Society for Neuroscience Policies on the Use of Animals and Humans in Neuroscience Research

Recently Council approved a revised version of the Society's Policy on the Use of Animals in Neuroscience Research and adopted a new policy on the use of human subjects in neuroscience research. The revised version of the animal policy, drafted by the Committee on Animals in Research, in conjunction with the editor-in-chief of *The Journal of Neuroscience* and the chair of the Publications Committee, is printed below. The amendment is contained in the "Recommended References" section. The Policy on the Use of Human Subjects in Neuroscience Research is printed after the animal policy.

Policy on the Use of Animals in Neuroscience Research

The Policy on the Use of Animals in Neuroscience Research affects a number of the Society's functions that involve making decisions about animal research conducted by individual members. These include the scheduling of scientific presentations at the Annual Meeting, the review and publication of original research papers in *The Journal of Neuroscience*, and the defense of members whose ethical use of animals in research is questioned by antivivisectionists. The responsibility for implementing the policy in each of these areas will rest with the relevant administrative body (Program Committee, Publications Committee, Editorial Board, and Committee on Animals in Research, respectively), in consultation with Council.

Introduction

The Society for Neuroscience, as a professional society for basic and clinical researchers in neuroscience, endorses and supports the appropriate and responsible use of animals as experimental subjects. Knowledge generated by neuroscience research on animals has led to important advances in the understanding of diseases and disorders that affect the nervous system and in the development of better treatments that reduce suffering in humans and animals. This knowledge also makes a critical contribution to our understanding of ourselves, the complexities of our brains, and what makes us human. Continued progress in understanding how the brain works and further advances in treating and curing disorders of the nervous system require investigation of complex functions at all levels in the living nervous system. Because no adequate alternatives exist, much of this research must be done on animal subjects. The Society takes the position that neuroscientists have an obligation to contribute to this progress through responsible and humane research on animals.

Several functions of the Society are related to the use of animals in research. A number of these involve decisions about research conducted by individual members of the Society, including the scheduling of scientific presentations at the Annual Meeting, the review and publication of original research papers in *The Journal of Neuroscience*, and the defense of members whose ethical use of animals in research is questioned by antivivisectionists. Each of these functions, by establishing explicit support of the Society for the research of individual members, defines a relationship between the Society and its members. The purpose of this document is to outline the policy that guides that relationship. Compliance with the following policy will be an important factor in determining the suitability of research for presentation at the Annual Meeting or for publication in *The Journal of Neuroscience*, and in situations where the Society is asked to provide public and active support for a member whose use of animals in research has been questioned.

General Policy

Neuroscience research uses complicated, often invasive methods, each of which is associated with different problems, risks, and specific technical considerations. An experimental method that would be deemed inappropriate for one kind of research may be the method of choice for another kind of research. It is therefore impossible for the Society to define specific policies and procedures for the care and use of all research animals and for the design and conduct of every neuroscience experiment.

The U.S. *Public Health Service Policy on Humane Care and Use of Laboratory Animals* (PHS Policy) and the National Institutes of Health *Guide for the Care and Use of Laboratory Animals* (NIH Guide) describe a set of general policies and procedures designed to ensure the humane and appropriate use of live vertebrate animals in all forms of biomedical research. The Society finds the policies and procedures set forth in the PHS Policy and the NIH Guide to be both necessary and sufficient to ensure a high standard of animal care and use and adopts them as its official Policy on the Use of Animals in Neuroscience Research (Society Policy). All Society members are expected to conduct their animal research in compliance with the Society Policy and are required to verify that they have done so when submitting abstracts for presentation at the Annual Meeting or manuscripts for publication in *The Journal of Neuroscience*. Adherence to the Society Policy is also an important step toward receiving help from the Society in responding to questions about a member's use of animals in research. A complete description of the Society's policy and procedures for defending members whose research comes under attack is given in the Society's *Handbook for the Use of Animals in Neuroscience Research*.

Local Committee Review

An important element of the Society Policy is the establishment of a local committee that is charged with reviewing and approving all proposed animal care and use procedures. In addition to scientists experienced in research involving animals and a veterinarian, the membership of this local committee should include an individual who is not affiliated with the member's institution in any other way. In reviewing a proposed use of animals, the committee should evaluate the adequacy of institutional policies, animal husbandry, veterinary care, and the physical plant. Specific attention should be paid to proposed procedures for animal procurement, quarantine and stabilization, separation by species, disease diagnosis and treatment, anesthesia and analgesia, surgery and postsurgical care, and euthanasia. The review committee also should ensure that procedures involving live vertebrate animals are designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society. This review and approval of a member's use of live vertebrate animals in research by a local committee is an essential

component of the Society Policy. Assistance in developing appropriate animal care and use procedures and establishing a local review committee can be obtained from the documents listed below and from the Society.

Other Laws, Regulations, and Policies

In addition to complying with the policy described above, Regular Members (i.e., North American residents) of the Society must also adhere to all relevant national, state, or local laws and/or regulations that govern their use of animals in neuroscience research. Thus, U.S. members must observe the U.S. Animal Welfare Act (as amended in 1985) and its implementing regulations from the U.S. Department of Agriculture. Canadian members must abide by the *Guide to the Care and Use of Experimental Animals*, and members in Mexico must comply with the *Reglamento de la Ley General de Salud en Materia de Investigacion para la Salud of the Secretaria de Salud* (published on Jan. 6, 1987). Similarly, in addition to complying with the laws and regulations of their home countries, Foreign Members of the Society should adhere to the official Society Policy outlined here.

The following principles, based largely on the PHS *Policy on Humane Care and Use of Laboratory Animals*, can be a useful guide in the design and implementation of experimental procedures involving laboratory animals.

Animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results.

Proper use of animals, including the avoidance or minimization of discomfort, distress, and pain, when consistent with sound scientific practices, is imperative.

Procedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anesthesia. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents.

Postoperative care of animals shall be such as to minimize discomfort and pain and, in any case, shall be equivalent to accepted practices in schools of veterinary medicine.

Animals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure. If the study requires the death of the animal, the animal must be killed in a humane manner.

Living conditions should be appropriate for the species and contribute to the animals' health and comfort. Normally, the housing, feeding, and care of all animals used for biomedical purposes must be directed by a veterinarian or other scientist trained and experienced in the proper care, handling, and use of the species being maintained or studied. In any case, appropriate veterinary care shall be provided.

Exceptions to these principles require careful consideration and should only be made by an appropriate review group such as an institutional animal care and use committee.

POLICY ON THE USE OF HUMAN SUBJECTS IN NEUROSCIENCE RESEARCH

Experimental procedures involving human subjects must have been conducted in conformance with the policies and principles contained in the Federal Policy for the Protection of Human Subjects (United States Office of Science and Technology Policy) and in the Declaration of Helsinki. When publishing a paper in *The Journal of Neuroscience* or submitting an abstract for presentation at the Annual Meeting, authors must sign a statement of compliance with this policy.

POLICY ON ETHICS

It is expected that authors submitting papers or abstracts will have conducted their work in strict accordance with the following statement on ethics approved by the Society for Neuroscience in November 1989 and amended in November 1993.

The Society for Neuroscience believes that progress in understanding the nervous system materially benefits human welfare. It recognizes that such progress depends on the honest pursuit of scientific research and the truthful representation of findings. While recognizing that both scientific error and differences of interpretation are a natural part of the creative process, the Society affirms that misconduct, in the form of fabrication, falsification, or plagiarism, jeopardizes the success of the entire scientific endeavor. Members of the Society assume an obligation to maintain the highest level of integrity in all scientific activities.

The primary responsibility for considering and resolving allegations of scientific misconduct lies within the individual academic communities and institutions where scientific work is carried out. The Society for Neuroscience therefore supports the principle that academic institutions should develop and have in place procedures to deal with allegations of scientific misconduct. However, the Society has a special responsibility and interest surrounding those scientific activities for which it is directly responsible, e.g., publication of *The Journal of Neuroscience* and the presentations at the Annual Meeting.

Every author of articles or abstracts submitted for publication in *The Journal of Neuroscience* or the neuroscience *Abstracts* agrees to assume full responsibility, within the limits of his or her professional competence, for the accuracy of the report. In the case of multiple-authored papers, each author should have made a significant intellectual or practical contribution to the scientific work; "honorary authorship," i.e., the granting of authorship to persons who have made no substantive contribution to a scientific report, is not appropriate.

Scientists must have access to their original research results. The retention of accurately recorded and retrievable results is essential for the progress of scientific inquiry. Moreover, errors may be mistaken for misconduct when primary results are unavailable. Primary data should remain in the laboratory and should be preserved as long as there may be a reasonable need to refer to them.

Authors submitting articles or abstracts do so with the understanding that reports have not been submitted elsewhere. An abstract is a proper forum for rapid communication of work that will subsequently appear as a full-length article. However, submission of abstracts reporting already published work or publication of multiple similar manuscripts or abstracts, i.e., duplicate publication, is improper. When previously published data are presented as part of a new manuscript or abstract, as in a gradually developing longitudinal data set, or if a subject group or condition is included again for comparison purposes, citations to the previously published work should appear explicitly in the new report.

Scientific publication is an important part of the process by which priority is established for experimental work and ideas. Duplicating without citation of text previously published by others or expropriating the experimental findings of others without attribution, i.e., plagiarism, is unethical. When authors of articles or abstracts have prepublication access to related work of others, as in a review process, care must be taken to avoid the appearance that priority is being claimed for work already done by others.

It is the responsibility of the authors, therefore, and not of the Society or the Editorial Board of *The Journal of Neuroscience*, to ensure that relevant prior discoveries are appropriately acknowledged in manuscripts that are submitted to the *Journal* for publication.

Questions raised about the conduct of experiments or their presentation will be evaluated preliminarily by the Editor of *The Journal of Neuroscience* (in the case of an article in the *Journal*) or by the Chair of the Program Committee (in the case of an abstract), in consultation with the Chair of the Publications Committee and the Secretary of the Society. If possible, the matter may be resolved informally at this level. However, if deemed appropriate, the matter will be referred to the institution where the scientific work in question was done. There, it would be expected that the matter would be reviewed in accordance with institutional procedures for handling allegations of misconduct. At all stages, every effort should be made to ensure that the process is fair and just, both for those who are accused of misconduct and for those who have raised the issue of scientific misconduct.

Based on their own findings or those of the institution, the *Journal* Editor or the Chair of the Program Committee, in consultation with the Chair of the Publications Committee and the Secretary of the Society, may recommend action to the Publications Committee. The Publications Committee will then decide on appropriate action, including, for example, retracting a published report. The Council of the Society and the relevant institution will be informed of any action that is taken. Council retains the right to consider additional action. In accordance with the Bylaws, this action could include, for example, expulsion from the Society. If it is found that allegations were not made in good faith, or were maliciously motivated, action may be recommended for those responsible.

In the event that a published article or abstract is to be retracted, a statement of retraction will be published in *The Journal of Neuroscience* or in the *Abstracts* for the next Annual Meeting.

BEHAVIORAL EFFECTS AND PENTYLENETETRAZOLE-INDUCED SEIZURE PROTECTION OF DIZOCILPINE AND LORAZEPAM ALONE OR IN COMBINATION IN MALE CD1 MICE. G.A. Pritchard*, J. S. Pratt and D. J. Greenblatt. Department of Pharmacology and Experimental Therapeutics, Tufts University School of Medicine, Boston, MA 02111.

To evaluate the potential interaction between the NMDA receptors and the GABAA receptor family, dizocilpine (DIZ) and lorazepam (LRZ), alone or in combination, were evaluated for their effects on a number of behavioral parameters as well as in a pentylenetetrazole (PTZ) seizure protection assay in male CD-1 mice. Animals were injected with DIZ or vehicle and 15 min later with LRZ or vehicle. Distance traveled, rears and stereotypy were measured using an activity monitor 40 min following the first injection for 20 min (4 x 5 min). The tail vein of each mouse was then cannulated and PTZ was infused until the animal had two tonic-clonic seizures. Behavioral effects of DIZ were observed only for the highest dose (0.1 mg/kg) and was evidenced by a significant (80%) increase in distance traveled during each of four intervals monitored. Rears and stereotypy were unaffected by DIZ at any concentration. Also, DIZ had no protective effect against PTZ-induced seizures. Lorazepam, however, significantly reduced horizontal activity, rears and stereotypy at all but the lowest concentration (0.2 mg/kg) in a dose-dependent manner. Similarly, LRZ had a dose-dependent protective effect against PTZ-induced seizures with all but the lowest concentration (0.2 mg/kg) significantly increasing the volume of PTZ needed to induce convulsions. When combined at the lowest and highest levels tested, DIZ and LRZ had effects similar to that of LRZ alone; no synergism was observed Furthermore, the eleveated horizontal activity induced by DIZ (0.1 mg/kg) was completely attenuated by LRZ (2.0 mg/kg).

637.10

DOSE-RESPONSE OF CYCLOPHOSPHAMIDE-INDUCED EMESIS IN THE FERRET. R.L. Wynn, A. Carter, R. Meszler*, L. Lao, B.M. Berman and R.H. Wong. Department of Family Medicine, School of Medicine, and Departments of Anatomy and Pharmacology, Dental School, University of Maryland, Baltimore, MD 21201

Nausea and vomiting are severe side-effects often associated with cancer chemotherapy and may affect treatment decisions. Cyclophosphamide is a commonly used chemotherapy agent for breast cancer and induces emesis in the ferret. In order to examine the emetogenic effect of cyclophosphamide, ferrets (1.0-1.8 kg) were placed under general anesthesia (isoflurane 5%-O_2 mixture) and were administered logarithmic doses of i.v. cyclophosphamide. The mean number (±SE) of emetic episodes and retches were: 2.2±0.9 episodes and 2.8±1.9 retches at 56 mg/kg, 7.3±3.2 and 30.5±17.5 at 100 mg/kg, 23.3±4.0 and 85.3±20.4 at 177 mg/kg, and 23.5±7.5 and 62.5±38.5 at 237 mg/kg. In addition, various antiemetics were given i.v. immediately following cyclophosphamide injection. Ondansetron reduced emetic episodes by 0% and 43% (0.04 and 0.07 mg/kg), metoclopramide by 65% and 98% (4.08 and 7.07 mg/kg), and droperidol by 16% and 24% (0.45 and 0.25 mg/kg). These results indicate that cyclophosphamide induces emesis in a dose-dependent manner and may be useful in evaluating conventional and complementary therapies for the treatment of chemotherapy-induced emesis. Support provided by the U.S. Army Breast Cancer Research Program #DAMD17-94-J-4325.

EFFECTS OF I.C.V. AND I.C. BETA-FUNALTREXAMINE ON DISCRIMINATIVE STIMULUS EFFECTS OF MORPHINE. J.A. Moretti* and A.M. Young. Department of Psychology, Wayne State University, Detroit MI 48202.

The present experiments investigated effects of the selective irreversible μ opiate antagonist beta-funaltrexamine (β-FNA) on discriminative stimulus and rate-altering effects of morphine sulfate (MS), the prototypic μ opiate agonist. Male Sprague-Dawley rats were trained to discriminate among 3.2 mg/kg MS and saline under a FR15 schedule of food reinforcement. Generalization curves for MS (0.32-5.6 mg/kg) were established using a cumulative dosing procedure. Rats were then dosed with 20 μg β-FNA, by either i.c.v. or i.c. administration. Morphine was retested 24 h, 72 h, and 8 d after β-FNA treatment, and weekly thereafter, until recovery of the maximal stimulus effects of MS was observed. β-FNA i.c.v. produced a loss of maximal MS-like stimulus effects for up to 72 h, and also increased the dose of MS required to suppress rates by approximately six-fold. After 22 days the rate-altering potency of MS returned to control values, and MS regained the capacity to produce a maximal stimulus effect, although the dose required for MS-like responding was still greater than control values. The effects of β-FNA i.c. were significant, albeit less pronounced than those seen with i.c.v. administration, demonstrating that β-FNA is more potent when administered i.c.v. The present data suggest that β-FNA can suppress the maximal stimulus effects of MS by alkylating a sufficient proportion of the receptor pool mediating these responses. (Supported by DA03796 and K02 DA00132.)

STIMULUS ADDITIVITY IN A DRUG DISCRIMINATION TASK: CREATING A MORPHINE CUE FROM OTC COMPOUNDS.
D.V. Gauvin,* R.J. Briscoe, K.L. Carl and F.A. Holloway, Department of Psychiat. & Behav Sci, Univ. Oklahoma H.S.C., Okla. City, OK 73190

This laboratory recently has published reports demonstrating simple effect-additivity of stimulus elements of compound drug stimuli (*PB&B*, 32:1017-1023; *Psychopharm* 110:309-319; *J Psychopharm* 7:52-59). With respect to stimulus control by compound stimuli, Fantino & Logan have suggested that the specific stimulus element or dimension which controls the behavioral operant is largely beyond experimental control and may even be idiosyncratic (1979, The experimental analysis of behavior: a biological perspective San Francisco: W.H. Freeman). Using a two-choice drug discrimination task, rats were trained with 3.2 mg/kg morphine and saline as training stimuli. We used a single subject analysis strategy to examine which specific element(s) of the compound morphine cue controlled behavioral choice. Cross-generalization profiles were determined for a number of over-the-counter (OTC) medications which were hypothesized to engender subjective elements of a compound morphine cue including sedation, lethargy, and analgesia: dextromethorphan, doxylamine, diphenhydramine, pyrilamine, pyridoxine, thiamine, and loperamide. When tested in combination with saline, none of the OTC compounds produced a group mean percentage of 'drug-appropriate' responding > 50%. Based on an individual rats' cross-generalization profile, each subject was tested for 'stimulus-element-additivity' by administering and testing variations of binary and ternary combinations of these same OTC compounds. A test combination was formulated from the addition of single OTC drug stimulus elements for each rat which engendered >95% morphine-appropriate responding. These test combinations appeared to be idiosyncratic, dose-dependent, and to follow rules predicted by simple effect-additivity.

CUMULATIVE vs ACUTE DOSE-RESPONSE PROCEDURES PRODUCE DIFFERENTIAL BAC AND DD FUNCTIONS FOR ETOH
R.J. Briscoe,* D.V. Gauvin, K.A. Carl, & F.A. Holloway
Dept Psychiat & Behav Sci, O.U.H.S.C., Oklahoma City, OK 73190

Twelve male S-D rats were trained to discriminate between 1.25 g/kg ETOH and saline injections, in a multi-cycle operant discrimination task. Once trained, complete dose-effect curves (DECs) were generated, once per month, using two different incremented (cumulative) dose procedures (DEC1 & 3: 0.25, 0.75, 1.25, 1.75, 2.25 g/kg or DEC2 & 4: 0.0, 0.625, 1.25, 1.875, 2.25 g/kg). The same doses were tested singly in acute testing sessions over the five month period. Similar cumulative behavioral DECs were generated within each cumulative procedure (DEC#1 vs DEC#3, $F(1,6)$=.23: n.s.; DEC#2 vs DEC#4 $F(1,6)$=.13: n.s.) however, significant differences were produced between the two dosing incremented procedures (ED50s: DEC1 vs DEC3: 1.06 ± .25 vs 1.06 ± .23; DEC2 vs DEC4: .74 ± .15 vs .73 ± .17). Tests of the 1.25 g/kg ETOH training dose engendered 100% ETOH-appropriate responding under acute testing procedures but only ~70% ETOH-appropriate responding under cumulative testing procedures. When blood alcohol concentrations (BACs) were quantified by GC assays, cumulative testing procedures always produced significantly lower BACs than acute testing procedures ($t(6)$=8.12, p<.001). Group mean BACs produced by the 1.25 g/kg ETOH training dose were 70 ± 6 mg/dl and 126 ± 5 mg/dl when tested in cumulative and acute procedures, respectively. Interestingly, response rate functions did not differ between either cumulative procedures or between cumulative and acute procedures. These data may suggest that differential dosing procedures, interacting with ETOH-associated metabolic processes (absorption or distribution) may influence the behavioral choice and blood alcohol concentration DECs in rats.

TRAINING DOSE AS A DETERMINANT OF STIMULUS GENERALIZATION WITH A MIXTURE OF DRUGS. I. P. Stolerman*, E. A. Mariathasan and J-A W White. Section of Behavioural Pharmacology, Institute of Psychiatry, De Crespigny Park, London SE5 8AF, U.K.

The dose of a drug used for training can influence the characteristics of drug discrimination behaviour established with single drugs. To determine whether this also applies to discriminations based on mixtures of drugs, three groups of rats (n=9-10) were trained to discriminate mixtures of (+)-amphetamine (0.2-0.8 mg/kg) plus pentobarbitone (5-20 mg/kg) from saline in a standard, two-lever procedure with food reinforcement; the ratio between the training doses was constant at 1:25 for each group. The groups acquired the discriminations to an accuracy of 90-97% and, in each case, generalization to amphetamine or pentobarbitone alone was clear and dose-related, but less than complete in most experiments (68-86%). There was also partial generalization when either apomorphine (50%) or nicotine (63%) was administered alone, but only in rats trained on the smallest amount of the mixture; in rats trained with the larger doses of the mixture, neither apomorphine nor nicotine increased responding above vehicle levels. Doses of pentobarbitone that were half of those used in training produced little or no discriminative response when administered alone to the rats trained with the two smallest doses of the mixture; the same doses of pentobarbitone increased responses to amphetamine or apomorphine in a supra-additive manner. Strikingly, some doses of apomorphine and pentobarbitone that alone produced only vehicle-like responding (11%) produced almost complete generalization (80%) in rats trained with 0.4 mg/kg of amphetamine plus 10 mg/kg of pentobarbitone; this interaction was not seen in the rats trained with either smaller or larger doses of the mixture. The complex pattern of results suggests that doses of drugs used for training play an important role in the discrimination of abused drug mixtures, but no simple rules to predict the influence of training dose have been ascertained (supported by NIDA grant DA 05543).

HOTPLATE SENSITIVITY: INDIVIDUAL DIFFERENCES, HABITUATION, AND STIMULUS INTENSITY. D.F. Emerich*, M.A. Plone, and M.D. Lindner. CytoTherapeutics Inc., Two Richmond Square, Providence, RI 02906

The hotplate test, which typically involves placing a rodent in a chamber with a heated floor and recording the latency of the first sign of discomfort, is one of the most frequently used procedures in the study of pain and analgesics, yet the psychometric properties of this test have not been fully characterized. We conducted a survey of the literature which revealed that: (1) higher hotplate temperatures are more common than lower temperatures, and (2) studies do not match subjects into groups to ensure that groups are equivalent before treatment begins. It is likely that subjects are not matched into groups because it has been reported that "behavioral tolerance" occurs. We assessed morphine dose-response curves in rats that had been habituated or were naive to a 50°C or 55°C hotplate. The data reveal that: (1) consistent with numerous previous reports, the lower temperature hotplate was much more sensitive to the effects of analgesic agents such as morphine, (2) there are reliable differences between individuals, and (3) habituation to the hotplate testing procedures does not reduce the analgesic effects of morphine (there was no evidence of "behavioral tolerance" to the test procedures). These results support the use of lower stimulus intensities, and the practice of assessing pretreatment response latencies to the hotplate in order to match subjects into groups before treatments are initiated.

HYPOTHALAMIC-PITUITARY-ADRENAL REGULATION: OTHER II

638.1

THE PATTERN OF CELLULAR ACTIVATION SEEN IN RESPONSE TO ACUTE RESTRAINT SUGGESTS COMMONALITIES AMONG "NEUROGENIC" STRESS MODELS. V. Viau* and P.E. Sawchenko. The Salk Institute, La Jolla, CA 92037.

Acute restraint reliably activates the hypothalamo-pituitary-adrenal (HPA) axis, and is among the more commonly employed stress models. To provide an overview of the CNS systems that are activated in response to this challenge, we followed the time course of Fos protein expression induced in rat brain by a single 30 min restraint session. The widespread patterns of cellular activation we observed were most robust in animals sacrificed at 1-2 hr after stress, and returned to near control levels by 4 hr. Cell groups evincing Fos induction included the paraventricular nucleus of the hypothalamus (PVH), where responsive neurons were localized principally in the hypophysiotropic zone of parvocellular division, with secondary accumulations in autonomic-related subdivisions and in oxytocin-rich aspects of the magnocellular neurosecretory system. Beyond the hypothalamus, Fos-ir neurons could be grouped as belonging to three broadly defined systems. Induction was prominent in the limbic region of the telencephalon, including the infra- and prelimbic cortices, the lateral septal nucleus, bed nucleus of the stria terminalis, and the basolateral and medial amygdaloid nuclei. A second major focus comprised cell groups involved in the processing of somatosensory and/or nociceptive information; such structures included the dorsal column nuclei, the periaqueductal gray, cholinergic cell groups of the mesopontine tegmentum, and the midline and intralaminar nuclear complexes of the thalamus. Finally, brainstem catecholaminergic cell groups reliably displayed robust restraint-induced Fos expression. Prominent among these were the locus coeruleus, and cells in the medial part of the nucleus of the solitary tract, as well as aminergic regions of the rostral and caudal ventrolateral medulla. This general pattern of restraint-induced cellular activation is strikingly similar to that which has been described following footshock or immobilization, and contrasts starkly with profiles seen in response to systemic stresses such as hemorrhage or immune challenge. While the categorization of certain stress models as "neurogenic" appears to have some basis in induced patterns of immediate-early gene expression, it remains to be determined whether they activate the central limb of the HPA axis through common circuitries and mechanisms.

638.2

SEQUENCE OF STRESS-INDUCED ALTERATIONS IN INDICES OF CELLULAR ACTIVATION IN PARVOCELLULAR NEUROSECRETORY NEURONS: MARKERS VERSUS MECHANISMS. K.J. Kovács* and P.E. Sawchenko. The Salk Institute, La Jolla, CA and Inst. Exp. Med., Budapest, Hungary.

Acute ether stress results in increased ACTH and corticosterone secretion that peak at 5 and 30 min, respectively, after the challenge. Using cRNA probes to intronic sequences of genes encoding ACTH secretagogues in parvocellular neurosecretory neurons of the paraventricular nucleus (PVH), we have found these events to be accompanied by rapid and transient transcriptional activation of corticotropin-releasing factor (CRF) hnRNA expression (peak at 5-15 min), and a delayed up-regulation of arginine vasopressin (AVP) hnRNA (90-120 min). To gain insight into possible molecular mechanisms regulating stress-induced CRF and AVP expression *in vivo*, we have compared the time course of ether stress-induced activation of representatives of three transcription factor classes: immediate-early genes (*c-fos* and NGFI-B), a POU-domain factor (Brn-2), and the cAMP-response element binding protein (CREB), using antisera specific to its transcriptionally active, phosphorylated, form (P-CREB). Functional DNA binding sites for both Brn-2 and P-CREB have been identified on the CRF promoter. In response to ether stress, *c-fos* and NGFI-B mRNA induction in the PVH were maximal at 30-60 min, and that of Fos protein peaked at 90-120 min. Brn-2 mRNA was found to be constitutively expressed in parvocellular and magnocellular compartments of the PVH, and its expression did not change over the 4 hr observation period we employed. P-CREB was induced in parvocellular neurons with a time course which paralleled that of CRF hnRNA expression, reaching a maximum 5-15 min after exposure to ether vapor. *In vivo* inhibition of protein synthesis by cycloheximide prior to stress resulted in a marked reduction of the Fos protein response to ether in the parvocellular PVH, and attenuated the stress-induced rise in AVP hnRNA. Cycloheximide treatment did not, however, alter significantly P-CREB induction or stress-induced CRF hnRNA expression. The stress-induced transcriptional activation of the AVP and CRF genes in hypophysiotropic neurons appear to involve independent mechanisms, that respectively do and do not require *de novo* protein synthesis.

638.3

MECAMYLAMINE ADMINISTRATION INTO THE FOURTH VENTRICLE ANTAGONIZES NICOTINE-INDUCED c-FOS EXPRESSION IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS. B.M. Sharp, J.D. Valentine, K.M. McAllen, F.J. Wilson*, and S.G. Matta. Minneapolis Medical Research Foundation and Departments of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis, MN 55404 and Dept Neuroscience and Cell Biology UMDNJ-RW Johnson Medical School, Piscataway, NJ 08854

Previous research from this laboratory suggests that nicotine (NIC) elicits ACTH secretion indirectly, by activating brainstem neurons that project to the paraventricular nucleus of the hypothalamus (PVN), a region containing CRH. The present study further examined this hypothesis using a polysynaptic marker for neuronal activation, c-Fos. In experiment 1, rats received iv injections of vehicle or 0.045-0.18 NIC at a rate of 0.09 mg/kg/min and were sacrificed 1 hr later. Consistent with previous findings, immunohistochemical analysis for c-Fos showed that the PVN was dose-dependently activated by NIC, with the lower doses primarily activating the CRH rich parvocellular region and the higher doses activating the magnocellular region as well. In experiment 2, rats received vehicle or 4 ug of the nicotinic antagonist mecamylamine (MEC) into the fourth ventricle 15 min before iv administration of 0.09 mg/kg NIC. The results showed that MEC antagonized NIC-induced c-Fos expression throughout the PVN. These findings are consistent with prior results suggesting that NIC elicits ACTH release by activating brainstem neurons that in turn activate the PVN. (Supported by DA03977)

638.4

NICOTINE'S INDUCTION OF c-FOS IN THE NTS-A_2/C_2 IS ANTAGONIZED BY FOURTH VENTRICULAR MECAMYLAMINE. J.D. Valentine*, S.G. Matta, K.M. McAllen and B.M. Sharp. Minneapolis Medical Research Foundation and Departments of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis, MN 55404.

Previous research from this laboratory suggests that nicotine (NIC) elicits ACTH secretion by activating brainstem catecholamine neurons projecting to the paraventricular nucleus of the hypothalamus. The present study further examined this hypothesis. In experiment 1, rats received iv injections of vehicle, 0.045, 0.09, 0.135 or 0.18 mg/kg NIC at a rate of 0.09 mg/kg/min and were sacrificed 1 hr later. Immunohistochemical analysis showed that NIC dose-dependently induced c-Fos expression throughout the NTS-A_2/C_2. This expression was a linear function of dose from 0.045-0.135 mg/kg, with the 0.18 mg/kg dose causing a far greater induction. In experiment 2, rats received vehicle or 4 µg of the nicotinic antagonist mecamylamine (MEC) into the fourth ventricle 15 min before iv administration of 0.09 mg/kg NIC. The results showed that only a small fraction of the NTS-A_2/C_2 neurons expressing NIC-induced c-Fos also contained the catecholamine systhesis enzyme tyrosine hydroxylase. However, MEC antagonized NIC-induced c-Fos expression throughout the NTS-A_2/C_2. The present results are consistent with the hypothesis that NIC elicits ACTH secretion via activation of brainstem neurons, some of which are catecholaminergic. (Supported by DA03977)

638.5

INDUCTION OF THE IMMEDIATE-EARLY GENE c-*fos* IN THE AUDITORY AND LIMBIC SYSTEMS FOLLOWING LOUD NOISE STRESS. S. Campeau*, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

The paraventricular nucleus of the hypothalamus is commonly thought to be the final common relay essential for stress-induced glucocorticoid release. However, the anatomical pathway(s) through which neurogenic stressors activate the paraventricular nucleus are not well delineated. In an attempt to determine more precisely how the paraventricular nucleus is activated by stress, a loud noise stimulus was used. Because the auditory system is already well characterized, it might provide a useful starting point to trace the pathway(s) ultimately innervating the paraventricular nucleus. Induction of c-fos mRNA was used to map the pattern of neural activation produced by loud noise.

Sprague-Dawley male rats (n = 4 per group) were used. Rats in one group served as naive controls. Rats in the other two groups were handled for 2 min and placed in the experimental cage for 10 min on each of 14 consecutive days. On Day 15, the animals were placed in the cage for 60 min, and for one group, a 110 dBA noise (20 - 20000 Hz) stimulus was turned on for the last 30 min. The rats were decapitated immediately upon removal from the cage, their trunk blood collected and processed for corticosterone radioimmunoassay. The brains were removed, frozen, and processed for c-*fos in situ* hybridization using a 680 nucleotide riboprobe.

Loud noise produced a reliable increase in plasma corticosterone concentration (20.3 ± 5.6 µg/dl) compared to handled/cage (0.6 ± 0.3 µg/dl) and naive controls (1.2 ± 0.4 µg/dl). Loud noise induced c-*fos* mRNA was observed in many forebrain and limbic areas as well as throughout the auditory system (from the cochlear nuclei to the auditory cortex). The pattern of activation in the forebrain and limbic systems parallels that obtained following swim and restraint stress (Cullinan et al., Neurosci., 64:477, 1995). Lesion studies are underway to determine which of the auditory relay nuclei provides the starting point of a multi-synaptic pathway ultimately innervating the paraventricular nucleus of the hypothalamus.

FOS IMMUNOREACTIVITY IN AMYGDALA AND HYPOTHALAMUS AFTER GRADED HEMORRHAGE IN THE RAT. M.P. Lilly, D.J. Putney and J.M. Simard*. University of Maryland at Baltimore, School of Medicine, Baltimore MD 21201.

We have previously reported potentiated responses of adrenocorticotropin (ACTH) to the second of two 10 ml/kg hemorrhages (hem) 24 h apart in the conscious rat. Limbic structures may modulate responses of the pituitary-adrenal (PA) system, and could play a role in potentiated PA responses. To study this, we measured fos-immunoreactivity (Fos-LIR) in brain regions after graded and/or repeated hem. Male Sprague-Dawley rats (350 gm) had chronic femoral arterial and venous catheters placed. Four days later conscious rats were bled 0, 5, 10 or 20 ml/kg over 3 min. Rats were killed 30, 60 or 90 min later and the brains were removed and frozen. Other rats had two 10 ml/kg hems 24 h apart and were killed 60 min p the second hem (10 ml/kg-H2). Fos immunostaining was done on 25µ frozen sections by the ABC method. Fos-LIR was evaluated qualitatively and semiquantitatively. Fos-LIR peaked 60 min after hem. No specific Fos-LIR was seen in brains after 0 or 5 ml/kg hem. After 10 ml/kg hem, we saw moderate Fos-LIR in the caudal central lateral (CeL) and the medial nuclei (MeA) of the amygdala, modest Fos-LIR in the supraoptic nucleus (SON) and no Fos-LIR in the paraventricular nucleus (PVN). After 20 ml/kg hem or 10 ml/kg-H2, we saw marked Fos-LIR throughout the central nucleus (CeA), SON and PVN and little Fos-LIR in MeA. These data show: 1) graded neuronal transcriptional activation after small hem, 2) repeated 10 ml/kg hem has a pattern of activation similar to 20 ml/kg hem, and 3) a lower threshold for hem activation of neurons in CeA & SON than in PVN. Thus, 10 ml/kg hem in the conscious rat activates cardiovascular neurons in amygdala, and a second 10 ml/kg hem produces more widespread neuronal activation. These data support the idea that amygdala neurons may play a role in potentiated PA responses to repeated hem. [Supported by NIH DK 02181]

TIME COURSE OF FOS STAINING FOLLOWING EXPOSURE TO RESTRAINT IN CHRONIC, INTERMITTENTLY COLD STRESSED ANIMALS. S. Bhatnagar* and M.F. Dallman, Dept. of Physiology, UCSF, San Francisco, CA 94143-0444.

Exposure of chronically stressed animals to a novel stressor results in similar or enhanced hypothalamic-pituitary-adrenal (HPA) responses to those in control animals despite the persistent negative feedback signal due to the chronic stress. It has been suggested that prior chronic stress produces a facilitatory trace that balances or overcomes the negative feedback effects of chronic stress, although the neuroanatomical sites subserving this facilitation are not yet known. We have shown that animals exposed to chronic, intermittent cold stress (4 h a day at 4C; CHR) exhibit enhanced HPA responses to a 30 min period of restraint compared to undisturbed controls (CTL). In the present study, we sought to determine the sites that may underlie this chronic stress-induced facilitation by immunohistochemistry for the fos protein. CHR and CTL animals were perfused under basal conditions, at 15 and 30 min during the 30 min period of restraint and at 30 and 60 min following termination of restraint. Preliminary data indicate that fos staining peaked in the paraventricular nucleus of the hypothalamus at 30 min post-restraint for both CTL and CHR animals, with no differences between groups in number of fos-stained cells at any time examined. Present data also indicate that staining in the arcuate nucleus is lower in CHR than in CTL animals at 30 min. Ongoing work is examining fos staining in other areas of the hypothalamus and brainstem with the goal of characterizing the neuroanatomical sites that may underlie chronic stress-induced facilitation of HPA responses to a novel stressor.

638.8

SEXUALLY DIMORPHIC MK801-INDUCED FOS-LIKE IMMUNOREACTIVITY (FLI) IN THE PVN OF THE RAT. N. Wintrip, D.M. Nance, and M. Wilkinson* Depts. of Obst. and Gynaecol., Physiol. and Biophys., and Anatomy and Neurobiology, Dalhousie U., Halifax, N.S., and Dept. of Pathology, U. of Manitoba, Winnipeg, Canada.

The non-competitive NMDA receptor antagonist MK801, is reported to activate the c-*fos* gene in various regions of the rat brain (Lee et al; Mol. Brain Res., 24:192). Also, the behavioural effects of NMDA appear to be sexually dimorphic (Hönack and Löscher; Brain Res., 620:167). We have examined induction of FLI in the PVN of male and female Sprague-Dawley rats 2h following s.c. injection of MK801 (0.1 or 1.0 mg/Kg b.w.; Fos antibody: Cambridge Res. Biochem.) using computer assisted image analysis. This approach has enabled us to identify subtle differences in the effects of MK801 which are difficult to detect by sequential examination of tissue sections.

Dose-dependent behavioural anomalies were seen in all MK801-injected rats with females exhibiting more pronounced disturbances at both high (1 mg/Kg) and low (0.1 mg/Kg) doses. Elevated levels of FLI were seen in the PVN of all MK801-treated rats compared to saline-injected controls. In general, high-dose (HD) MK801 induced higher levels of FLI in the PVN of adult male rats compared to like-treated cycling or lactating females (m.>fem.>lac.). Levels of FLI in the PVN of HD MK801-treated male and female 14 day old rats were similar and resembled those seen in adult males. In contrast, low dose (LD) MK801 induced more FLI in the PVN of cycling females compared to adult males. Gonadectomy did not affect the FLI response to LD MK801 in females but did increase levels in males. In adult female rats androgenized by testosterone (T) on postnatal day 2, levels of both HD and LD MK801-induced FLI in the PVN resembled those seen in like-treated adult males. These results suggest that the observed c-fos response to MK801 is T-dependent. Supported by Can. MRC.

EFFECT OF DURATION OF ADRENALECTOMY AND LIPOPOLY-SACCHARIDE ON C-FOS EXPRESSION IN THE PARAVENTRICULAR AND SUPRAOPTIC NUCLEI. A.A. Gerall*, S.B. Martin-Schild, and R.L. Chan. Dept. of Psychology, Tulane University, New Orleans, LA 70118.

Adrenalectomy (ADX) has been shown to enhance neuronal activity in the paraventricular nucleus of the hypothalamus (PVN) as measured by expression of c-fos-like protein (CFI) and CRH mRNA. Explored in the present study, were the influences of ADX duration and a pathogenic challenge on PVN and supraoptic nucleus (SON) expression of CFI.

Twenty-five intact or ADX Sprague-Dawley male rats were injected with either phosphate buffered saline (PBS) or 0.13 mg/kg bw lipopolysaccharide (LPS) 2 hr before perfusion. Experimental variables were: ADX duration, short term (<14 days) or long term (>21 days); and pre-perfusion challenge, control (PBS) or pathogen (LPS). Immunocytochemistry was performed using c-fos antiserum (Cambridge Biochem. Inc.) and solutions obtained from Vectastain Elite Sheep Kit. Immunoreactive products were counted using an computer-image analyzer.

