacity of muscarinic receptors linked to the phosphoinositide second messenger system using postmortem AD and matched control prefrontal cortex.

Activation of phosphoinositide hydrolysis was measured using membranes incubated with [^{3}H]phosphatidylinositol (PI). G-protein-coupled stimulation of phospholipase C was concentration-dependently activated by GTPγS and this response was 40% lower in AD than control membranes. Inclusion of carbachol to activate muscarinic receptors coupled with G-protein-mediated PI hydrolysis was impaired by 45% in AD membranes. Further analysis of the data indicated that the G-protein deficit in AD had a predominant influence on the lowered response to carbachol. Similar deficits in the responses to other cholinergic agonists were observed in AD membranes. A range of impairments were observed when non-cholinergic agonists were studied and when the responses to GTPγS and to cholinomimetics were measured in additional brain regions. These results demonstrate that there are severe deficits in the phosphoinositide signal transduction system in AD and that impaired G-protein function is an important contributory factor.

DIFFERENTIALLY ALTERED G-PROTEIN-MEDIATED SIGNALLING IN ALZHEIMER'S DISEASE: A STUDY OF STAGED AUTOPSY CASES

T.G.Ohm* (1), R.Zarski (1), D.Rieger-Hug (2), and J.Bohl (3)
(1) Institut für Anatomie, Charité, Humboldt-Univ. 10098 Berlin,
(2) Zentrum der Morphologie, J.W.Goethe-Univer, 60590 Frankfurt,
(3) Neuropathologie. J. Gutenberg-Universität, 55131 Mainz, Germany

G-proteins are the interface between many receptors and effectors. In recent studies we showed that both stimulatory ß-adrenoceptors and inhibitory A1-adenosine receptors are unaltered in Alzheimer's disease (AD) (Lemmer et al., 1993). The ß-adrenoceptor-coupling to the stimulatory Gs-protein and the Gs-effector-coupling, was altered, whereas the inhibitory receptor/Gi/effector-coupling was intact (Schnecko et al., 1994). In the present study we determined hippocampal G-proteins by means of standardized Western-blotting in 12 AD-cases and 11 age- and post mortem delay-matched individuals with no clinical history of cognitive impairment. However, 6 meet criteria for stages II&III of AD-related neurofibrillary changes (Braak and Braak, 1991). Data are shown as as percent of control (stage 0) of standardized means.

Stage	Go	Gs	GsH	GsL	Gi
II/III	65.8	52.4*	37.9*	63.0	61.2
V (AD)	61.2	48.9**	42.8	50.8**	32.3**

(*=p<0.05, **=p<0.02 vs control; Kruskal-Wallis test)

There is no correlation between G-protein level and G-protein-mediated effector stimulation or inhibition.

CALCINEURIN-LIKE PHOSPHATASE ACTIVITY IN CONTROL AND ALZHEIMER'S DISEASE STRIATE CORTEX. C.J. Ladner and J.M. Lee*.
Neuroscience Program, Departments of Pathology and Pharmacology, Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153

Neurofibrillary tangles found in the brains of individuals with Alzheimer's disease (AD) are composed of abnormally hyperphosphorylated forms of tau protein. The phosphorylation state of proteins is determined by the balance of kinase and phosphatase activities. Thus, the increase in tau phosphorylation may result from an increase in kinase activity and/or a decrease in phosphatase activity. The present study examined calcineurin-like phosphatase activity in homogenates of postmortem striate cortex from age matched controls (n=6) and AD cases (n=7). The homogenates were separated into particulate and cytosolic fractions. Phosphatase activity was assessed using the substrate p-nitrophenylphosphate (10 mM) and measured as a change in absorbance (λ=405 nm) due to the formation of p-nitrophenol. Measurements of phosphatase activity were determined in the presence or absence of calcineurin activators (1 mM $NiCl_2$ and 0.1 mM $CaCl_2$) and calcineurin inhibitors (200 μM trifluoperazine and 300 μg/ml cyclosporin A). In control particulate fraction, a significant increase in phosphatase activity was observed in the presence of nickel. The nickel-stimulated increase in phosphatase activity was antagonized by trifluoperazine and cyclosporin A. These biochemical properties of the particulate phosphatase activity are consistent with calcineurin. As a percentage of basal, nickel produced a 65% increase in phosphatase activity in control particulate fractions, but only a 24% increase in AD samples ($p<0.03$, student's t-test). Absolute values of basal activity did not significantly differ between control and AD samples. In the cytosolic fraction, no stimulation of phosphatase activity by divalent cations nor inhibition by TFP and CsA was observed. In addition, no differences between control and AD cytosolic samples were found. These findings suggest that particulate calcineurin-like activity may be reduced in striate cortex in AD. Current studies are examining the relationship between calcineurin activity with changes in neuropathology.