Results confirm short term ADX non-challenged animals have significantly more CFI-ir in PVN neurons than intact animals. However, extending the duration of ADX before perfusion significantly diminished PVN CFI-ir. ADX resulted in more than 2x the CFI-ir in both the PVN and SON than in intact animals exposed to LPS. The main factors, ADX and LPS appear to be additive. LPS elicited a greater effect on neuronal activity in the PVN in long term ADX (14x) than short term ADX (3x). The difference was primarily due to increased baseline levels of CFI-ir within the parvocellular PVN of short term ADX PBS animals, which was 7x greater than that of long term ADX PBS animals. The duration of ADX had no influence over CFI-ir in the SON. Adjustment over time to ADX might result from a change in c-fos expression in parvocellular neurons but more likely is due to modifications in glucocorticoid receptor dynamics in CRH neurons or those regulating CRH neurons.

CHRONIC CENTRAL ADMINISTRATION OF NEUROTENSIN: EFFECTS ON HYPOTHALAMIC-PITUITARY-ADRENAL ACTIVITY AND BEHAVIOR. Wayne B. Rowe[1]*, U.K. Hanisch[2], Shakti Sharma[1], Michael J. Meaney[1] and Rémi Quirion[1] [1]*Dept. of Psychiatry and Neurology/Neurosurgery, Douglas Hospital Research Center, McGill University, Montreal, Canada, H4H 1R3,* [2]*Max-Delbrück-Centrum, Robert-Rössle-Strasse 10, 13125 Berlin-Buch, Germany.*

Neuroendocrine studies suggest an important neuromodulatory role of neurotensin (NT) on hypothalamic-pituitary-adrencortical (HPA) function. NT produces significant increases in plasma ACTH and corticosterone (B) levels as early as 15 min following an acute central injection (1 pmol), and levels remain elevated for up to 4 hrs (Rowe et al., *J. Neuroendo.*, 1995, 7:109-117). We examined the HPA and behavioral effects of continous central NT infusion (1 pmol/hour for 14 days; via Alzet minipumps) into the lateral ventricle of male, 3 month old Long-Evans rats. Significant increases ($p < 0.05$) in basal HPA activity occurred during the dark phase of the diurnal cycle in the NT-treated animals compared to saline controls. At the end of the 14 day NT-infusion period, mineralocorticoid (MR) and glucocorticoid (GR) receptor levels were assessed in several brain areas. No differences in MR binding capacity were noted in hypothalamus, pituitary or hippocampus. A significant reduction ($p < 0.05$) in GR binding occurred in the hippocampus of chronic, NT-treated animals. NT- and saline-treated rats exhibited comparable ACTH and B levels during a 20-min immobilization stress; however, following termination of the stressor, plasma ACTH and B levels were significantly ($p < 0.05$) higher in the NT-treated group. This increase in HPA activity following stress may be associated with an impairment in HPA negative-feedback inhibition in the NT-treated animals. Taken together, these findings suggest that chronic NT treatment functions as a chronic stressor, elevating basal HPA activity, decreasing GR binding as well as altering negative-feedback and HPA responses to acute stressors. A significant decrease ($p < 0.05$) in mean locomotor activity was also noted in the chronically-treated NT animals following exposure to a novel environment. This decrease was restricted only to the first day of testing. As one of the behavioral charactistics of HPA hyperactivity is an increase in reactivity towards novelty (Stenzel-Poore et al., 1994, *J. Neurosci.*, 1994, 14: 2579-2584) it is possible that a NT-induced increase in HPA activity may in part be related to the behavioral response to novelty seen in these animals. Supported by MRC and FCAR.

DEVELOPMENTAL SHIFT IN ADRENERGIC RECEPTOR TYPE MEDIATING CATECHOLAMINE EFFECTS ON STRESS-INDUCED ACTH SECRETION IN THE RAT. C.-D. Walker*, D. Lavallée. McGill University, Douglas Hospital Research Center, Montréal, Canada.

During the first 2 weeks of life, rats exhibit low basal and stress-induced corticosterone (B) secretion and blunted adrenal sensitivity to ACTH. Maternal separation for 24h (SEP) increases basal adrenocortical activity, potentiates stress responses and most likely results in sympathetic activation. However, how increased catecholamine secretion following SEP could participate in the enhanced ACTH secretion is unknown. Before testing the effects of adrenergic blockade on ACTH secretion following SEP, we first used a 3min exposure to ether as an acute stressor known to stimulate catecholamine release. The effects of propranolol (3mg/kg,ip,-60min), prazosin (0.4, 2 mg/kg,ip,-60min) or idazoxan (1, 5 mg/kg,ip,-30min) pretreatment on basal and ether-induced ACTH and B secretion were determined in 9-10 days-old (d) and in 22-23d intact neonates. Saline pretreatment was used as a control. Blood samples were collected at 0, 5, and 30min after the onset of ether stress. Both prazosin and idazoxan increased basal and stimulated ACTH and B secretion at the highest doses in 10d neonates compared to saline-treated controls. Propranolol had no effect on ACTH or B release. In contrast, in 22d neonates, propranolol and prazosin decreased stress-induced ACTH secretion in an adult-like fashion while idazoxan tended to increase basal ACTH secretion. These results suggest that the control of neonatal ACTH secretion by alpha1-adrenergic receptors shifts from being inhibitory to mainly stimulatory with age. Alternatively, age-related changes in the distribution of hypothalamic adrenergic receptor types or efficacy of coupling to second messengers might dictate different effects on ACTH secretion in early neonatal life. We are now determining whether changes in central catecholamine release and/or alpha1-adrenergic receptors would affect the control of ACTH release following SEP in neonates. (Funded by NSERC and FCAR of Canada).

DISSOCIATION BETWEEN HORMONAL AND BEHAVIORAL STRESS RESPONSES TO THE FORCED SWIM TEST IN LACTATING RATS. D. Lavallée, G. Trottier, J. Rochford, P. Boksa*, C.-D. Walker. McGill University, Douglas Hospital Research Center, Montréal, Canada.

Lactation in the rat is associated with elevated corticosterone (B) release and blunted adrenocortical responses to stress. Because B secretion in the forced swim test (FST) at the time of the first swim (15min) is thought to facilitate immobility retention in a second session (5 min) 24h later, we determined whether lactating females would exhibit changes in immobility related to the magnitude of their basal and stress-induced ACTH and B secretion. Females in early (EL, d8-10) or late (LL, d17-19) lactation were compared to virgins or male rats for their acquisition and retention of immobility as well as for their ACTH and B responses to the FST. Intact lactating and virgin females were compared to their adrenalectomized (ADX, 5 days) or ovariectomized (OVX, 10 days) counterparts. Although ACTH and B responses to stress were similar in males and virgin females, immobility scores were greater in males than in virgins on both days of testing. Immobility retention occured in young males, but was not observed in any of the female groups, lactating or not. In contrast, basal B secretion was elevated in lactating females (EL>LL>V), the magnitude of the ACTH response was blunted in intact and ADX lactating females compared to virgins (V>EL>LL), but no differences in immobility scores were observed as a function of lactation. In OVX females (V or EL) immobility was decreased and basal ACTH and B was slightly reduced compared to intact rats. We conclude that: 1) dissociation between endocrine and behavioral responses occur as a function of sex and lactational status, questioning the facilitatory effect of B on immobility retention and 2) blunted stress responses in lactating females are not caused by increased basal B and thus enhanced inhibitory feedback on the adrenocortical system since they are still observed in ADX females. DIFFERENTIAL PROCESSING OF THE NEURO-ENDOCRINE PROTEIN "VGF" IN MAMMALIAN HYPOPHYSIS. G-L. Ferri*, R.M. Gaudio, I.F. Castello, A. Rinaldi#, A. Levi#, P. Berger°, R. Possenti# Univ. Dept. Cytomorphology, Cagliari & Oasi IRCCS, Troina, #CNR Inst. Neurobiology, Rome, Italy; °Inst. Biomed. Aging, Acad. Sciences, Innsbruck, A.

The neuro-endocrine protein "VGF" contains multiple potential cleavage sites and a cleavage-amidation site. Antisera to five VGF domains, plus the putative amidated sequence (*NH_2) were used in immunocytochemistry and Western blot. In Guinea-pig, bovine, pig and human (n=8-15/species) all sera stained anterior pituitary endocrine cells. As in rat, immuno-reactivity for the VGF domains was mainly found in lactotropes and/or gonadotropes, though incomplete overlap and inter-species differences were seen. Large, intermediate and small molecular weight forms were found in Western blot with most sera, while *NH_2-immunoreactivity was restricted to intermediate-small forms. In rat, no reactivity was found for the *NH_2-serum, in either immunocytochemistry or Western blot.

Thus, C-terminally amidated VGF fragments would be produced in a number of mammals. As for many regulatory peptides, C-terminal amidation may suggest biological significance of such *VGF* gene products.

HIGHLY SENSITIVE BRAINSTEM SITES FOR GLUCOPRIVIC STIMULATION OF THE ADRENAL MEDULLA. S. Ritter* and T.T. Dinh. Dept of VCAPP, Washington State University, Pullman, WA 99164-6520 USA.

Glucoreceptors controlling adrenal medullary secretion are known to be centrally located since administration of glucoprivic agents directly into the brain elicits a sympathoadrenal response. In addition, systemic glucoprivation elicits sympathoadrenal response in decerebrate rats, indicating that glucoreceptors are located in the hindbrain. The present study mapped the hindbrain between the facial nerve and obex of rats (n=70) for glucoreceptive sites. The antimetabolic glucose analogue, 5-thioglucose (5TG, 12-24 ug in 100-200 nl) and 0.9% saline were injected through small diameter cannulas. Blood was collected at 8 intervals during a 195 min period beginning 15 before the injection. At positive sites, blood glucose began to rise with short latency and peaked at about 60 min post injection. Positive sites were found to be closely associated with catecholamine (CA) cell groups, especially A1/C1 and C2, where 24 ug of 5TG raised glucose levels from 92 to 240 mg/dl. Surrounding sites, including ventricular sites, were less positive or negative. These hindbrain CA neurons may be involved in the adrenal medullary hyperglycemic response, since they express Fos-like immunoreactivity in response to glucoprivation and those of A1/C1 directly innervate adrenal medullary preganglionic neurons. However, additional experiments will be required to determine whether A1/C1 and C2 neurons are themselves glucoreceptive or whether other neurons in close proximity to these CA neurons are the putative glucoreceptor cells.

638.16

METYRAPONE'S EFFECTS ON CONDITIONED FEAR'S ENHANCEMENT OF MORPHINE ANALGESIA IN FEMALE SPRAGUE-DAWLEY RATS. H.S. Stock*, B.J. Caldarone, G.C. Abrahamsen, D.L. Mongeluzi, & R.A. Rosellini. Dept. of Psychology, University at Albany: SUNY, Albany, NY 12222.

A number of studies have reported that both the immediate and proactive effects of exposure to a shock stressor are less pronounced in female than in male rats. A separate area of research has demonstrated that female rats are less reactive to the analgesic effects of morphine than males. Experiments from our laboratory, as well as others, have found that exposure to a context associated with shock (i.e., conditioned fear context), at the time of morphine administration, enhances the analgesic effects of morphine. We have recently demonstrated that female rats show less pronounced conditioned fear-induced enhancement of morphine analgesia than male rats. The purpose of the present experiment was to begin to elucidate some of the hormonal mechanisms that may mediate this previously observed sex difference. In the present experiment female rats were injected with 75mg/kg of metyrapone, a corticosterone synthesis inhibitor. This dose has been demonstrated to suppress a female's stress-induced corticosterone levels to that of males. Three hours after injection the females were tested for enhancement of morphine analgesia during re-exposure to the conditioned fear context. The results demonstrated that females that were exposed to the conditioned fear context and pre-treated with metyrapone had higher morphine-induced analgesia than the control groups. The finding from this experiment suggests that corticosterone may play a role in mediating a female's response to conditioned fear-induced enhancement of morphine analgesia.

DEPRENYL INHIBITS THE DEVELOPMENT OF MAMMARY TUMORS IN RATS. S. ThyagaRajan*, S. Y. Felten and D. L. Felten, Dept. of Neurobiol. & Anat., Univ. of Rochester, Rochester, NY 14642.

Deprenyl, an irreversible monoamine oxidase-B (MAO-B) inhibitor, has been reported to decrease the incidence of spontaneous mammary tumors in old female rats by suppressing the metabolism of dopamine in the hypothalamus. Further, numerous studies have shown that deprenyl has a neuroprotective function independent of its MAO-B inhibitory activity. The purpose of this study was to investigate whether deprenyl can exert a neuroprotective effect in rats with dimethylbenzanthracene (DMBA)-induced mammary tumors. Female Sprague-Dawley rats (28-29 days old) were injected i.p. with 0.25 mg/kg or 2.5 mg/kg of deprenyl (Dep) or the vehicle (saline) daily for 4 weeks before the administration of DMBA. Following the administration of DMBA, the rats were treated with saline or deprenyl daily for 26 weeks . Below are the results of tumor number and body weight measurement at the end of the treatment period.

	Number of tumors/rat	Incidence of tumors	Body weight (gms)
Saline/Saline	2.8±0.3	87%	425±12
Dep 0.25/Saline	2.4±0.2	53%	409±14
Dep 2.5/Saline	2.4±0.3	53%	396±11
Saline/Dep 0.25	2.3±0.5	67%	431±15
Dep 0.25/Dep 2.5	1.7±0.2	60%	434±17
Saline/Dep 2.5	1.5±0.3	40%	396±10
Dep 2.5/Dep 2.5	1.4±0.2	33%	399±7

These results demonstrate that treatment with 0.25 mg and 2.5 mg of deprenyl pre- and post-administration of DMBA, and with 2.5 mg of deprenyl following the administration of DMBA causes inhibition of mammary tumor development in rats possibly by maintaining the activity of the tuberoinfundibular dopaminergic system in the hypothalamus.

639.2

TUMORS SECRETING PLACENTAL LACTOGEN-I (PL-I) OR HYPOTHALAMIC IMPLANTS OF LACTOGENIC HORMONES INHIBIT SUCKLING-INDUCED PROLACTIN BUT NOT THE ANTE-PARTUM PROLACTIN SURGE. R.J. Flietstra and J.L. Voogt*. Physiology Dept., Univ. of Kansas Med. Ctr., Kansas City, KS 66103.

Prolactin (PRL) secretion is inhibited by dopamine (DA) released from tuberoinfundibular dopaminergic (TIDA) neurons of the hypothalamus. High PRL levels stimulate TIDA neurons, inhibiting further PRL release. Other lactogenic hormones, specifically placental lactogens (PLs), can participate in this negative feedback loop. High circulating levels of PLs at midpregnancy terminate the twice daily PRL surges in female rats. In the dark period preceding parturition, however, an ante-partum PRL surge occurs despite continuously high levels of PL. Intrahypothalamic pituitary grafts also had no effect on this surge (Br. Res. Bul. 36:413, 1995). The aim of this study was to examine if the lactogenic hormone negative feedback loop is operational during the ante-partum surge. Sprague-Dawley rats were mated and received media or $1x10^6$ Rcho-1 (PL-I secreting) or HRP-1 cells (nonsecretors of lactogens) under the kidney capsule on the 10th day of pregnancy. Other pregnant rats received a hypothalamic implant of 25μg of albumin, ovine PRL or rat PL-I on day 19 or 20 of pregnancy. Serial blood samples were taken via carotid cannula from all rats. Two to 3 days following parturition, pups were removed for 4-6 hours, returned, and trunk blood samples taken after 1 hr suckling. Rcho-bearing rats (peak PRL level, 131 ng/ml) did not have a significantly reduced ante-partum PRL surge as compared to HRP-bearing (peak PRL level, 107 ng/ml). Yet suckling-induced PRL release was reduced by 86% in the Rcho-bearing dams as compared to the control dams ($p<.05$). Similarly, ante-partum PRL release was not reduced in rats given hypothalamic PRL (peak PRL level, 82 ng/ml) or PL-I (peak PRL level, 125 ng/ml) as compared to albumin-implanted dams (peak PRL level, 92ng/ml). However, suckling-induced PRL release was reduced more than 89% in both groups as compared to control rats ($p<.05$). This suggests that the lactogenic hormone negative feedback loop which is present during most of pregnancy and early lactation, is not operational just prior to parturition. Supported by NIH Grant HD 24190.

CHEMOTHERAPEUTIC EFFICACY: INFLUENCE OF PSYCHOSOCIAL FACTORS ON THE RESPONSE OF A MOUSE MAMMARY CARCINOMA (SC115). **L.R. Kerr, M.S. Grimm, W.A. Silva, T. P. O'Connor*, J.T. Emerman, J. Weinberg. Dept. of Anatomy, University of British Columbia, Vancouver, B.C., V6T 1Z3, Canada.**

In the present study, we demonstrated that psychosocial factors significantly altered the response of the transplantable androgen responsive Shionogi mouse mammary carcinoma (SC115) to adriamycin (AD) and cyclophosphamide (CY). Male DD/S mice were either reared individually then group housed (IG), or reared group housed and then singly housed (GI) following tumor cell or vehicle injection. Chemotherapy or drug vehicle injections (3 times at 7 day intervals) were started when tumors reached 1 g. To monitor the toxic effects of chemotherapy, control mice bearing no tumors (NTC) also received 3 chemotherapy treatments beginning 16 days following tumor vehicle injection. Survival probability was significantly increased in mice in IG (47%) compared to GI (19%) groups due to greater inhibition of tumor growth. The number of deaths due to the toxicity of chemotherapy was similar between groups. This animal tumor model should aid in elucidating mechanisms that may govern the responsiveness of tumors to chemotherapy and the variability of chemotherapeutic efficacy in human cancer patients.

PROLONGED TREATMENT OF PERTUSSIS TOXIN AFFECTS MORPHINE'S ACTION ON TIDA NEURON ACTIVITY AND PROLACTIN SECRETION. J.T. Pan* and J.Y. Lin, Dept. Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan, R.O.C.

The effects of pertussis toxin (PTX) pretreatment on basal and morphine-affected changes of tuberoinfundibular dopaminergic (TIDA) neuron activity and serum prolactin level in ovariectomized Sprague-Dawley rats treated with a long-acting estrogen (polyestradiol phosphate, 0.1 mg/rat, sc) were assessed in the study. The activity of TIDA neurons was determined by measuring the turnover rate of dopamine, the concentrations of DOPAC or the accumulation of DOPA in the median eminence. Acute (30-90 min) treatment of PTX (0.025-2.5 μg/rat, icv) had no significant effect on any of the parameters measured. Prolonged (24 h) treatment of PTX (1 μg/rat, icv), while had no effect on basal TIDA neuron activity either, significantly reduced morphine's (10 mg/kg BW, sc) inhibitory effect on TIDA neuron activity (using DOPA, but not DOPAC as the index), and stimulatory effect on PRL release. The dopamine levels in the median eminence, however, were significantly reduced by prolonged treatment of PTX, indicating a reduction of TIDA neurons. These results suggest that PTX-sensitive GTP-binding proteins may be responsible for the maintenance of TIDA neurons, and for mediation of the inhibitory effect of morphine on TIDA neuron activity, and in turn, the stimulation of prolactin secretion.

ONTOGENY OF ADRENAL NITRIC OXIDE SYNTHASE ACTIVITY AND RESPONSE TO ENDOTOXIN. J.R. Tobin* and L.C. Moore. Department of Anesthesia, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27157-1009

Nitric oxide (NO) acts as an inhibitory neurotransmitter in the autonomic nervous system and has been isolated in the adrenal medulla and cortex. In the adrenal cortex NO inhibits steroid secretion. Developmental differences in sympathoadrenal responses to stress and endotoxemia have been clinically noted with early fatigue in juveniles. We examined the ontogeny of nitric oxide synthase (NOS) activity in rat adrenal, the adrenal NOS response to endotoxin, and effect of treatment with systemic dexamethasone.

Wistar Kyoto rats of four age groups were studied (<48 hrs, 2, 4, and 12 wks of age [n=8/group]). Animals were anesthetized with pentobarbital ip and adrenals were harvested, homogenized and centrifuged (10000*g for 15 min at 4°C). In a second experiment, endotoxin (1 mg/kg ip) or saline was administered to 4 and 12 week old rats (n=8/group) 4 hr prior to harvest. A third cohort (n=8/group) of 8 week old rats received saline or dexamethasone (0.2 or 2.0 mg/kg ip daily) for 1 week. NOS activity was assayed in supernatant cytosolic fractions by conversion of [^{14}C]-arginine to [^{14}C]-citrulline. Data were analyzed by ANOVA or the Kruskal-Wallis test with $p<0.05$ considered significant (*).

NOS activity in adrenals is greatest in newborn rat pups and declines with age (<48 hr: 9.04±1.51, 2 wk: 7.39±0.8, 4 wk: 5.68±0.48*, 12 wk 3.98±0.50* pmol/mg prot/min [mean ±S.E.]). The 12 week group was statistically different than all other age groups. Endotoxin elicits an increase in NOS activity in 4 week old rats: 22.1±4.3* vs saline control 6.0±0.5, but no increase in 12 week old rats: 3.89±0.62 vs saline 2.98±0.3 pmol/mg prot/min. Western blotting demonstrated increased expression of NOS protein. Dexamethasone causes a dose-dependent decrease in adrenal NOS : saline 4.37±0.5, 0.2 mg/kg 3.21±0.53, 2.0 mg/kg 1.95±0.28* pmol/mg prot/min.

Age related differences in sympathoadrenal responses to stress are correlated with developmental differences in adrenal NOS expression. As NO appears to act as an inhibitory neurotransmitter in the adrenal, age related differences in NOS expression may partially explain juvenile sympathoadrenal fatigue during stress and endotoxemia. Dexamethasone elicits dose dependent adrenal atrophy and decreased adrenal NOS.

NITRIC OXIDE SYNTHASE SUBTYPE I AND SUBTYPE III IN THE PINEAL GLAND OF THE SHEEP: AN EXPERIMENTAL IMMUNOHISTOCHEMICAL STUDY. **M.O. LÓPEZ-FIGUEROA[1], J.P. RAVAULT[2], B. COZZI[3]* AND M. MØLLER[1]** [1] Institute of Medical Anatomy, University of Copenhagen, DK-2200 Copenhagen, Denmark; [2] Institute of Anatomy of Domestic Animals, University of Milan, I-20133 Milan, Italy; [3] Institute of Comparative Physiology, University of Tours, F-37200 Tours, France.

By use of immunohistochemistry, nerve fibres immunoreactive to subtype I (neuronal) of the enzyme nitric oxide synthase (NOS) were demonstrated in the pineal gland of sheep. The NOS-immunoreactive fibres were located in the pineal capsule and the connective tissue septae of the gland, but nerve fibres were also present adjacent to blood vessels and intraparenchymally between the pinealocytes.

By use of an antibody directed against subtype III (endothelial), only the endothelium of pineal blood vessels was stained. The pinealocytes of the sheep were not stained neither by the antibody against subtype I nor subtype III.

In order to trace the origin of the NOS-immunoreactive nerve fibres, a series of sheep had both superior cervical ganglia removed. NOS nerve fibres were still present in the gland one month after the ganglionectomy. Also the endothelial NOS-immunoreactivity was present one month after the bilateral superior cervical ganglionectomy.

Thus, our data show a prominent innervation of the sheep pineal gland with nitric oxide synthase immunoreactive fibres with origin outside the sympathetic nervous system. This indicates that the sheep pinealocyte metabolism and the regulation of the circulation might be influenced by nitric oxide originating both in non-sympathetic nerve fibres as well as by nitric oxide with origin in the endothelium of the blood vessels. The nitric oxide, located presynaptic in the nerve fibres, might also regulate release of neuropeptides located in the same fibres.

THE USE OF THE NEUROTROPIC VIRUS PSEUDORABIES TO DEMONSTRATE CNS PATHWAYS TO THE RAT FOOTPAD - AN EXTENDED VIEW OF THE ATONOMIC NEURAXIS. B.J. Oldfield* and R. Miselis+. Howard Florey Institute, University of Melbourne, Australia 3052 and University of Philadelphia, PA 19104+

The innervation of the footpad has been utilised recently as a model for the chemical coding of defined autonomic pathways. The aim of this study is to use the transynaptic transfer of psuedorabies virus (PRV) to map the distribution of chains of connected neurons directed to sudomotor and vasomotor endpoints in the footpad. Thirty four male Sprague Dawley rats were anaesthetised with sodium pentobarbitone (60 mg/kg i.p.) and 0.5 µl of a solution containing PRV was injected into several sites in the left forepaw. After survival periods ranging between 24 and 100 hours, rats were reanaesthetised and perfused transcardially with 4% paraformaldehyde. Frozen sections were exposed to antisera raised against PRV as well as tyrosine hydroxylase (TH) and a range of peptides. Infected neurons were first detected in the ipsilateral stellate ganglion 40 hrs. after inoculation. Infected neurons included populations, which were TH-positive and TH-negative (cholinergic, approx 30%). Over the next 50 hrs. infected neurons were found first in the sympathetic preganglionic cell groups of the upper thoracic spinal cord then coincidentally in the rostroventrolateral medulla and parvocellular paraventricular nucleus (PVN). Up to 50% of the neurons in the medulla were catecholaminergic whereas infected neurons in the PVN were not vasopressin positive and less than 1% were colocalised with oxytocin. Subsequently neurons were infected in the lamina terminalis, bed nucleus of the stria terminalis and preoptic area. Despite a general codistribution of the latter neurons with neurons containing atrial natriuretic peptide (ANP) none were found to the ANP-positive. These results demonstrate discrete populations of neurons that are directed to the footpad and provide the basis for neurochemical coding of these pathways.

This work was supported by grants from the NHMRC, Australia.

INFLUENCE OF SYMPATHETIC DENERVATION OF THE EYE ON OUTFLOW OF THE INTRAOCULAR FLUID. M.I.Rasumovskij*, N.V.Balashov, A.R.Grigorian, Institute of Occupational Guidance, Lab. of Vision Physiology, 195067, St.Petersburg, Russia.

In experiments on anaesthetized cats the effects of sympathetic denervation of the eye on the outflow of the intraocular fluid, which is one of the main factors of the level of intraocular pressure, have been investigated. The accuracy of the eye sympathetic denervation was controlled morphologically and by the level of adrenaline in the iris and cyliary body. The results clearly demonstrate that the level of the background outflow of the intraocular fluid was practically the same both in control and sympathectomized groups of animals. When the intraocular pressure was rised step by step the sharp increasing of the outflow of intraocular fluid in denervated eye was observed. At the same time the visible decreasing of noradrenaline in eye tissue was marked. These findings suggested that postganglionic sympathetic fibres exert direct regulatory action on the eye vasomotor tones and drainage apparatus and any disturbances in this system can lead to loss adaptive functions supporting intraocular pressure on normal level.

PROADRENOMEDULLIN N-TERMINAL 20 PEPTIDE (PAMP) REDUCES NICOTINE-INDUCED CURRENTS IN BOVINE ADRENAL CHROMAFFIN CELLS. I. Shibuya, T. Nagatomo, N. Kabashima, Y. Ueta, Y. Toyohira,[1] Y. Uezono,[1] N. Yanagihara,[1] A. Wada,[2] F. Izumi[1] & H. Yamashita* Depts. of Physiol. and Pharm.,[1] Univ. of Occup. and Environ. Health, Kitakyushu 807, Japan and Dept. of Pharm.,[2] Miyazaki Medical collage, Miyazaki, 880, Japan

Proadrenomedullin N-terminal 20 peptide (PAMP), a novel peptide processed from the adrenomedullin precurser, is co-secreted from adrenal medulla with adrenomedullin as well as catecholamines. Both PAMP and adrenomedullin were shown to have hypotensive effects (FEBS Lett. 351, 1994). Recently, it has been reported that PAMP reduces catecholamine secretion induced by the nicotinic receptor stimulation (J. Neurochem., 64, 1995). To elucidate the anticholinergic mechanisms of PAMP, we recorded nicotine-induced currents from bovine adrenal chromaffin cells and analyzed the effects of PAMP on the currents by using the whole-cell patch-clamp technique. PAMP alone (10^{-6}-10^{-9} M) did not induce ionic currents at a holding potential of -80 mV, however, it dose-dependently reduced inward currents induced by nicotine (Nic, 10^{-5} M). The inhibition remained for about 10 min after washout of PAMP. When applied during Nic stimulation, PAMP accelerated the desensitization process. These results suggest that PAMP inhibits nicotinic currents by increasing the rate of desensitization and that PAMP may play a role as an anti-hypertensive hormone by inhibiting catecholamine secretion via autocrine and/or paracrine.

639.10

INNERVATION PATTERN OF SYMPATHETIC PREGANGLIONIC NEURONS PROJECTING TO SUPERIOR CERVICAL AND STELLATE GANGLIA. K. Asamoto*, N. Tamamaki and Y. Nojyo., Dept. of Anatomy, Fukui Medical School, Matsuoka, Fukui 910-11, Japan.

Anterograde labeling technique with PHA-L was employed to observe the arborization pattern of a single preganglionic axon in the superior cervical ganglion (SCG) and stellate ganglion (STG) of rats. We drew three preganglionic axons in both SCG and STG in their full length. In SCG, the labeled axon extended for 600-700 µm in the rostrocaudal and about 200 µm in the transverse direction. Terminal twigs of each preganglionic axon surrounded 11, 14 and 11 postganglionic neurons, respectively. In STG, the extent of axonal arborization was 400-800 µm in the rostrocaudal and 400 µm in the transverse direction. These axons surrounded at least 21, 19 and 20 postganglionic neurons, respectively. We also observed the segmental relationship between upper thoracic spinal cord and cervical sympathetic ganglion detecting c-fos like protein in postganglionic neurons after electrical stimulation of ventral roots at each spinal segment. We could observe clear segmental relationship between spinal cord and STG, but not between spinal cord and SCG.

639.11

EFFECT OF PARATHYROID HORMONE AND CALCITONIN ON CHOLINERGIC NEUROTRANSMISSION IN RAT PARATHRYOID GLANDS D.P.Cardinali*, J.E.Stern, Depto. de Fisiologia, Facultad de Medicina, Universidad de Buenos Aires, Buenos Aires, Argentina.

We have shown in previous studies that the activity of sympathetic and parasympathetic nerves in the cervical region affect parathyroid hormone (PTH) and calcitonin secretion. Additionally, cholinergic neurotransmission in superior cervical ganglion (a site of origin of the sympathetic innervation to the thyroid-parathyroid territory) was significantly modified by calciotropic hormones. To further substantiate the hypothesis of the existence of a feedback loop in neural regulation of calcium homeostatic hormones, the effect of PTH and calcitonin on ^{3}H-choline uptake and on ^{3}H-acetylcholine synthesis by rat parathyroid glands were examined. Choline uptake synthesis was measured by incubating freshly dissected parathyroid glands with ^{3}H-choline in the presence or absence of hemicolinium-3 (a specific inhibitor of the high affinity carrier of choline). Acetylcholine synthesis was assayed by the conversion of ^{3}H-choline to ^{3}H-acetylcholine. Incubation of tissue with PTH or calcitonin resulted in a bell-shaped, dose-dependent inhibition of ^{3}H-choline uptake. The effect of PTH was blunted by preincubation with NLe8-18-PTH (3-34) amide (a specific PTH antagonist). PTH induced a dose-dependent inhibition of ^{3}H-acetylcholine synthesis, effect also blocked by the specific peptide antagonist. Calcitonin was effective to block ^{3}H-acetylcholine synthesis only at a concentration of 10^{-7}M. This results indicate that in vitro, PTH and to a less extent calcitonin, inhibit cholinergic activity in rat parathyroid glands. In view of the inhibitory effect that parasympathetic terminals have on PTH secretion, this feedback mechanism could facilitate a fast release of PTH upon a hypocalcemic challenge

SYMPATHETIC STIMULATION ACCELERATES WOUND HEALING AT THE EPIDERMAL AND DERMAL LEVELS OF SKIN L.R. Kim and B.H. Pomeranz* Departments of Physiology and Zoology, University of Toronto, Toronto, ON, Canada M5S 1A1

Neurogenic inflammation is mediated by unmyelinated sensory afferents and sympathetic efferents. Although inflammation is the initial stage of wound healing, the role of nerves in wound healing is not well-established. In a recent study we demonstrated that sympathetic post-ganglionic neurons (SPGNs) were necessary for normal rates of cutaneous wound healing since sympathetic denervation significantly attenuated the rate of wound healing.

The present study further elucidates the role of SPGNs in cutaneous wound healing. After stimulation of the SPGNs using 0.2mg/kg of 6-hydroxydopamine (6-OHDA) applied locally during the inflammatory period, we report a 43% increase in breaking strength, a measure of dermal collagen re-establishment ($p<0.05$, $n_e=13$, $n_c=10$, one way ANOVA). Furthermore, a 38% increase was found in the rate of epidermal wound healing as measured by transcutaneous electrical resistance (TER) ($p<0.05$, $n_e=21$, $n_c=18$, one way ANOVA). This new method we have developed has been histologically shown to demonstrate the re-establishment of the ion-resistant rat epidermis. Control animals were given the vehicle solution, 1% ascorbic acid. These results show that chemical stimulation of SPGNs markedly accelerates skin wound healing at both the epidermal and dermal levels. These are the first studies to show a role for SPGNs in the regulation of wound healing. It has been suggested that the SPGNs promote neurogenic inflammation and thus wound healing by the secretion of NA, ATP, and the *de novo* synthesis of prostaglandins at the sympathetic terminal.

ADRENOCORTICAL SYMPATHETIC CO-CULTURES: A MODEL FOR THE STUDY OF NEURAL-ADRENOCORTICAL INTERACTION. J.L. Buberel*, M.A. Holzwarth, Neuroscience Program and Department of Physiology, University of Illinois, Urbana, Illinois, 61801.

In order to study the sympatho-adrenal interactions of the adrenal cortex, we have established co-cultures of adrenocortical and sympathetic ganglion cells. Sympathetic neurons from sympathetic chain ganglia of 4-6 day old rat pups are grown in supplemented DME/F12 medium and dissociated adrenocortical (AC) cells from adult rats are added at various times. We have used immunocytochemistry (ICC) to characterize the cell cultures and to study the relationships between the sympathetic neurons and AC cells. The sympathetic neurons usually cluster in groups of 2-10, and begin to extend neurites within 24 hours. Neurite length can exceed 5 mm, and neurites often form fascicles after 4 days. These sympathetic neurons, identified by 2H3 ICC, continue to express tyrosine hydroxylase and dopamine-β-hydroxylase. A subpopulation are also immunoreactive for VIP. We have used synaptophysin ICC as a marker for neuronal maturation and potential for functional autonomic synapse formation. Synaptophysin is detectable after 2 days, and forms puncta along neurites and cell bodies after 4 days, suggesting the formation of presynaptic release sites. AC cells are generally rounded, contain many lipid droplets, express 3-β-hydroxysteroid dehydrogenase, and secrete steroids. The addition of AC cells to sympathetic cultures at days 2, 7, and 14 does not appear to affect neurite extension or the expression of 2H3, dopamine-β-hydroxylase, tyrosine hydroxylase, or synaptophysin in the sympathetic neurons. The neurites grow close to, over, and around the AC cells. Thus, neither the presence of the AC cells nor their secreted products, appear to inhibit the growth of the neurites from the sympathetic neurons. The close morphological relationship attained in vitro suggests that this model is a useful tool for the study of the sympathetic control of AC cellular functions.

639.14

PRIMARY CO-CULTURE OF CORTICOSTEROIDOGENIC AND CHROMAFFIN CELLS FROM THE FROG INTERRENAL GLAND AS A MODEL OF MEDULLARY CONTROL OF STEROIDOGENESIS.
S.L. Shepherd* and M.A. Holzwarth. Neuroscience Program and Department of Physiology, University of Illinois, Urbana, IL 61801

Recent studies show that adrenocortical cell secretion is modulated by adrenal medullary cells, and hence, indirectly by splanchnic nerve activity. We have chosen the frog adrenal as a model to study the chromaffin cell modulation of adrenocortical secretion because chromaffin and adrenocortical cells are interspersed. Also, the frog chromaffin cells, like a subpopulation of their mammalian counterparts, extend processes which might allow direct interactions between corticosteroidogenic and chromaffin cells. To facilitate the investigation of adrenal cell interactions, we have established and characterized primary cell co-cultures of frog adrenal cells. The corticosteroidogenic cells have a low basal steroid secretion rate ($1.4x10^{-5}$ng/cell/24hr corticosterone (B), $9.7x10^{-5}$ng/cell/24hr aldosterone (aldo)) and respond to 10^{-8}M ACTH with an increase in B (15-fold) and aldo (5.3-fold) secretion. Chromaffin cells cultured in the presence of adrenocortical cells extend unbranched processes of 50 to 300 μm which often abut upon or overlie adrenocortical cells. The chromaffin cells continue to express tyrosine hydroxylase, PNMT, dopamine ß-hydroxylase, and enkephalin and are also immunoreactive for NCAM and linc (amphibian neural cell marker). Techniques for demonstrating transmitter release from chromaffin cells and adrenocortical steroidogenesis at the level of single cells are being optimized. We use indirect immunofluorescence of dopamine ß-hydroxylase, a chromaffin granule membrane antigen, to show neurotransmitter release from chromaffin cells elicited by 10 minute stimulation with 2 mM carbamylcholine or 55 mM potassium. Activation of adrenocortical cells following 30 minute stimulation with 2 mM carbamylcholine or 10^{-8}M ACTH is shown by Fos. These techniques will be used to test the hypothesis that chromaffin cell activity directly modulates steroidogenesis.

DRINKING AND BLOOD PRESSURE RESPONSES TO CENTRAL INJECTION OF L-NAME IN CONSCIOUS RATS. H. Liu, M.L. Terrell, J.Y. Summy-Long†, M. Kadekaro*. Division of Neurosurgery, UTMB, Galveston, TX and †Department of Pharmacology, Hershey Medical Center, Pennsylvania State University, Hershey, PA.

We studied the effect of N^G-nitro-L-arginine methyl esther (L-NAME), a potent blocker of nitric oxide (NO) synthase, on water intake and blood pressure (BP) responses in conscious male albino rats during osmotic stimulation and hemorrhage. Thirty min after injection of 1.0 M NaCl (15 ml/kg, s.c.) or 10 min after the beginning of hemorrhage (0.7 ml/min to a 20% blood volume loss), artificial cerebrospinal fluid (aCSF) or L-NAME (10, 250 or 500ug/5μl) were injected icv. Ten min later, water was presented to rats and its cumulative intake was measured for 2h. During osmotic stimulation and hypovolemia, L-NAME at doses of 250 and 500μg, but not 10μg, attenuated ($p<0.05$) water intake compared to the control group. Mean arterial BP, which increased 30 min after osmotic stimulation ($p<0.05$), remained at pressor levels after 250 and 500μg of L-NAME, but decreased progressively below basal levels after treatment with aCSF and the lowest dose of L-NAME (10μg). Ten min after starting hemorrhage, BP fell ~ 60 mm Hg ($p<0.05$) in all groups but increased after hemorrhage ceased. The fall in BP associated with hemorrhage returned to control levels after treatment with 250 and 500μg of L-NAME but not after aCSF or 10μg of L-NAME. These results indicate that NO is involved in the regulation of drinking behavior and may have an important role in the central control of BP during osmotic stimulation and hypotensive hemorrhage. FLAVONES ANTAGONIZE LIPOPOLYSACCHARIDE-INDUCED SICKNESS IN MICE. R. J. Fishkin, R. Corbett* and J. T. Winslow.
Hoechst-Roussel Pharmaceuticals, Inc.
Neuroscience PGU, Somerville, NJ 08876-1258.

Previous studies indicate that indomethacin, methylprednisolone and an interleukin-1 receptor antagonist inhibit lipopolysaccharide (LPS)-induced sickness behavior in rats. In the current studies we replicated and extended these findings in the mouse to a novel class of anti-inflammatory drugs: flavones. A relatively low dose of LPS (15 μg/kg, ip) consistently induced a 50% reduction in the social investigation of a juvenile conspecific by an adult male mouse. Pretreatment with methylprednisolone (30 mg/kg, ip), indomethacin (3-10 mg/kg, ip), and ibuprofen (10 mg/kg, ip), but not tenidap (1-100 mg/kg, ip) 1 hr before LPS injection completely blocked LPS-induced sickness behavior. Dexamethasone (0.1 mg/kg, ip) significantly attenuated LPS-induced sickness behavior. The flavones L82-05971 (0.25 mg/kg, ip), L86-8276 (0.03 mg/kg, ip) and chrysin (10 mg/kg, ip) also antagonized LPS-induced sickness. The psycho-motor stimulant amphetamine (2-4 mg/kg, ip) did not relieve, and actually exacerbated LPS-induced decreases in investigation. This model may provide a sensitive method of identifying compounds which selectively antagonize behavioral effects associated with interleukin release.

Spatial organization and representation are impaired in Cushing's disease. **H. Forget[1], H. Cohen[1]*, M. Somma[2], and A. Lacroix[3]. [1]Laboratoire de neuroscience de la cognition, Université du Québec, Montréal, Qc, H3C 3P8, Canada; [2]Service d'Endocrinologie, Hôpital Notre-Dame et [3]Service d'Endocrinologie, Hôpital Hôtel-Dieu, Université de Montréal, Qc, H2L 4K8, Canada.**

It is now well established that the brain is a major target for glucocorticoid hormones and that cognition and emotion are affected by inadequate levels of circulating hormones. The hippocampus is a crucial structure as it is the richest in glucocorticoid-binding receptors and is thus particularly vulnerable to glucocorticoid excess. In this study, we tested whether an excess of glucocorticoid hormones has an effect on the treatment of spatial organization and representation. In the animal litterature, both location and identity of an object depend upon hippocampal integrity. In this perspective, we compared the spatial organization and representation (line orientation, visual organisation, visual recognition, Block Design, Object assembly, Picture completion) of 12 patients with chronic hypercortisolemia due to Cushing'disease (CD) to that of healthy control subjects yoked for age, sex and education (mean age= 45.2±9.4 yrs; mean education= 12.3±9.3 yrs). MANOVA results showed a general impairment in spatial tasks (Pillais=.5511, $F_{1,21}$= 3.27,p=.027) and, except for visual recognition, subsequent univariate F tests showed group differences in all tasks (all p's < .05). These results show that impairment in the treatment of spatial information may be associated with elevated cortisol levels in patients with CD. It remains to be established whether the observed deficits in the treatment of spatial information, in CD patients, occur at a perceptual or at a processing/treatment level.

DOPAMINE MODULATION OF GABA NEUROTRANSMISSION IN HYPOTHALAMIC ARCUATE NUCLEUS NEURONS. A.B. Belousov* and A.N. van den Pol. Dept. Biology, Stanford Univ., Stanford, CA 94305 and Sect. Neurosurgery, Yale Univ., New Haven, CT 06520.

Dopamine (DA) neurons and their terminals are widely distributed within the hypothalamus and DA plays an important role in the regulation of the hypothalamic neuroendocrine system. In our previous work, DA (30 μM) was found to decrease glutamate neurotransmission. This DA effect was partly due to a decrease in the amplitude and frequency of excitatory post-synaptic potentials (EPSPs), and could also be due to a DA-mediated increase in GABAergic activity. To explore the hypothesis that activation of GABAergic neurons might be one of the mechanisms of DA's inhibitory effect on glutamate activity we used whole cell patch clamp recording of neurons (n=49) cultured from the hypothalamus or arcuate nucleus. In current clamped neurons (average membrane potential -60 mV), DA application (10-200 μM) caused an increase in the frequency of spontaneous GABA-mediated IPSPs in the majority of the tested cells (10 of 11). In cells held at -25 mV, DA (10 μM) evoked the appearance of inhibitory postsynaptic currents (IPSCs) in 4 of 5 cells and significantly increased the amplitude (3 of 11 cells; by 150%+) and frequency (9 of 11; 300%+) of spontaneous IPSCs. The spontaneous and DA-evoked IPSCs were blocked by 50 μM bicuculline, verifying their GABAergic origin. This finding together with data showing that DA had no effect on the input resistance suggested that the observed DA effects were at least partly achieved through the potentiation of GABA release.

639.19

CALCIUM REGULATION OF HYPOTHALAMIC FOS GENE EXPRESSION FOLLOWING DEPOLARIZATION D.M. Witt* and H. Gainer, Lab. of Neurochemistry, NINDS, NIH Bethesda, MD 20892.

The complexities of the *in vivo* environment in the brain make it difficult to determine the signal transduction mechanisms involved in stimulus-coupled neuropeptide gene expression. Therefore, we have developed an *in vitro* slice explant model for examining the effects of neurotransmitter / neurosteroid stimulation of neurons in a controlled environment. Using electrophysiological and organotypic slice explant technologies, acute slice explants were used to study Fos expression in the paraventricular nucleus of the hypothalamus (PVN) derived from postnatal rats. In 1.5 hrs of stimulation *in vitro* , either K^+ (40 mM), glutamate (100 μM) or veratridine (1 μM) depolarization produced varying degrees and topographically distinct patterns of Fos expression in magnocellular, parvocellular and periventricular regions of the PVN as well as the suprachiasmatic nucleus. The role of calcium in Fos gene expression, using the above depolarization paradigms, was examined either in the absence of extracellular calcium or by pretreating the acute slice explants with N- channel or L-channel calcium blockers. In the absence of extracellular calcium, Fos induction did not occur after depolarization. The L-channel dihydropyridine (Nifedipine, 1 μM) was most effective in inhibiting depolarization induced Fos expression. In contrast, the N-channel blocker (ω -conotoxin, 1 μM) had little or no effect on Fos expression. These data strongly implicate calcium influx, via L-channels, as the principal mechanism of depolarization-induced Fos gene expression in neurons in the mammalian hypothalamus and suggests that this experimental preparation will be very useful in exploring the regulation of other immediate early genes, and neurotransmitter / neuromodulatory influences.

GASTROINTESTINAL REGULATION: GASTROESOPHAGEAL CONTROL

640.1

THE EXISTENCE OF NEURONS IN THE PARAVENTRICULAR NUCLEUS(PVN) PROJECTING TO BOTH POSTERIOR PITUITARY AND STOMACH. B.H. Lee*, W.S. Choi, K.J. Cho, M. O. Kim, H.J. Sohn[1], R.R. Miselis[2], S.H. Baik[1]. Dept. of Anatomy, Medical School, Gyeongsang Nat'l Univ., [1]Dept. of Anatomy, Medical School, Seoul Nat'l Univ., Republic of Korea, and [2]Inst. of Neurol. Sci., Univ. of Pennsylvania, Philadelphia, PA19104.

The efferent fibers from magnocellular and parvicellular subunits of the PVN have been known to subserve separate roles in posterior pituitary and brainstem nuclei supplying the vagus nerve (neuroendocrine and autonomic functions, respectively). To investigate the neurons projecting to both neuroendocrine and autonomic nervous systems especially projecting to the stomach, viral and CT-HRP retrograde transneuronal labelling methods were used. Pseudorabies virus(PRV) was injected into the stomach wall of the adult Sprague-Dawley rats. After 2 days, the rats were given another injection of CT-HRP into the posterior pituitary with the aid of stereotaxic frame . After totals of 3 ~ 5 days of survival, rats were perfused with 4% PLP and their brains were processed for triple detection of PRV, CT-HRP or oxytocin. In longer surviving groups, some cells in the lateral magnocellular group of PVN throughout the whole brain areas showed triple immunoreactivity. In conclusion, this study demonstrates that some of the CNS oxytocinergic cells and gastric motor neurons share their origins from the same cell.

640.2

BICUCULLINE IN THE DORSOMEDIAL HYPOTHALAMIC NUCLEUS INCREASES INTRAGASTRIC PRESSURE IN RATS. D.V.Sivarao, A.Van Bergen and P.J.Hornby*. Department of Pharmacology, LSUMC. New Orleans, LA 70112.

Blockade of GABAergic tone in the dorsomedial hypothalamus (DMH) increases intestinal motility (Greenwood and DiMicco, Am.J.Physiol. 268:G514-G521, 1995). Hypothesis: Microinjection of bicuculline methiodide (BMI) into the DMH increases gastric motor function. Methods: BMI (30 pmol in 30 nl) or vehicle were microinjected into the DMH of αchloralose-anesthetized rats. Intragastric pressure (IGP, cmH_2O), pyloric minute motility index (PMMI), mean blood pressure (BP, mmHg) and heart rate (HR, bpm) were compared before and after microinjection by student's t-test. Results:

	DMH		NEAR DMH	OUTSIDE DMH
	Δsaline(N=3)	ΔBMI(N=6)	ΔBMI (N=6)	ΔBMI (N=18)
Peak IGP	0.0±0.0 [1]	1.4±0.1*	0.4±0.1	0.1±4.9
PMMI	0.0±0.0	-0.8±0.8	-0.3±1.1	0.1±6.1
BP	-3±2	28±5*	25±3*	3±2
HR	-1±1	67±13*	51±8*	10±5

[1]Mean±SEM; * P<0.05 compared to saline control. Atropine (0.5mg/kg i.v.) abolished the effect of BMI microinjection into DMH on IGP (0.4±0.1) but not on BP (19±7) and HR (48±10). Conclusions: BMI microinjection into DMH, but not into the surrounding areas, significantly increases IGP through a vagally-mediated pathway. Thus, modulation of resident GABAergic tone in this hypothalamic nucleus may contribute to stress-evoked effects on gastric motor function. Supported by PHS grant DK 42714 and the A.P. Sloan Foundation.

EVIDENCE OF THE INVOLVEMENT OF GASTRIC VAGAL AFFERENTS ESOPHAGEAL COLLATERAL IN A REFLEX ACTION: SHORT VAGO-VAGAL REFLEX.
J.Y. Wei*, Y.H. Wang, Y. Taché and V.L.W. Go Dept of Medicine, Brain Res Inst and CURE/Gastroenteric Biol Ctr, UCLA Los Angeles, CA 90024-1782.

Esophageal distension (ED) has been shown to induce gastric relaxation, and vagal cooling does not completely abolish this effect (Dig Dis Sci 34:873-881, 1989). We have reported that gastric vagal afferents may emit esophageal collateral branches before reaching the stomach (J Auton Nerv Syst 1995, in press). Aim: using an isolated gastroesophagus in vivo preparation, to determine if short-term lower esophageal distension (ED) can alter intragastric pressure (IGP). Overnight fasted, urethane anesthetized rats were used. Three ligatures were made at cervical esophagus, pylorus and gastroesophageal junction but the gastric vagus nerve was kept intact. A double-lumen catheter was inserted into the stomach for infusing, draining saline and measuring IGP. The basal IGP was kept at 4 to 5 cm H_2O. A catheter with latex balloon was placed at lower thoracic esophagus and distended with a bolus of saline for ~ 5 sec. The IGP (Mean ± SEM cm H_2O) was decreased 0.74 ± 0.09 (N=8) for 0.5 ml ED; 0.51 ± 0.04 (N=10), 0.50 ± 0.08 (N=8) and 0.42 ± 0.08 (N=7) for 0.4, 0.3 and 0.2 ml ED, respectively ($p<0.05$ ANOVA). Bilateral vagotomy reduced the effect of 0.5 ml ED from 0.74 ± 0.09 to 0.36 ± 0.01 (N=4), whereas a further bilateral splanchnicotomy rebounded, instead to abolishing, the effect of 0.5 ml ED from 0.36 ± 0.01 to 0.45 ± 0.03 (N=3) ($p< 0.05$, ANOVA) indicating the splanchnic nerve provided a tonic excitatory influence to IGP. These results indicate that a shot-term ED can induce gastric relaxation. About 50% of this effect is CNS-dependent, probably via long vago-vagal reflex, whereas the other 50% can be maintained without CNS and ENS involvement, probably via proposed gastric vagal-esophageal collateral reflex arc, short vago-vagal reflex. (Supported by NIH Grants NS 28433 & DK30110)

PYY-CONTAINING NEURONS AND TERMINALS IN THE NUCLEI RELATED TO THE AUTONOMIC REGULATION IN RATS. H. Yang*, L. Wang, H. Wong, and Y. Taché. CURE. VA Medical Center. Brain Research Institute and Dept. of Medicine, UCLA. Los Angeles, CA 90073, U.S.A.

We previously reported that microinjection of PYY into medullary nuclei related to the vagal regulation stimulated gastric acid secretion (AJP 268, 1995). In this study, using a specific polyclonal antibody against PYY (CURE antibody Core, #9152), immunohistochemistry was performed to examine the location of PYY-positive neurons and terminals in the nuclei related to the autonomic regulation in colchicine treated rats. In the medulla, high density of PYY-immunoreactive nerve terminals and fibers were observed in the dorsal vagal complex and raphe pallidus throughout their caudal to rostral extension, while moderately dense networks were found in the area postrema, raphe obscurus (Rob), nucleus ambiguus and the nearby reticular formation. A group of large cells were located in the ventrolateral medulla area throughout the same caudal-rostral extension as the Rob. The cells in the caudal part of this cell column were a dense group but gradually became scatter as it extended rostrally. A few PYY-positive cells were observed in the rostral part of the nucleus solitary tract. Another large group of neurons were located in the caudal pons at the segment between the facial nerve and the Rob. These were small cells scattered within 1 mm in both sides around the midline. A moderate terminal network and a few cells were located in the locus coeruleus in the pons. PYY-containing fibers formed a loose distributed network in the periaqueductal gray in the midbrain. In the hypothalamus, dense PYY-positive terminals were located in the paraventricular nucleus and arcuate nucleus while moderate dense fibers were observed in the lateral hypothalamus, supraoptic nucleus and median eminence. A few cells were observed in the arcuate nucleus and the area dorsolateral to the ventromedial hypothalamic nucleus. Small PYY-positive cells and fibers also scattered in the amygdaloid nuclei throughout its caudal-rostral extension. These results indicate that centrally originated endogenous PYY may play an important role in the autonomic regulation.

640.5

BOMBESIN-LIKE IMMUNOREACTIVE (LI) NERVE TERMINALS IN THE DORSAL VAGAL COMPLEX (DVC) IN RAT, AN ELECTRON MICROSCOPIC ANALYSIS. Richard B. Lynn*[1], Lesley S. Bechtold[1], Richard R. Miselis[2]; [1]Dept. of Medicine, Thomas Jefferson Univ., Philadelphia, PA 19107; [2]Dept. of Animal Biology, Univ. of Pennsylvania, Philadelphia, PA 19104

Bombesin inhibits gastric function and induces satiety when microinjected into the DVC. At the light level bombesin is in apparent nerve terminals in the DVC which includes the dorsal motor nucleus of the vagus (DMV) and the nucleus of the solitary tract (NTS). Electron microscopy was used to determine if synaptic contacts were present. We used a preembedding immunoperoxidase technique with bombesin antiserum (Incstar). Frequent thin sections (0.35μ) were stained with toluidine blue to identify anatomic sites. Ultrathin sections were examined using a Zeiss 10 TEM. In the DMV, bombesin-LI nerve terminals typically contacted small to medium sized dendrites (0.9-1.7μ). Occasional bombesin-LI terminals were associated with a full range of postsynaptic structures including large (proximal) dendrites, small dendrites, perikarya and rarely axon terminals. Of 65 axo-dendritic contacts studied in the DMV there were 38 asymmetric and 15 symmetric synapses, and 12 nonsynaptic close apositions. Similar to other neuropeptides, the bombesin-LI reaction product was predominantly over dense core vesicles located in regions distant from the synaptic junction. Bombesin-LI nerve terminals in the NTS have a similar profile of contacts. Bombesin containing nerve terminals in the DVC form mostly axo-dendritic contacts. This study provides further evidence that bombesin is a neurotransmitter/ neuromodulator in the DVC, potentially effecting vagal motoneurons. Support: DK02094(RL); GM27739(RM)

640.6

SEROTONIN AUGMENTS TRH ANALOGUE-STIMULATED GASTRIC AID SECRETION BUT NOT ANTRAL MOTILITY AFTER MICROINJECTION INTO THE DORSAL VAGAL COMPLEX (DVC).

J. Chi and R.L. Stephens Jr.*, Dept. of Physiology, The Ohio State University, Columbus, Ohio 43210.

TRH and serotonin (5-HT) interact at the DVC to augment gastric acid output (GAO) and erosions. It is unclear whether the TRH/5-HT interaction at the DVC extends to gastric motility. Urethane anesthetized 24-hr fasted rats were equipped with a gastric fistula for the acid studies or serosal antral strain gauges for the motility study. 5-HT (49 pmol) produced a 100% increase in stable TRH analogue RX77368 (RX; 4pmol)-induced stimulation of GAO after DVC co-microinjection (10nl) [mean ± SEM , acid output (μ mole/1hr) RX: 37 ± 3 ; RX + 5-HT: 74 ± 10; p< 0.05] By contrast, no significant changes in antral motility was evident comparing RX and RX + 5-HT injection into the DVC (Mean ± SEM; n= 3-5):

RX (4 pmoles)	RX	—	RX	RX	RX	RX
5-HT (pmole)	—	49	49	4.9	0.5	0.005
30 Min Mot. index (% basal)	270 ±70	139 ± 34	387 ± 98	320 ± 92	298 ± 63	256 ± 19

Systemic fluoxetine pretreatment did not alter RX (4pmol)-stimulated gastric motility after DVC injection. The results suggest that TRH analogue-stimulated GAO but not antral motility is enhanced by enhanced 5-HT levels in the DVC. Supported by DK 47432.

640.7

THE EFFECTS OF BOMBESIN ON THE VAGAL AFFERENT TRANSMISSION IN THE NUCLEUS TRACTUS SOLITARIUS (NTS) OF ANESTHETIZED RATS. H.J. Park[1], M.Y. Park[1], M.S. Kim[1], E.H. Lee[1], Y.L. Lee[1], H.C. Shin[1], S.C. Lee[2]* Dept. of Physiology[1], College of Med., Hallym Univ., Chunchon, Korea & Dept. of Physiology[2], College of Med., Ewha Womans Univ., Seoul, Korea

A dense plexus of bombesin immunoreactive terminals has been found in the NTS (Ladenheim *et al.*, 1992). Intracisternal injections of bombesin have ulcergenic effects in the stomach (Tache, 1982) and bombesin microinjected into the dorsal vagal complex inhibits TRH-stimulated gastric contractility in rats (Heymann-Monnikes *et al.*, 1990). These studies suggest that bombesin may play important roles in the control of visceral functions. The present study was carried out to test the effects of intracisternal administration of bombesin (0.001, 0.01, and 0.1 μg) on the NTS neuronal activities evoked by the electrical stimulation of the vagus nerve of anesthetized rats. Quantitative determination of the effects of bombesin on the afferent sensory transmission was made by generating post-stimulus time histograms. Low doses (0.001 μg) of bombesin did not change the afferent transmission during the 40 min post-injection period. However, medium doses (0.01 μg) of bombesin significantly ($P < 0.01$) inhibited the afferent transmission in the 16 to 35 min post-drug period (-23.9 ± 7.8%). High doses (0.1 μg) of bombesin exerted either significant inhibitory (-38.9 ± 13.7%, $P < 0.01$) or facilitatory (+27.1 ± 7.5%, $P < 0.05$) effects on the responsiveness of NTS neurons. These results indicate that endogenous bombesin-like peptide present in the NTS may participate in the processing of visceral afferent information (supported by KME 93' Basic Medical Research Fund granted to Dr. H.J. Park).

CENTRAL APPLICATIONS OF PEPTIDE YY (PYY) ALTERS GASTRIC FUNCTIONS VIA VAGAL PATHWAYS C.H.Chen, R.C.Rogers*, R.L.Stephens Jr. Dept. Physiol. Ohio State U. Columbus, OH 43210

A postprandially released ileal hormone, peptide YY (**PYY**), can inhibit proximal gut acvtivities and has been associated with the "ileal brake" phenomenon. In addition, circulating PYY has been shown to enter the dorsal vagal complex (**DVC**) region in the medulla [Hernandez, et al., AJP, 1994], which contains the "vago-vagal reflex" control circuits. Therefore, we predicted that central injection of PYY into the brainstem will alter gastric functions via vagal pathways. In the present study, two different parameters of gastric activity, antral motility and emptying, were monitored following central injection of PYY. 1) The antral motility data demonstrated that unilateral injection of PYY (20.0 and 2.0 fmol in 20 nl) directly into the DVC produced significant suppression of the thyrotropin-releasing-hormone (**TRH**) stimulated increase of the antral motility in urethane-anesthetized rats. This dose-dependent inhibitory effect was completely eliminated with an ipsilateral cervical vagotomy. 2) The effect of an intracisternal (**ic**) injection of PYY on the rate of gastric emptying was investigated in awake rats. The result showed that a dose-dependent inhibition of gastric emptying was observed following the ic injection of PYY (400, 40, and 0.04 fmol in 10 μl). Subdiaphragmatic vagotomy eliminated the PYY inhibitory effect on gastric emptying. These studies confirmed that PYY is able to inhibit gastric functions, such as motility and emptying, by acting via the DVC. These data support the hypothesis that PYY elicits the "ileal brake" effect on the stomach by altering the activity of vago-vagal reflex circuits. However, the specifics of the neuronal responses by components of the DVC to PYY application will require both in vivo and in vitro electrophysiological methods.

THE MECHANISMS OF ANTIULCER ACTION OF PRORANOLOL IN RATS. S. K. Kaan and C. H. Cho. Dept. of Pharmacology, The University of Hong Kong, Hong Kong. (SPON: The Hong Kong Society of Neurosciences).

Although propranolol, a non-selective beta-adrenergic antagonist, has been shown to have an antiulcer action, the mechanisms for this action are still unclear. The aim of this study was to investigate these mechanisms in three ulcer models, i.e. 60% ethanol, 30 mg/kg indomethacin and cold-restraint stress. The relationship between gastric mucosal blood flow (GMBF) and systemic blood pressure was also studied. Male Sprague-Dawley rats were used in the whole experiment. Pretreatment with propranolol (5 or 10 mg/kg) given either intraperitoneally or orally dose-dependently prevented gastric mucosal damage in these three ulcer models. The drug decreased GMBF which was probably due to its depression action on systemic blood pressure. Propranolol preserved the adherent and intramucosal mucus in all three ulcer models and increased the mucosal potential difference. In addition, the membrane stabilizing activity of propranolol may contribute to the elevation of potential difference. These findings indicate that propranolol strengthens the mucosal barrier and tightens the gap junction by the mechanisms of preservation of mucosal mucus and stabilization on mucosal membrane in the stomach. The action on GMBF does not responsible for the antiulcer action of the beta blocker.

640.10

RELATIONSHIPS OF IGLES TO ENTETRIC GLIA AND NEURONS IN THE RAT ESOPHAGUS: FURTHER INDICATIONS OF A MECHANOSENSOR-LOCAL EFFECTOR ROLE. W.L. Neuhuber*1, M. Kressel1, M. Dütsch1, J. Wörl1, and H.R. Berthoud2, 1 Anatomy Inst., Univ. Erlangen-Nürnberg, D-91054 Erlangen, and 2Pennington Biomed. Res. Ctr, Baton Rouge, LA 70808

Intraganglionic laminar endings (IGLEs) are prominent structures of vagal afferent origin with unknown function, distributed to enteric ganglia particularly in the esophagus and stomach (Berthoud&Neuhuber 1994). Combining anterograde tracing, immunocytochemistry, confocal laser scanning and electron microscopy, we attempted to gain more insight into structural details of IGLEs indicative of a possible function. Rat nodose ganglia were injected with WGA-HRP or DiI to anterogradely label IGLEs in the esophagus. Tissues were processed for electron microscopy (WGA-HRP) and immunocytochemistry for calretinin (DiI). Esophagi from untreated rats or from animals subjected to unilateral cervical vagotomy were processed for immunocytochemistry for calretinin or calbindin alone, or in combination with S-100 or vinculin. Results indicate that: 1) IGLEs are the only significant vagal afferent terminal structures in the striated muscle coat of the esophagus; 2) they are located mainly on the surface of myenteric ganglia immediately beneath the basal lamina. They contain numerous mitochondria, small clear vesicles and a fine filamentous "receptor matrix"; 3) IGLEs interdigitate with fine glial processes co-staining for both S-100 and vinculin which probably provide a three-dimensional framework connected to the perigangliona extracellular matrix; 4) IGLEs co-stain for both calretinin and calbindin, two markers which are typically found in rapidly adapting mechanosensors (Duc et al. 1993); 5) they form synaptic contacts with enteric neurons. Taken together, these data may indicate a mechanosensor function of IGLEs which may, in addition, synaptically influence enteric neurons as previously suggested (Neuhuber 1987). 641.1

HEPATIC VAGAL AFFERENT INNERVATION OF THE GI TRACT.

R.J. Phillips*, E. Baronowsky and T.L. Powley. Psychological Sciences, Purdue University, West Lafayette, IN 47907.

Metabolic and feeding functions have been correlated with the hepatic branch of the vagus and attributed to the liver, in part for lack of information about the branch's non-hepatic projection fields. Although hepatic motor projections to the GI tract have been partially mapped (AJP, 260, R200-7, 1991), neither the nerve's afferent projections to, nor terminal specialization's in, the GI tract have been described. To survey these afferents, male SD rats (n=11) were given partial subdiaphragmatic vagotomies sparing only the hepatic branch and then injected i.p. with Fluoro-gold (1mg). Each rat received an injection of 3 µl WGA-HRP in the left nodose ganglion 3 days before sacrifice. All animals were perfused 2 weeks after vagotomy. The medulla was sectioned (56 µm) and prepared to verify the vagotomy (Fluoro-gold: 3/4 of the sections) and nodose injection (HRP: 1/4 of the sections). The nodose ganglia, entire stomach, first 8 cm of duodenum, and cecum were prepared as wholemounts and processed with TMB. Different terminal types were counted with a sampling grid. Hepatic innervation of the ventral stomach consisted of one or two bundles entering at the lesser curvature and wandering to the fundus where they branched into terminal fields. The only fibers on the dorsal stomach were distal branches and terminals that wrapped around the greater curvature of the fundus from the ventral side. The hepatic branch supplied the fundus with both intramuscular arrays (IMAs-- which have been associated with tension reception) and intraganglionic laminar endings (IGLEs). Afferents were also supplied to the distal antrum and the pylorus (IMAs). Duodenal innervation was, overall, denser in the first 2 to 4 cm and dwindled progressively along the small intestine. Cecal afferents were sparse, consisting of a few fibers in and near the ileocecal junction. Duodenal and cecal afferent endings were predominately IGLEs. These results indicate that the hepatic branch carries information from the fundus, antrum, pylorus, duodenum, and cecum. Further, the different types of terminals it supplies suggest that the branch mediates a multiplicity of GI sensory functions. NIH DK27627 AND NIMH MH01023.

641.2

ACTIONS OF CHOLECYSTOKININ IN GANGLIA OF THE GUINEA PIG SPHINCTER OF ODDI.

A. P. Gokin†° and G. M. Mawe°*. °Dept. of Anatomy & Neurobiology, Univ. of Vermont, Burlington, VT, USA 05401; †Bogomoletz Inst. of Physiology, Kiev, Ukraine, 252024

Following meals, cholecystokinin (CCK) acts in the sphincter of Oddi (SO), as well as in the gallbladder, to promote the flow of bile into the lumen of the intestine. Motility studies indicate that CCK's action in the SO is neurally mediated. SO ganglia are comprised of three types of neurons based on electrical properties [Wells and Mawe; Am. J. Physiol. 265: G258-H269, '93], and they contain distinct groups of neurons that express excitatory or inhibitory neuroactive compounds [Wells et al., J. Comp. Neurol. 352:106-116, '95]. To assess CCK's action in SO ganglia, intracellular recordings were made from 85 neurons in intact SO preparations, and CCK was applied by pressure ejection (0.1 mM, 20 PSI, 0.01 - 3.0 sec) or superfusion (1 - 100 nM). CCK had a direct excitatory effect on tonic and phasic cells in SO ganglia. In tonic cells (n= 23) CCK typically caused a prolonged depolarization that was accompanied by the generation of action potentials at high frequency during most of the depolarization. In phasic cells (n= 53/55), CCK caused a brief and/or prolonged depolarizations that were associated with increased excitability. In AH cells, CCK sometimes caused a slight depolarization(n= 3/7), and it caused an increase the amplitude and duration of the prolonged afterhyperpolarization. In summary, CCK has a direct, excitatory effect on the majority of SO neurons. Further studies will be required to determine whether CCK's ganglionic action results in an increased output from inhibitory neurons to relax the SO, and/or increased output from excitatory neurons to pump bile through the SO. Supported by DK 45410 & NS26995.

SYNAPTIC TRANSMISSION IN RABBIT PANCREATIC GANGLIA.

J.A. Love*, Dept. of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS 39216

Pancreatic ganglia are innervated by vagal, sympathetic, myenteric, and primary afferent nerves and provide the postganglionic parasympathetic innervation to pancreatic endocrine and exocrine cells as well as the pancreatic duct. Presently, little is known of the synaptic transmitters and resulting potentials which regulate the firing of pancreatic neurons and thus parasympathetic output to the secretory cells. To study this question portions of rabbit pancreas, with or without the duodenum attached were removed and intracellular recordings were made from pancreatic neurons in single or interconnected ganglia. Pancreatic neurons had an RMP of 51 ± 1mV (mean ± S.E.) and exhibited a phasic firing pattern. Single stimuli of attached nerve fibers evoked nicotinic fast EPSPs and action potentials while repetitive stimulation also revealed slow cholinergic and non-cholinergic EPSPs. Low frequency (0.5 Hz) nerve stimulation resulted in variable synaptic responses with frequent failures. Atropine (2µM) increased the mean synaptic response while reducing failures. Exogenous muscarine (10µM) decreased the mean synaptic response and increased failure frequency. At higher stimulus frequencies (5-10 Hz) facilitation of synaptic transmission occurred resulting in frequent action potentials with few failures even in the absence of any slow EPSPs. Application of norepinephrine (NE) or the α_1 agonist phenylephrine (5-10 µM) depolarized (8 ± 1mV) 8/19 neurons and facilitated synaptic transmission while 7/15 neurons responded to NE with hyperpolarizations (8 ± 1 mV) and synaptic inhibition. Adrenergic inhibition of synaptic transmission predominated in ganglia from the head/neck region of the pancreas while adrenergic facilitation was only observed in ganglia isolated from the body/tail region. Thus, a variety of synaptic mechanisms mediated by multiple neurotransmitters interact to determine the output of pancreatic neurons to the endocrine and exocrine pancreas. Supported by NIH

GLUTAMATE AND N-METHYL-D-ASPARTATE RECEPTORS IN THE PANCREAS: LOCALIZATION AND FUNCTION.

A. Kirchgessner* and M.-T. Liu Dept. of Anat.& Cell Biol., Columbia University, New York, NY 10032.

Prior studies have suggested that N-methyl-D-aspartate receptors (NMDARs) are present in the pancreas. The present study was carried out to (i) locate NMDARs in this organ, (ii) determine if glutaminergic neurons are present in pancreatic ganglia; and (iii) determine whether visceral NMDARs can mediate long term potentiation (LTP). Glutamate (Glu) was detected immunocytochemically in pancreatic neurons in the guinea pig and rat. All of the neurons that were Glu-immunoreactive (ir) were co-stained with antibodies to ChAT. Glu-ir nerve fibers were found traveling along blood vessels and in the vicinity of acini. The majority of neurons in pancreatic ganglia expressed NMDARs. In addition, NMDARs were expressed by insulin-immunoreactive islet cells. NMDA depolarized pancreatic neurons and induced them to spike repetitively; this effect was blocked by the selective NMDA receptor antagonist, D-AP5 (50 µM) and Mg^{2+} (1 mM). Pancreatic neurons that responded to NMDA were surrounded by Glu-ir terminals. High frequency stimulation with trains of pulses (ten at 100Hz, 500 msec), delivered to intrapancreatic ganglionic connectives, potentiated the amplitude of fEPSPs to 138% of control. This potentiation lasted for 50 min and was blocked by the noncompetitive NMDA receptor antagonist, MK801. These observations are consistent with the idea that Glu and NMDARs participate in fast neurotransmission in pancreatic ganglia. The data are also consistent with the possibility that the synaptic release of Glu can stimulate NMDARs to induce LTP. Supported by grants NS01582 and the American Diabetes Association.

INHIBITION OF JEJUNAL ALANINE ABSORPTION BY VASOACTIVE INTESTINAL PEPTIDE: ROLE OF CAPSAICIN SENSITIVE PRIMARY AFFERENTS.

C.F. Nassar, K.A. Barada, S.F. Atweh and N.E. Saadé*. Fac. of Med. American University of Beirut - Lebanon.

The purpose of this study is to assess the role of capsaicin sensitive primary afferents (CSPA) in the inhibition of rat jejunal alanine absorption by vasoactive intestinal peptide (VIP). Continuous intravenous infusion of VIP (11.2 ng/kg-min) reduced alanine absorption by 60% in control rats and 24% in rats neonatally treated with capsaicin ($p<0.05$). In vitro, VIP decreased alanine uptake by jejunal strips in a dose dependent manner. In the presence of 20 nM VIP, alanine uptake by full thickness jejunal strips was reduced by 53% in control rats and by 19% in rats treated neonatally with capsaicin ($p<0.05$). On the other hand, the effect of VIP on alanine uptake by mucosal scrapings was similar in both groups of rats. In rats whose jejunae were pretreated with benzalkonium chloride (BAC), VIP's inhibitory effect on alanine uptake was markedly reduced. Kinetic analysis of jejunal alanine uptake in the presence and absence of VIP revealed that it reduced Na dependent alanine transport by decreasing the affinity of its transporter. We conclude that VIP's inhibition of alanine uptake is neurally mediated and involves a change in the affinity for alanine uptake.

641.6

LOCALIZATION OF CALCIUM RECEPTOR EXPRESSION IN CELLS OF THE RAT MYENTERIC PLEXUS.

K.V. Rogers[1*], C.Dunn[1], J.Chin[1], S.C.Hebert[2], D.Soybel[2], E.M.Brown[2], 1) NPS Pharmaceuticals, Inc., Salt Lake City, UT 84108, and 2) Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115.

We have previously mapped the expression pattern of calcium receptor (CaR) mRNA in cells in specific regions of the CNS and have postulated that the ability to sense changes in extracellular calcium may play an important functional role in a subset of CNS neurons. Systemic hyper- and hypo-calcemia are associated with disorders of intestinal motility and neurons in the myenteric plexus play a critical role in the regulation of gastrointestinal (GI) peristalsis. We have localized expression of CaR mRNA, using *in situ* hybridization, and CaR protein, using immunocytochemistry, in cells of the myenteric plexus of the rat GI tract. Stomach, duodenum, jejunum, ileum, proximal colon, and distal colon were assayed for rat CaR by PCR and CaR mRNA was detected in all of these regions. Sections from these same regions were hybridized with a ^{33}P-labeled riboprobe complementary to the rat CaR (antisense probe) or a control (sense strand) riboprobe. A subset of cells with cell bodies located in the myenteric plexus showed hybridization with the antisense CaR riboprobe; sense strand controls showed no hybridization. Adjacent tissue sections were stained with an antibody generated to a portion of the amino terminal region of the CaR and staining of a subset of cells in the myenteric plexus as well as processes that extended beyond the plexus was observed. This pattern of expression was present throughout the GI tract from stomach to distal colon. These observations suggests that CaR expressing cells in the myenteric plexus may play a role in the regulation of GI peristalsis. In addition, the presence of these cells throughout the length of the GI tract suggests that the CaR may be involved in the coordination of motility between different regions of the intestine.

641.7

IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUTAMATE AND N-METHYL-D-ASPARTATE RECEPTORS IN THE ENTERIC NERVOUS SYSTEM. M.-T. Liu, M. Howard*, M.D. Gershon, and A. Kirchgessner. Dept. of Anat.& Cell Biol., Columbia Univ., NY, NY 10032.

Prior studies have suggested that N-methyl-D-aspartate receptors (NMDARs) are present in the gut. The present study was carried out to (i) locate NMDARs in the gut, and (ii) determine if glutamate-immunoreactive (Glu-ir) neurons are present in the enteric nervous system (ENS). Glutamate (Glu) immunoreactivity was detected in neurons in the submucosal and myenteric plexuses in all regions of the rat and guinea pig bowel. Glu immunoreactivity was also observed in paravascular nerves and nerve fibers in the enteric plexuses, longitudinal muscle and mucosa. In the guinea pig submucosal plexus, ~ 27 % of neurons were Glu-ir. All of the submucosal neurons that were Glu-ir were co-stained with antibodies to choline acetyltransferase (ChAT), substance P, and calbindin, which are putative primary afferent neurons. In the guinea pig myenteric plexus, ~ 5 % of neurons were Glu-ir, all of these contained ChAT, and those with a Dogiel type II morphology were calbindin-immunoreactive. In the rat bowel, ~ 53 % of submucosal and ~ 15 % of myenteric neurons were Glu-ir. In both plexuses, all Glu-ir neurons contained ChAT, and a subset were co-stained with antibodies to VIP, calbindin and calretinin. The majority of neurons in the ENS expressed NMDARs and, in a subset, there was coincident expression of NMDARs with Glu. These observations are consistent with the idea that enteric Glu and NMDARs play a role in the function of the ENS. The data are also consistent with the possibility that Glu may be a marker of submucosal intrinsic primary afferent neurons. Supported by NIH grants NS01582, NS12969 and the American Diabetes Association.

5′ UNTRANSLATED PREPROTACHYKININ DNA DIRECTS TRANSGENE EXPRESSION IN ENTERIC NERVES OF MOUSE SMALL INTESTINE. A.M.Yunker*, R.G. Lorenz, C.B. Latham, and K.A. Roth. Department of Pathology, Washington University School of Medicine, St. Louis, MO 63110.

Products of the preprotachykinin (PPT) gene, such as substance P (SP) and other related peptides, are localized in subpopulations of neurons throughout the peripheral nervous system (PNS). Although sensory and autonomic nerves utilize tachykinins as neurotransmitters, the molecular signals that control cell-specific tachykinin expression are unknown. Therefore, transgenic mice containing either 5.5 kb of 5′ flanking region of PPT gene fused to human growth hormone (hGH) gene or 9.5 kb of 5′ PPT sequence fused to a non-bioactive mutant hGH reporter gene were generated to allow characterization of the DNA sequences necessary for cell-specific tachykinin expression. Seven lines of mice were established, and the pattern of transgene expression was examined in whole-mount preparations of ileum using immunohistochemical methods. Colocalization of SP- and hGH-like-immunoreactivity (-ir) was found in transgenic mice, but not non-transgenic littermates, from 2/2 lines containing the 5.5 kb construct and 4/5 lines containing the 9.5 kb construct, although disparate hGH- and SP-ir was observed. SP- and hGH-ir was localized in varicose and non-varicose nerves found within myenteric ganglia and interganglionic nerve bundles, and in nerves of the circular muscle plexus in 5/6 transgenic lines. Interestingly, hGH-ir was found only in occasional varicose nerves in myenteric and submucosal ganglia in 1/4 lines containing the 9.5 kb construct. Colocalization of SP- and hGH-ir was also found in submucosal preparations from animals containing either 5.5 or 9.5 kb construct, as staining was observed in paravascular nerves associated with submucosal arterioles, occasional submucosal neurons, and interganglionic nerves of the submucosal plexus. These data suggest that the 5′ flanking region of the PPT gene contains sufficient information to permit cell-specific tachykinin expression in the PNS.