774.14

PROTEIN KINASE C LEVELS AND ACTIVITY IN CULTURED SKIN FIBROBLASTS FROM AFFECTED AND NON-AFFECTED MEMBERS OF THE SWEDISH FAMILY WITH THE AMYLOID PRECURSOR PROTEIN 670/671 MUTATION. M. Vestling*, A. Adem, L. Lannfelt and R. F. Cowburn.
Department of Clinical Neuroscience and Family Medicine, Karolinska Institute, S-141 86 Huddinge, Sweden.

The familial Alzheimer's disease-causing amyloid precursor protein (APP) 670/671 double mutation has been shown to give a 3-fold increase of ß-amyloid production in cultured fibroblasts from affected individuals. Since APP processing can be regulated by protein kinase C (PKC) activation, we investigated whether the phenotype of the APP 670/671 mutation included a PKC deficit in primary skin fibroblasts.

PKC activities and levels were studied in the particulate and soluble fractions from 6 mutation bearing and 7 control cell lines. PKC activity in the soluble fraction, determined as the phosphorylation of endogenous histone substrate, showed an age-related decline ($r=-0.569$, $p<0.05$, Fisher's test) when data from all 13 cell lines was analysed together. No significant differences were seen in soluble PKC activity between mutation-bearing and control cell lines, the mean (± SEM) values being 251 ± 20.2 and 225 ± 21.4 pmols/min/mg protein, respectively. PKC activities in the particulate fractions were below the assay detection limit.

[^{3}H]Phorbol-12,13-dibutyrate binding studies revealed no significant differences in PKC levels between mutation-bearing and control cell lines when assays were performed using a ligand concentration of 10 nM. The mean (± SEM) PKC levels in the soluble fractions were 7.84 ± 0.50 and 6.56 ± 0.74 pmols/mg protein, respectively. The corresponding values for the particulate fractions were 2.39 ± 0.24 and 2.21 ± 0.15 pmols/mg protein.

It is concluded that the APP 670/671 mutation does not result in altered fibroblast PKC levels and activity. This is in contrast to the reported PKC deficits in fibroblasts from other sporadic and familial Alzheimer's disease cases.

774.15

AGING CAUSES SELECTIVE LOSS OF CALBINDIN-D_{28K} FROM THE CHOLINERGIC NEURONS OF THE HUMAN BASAL FOREBRAIN. C.-K. Wu[1*], M.-M. Mesulam[2] and C. Geula[1].
[1]Harvard Medical School, Boston, MA 02215 and [2]Northwestern University Medical School, Chicago, IL 60611.