641.9

CHEMICAL CODING OF NEURONS IN THE SMALL AND LARGE INTESTINE OF THE MOUSE. H.M. Young*, Q. Sang and J.B. Furness. Department of Anatomy and Cell Biology, University of Melbourne, Parkville, 3052, Victoria, Australia

The chemical coding of neurons in the small and large intestine of the mouse has been examined using immunohistochemistry. In both the small and large intestines, the largest classes of nerve cell bodies in the myenteric plexus displayed the following combinations of markers: NOS+/VIP+/NPY+, NOS+/VIP+/NPY-, NOS-/VIP-/NPY+, calretinin+/SP+, calretinin+/SP- and calretinin-/SP+. There was almost no overlap between NOS/VIP and SP, NOS/VIP and calretinin, NPY and calretinin or between NPY and SP. GABA and calbindin were also found in small populations of neurons. The calretinin-/SP+, calretinin+/SP-, NOS+/VIP+/NPY- and NOS-/VIP-/NPY+ were found to be interneurons, whereas circular muscle motor neurons had the coding NOS/VIP/±NPY or SP/±calretinin. By analogy with other species, it is likely that the NOS/VIP neurons are inhibitory and the SP neurons are excitatory motor neurons. Using myotomy and myectomy operations, the NOS/VIP neurons in both the small and large intestines were found to project anally, whereas the calretinin neurons appear to project locally.

TRANSNEURONAL LABELING OF NEURONS IN THE ADULT RAT CENTRAL NERVOUS SYSTEM (CNS) AFTER INJECTION OF PSEUDORABIES VIRUS (PRV) INTO THE DISTAL COLON. W. C. de Groat, M. Brisson, S.L. Erdman, G. Matsumoto*, J.R. Roppolo, J.P. Card and M.A. Vizzard. Univ. of Pittsburgh, Departments of Pharmacology and Neuroscience, Pittsburgh, PA 15261.

PRV tracing was used to identify sites in the CNS involved in the neural control of colonic function. PRV ($7X10^8$ pfu/ml; 1µl at three sites, 1-1.5" from anus) was injected unilaterally into the wall of the distal colon and the distribution of PRV-infected (PRV-I) neurons was examined (72,84,96 hr, n=2 at each time). In the L3-S1 spinal cord (S.C.), the majority of PRV-I cells were present in the S1 S.C. in the: 1) sacral parasympathetic nucleus (SPN; 72-96 hr), 2) dorsal commissure (DCM; 72-96 hr) and 3) dorsal horn (DH; 84-96 hr). The number of PRV-I cells in the S1 SPN was greater than that in L6 by a minimum ratio of 5:1 at 72 hrs. In the T13-L2 S.C., PRV-I cells were present in: 1) the intermediolateral cell column (72-96 hr), 2) DCM (72-96 hr) and 3) DH (84-96 hr). PRV-I DRG cells were present in the L1, L2, L6 and S1 DRG; however, most PRV-I cells were in L6-S1. Few PRV-I cells were present in the L5 DRG. S.C. sections (L1,L2,L6,S1) were also processed for NADPH-diaphorase activity (N-d; a presumed indicator of neuronal nitric oxide synthase). N-d positive (+) colon preganglionic neurons (PGNs) make up a much larger % (25.4%, L1) of N-d+, sympathetic PGNs compared to Nd+, parasympathetic PGNs (5.6%, S1). N-d fibers were present along the lateral edge of the L6-S1 DH extending into the SPN. N-d varicosities surrounded N-d negative, PRV-I cells in the dorsal region of the SPN. PRV labeling at 72-96 hr was also observed in a variety of supraspinal sites: DMV, NTS, inferior olive, A5, C1, hypothalamus, PAG, nucleus subcoeruleus, A7, Red nucleus (N.), N. ambiguus, raphe, central gray, Edinger Westphal N. and cortex and most notably the pontine micturition center (PMC); a region conventionally viewed as controlling bladder and urethral function. In conclusion, these results suggest that the PMC may have broader functions beyond those related to the control of the urinary tract and that the parasympathetic component (L6-S1) of colonic spinal neurons has a segmental distribution distinct from that of bladder or urethra.

641.11

LUMBAR SYMPATHETIC NERVES REGULATE NITRIC OXIDE-DEPENDENT NON-CHOLINERGIC CONTRACTIONS IN CAT COLON. K. Venkova and J. Krier*, Dept. Physiol., Michigan State Univ., East Lansing, MI 48823

The effects of lumbar sympathetic nerves (lumbar colonic nerves, LCN) on non-cholinergic contractile responses evoked by electrical stimulation of the pelvic nerve (PN) were studied "*in vitro*" by isometric force measurements of colon longitudinal and circular muscle in the presence of atropine (0.5µM). The preparation consisted of a mucosa-free smooth muscle sheet (2.5 x 4.5 cm) of cat mid-distal colon with attached LCN and ipsilateral pelvic plexus ganglia and PN. The smooth muscle preparation was pinned flat to the bottom of an organ bath (85 ml). Two muscle strips (2 mm wide and 3.5-4 mm long) were cut parallel to the longitudinal and the circular layer, respectively. The ends of each muscle strip remained attached to the smooth muscle sheet. Force transducers were attached to the middle of each muscle strip for 'bridge-like' recordings of mechanical activity from the longitudinal and circular muscle layer. Bipolar platinum electrodes were placed on the PN and the LCN. Electrical stimulation (2-5 Hz for 30 s) of the PN caused inhibition of spontaneous contractions followed by a sustained contraction of longitudinal and circular muscle after the period of stimulation. In both muscle layers, the non-cholinergic contractions were blocked by hexamethonium (50 µM) and reduced by 80 % in the presence of a nitric oxide synthase inhibitor, N-Nitro-L-Arginine (100 µM). Electrical stimulation of LCN (0.5-20 Hz) caused a frequency-dependent reduction of the nitric oxide-dependent PN-evoked non-cholinergic contractions. The inhibitory effect of LCN stimulation was abolished by guanethidine (50 µM). In summary, the data show that nitric oxide-dependent non-cholinergic contractions of longitudinal and circular muscle of cat colon are regulated by adrenergic fibers in LCN. (NIH-DK-29920)

641.12

BASAL NITRIC OXIDE INHIBITION ENHANCES NEURALLY-EVOKED CHLORIDE SECRETION IN GUINEA PIG DISTAL COLON. R.A. Reddix, A.J. DiMaggio, Jr., P.D. Feldman*. Dept of Pharmacology, LSU Medical Center, New Orleans, LA. 70112.

The aim of this study was to test the hypothesis that basal release of nitric oxide **(NO)** modulates neurally-evoked ion secretion in guinea pig distal colon. Submucosa/mucosa preparations were mounted in Ussing flux chambers. Changes in the short-circuit current (Isc) served as an index of active, electrogenic ion transport. Electrical field stimulation (**EFS**; 10Hz, 15 V, 0.5 msec) for 90 sec evoked a biphasic increase in Isc. Pretreatment with the NO chelator, hemoglobin (**Hb**; 15 mg/10 ml) significantly enhanced both peaks (pk1: 109.2 ± 2.8, pk2: 118.3 ± 4.8 %, n = 7-10, $p<0.05$) compared to vehicle (pk1: 93.1 ± 3.9 and pk2: 90 ± 3.3 %, n = 7-10, $p<0.05$). Secretion induced by carbachol (0.1µM), substance P (**SP**; 1 αM) and vasoactive intestinal polypeptide (**VIP**; 0.1 µM) was examined in the absence and presence of Hb. Sequestration of NO significantly enhanced secretion induced by VIP (Veh: 41.1 ± 9.3; Hb: 72 ± 13.5 %, n = 7, $p<0.05$) but had no effect on the carbachol and SP response. The results suggest that tonic NO release modulates neurally mediated increases in ion secretion in part by suppressing submucosal neural activity and postsynaptic VIP receptor activation.

Supported by a PhRMAF Research Grant.

A NON-INVASIVE METHOD FOR QUANTIFYING PAIN-RELATED ACTIVITY IN THE HUMAN PRIMARY SOMATOSENSORY CORTEX

R. Dowman*, Dept. Psychology, Clarkson Univ. Potsdam N.Y., 13699-5825.

We attempted to isolate scalp potentials generated by pain-related cortical activity by subtracting the somatosensory evoked potential (SEP) elicited by stimulation of the sural nerve at the pain threshold level from SEPs elicited at physiologically-defined noxious levels. This difference SEP included a mid-latency negative potential whose amplitude increased with increasing noxious stimulus intensity. The peak latency of the negative difference potential evoked by stimulation of the sural nerve at the ankle (106.5 ms) was longer than that evoked by stimulation of the nerve at a point 14.41 cm proximal to the ankle site (91.2 ms). (A similar latency difference was obtained from quantitative estimates of the onset of this potential.) These data demonstrate that the negative difference potential arises from activity in peripheral afferents with conduction velocities of about 9.4 m/s (i.e., A-delta afferents). A dipole source localization analysis of the negative difference potential demonstrated that it was best-fit (>95% of the variance) by a single source located in the primary somatosensory cortex (SI). Hence, this negative difference potential appears to reflect largely, if not exclusively, the response of SI neurons to noxious inputs. (Supported by N.I.H. NS28797.)

REGIONAL AND GLOBAL CEREBRAL BLOOD FLOW DURING PAIN PROCESSING BY THE HUMAN BRAIN.

R.C. Coghill*, C.N. Sang, R.H. Gracely, M.B. Max, K.F. Berman[1], G.J.Bennett, M.J. Iadarola. Neurobiology and Anesthesiology Branch, NIDR and [1]Clinical Brain Disorders Branch, NIMH, NIH, Bethesda, MD 20892

Mapping cerebral blood flow (CBF) using positron emission tomography (PET) now constitutes an important tool for the study of pain processing by the human brain. Despite the growing numbers of such investigations, pain-induced changes in both regional and global CBF have yet to be studied in a fully quantitative manner, a step critical for investigations of analgesic effects or graded responses during different pain states. We recruited pain-free volunteers to participate in a quantitative $H_2{}^{15}O$ PET study of CBF changes during both painful and non-painful stimulation of the upper right arm. Preliminary analyses (N=13) reveal that pain evoked by intradermal injection of 250µg capsaicin (CAP) produced robust global CBF **decreases**, from 48.7±2.3 ml/100g/min during rest to 37.0±2.1 ml/100g/min during CAP pain (ANOVA $p<0.0005$). These global blood flow changes exceeded those likely supported by the small (2.0mm Hg) but significant decrease in pCO_2 that occurred during CAP pain. CBF was normalized to global CBF to identify regional CBF differences between CAP, vibration (VIB) and resting states. CAP produced statistically reliable activation (Statistical Parametric Mapping, $p<0.001$) of brain areas likely to be involved in sensory and attentional processing, including the thalamus, anterior cingulate cortex, and the primary somatosensory cortex. Additionally, normalized CBF increases were detected in regions likely to be involved in the coordination of motor responses, including the putamen, superior colliculus, red nucleus, and cerebellum. Non-painful vibrotactile stimulation produced significant activation only in somatosensory fields adjacent to the posterior aspect of the lateral sulcus. These results confirm activation of sensory, attentional, and motor networks related to the pain experience and identify a previously undescribed global CBF decrease during severe pain. Furthermore, comparisons between CAP and VIB indicate that a robust painful stimulus may indeed produce greater activation of brain regions such as the thalamus and SI than a non-painful stimulus.

642.3

COINCIDENT OR DERMATOMAL THERMALLY INDUCED PAIN AFFECTS VIBROTACTILE SENSITIVITY.

L. Maxfield and S.J. Bolanowski*. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244-2340.

We have previously shown that heat-induced pain co-localized with vibratory stimuli can substantially increase detection thresholds (mean increase = 7.3 dB) in three of the four tactile channels (P, NP I, NPIII) (Apkarian, et al. *Somatosen. Motor Res., II*: 1994). This study was designed to extend these findings by measuring this pain-touch interaction in the fourth psychophysical channel (NP II), to determine site specificity of this effect, and to assess whether cold-induced pain acts similarly. Human detection thresholds (2AFC) were measured on the right thenar eminences of five normal observers across sessions in which pain site and thermal type was varied. First, thresholds were significantly elevated under heat-induced, co-localized pain with vibrations activating the NP II channel (mean increase = 4.8 dB). Second, heat-induced pain measurably increased thresholds when presented within the dermatome at different sites, non-coincident to the vibratory stimulus, though this effect was somewhat channel-specific: substantial increases were found for the NP I and NP III channels (2.4 dB and 2.9 dB, respectively) but not for P channel. Third, cold-induced pain elevated thresholds substantially, but to a lesser degree than heat-induced pain (mean increase = 3.6 dB). Pain was never found to induce changes in vibrotactile sensitivity when the painful stimuli were presented outside the dermatome, either ipsilaterally or contralaterally. Our current results suggest that, because dermatomal pain affects vibrotactile sensitivity, the locus of the pain-touch effect may be subcortical. Further, the effects across heat-induced and cold-induced pain suggest that the underlying fiber populations act differently in these pain-touch interactions.

642.4

INNERVATION TERRITORY OF SYMPATHETIC EFFERRENTS IN HUMAN SKIN.

M. Schmelz[2], R. Schmidt[1], C. Forster[2], M. Ringkamp[2], H.O. Handwerker[2]* and H.E. Torebjörk[1]. [1]Department of Clinical Neurophysiology, University of Uppsala, Sweden and [2] Department of Physiology and Experimental Pathophysiology, University of Erlangen/Nürnberg, Germany.

Microneurography techniques were employed to record from C-fibers in the peroneal nerve of healthy volunteers. The units were identified by their constant latency response to electrical stimulation of their terminals in the skin from intracutaneous needle electrodes at 4 s intervals. Responsiveness to physical stimuli (v. Frey filaments, feed-back controlled radiant heat) and sympathetic provocation tests was determined by slowed conduction velocity during the relative refractory period as previously described (Schmidt et al., J Neurosci. 15(1):333-341, 1995). Sympathetic efferent units were identified according to their characteristic reaction to maneuvers enhancing the sympathetic outflow. In a sample of 95 fibers nine units were found unresponsive to physical stimuli but responded to sympathetic provocation tests. Conduction velocities were lower (.75 ± .08m/s) than those of afferent units. Most of them were located in the toes and distal part of the foot dorsum. Spontaneous activity in these units was absent or that low that their innervation territories could be mapped by means of trains of transcutaneous electrical stimuli. Two units had 2 and 4 separate territories, resp. Mean innervated area was found to cover 133 mm^2 (24-255 mm^2). Innervation territories of sympathetic units were about of the same size throughout the different regions of the leg and foot including the toes. Two unit could be tentatively classified as vasoconstrictor and sudomotor unit resp. by cooling and warming the subject. We conclude that microneurographic techniques can be used to delineate cutaneous innervation territories of sympathetic efferents. A rough estimate of innervation density for sympathetic units was derived.

Sex Differences in Pain Perception and PET Analysis of Cerebral Activation Patterns During Noxious Thermal Stimulation.

P. Paulson*, S. Minoshima, T. Morrow and K. Casey. Depts of Neurology, Physiology, and Division of Nuclear Medicine, University. of Michigan and Neurology Research Laboratories, VAMC, Ann Arbor, MI 48105.

Sixteen healthy subjects, matched for age and handedness received repetitive innocuous (40°C) and noxious (50°C) 5 sec thermal stimuli to the left forearm. Each subject rated the intensity of each stimulation series according to a magnitude estimation procedure in which 0 = no heat sensation, 7 = barely painful and 10 = barely tolerable. Sex differences in pain perception were tested for significance using the Students t-statistic. Females perceived the 50°C stimulus as being more painful than the males ($p = 0.003$). At the same time, positron emission tomographic (PET) scans of cerebral blood flow (CBF) were performed after an intravenous bolus injection of H215O (66 mCi). Four scans were acquired at each temperature. Mean CBF images were created for each experimental condition and oriented onto standardized stereotaxic coordinates. Subtraction images were created between conditions for each subject and averaged across subjects of the same sex. Statistical thresholds were established with corrections for multiple comparisons. Guided by a priori hypotheses the following structures were ssampled and showed significant percentage increases in CBF: contralateral thalamus, cingulate cortex, S2 and S1 cortex, insula, thalamus, medial dorsal midbrain and cerebellar vermis. Although females showed a trend for enhanced CBF in the contralateral frontal cortex, ipsilateral thalamus and cingulate cortex compared to the males, these differences were not statistically significant ($t = 6.34, 5.41$ and 4.02, respectively; threshold 7.6), perhaps due to the small sample size. These results indicate that males and females perceive pain differently and suggest these differences may be associated with differences in activation of the neural mechanisms mediating the sensory and, possibly, the affective components of acute noxious thermal pain.

642.6

TEMPERATURE LOCALIZATION WITHOUT TACTILE INFORMATION IN A DEAFFERENTED PATIENT.

C. Morin*, M.C. Bushnell and Y. Lamarre. Université de Montréal, Montréal, Québec, Canada H3C 3J7.

In SI cortex heat sensitive neurons have receptive fields (RFs) as small as a single digit (Kenshalo & Isensee, 1983). We have evaluated the contribution of thermal RF information to the localizaton of temperature in a patient with selective loss of large diameter primary afferent fibers.

A female patient (age 47) with A$\alpha\beta$ deafferentation was tested for spatial discrimination of thermal stimuli. Clinical tests showed a total loss of touch, vibration and kinesthesia senses for the body and parts of the head. A sural nerve biopsy revealed severe demyelination of large fibers. Five normal women (mean age 42) were also studied. Temperature localization was determined on the forearm and fingers (deafferented regions) and on the forehead (intact region). Thermal pulses (5s, 1-cm diameter thermode) were applied to 5 spots on the arm or forehead, separated by 2 cm, or on the glabrous finger tips. Cold (20°, 0°C), heat (40°, 49°C) and a thermally neutral stimulus (32°C) were tested.

Both the patient and controls localized 100% of the stimuli on the forehead. On the finger tips the controls localized all stimuli, but the patient performed below chance (<20% correct) for 32° and 40°C, at 45% with 20°, 60% at 0° and 67% at 49°C. On the forearm, neither the patient nor controls localized more than 75% of the stimuli. The ability of controls to localize the stimulus on the forearm was not affected by stimulus temperature (ANOVA, $p=0.2$), and at all temperatures except 32°C, the performances of the patient and controls did not signficantly differ (X^2, $p's>0.1$). At 32°C the patient localized only at chance level, and performed significantly worse than controls ($p<0.01$).

These data suggest that activity in thermal pathways can contribute to temperature localization. On the finger tips, tactile localization is superior to thermal localization, but on the forearm, thermal localization may be as accurate as tactile. Supported by the Canadian MRC and Québec FRSQ.

CEREBRAL ACTIVATION IN THE HUMAN BRAIN BY PAIN, TEMPERATURE AND AN ILLUSION OF PAIN. M.C. Bushnell*, A.D. Craig, E.M. Reiman, L.-S. Yun, and A. Evans. Univ. Montréal & Montreal Neurol. Inst., Montréal, Canada, and Good Samaritan Reg. Med. Ctr. & Barrow Neurol. Inst., Phoenix, AZ.

Pain and temperature sensations are known to have a strong anatomical association. A direct interaction between these senses is demonstrated by the thermal grill illusion, whereby a sensation of burning pain is produced when the skin is stimulated with interlaced bars of innocuous warm and cool. We studied the neural basis of this illusion in humans using functional brain imaging.

Positron emission tomography (PET) was used to measure regional cerebral blood flow (rCBF) following bolus injections of $H_2{}^{15}O$ in 11 normal volunteers during stimulation of the hand with neutral (34°C), innocuous cool (20°C), innocuous warm (40°C), painfully hot (47°C) and painfully cold (5°C) stimuli, as well as during the thermal grill illusion (interlaced bars of 20° & 40°C). Statistical brain maps were derived, and global searches of the brain and directed searches of thalamus and SI, SII, anterior cingulate and insular cortices were performed.

Compared to 34° stimulation, all stimuli, whether innocuous or painful, produced significant rCBF increases in contralateral insular cortex. Painful heat, painful cold and the thermal grill pain illusion produced additional rCBF increases in contralateral thalamus and anterior cingulate cortex. Painful heat activated SI cortex, and both painful and innocuous stimuli activated regions near SII.

These data indicate that whereas insular cortex is involved in both pain and temperature processing, anterior cingulate cortex is activated by pain. The finding that an illusion of pain caused by innocuous temperatures leads to activation patterns similar to true noxious stimulation suggests that integration of pain and temperature in thalamus and cortex underlies the illusion. Supported by the Flinn Foundation, Barrow Neurol. Foundation and the Canadian MRC.

FUNCTIONAL MAGNETIC RESONANCE IMAGING OF HUMAN SOMATOSENSORY AND CINGULATE CORTEX DURING PAIN AND PARAESTHESIA EVOKED BY MEDIAN NERVE STIMULATION. K.D. Davis*[1], M.L. Wood[2], A.P. Crawley[2] and D.J Mikulis[2]. [1]Div. of Neurosurgery and [2]Dept. of Radiol., U. of Toronto, The Toronto Hospital, Toronto, Ont., Canada M5T 2S8.

Positron emission tomography studies suggest that the primary somatosensory (SI) and cingulate (Cg) cortices play a role in the perception of noxious thermal stimuli. In this study, we investigated whether transcutaneous electrical nerve stimuli could be used with non-invasive functional magnetic resonance imaging (fMRI) techniques to study specific pain-related cortical activity in SI and Cg.

All data were collected from normal male and female subjects. Images were obtained with a 1.5T MRI scanner. Each protocol typically consisted of alternating sets of 6 images during a task and 6 images at rest for a total of 72 images. Conventional gradient echoes were used with the following parameters: TR=68ms, TE=40ms, ~6sec/image, 30x22cm FOV, 256x128 matrix, 4mm slice, 45° flip angle. Electrical stimuli were applied to the median nerve and the intensity of stimulation was adjusted in each subject to evoke either non-painful paraesthesia or pain in the distribution of the nerve. Activated regions were determined by statistical analysis of the mean intensity signal differences of each pixel during the task and controls.

Stimuli that evoked non-painful paresthesias activated discrete areas of S1 but did not activate Cg. Painful stimuli activated both SI and Cg. Cg activation was in the caudal portion of the anterior Cg, in or close to caudal area 24. In some subjects, increasing intensity of pain was associated with a larger region of activation within SI. In some cases, the mean intensity signal within an activated region correlated to the intensity of evoked pain. These data indicate that electrical stimuli and fMRI can be used to study pain-related cortical activity and confirm the involvment of SI and Cg in pain perception.

PAIN MODULATION: ANATOMY AND PHYSIOLOGY—HUMAN STUDIES

643.1

AFFERENT CONDITIONING PRODUCES DIFFERENT EFFECTS ON CLINICAL AND EXPERIMENTAL PAIN IN CHRONIC LOW BACK PAIN PATIENTS. G.Cheing and C.W.Y. Hui-Chan*. School of Physical & Occupational Therapy, McGill University, Montreal, Canada, H3G 1Y5.

The objective of this study was to determine whether *chronic* clinical pain, *acute* experimental pain, and the flexion reflex (FR), will be modified in a similar or different manner by transcutaneous electrical nerve stimulation (TENS) in chronic low back pain patients.

Thirty young subjects suffering from low back pain longer than six months were studied. They were matched with respect to gender and severity of pain, then randomly assigned to two groups, receiving either TENS or sham TENS to the lumbro-sacral region for 60 min. The FR was elicited by a maximally tolerable electrical stimulation applied to the subject's right sole, and recorded electromyographically from the biceps femoris and tibialis anterior. Subjective pain sensation of the low back pain (clinical pain) and the electrical stimulation (experimental pain) were measured by two separate visual analogue scales. ANOVA and Tukey tests were used to analyze the data obtained *before, during* and, up to 60 min *after* TENS or sham stimulation.

The pre-stimulation control value of subjective low back pain sensation was decreased to 62.9% in the TENS group ($p<0.01$), but not in the placebo group. In contrast, there was no significant decrease in both the experimental pain sensation and the FR *before, during* and *after* TENS or sham stimulation within each group, and between the two groups. These results show that chronic and acute pain were modified by TENS in a different manner. It is known that the neural pathways mediating the two types of pain are different. Our present findings suggest that there could also be different anti-nociceptive mechanisms for chronic and acute pain in chronic low back pain patients.

MORPHINE AND SKIN BLOOD FLOW (SBF) CHANGES IN NEWBORN INFANTS. T. N. K. Raju* T. Roohey A. N. Moustagiannis and K. M. McCulloch. Dept. Pediatrics, Univ. of Illinois, Chicago IL 60612.

We have shown that SBF increases with pain in newborn infants. Here we assessed morphine-induced SBF using a non-invasive, laser Doppler method 20–30 min before, 20–30 min during, and 35–45 min after placement of percutaneous central venous catheters (PCVC) in 18 infants (median birth weight 1100 g, age 5 days). Ten of these were given 0.05–0.1 mg/kg IV morphine just before PCVC placement and 8 were not. Changes in hear rate (HR) and SBF (ml/100g/min) are shown below.

Variable	Group	Baseline	During	After
SBF	Morphine.	22.5±9.5	22.6 ±7.7	19.3±7
	No morphine.	23.7±8	45.3±34†	21 ±5
HR (bpm)	Morphine	156±13	154 ±13	151±13
	No morphine	161 ±11	168 ±9 †	167 ±11†

(†P <0.05 vs baseline & morphine group.) Respiration and O_2 saturation changed minimally in both groups. Without morphine SBF increased in 7/9 (overall $\bar{x}$ change +97%, $P < 0.05$); with morphine SBF changes were minimal during PCVC placement. SBF changes returned to baseline during recovery in both groups. We conclude: 1) IV morphine prevented a substantial SBF increase from pain, perhaps reflecting an analgesic effect; 2) non-invasive SBF can serve as a measure of pain and analgesia.

643.3

EFFECT OF CAPSAICIN ON HUMAN JAW REFLEX EVOKED BY ELECTRICAL TOOTH PULP STIMULATION. [1]P. Kemppainen*, [1]A. Waltimo, [1]T. Waltimo, [1]M. Könönen and [2]A. Pertovaara. [1]Dept. of Prosthetic Dentistry and [2]Dept. of Physiology, Univ. of Helsinki, Finland.

The effect of selective activation of nociceptive primary afferent fibers by capsaicin on a masseteric reflex was studied in healthy human subjects. The inhibitory masseteric reflex was evoked by constant current (single pulses) stimulation of the upper incisor. The sensation of the tooth pulp stimulation was evaluated by visual analogue scale (VAS). The magnitude of the reflex response was determined by jaw force measurements and electromyographic recordings (EMGs) from the active masseter muscle. The inhibitory masseteric reflex could be induced already at nonpainful tooth pulp stimulation and the magnitude of the reflex was elevated with increasing current values. Capsaicin (1 %) applied topically to the skin of the cheek produced a burning spontaneous pain sensation. During capsaicin treatment the VAS ratings for the tooth pulp stimulation were significantly reduced, whereas no marked changes were found in the magnitudes of the jaw reflex responses. Thus, the influence of selective activation of nociceptive fibers of the facial skin by capsaicin on the tooth pulp-evoked sensory and reflex responses differs from the effect of capsaicin on a nociceptive withdrawal reflex of the limb.

643.4

EFFECT OF ACUPUNCTURE ON SYMPTOMATIC KNEE OSTEOARTHRITIS. R.H. Wong*, B.M. Berman, L. Lao, P. Langenberg, M. Esfahani, and M.C. Hochberg. Departments of Family Medicine, Epidemiology and Preventive Medicine, and Medicine, University of Maryland School of Medicine, Baltimore, MD 21201

Osteoarthritis is a common disease in which there is no specific or curative therapy. The aims of this study were to compare self-reported pain, stiffness and physical function for patients receiving acupuncture plus conventional therapy or conventional therapy alone in patients with osteoarthritis of the knee and to assess the possible adverse effects of acupuncture. Seventeen patients, mean age 70±8 years, with moderate to severe osteoarthritis of the knee (fulfilling the American College of Rheumatology (ACR) classification criteria) were enrolled and randomized into either a control (n=9) or acupuncture group (n=8). The control group received baseline anti-rheumatic drug therapy for eight weeks. The treatment group was treated twice a week for eight weeks with acupuncture. Outcome assessments of pain and physical function using both the Western Ontario and McMaster (WOMAC) and the Lequesne Osteoarthritis Indices, and a fifty-foot walk time were performed at baseline and four-week intervals with follow-up at weeks 12 and 24. The WOMAC Osteoarthritis Index indicated that the acupuncture group improved significantly at weeks 4 ($p\leq0.05$), 8 ($p\leq0.02$), and 12 ($p\leq0.01$) using Wilcoxon's signed rank test for paired data with two-tailed P values. The Lequesne Index also showed significant improvement at week 8 ($p\leq0.05$) for the acupuncture group. There was no significant difference found in the fifty-foot walk times, and no significant adverse effects reported after acupuncture treatment. For the control group, no significant differences were found in the outcome assessments. The results indicate that acupuncture is associated with significant improvement in pain and physical function in patients with osteoarthritis of the knee. Support provided by NIH RFA#1-R21-RR09327-01.

GABA$_B$ AGONIST, BACLOFEN, REDUCES CENTRAL PAIN WITHOUT IMPAIRING SOMATIC SENSATION.

A.Ueda, Y.Kawakami#, T.Taira, A.Komatsu*#, K.Takakura. Departments of Nurosurgery and Physiology#, Tokyo Women's Medical College, 8-1 Kawada-cho, Shinjuku-ku Tokyo, Japan

Intrathecal injection of 50μg baclofen suppressed central pain in post stroke patients (Taira 1994). Substantial pain relief (pain score 1-2/10) lasted for 12-24 hours in five of six patients. On the contrary, somatic sensation and motor control were not impaired by intrathecal baclofen. First, we investigated the discrepancy in effects of baclofen on pain and somatic sensation. Field potentials evoked by sciatic nerve stimulation were recorded in the dorsal horn of the spinal cord in anesthetized rats. Early components (within 2 ms latency) of field potentials evoked by low intensity stimulation were not affected by application of 15μg baclofen. The early components of field potentials recorded in this experiment may involve single or a few synapses. In contrast, the amplitudes of late components (80 ms latency) evoked by high stimulus intensity decreased to 55% of the control value. Next, using the H reflex, we demonstrated that 15 μg baclofen had no effect on H wave amplitude. The results suggest that baclofen, in the spinal cord, has little effect on single synaptic responses. This may account for the discrepant effects on pain, somatic and motor control.

643.6

INTERACTIONS BETWEEN LOW THRESHOLD MECHANORECEPTORS AND NOCICEPTORS DURING SECONDARY HYPERALGESIA.

F. Cervero* and J.M.A. Laird. Department of Physiology and Pharmacology, University of Alcalá de Henares, 28871 Madrid, Spain.

Hyperalgesic states are characterized by an increase in the pain evoked by nociceptor stimulation and by a central alteration in the processing of low-threshold mechanoreceptor input such that their stimulation evokes pain (allodynia). In this study we have examined if stimulation of low-threshold mechanoreceptors from an area of secondary hyperalgesia could evoke nociceptor activity expressed as local vasodilatations (axon reflexes).

Experiments were conducted on normal human volunteers. Cutaneous blood flow and temperature in two different points were measured with a Laser Doppler instrument. Hyperalgesia was induced by the application of mustard oil (25%) or by intradermal injections of capsaicin (25-50 μg) in the volar skin of one forearm. Stimulation of low threshold mechanoreceptors was achieved by brushing or stroking the skin. Pain ratings (VAS) and simultaneous recordings of blood flow and skin temperature were obtained.

Stimulation of low threshold mechanoreceptors in normal skin before the induction of secondary hyperalgesia or outside these zones once induced, did not evoke changes in skin blood flow. However gentle stimulation of the skin in areas of secondary hyperalgesia evoked painful sensations as well as localized increases in blood flow. These changes required continuous low intensity mechanical stimulation and outlasted the duration of the stimulus. Cooling the area of primary hyperalgesia reduced the vascular responses and the pain sensation evoked by gentle mechanical stimulation. These results show an interaction between low threshold mechanoreceptors and nociceptors appearing simultaneously with the development of the central changes of secondary hyperalgesia. Support: DGICYT APC-93-0102 and PB-93-0491.

CHANGES IN SKIN AND MUSCLE SENSITIVITY IN DYSMENORRHEIC VS NORMAL WOMEN AS A FUNCTION OF BODY SITE AND MONTHLY CYCLE.

M.A. Giamberardino*, K.J. Berkley*, S. Iezzi, P. de Bigontina, L. Vecchiet. Inst. of Medical Pathophysiology, G. D'Annunzio Univ., 66100 Chieti, Italy and Program in Neuroscience, Florida State Univ., Tallahassee, FL, USA.

Changes were investigated in skin and muscle sensitivity of 7 dysmenorrheic vs 7 normal women as a function of body site inside and outside the metameric field of reproductive organs and monthly cycle. Pain thresholds to electrical stimulation were measured for *two abdominal areas* (inside reproductive field--symmetrical sites of the left and right rectus abdominis and overlying skin, 4 cm lateral to the navel) and for *two limb areas* (outside reproductive field--deltoid and quadriceps and overlying skin of one side). Measurement was repeated 4 times during a 28-day cycle; i.e., on days 2-6, during menstruation (phase a); 12-16, periovulatory (phase b); 17-22, luteal (phase c); 25-28, premenstrual (phase d).

Presence of dysmenorrhea: thresholds in dysmenorrheic women were normal in skin but lower than normal in muscle in every site with a significant difference for the abdomen in all phases and for the deltoid in phases a and b. Body site: in dysmenorrheic and normal women muscle thresholds were lower in the abdomen than in the limbs. Cyclic variations: in dysmenorrheic and normal women the highest threshold value was in the luteal phase (phase c) for both skin and muscle while the lowest occurred periovulatorily (phase b) for skin and perimenstrually (phases a or d) for muscle. This monthly trend was significant in muscle in every site for dysmenorrheic women but only in the abdomen for normal women.

Hyperalgesia is evident in muscle but not in skin both inside and outside the metameric fields of reproductive organs for dysmenorrheic women but only inside them for normal women. Sensitivity increases periovulatorily in skin and perimenstrually in muscle and decreases in the luteal phase for both tissues regardless of body site and dysmenorrhea status, but a significant monthly rhythm appears only in hyperalgesic areas. PAIN MODULATION: ANATOMY AND PHYSIOLOGY—BRAINSTEM

644.1

EFFECTS OF UNILATERAL NUCLEUS TRACTUS SOLITARIUS LESIONS ON CENTRALLY-MEDIATED HYPERALGESIA.

E.P. Wiertelak* & B. Roemer. Dept. of Psychology, Macalester College, St. Paul, MN 55105.

Endogenous hyperalgesia circuitry can be activated in response to a variety of aversive events. Specifically, illness-causing agents (such as emetics or pyrogenics) have been shown to produce internal aversive occurrences that result in the enhancement of pain sensitivity as measured by the tail-flick test (TF). Recent evidence has also shown that s.c. formalin (right hindpaw) activates a centrifugal pathway that results in hyperalgesia measurable using the TF test. While the neural circuitry responsible for these centrally mediated hyperalgesias has only recently come to be investigated, current evidence strongly suggests that illness-induced hyperalgesia originates in the viscera at vagal terminals, implicating that the ascending message may involve mediation in the hind brain at the nucleus tractus solitarius (NTS).

The present studies investigated the possibility that lesions (unilateral, electrolytic) of the NTS would disrupt centrally mediated hyperalgesias. After a recuperative period, pain responsivity was tested in lesioned and sham-lesion control animals following injection of lipopolysaccharides (LPS; intraperitoneal, IP; pyrogenic) lithium chloride (LiCl; IP, emetic), or formalin (right hindpaw; irritant). Preliminary results indicate that NTS lesions disrupt hyperalgesias produced by LPS and LiCl, but not formalin. Supported by NIH/NIDA grant 1R29DA09289-01 to EPW.

644.2

PROJECTION OF MET-ENKEPHALIN NEURONS TO NORADRENERGIC CELLS IN THE DORSOLATERAL PONTINE TEGMENTUM: A POSSIBLE ROLE IN MODULATING NOCICEPTION.

J.E. Holden* and H.K. Proudfit, Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60612

The dorsolateral pontine tegmentum (DLPT) plays a major role in modulating nociception. Neurons in the ventromedial medulla (VMM) project to the DLPT and activate spinally-projecting neurons which modify nociceptive stimuli. We recently demonstrated that a population of these VMM neurons are immunoreactive for methionine-enkephalin (mENK) and can be retrogradely labeled from the DLPT. Met-Enk terminals were also found in apposition to tyrosine hydroxylase-immunoreactive (TH) cells in the DLPT, suggesting that mENK cells from the VMM innervate noradrenergic cells in the DLPT.

To verify these findings, iontophoretic injections of the anterograde tracer, Fluoro-Ruby (FR), were made into the VMM. Axons from cells in the VMM were double-labeled with both FR and mENK. These double-labeled axon terminals were found in apposition to TH cells in the DLPT. A number of double-labeled terminals were also found in other areas known to participate in antinociception, including the parabrachial region, the nucleus reticularis pontis oralis (RPOo) and the subcoeruleus region. These findings suggest that the VMM mENK neurons that innervate spinally-projecting noradrenergic cells in the DLPT are involved in modulating nociception. (Supported by USPHS grant DA03980, National Institute on Drug Abuse and NR07075-03, National Institute of Nursing Research).

644.3

SUBCUTANEOUS FORMALIN INDUCED ACTIVITY OF ON- AND OFF-CELLS OF THE ROSTRAL VENTROMEDIAL MEDULLA.

V. Tortorici*, E. Vásquez and H. Vanegas. Instituto Venezolano de Investigaciones Científicas (IVIC), P.O. Box 21827, Caracas 1020A, Venezuela.

The formalin (FOR) test is widely used to measure behavioral responses to a long-lasting nociceptive stimulus capable of eliciting a sequence of pain-related events characterized by an early (acute) phase and a late (tonic) phase, but the neural mechanisms involved have not been clearly identified electrophysiologically. This study evaluates the possible role of medullary on- and off-cells, which are putative nociception-modulating neurons that project to the spinal cord, during the time course of the effect of FOR.

The activity of medullary neurons was recorded in rats during application of noxious heat to the tail or noxious pinch to a paw. Thiopental anesthesia kept the animals free from signs of pain or discomfort while stable responses to noxious stimulation occured. On- and off-cells were characterized, since on-cells increase and off-cells stop their firing just before tail-flick or immediatly after noxious pinch. Thereafter FOR (100 µl, 10%) was subcutaneously injected in one of the hindpaws and the responses of the on - and off-cells were studied for 65 min.

FOR produced both early and late excitatory responses on the firing frequency (358.64 and 242.54% respectively) in all the on-cells tested, but only inhibition of activity (61.12%) during the early phase in the off-cells. During the late phase the off-cells showed only a reduction of 16.67% in their firing frequency. This suggests the existence of a new possible balance of activity between the two classes of neurons, probably induced by the tonic situation, in which the supressive effect of off-cells during the late phase probably is not sufficcient to cause inhibition of on-cells. Also, the interphase period, behavioraly defined as a zone of no pain, can be the result of the continuous firing observed during this interval in the off-cells.

(Supported by grant S1-2672 of CONICIT).

644.4

EFFECTS OF "DEEP MUSCLE PAIN" ON TRIGEMINAL MOTONEURONS AND INTERNEURONS DURING FICTIVE MASTICATION.

K-G. Westberg*, P. Clavelou, G. Schwartz, J.P. Lund, C. Valiquette. CRSN and Fac. Méd. Dent., Univ.de Montréal, Québec, H3C 3J7, Canada.

Evaluation of data from clinical studies show that chronic muscle pain is not associated with tonic hyperactivity, as postulated by the vicious cycle theory. Instead, resting EMG activity appears normal. During function, agonist activity is less than normal, while antagonist activity tends to rise slightly. Experimental pain causes similar changes in muscle activity in man and animals. The specific aim of the present study was to evaluate how nociceptive muscle inputs act on the brainstem oro-facial motor circuitry during masticatory movements. Rabbits were anaesthetized with halothane, decerebrated at the precollicular level and paralyzed. Fictive mastication was evoked by repetitive stimulation of the cortico-bulbar tract and monitored in the trigeminal motoneuron subnuclei. Muscle pain was induced by injections (160µl) of hypertonic saline (5%) into the deep portion of the masseter muscle. Changes in the masticatory motor pattern and the firing properties of interneurons located in the oral subnucleus of the spinal trigeminal tract, were simultaneously analyzed before, during and after fictive mastication induced in the presence or absence of the noxious stimulations. Our results show that muscle nociception reduces the masticatory frequency and the frequency of discharge of the jaw motoneurons. Clear modifications of the firing frequency were also observed in 11 out of 13 interneurons that were rhythmically active during fictive mastication. An increased firing frequency was the main finding. Our results suggest that muscle nociceptive inputs adapt the movement pattern through actions on the rhythm and burst generating components of the brainstem central pattern generator for mastication.

644.5

THE ROLE OF THE ROSTROVENTRAL MEDULLA (RVM) IN I.V. SEROTONIN PRODUCED INHIBITION OF THE TAIL FLICK (TF) REFLEX IN RATS.

C.L. Thurston*, J.T. Ranieri, D. Barnes-Noble. Dept. Biomedical Sciences, Univ. South Alabama, Mobile, AL 36688.

I.v. administration of serotonin inhibits the TF reflex through activation of vagal afferents. Previous studies with electrical stimulation of vagal afferents showed that vagal stimulation inhibits OFF cells and excites ON cells of the RVM at intensities that inhibit the TF reflex. The current study examined the possible role of the RVM in i.v. serotonin-induced antinociception.

Serotonin dose-dependently attenuated the TF reflex and produced the Bezold-Jarish reflex. Lidocaine microinjections into the RVM attenuated the inhibition of the TF reflex produced by 80 µg serotonin. Electrophysiological recordings in the RVM showed that serotonin predominately inhibits OFF cells and excites those ON cells with low background activity. Bilateral cervical vagotomy decreased the background activity of OFF cells and increased the background activity of ON cells and attenuated the serotonin-produced changes in neural activity. These findings are similar to the earlier findings with electrical stimulation of vagal afferents.

644.6

ANTINOCICEPTION AND IMMOBILITY PRODUCED BY MICROINJECTION OF LOW DOSES OF KAINIC ACID INTO THE RVM OF THE RAT.

M.M. Morgan*, P.K. Whitney, M.E. Thompson, & L. Springmeyer. Dept. of Psychology, Washington State Univ., Vancouver, WA 98663.

The pathway for modulation of nociception from the periaqueductal gray to the rostral ventromedial medulla (RVM) to the spinal cord has been well characterized. Antinociception mediated by this circuit appears to be part of a defensive reaction. For example, activation of the ventrolateral PAG produces both antinociception and immobility. Because the PAG projects to the RVM, the present study examined whether the RVM is part of the pathway mediating immobility.

Male Sprague-Dawley rats were chronically implanted with a guide cannula aimed at the RVM and injected with low doses of kainic acid (4, 20, & 40 pmol in 200 nL) or saline. Microinjection of kainic acid into the RVM produced a dose dependent inhibition of locomotion in the open field test (i.e. no effect with 4 pmol vs a maximal effect with 40 pmol) even though rats were capable of movement. Moreover, immobility in the open field was consistently associated with antinociception on the hot plate test.

The immobility and antinociception seen in the present study are similar to the effects produced by activating neurons in the ventrolateral PAG and suggest, along with anatomical and physiological data, that these behaviors are mediated via a ventrolateral PAG to RVM pathway. Presumably, the PAG and RVM are part of an integrated defense circuit coordinating responses to potentially life threatening situations.

644.7

DISTRIBUTION OF TYROSINE HYDROXYLASE IMMUNOREACTIVE (TH-IR) APPOSITIONS ONTO PHYSIOLOGICALLY IDENTIFIED NEURONS IN THE RAT ROSTRAL VENTROMEDIAL MEDULLA.

X. Meng,* B. Budra, K. Skinner, H.L. Fields. Dept. of Neurology and the William B. Keck Center for Integrative Neuroscience, UCSF, San Francisco, CA 94143

TH-IR fibers and terminals are present throughout the rostral ventromedial medulla (RVM) and the activity of RVM neurons is influenced by noradrenergic inputs. There are two classes of putative pain modulating neurons in RVM: on-cells and off-cells, which respectively burst or pause prior to withdrawal reflexes. On-cells respond to iontophoretic application of noradrenaline (NA) and other alpha-adrenergic receptor agonists. To better understand the contribution of NA to the control of RVM neurons, we analyzed the anatomic distribution for catecholaminergic termination upon these two physiological cell classes in RVM.

On- and off-cells were identified by the change in their discharge rate in relation to nociceptive withdrawal reflexes and labeled by intracellular injection of neurobiotin in the lightly anesthetized rat. Sections containing labeled cells were visualized with a Texas red fluorophore conjugated to avidin and were subsequently processed for TH-IR using goat anti-rabbit IgG as a secondary antibody conjugated to a Bodipy fluorophore. The distributions of the two fluorophores were then mapped using a confocal laser scanning microscope (BIORED 600).

Seven RVM neurons (4 on, 3 off) were intracellularly labeled. Each on- and off-cell had a number of close TH-IR appositions. Appositions more commonly occurred on dendrites than on the somas of on-cells. There was a trend toward greater average density of TH-IR appositions onto on-cells.

These observations provide evidence that putative pain modulating neurons in RVM receive direct noradrenergic inputs.

644.8

$GABA_A$ RECEPTOR SUBUNITS ON BULBOSPINAL NEURONS OF THE RAT.

A.T. Hama[1]*, J.M. Fritschy[2], W. Sieghart[3] and D.L. Hammond[1]. [1]Dept. Anes. & Crit. Care, Univ. Chicago, Chicago, IL USA 60637, [2]Inst. Pharmacol., Univ. Zurich, CH-8057 Zurich, Switzerland, [3]Dept. Biochem. Psychiat., Univ. Clinic Psychiat., A-1090 Vienna, Austria.

Microinjection of $GABA_A$ receptor ligands in the n. raphe magnus (NRM) or n. reticularis gigantocellularis pars α (NGCpα) modulates nociceptive sensitivity. It is not known whether these effects are mediated by spinally-projecting neurons of the NRM and NGCpα. This study examined whether neurons of the NRM and NGCpα that project to the spinal cord also possess $GABA_A$ receptors. Male S-D rats were perfused with 4% paraformaldehyde 10-14 days after injection of 2% Fluoro-Gold (FG) in the spinal cord. Transverse 25 µm sections were incubated in rabbit anti-serotonin (5HT) antiserum and either guinea pig anti-α_1 (1-16) subunit or guinea pig anti-α_3 (1-15) subunit antibodies. Other sections were incubated in goat anti-5HT antiserum and rabbit anti-α_1 (1-9) subunit antibodies. Primary antisera were visualized using CY3- or FITC-linked secondary antibodies. Neurons in the NRM and NGCPα were immunoreactive (IR) for the α_1 subunit, but none of these neurons were IR for 5HT. Of the α_1-IR neurons, a portion projected to the spinal cord as indicated by the presence of FG. NRM and NGCPα neurons were also IR for the α_3 subunit. Many, but not all of these neurons were also IR for 5HT. A portion of both populations of α_3-IR neurons contained FG. The differential distribution of α_1 and α_3 subunits, which confer different pharmacologic properties to $GABA_A$ receptors, suggests that NRM and NGCpα neurons that project to the spinal cord may be modulated by different types of the $GABA_A$ receptor. Supported by DE11423 and DA07255.

MORPHINE AND SOMATOSTATIN INTERACT TO REDUCE FOS-LI WITHIN TRIGEMINAL SUBNUCLEUS CAUDALIS AFTER CORNEAL STIMULATION IN THE RAT. D.A. Bereiter* and B.H. Tonnessen. Depts. of Neuroscience & Surgery, Brown Univ/RI Hospital, Providence, RI 02903

Corneal stimulation at noxious intensities produces Fos-like immunoreactivity (Fos-LI) in two spatially distinct transition regions of the spinal trigeminal nucleus (Vi/Vc and Vc/C1). Fos is the protein product of the immediate early gene c-*fos* and is a reliable marker for nociceptive-responsive neurons in the medullary dorsal horn. Morphine and somatostatin have been implicated as putative mediators of antinociceptive behavior among central trigeminal neurons. To assess the role of mu opioid and somatostatin receptor activation on Fos-LI, morphine (0.01-10 nmol) or octreotide (long-acting somatostatin analog, 0.1-1 nmol, icv) was given alone or in combination 20 min prior to corneal application of mustard oil to male rats anesthetized with pentobarbital. Mean arterial pressure (MAP) and heart rate (HR) were monitored in all groups. Neither morphine nor octreotide affected Fos-LI at the periobex Vi/Vc level, in ventrolateral medulla or NTS. In contrast, both morphine and octreotide caused a dose-related decrease ($P < 0.01$) in Fos-LI among laminae I-II neurons at the Vc/C1 transition level. Combined morphine (0.01 nmol) plus octreotide (1 nmol) caused a greater reduction in Fos-LI in laminae I-II at Vc/C1 than the additive effect of each drug alone. Morphine attenuated the MAP and HR responses to corneal stimulation in a dose-related manner, whereas octreotide had no consistent effect when given alone or in combination with the lowest dose of morphine. The magnitude of Fos-LI among laminae I-II Vc/C1 neurons was well-correlated with the MAP response to corneal stimulation under different doses of morphine ($r = 0.63$, $P < 0.01$), but not after octreotide. The results indicate that morphine and somatostatin interact centrally to reduce the expression of c-*fos* among corneal-responsive Vc/C1 neurons, but not Vi/Vc neurons. The neural substrate that mediates the apparent interaction between morphine and somatostatin and c-*fos* expression is separate from that which mediates the autonomic responses to corneal stimulation. Supported by NIH grant NS 26137.

PAIN MODULATION: PHARMACOLOGY—NMDA AND NO

645.1

REPETITIVE STIMULATION AND NALOXONE FOLLOWING OPIOID EXPOSURE INDUCE NMDA RECEPTOR-DEPENDENT LONG TERM POTENTIATION (LTP) IN ISOLATED RAT SPINAL CORD. J.-Q. Feng and J. J. Kendig*, Dept. of Anesthesia, Stanford Univ. Sch. of Medicine, Stanford, CA 94305

Recent evidence suggests that hyperalgesia induced by prolonged noxious stimulation and by precipitated withdrawal from opioids may have mechanisms in common. In isolated neonatal rat spinal cord, a prolonged (30 min or longer) significant increase in area of a nociceptive-related slow ventral root potential (sVRP) was induced by either tetanic (10 s^{-1}, 1 min) stimulation to a dorsal root (124% of control ± 22.4, mean ± SD, N=28) or by naloxone 200 nM following morphine 200 nM (142±17.5, N=6) or alfentanil 200 nM (148%±29.2, N=11). MK-801 20 nM had no effect on sVRP area alone but given before the tetanus or coadministered with the opioids blocked the increase in sVRP area induced by either tetanic stimulation or opioid. MK-801 20 nM shifted the morphine dose-response curve for sVRP depression significantly to the left. The results are consistent with a prolonged NMDA receptor-mediated excitatory effect exerted by repetitive stimulation and by μ opioid exposure. The phenomenon may represent the first step in a central sensitization that underlies both tolerance and neuropathic pain.

645.2

PHARMACOLOGICAL CHARACTERIZATION OF N-METHYL-D-ASPARTATE (NMDA) RECEPTORS IN SPINAL CORD OF NORMAL AND NEUROPATHIC RATS H. Wei*, L.B. Jakeman, and D.W. Bonhaus, Syntex Research, Palo Alto, CA 94304

Spinal cord NMDA receptors play a key role in nociception and in the sensitization of neurons following nociceptive input (wind up). Thus, NMDA receptor antagonists with selectivity for spinal cord receptors may be useful analgesics and may prevent the development of hyperalgesia or allodynia following nerve injury. We characterized the NMDA receptors present in spinal cords of rats with a painful neuropathy of the left hind foot (the "Bennett" model). Receptors were characterized in membrane homogenates and by receptor autoradiography using [^{3}H]MK 801 or [^{3}H]TCP. No difference in the density of NMDA receptors was detected between normal and neuropathic rats in the L4-L5 region of the spinal cord (fmol/mg protein equivalent; mean ± sem).

		Left dorsal horn	right dorsal horn
control	N=6	69.6 ± 6.6	64.8 ± 6.8
neuropathic	N=6	74.9 ± 6.9	71.9 ± 2.7

However, spinal cord NMDA receptors could be distinguished from those in brain cortex. Spermidine allosterically increased [^{3}H]TCP binding to NMDA receptors in brain cortex membranes (39±8%) but had no effect on [^{3}H]TCP binding to spinal cord membranes (2±1%). In this regard spinal cord NMDA receptors resembled those in the cerebellum (0±2%). These findings indicate that while there may be no change in the density of spinal cord NMDA receptors in neuropathic rats, spinal cord NMDA receptors can be distinguished from receptors in the cortex. Thus, it may be possible to develop NMDA receptor antagonists with selectivity for the spinal cord.

645.3

DIFFERENTIAL INVOLVEMENT OF EXCITATORY AMINO ACID RECEPTORS IN MEDIATING HYPERRESPONSIVENESS OF DORSAL HORN NEURONS IN NEUROPATHIC RATS. J.W. Leem*, E.S. Park, E.J. Choi, T.S. Nam and K.S. Paik. Dept. of Physiology, Yonsei Univ. Col. Med., SEOUL, 120-752, Korea.

The aim of this study is to investigate the roles of excitatory amino acid (EAA) receptors in enhanced responses of spinal dorsal horn neurons to mechanical stimuli seen in neuropathic rats.

Neuropathic rats were made by an unilateral ligation of L5-6 spinal nerves. Activity of wide dynamic range (WDR) lumbar dorsal horn neurons evoked by brush and pinch stimulation of the receptive field (RF) was recorded, and effects of iontophoretically applied EAA receptor antagonists on mechanically evoked responses were tested. Comparison was made between neuropathic and normal rats.

Both brush-evoked and pinch-evoked responses of WDR neurons were enhanced in neuropathic rats, as compared to in normal rats. Enhanced brush-evoked response was suppressed by AMPA, non-NMDA antagonist, whereas enhanced pinch-evoked response was suppresed by AP-5, NMDA antagonist. No suppression by either antagonist was observed in normal WDR neurons.

The results implicate that enhanced response to non-noxious mechanical stimulus is mediated by non-NMDA receptor whereas that to noxious one is by NMDA receptor in this rat model of peripheral neuropathy. (Supported by a Grant from KOSEF)

NMDA RECEPTORS INVOLVEMENT IN MORPHINE BUT NOT OXOTREMORINE-INDUCED ANALGESIA. V. Cestari, C. Rossi-Arnaud*° and F. Pavone^. Università "La Sapienza", Dip. di Genetica e Biologia Molecolare, 00185 Roma, Italy. °Università "La Sapienza", Facoltà di Psicologia, 00185 Roma, Italy, ^Ist. di Psicobiologia e Psicofarmacologia (C.N.R.) - 00198 Roma, Italy.

Recent results show an involvement of the glutamatergic system in modulating pain responses in animals. A number of data show that the activation of the NMDA receptors plays an important role in chronic pain and spinal nociceptive processes.

Two groups of experiments were carried out in order to investigate if NMDA receptors were involved in the well known analgesic response induced by the stimulation of the cholinergic or the opioid systems. In a first group of experiments, CD1 mice were injected with the non-competitive NMDA receptor antagonist MK-801 (0.075, 0.1, 0.125, 0.15 mg/kg, i.p.) and 15 minutes later with vehicle or oxotremorine (0.03 mg/kg, i.p.). After 15, 30 and 60 minutes from the second injection, they were tested in the tail-flick test. The results showed no significative effects on pain sensitivity of mice injected with MK-801. Moreover, MK-801 did not significantly modify the analgesic effect of oxotremorine. On the other hand, the results of a second group of experiments showed that the antinociceptive response induced by the administration of morphine (5, 10 mg/kg , i.p.) was potentiated by MK-801 (0.075, 0.1, 0.125, 0.15 mg/kg, i.p.). The present results support the hypothesis that the glutamatergic system is involved in the antinociceptive effects induced by the stimulation of the opioid system, while they seem to rule out that in our experimental conditions NMDA receptors mediate the analgesic response due to the cholinergic activation.

NMDA ANTAGONIST, MK-801, BLOCKS THE DEVELOPMENT OF TOLERANCE TO SWIM STRESS-INDUCED ANALGESIA IN MICE. John M. Owen*, Michael W. Haydel and Anthony L. Vaccarino, Department of Psychology, University of New Orleans, LA 70148.

Several lines of evidence indicate a critical role of the *N*-methyl-D-aspartate (NMDA) receptor in the development of tolerance to morphine-induced analgesia. The present study examined the involvement of the NMDA receptor in the development of tolerance to swim stress-induced analgesia (SSIA). To examine the development of tolerance to repeated stress, male Swiss mice were swum individually for 3 minutes daily in water maintained at 32°C for 15 days. A control group was swum on day 1 and day 15 day only. Pain sensitivity was assessed on day 1 and day 15 in the hot-plate test (56°C) prior to (baseline) and after swim stress. The latency to hind-paw flick was measured and a cut-off period of 60 seconds was imposed to avoid tissue damage. To examine the role of the NMDA receptor, mice were injected with either MK-801 (0.075 mg/kg, i.p.) or saline 15 minutes prior to swimming on days 1-14. Control mice also received daily injections of MK-801 or saline. Repeated stress was found to produce tolerance to SSIA. Pretreatment with MK-801 prevented the development of tolerance to SSIA. These results suggest that tolerance to SSIA is mediated in part by the NMDA receptor. This research was supported by a LSU Neuroscience Incentive Grant.

N-METHYL-D-ASPARTATE AND NEUROKININ RECEPTORS ARE CRITICAL FOR THE INDUCTION OF LONG-TERM POTENTIATION OF C-FIBER-EVOKED FIELD POTENTIALS IN RAT SPINAL DORSAL HORN. J. Sandkühler, X.-G. Liu and M. Zimmermann*. II. Physiologisches Institut, Universität Heidelberg, 69120 Heidelberg, FRG.

Long-term potentiation (LTP) of C-fiber-evoked field potentials in spinal dorsal horn may underly the prolonged central changes of nociception. In this work the roles of N-methyl-D-aspartate (NMDA) and neurokinin (NK1 and NK2) receptors for the induction of LTP were evaluated by superfusion of rat spinal cord with selective agonists and antagonists of NMDA and neurokinin receptors. Superfusion of spinal cord with NMDA receptor antagonist D-(-)4-(3-phosphonopropyl)piperazine-2-carboxylic (D-CPP, 500 nM) for 30 min before and for 30 min after conditioning tetanic nerve stimulation had little effect on the amplitude of C-fiber-evoked potentials but completely blocked LTP in all 5 rats tested. Superfusion of spinal cord with NMDA (1 μM, 10 μM or 50 μM) induced LTP in only 2 out of 8 rats. Superfusion of the spinal cord with the NK1 receptor antagonist RP 67580 at 5 μM inhibited the amplitudes of C-fiber-evoked potentials by 60% but had no effect at 1 μM. NK2 receptor antagonist SR 48968 at 100 nM depressed the amplitudes of C-fiber evoked field potentials by 80% but had no effect at 10 nM. The superfusion of spinal cord with RP 67580 (1 μM) performed for 30 min before and for 30 min after tetanic stimulation blocked the induction of LTP completely in all 5 rats tested. Superfusion with SR 48968 (10 nM) blocked LTP in 5 out of 7 rats tested. The superfusion of spinal cord with substance P at 1 μM, 10 μM and 100 μM never induced LTP in 5 rats tested. In conclusion, the activitation of NMDA or neurokinin receptors is necessary but not sufficient to induce LTP of C-fiber-evoked field potentials in rat spinal dorsal horn. CONTRIBUTIONS OF NMDA RECEPTORS TO HYPERALGESIA INDUCED BY INJECTION OF MUSTARD OIL INTO THE ANKLE JOINT OF THE SPINALIZED RAT. E. Silva, C.L. Cleland* and G.F. Gebhart. Depts of Pharmacology, and Physiology and Biophysics, Univ. of Iowa, Iowa City, IA 52242 and Dept of Physiology, Universidad de los Andes, Merida, Venezuela.

Hyperalgesia is a pathological state in which noxious stimulation evokes greater amounts of pain. Numerous studies have implicated NMDA receptors *in experimental models of hyperalgesia*. The goal of these experiments was to determine if NMDA receptors preferentially mediate hyperalgesic nociception over acute nociception in a spinal model of hyperalgesia.

Rats were anesthetized with pentobarbital (45 mg/kg). Their spinal cords were transected at T8-T9, an electrode was placed on the sciatic nerve, and either an intrathecal catheter was inserted at T8 and guided to L1-L2 or a catheter was implanted in the jugular vein. The following day, hyperreflexia was induced by injection of 10 μl of mustard oil into the ankle joint, which caused a rapid onset, long lasting facilitation of the flexion withdrawal reflex elicited by C-fiber intensity (10 mA) electrical stimulation of the sciatic nerve and measured by recording the EMG in the hamstring muscles. NMDA antagonists, APV (i.t.) and ketamine (i.v.), were administered 21 minutes following mustard oil injection or, for control experiments, in the absence of mustard oil injection into the ankle.

APV (0.1-100 nmoles) and ketamine (0.05-10 mg/kg) dose-dependently inhibited both the hyperreflexive and the baseline responses. The ED_{50} for APV was approximately 20 nmoles for both hyerreflexia and baseline responses, although the ED_{50} for ketamine was slightly less for hyperreflexive (~2 mg/kg) than for baseline (~5 mg/kg) responses. These results demonstrate that NMDA receptors are involved in both acute and mustard oil-induced hyperreflexive nociception in spinalized rats.

645.8

MODULATION OF SPINAL VISCERAL NOCICEPTIVE TRANSMISSION BY SPINAL NMDA RECEPTOR ACTIVATION IN THE RAT - R. Kolhekar* and G. F. Gebhart, Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242.

Modulation of responses of L_6-S_2 spinal neurons to colorectal distention (CRD; 20-80 mmHg, 30s) was examined following activation of spinal NMDA receptors in pentobarbital-anesthetized rats. Neurons were recorded extracellularly and drugs (0.1-1 pmoles) were administered by pressure ejection from a multibarrel-electrode assembly. Administration of NMDA as well as D-serine, but not saline, in the vicinity of neurons responsive to CRD produced significant increases in the magnitude of neuronal responses to CRD as well as neuronal discharges after the termination of CRD. NMDA also increased the gain of the stimulus intensity-encoding functions of neurons to CRD and lowered thresholds for neuronal responses to CRD. Convergent cutaneous receptive fields of viscerosomatic neurons responsive to CRD also showed expansion after administration of NMDA or D-serine. All of the above facilitatory effects were produced within 30s-4 min of NMDA or D-serine administration and were blocked by coadministration of D-APV or 7-CK, respectively. Repeated high-intensity electrical stimulation (10 mA, 30s, 1 Hz) in convergent cutaneous receptive fields of neurons responsive to CRD produced a facilitation of neuronal responses to subsequent noxious CRD in a D-APV-sensitive manner.

Taken together, these results demonstrate that excitatory amino acids acting at spinal NMDA receptors enhance spinal transmission of visceral nociceptive input. Spinal NMDA receptors are therefore implicated in the generation of hyperexcitability phenomena manifest as visceral hyperalgesia, allodynia and expanded referral of visceral pain.

2-AMINO-5-PHOSPHONOVALERIC ACID(AP5) BLOCKS COLORECTAL SENSITIZATION BY TURPENTINE. Y.Ide*, Y. Maehara, S. Tsukahara, L. M. Kitahata, and J.G. Collins. Anes. Dept., Yale University School of Medicine, New Haven, CT 06510

The aim of this study was to examine possible involvement of NMDA receptors in the development of the inflammatory-induced sensitization of the colon by turpentine.

Under pentobarbital anesthesia (40 mg/kg IP), Sprague-Dawley rats were prepared with a laminectomy from T12 to L1 for intrathecal administration of AP5. Physiological parameters were maintained within normal limits. Animals were divided into two groups, control group with 50 μl of saline(NS) and AP5 group(AP5) with 10 mM AP5 in 50 μl saline. Visceromotor response threshold to CRD was determined during control study. After the baseline study, AP5 or saline was administered, and 5 min later VMR threshold was determined. Then 1 ml of 25% turpentine was injected rectally. VMR thresholds were determined every 5 min thereafter for the remaining 90 min. ANOVA and t-test were used for statistical analysis. Turpentine treatment in the saline group resulted in a significant decrease in VMR threshold over the 90-min observation period. In contrast, animals pretreated with AP5 showed no such reduction in VMR threshold during the 90-min observation period. These results suggest that inflammatory disorders of the bowel induced by turpentine produce sensitization involving spinal sensory mechanisms mediated NMDA receptors. (Supported by: NIH Grant NS-09871)

ADRENAL MEDULLARY TRANSPLANTS ATTENUATE SPINAL CORD cGMP PRODUCTION IN RESPONSE TO PERIPHERAL NERVE INJURY. J.B.Siegan*,A.T.Hama, and J.Sagen. Dept of Anatomy and Cell Biology, Univ. of Illinois at Chicago Medical Center, Chicago, IL 60612.

NMDA receptor activation has been shown to result in a Ca^{2+} dependent increase in cGMP through the production of nitric oxide. In the spinal cord, this cascade of events has been implicated in the persistence of pathological pain following injury. Previous studies in our laboratory have demonstrated that the transplantation of adrenal medullary tissue into the spinal cord subarachnoid space can alleviate chronic pain in animal models. The purpose of this study was to determine whether adrenal medullary transplants act via attenuation of cGMP production in spinal nociceptive regions. Neuropathic pain was induced by unilateral constriction of the sciatic nerve. Two weeks following nerve injury, rats were transplanted with either adrenal medullary or control striated muscle tissue in the spinal subarachnoid space. One week after transplantation, dorsal spinal cord segments (L4-L5, the region of sciatic nerve innervation) were dissected and assayed for cGMP using routine radioimmunoassay. Results demonstrated a marked increase in cGMP levels in animals with peripheral nerve ligation, ipsilateral to the chronic constriction injury. The elevated cGMP levels were also found in nerve ligated animals with control transplants. However, chromaffin cell transplants reduced cGMP below basal in nerve injured and intact (non-lesioned) animals. These results demonstrate that cGMP production can be significantly reduced via adrenal medullary transplants, paralleling the transplant-mediated attenuation of chronic pain. In summary, the results suggest that adrenal medullary transplants may intervene in the cascade of events initiated via the activation of NMDA receptors in pathological pain. Supported by NS25054.

INTERACTION BETWEEN SPINAL NEOSTIGMINE AND CLONIDINE IN SHEEP: ROLE OF NITRIC OXIDE. C TONG*, Z XU, JC EISENACH, The Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27157-1009

Several lines of evidence suggest that α_2-adrenergic agonists produce analgesia after spinal injection in part by causing acetylcholine (ACh) release. As such, spinal injection of the cholinesterase inhibitor, neostigmine, has been shown to enhance spinal clonidine-induced antinociception in animals. Other data suggest the antinociceptive effects of spinally released ACh are mediated in part by nitric oxide (NO). The current study examined the role of NO in the clonidine-neostigmine interaction in sheep. Following approval from the Animal Care and Use Committee, 7 sheep were prepared with chronic lumbar intrathecal (i.t.) catheters. Dose responses to analgesia (foreleg withdrawal to noxious mechanical stimulus) were obtained to i.t. clonidine, i.t. neostigmine, their combination, i.t. n-methyl-l-arginine (NMLA), i.t. NMLA plus clonidine, and i.t. NMLA plus clonidine and neostigmine. Treatments were compared by 2-way ANOVA on the dose responses and by 1-way ANOVA on the calculated ED50 for each treatment, with $P<0.05$ considered significant. I.t. clonidine produced dose-dependent antinociception, whereas i.t. neostigmine and NMLA were without effect. Neostigmine significantly enhanced clonidine antinociception. NMLA did not affect clonidine-induced antinociception, but blocked the interaction between clonidine and neostigmine. These data agree with previous data in sheep that spinally administered α_2-adrenergic agonists cause antinociception, whereas there is no evidence of chronic spinal cholinergic tone, such that spinal neostigmine alone causes antinociception. Similarly, lack of effect of NMLA alone on antinociception suggests no chronic release of NO in the unstimulated state.

EFFECTS OF NITRIC OXIDE SYNTHASE INHIBITORS ON THE OXOTREMORINE-INDUCED ANALGESIA. F.Pavone*, H.Machelska° and B.Przewlocka° Inst. Psychobiology and Psychopharmacology, CNR, Roma, Italy. ° Inst. Pharmacology, PAN, Krakow, Poland.

Recently it has been suggested that nitric oxide could play an important role in peripheral and central cholinergic analgesia. The present research was designed to find out whether the oxotremorine-induced antinociception was mediated by nitric oxide. In a first set of experiments it has been observed that the intraperitoneal injection of the inhibitors of nitric oxide synthase, N^G-nitro-L-arginine methyl ester (L-NAME) and N^G-nitro-L-arginine (N-ARG), in doses of 10 and 20 mg/kg, had no effect on the thermal nociceptive threshold of male CDI mice. When administered before oxotremorine (0.005, 0.01, 0.02, 0.03mg/kg), L-NAME and N-ARG significantly potentiated the dose-dependent analgesic effects of the muscarinic agonist. In a second set of experiments intrathecal administration in rats of Wistar strain of L-NAME (50, 400 µg/5µl) did not change the nociceptive threshold, but dose-dependently potentiated the effects of oxotremorine injected i.p.. in a dose 0.02 µg/kg, both in paw pressure and in tail flick tests. The NO donor SIN-1 (10,100µg/5µl), without effects when given alone, antagonized oxotremorine-induced analgesia in both tests used. The obtained data indicate that nitric oxide exerts an inhibitory action on cholinergic-induced analgesia and evidenced the pronociceptive effects of NO in the spinal cord.

THE CONTRIBUTION OF NITRIC OXIDE AND SUBSTANCE P RECEPTOR ACTIVATION TO FORMALIN EVOKED SPINAL C-FOS EXPRESSION V. Chapman, J. Buritova, P. Honoré & J.M. Besson*, INSERM U.161, 2 rue d'Alésia, 75014 Paris.

We have investigated the contribution of substance P and nitric oxide (NO) to formalin evoked spinal expression of c-Fos. Both of these receptor systems are strongly implicated in the spinal processing of prolonged, but less so acute, nociception.

Three hours after intraplantar formalin Fos-immunoreactive (Fos-LI) neurons (total expression 175±13 neurons per section) were essentially located both in the superficial (94±6 Fos-LI neurons) and deep (57±6 Fos-LI neurons) laminae of the dorsal horn of L4-L5 segments of the spinal cord. Systemic administration of 7-Nitro indazole (7NI), a selective inhibitor of neuronal nitric oxide synthase, 30 minutes prior to intraplantar formalin, dose relatedly reduced the deep laminae expression of c-Fos. The highest concentration of 7NI (15mg/kg) significantly inhibited the number of Fos-LI neurons in the deep laminae of the dorsal horn (42±8% of control expression, $p<0.05$), in addition there was a tendency towards a reduction of superficial c-Fos expression.

In the second part of this study the effect of systemic administration of the selective neurokinin 1 receptor antagonist, RP67580 on formalin evoked c-Fos expression was studied. RP67580 dose relatedly reduced the number of formalin evoked Fos-LI neurons in both the superficial and deep laminae of the dorsal horn of the spinal cord, with 1500µg/kg of RP67580 significantly reducing both the superficial and deep laminae expression of c-Fos (24±4% and 35±7% reduction of control expression respectively, $p<0.05$ for both). In contrast 1500µg/kg of RP68651, the inactive isomer of RP67580, did not significantly influence formalin evoked c-Fos expression. Neither 7NI or RP67580 influenced the peripheral formalin evoked inflammation.

These results clearly demonstrate the contribution of both substance P and NO to inflammatory evoked c-Fos expression at the spinal level, however they also illustrate that substance P influences noxious events both in the superficial and deep laminae of the dorsal horn, whereas NO appears to preferentially influence deep laminae neurons. Since the peripheral inflammatory process was not influenced these effects are probably due to a central site of action.

645.14

INVOLVEMENT OF NITRIC OXIDE IN PROSTAGLANDIN $F_{2\alpha}$-INDUCED LONG LASTING ALLODYNIA . Y.Saito*, Y.Kirihara, K.Hara, M.Kaneko, Y.Yamamori and Y.Kosaka, Dept. of Anesthesiol., Shimane Med.Univ., Izumo, Shimane 693 Japan

We have reported that intrathecal (i.t.) prostaglandins (PGs) induce long lasting allodynia (Neurosci. Abst., 1993; Pain, in press). The present study examined the effect of nitric oxide synthase inhibitor (NOSI) on the $PGF_{2\alpha}$-induced long lasting allodynia.

Male Sprague-Dawley rats weighing 300-350 g were used. The response of the animals to non-noxious mechanical stimulus produced by Semmes-Weinstein monofilaments (SWM) was graded from 0 (=no response) to 3 (=vigorous escape and frequent vocalization). Each SWM was applied at 3 different sites (neck, flank and hip) on the right and left side of the body. Agitation score (AS) was calculated as sum of the scores in six sites. Following the determination of baseline score, NOSI; N^G-monomethyl-L-arginine acetate (L-NMMA ;100-1000 µg) or normal saline was intrathecally administered 30 min before (pretreatment) or after (posttreatment) i.t. injection of 100 ng $PGF_{2\alpha}$. Measurements were repeated for 7 days.

Posttreatment with L-NMMA relieved the increase of ASs induced by $PGF_{2\alpha}$ in a dose dependent fashion for 60 min and then ASs returned to the baseline level while saline had no effect on the increase of ASs. Pretreatment with less than 300 µg of L-NMMA temporarily attenuated the increase of ASs induced by $PGF_{2\alpha}$. In most animals, i.t. administration of $PGF_{2\alpha}$ following pretreatment with 1000 µg of L-NMMA did not produce any increases of ASs for 7 days. These results suggest that NO may participate in the initiation of $PGF_{2\alpha}$-induced long lasting allodynia in the spinal cord.

ANTINOCICEPTION AFTER AN INTRATHECAL INJECTION OF *W*-NITRO-L-ARGININE (L-NAME) IN MICE. A.A. Larson* and K. F. Kitto. Department of Veterinary Pathobiology, University of Minnesota, St. Paul, MN 55455, U.S.A.

The present study was designed to determine the role of nitric oxide (NO) in nociception by assessing the effect of L-NAME, a NO synthase inhibitor, on nociception. Although L-NAME has been found to inhibit hyperalgesia, antinociception following 5 nmoles of L-NAME was not observed at 1 or 6 hours after its injection when tested using the hot plate, tail flick or writhing assays. However, 16 and 24 hr after its injection intrathecally, L-NAME (10 to 100 nmoles) produced a dose-related inhibition of acetic acid-induced writhing behaviors without affecting the latency of response to the thermal stimuli of the hot plate or tail flick assays. Full recovery was observed at 48 hr. L-arginine alone did not alter nociception, however, pretreatment with 120 nmoles of L-arginine completely prevented the antinociceptive effect of 30 nmoles of L-NAME, suggesting that the effect of L-NAME was due to its ability to inhibit NO synthesis. It does not appear that inhibition of NO synthesis persists for 24 hr as L-arginine, injected 30 min prior to nociceptive testing, failed to reverse the antinociceptive effect of L-NAME. The inhibition of writhing by L-NAME was not mimicked by pretreatment intrathecally with either 10 nmoles of methylene blue, an inhibitor of guanylate cyclase, or a dose as high as 300 nmoles of D-NAME, the inactive isomer of L-NAME. Together these data suggest that antinociception observed 24 hr after injection of L-NAME is brought about by a transient inhibition of NO synthesis. These data suggest that NO does not mediate but sustains a normal nociceptive tone along specific pain pathways. *(Supported by NIDA 04090)*

SEROTONERGIC CELLS, NITRIC OXIDE NEURONS, AND SITES OF MUSCARINIC ANALGESIA COINCIDE IN ROSTRAL VENTRAL MEDULLA OF RATS. Edgar Iwamoto*. Dept. of Pharmacology, Univ. of Kentucky College of Med., Lexington, KY 40536

Muscarinic agonists microinjected into the rostral ventral medulla (RVM) of rats produce antinociception in the hot-plate and tail-flick tests which may be mediated by nitric oxide and cGMP (Iwamoto and Marion, JPET 271:601, 1994). Located at the juncture and vicinity of the gigantocellular reticular nucleus pars *alpha* (GiA) and the lateral paragigantocellular nucleus (LPGi) are neurons containing mRNAs coding for soluble guanylyl cyclase and for neuronal nitric oxide synthase (Iwamoto *et al.* Soc. Neurosci. 19:968, 1993). The present study was designed to test the hypothesis that the muscarinic analgesia mediated by nitric oxide in the RVM is transduced by serotonergic neurons. Complementary oligos to neuronal nitric oxide synthase or serotonin transporter mRNAs were 3'-end labeled using [α-^{33}P]dATP, hybridized to 20 μ sections of rat RVM, and localized by film and emulsion autoradiography. The *in situ* hybridization pattern of cells in RVM containing the serotonin transporter reflected the known locations of B2 and B3 cells, and a portion of labeled B3 neurons coincided with GiA and LPGi neurons labeled by the nitric oxide synthase oligo. These results are consistent with the hypothesis that muscarinic analgesia may be mediated by a m1/nitric oxide/cyclic GMP transducer apposed to descending serotonergic pathways originating from the rat RVM. This could explain why cholinergic analgesia is blocked by intrathecal administration of serotonin receptor blockers (Iwamoto and Marion, JPET 265:777, 1993). Supported by NIH NS 28847

Capsaicin Evokes the Release of i-CGRP from Dorsal Horn Slices in a Nitric Oxide Dependent Manner. Mary G. Garry,* Ph.D. Department of Anesthesiology, Univ. of Texas Southwestern Medical Center, Dallas, TX 75235

Sodium nitroprusside, a nitric oxide (NO) donor, evokes the release of neuropeptides from primary afferent neurons in dorsal horn spinal cord slices in an NO-dependent and NO-independent manner (*Garry et al., J. Neurosci. 14:4329*). To further elucidate whether NO is involved in peptide release from nociceptive neurons, we examined whether the effects of capsaicin, [CAP; a neurotoxin which selectively stimulates nociceptive primary afferent neurons and evokes the release of peptides such as calcitonin gene-related peptide (CGRP)] are dependent upon an NO mediated mechanism. Rat spinal cords were ejected by hydraulic extrusion. The dorsal horn of the lumbar enlargement was isolated and placed into chambers which were superfused with oxygenated Kreb's buffer (pH 7.4) for a 60 min equilibration period. Following the equilibration period, tissues were superfused with Kreb's buffer (veh; n=5) or CAP (1μM; n=5) to evaluate the effect of CAP on CGRP release. To determine whether CAP evokes CGRP release via an NO dependent mechanism, tissues were superfused in the presence of CAP alone (1μM, n=7) or L-NAME (200 nM; a nitric oxide synthase inhibitor, n=4) prior to and during stimulation with CAP. The amount of immunoreactive CGRP (iCGRP) in the superfusates was assessed by RIA. Raw data were analyzed using ANOVA. Basal levels of i-CGRP release were 1,462.2±170 fmol/g/6min whereas 1μM CAP significantly increased i-CGRP release to 13,473.2± 970.8 fmol/g/6min ($F_{1,9}$=135.49; p<0.0001). In the presence of L-NAME, CAP-evoked i-CGRP release was significantly reduced to 4,793.7±687.2 ($F_{1,9}$=38.14; p<0.001). In support of these data, we also observed that CAP evokes a dose-dependent (1-30μM) increase in citrulline production in dorsal horn slices. Collectively, these results indicate that CAP evokes the release of i-CGRP from dorsal horn slices via an NO dependent mechanism. These data suggest that the NO dependent hyperalgesia which has been observed at the level of the spinal cord, maybe due to the effect of NO on the release of certain neuropeptides. These studies are supported by the Sid W. Richardson Foundation.