Age-related changes in calbindin-D_{28K} immunoreactivity within the cholinergic neurons of the basal forebrain (BFCNs) were studied in the human brain and compared to changes in choline acetyltransferase(ChAT) and nerve growth factor receptor (NGFr) immunoreactivity. Calbindin-D_{28K}, ChAT and NGFr were visualized immunohistochemically in adjacent sections of the basal forebrain in 12 brains from normal individuals 20-91 years old. The BFCNs in the majority of individuals over 70 years (n=6 of 7) displayed a marked loss of calbindin-D_{28K} immunoreactivity when compared with individuals younger than 70 years of age (n=5). This loss was observed in all BFCN groups and reached a magnitude of 80%. ChAT and NGFr immunoreactivity, which are co-localized with calbindin-D_{28K} in these cholinergic neurons, displayed no similar age-related loss, indicating the selectivity of this observation. Loss of calbindin-D_{28K} would deprive cholinergic neurons of the capacity to buffer intracellular calcium levels and leave them vulnerable to processes which increase intracellular calcium and thus lead to neuronal death. The age-related loss of calbindin-D_{28K} from the BFCNs is a potential mechanism for the selective loss of these neurons in neurodegenerative diseases of the elderly, such as Alzheimer's disease.

774.16

INCREASED GLUCOCORTICOID (GR) AND MINERALOCORTICOID (MR) RECEPTOR mRNA EXPRESSION IN HIPPOCAMPAL SUBREGIONS FROM ALZHEIMER'S DISEASE PATIENTS. J.A. Davis* and R.M. Booze. Dept. of Pharmacology, Univ. of Kentucky, Lexington, KY 40536-0084.

Corticosteroids have been implicated in the pathogenesis of neurodegenerative disorders such as Alzheimer's disease. This study examined GR and MR mRNA expression in human post-mortem brain tissue from Alzheimer's disease (AD) patients and age-matched controls. Tissue was collected from 27 AD patients (age=79.5±1.5 yrs; 15 women, 12 men) and 10 control patients (age=75.3±2.8 yrs; 7 women, 3 men) from the ADRC at Sanders-Brown Center on Aging. Brodmann Area 9, hippocampus and cerebellar tissue was collected and immersion-fixed in 4% paraformaldehyde. Tissue blocks were cryoprotected and sectioned (40µm) at -17°C onto Vectabond coated slides. Stained and hybridized sections were counted (positive cells/100 µm^2) using the MCID M4 imaging system. Thioflavin-S stain confirmed the presence of amyloid plaques and neurofibrillary tangles in AD brains. Following non-isotopic *in situ* hybridization of GR and MR mRNA, significantly higher levels of MR mRNA expression were observed in Area 9 from AD patients relative to controls (18.65 cells/100µm^2 versus 7.50 cells/100µm^2). The CA3 region from AD patients exhibited a modest 44% elevation in MR mRNA expression compared to controls (32.72±2.51 versus 22.65±7.16 cells/100µm^2, respectively). Slightly elevated levels of GR mRNA expression was detected only in the CA1 region of AD brain (20.13±3.69 cells/100µm^2) compared to GR mRNA message expression in the CA1 region from control tissue (16.45±1.45 cell/100µm^2). This data suggests that altered expression of corticosteroid receptors could have a role in neurodegeneration observed with normal aging and AD. Progressive failure of calcium homeostasis initiated by glucocorticoid action is associated with cell loss in aging and AD. Our experiments indicate that individual variation in aging and AD is an important factor with regard to assessing mechanisms which underlie cell loss. (Supported by AG10836)

17α-ESTRADIOL EXERTS NEUROPROTECTIVE EFFECTS ON SK-N-SH CELLS. J.W. Simpkins, P.S. Green, J. Bishop and N. Tumer*, Center for the Neurobiology of Aging and the Departments of Pharmacodynamics and Pharmacology, GRECC, VA Medical Center, University of Florida, Gainesville, FL.

Estradiol (E2) has been shown to exert organizational, neurotrophic and neuroprotective effects in the central nervous system. The present study assessed the specificity of the neuroprotective effects of estradiol for the potent 17ß-isomer. SK-N-SH cells from a human neuroblastoma cell line which we have shown to be estrogen-responsive, were cultured at low or high plating density. Cells were then exposed to 17ß-E2 (0.2 or 2nM), 17α-E2 (0.2 or 2nM), cholesterol, testosterone, or dihydrotestosterone (all at 2nM), progesterone or corticosterone (0.2 to 200 nM). Cultures were insulted by serum deprivation, which caused a profound loss of cells. At 1 or 2 days of serum deprivation and steroid hormone replacement, the protection afforded cells by the steroid addition was assessed. Serum deprivation killed about 90% of cells cultured at both low and high plating density. Both 17α- and 17ß-E2 provided a dose-dependent protection of SK-N-SH cells at either plating density. By contrast, none of the other steroids tested protected cells from the insult of serum deprivation. The addition of progesterone (2nM) to cultures did not effect the cytoprotection observed with either isomer of estradiol at either dose. These results indicate that the neuroprotective effects of estrogens are not a general steroid effect and do not relate to the potency of estradiol isomers, as assessed by binding to cytosolic estrogen-receptors or responses of peripheral estrogen-responsive tissues. As such, the neuroprotective effects of estrogens may be mediated by a non-genomic mechanism. (Supported by NIH AG10485 and Apollo Genetics, Inc.)

EFFECTS OF U-101033E ON THE EXPRESSION OF AMYLOID PROTEIN PRECURSOR, APOLIPOPROTEIN E, GLIAL FIBRILLARY ACIDIC PROTEIN, AND B-AMYLOID EXPRESSION FOLLOWING A BILATERAL CAROTID OCCLUSION IN THE GERBIL. J.A.Oostveen*, D.B.Carter, E.Dunn, and E.D.Hall. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Previously we have shown that a brief period of bilateral carotid occlusion (BCO)-induced forebrain ischemia in gerbils triggers a progressive expression of amyloid protein precursor (APP), apolipoprotein E (APO-E), glial fibrillary acidic protein (GFAP), and β-amyloid (β-AP) in the selectively vulnerable CA1 region of the hippocampus. The increase in immunoreactivity is secondary to the degeneration of the CA1 neurons. Oxygen radicals and lipid peroxidation (LP) have been demonstrated to play a role in post-ischemic neuronal damage, and recent literature suggests a possible link between early oxidative stress and subsequent APP expression. Therefore, the present investigation examined the effect of a novel brain penetrating pyrrolopyrimidine LP inhibitor (U-101033E) on APP, APO-E, GFAP, and β-AP expression. Gerbils were treated at 30 mg/kg p.o. 30 min prior to the BCO and 2 hrs post-ischemia, followed by daily dosing for the next three days. U-101033E provided a significant decrease in the expression of all markers ($p<0.05$), which correlated with a significant effect on preservation of the CA1 neuronal cell population ($p<0.05$) as determined by cresyl violet histochemistry. Lipid peroxidation inhibitors may provide attenuation of various response proteins to ischemic injury, probably through reduction of neuronal cell damage.

774.19

SUBSTANCE P POTENTIATES INTERLEUKIN-1β- AND LPS-INDUCED RELEASE OF IL-6 FROM HUMAN ASTROCYTOMAS. C.E. Nolan, K. Richter, M.A. Collins, and R.B. Nelson*. Department of Neuroscience, Pfizer Central Research, Groton, CT.

Astrocytes responding to optic nerve transection upregulate high-affinity substance P-binding sites (NK-1 receptors) within a month following the injury (PNAS 86:5193). The functional consequences of NK-1 receptor upregulation on reactive astrocytes are unknown. Because this receptor upregulation occurs in the context of an inflammatory response to brain injury, we sought to determine how substance P (SP) interacts with pro-inflammatory factors in modulating reactive astrocyte function. We first determined (as previously reported) that in U373 cells SP alone causes a moderate dose-dependent increase in both IL-6 release and intracellular calcium levels. Both effects are blocked by the non-peptide NK-1 antagonist CP-96345. The maximal SP-evoked IL-6 release is at least 10-fold *less* than the maximal release evoked with the pro-inflammatory agents IL-1β or lipopolysaccharide (LPS). However, we found that SP can interact synergistically with either IL-1β or LPS to increase IL-6 release. For example, 1 pM IL-1β and 100 nM SP added *separately* to U373 cells caused a total increased IL-6 release of 2250 pg/ml, but in combination produced an increase of 3350 pg/ml, a 43% synergism. A more dramatic synergism was found between 100 nM SP and and 10 μg/ml LPS where the increase in IL-6 release caused by the combination of both agents was 200% greater than the total release evoked for both agents added separately. This potentiation occurred over a limited dose range for both IL-1β and LPS and did not appear to be attributable simply to shifting the EC_{50}s for these agents. The present findings suggest that substance P may potentiate cytokine-evoked release of IL-6 from reactive astrocytes. Since astrocyte overexpression of IL-6 *in vivo* has been shown to produce neurodegeneration, NK-1 antagonists may have therapeutic application in neuropathologies involving chronic CNS inflammation, such as Alzheimer's disease, multiple sclerosis, and Parkinson's disease.