NEUROPATHIC CHANGES IN MICE AFTER INTRATHECAL APPLICATION OF L-NAME AND/OR STRYCHNINE. T. M. Laughlin*[1], K. F. Kitto[1], R. P. Yezierski[2], G. L. Wilcox[1,3]. [1]Dept of Pharmacology and [3]Graduate Program in Neuroscience, Univ. of Minnesota, Minneapolis, MN 55455. [2]Dept. of Neurological Surgery and The Miami Project, Univ. of Miami, Miami, FL 33136.

N^{ω}-nitro-L-arginine methyl ester (L-NAME), a nitric oxide synthase (NOS) inhibitor, has been used to study the involvement of nitric oxide in acute and chronic nociception of rodents. Injections of L-NAME in rat dorsal horn produce delayed spinal cord lesions associated with hyperalgesia and allodynia. The involvement of neuronal nitric oxide in activity-dependent cerebrovascular control suggests that these lesions result from ischemia and excitotoxicity. We tested whether intrathecal (i.t.) L-NAME and/or strychnine, a glycine receptor antagonist that produces acute allodynia, would synergize in this lesioning process.

750 mM L-NAME, 325 mM L-NAME + 54 nmol strychnine, 750 mM D-NAME, 54 nmol strychnine, or saline were injected i.t. in male ICR mice. L-NAME was given as a pretreatment one hour before saline or strychnine. The second injection was followed 10 min later by an intraplantar injection of formalin (4%) to drive the dorsal horn. Hyperalgesia was tested by the hot plate (52.5°C) and hot water tail flick (53°C) tests. Cold allodynia was tested by multiple applications of 10 µl acetone to each hind paw. Behavioral tests were administered prior to treatment and repeated on days 4, 7, 14, and 15. Fifteen days after treatment, mice were challenged with i.t. morphine (0.15, 1.5, 15 nmol) to determine opioid sensitivity in the hyperalgesic state. Finally, mice were perfused transcardially with 10% formalin, the spinal cords removed by laminectomy, sectioned at 50 µm and stained with cresyl violet.

Two weeks after i.t. L-NAME, mice showed hyperalgesia in the tail flick test and allodynia in the acetone test. Coadministered strychnine enhanced responses only in the acetone test. L-NAME-treated mice were resistant to i.t. morphine in the tail flick test, whereas mice given L-NAME plus strychnine showed dose-related morphine antinociception. Cold allodynia was inhibited by morphine, although not in a dose-related manner. These behavioral indicators of enhanced nociception were not accompanied by pronounced lesions like those seen in rats, suggesting a strong species dependence. The behavioral findings suggest that similar plastic changes take place in mice and rats after high doses of NOS inhibitors and neuronal activators. RETINAL FUNCTION

646.1

DEVELOPMENT OF COUPLING BETWEEN DIRECTION-SELECTIVE RETINAL GANGLION CELLS. D. I. DeBoer, W. H. Baldridge* and D. I. Vaney. Vision, Touch & Hearing Research Centre, The University of Queensland, Australia.

The On-Off direction-selective (DS) ganglion cells in rabbit retina comprise four distinct subtypes, which orthogonally code the direction of image motion. Each subtype provides complete coverage of the retina, with little overlap between neighbouring cells of the same subtype. This study investigated the postnatal development of the territorial organisation and the coupling patterns of the On-Off DS cells. Following pentobarbitone overdose, the eyes were enucleated, the mounted retinae superfused with Ames medium, and DAPI-labelled ganglion cells were injected with Neurobiotin. By postnatal-day 10, the presumptive DS cells had an adult-like organisation, with only about 40% of injected cells showing strong homotypic tracer coupling to a territorial array of DS cells. At postnatal-day 5 and earlier, however, most injected cells appeared to be coupled not only to a regular array of neighbouring DS cells, but also to one or more arrays of overlying DS cells. Consequently, coupled somata were located inside the dendritic field of the injected cell, unlike the adult pattern, producing multiple dendritic-field overlap between coupled cells. Thus, there appears to be both 'homo-subtypic' and 'heterosubtypic' coupling between the developing On-Off DS cells, with subsequent uncoupling to produce the adult pattern. The immature coupling pattern appears to be more complex than would be required to simply shape the territorial organisation of the DS ganglion cells; the heterosubtypic coupling may thus serve additional processes requiring coordinated communication between the different subtypes of DS cells. Moreover, our findings indicate that the subtypes of On-Off DS cells are morphologically established before ganglion cells are visually responsive, with important implications for how direction selectivity develops.

646.2

DIRECTIONAL SELECTIVITY IN RETINAL GANGLION CELLS IS ABOLISHED BY NEOMYCIN. R. J. Jensen*. Southern College of Optometry, Memphis, TN 38104.

Findings from several studies suggest that the antibiotic neomycin may block voltage-activated P- or Q-type Ca^{2+} channels. In a recent study (Jensen, *J. Neurophysiol.*, In press) it was found that the Q-type Ca^{2+} channel blocker ω-conotoxin MVIIC abolishes directional selectivity in ON/OFF directionally selective ganglion cells in the rabbit retina. This effect was not observed with either T-, L-, N-, or P-type Ca^{2+} channel blockers. The present study was undertaken to see if neomycin could abolish directional selectivity in these ganglion cells.

Extracellular recordings were made from ON/OFF directionally selective ganglion cells in superfused rabbit retinal strips. At 480-800 µM, neomycin abolished directional selectivity in these cells (n = 7) by bringing out a response to movement in the null direction that was similar in magnitude to the response to movement in the preferred direction. The effect of neomycin was rapidly reversible upon washout. Similar findings were obtained with gentamicin, streptomycin, and tobramycin but only at concentrations greater than 1000 µM. In conclusion, neomycin and other aminoglycoside antibiotics appear to block ω-conotoxin MVIIC-sensitive Ca^{2+} channels in the retina. (Supported by NIH EY07318)

646.3

Linear contribution to directional selectivity in cat retinal ganglion cells. M.H. Rowe*, Neurobiology Program, Ohio University, Athens, OH 45701.

Directionally selective simple cells in cat visual cortex often have receptive field profiles that are oriented in the space-time plane, and this form of spatio-temporal coupling provides the basis for their directional selectivity. Recent examination of phasic W-cells in the cat retina (Rowe and Palmer, 1995) revealed the presence within many of their receptive fields of multiple subregions that can be separated in either space or time. Some of these cells are directionally selective and it is possible that these cells could show the same form of spatio-temporal coupling that has been described in cortical simple cells.

Linear spatio-temporal response profiles were generated for a number of directionally selective W-cells using a reverse correlation procedure. The spatial axis of the profile was either aligned with the axis of directional preference or orthogonal to it. In most cases, these response profiles were spatio-temporally separable, indicating that linear mechanisms did not contribute to the cell's directional selectivity. In a few cases, weak spatio-temporal coupling was observed when the spatial axis was aligned with the axis of directional preference, i.e., the response profiles showed a space-time orientation that predicted the cell's directional preference. However, these contributions were generally small. The sample of directionally selective cells also included one suppressed-by-contrast cell whose spatio-temporal response showed a clear orientation consistent with its directional preference. These data suggest that linear spatio-temporal summation does not contribute significantly to directional selectivity in cat retinal ganglion cells.

ANALYSIS OF DECOUPLING EFFECT OF CYCLIC GMP ON GAP JUNCTIONS BETWEEN RETINAL NEURONS, USING PROTEIN KINASE INHIBITORS. E.-I. Miyachi* and C. Nishikawa. Dept. of Physiol., Fujita Health Univ. Sch. of Med., Toyoake, Aichi 470-11, JAPAN

Intracellular injection of cyclic GMP or soluble guanylate cyclase activators, such as nitric oxide (NO) and arachidonic acid, closed gap junctions between horizontal cells in carp and turtle retinas (Miyachi et al., NeuroReport 1: 107-110, 1990; Miyachi et al., NeuroReport 5: 485-488, 1994). To determine whether the blocking effect of cyclic GMP on the gap junctions was through the action of cyclic GMP-dependent protein kinase, we examined the status of dye-coupling with Lucifer Yellow CH among luminosity-type horizontal (H1) cells in the carp retina, by injection of protein kinase inhibitors into the cells. Dye-coupling among horizontal cells was observed after the intracellular injection of the mixture of cyclic GMP and a cyclic GMP- and cyclic AMP-dependent protein kinase, A-3 (N-(2-aminoethyl)-5-chloronaphthalene-1-sulfonamide hydrochloride). Dye-coupling was observed also after the injection of the mixture of cyclic GMP and cyclic GMP-dependent protein kinase inhibitor peptide (Arg-Lys-Arg-Ala-Arg-Lys-Glu) into the horizontal cell, indicating that the inhibitor suppressed the decoupling effect of cyclic GMP. The same kinase inhibitor did not suppress the decoupling effect of cyclic AMP on the gap junctions. On the other hand, a single cell was seen fluorescing after the injection of the mixture of cyclic GMP and cyclic AMP-dependent protein kinase inhibitor peptide (Arg-Gly-Try-Ala-Leu-Gly). These findings suggest that the blocking effect of cyclic GMP on gap-junctional intercellular communication among horizontal cells is through the action of cyclic GMP-dependent protein kinase, and that cyclic GMP modulates the gap junctions in a manner independent of the well-known dopamine/cyclic AMP pathway in the horizontal cell.

PHYSIOLOGICAL PROPERTIES OF AXON BEARING WIDE FIELD AMACRINE CELLS IN THE RABBIT RETINA. W. R. Taylor and H. Wässle*, Max-Planck-Institut für Hirnforschung, D-60528 Frankfurt, Germany.

Axon bearing wide field amacrine cells in the rabbit retina have a central sparse dendritic arbor, from which several axon-like processes emerge. The axons are generally straight, randomly oriented and can be several millimeters in length (Vaney et al., 1988[1]). We address two questions important for the physiology of these cells. 1) Do the cells generate action potentials? 2) How large is the receptive field?

Patch-clamp recordings were made from cells in the ganglion cell layer of an isolated, dark adapted, flat-mounted rabbit retina preparation. Light stimuli were generated on a computer monitor that was imaged onto the photoreceptor layer through the microscope condenser. Cell morphology was revealed by neurobiotin staining

Action potentials were elicited during depolarization. The receptive field centre had a diameter similar to that of the dendritic arbor. There appeared to be an excitatory central region and a larger inhibitory surround. The cells generated transient excitatory currents in response to a light step. The excitatory current decayed with a time constant of about 50ms.

These cells receive input across a relatively small dendritic arbor and distribute their output via action potentials across a much wider axon terminal system. The mosaic of these cells could provide a rapidly responding, global measure of the luminance across the retina.

CONTRIBUTION OF THE BETA GANGLION CELL SURROUND TO INFORMATION PROCESSING. Y.Tsukamoto[1]*, R.G. Smith[2] and P. Sterling[2] Hyogo Col. Med., Hyogo, 663 Japan[1] Dept. Neurosci., U. Penn, Phila.PA. 19104[2]

Spatial correlation in a natural scene is exponential. Therefore, cone signals contributing to a receptive field center are strongly correlated and those contributing to the surround are weakly correlated. Summing the center signals improves the signal/noise ratio (S/N) compared that of a single cone (Tsukamoto et al, '90), but the effect of subtracting the surround signals is unknown. We compared the S/N improvement (I) for the center only and for center-surround. The computation incorporated known cone and beta ganglion cell densities and receptive field parameters, plus scenes of different spatial frequency composition (characterized by the space constant, λ) When high frequencies are abundant (λ<0.1mm), S/NI is slightly greater for the center-surround than for the center only and correlations between neighboring cells are slightly enhanced. When low frequencies are abundant (λ>0.1mm), S/NI for center-surround is less than for the center only and correlations between neighboring cells are reduced. The effects of the surround on S/NI are nearly constant with eccentricity, due to the relative expansion of the center. S/NI is always considerably higher for peripheral than for central cells. The overall design improves encoding by central beta cells of high spatial frequencies (preserved by smooth pursuit eye movements) and encoding by peripheral beta cells of lower spatial frequencies (arising from blur due to smooth pursuit).

CONTRAST GAIN CONTROL IN THE LOWER VERTEBRATES RETINAS. J.-L. Wang and K.-I. Naka*. Dept. of Ophthalmol. and Dept. Physiol. & Biophysics., NYU Med. Ctr., New York, NY 10016.

Control of contrast sensitivity was studied in the retinas of the channel catfish and that of the kissing gourami. The former preparation is dominantly monochromatic and the latter is bichromatic. Recordings were made from horizontal, amacrine, and ganglion cells and results were analyzed by Wiener analysis, in which the kernels represent the contrast (incremental) sensitivity. Modulation responses from horizontal cells are linear, in that the waveform and amplitude of first-order kernels are independent of the depth of modulation. In the N (sustained) amacrine and ganglion cells, contrast sensitivity was low for a large modulation input and was high for a small modulation input. In most of the cells, the control of contrast gain did not affect the dynamics of the response since the waveform of the first-order kernels remained unchanged when the contrast sensitivity increased more than 5-fold. An analysis of a cascade of the Wiener type shows that the control of contrast sensitivity in the proximal retinal cells can be explained by assuming the presence of a (static) saturation nonlinearity. Such a nonlinearity must exist somewhere between the horizontal cells and the amacrine cells. The functional implications are as follows: 1) neurons exhibit greater sensitivity to input of lower contrast, 2) saturation of a neuronal response can be prevented because of the lower sensitivity in the case of an input with large contrast, and 3) over a large range of modulation depths, the amplitude of the response remains approximately constant.

CONTRAST FLICKER ERG RESPONSES TO CONE-ISOLATING STIMULI. David H. Brainard, Jack B. Calderone, and Gerald H. Jacobs*. Department of Psychology and Neuroscience Research Institute, UC Santa Barbara, 93106

The potentials measured by the flicker ERG originate at multiple sites in the retina. To exploit the ERG to understand the flow of information through the retina, it is necessary to develop techniques that allow one to distinguish activity at individual sites or in particular pathways. To this end, we have recorded flicker ERG responses to stimuli whose spectral properties isolate individual classes of cone photoreceptors. Stimuli were presented on a computer-controlled color monitor. The color of the stimulus field was modulated temporally around a fixed mean level of illumination. Control software allowed us to specify independently the modulation contrast seen by human long, middle, and short wavelength sensitive cones. ERG responses were recorded both to cone isolating stimuli and to stimuli that modulated multiple cone classes in various combinations. We began by measuring the contrast response function for isochromatic flicker. As others have found, the shape of this function depends heavily on temporal frequency. At 18.75 Hz, we recorded reliable responses to cone-isolating flicker for all three classes of cone. At low contrasts, the contrast response functions for all three cone classes are linear. We used a flicker-photometric paradigm to assess how signals from the three cone classes are combined. In this technique, the responses to various cone-isolating stimuli and combinations of cone-isolating stimuli are balanced against the responses generated by an interleaved reference stimulus. Two subjects gave differing results: for one subject the rule of combination was close to linear, in a second subject we observed strong spectral opponency between the long and middle wavelength sensitive cones.

DYNAMICS OF ADAPTATION TO CHANGING SPATIAL STRUCTURE IN THE TIGER SALAMANDER RETINA. S.M. Smirnakis*[,1], M.J. Berry[2], D.K. Warland[2], W. Bialek[3], and M. Meister[2]. [1]Physics Dept and Medical School, Harvard University; [2]MCB Dept, Harvard University; [3]NEC Research Institue, Princeton, NJ.

The neural code employed by the retina is known to adapt dynamically to changes in the statistics of the visual scene, such as the mean intensity and temporal contrast. Here we focus on how the retina adapts to changes in the spatial correlation length of the image. Isolated salamander retinae were stimulated with flickering checkerboard patterns and ganglion cell spike trains were recorded extracellularly with a multi-electrode array. The intensity of each checker was chosen randomly every 30 ms from a Gaussian distribution of fixed mean (photopic range) and root-mean-square contrast (24% of the mean). Every 100 s, the size of the checkers was changed, ranging from ~1/4 of a ganglion cell receptive field center to the full field. We observed adaptation to these transitions in both the ganglion cell firing rate and the reverse correlation to the stimulus.

The steady-state firing rates of ganglion cells depended on checker size; larger receptive field centers correlated with maximal responses for larger checkers. After a transition in checker size, the firing rate approached steady-state exponentially. When alternating between full field and 100 µm checker stimulation, the rate of 25 out of 45 ganglion cells decreased with adaptation for both transitions; the decline ranged from 5% to 100% of the final value, with time constants clustered around 10 s. This suggests that there are at least two independent sites of adaptation in the retina. Because the stimuli all had the same local statistics, it is unlikely that either site is in the photoreceptors. Furthermore, changes in spatial correlation length also altered the temporal aspects of the neural code: reverse correlation showed that the response latency of both the center and the surround decreased for larger checkers.

NEURAL CODING IN THE *LIMULUS* VISUAL SYSTEM

CL Passaglia*, FA Dodge, and RB Barlow
Institute for Sensory Research, Syracuse University, NY 13244

The *Limulus* eye samples its visual world with a relatively small number of retinal receptors and optic nerve fibers (~1000). High environmental noise further limits the information capacity of the optic nerve, and yet male *Limulus* can detect females both day and night. Is the eye tuned to detect mates? We address this question by measuring the spatiotemporal transfer function (STTF) of the eye, defining the spectral properties of the environment, and developing a computational model of the eye to explore the information content of the optic nerve.

We measured STTFs of single optic nerve fibers from submerged animals using an sinewave generator-recorder system (VENUS). We also recorded optic nerve responses from behaving animals in their natural environment. We then computed "neural images" for both sinusoidal patterns and natural underwater scenes recorded with a camera mounted on the behaving animal By analyzing the "neural images" and conducting parametric studies of the model eye, we studied the eye's tuning properties and its ability to cope with environmental noise.

We found that computed "neural images" accurately represent recorded optic nerve activities and thus validate the model. We also found that the structural and physiological properties of the eye are better tuned to the spatiotemporal features of a female than to those of environmental noise.

ANATOMICAL IDENTIFICATION OF SHORT WAVELENGTH SENSITIVE (S) CONE INPUT TO H1 AND H2 HORIZONTAL CELLS IN MACAQUE MONKEY RETINA. A.K. Goodchild, T.L. Chan and U. Grünert*. Department of Physiology F13, The University of Sydney, N.S.W. 2006, Australia.

In lower vertebrates horizontal cells have selective connections to cones of different spectral types. In primates, the presence of such selectivity remains controversial. In order to address this question anatomically, we studied the connections of H1 and H2 horizontal cells with putative S cones in macaque monkey retina. Horizontal cells were labelled in two ways: 1) An *in vitro* wholemount preparation was used to inject horizontal cells intracellularly with Neurobiotin. 2) In paraformaldehyde fixed retinas horizontal cells were labelled with DiI. The fluorescent DiI label was photoconverted to a permanent reaction product (Sandell and Masland, *J. Histochem. Cytochem., 35:555, 1988*). The retinas were then processed with antibodies against human S cone pigment (JH455, kindly provided by Dr. J. Nathans). The following results were obtained. Labelled S cones made up less than 10% of the cone population; they formed a regular array similar to that described previously (DeMonasterio et al., *Science 213:1278, 1981*). The entire cone including its pedicle was labelled, enabling us to investigate the contacts of S cone pedicles with labelled horizontal cells. Most H1 horizontal cells (34 of 41 cells) did not contact S cones. Labelled dendrites were seen passing over S cone pedicles but not contacting them. In those cases where H1 cells contacted S cone pedicles (7 of 41 cells) comparatively few (always less than 3) dendritic terminal knobs made these contacts. H2 cells (n=4) contacted all S cone pedicles within their dendritic field. Dendrites of H2 cells tended to aggregate at the S cone pedicle. Contact was made by numerous dendritic terminal knobs, whereas contacts with unlabelled pedicles were only sparse. Our anatomical findings suggest that H1 cells receive little or no input from S cones, whereas H2 cells receive input from all cone types. Our results are in good agreement with the recent physiological findings of Dacey and Lee (*ARVO Abstr., IOVS 36:10, 1995*).

RECOVERY PHASE OF THE MURINE RETINAL ROD PHOTORESPONSE DETERMINED FROM THE ERG BY A TWO-FLASH PROTOCOL. A.L.Lyubarsky* and E.N.Pugh, Jr. Department of Psychology and Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, PA 19104

The a-wave of the murine ERG reflects the activation phase of the rod photocurrent response, whereas the photoresponse recovery phase is obscured by other components of the ERG. We recorded corneal ERGs of CBA/CAJ mice, dark adapted for 2 hr and anesthetized with a ketamine-xylazine-urethane mixture. Whole-retina stimulation was provided by pairs of light flashes. The amplitude of the a-wave response to the second, saturating flash was used as a measure of the degree of rod recovery from the first. The entire recovery time course from flashes producing 300 - 20,000 photoisomerizations/rod (Rh*/rod) was reconstructed by varying the intervals between flashes. The reconstructed responses were similar to those previously recorded from the photoreceptor layer of isolated rat retina[1]. Over the intensity range 300-5000 Rh*/rod recovery half-times increased linearly with ln(Rh*/rod), with an apparent time constant of 0.3 s.

THE LOW-FREQUENCY VOLTAGE NOISE IN THE ROD NETWORK OF THE DARK-ADAPTED FROG. K. Djupsund*[1,2] and T. Hariyama[3]
[1]Depts of Biosciences and of Ecology and Systematics, FIN-00014 Univ Helsinki, [2]Dept Physiology, FIN-90220 Univ Oulu, Finland and [3]Research Center for Applied Information Sciences, Tohoku Univ, Sendai 980-77, Japan.

Previous studies [e.g. Baylor et al., J Physiol 309, 591-621] have shown that isomerization events in isolated rods occur in the low-frequency spectral range. To see how these results correspond to the noise output in the intact rod network we studied the low-frequency voltage noise in dark-adapted frog (Rana ridibunda) rods and estimated the equivalent isomerization rates.

The study was carried out by intracellular recordings in completely dark-adapted (>15h) eyecups. In addition we verified the pigment composition with HPLC. The IC recordings consisted of flash responses and 200 s. noise periods in darkness and under a background of 1 isomerization per rod*s (=1 Rh*/s), in 10 cases in two temperatures. The spectral analysis was done with 1024 point FFT/Hanning windowing.

The visual chromophore was purely A_1. The amount of equivalent isomerizations in the voltage variance under 1Hz in darkness equalled 0.17±0.10 Rh*/s (n=17) at 10°C and had a Q_{10} of 3.3 (ΔT=4°C, n=10). Our two estimation methods also indicated a significant (36%-54%) non-isomerization induced component in the noise variance, reducing the rates and Q_{10} of the isomerization-induced noise to 0.12±0.07 or 0.069±0.035 Rh*/s and 1.8 (one method only), respectively.

These results indicate that the dark noise levels in the rod network are higher than in isolated rods, but the temperature characteristics are relatively similar. The differences might be explained by e.g. additional processes in the network or a covariance between the noise components.

DUPLICITY WITHIN THE ROD MECHANISM OF RAT. F. Naarendorp* Psychol. Dept., Northeastern University, Boston, MA 02115.

Flicker studies on human revealed two separate rod pathways: a slow and a fast pathway (Conner, *JPhysiol, 332, '82*). Rod flicker threshold vs illuminance functions showed a double branch and flicker frequencies of 14-15 Hz appeared invisible over a limited range of retinal illuminance. In this range, a slow and a fast rod signal are thought to interfere destructively with each other and cancel flicker visibility (Stockman et al, *JOSA, 8, '91*). We examined whether a similar duality of temporal function occured in the rod system of rat. Electroretinographic (ERG) responses to square-wave flicker or to sinusoidally modulated light were recorded at the cornea of anesthetized, male, albino rats. Results were as follows: (a) in a plot of CFF vs luminance, CFF increased to about 15 Hz when the luminance reached -2.3 log cd/m^2, then decreased to 11 Hz over the range of -2.0 to -0.8 log cd/m^2. Above -0.5 log cd/m^2 rod CFF rose again reaching 19 Hz at 1 log cd/m^2. (b) flicker amplitude vs luminance curves showed that, up to 0.5 log cd/m^2, response amplitudes to 3-5 Hz flicker increased monotonically. Amplitudes to 7-15 hz flicker first increased then began to decrease at -2.0 log cd/m^2. Responses to 13-15 Hz flicker disappeared completely at -1.5 log cd/m^2 but reappeared at -1.0 log cd/m^2 when amplitudes for frequencies > 7 Hz began to grow again. Above this intensity response amplitudes to 17 and 19 hz flicker were measurable. The phase of the response to 13 Hz flicker at -2.0 log cd/m^2 was shifted by 180° relative to that recorded at -0.5 log cd/m^2. Our data suggest that there is a duality of temporal function within the rod system of rat and it strongly resembles that of human.

PHASIC AND TONIC RESPONSES IN THE RETINA OF THE PIGEON: DISTRIBUTION AND DIFFERENTIAL CHROMATIC PROPERTIES. J. Mpodozis*, R. Panteon and J-C. Letelier. Departamento de Biología, Facultad de Ciencias, Universidad de Chile. Casilla 653, Santiago, Chile.

The response characteristics of the pigeon's retinal ganglion cells were examined by direct intraretinal extracellular recordings. According to their temporal dynamics, two types of responses, tonic and phasic, were found. Phasic cells are mostly ON/OFF movement sensitive units, while tonic cells show predominantly exclusive ON or exclusive OFF responses, and lack movement sensitivity. Furthermore, phasic and tonic units have different chromatic properties. Phasic cells show very wide action spectra, and 50% of them show clear responses to the movement of a pure chromatic edge in the long-short and long-middle spectral range. On the other hand, tonic cells have narrow action spectra, and 30% of them show well defined inhibitory color opponent surrounds. We also studied the spatial distribution in the visual field of these responses. Phasic responses can be found in the whole retina, but they are more abundant and densely packed in the lateral retina around the lateral fovea. Tonic responses are almost exclusively present in the dorso-temporal retina. Accordingly, we think that these two kinds of ganglion cell responses contribute to generate the differential perceptual properties that the frontal and lateral gaze of birds have.

A CONNEXIN GENE HOMOLOG IN THE GIANT DANIO RETINA T.L.E. Wagner*, and D.G. McMahon. Department of Physiology, University of Kentucky, Lexington, KY 40536.

Gap junctions are closely apposed areas of cell membranes which contain gap junctional channels, or connexons. (Individual subunits are called connexins.) In the retina they mediate lateral inhibition in the outer plexiform layer by connecting horizontal cells. Retinal gap junctions also serve as an excellent model for gap junctions found throughout the nervous system.

We have cloned from the giant danio (*Danio aequipinnatus*) a partial cDNA (GDRET-1) which shares high sequence homology and similarly predicted structural features with previously cloned connexins. This clone was isolated from retinal RNA using reverse transcriptase polymerase chain reaction (RT-PCR) and a set of degenerate primers based on conserved areas of previously cloned connexins. The cloned sequence was compared to those of previously sequenced connexin genes in nucleic and amino acid forms (PCGENE, IntelliGenetics). Of the rat connexins previously cloned, GDRET-1 is most similar to rat cx43. Identity at the nucleotide level is 72%, and at the amino acid level is 73% with 79% homology. GDRET-1 has been confirmed as part of the giant danio genome by Southern analysis. Additionally, we have shown that GDRET-1 is expressed in the retina using RT-PCR with specific primers and Rnase protection assay.

We are presently creating giant danio retinal and brain cDNA libraries for use in isolating the full length clone. Supported by NIH EYO9256.

60-Hz MAGNETIC FIELD EXPOSURE REDUCES OCULAR PHOTOPIGMENT AND HEPATIC RETINOIDS IN *M. DOMESTICA*.

A.T.C.Tsin*, Y. Moreno, J.W. Rhodes, S. Ziari, M.de la Garza and N. Mata. Division of Life Sciences The University of Texas at San Antonio, San Antonio, TX 78249.

60-Hz magnetic fields (MFs) have been shown to affect neuroendocrine functions such as melatonin level in blood. However, it is not known if MFs might also influence visual function by a modification of visual pigment chromophore which is located in the hydrophobic pocket of the visual protein opsin. Adult female marsupials (*Monodelphis domestica*) were subjected to 60-Hz MFs for over 2 months prior to sampling. The MF, a circular rotating vector with rms flux density of 500 mG (50 uT), was on for 20 hrs out of each 24-hr day. Control animals were housed in the same building but located over 90 ft from the MF coils. Ambient 60-Hz MFs were 0.3 mG or less. No significant reduction in body weight and other visible pathology were noted in all animals. Retinas and livers were extracted for retinoids and analyzed by standard HPLC methods. All-trans and 11-cis retinal chromophores recovered from 60-Hz treated animals were reduced compared with controls (i.e. 44 vs 67 pmol/eye, all-trans retinal; 28 vs 35 pmol/eye, 11-cis retinal). Similarly, concentration of retinyl palmitate in liver of treated animals (0.5 mmol per gm liver) was lower than controls (2.4 mmol per gm liver). Liver retinol was also lowered in the treatment group (0.3 vs 1.32 mmol per gm liver in controls). The mechanism of action of MFs to reduce visual pigments and vitamin A in *M. domestica* is not known at present.

CHANGES IN THE PUPILLARY LIGHT REFLEX OF THE *RD* MOUSE WITH AGE AND THE EFFECTS OF PHOTORECEPTOR TRANSPLANTS

S.K. Parapuram, S.J.O. Whiteley*, T.M.P. Litchfield and R.D. Lund Dept. Pathology, Institute of Ophthalmology, Bath St. London, EC1V 9EL, U.K.

The retinal degeneration (*rd*) mouse is a model for retinitis pigmentosa. It has a mutation in the β-subunit of cGMP-phosphodiesterase which causes photoreceptor degeneration starting at day 8 and complete by 3 weeks of age. The rapid and total loss of the photoreceptors renders the model particularly useful for investigating the potential of transplants to reconstruct the retina. Although a number of groups have transplanted photoreceptors to the subretinal space (Gouras et al., 1992; Invest. Ophthalmol. Vis. Sci. 33:2579-2586) there are no published data on the function of such transplants. Using a computerised pupillometry system we have studied the pupillary light reflex (PLR) of the *rd* mouse over time as a baseline for evaluating the function of retinal transplants in these animals. The amplitude, velocity and latency of the constriction was analysed at two different light intensities. The PLR was studied in *rd* mice at ages of 3 months, 6 months and 9 months. We found an increase in both the amplitude and latency of the PLR with time, at both light intensities. The response of 9 month old animals showed a greater amplitude and latency than the 3 month old *rd* mice.

Retinal dissociates from new-born mice were transplanted successfully into *rd* retinae. The anatomical evidence is presented. The responses recorded from eyes that had received transplants differed from those of control eyes.

RETINAL DAMAGE OF SOLAR ORIGIN IN A VANISHING SPECIES OF AMPHIBIAN, *RANA CASCADAE*.

K. V. Fite*, L. Bengston, A. Blaustein, H. Hewitt, Neuroscience and Behavior Program, UMASS Amherst, MA 01003.

Thinning of the stratospheric ozone layer is associated with a destructive effect of increased UV-B on egg-hatching success in *R. cascadae*, one of 5 Northwestern amphibian species undergoing severe population declines (Blaustein, et. al, PNAS, 1994).

Quantitative histopathological analysis of the outer retina in three groups of frog--adult *R. cascadae*, normal *R. pipiens* (northeastern leopard frog) and experimentally light-damaged *R. pipiens* -- was conducted. Both retinas from 3 frogs in each group were evaluated using samples taken from superior and inferior retinal regions, embedded in epon, sectioned at 1μ thickness and stained with thionin for light-microscopy evaluation.

Results: A similar profile of histopathological features were observed both in *R. cascadae* and in experimentally light-damaged *R. pipiens*: abnormal clumps of melanin pigment, abnormal rod outer segments, reduced number of cones, and vacuolated inner segments. In *R. cascadae*, the inferior retina was substantially more abnormal than the superior retina. Relatively few abnormalities were observed in normal *R. pipiens*. These findings are consistent with the hypothesis that increased UV-B in solar radiation may be having deleterious effects in retina of amphibians and contributing to the worldwide "vanishing amphibian" crisis. FUNCTIONAL AND PATHOLOGIC CONSEQUENCES OF THE Q-64-TER RHODOPSIN MUTATION IN AUTOSOMAL DOMINANT RETINITIS PIGMENTOSA.

A.H. Milam*[1] Z.-Y. Li,[1] A.V. Cideciyan,[2] S.G. Jacobson,[2] U. of Wash.,[1] Seattle, WA 98195-6485, and U. of Miami,[2] Miami, FL 33101.

Clinical and histopathjologic observations were made on the retinas of a 50 year old patient donor with autosomal dominant retinitis pigmentosa due to the Q-64-ter stop codon rhodopsin mutation. The donor was a member of a large kindred whose affected members show variable severity of retinal disease. On clinical examination 4 mos *ante mortem*, the donor's acuities were 20/60, and kinetic perimetry showed a midperipheral scotoma with retained function centrally and in the far periphery. Test results in a mildly affected family member were consistent with reduction of rod outer segment membrane and existence of only wild-type rhodopsin in functioning rod outer segments. Microscopy of the donor retina revealed that rods and cones were reduced in number in the macula and far periphery and their outer segments were quite short. Rhodopsin was delocalized to the rod inner segments and somata, and many peripheral rods gave rise to rhodopsin-positive neurites that bypassed the inner nuclear layer and reached the inner limiting membrane. The rod neurites contained numerous multivesicular bodies and 50 nm vesicles that were synaptophysin and SV2 immunopositive. The delocalized rhodopsin in the rod somata and neurites was labeled with mAbs specific for the N and C termini of rhodopsin, indicating that at least some of it was wild type. Quantitative EM immunolabeling with the two anti-rhodopsin mAbs indicated that wild type but not mutant rhodopsin was present in the rod outer segments. The microscopic findings correlated well with results from visual function testing. Studies are in progress to determine if the rod neurite sprouting found in this and other RP retinas is a response to growth factor upregulation in response to ongoing photoreceptor death. *Supported by EY0-1311, -1730, & -5627, The Foundation Fighting Blindness, and Research to Prevent Blindness, Inc.*

FELINE RETINAL DEGENERATION RESULTING FROM DIETARY ß-ALANINE.

H. Imaki,* J.M. Messing and J.A. Sturman, New York State Institute for Basic Research in Developmental Disabililities, 1050 Forest Hill Road, Staten Island, NY 10314

It has long been known that cats are dependent on a dietary source of taurine to maintain their body pools because they have a limited capacity for biosynthesis. In this study we have used ß-alanine, which utilizes the same uptake system as taurine, in an attempt to lower taurine concentrations. Adult female cats were fed a completely defined taurine-free synthetic diet alone or supplemented with 0.05% taurine for at least 2 years and then provided with 5% ß-alanine in the drinking water for 20 weeks, each cat consuming approximately 500g ß-alanine. As noted in other species, ß-alanine reduced taurine concentrations globally in all cats.

Light and electron microscopic examinations of retinas from these cats revealed that ß-alanine ingestion accelerates the photoreceptor degeneration and elimination demonstrated previously in cats after a long period of taurine deprivation. The degree and extent of degeneration resulting from ß-alanine treatment was approximately proportional to the reduction in retinal taurine concentration, determined in the contralateral eye. Thus some cats fed the taurine-supplemented diet showed relatively normal retinal structure and the highest retinal taurine, others had reduced number of photoreceptors with markedly shortened or disorganized inner and outer segments and lower retinal taurine. Among the cats fed the taurine-free diets, one showed no remaining photoreceptors in any areas examined, and the lowest taurine in the retina, while others displayed varying degrees of degeneration. In general, the most severe changes were noted in the nasal and optic disc regions, and the least in the inferior region.

INCREASED EXPRESSION OF RETINAL TIMP3 mRNA IN SIMPLEX RETINITIS PIGMENTOSA IS LOCALIZED TO PHOTORECEPTOR-RETAINING REGIONS.

C. Jomary*, S.E. Jones and M.J. Neal. British Retinitis Pigmentosa Society Laboratory, U.M.D.S., St Thomas' Hospital, London, U.K.

The tissue inhibitor of metalloproteinases-3 (TIMP3) gene is the most recently characterized member of a family of genes whose products are implicated in extracellular matrix remodelling. We have shown by differential cDNA library screening and RNA-blot analysis that increased expression of TIMP3 mRNA occurs in retinas affected by simplex retinitis pigmentosa (RP). We here report the cellular distribution of TIMP3 overexpression in dystrophic retinas determined by *in situ* hybridization.

Paraformaldehyde-fixed control and RP-affected human retinas were frozen in isopentane and 10 μm sections cut on a cryostat. Acetylated sections were hybridized with ^{35}S-labelled sense and antisense riboprobes complementary to human TIMP3 and autoradiographed.

In control retinas, no TIMP3 mRNA expression was detected. In contrast, in RP simplex-affected retinas, a striking pattern of expression was observed. In regions lacking photoreceptors, no signal was detected. However, where there were residual photoreceptors, expression of TIMP3 mRNA was localized particularly to the photoreceptor inner segments and the inner retina.

The induction of TIMP3 mRNA overexpression in pre-degenerative photoreceptors suggests disruption of photoreceptor cell-matrix interactions, which in turn may lead to activation of apoptotic cell death programs.

A CHANGE IN THE NUMBER OF NADPH DIAPHORASE-STAINED RETINAL CELLS IN STREPTOZOTOCIN-INDUCED DIABETIC RAT RETINA. E.Roufail[1,2], S.M.Rees[1], R.Rajan[3*] & D.Ehrlich[2]. [1]Department of Anatomy and Cell Biology, University of Melbourne, Parkville 3052,; [2]Department of Ophthalmology, University of Melbourne, Parkville, Victoria, 3052; [3]Department of Physiology, Monash University, Clayton, Victoria, 3186 Australia.

NADPH diaphorase (NADPHd) is a nitric oxide synthase (NOS) which is found in amacrine cells closely associated with the retinal vasculature in the rat retina. NOS is required for the production of nitric oxide (NO) a potent vasodilator and neuronal NOS may play a role in linking the control of the retinal vasculature with neuronal metabolism. We aimed to assess any changes that might occur in this population of neurons over time in streptozotocin (STZ)-induced diabetic rats where the retinal vasculature is known to be dysfunctional. Diabetes was induced with a single intravenous injection of STZ (70 mg/Kg) and rats allowed to survive for 3 weeks (n=9), 8 weeks (n=6) and 8 months (n=7).Treated and age-matched control rats were killed with an overdose of sodium pentobarbital and the right eye from each animal dissected and fixed in buffered 4% paraformaldehyde for 2h. The retina was flat mounted and stained for NADPHd histochemistry. Counting of stained-cells was performed double blind. By 3 weeks there was a significant decrease of 21% in the total number of positively-stained cells in the retinas of the diabetic group (2479±129) (mean±SEM) compared to the control group (3148±158) ($p<0.01$).The difference persisted at 8 weeks and 8 months. The observed decrease in NADPHd-positive cells in the diabetic rat retina suggests a possible loss of NOS activity and NO production which develops during the early stages of diabetes and persists long term. This loss of NOS activity may be involved in the early capillary changes which occur in the pathogenesis of diabetic retinopathy.