DEGENERATIVE DISEASE: PARKINSON'S—TRANSPLANTATION, PALLIDOTOMY AND IMAGING

TROPHIC SUPPLEMENTS OF MESENCEPHALIC CELLS IN HIBERNATION MEDIA ENHANCES SURVIVAL OF DOPAMINE NEURONS. P.M. Carvey*, L.R. Ptak and Z.D. Ling. Research Center for Brain Repair, Rush-Presbyterian-St. Lukes M.C., Chicago, IL 60612.

Mesencephalic neurons destined for transplantation into the striatum of patients with Parkinson's disease (PD), are generally held in hibernation (high K^+ salt solutions at 4°C) for several days prior to surgery. During this time, tissue viability can drop by as much as 10%/day. We evaluated the effects of supplementing the hibernation media with various trophic solutions including striatal extracts, human placental cord serum (HPCS), fetal calf serum (FCS), brain-derived neurotrophic factor (BDNF) and epidermal growth factor (EGF) to assess their effects on the survival of hibernated cells. E15 rostral mesencephalic tegmentum cells containing DA neurons were harvested, processed and immediately placed into hibernation media alone or with various trophic supplements. After 5 days the cells were washed, viability was assessed using trypan blue exclusion, and 100,000 viable cells were seeded onto established E15 striatal feeder cultures (100,000 cells/cm^2). After 72 hours, the cultures were processed for immunocytochemistry and the number of tyrosine hydroxylase immunoreactive (THir) neurons was assessed. All trophic supplements enhanced viability relative cells held in hibernation media only. This effect was not due to a stabilizing effect of protein on the media since bovine serum albumin did not alter viability. Striatal extracts, HPCS and FCS also enhanced the "survivability" of THir cells disproportionately. Thus, these trophic supplements not only increased survival in hibernation, but once plated out at equivalent seeding densities, a larger number of THir cells with more developed processes was observed. These data demonstrate that trophic supplements can enhance the viability as well as survival of DA neurons held in hibernation. Trophic supplements may reduce apoptosis initiated during storage thereby reducing the impact programmed cell death has on the survival of DA neurons following transplantation. (Supported by 1RO1NS33174).

775.2

ADDITION OF ADENOVIRAL VECTORS TO EMBRYONIC VENTRAL MESENCEPHALON CELL SUSPENSIONS USED FOR STRIATAL IMPLANTATION INTO 6-OHDA-DENERVATED RATS INDUCES DETRIMENTAL IMMUNE RESPONSES. E. Roy*, L. Grégoire, F. Tardif, P. J. Bédard and C. Gravel. Neurobiology Res Center, Fac. of Med., Laval Univ., Québec, Canada, G1J 1Z4.

As survival and differentiation of embryonic dopaminergic cells *in vitro* can be enhanced by exposure to neurotrophic factors, it may be possible to enhance survival and differentiation of dopaminergic donor cells *in vivo* in grafting trials by exposing them to an increased supply of such factors. In practice however, this is difficult to achieve and very invasive techniques such as intraparenchymal cannulation or coadministration of genetically-engineered cells are required. An alternative strategy would be to use gene transfer techniques to confer *in situ* increased expression of neurotrophic factors to donor and/or host cells. To test such a strategy, we have performed intrastriatal transplantation of embryonic ventral mesencephalon (VM) cell suspensions into the striatum of 6-OHDA-denervated rats using our standard protocols (Rioux *et al.*), with or without the addition of 3 x 10^7 pfus of E1-deleted adenoviral vectors encoding either E.coli LacZ (Ad5-CMV-LacZ) or human BDNF (Ad5-CMV-BDNF) in the inoculum. Striatal tissues were analysed 7 days after grafting. Addition of either adenoviral vectors to the donor suspension has detrimental effects on graft survival and differentiation, as illustrated by the reduced numbers of surviving TH+ cells and their restriction to a smaller area of the host striatum. Perivascular cuffs are observed and Mac-1 immunoreactivity is increased in the striatum of animals grafted with the suspensions supplemented with either vector, and GFAP+ cells are much less numerous in the graft in comparison to controls. We suggest that these effects result from the immune rejection of both grafted and host infected cells triggered by the presence of the adenoviral vectors in the tissues. Immune rejection of adenovirus-infected cells have been documented before by us and others in peripheral organs, but have not been reported yet in CNS tissues. We believe that the damage caused to the blood-brain barrier by the grafting procedure is instrumental in this rejection process, and we will suggest alternative strategies to prevent this rejection. [Supported by the MRC, the Parkinson Foundation of Canada and the Canadian Networks of Centres of Excellence.]

STRIATAL TRANSPLANTATION OF MICROENCAPSULATED BOVINE CHROMAFFIN CELLS REDUCES ROTATIONAL BEHAVIOUR IN THE RAT MODEL OF PARKINSONISM. P.W. Tsang, H.C. Kwan* and A.M. Sun. *Department of Physiology, University of Toronto, Toronto, ON, M5S 1A8, CANADA.*

Striatal transplantation of dopamine-producing tissue has been proposed as a possible treatment for Parkinson's disease. To avoid the ethical issues associated with the use of human fetal tissue, transplantation of chromaffin cells from the adrenal gland has been suggested; however, survivability of these transplants is quite low. In our study, we assess the efficacy of bovine chromaffin cell transplants immunoisolated within a permselective biocompatible polymer membrane vs. free cell transplants in the rat model of parkinsonism.

In vitro studies compared levels of high-potassium depolarization-evoked release of catecholamines from free chromaffin cells vs. cells microencapsulated within alginate/poly-lysine/alginate (APA) capsules. Results of a perifusion study showed comparable levels of release from both free and encapsulated cells; 1 x 10^4 encapsulated cells released approximately 4700 ng of noradrenaline, 5000 ng of adrenaline and 350 ng of dopamine. *In vivo* testing compared the effects of sham (empty capsule), free cells and encapsulated cells implanted into the striatum of male Wistar rats with unilateral 6-hydroxydopamine lesions of the substantia nigra. Lesions resulted in rotational behaviour upon administration of the dopamine agonist, apomorphine (APO). Weekly APO challenges revealed significant differences in the 3 experimental groups, with an average of 29.3 ± 3.6% reduction in the number of rotations in the sham group, 49.8 ± 4.6% reduction in the free cell group and 68.2 ± 4.4% reduction in the encapsulated cell group, in excess of 16 weeks post-transplantation (n_s = 5, n_f = 5, n_e = 6; one-way ANOVA, $p < 0.001$). The results demonstrate that the APA membrane allows the passage of secreted catecholamines out of the capsule. The use of immunoisolated cells may improve cell survival following transplantation, thus reducing rotational behaviour in our animal model.

CHARACTERIZATION OF HSV-1-EXPRESSED TYROSINE HYDROXYLASE IN A NON-DOPAMINERGIC CELL LINE. F. Serrano*, M.A. Bender†, W.F. Goins†, M.J. Zigmond, J.C. Glorioso† and T.G. Sherman. Department of Neuroscience and †Department of Molecular Genetics and Biochemistry, University of Pittsburgh, Pittsburgh, PA 15260.