A NON-HUMAN PRIMATE MODEL OF RETINITIS PIGMENTOSA
D.H. Grosof*, K.K. Ohlemiller, B. Falsini, J. Mosinger-Ogilvie, H.J. Kaplan, M.S. Silverman. Ophthalmology & Visual Sciences, Washington Univ. & Central Institute for the Deaf; St. Louis, MO 63110.

Our **purpose is** to develop and evaluate a primate model for human retinitis pigmentosa (RP), using sodium iodoacetate (IAA) to induce photoreceptor degeneration. Noell (1953) found that IAA induces a degeneration histologically similar to RP. We examined the ERG, fundus appearance and retinal histology in two macaque monkeys, which were followed for 16 and 19 months after acute systemic IAA administration. Visually guided behavior remained, and the effects in the two eyes were similar. A novel non-invasive quasi-focal cone ERG method (Wolf & Grosof, 1995) indicated that IAA spares the function of macular cones only and that the foveal cones were less affected by IAA than parafoveal cones. Over the course of several months cone ERGs decreased, and the fundus showed typical RP signs: vascular narrowing, waxy pallor of the disc, and retinal pigment epithelial cell and choriocapillary atrophy. Confirming Noell, we found the outer nuclear layer (ONL) to be devastated except in the central retina, where a gradient of damage extended from a relatively normal fovea to a monolayer of cone-like ONL somata outside the macula. The inner retina was grossly normal. Also observed in all the IAA retinas was the occasional RP complication of cystoid macular edema.

Conclusions: IAA acutely ablates the photoreceptor layer except in the macula. Macular cones surviving the initial toxic insult survive and function for many months, even as the retina appears to degenerate in an RP-like way. IAA treated primates show anatomical and physiological changes characteristic of RP, and therefore appear to be a useful model of RP.

REVERSE CORRELATION MAPPING OF SUBTHRESHOLD SYNAPTIC POTENTIALS IN CAT PRIMARY VISUAL CORTEX. L. Glaeser, V. Bringuier, Y. Frégnac*, L. Borg-Graham, C. Monier (1), and G. Fleury (2). Institut Alfred Fessard CNRS (1), and Ecole Supérieure d'Electricité (2), France.

Extracellular analysis of cortical receptive fields (RFs) have revealed the existence of "unresponsive" surround regions by their modulatory effect on the cell's response to a stimulus presented within the minimal discharge field (MDF). Obtaining direct evidence for subthreshold excitatory and inhibitory regions extending beyond the classical RF requires methods for generating, recording, and detecting physiologically identified EPSPs and IPSPs.

Simple cells in area 17 of anaesthetized cats were recorded using sharp intracellular and whole-cell patch electrodes while providing pseudo white noise input (small light and dark bars flashed randomly in the visual field every 50ms). The following algorithms were used to detect occurrence times of PSPs in the waveform: (a) threshold-crossing of membrane potential, (b) threshold-crossing of waveform energy calculated with respect to the average baseline within a brief time window, and (c) prototypical and waveform-specific template matching to discriminate between fast and slow IPSPs and EPSPs, Ca^{++} and Na^{+} spikes. Discrete event trains were correlated with the stimulus ensemble to yield high spatial resolution IPSP and EPSP maps.

Subthreshold maps show both excitatory and inhibitory regions extending up to nine times the area of the classical MDF. Map variance peaked when template matching was used (especially for inhibitory-like events). All excitatory profiles were consistent with stimulus-locked waveforms averaged at each spatial location for both types of stimuli. Moreover, the reverse correlation technique revealed inhibitory regions which were undetected using stimulus-locked averaging. The physiological nature of the subthreshold events detected was established from recordings at different membrane potentials and/or during QX 314 application.

We thank Ralph Freeman for providing stimulus generation algorithms. This work was supported by grants to Y.F. from HFSP and Conseil de l'Essonne.

ROLE OF VOLTAGE DEPENDENT INACTIVATING CONDUCTANCES IN THE CONTROL OF THE VISUAL INTEGRATION FIELD PROFILE IN CAT AREA 17
V. Bringuier, F. Chavanne, C. Monier, L. Glaeser, Y. Frégnac, J. Lorenceau and K. Grant*. Institut Alfred Fessard, 91198 Gif-sur-Yvette, France.

Neurons of the primary visual cortex integrate information over a visual area larger than their minimal discharge field (MDF). Intracellular recordings in cat area 17 *in vivo* allowed us to study responses to peripheral stimuli, their voltage and time-dependency.

Our stimuli consisted of gratings drifting for 400 ms in a restricted portion of the visual field. Four types of spatial configurations were used: inside the MDF, "near" periphery, "far" periphery and "global" ("near"+"far") periphery. Voltage dependency was studied by coupling different levels of depolarizing (usually subthreshold) and hyperpolarizing current steps with visual activation. Temporal dependency was assessed by setting the onset of the current pulse either 1000 ms before or coincident with the initiation of the visual response.

In all cells studied, peripheral stimulation from regions up to 10° away from the border of the MDF elicited a response. At resting potential, these responses were usually depolarizing, but hyperpolarizations were elicited in a few cells. Some hypercomplex cells showed a pure *excitatory* response to a stimuli localized in the end-zones and the side bands. When weak or absent at rest, visual depolarizing potentials could be enhanced or revealed by current-induced *depolarizations*. Finally, temporal coincidence of the current step and visual response could further boost excitatory potentials with respect to the one second delayed response. We hypothesize that voltage dependent inactivating conductances in the vicinity of the post-synaptic site may regulate the gain of these connections.

THE CONTRIBUTION OF LGN M AND P LAYERS TO THE CONTRAST SENSITIVITY OF PRIMATE V1 NEURONS. **J.D. Allison[1] *, P. Melzer[1,2], Y. Ding[1], J. Dinger[2], A.B. Bonds[3], and V.A. Casagrande[1,2]. Depts. of Cell Biology[1], Psychology[2] and Electrical Engineering[3], Vanderbilt University, Nashville, TN 37232.**

Magnocellular (M) neurons in the LGN of primates, including bush babies, exhibit higher contrast sensitivity (i.e. lower contrast thresholds) and saturate at lower stimulus contrast than parvocellular (P) LGN neurons. The contributions of M and P LGN neurons to the contrast sensitivity of individual V1 cells are unknown. To examine this issue we inserted an injection/recording electrode containing 25 mM GABA in saline into either the contralaterally innervated M (layer 1) or P (layer 6) layers of the LGN in 8 bush babies. Multiunit activity was recorded to identify the layers and locate the receptive fields. We then inserted a recording electrode into V1 and, after lining up the cortical and LGN receptive fields, measured the contrast response functions (CRFs) of single V1 neurons using spatio-temporally optimized drifting sine-wave gratings presented to the contralateral eye. The CRF of each V1 neuron was retested after blocking activity in either the M or P layer with an injection of GABA. When the M layer was blocked ($n=6$), the average contrast sensitivity of V1 neurons was reduced from 16.8 to 8.2 ($t=2.95$; $P<0.05$). When the P layer was blocked ($n=6$), the average peak response amplitude at high stimulus contrast levels (i.e. 56%) was significantly reduced from 21.4 spikes/s to 8.3 spikes/s ($t=1.95$; $P<0.05$). M cells contribute predominantly to the low contrast/high sensitivity component of the CRF of V1 neurons while P cells mainly contribute to the high contrast/low sensitivity component. These results suggest that V1 neurons receive input from *both* M and P LGN cells.

TEMPORAL PROPERTIES OF MAGNO AND PARVO SUBSYSTEM INTERACTIONS: VEPS TO SIMULTANEOUS OR ALTERNATING STIMULATION. S. Suter*, P.S. Suter, D.T. Perrier, B.J. Gragg and T.B. DeLouth. Vision Laboratory, Psychology Dept., California State University, Bakersfield, CA 93311.

The magnocellular (M) inhibits the parvocellular (P) visual subsystem. We present VEP evidence that M/P interactions are subject to important temporal influences. Steady-state VEPs (2nd harmonic) were recorded (Oz to T3) in two experiments from 21 and 22 adults. Stimuli subtending 14 deg were horizontal gratings differing in spatial and temporal frequency and contrast (M = 0.86 c/deg with 17%C at 15 Hz, P = 5.00 c/deg with 84%C at 3 Hz). In Exp. 1, M and P stimuli were rapidly alternated. P duration was always 1.667 s; M duration varied across trials from 10.667 to .333 s. M amplitudes increased by 35% and P amplitudes decreased by 65% as M duration shortened. These results are consistent with either preferential adaptation of P across time, or optimal P inhibition during shorter M durations. In Exp. 2, M and P stimuli were presented for 45-s trials either simultaneously by interleaving video frames, or separately. For both conditions, M amplitudes did not increase, whereas P amplitudes increased across the first 20 s. Thus, the decreased P amplitudes in Exp. 1 are not due to P adaptation. Consistent with M on P inhibition, P amplitudes were smaller in the simultaneous condition, while M amplitudes did not differ between conditions. The M subsystem achieves steady-state quicker as compared to the P subsystem. M on P inhibition is greatest when M is stimulated for brief intervals.

EFFECTS OF ADAPTING ON SPATIOTEMPORAL RECEPTIVE FIELD STRUCTURE IN CAT STRIATE CORTICAL SIMPLE CELLS. A.B. Saul*. Dept. of Neurobiology, U. of Pgh. Sch. of Med., Pittsburgh PA 15261.

Adapting changes timing, as well as amplitude (Vis. Neurosci. 12:191-205, 1995). Simple cell responses to drifting gratings are delayed at onset, but unaffected at offset. By examining receptive field structure in control and adapted states, we have gained some insights into the origins of these specific aftereffects. These studies also address general issues of the generation of response properties.

Simple cells were recorded in anesthetized, paralyzed cats. Maps were obtained using both sinusoidally-modulated and briefly flashed bars. The 4-second trials that generated these maps were preceded by 8-second periods in which the screen was either blank, to obtain control maps, or in which a drifting grating was presented to obtain adapted maps, with all conditions interleaved. Analysis of the responses consisted of amplitude and timing measures at each position, and predictions of responses to drifting gratings.

Both amplitude and timing of responses to stationary stimuli were altered by adapting. The main result is that the predictions of the drifting grating responses from these stationary maps showed the characteristic delay of response onset after adapting. Although these predictions integrate responses at all receptive field positions, the effects were generally due to delayed onsets at just a few positions. Predictions of the aftereffects in spatial and temporal frequency tuning also corresponded with results obtained from drifting gratings.

Previous studies have demonstrated through population comparisons that receptive field structure is correlated with response properties. The current experiments extend these results to comparisons within single cells. They also extend our notions of how specific adaptation aftereffects are, showing differential behavior in different parts of the receptive field. These new data are consistent with a model where adapting potentiates inhibition between simple cells that are in push-pull arrangements.

STROBE REARING ALTERS THE SPATIOTEMPORAL STRUCTURE OF SIMPLE CELL RECEPTIVE FIELDS IN CAT AREA 17.

A.L. Humphrey* and A.B. Saul. Dept. of Neurobiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261

In most simple cells, a link exists between spatiotemporal (S-T) receptive field structure and direction selectivity (DS). S-T oriented receptive fields possess gradients of response timing which confer a preferred direction of stimulus movement across the receptive field. Non-DS cells lack S-T orientation. Here we further examine the link between receptive field structure and DS using a developmental paradigm that specifically affects direction selectivity.

Cats were raised from birth to 8 mo. of age in 8 Hz strobe illumination. Drifting gratings were used to measure the selectivity of >40 cells for stimulus direction, spatial and temporal frequency and contour orientation. Receptive field structure was assessed using stationary, sinusoidally modulated bars, which allowed measures of response latency and absolute phase at different positions in the receptive field.

Cortical cells were normal in all measures except DS and S-T structure. Fewer than 10% of the cells were DS, compared to >80% in normally reared cats. All non-DS cells lacked S-T oriented receptive fields; they displayed uniform response timing within each ON and OFF zone and abrupt jumps in timing between zones, like non-DS cells in normally reared cats. In strobe cats, this change in S-T structure is due in part to an absence of receptive field positions with absolute phase lags and long latencies. Such positions are observed in normally reared cats and may reflect inputs from lagged cells of the lateral geniculate nucleus. Their absence in strobe cats may indicate failure of the lagged afferents to drive cortical cells.

In summary, these results provide further support for the role of S-T structure in conferring direction selectivity in simple cells. Strobe rearing eliminates direction selectivity by altering the timing of cortical responses within the receptive field.

648.7

A ROLE FOR $GABA_a$-MEDIATED INHIBITION IN GENERATING THE SPATIOTEMPORAL STRUCTURE OF SIMPLE CELL RECEPTIVE FIELDS.

A.Murthy*, K. Sun & A.L. Humphrey. Dept. of Neurobiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261

Many simple cells possess gradients of response timing across their receptive fields. This property is known as spatiotemporal (S-T) orientation, and it is correlated with cells' direction selectivity (DS). The mechanisms underlying S-T orientation are unknown; they may reflect inputs from the lateral geniculate nucleus, the striate cortex, or both. Here we examine the role of intracortical inhibition.

The $GABA_a$ antagonist N-methyl-bicuculline (NMB) was iontophoresed onto simple cells in cat area 17, and its impact on S-T structure and DS were measured. S-T structure was determined using stationary, sinusoidally modulated sinewave gratings at different spatial phases. Direction selectivity was measured with drifting gratings. All stimuli were randomly interleaved in the control and NMB conditions. The first harmonic response was a valid measure, even during NMB application.

Of 11 direction-selective cells with S-T oriented receptive fields, 7 showed NMB-induced reductions in DS and S-T orientation. Response timing became more uniform across their receptive fields. For these cells, changes in the two measures were correlated ($r=0.87$; $p<0.01$). In contrast, the other 4 direction-selective cells showed little or no change in DS despite NMB-induced increases in their visually driven activity. S-T orientation in these cells was affected more variably.

These data show that S-T structure and DS covary in single cells; this extends previous observations based on comparisons among populations of cells. In addition, the data reveal that $GABA_a$-mediated inhibition can act to create direction selectivity through its impact on S-T structure. However, heterogeneity appears to exist among simple cells in the dependence of their direction selectivity on this inhibition.

SPATIAL SUMMATION PROPERTIES OF THE MACAQUE V1 NEURONS IN THE RETINOTOPIC REPRESENTATION OF THE BLIND SPOT.

H. Komatsu*, I. Murakami, M. Kinoshita Lab. of Neural Control, National Institute for Physiological Sciences, Okazaki, Aichi, 444 Japan.

In a previous study (*Neuroscience Research Suppl.* 19), we have shown that when a large stimulus covering the blind spot (BS) is presented monocularly, it activated about 15% of neurons in the retinotopic map of the V1 representing the BS. Many of these neurons were located in layer 6, and most of them had very large receptive fields that covered large parts of the BS and extended out of it. We suggested that these neurons may consist of an important part of the neural mechanisms of filling-in at the BS by importing visual information from the surround to the inside of the BS in the retinotopic representation in V1. In the present study, we examined the spatial summation properties of these neurons in order to determine the spatial characteristics of such huge receptive fields. Two monkeys were trained a visual fixation task, and visual responses of neurons were recorded using stationary stimuli of various sizes and at various locations with respect to the BS. The following two properties were found. (1) Many of these neurons preferred larger stimuli to some extent, in contrast to most of the V1 neurons which are suppressed by a large stimulus. This suggests that spatial summation of visual information takes place across a rather large visual field. (2) In some of the neurons, onset of the response was delayed systematically with increasing the distance between the stimulus and the center of the receptive field, whereas the magnitude of the responses was not decreased systematically. This seems to suggest that propagation of activities involved in the formation of a huge receptive field occurs in a cortical level.

EVIDENCE FOR SCALE-INVARIANT MEDIAL AXIS REPRESENTATION IN PRIMATE STRIATE CORTEX.

T.S. Lee*, Dept. of Brain and Cognitive Sciences, MIT; Div. of Applied Sciences, Harvard University.

Striate cortical complex cells' responses are enhanced preferentially at the boundaries and at the center of texture squares and texture strips [Lee et al. ARVO 1995]. We hypothesized that the response peak close to the center of the texture figure is the neural correlate of the medial or symmetry axis representation of a visual object. To test this hypothesis, we isolated 43 complex cells in the striate cortex of an awake behaving rhesus monkey and studied their responses to texture strips of different widths, ranging from 2 degrees to 6 degrees in visual angle. The cells' RF were located at $3° \pm 0.7°$ eccentricity from the fovea. Each strip stimulus was presented at a randomized series of sampling positions relative to the cells' CRF (size $< 0.3°$) while the monkey fixated. The spatial sampling intervals were 0.5° for the 6° and 4° wide strips, 0.375° for the 3° wide strips, and 0.25° for the 2° wide strip. 9 of the 25 cells that were tested with 6° strips, 23 of the 37 cells tested with 4° strips, 8 of the 13 cells tested with 3° strips and 4 of the 4 cells tested with 2° strips showed an enhanced response at the center of the strips. 10 of the 28 cells that were examined for at least two widths exhibited central response peaks across scale. Strips were also sampled across different cross-sections and the enhanced responses were observed along the midline of the strips. This invariance of response enhancement along the midline and across multiple widths further suggests the plausibility of a medial axis representation in V1. The decrease in the proportion of the cells exhibiting the medial peaks with increasing strip width reflects a spatial constraint that limits the medial axis computation to a narrow range of spatial scale at each eccentricity. However, strips of comparable widths elicit stronger medial response at 5° eccentricity, indicating that the medial axis of different ranges of object dimension might be computed at different eccentricities in V1.

DO SIMPLE CELLS IN THE CAT'S STRIATE CORTEX ENCODE BINOCULAR DISPARITY THROUGH POSITION AND PHASE INCONGRUITIES?

A. Anzai, I. Ohzawa, R. D. Freeman, and T. E. Cohn*. Group in Vision Science, School of Optometry, University of California, Berkeley, CA 94720-2020

The visual system utilizes binocular disparity to obtain information about the relative depth of objects in space. Most cells in the striate cortex are selective to binocular disparity, suggesting that these neurons form the first processing stage for stereopsis (Barlow et al. 1967; Pettigrew et al. 1968). It has been suggested that binocular disparity is encoded by spatial offsets (position disparities) of left and right eye receptive fields (RFs) that have identical internal structure (Nikara et al. 1968; Maske et al. 1984). However, we have shown with detailed RF mapping studies that RF profiles for the two eyes are not necessarily the same and that binocular disparity can be encoded through differences in RF phase between the two eyes without position disparity (Freeman & Ohzawa, 1990; DeAngelis et al. 1991). This raises a question as to whether simple cells encode binocular disparity through phase disparity alone or through both position and phase disparities. To answer this question, we simultaneously map RFs of multiple simple cells in anesthetized and paralyzed cats to obtain phase disparity for each cell as well as position disparity between the cells. We then determine the relative contributions of phase and position disparities to the binocular disparity tuning of the cells.

Dynamic noise patterns generated according to binary m-sequences are presented over the RF locations on two graphic displays, one for each eye, to map left and right eye RFs simultaneously. Responses of cells to the noise patterns are cross-correlated with the stimulus sequence to obtain RF maps. These maps are then fitted with a Gabor function to estimate phase and center coordinates of the RFs. Phase and relative position disparities are obtained from the estimated parameters.

We find that the majority of simple cells exhibit incongruities in position as well as in phase. Although the contribution of position disparity to the disparity preference of some cells is substantial, position disparity is generally limited to the extent that is equivalent to a 90° phase disparity. Therefore, we conclude that these simple cells encode binocular disparity through both position and phase incongruities but position disparity alone may not be sufficient to encode large disparities. COMPARISON OF THE CLASSICAL AND THE INTEROCULAR SUPPRESSIVE RECEPTIVE FIELD USING RECEIVER OPERATOR CHARACTERISTIC ANALYSIS REVEALS A CLOSE SPATIAL CORRESPONDENCE IN ANAESTHETISED CAT. Tobe C.B. Freeman, Frank Sengpiel, and Colin Blakemore*. University Laboratory of Physiology, Oxford OX1 3PT, U.K.

Interocular suppression is observed in cat primary visual cortex when a cell responding to an optimal grating in one eye is presented with an orthogonally oriented stimulus to the receptive field in the other eye (Sengpiel et al. 1995. Vision Research 35:179-95). We sought to determine the area within the visual field over which this suppressive binocular interaction could be evoked. The entire receptive field of the dominant eye was stimulated with a drfiting sinusoidal grating of optimal orientation and direction of drift. The receptive field of the other eye was probed with a small, orthogonally oriented drifting grating patch placed in random sequence in a matrix of positions within and around the classical receptive field. Using a monocular probe stimulus of optimal orientation, the classical receptive field in that eye was also mapped in a similar fashion.

We used Receiver Operator Characteristic (ROC) analysis to estimate the significance of the changes in firing rates. The technique allowed us to make direct statistical comparison between the classical and suppressive receptive field profiles in the same eye.

We find that the spatial organization of the interocular suppression field matches closely that of the classical receptive field in both location and size (70 cells, of which 15 were analysed in detail). Interocular suppression can be elicited over a range of non-optimal orientations and spatial frequencies (Sengpiel et al. op. cit.), while its spatial extent is similar to that of the classical receptive field.

TWO DIFFERENT MECHANISMS UNDERLIE SUPPRESSIVE PHENOMENA IN CAT PRIMARY VISUAL CORTEX. Frank Sengpiel*, Roland J. Baddeley, Tobe C.B. Freeman, Richard Harrad[1] and Colin Blakemore. University Laboratory of Physiology, Oxford OX1 3PT, U.K. and [1]Bristol Eye Hospital, Bristol BS1 2LX, U.K.

In cat area 17 (V1) the response of a cell to an optimal stimulus in one eye can usually be reduced by an orthogonally oriented grating either presented to the other eye (*interocular suppression*) or superimposed in the same eye (*cross-orientation inhibition*). Sengpiel et al. (1994) reported that interocular suppression causes a reduction in response proportional to the unsuppressed level of response, with no shift of contrast threshold. But Bonds (1989) reported that cross-orientation inhibition raises contrast threshold without changing response *vs* contrast gain. Here we compared these two types of suppression, and *surround inhibition*, in the same neurons.

For 25 neurons in V1 of anaesthetized paralysed cats, we measured response, R, to 1) dichoptically presented orthogonal gratings, 2) superimposed orthogonal gratings, and 3) a circular grating patch surrounded by an iso-oriented grating in an annular window (so as to elicit surround or end inhibition). In each condition, the contrast c of the excitatory stimulus was varied randomly, while that of the suppressive grating was kept constant. Data were fitted by a hyperbolic ratio function, $R = R_{\max} \cdot c^n / (c_{50}^n + c^n) + b$.

For all cells tested, cross-orientation inhibition was best described as an increase in c_{50}, while for 53% of cells, interocular suppression was best described as a reduction in R_{max}. Inhibition by surround stimuli was about equally well fitted by changes in either c_{50} or R_{max}. Our data suggest that different inhibitory mechanisms, one 'divisive' and one 'subtractive', may operate in V1 to mediate the various types of suppression.

SPATIAL PHASE GRADIENTS IN NEOCORTICAL EEGs GIVE MODAL DIAMETER OF "BINDING" DOMAINS IN PERCEPTION. W. J. Freeman*, J. M. Barrie, M. Lenhart, R. X. Tang. Dep't of Molecular & Cell Biology, Univ. of California, Berkeley CA 94720

Spatial patterns of EEGs were derived from 8x8 epidural electrode arrays (0.5-0.8 mm spacing) on the olfactory bulb (OB), prepyriform cortex (PC), and the visual, auditory and somatic cortices of rabbits. Phase was measured for components of the aperiodic wave forms in segments (64-512 msec) with AM-FM modulated Fourier components. Phase gradients in the OB had the form of a cone, for which the location and signs of the apices (maximum lead/lag) varied randomly. Phase velocity converged to 1.80±0.43 in m/s, the estimated conduction velocity of mitral-tufted axon collaterals. Most (80%) phase gradients in PC had the conduction velocity of olfactory tract (2.6 m/s). Others were endogenous gradients at 1.0 m/s for activity in low gamma and high beta ranges (20-60 Hz). Neocortical velocities had skewed distributions, with modes dependent on frequency, from 2.0 m/s at 22 Hz to 3.5 m/s at 48 Hz. Commonality ("phase locking", "binding") was defined as oscillation within the half power range (± cos 45º). An invariant estimate emerged on multiplying the phase velocity in mm/ms by 0.25 cycle in ms = 21.0±0.5 mm for modal diameter of most neocortical domains, but 6.1±2.5 m/s for some in somatic cortex. This is consistent with ECoG data from exposed human cortex (<2 cm) and with cat unit recordings (for example, at 40 Hz the estimated lag across 7 mm is O.55 ms).

648.14

INTER-OCULAR DISPARITY AND VARIATION IN RECEPTIVE FIELD POSITION AND ORIENTATION PREFERENCE STUDIED BY TETRODE RECORDINGS IN CAT AREA 17. P. A. Hetherington*, N. V. Swindale, & D. Zhao. Department of Ophthalmology, University of British Columbia, 2550 Willow St., Vancouver, BC, Canada, V5Z 3N9.

Tetrodes are four closely-spaced metal microelectrodes that allow the simultaneous recording of multiple single units. We used the tetrode technique to study variations in receptive field position (RFP), orientation preference (OP), and inter-ocular orientation and receptive field disparity among local (100µm) groups of neurons in cat area 17. Units were stimulated with moving bars (0.25-0.5° x 1.5-2.0°) and isolated off-line using the peaks, valleys, and phase angles of the spike waveforms from the 4 channels. Our preliminary observations are based on recordings from 77 cells in 15 sites in area 17 of paralyzed cats anesthetized with isoflurane and NO_2. Between 3 and 9 cells were simultaneously recorded at each site. In agreement with a previous study using tetrodes (Maldonado & Gray, 1994, *SNA*, 266.10), the average maximum range in OP between cells of the same cluster was 28.6°, and varied from 9.1° to 85.5°. The variation in OP of cells within a cluster receiving ipsilateral eye input was correlated (r=.77) with the variation in OP of the same cells receiving contralateral input. The average amount of variation in OP within an eye (ipsi=4.91°, contra=5.11°) was slightly greater than the average variation between the eyes (3.18°). The RFP also varied within clusters: the average maximum range in RFP between cells of the same cluster was 1.10°, and varied from 0.41° to 1.67°. The average RF width (s.d. of a best-fit Gaussian) was 0.59°, and varied on average 0.42° within a cluster. The RFP scatter was greater in the horizontal (0.36°) than in the vertical (0.28°) dimension, but this difference was not statistically significant (p=.09). Ipsilateral RFP variation was similar to the variation in contralateral RFP within a cluster (0.53° vs. 0.57°), and there was an average of 0.46° inter-ocular disparity in RFP (N=37). Because RFP and OP were measured simultaneously in neighboring cells, it is unlikely that the variations within each cluster were due to eye movements. These variations among neighboring neurons may be necessary for dimension reduction in cortex. Supported by grants from MRC Canada to NVS and from NSERC to PAH.

SYNCHRONIZATION OF SINGLE UNIT SPIKE TRAINS IN CAT VISUAL CORTEX IS STIMULUS DEPENDENT

W.A. Freiwald*, A.K. Kreiter, and W. Singer, Max-Planck-Institut für Hirnforschung, D-60528 Frankfurt, F.R.G.

Theoretical considerations and results from multi-unit recordings suggest that synchronization of neuronal activity could serve as a binding mechanism in the formation of neuronal assemblies. To investigate, whether the synchronization between *single cells* depends on stimulus properties, we recorded simultaneously with several stereotrodes multiple single units in area 17 of the anaesthetized cat. Amplitude and position of the correlation peaks were strongly influenced by the orientation of the moving bar stimuli. The changes of correlation peak position followed in most cases the rule that the more strongly activated cell leads by up to 10 ms over the other. The effect of different global stimulus configurations on the synchronization between pairs of single cells was studied with two different paradigms. If the receptive fields (RFs) of both cells were spatially separated and colinearly oriented, they were simultaneously activated either by a long bar moving over both RFs or by two independent bars moving in opposite directions, each one over only one of the two RFs. Neurons with overlapping RFs but different preferred orientations were both activated either by a single stimulus, or with two bars, their orientations matching approximately the respective preferences of the two cells. We found in both paradigms that for cells which had synchronized their spikes in response to a single coherent stimulus synchronization was reduced or absent when they were activated by two incoherent stimuli. The reverse pattern was never observed.

We conclude that correlations between single units depend on the actual stimulus configuration and do not directly reflect the fixed anatomical connectivity. Furthermore, the results indicate that synchronous activity could serve to define the set of neurons whose responses represent features of the same visual stimulus.

INTERHEMISPHERIC SYNCHRONIZATION IN CAT VISUAL CORTEX IS COMPARABLE TO SYNCHRONY WITHIN HEMISPHERES. A.K. Engel*, P. König, P.R. Roelfsema, M.H.J. Munk and W. Singer. Max-Planck-Institut für Hirnforschung, Deutschordenstr. 46, 60528 Frankfurt, Germany

Recent studies of neuronal interactions in the visual cortex indicate that synchronous firing of neurons may be relevant for the integration of distributed responses into coherent representational patterns. One important step in validating this hypothesis is the demonstration that synchrony can also occur between neurons located in different cerebral hemisperes. Several years ago, we have reported the existence of such interactions in cat visual cortex. We have now investigated the features of interhemispheric synchronization in greater detail to facilitate comparison with the synchrony observed within each hemisphere. Multiunit and field potential responses were recorded simultaneously from left and right area 17. Our results demonstrate that strong temporal correlations with a precision in the millisecond range can be observed between neurons in left and and right striate cortex. On average, the synchronization occurred without phase lag. The strength of the interactions was comparable to that observed within each hemisphere and was dependent on the overlap of the receptive fields but not on differences in the neurons' preferred orientations. If synchronization occurred, it was almost always associated with an oscillatory modulation of the responses at frequencies in the range of 30-80 Hz. Similar to the synchrony observed within hemispheres, the interhemispheric interactions were influenced by the configuration of visual stimuli. Synchrony was weak for incoherent stimulus arrangements and was higher if stimuli with similar orientation or direction of motion were used to coactivate different cell groups. The interactions were completely abolished in cats where the corpus callosum had been sectioned prior to the physiological experiment, demonstrating that the synchronization is mediated by connections at the cortical level and not by driving common input from subcortical structures. Taken together, the data are compatible with the hypothesis that synchrony may be exploited to establish relationships between responses of spatially distributed neurons, synchronization across the hemispheres then serving for the binding of signals arriving from different visual hemifields.

NEURONS RESPONDING WITH DIFFERENT LATENCIES AND TIME COURSES TO A VISUAL STIMULUS ENGAGE IN NEAR-ZERO DELAY MUTUAL CORRELATION IN THE VISUAL CORTEX OF AWAKE MONKEY. R.Eckhorn*, R.Rutschmann, T.Woelbern, A.Frien, R.Bauer. Deptm. Physics, Philipps-University, Renthof 7, D-35032 Marburg, Germany.

We studied visual temporal coding by investigating the internally generated signal correlations of neurons activated by the same visual stimulus. Single- (SUA), multiple-unit (MUA), and local field potential (LFP, 10-140 Hz) were recorded in the striate cortex of an awake macaque monkey by a linear array of 7 fiber μ-electrodes and analyzed by cross-correlation methods. During a fixation task the RFs were stimulated by a sinusoidal grating (switched on at preferred orientation and spatial frequency, stationary for 1s, then drifting at a local temporal modulation of 2 Hz for 3s). Classification of neurons into simple and complex (classical test of spatio-temporal modulation) did not reveal the separable classes as in anesthetized animals. Nevertheless, we divided the distribution into simple- and complex-like cells according to their depth of modulation. Their response latencies to the onset of the grating were not different, having a broad temporal dispersion with groupings around 50, 100 and 145 ms (N=72). Activities were typically non-rhythmic before and during the rising phase of the transient response to stimulus onset. During later response epochs, including stationary and slow movement stimulation, fast oscillatory components of high amplitudes dominated the neural signals (35-60 Hz). Both, phasic and rhythmic response epochs revealed cross-correlation center peaks close to zero delay (few ms) including SUA-LFP, MUA-MUA and MUA-LFP correlations at the same and different recording sites (cortical distance: 0-4.5mm). The SUA-LFP correlation peak delay differences of stationary and moving gratings were significantly less than zero ($p<0.01$) and showed slightly different values for simple- and complex cells (C: -0.09±0.20 ms, N=18 / S: -0.34±0.32 ms, N=29). The present results support previous observations of cortical temporal coding around zero-delay. Near-zero correlation was present independent of onset response latency and PSTH-course, non-rhythmic and rhythmic epoch, small and large cortical separation, simple and complex cell, MUA and LFP. However, resolving cross-correlations over response time revealed rather complex temporal patterns depending on neuron and stimulation. (Supported by DFG: Ec53/6 and 53/7 to R.E.)

OSCILLATORY GROUP ACTIVITY REVEALS SHARPER ORIENTATION TUNING THAN CONVENTIONAL MEASURE IN PRIMARY VISUAL CORTEX OF AWAKE MONKEY. A.Frien, R.Eckhorn, T.Woelbern, R.Bauer, H.J. Reitboeck*. Deptm. Biophysics, Philipps-University, D-35032 Marburg, Germany

Orientation selectivity is a prominent characteristic of neurons in the visual cortex. We asked, whether fast oscillatory group signals (35-60Hz) show sharper orientation tuning than the conventional measure (integrated response). This is expected if neurons that code similar visual features (e.g. orientation) engage in mutually facilitating oscillations. From 7 fiber μ-electrodes we recorded single and multiple unit activity (MUA) and local field potentials (LFP, 10-140 Hz) in the macaque striate cortex. In a fixation task the RFs were stimulated by a sinusoidal grating at different orientations. Orientation tuning of MUA in V1, utilizing the conventional measure, was nearly as sharp as for single units (73.6±27.6°, N=70). The latter exceeds reported values [e.g., Vogels et al, Exp Brain Res, 84:1, 1991] which is mainly due to our sinc interpolation algorithm. In addition, we found that oscillatory components of MUA reveal a significant reduction in the halfwidth of the orientation tuning compared to that of the integrated response ($p < 0.01$; difference: 8.4±10.5° / oscill: 75.4±16.0° / integr: 83.8°±20.2°). For oscillatory MUA components 100 (of 119) recording positions were sharply tuned while there was not a single for oscillatory LFP ("sharp tuning": response drops below half of its maximal value). Therefore we calculated an index of orientation (OI = max. response / min. response - 1), obtaining also significantly sharper orientation tuning for LFP oscillations than for the integrated LFP response ($p < 0.05$; OI(oscill) = 0.40±0.28, OI(integr) = 0.30±0.17; N=119). The large width of the present LFP orientation tunings is in contrast to the sharp orientation tuning of previous results for stimulation with moving bars [Eckhorn et al, NeuroReport 4:243, 1993]. This effect is probably due to the different extent of the cortical circuits activated by the two stimuli. In summary, our results support previous proposals that neurons of similar orientation preference engage in a common, synchronized oscillation when stimulated close to this orientation. The sharper tuning of oscillations compared with the integrated responses proves, in addition, that the oscillatory components mutually facilitate while this is not the case for the other components. It is probable, therefore, that this facilitation has implications for the perception of oriented visual structures. (Supported by DFG Ec 53/6 and 53/7 to R.E.)

VISUALLY INDUCED GAMMA BAND RESPONSES IN HUMAN EEG

M.M. Müller, J. Bosch, T. Elbert*,J. Riera, M. Valdes-Sosa, and B. Rockstroh
Dept. of Psychology, University of Konstanz, P.O. Box 5560, D-78434 Konstanz, Germany.

On the basis of animal studies, gamma-band oscillations have been proposed as a possible fundamental physiological mechanism solving the binding problem. In contrast to evoked gamma-band responses (GBR), induced GBRs are neither time nor phase locked to the stimulus onset. Averaging of trials most certainly will result in the disappearance of GBRs in the grand mean. In addition, the anatomical location of Area 17 may lead to a neutralization of electrical dipoles when visual full field stimulation is carried out.

Seven subjects were either stimulated with a long moving bar (coherence) or two bars moving in opposite direction (incoherence) on the left side of the screen, while fixating a cross at the center. Electrodes were placed pario-occipitally (10-20 system). Single trials were analyzed by Gabor transformed spectral analysis. The resulting evolutionary spectrum showed significantly higher gamma band activity in combination with alpha suppression at the contralateral hemisphere during coherent movement as compared to incoherent movement.

VISUAL CORTEX: STRIATE VII

649.1

MAXIMIZATION OF INFORMATION IS CONSISTENT WITH THE ORGANIZATION OF VISUAL CORTEX. B.J. Richmond* and G.X. JIN. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

The patterns of connections among neurons probably arise from genetically specified rules rather than from the exact specification of structure. We have studied the consequences of one simple rule: that the network has developed to preserve as much information as possible across neuronal layers (the biologically-inspired Hebb rule is a special case of this). We considered 4 structures for a layer of neurons, adapting each according to this rule. (1) The neurons have independent noise on the outputs and noiseless inputs (a case examined closely by Linsker). (2) The neurons have correlated noise on the outputs and noiseless inputs. (3) The neurons have correlated inputs with no further noise added. (4) There is correlated noise on the inputs and the neurons have correlated instrinsic noise which is independent of the noise on the inputs. These different models make different predictions about the correlation of noise on the inputs with the correlation of signals on the outputs, and the role of noise in the speed of network adaptation. We compared the first prediction, i.e., the effect of correlated input noise on correlated output signal, with recordings of neuronal pairs made by Gawne and Richmond in V1 and IT cortices, and Ghose and Freeman in V1. For Gawne and Richmond, the input noise was correlated at about 5% variance, and the output information was about 10% redundant. Ghose and Freeman found the same input noise correlation and about 15% signal correlation. The model with correlations on both the inputs and within the layer (model 4 above) matches the experimental results almost exactly. The results are consistent with the assumption that the visual cortex self-organized according to a rule that maximizes the preservation of local information across layers.

649.2

TIME SCALES IN THE INFORMATION PROCESSING DYNAMICS OF PRIMATE STRIATE CORTICAL COMPLEX CELLS. G.X.Jin* ,T.J.Gawne, J.A.Hertz, and B.J.Richmond. Laboratory of Neuropsychology, National Institute of Mental Health, Bethesda MD 20892, and NORDITA, DK-2100 Copenhagen, Denmark.

The time scales associated with the dynamics of neural information processing are not well understood. We measured information transmission in the responses of V1 complex neurons in awake monkeys to sequences of two-dimensional black-and-white patterns presented as a movie in both fixed and random orders. The speed of the movie was varied, the duration of each pattern in the sequence ranging from 16ms to 128ms.

The responses elicited by the fixed sequence were quite sterotyped, with pulses related to the pattern change often appearing to be aligned across trials, as reported by Bair and Koch for MT neurons. For the random sequences, we estimated the information transmitted about stimulus pattern using a neural network. We found: (1) The stimulus-related information rises as the duration of the patterns in the sequence increases. (2) Information begins rising about 60ms after the stimulus appears. (3) Information rises steeply during the next 40ms and then continues to rise more gradually through at least another 90ms. (4) The duration of the information rise is never longer than the length of the presentation period for a pattern. (5) The rate of information transmission peaks between 10 and 20 bits/sec, and remains high for a substantial proportion of the stimulus duration. Points (3) and (5) taken together show that the response carries a large amount of redundant information. (6) There is information about the preceding stimulus in the visual response to the current stimulus, i.e., there is a short memory of the preceding stimulus; this memory lasts for at least 30 ms.