The delivery of foreign genes into CNS neurons may aid in the treatment of certain neurodegenerative diseases, such as Parkinson's disease. Herpes simplex virus (HSV-1) is one tool that demonstrates particular promise for this function. We have previously presented information on our design and construction of a non-replicating HSV-1 variant that utilizes the expression of a transcriptional activator (GAL4:VP16) as a means of prolonging targeted gene expression during viral latency in cells of the CNS (Soc. Neurosci. Abstract 79.19, 1994). What remains unknown, however, is information describing the full complement of expressed genes required for the phenotypic conversion of non-catecholaminergic cells into dopaminergic cells. To begin addressing this question, we are now investigating the kinetic variables of virally-derived tyrosine hydroxylase (TH) expressed in non-dopaminergic cells in culture. Vero cells, a stable line derived from monkey kidney cells, were infected with HSV-1 constructs expressing the TH gene, either alone or in combination with the GAL4:VP16 transactivator. TH-vector infected Vero cells produced detectable TH protein at 24 h post-infection, and this TH protein was shown to be enzymatically active in an *in vitro* assay for TH activity. Expressed TH was 4-fold increased in activity after 48 h of infection compared to 24 h. Co-infection of cells with the GAL4:VP16 virus produced no additional effect at 24 h; however, a 3-fold increase in TH activity was found after 48 hr compared to infection with the TH construct alone. Preliminary studies indicate that Vero cells expressing TH are capable of producing quantifiable levels of DOPA. (Research is supported by NINDS grant MH19608; F.S. by NIMH Training grant MH18273.)

LONG-TERM GENE EXPRESSION IN VIVO, DRIVEN BY A TYROSINE HYDROXYLASE PROMOTER IN A DEFECTIVE HERPES VIRUS AMPLICON VECTOR. M.Belloni, B.Conti, H.J.Federoff [1], B.K.Jin, T.H.Joh *. Cornell Univ.Med.Coll.at The Burke Med. Res. Inst., White plains, NY 10605., [1]Albert Einstein Coll. Med., Bronx, NY 10461.

Defective herpes simplex type 1 (HSV-1) viral vectors have been widely used for *in vivo* gene transfer in the central nervous system (CNS). Because the duration of gene expression directed by the viral promoters in amplicon vectors is short-lived, we constructed an amplicon vector in which gene expression was directed by the tyrosine hydroxlase (TH) promoter. A 9.0 kb fragment of 5' upstream DNA sequence of the rat TH gene, previously shown to direct tissue-specific expression in transgenic mice, was fused to LacZ gene in HSV amplicon (THlac). The viral IE4/5 promoter (HSVlac) was used as a control. Sprague Dawley rats received unilateral stereotaxic injections of virus stock into substantia nigra (SN). To determine retrogradely transported expression, virus stock was injected stereotaxically into striatum. After three weeks rats were sacrificed for X-gal histochemical and TH immunocytochemical analysis. In rats receiving nigral injections of THlac, expression of the LacZ gene was observed in neurons as well as glia. In rats receiving striatal injections, blue cells were also observed in SN ipsilateral to injection side. These blue cells were nigral dopaminergic neurons evidenced by double staining with TH immunocytochemistry. In contrast, neither nigral nor striatal injection of HSVlac resulted in prolonged gene expression. The present study suggests that a neuronal, but not a viral promoter, will direct longer-term expression in adult brain. Supported by NIH grant, MH24285.

CHARACTERIZATION OF FIBROBLAST CELLS GENETICALLY MODIFIED TO PRODUCE L-DOPA *IN VITRO* AND *IN VIVO*. C. Bencsics*, S. R. Wachtel, D. Young and U. J. Kang. Dept. of Neurology, University of Chicago, Chicago, IL 60637.

In previous studies, we have generated cells (FFK1THGC) which produce L-DOPA by doubly transducing primary fibroblasts with the cDNA's for tyrosine hydroxylase (TH) and GTP cyclohydrolase 1 (GTPCH1). These cells produce L-DOPA spontaneously since they produce tetrahydrobiopterin (BH4) which is the cofactor for TH.