649.3

HOW MUCH INFORMATION IS CARRIED BY CORRELATED NEURONS? P.E. Latham*, G.X. Jin, T.J. Gawne, and B.J. Richmond. Lab. of Developmental Neurobiology, NICHD, and Lab. of Neuropsychology, NIMH, Bethesda, MD 20892.

Experimental results from V1, IT and MT indicate that neuronal responses are correlated ($\rho_S \equiv$ signal correlation $\approx 15\%$ and $\rho_N \equiv$ noise correlation $\approx 5\%$). How much do these correlations affect the amount of information a population of M neurons can carry about a stimulus? For a Gaussian signal and noise, and a signal to noise ratio of S/N, the mutual information, I, is given by

$$I = \frac{M-1}{2}\log\left[1+\frac{S}{N}\frac{[1-\rho_S]}{[1-\rho_N]}\right]+\frac{1}{2}\log\left[1+\frac{S}{N}\frac{[1+(M-1)\rho_S]}{[1+(M-1)\rho_N]}\right].$$

As long as the signal is not totally correlated ($\rho_S < 1$), the information scales as the number of neurons, M. Correlations in the signal induce correlations in the response, so the information scales as M even when the neurons are correlated. For a completely correlated signal ($\rho_S = 1$) and uncorrelated noise ($\rho_N = 0$), the information scales as $\log(M)$. Finally, for a completely correlated signal ($\rho_S = 1$) but slightly uncorrelated noise ($\rho_N > 0$), the information asymptotes to a constant. In our poster we extend these results to non-Gaussian distributions, and discuss ways to compute information from neuronal populations in realistic experiments.

649.4

COMPUTING MEAN FIRING RATES OF ENSEMBLES OF REALISTIC NEURONS. A.G. Siapas, E. Todorov and D.C. Somers* MIT, E25-147A, Cambridge, MA 02139

Realistic models of neural circuits typically are too complex to be analyzed exactly and have too many parameters to be fully explored in computer simulations. Thus, methods for characterizing the collective dynamics of such systems are needed. Here, we develop a technique for approximating the mean firing rate of highly interconnected, homogeneous groups of neurons that receive Poisson input. This technique applies to single compartment neurons with realistic synaptic and intrinsic currents. Assuming only that conductances equal their averages, we derive a nonlinear equation relating the mean firing rate to the cellular and network parameters. This approach extends to the analysis of multiple neuronal groups, for which a system of equations is derived.

We compare our analytical results to simulations and observe a close fit for most parameter settings. In a system with 2 excitatory and 2 inhibitory groups with a total of 250 cells, the approximation error is less than 2%. The accuracy of mean firing rate calculations depends on proper estimation of the afterhyperpolarization reset potential. Unlike most related techniques which assume a constant reset potential, our method computes this potential as a function of input. The current form of our analysis is inaccurate only near threshold input levels where conductance variability significantly affects firing rate. We are presently extending the approximation technique to take this variability into account.

Computing the mean firing rate with our technique reduces to solving a system of nonlinear equations, which is much faster than full simulation. In addition to guiding the search for suitable model parameters, our technique also can yield analytical insights not available through simulations. For example, we can estimate the sensitivity of the mean firing rates to changes in model parameters. In addition, the system of equations can be solved directly to find parameter settings that achieve a desired set of mean firing rates.

649.5

SUBCORTICAL CONTROL OF SYNCHRONIZATION OF CORTICAL ACTIVITY: A MODEL. P. König, P.F.M.J. Verschure*. The Neurosciences Institute, San Diego, CA 92121.

A large body of experimental results suggest that the synchronization and desynchronization of neuronal activity is an important feature of cortical dynamics. These processes may serve binding and segregation of neuronal populations forming representations of perceived objects. An implication of this hypothesis is, that not only the level of neuronal activity, but also the level of coherence in the cortical network is regulated.

Here a model of the interaction of cortical areas with subcortical structures is presented, which addresses this issue. In the cortical network the distribution of synapses along the dendritic tree is captured by taking into account their finite electrotonic length. This parameter specifies the size of the set of effective synapses. The electrotonic length is influenced by modulatory transmitters released by the afferents of subcortical neurons, which are modeled to be very sensitive to synchronous input and are assumed to perform a spatial integration of cortical activity, thus forming a regulatory system for the level of cortical synchronization. These general principles have been applied to a model of the visual cortex demonstrating the adjustment of the interaction of cortical neurons to the degree of coherence present in the visual stimulus. Furthermore, this mechanism allows the regulation of the spatial scale of cortical processing. These results are in accordance with recent experimental observations (Munk et al. 1994, Neuroscience Abstracts), which demonstrate the involvement of the parabrachial nucleus in the regulation of cortical synchronization.

In conclusion, this study contributes to the evidence that dendritic processing forms an integral part of the function of neurons. Moreover subcortical structures can modify dendritic integration in cortical neurons and thus influence their degree of synchronization.

SINGLE UNIT RECORDING CAPABILITIES OF A 100 MICROELECTRODE ARRAY. C. T. Nordhausen*, E. M. Maynard, P. J. Rousche, R. A. Normann, Moran Laboratories, Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112, USA

Recently, the focus of many cortical electrophysiological studies has switched from the conventional single microelectrode approach to multielectrode investigations. This has been the result of the interest in the parallel processing aspects of cortex, and the spatiotemporal firing patterns of ensembles of neurons. We have developed a three dimensional silicon electrode array, the Utah Intracortical Electrode Array, which provides 100 separate channels for neural recording in cortex.

In order to demonstrate the efficacy of the electrode array for intracortical recording, we have quantified various aspects of its acute and chronic recording capabilities. Our preliminary results from acute preparations indicate that 60 to 70% of the electrodes yield evoked neural activity. Histology indicates that the majority of the remaining electrodes do not yield neural activity because they are positioned over a sulcus. The amplitude of the responses recorded with the array range from 40 to 180 μV with background noise on the order of 10 to 15 μV. Although the signal to noise ratio of these recordings is not as high as in the case of single microelectrodes, we are able to identify, on average, 3.5 units for each electrode that has recordable activity using time and amplitude window discrimination techniques. We have identified and tracked the same units for up to 4 weeks postimplant in ongoing chronic implantations. These results indicate that the electrode array provides a stable substrate for long term neural recording in cortex.

The recording capabilities of the array combined with the large number of available electrodes allow for a wide range of potential applications. Long term studies of specific groups of neurons in cortex are possible because of the stability of the electrode array. The identification of single units make it possible to acutely record from hundreds of units simultaneously.

OPTIMAL POPULATION CODES FOR A FUNCTIONAL ANALYSIS OF VISUAL CORTEX DYNAMICS. M.A. Giese, A.C. Akhavan*, W. Erlhagen, D. Jancke, A. Steinhage, H.R. Dinse, G. Schöner. Institut für Neuroinformatik, Ruhr-Universität, Bochum, Germany and CNRS-LNC, Marseille, France.

Application of population codes for a simple reconstruction of the stimulus or effector response from neural response data does not reveal much insight in the functional mechanisms in the neural substrate. We redefine population code as a class of algorithmic schemes projecting a set of measured neural activities onto one or more interesting parametric dimensions. Specifying these dimensions by a task or stimulus makes collective neural response data usefully interpretable.

Regarding population coding as a mathematical estimation problem we construct an optimal population estimator for the neural activity distribution over an abstract parameter space. We use a linear population estimator with well defined statistical properties derived by generalization from the optimal linear estimator described by Salinas & Abott (*J. of Comp. Neurosc. 1: 89, 1994*). Estimated activity distributions from cat primary visual cortex can directly be compared to predictions derived from a neural field model on dynamical spatio-temporal interactions in the visual field. The model reproduces psychophysically observed attraction and repulsion effects. It yields predictions for the activation dynamics in the underlying neural ensemble, which are specific for the functional properties of the neural substrate.

PRESERVED MOTION DISCRIMINATION IN MONKEYS WITH EARLY LESIONS OF STRIATE CORTEX. T. Moore, A.B. Repp, H.R. Rodman*, C.G. Gross. Department of Psychology, Princeton University, Princeton, NJ 08544.

The ability to discriminate visual stimuli on the basis of presence or direction of motion has been reported to survive damage to striate cortex in humans. In contrast, we previously reported (Moore et al., NS Abs. 19: 1801, 1994) that monkeys with unilateral striate lesions could not distinguish direction of motion in small (5 deg. diameter) dynamic random dot displays presented in the hemifield contralateral to the lesion. To address the possible role of stimulus size and retinal position in the residual visual capacity following striate cortex damage, we tested the ability of 3 monkeys with unilateral striate lesions made in infancy (5-6 weeks) to discriminate direction of motion in considerably larger (15 deg. diameter) displays of 0.5 deg. random dots centered at 13.5 deg. on the horizontal meridian. Magnetic resonance imaging indicates a complete lesion in one subject and only limited sparing of the peripheral field representation in striate of the other two. A go/no-go paradigm using a saccadic eye movement response was employed to test the monkeys' ability to discriminate upward from downward motion at 4 and 20 deg./sec. All monkeys learned the tested discriminations in both hemifields. The results suggest that in monkeys with striate cortex damage, some motion discrimination capacity is indeed preserved, at least after early lesions.

STABILITY AND VARIABILITY OF VISUAL FIELD DEFICITS IN BRAIN DAMAGED PATIENTS, E. Kasten*, S. Wüst and B. A. Sabel. Inst. of Med. Psychology, Medical Faculty, Otto-von-Guericke Univ., Leipziger Str. 44, 39120 Magdeburg, Germany.

Thirtysix brain-damaged patients with visual field deficits were investigated to study the variability of the blind visual field (15 stroke, 9 trauma, 4 brain surgery, 3 inflammation, 4 cerebral hemorrhage, 1 cerebral degeneration). In addition to the assessment with the Tübinger automatic perimeter we used the computer programs PERIMAT (light detection), PERIFORM (form recognition) and PERICOLOR (color perception) for a more exact diagnostic of the the mid-section of the visual field up to 12.5° vertical and 20° horizontal eccentricity. Five repeated measurements were made in 5 independend sessions and the results were then compared. There was a surprising and reliable stability of visual field defects with correlations across the 5 sessions from r=0.86 up to r =0.94, depending on which diagnostic test was applied. Individual differences in physical health or mental condition, the age, the attention span, the cause of the lesion or the extent of the restricted visual field of the patients had no significant influence on the variability of visual field defects. Further analysis showed that most patients had no or very few islands of residual vision. 41.2% of stimulus locations in the blind area were only seen once, 27.1% twice, 18.8% three times, 8.2% four times and 4.7% in all 5 measurements. Perceived items to which the patient responded correctly only once or twice may perhaps be due to fixation instability or attentional deficits. In conclusion, there are only few reliable islands of residual vision in the blind area of most patients. [Supported by Kuratorium ZNS and DFG-No. Sa 433/6-1]

SPATIAL AND TEMPORAL FREQUENCY SENSITIVITY IN HUMAN STRIATE CORTEX MEASURED WITH FUNCTIONAL MRI (fMRI) J.B. Demb*, G.M. Boynton, S.A. Engel, J.D.E. Gabrieli, D.J. Heeger, and G.H. Glover Depts. of Psychology and Radiology, Stanford University, Stanford, CA 94305

Human spatial sensitivity depends on the temporal frequency of the stimulus. At high temporal frequencies (TF), sensitivity to sinusoidal gratings is best below 3 c/deg while at low TF, sensitivity is best between 3 and 6 c/deg. In addition, sensitivity to high spatial freqency (SF) gratings decreases with eccentricity. This study measured activation in human striate cortex (V1) to examine the neural correlates of pattern vision. We measured blood oxygen level-dependent (BOLD) fMRI signal in V1 while subjects viewed counterphase modulating full-field sine-wave gratings. We used a T2*-weighted gradient echo spiral sequence (1.5T, .78x.78x5mm voxel size, TR=75ms, TE=40ms, FA=23deg) and a cross-correlation analysis. Our results were consistent with psychophysical measurements. Low SF gratings produced best correlations with the stimulus at high TF while high SF gratings produced best correlations at low TF. Posterior regions of V1, close to foveal representations, were primarily activated by high SF/low TF stimuli. Anterior regions of V1, corresponding to peripheral representations, were primarily activated by low SF/high TF stimuli. These results may be a consequence of variations in receptive field size or a change in the relative amount of parvocellular and magnocellular input along V1.

COMPARISON OF VISUAL CONTRAST-RESPONSE FUNCTIONS USING MAGNITUDE ESTIMATION PSYCHOPHYSICS AND FUNCTIONAL MAGNETIC RESONANCE IMAGING. M.R. Peters, B.J. Anderson*, and E.A. DeYoe, Dept. of Cell. Biol. & Anat., Med. Coll. of Wisc., Milwaukee, WI 53226.

Areas of the striate and extrastriate cortices which are responsive during a contrast scaling task were identified using functional magnetic resonance imaging (FMRI). For these areas, the relationship between perceived contrast and the magnitude of the FMRI signal was examined.

During gradient-recalled echo planar imaging, both the FMR signal and psychophysical data were simultaneously collected. Four human subjects were each placed in the scanner and allowed five minutes to adapt to the background luminance. During the trials they viewed sine-wave gratings varying in contrast from 5-100%. Subjects used simple hand signals to indicate estimated contrast from a modulus-free scale of their own choosing.

For each voxel, the psychophysical estimates of stimulus contrast and FMR response magnitudes were compared as a function of the physical stimulus contrast. For each of the 4 subjects, the estimates of stimulus contrast were linear with physical contrast when plotted in log-log coordinates, though for 1 subject a "ceiling" effect was observed at the highest contrasts. For some, but not all voxels in V1, the MR signal amplitude matched the psychophysical function. This variation may reflect differences in either the underlying neuronal response, the hemodynamic mechanisms responsible for the FMRI signal, or other as yet unidentified factors. However, the close correspondence of the psychophysical and FMRI responses for some voxels suggests that this approach can identify sites potentially responsible or supporting the perceptual events.

VISUAL TEXTURE PERCEPTION IN HUMANS: fMR AND PET STUDIES. L. Beason-Held*, N. Azari, K. Purpura, L. Optican, J. Krasuski, M. Schapiro, S. Rapoport, J. VanMeter. Nat. Inst. of Health, Nat. Inst. on Aging, Lab. Neurosci., Bethesda, MD 20892.

To investigate cortical responses to a specific set of features within visual stimuli, isodipole textures were presented to 6 healthy young subjects during H215O positron emission tomography (PET) and blood oxygenation level dependent (BOLD) functional magnetic resonance (fMR) imaging. Two families of textures were used: Random textures in which the pattern of black and white checks were arranged in a random fashion, and Even textures in which the black and white checks were ordered to produce extended contours and rectangular blobs at multiple spatial scales. During fMR scanning, the subjects were presented with either Random or Even textures interwoven with alternating blocks of a control fixation condition. Relative to fixation, Random stimulation produced slight activation in the primary visual cortex (Area 17). In contrast, Even stimulation resulted in increased striate as well as extrastriate (Areas 18, 19) activation. As for the PET study, the subjects were given four scans during Random stimulation and four during Even stimulation. The results from this study support the fMR findings, in that Even stimulation increased blood flow in the primary and extrastriate cortices relative to Random stimulation. Together, these results suggest that early form processing is not limited to extrastriate cortex, and mechanisms in both striate and extrastriate cortex are sensitive to the ordered features present in the more visually salient Even textures.

CHANGES IN REGIONAL CEREBRAL BLOOD FLOW BY FLASH AND PATTERNED VISUAL STIMULATION IN MONKEY VISUAL CORTEX. K. Imamura*[1,2], H. Onoe[1,2], T. Shiomitsu[1,2], K. Onoe[1], H. Tsukada[1,3], T. Kakiuchi[3], and Y. Watanabe[1,2]. [1]Subfemtomole Biorecognition Project, JRDC, Osaka 565, [2]Osaka Bioscience Institute, Osaka 565, [3]Central Res. Lab. Hamamatsu Photonics K.K., Shizuoka 434, Japan.

We studied changes in the regional cerebral blood flow (rCBF) induced by visual stimulation using $H_2{}^{15}O$ and positron emission tomography (PET). Averaged subtraction images of different experimental conditions were made and signals were superimposed on magnetic resonance (MR) images after statistical evaluation(ref.). We found that (1) it was more difficult to obtain significant signals in the visual cortex under anesthetized and paralyzed condition than awake condition, (2) larger signal was obtained in binocular stimulation than monocular stimulation, (3) flash stimulation induced large signals in the visual cortex as moving line-pattern stimulation, (4) activity in the frontal region, including the cingulate cortex was decreased by visual stimulation, (5) visual stimulation applied to the deprived eye of monkeys that had been suffered monocular deprivation over the sensitive period still induced some responses in the visual cortex. These results show not only dynamic change in rCBF by visual stimulation but also dissociation between the generation of action potential and rCBF-change in the visual cortex.

IS THERE A 'FINAL COMMON PATHWAY' FOR THE TWO MONOCULAR VIEWS? T.J. Andrews*, L.E. White, D. Binder and D. Purves. Department of Neurobiology, Duke University, Durham NC 27710.

The "singleness" of human binocular vision is usually explained by the blending of information generated by each eye into a common stream that ultimately leads to perception. This scheme is exemplified by the phenomenon of stereopsis, which depends on binocularly driven cells in the primary visual cortex that are sensitive to spatial disparity. To ask whether the concept of monocular blending pertains to all aspects of vision, we repeated an experiment on flicker-fusion carried out by Charles Sherrington (Br. J. Psychol. 1: 26-60, 1904) nearly a century ago. The critical flicker-fusion frequency (CFF) is the frequency at which a flickering light is perceived as being fused 50% of the time. We determined the CFF for 25 subjects in two situations: (1) trains of light flashes presented synchronously to both eyes; and (2) the same trains presented asynchronously to the two eyes. If the independent views of the two eyes are fused in a binocular processing stream, then the critical flicker-fusion frequency should be much lower in the alternating presentation than in the synchronous presentation. One-second trains of flashes generated by two stroboscopic light sources were presented dichoptically; the frequency of flashes (20-65 Hz) and their temporal relationship were controlled by computer. Contrary to prediction, we found, as did Sherrington, only a small difference between the two conditions (mean synchronous CFF $\pm$ SD = 47.3 $\pm$ 4.1 Hz; mean asynchronous CFF $\pm$ SD = 46.3 $\pm$ 4.2 Hz). We conclude that binocular convergence at a cellular level, which is essential for some aspects of visual perception, may not be a general rule. Perhaps, visual perception in this circumstance derives from the activation of circuitry that elaborates monocular information independently.

EVALUATION OF PSEUDORANDOM M-SEQUENCES FOR HUMAN VISUAL EVOKED NEUROMAGNETIC RESPONSES. H.-W. Chen, C. Aine*, D. Ranken, E. Best, E. Flynn, and C.C. Wood. Biophysics Group, M715, Los Alamos National Laboratory, Los Alamos, NM 87545

The primary goal of this study is to assess the utility of using m-sequence stimuli, a general form of steady-state stimuli with broadband frequencies, in visual neuromagnetic studies. Three primary reasons for examining m-sequence stimuli are: 1) m-sequences are orthogonal to output noise (random or periodic) and may, therefore, enhance the signal-to-noise (S/N) ratio; 2) different m-sequences are orthogonal to one another and may, therefore, permit the simultaneous presentation of multiple stimuli at different locations, allowing for faster data acquisition; and 3) m-sequence results, in conjunction with nonlinear systems analysis, may provide information about the system's nonlinear dynamics. In this study, we evaluated the utility of m-sequences by comparing the S/N ratio per unit time obtained using both transient and m-sequence stimuli. In addition, the possibility of resolving two responses evoked by paired stimuli was also examined.

Evoked magnetic fields were recorded with a BTi 7-channel SQUID-coupled gradiometer system in a magnetically-shielded chamber. Experimental paradigms using both transient (266 ms duration and ~1 Hz rate of presentation) and m-sequence visual stimuli (with length 1023 at 30 Hz rate) were conducted. A single stimulus was presented at a single location (3^0), or pairs of stimuli were presented at three different eccentricities (0.8^0, 1.6^0, and 3^0) in the visual field. Results from three subjects show that the S/N ratio for the m-sequence study was 2-3 times higher than the transient study, for single stimulus placements, when total length of stimulus presentation time was equated across studies. The amplitude distributions across the 7 sensors were similar for transient and m-sequence stimuli. In addition, the time courses across the 7 sensors were not proportional to one another, suggesting the existence of multiple evoked visual sources. The response distributions evoked by the m-sequence pairs were quite similar to the distributions evoked by single stimuli. Thus far, it appears that m-sequence stimuli provide a useful approach for MEG/EEG studies of vision.

HIGH-SPEED IMAGING OF NEURAL ACTIVITY IN THE TURTLE CORTEX EVOKED BY "MOVING STIMULI"

David M. Senseman*

Div of Life Sciences, Univ of Texas at San Antonio, San Antonio, TX 78249

To examine the idea that the turtle dorsal cortex may be important in the detection of movement, visually-evoked activity in the cortex was monitored using combined multi-site optical recording and video imaging techniques. The image at left shows the outlined of a 464-element photodiode array superimposed on the unfolded cortical sheet using an isolated eye/brain preparation of the turtle, *Pseudemys scripta*. "Moving stimuli" were generated using a matched-pair of laser diodes (3 mW, 670 nm) that delivered two light spots (200 ms duration) under computer control. Optical signals at right show that depolarization of the dorsal cortex (filled box in grid) is longer (arrow) when visual stimulation was switched between a rostral and a caudal located spot (thick trace) than the responses observed when both light spots were delivered at the same visual location (thin traces).

LAMINAR AND COMPARTMENTAL ORGANIZATION OF IMMUNOCYTOCHEMICALLY LOCALIZED AMPA RECEPTOR SUBUNITS IN MACAQUE PRIMARY VISUAL CORTEX. R.K. Carder*. Zanvyl Krieger Mind/Brain Institute and Dept. Psychology, Johns Hopkins University, Baltimore, MD 21218.

Fast excitatory synaptic neurotransmission in the visual system is mediated predominantly by α-amino-3-hydroxy-5-methyl-4-isoxazole proprionic acid (AMPA) receptors. Cloning and expression studies have demonstrated that AMPA receptors are composed of multiple subunits with each subunit conferring unique pharmacological, kinetic, and gating properties. By use of subunit-specific antibodies, this study explored the organization of AMPA receptor subunits within the adult macaque primary visual cortex (V1). Immunoreactivity for each of the three AMPA subunits, GluR1, GluR2-3, and GluR4, consisted of rich plexuses of punctate profiles localized within the neuropil and to varying degrees somata and proximal processes. GluR1, GluR2-3, and GluR4 immunoreactivity was present through the thickness of V1, but was densest in three bands that corresponded to layers II - IVA, IVC and VI. Within different layers of V1 the immunostaining for AMPA subunits formed distinct patterns. In layer IiII, patches of intense immunostaining coincided with CO-rich blobs; in layer IVA, intense subunit staining formed a conspicuous honeycomb pattern; and in layer IVC subunit staining formed a very fine lattice. The principal observations of the present study are that the major subunit variants of the AMPA receptor are distributed in very similar patterns, with the greatest densities in zones of geniculocortical afferent terminations.

APPLICATION OF L-Arg AND L-NOArg MODIFY CELLULAR RESPONSES IN THE PRIMARY VISUAL CORTEX OF THE CAT. J. Cudeiro*, C. Rivadulla, R. Rodríguez, S. Martínez-Conde and C. Acuña. Departamento de Fisiología, Universidad de Santiago and Departamento de Ciencias de la salud I, Universidad de La Coruña, Spain.

Fibres arising from the brainstem provide cholinergic input to the lateral geniculate nucleus (dLGN), while the visual cortex receives a cholinergic input from the basal forebrain. Recent evidence has shown that nitric oxide synthase (NOS), synthetic enzyme for nitric oxide (NO), is co-localized with ACh in both pathways[1,2]. We have previously shown that NO is necessary for the transfer of visual information in the dLGN, gating visual input by an action involving NMDA receptors[3,4]. Here we extend these observations by examining the role of NO in the primary visual cortex.

Experiments were carried out on paralysed, anaesthetised adult cats (halothane 0.5-1% in N_2O and O_2 70:30; Gallamine 10 mgr/kg/h). Seven barrelled micropipetes were used for extracellular recording and iontophoretic ejection of drugs. The effect of application of L-NOArg (N^G-nitro-L-arginine, an inhibitor of NOS) and L-Arg (L-Arginine, the physiological substrate of NOS) was tested on spontaneous, visual and NMDA/AMPA evoked responses. In 14/40 cells application of L-NOArg produced a decrease both in spontaneous and visual responses, without changing visual specificity. This effect was reversed in 11/14 by co-application of L-Arg (itself without effect), and is therefore consistent with our data in the dLGN. Surprisingly, in 16/40 cells application of L-Arg abolished cell responses, even using very low ejection currents. This effect was unaltered by L-NOArg in any case. 25% of cells were unaffected by either drug, alone or in combination. There was no clear relationship between the effect seen and either cell type or laminar position. In a different block of experiments, we have observed that ejection of L-NOArg essentially suppresed both NMDA and AMPA responses in 40% of cells.

While it seems likely that a significant proportion of cortical cells respond to NO in a manner similar to the effect we have already demonstrated in the dLGN, the intriguing and potent action of L-Arg on a large number of cells remain unexplained.

A Simple Model of Cortical Excitatory Cells Linking NMDA-Mediated Currents, ISI Variability, Spike Repolarization and Slow AHPs. T.W. Troyer* and K.D. Miller, W.M. Keck Center for Integrative Neuroscience, UCSF, San Francisco CA 94143

Integrate-and-fire models assume neurons integrate many fast synaptic inputs until threshold, then fire a spike that resets membrane voltage to rest. Such models can account for rate coding and classical receptive fields. However, their applicability to excitatory cells in cerebral cortex is challenged by the following observations: (1) interspike intervals (ISIs) have high variability, which is inconsistent with integration of many random synaptic events; (2) excitatory cortical cells typically do not repolarize near rest after spiking; (3) chronic infusion of APV blocks visual cortical responses, suggesting an important role for slow synaptic events; (4) specific blockade of fast excitatory transmission by chronic infusion of CNQX (specificity verified by iontophoresis) does not block visual responses in V1 (CNQX data from the laboratory of Michael Stryker).

Previous models have invoked a delicate balance of excitation and inhibition and perhaps (2) to explain (1). Motivated by (3) and (4), we incorporate NMDA receptors and negative feedback from a slow AHP along with (2) to arrive at a simple and robust single-cell model consistent with (1)-(4). Synaptic currents with a large NMDA-mediated component lift the membrane voltage near threshold. Incomplete repolarization returns the cell to this sensitive state. Because spikes result from small current excursions, the neuron has large gain and displays high ISI variability, as noted in previous models. Maintaining this sensitivity requires a balance of inward and outward currents, achieved here through slow, spike-evoked AHPs that compensate for changes in synaptic input. This adaptive balancing maintains wide dynamic range over long time scales despite high gain at short time scales. This model also qualitatively reproduces a peculiar bursting pattern displayed by a few well isolated units in the CNQX experiments. We are exploring possible functional roles these mechanisms could play in information processing on fast and slow time scales.

SPATIAL ORGANISATION AND SELECTIVITY OF THE INTERACTING COMPONENTS UNDERLYING RESPONSES OF CELLS HIGHLIGHTING DISCONTINUITY OR INTERSECTIONS IN THE VISUAL WORLD.
H.E. Jones*, K.L. Grieve and A.M. Sillito. Dept. of Visual Science, Inst. of Ophthalmology, Bath St., London EC1V 9EL, UK.

Areas outside the receptive field excitatory discharge centre can exert very potent effects on visual cortical cell responses. These effects can be inhibitory, and are frequently linked to end-zones or side-bands, or both, although in some cases they may effectively surround the field (DeAngelis et al. 1994, *J. Neurophysiol.* 71:347-374; Li & Li 1994, *Vision Res.* 34:2337-2355). Facilitatory and/or disinhibitory effects can also be elicited from outside the excitatory discharge centre but there is little evidence regarding their spatial organisation. These influences are brought into strong focus by particular configurations of stimuli overlying the classical receptive field and the surrounding area of visual space. In some cells they may reflect a network effect serving to signal orientation discontinuity or intersections. Here we report evidence from primate V1 showing that both the facilitatory/disinhibitory and inhibitory influences are strongly dependent on the direction of stimulus motion, as well as the relative orientation, of stimuli driving the classical receptive field and surrounding areas of visual space. Areas producmg facilitatory effects are not necessarily uniformly distributed around the receptive field and may be very localised. For example the response to an optimally oriented grating patch overlying the classical receptive field may be most strongly enhanced by an additional orthogonally oriented patch, drifting in one direction only and displaced to a location adjacent to one corner of the field. The spatial localisation, directionality and orientation requirements for the secondary stimulus suggest a mechanism in V1 focusing on very specific facets of the visual world, for example the vectors of motion associated with an intersection such as a corner moving through space. They emphasise the need to dissect the functional organisation of primate V1 with more complex stimulus configurations.

EFFECTS OF METABOTROPIC RECEPTOR AGONISTS IN THE FELINE VISUAL CORTEX. P.M. Venters and A.M. Sillito. Dept. of Visual Science, Inst. of Ophthalmology, Bath St., London EC1V 9EL, UK.

We were interested in effects following from the Group 1 phosphoinositide linked metabotropic receptors (mGluRs) in the visual cortex, and particularly actions that derived from modulation of the potassium channels underlying the M current, because this might provide a means of local modulation of excitability superimposed on cholinergic influences in the neocortical circuitry. To this end we used microiontophoretic techniques to explore the action of a range of mGluR agonists on the visual and drug driven responses of cells in layers II-VI of the cat primary visual cortex. To our surprise we saw only a few examples of the type of facilitatory effects previously associated with the cholinergic modulation of the M-current (Sillito and Kemp 1983, *J. Physiol.* 250:287-304; Murphy *et al.* 1993, *J. Neurophysiol.* 69:1465-1474) and these were on cells in layers V and VI.

The predominant effect (90% of the cells) was a selective suppression of visual driving. Thus for example iontophoretic application of the multiple mGluR receptor agonist 1S,3R-ACPD depressed or blocked the visual response of cortical cells to an optimally oriented moving bar, but did not influence the responsiveness of the cells to iontophoretic pulses of NMDA or AMPA. Thus the post synaptic excitability of the cells to the agonists acting at the postsynaptic glutamate receptors was not changed whilst the visually driven response was. This effect seems most logically explained by a presynaptic effect mediated via Group 2 mGluRs. We observed it in cells throughout layers II-VI and its prevalence suggests that presynaptic control of the transfer of visual information may play an important functional role in the microcircuitry of the visual cortex.

650.6

MOLECULAR COMPONENTS OF THE cGMP SECOND MESSENGER SYSTEM ARE PRESENT IN RAT VISUAL CORTEX

D.Samanta Roy*, P.A. Kingston, and C.J. Barnstable, Interdepartmental Neuroscience Program, Dept. of Ophthalmology and Visual Sciences, Yale University School of Medicine, New Haven, CT 06510

Retrograde messengers such as nitric oxide (NO), and some of the transmitters implicated in learning and memory, as well as in synaptic changes during development, have been shown to affect the concentration of cGMP. cGMP exerts its effects through three known pathways, namely 1) cGMP-gated cation channels, 2) cGMP dependent protein kinases, and 3) cGMP regulated phosphodiesterases. We have presented a model to suggest how these might interact to modulate cell excitability (Ahmad *et al*, Neuron 12: 155, 1994). We wish, however, to determine the general applicability of this model to the brain, in particular the visual cortex.

To begin to study how cGMP might affect development and plasticity in mammalian visual cortex, we have examined the distribution and developmental expression of a series of molecules involved in cGMP metabolism and cGMP effector molecules. Using RT-PCR, we have detected expression of the cGMP-gated cation channel, cGMP kinase, cGMP stimulated phosphodiesterase, and the 61 and 63 kD forms of the calcium-calmodulin dependent phosphodiesterase in adult rat visual cortex. Preliminary in situ data using digoxigenin-labelled RNA probes for the rod cGMP-gated cation channel, suggests a rostral to caudal gradient of expression in the rat cortex, with the highest level appearing in the occipital cortex. Moreover, there appears to be only a subset of neurons labelled with the densest staining in layers II/III and V/VI.

In summary, we have found many of the molecular components of the cGMP second messenger system to be present in adult rat visual cortex, and have found the cGMP-gated channel to be localized to discrete layers of the visual cortex. These findings, together with the known effects of NO and cGMP in other brain regions, suggest an important role for the NO/cGMP system in visual cortical function.

DISTRIBUTION OF ADENOSINE A1 RECEPTORS IN PRIMARY VISUAL CORTEX OF MONKEY

S. Larocque*, R.Z. Cohen, V. Zhao, and A. Chaudhuri
Dept. of Psychology, McGill University, Montreal, Canada

The adenosine A1 receptor has been implicated in a variety of physiological functions, including inhibition of neurotransmitter release. Adenosine binds to A1 receptors with high affinity and inhibits adenyl cyclase. The distribution of this receptor in visual cortex has not been previously reported.

Receptor binding in the primary visual cortex of normal and monocularly-deprived vervet monkeys was determined by in vitro autoradiography with the agonist [^{3}H]-CCPA. Thaw-mounted sections (15 μm) were treated to the radiolabeled ligand for three hours at room temperature. Non-specific binding was estimated on adjacent sections by adding 50nM cyclopentyladenosine in the incubation medium. Standard washing protocols were then followed and the sections were air dried. The slides were exposed to Hyperfilm-^{3}H (Amersham) at room temperature for 10 days, along with plastic standards of ^{3}H (Amersham).

We have found intense labeling in layer V and moderate labeling in the supragranular layers of primary visual cortex (area 17 or V1). The layer V distribution was especially striking because of contrast with the poor labeling in layers IV and VI. This pattern was unchanged in animals that had a monocular occlusion for up to six days. There was no evidence of modulation in receptor density in either set of ocular dominance columns.

MODULATION OF SYNAPTIC INPUTS TO VISUAL CORTICAL NEURONS BY ADENOSINE AND 5-HT

Juan Varela, Kathryn Richards and Sacha B. Nelson* Dept. of Biology, Center for Complex Systems, Brandeis University, Waltham MA 02254

Although receptors for a variety of neuromodulators including serotonin (5-HT) and adenosine (ADE) are present in the visual cortex, their physiological actions have mostly been inferred from studies in other preparations. In order to study these effects directly, we made whole-cell voltage and current clamp recordings from pyramidal neurons in layers 2/3 and 5 of rat primary visual cortical slices, under visual control, using infrared videomicroscopy. ADE (10-100 μM) reduced the frequency of spontaneous EPSCs from 1.18 to 0.33 Hz without apparent change in their amplitude. EPSCs evoked by local intracortical stimulation were decreased by 40-75%. For stimuli which evoked minimal (apparently unitary) responses, ADE dramatically increased the failure rate. ADE also enhanced the synaptic facilitation and decreased the synaptic depression evoked by brief stimulus trains (5 @ 20 Hz).

Effects of 5-HT (10-50μM) and the specific 5-HT1B agonist CGS 12066A (20μM) were more heterogeneous. Spontaneous EPSC frequency and amplitude were not significantly affected (n=6). Minimally evoked EPSCs were reduced in 3/6 cells tested, and failures were increased (2/6). 5-HT at these doses did not directly alter neuronal excitability as measured by holding currents and the threshold for antidromic activation. These results suggest that ADE and 5-HT may act presynaptically in the visual cortex but may differ in their specific synaptic targets.

VISUAL DEPRIVATION DOES NOT ALTER MUSCARINIC RECEPTOR PROTEIN DISTRIBUTION IN AREA 17 OF RHESUS MONKEYS. M. Tigges, J. Tigges*, H.D. Rees, D.B. Rye and A.I. Levey. Yerkes Primate Center and Dept. of Neurol., Emory Univ., Atlanta, GA 30322.

Acetylcholine has been implicated in the normal function of visual cortex and in ocular dominance plasticity. We used antibodies to muscarinic cholinergic receptor proteins m_1 and m_2 to investigate the expression of these proteins in area 17 of a normal rhesus monkey and of 2 monkeys raised with a black contact lens on one eye from birth and 2 monkeys with long-term monocular eyelid suture as adults. In area 17 of the control brain, immunoreactivity of both proteins was distributed in a complex laminar pattern. Adjacent cytochrome oxidase sections were used to confirm assignment of immunoreactivity to various layers. m_1 was densest in layers 6 and 2/3, followed by layer 5. Layer 4 contained several bands of different intensities. A thin light band of reaction product ran through 4A, 4B reacted darker; another thin, but very light band occurred at the 4C/5 border. The remainder of 4C was moderately light. In contrast, m_2 reactivity was densest in lower layer 4C. The honeycomb pattern of 4A was reactive and layers 2/3 exhibited alternating dense and light regions. Layer 5 was slightly lighter than 4C, and layers 4B and 6 were stained the least. m_1 antibody reacted predominantly with neurons, m_2 antibody labeled mostly processes. In area 17 of visually deprived monkeys, the distribution of the 2 receptor proteins appeared normal, except that in one lidsutured monkey a thin band at the 4C/5 border reacted more densely with m_2 antibody than 4C. Thus, these proteins seem to be insensitive to monocular elimination of visual input via occlusion from birth and to long-term elimination of pattern vision imposed on the adult visual system.

NEUROCHEMICAL ORGANIZATION OF MACAQUE STRIATE CORTEX: CORRELATION OF CYTOCHROME OXIDASE WITH NOS, NADPH-DIAPHORASE, NMDAR1, AND Na^+K^+ATPASE. M. Wong-Riley*, W. Liebl and Z. Huang, Dept. of Cellular Biology & Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226.

Previous studies indicate that a) cytochrome oxidase (C.O.)-rich puffs in the macaque striate cortex sustain a higher level of maintained neuronal activity than interpuffs, b) neuronal and synaptic properties differ between these two compartments, and c) asymmetric, glutamate (Glu)-immunoreactive synapses predominate in puffs. A major Glu receptor family is NMDA, which is implicated in the stimulation of nitric oxide synthase (NOS) and in the production of NO, a gaseous intra- and inter-cellular messenger (Garthwaite, 1991; Dawson & Snyder, 1994). To determine if these neurochemicals are enriched in puffs, we processed serial frozen sections of the monkey visual cortex for C.O., NOS, NADPH-diaphorase, NMDAR1, and Na^+K^+ATPase (a major energy-consuming enzyme), respectively. We found that they all have a heterogeneous pattern of distribution in the supragranular layers that centered on puffs, but the labeling of NOS was the lightest. In addition, the staining of all five were intense in layer 4C and, with the exception of NOS, exhibited a honeycomb pattern in 4A. At the EM level, the density of NOS-positive immunogold particles was significantly higher in C.O.-rich type C cells than in the other cell types of puffs. Thus, our results are consistent with an excitatory synaptic circuitry in puffs that involves glutamate and NMDA receptors, as well as nitric oxide in selective cell types. The excitatory synaptic activities are likely to impose a higher energy demand in puffs than in the surrounding interpuffs.

EFFECTS OF MONOCULAR IMPULSE BLOCKADE ON GABA IMMUNOREACTIVE NEURONS IN CYTOCHROME OXIDASE (C.O.)-RICH PUFFS OF THE MACAQUE STRIATE CORTEX: QUANTITATIVE EM ANALYSIS. F. Nie, E. Godfrey* and M. Wong-Riley, Dept. of Cellular Biology & Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226

Previously, we have shown that GABA-immunoreactive (GABA-IR) neurons in supragranular puffs of the monkey striate cortex have high levels of cytochrome oxidase (C.O.) activity. We now have examined the effects of 2 weeks of monocular TTX treatment on these neurons in activity-deprived and non-deprived puffs (DP and NP). In ultrathin sections of DPs doubly labeled for C.O. and GABA, GABA-IR cells and GABA-IR terminals showed a significant shrinkage in their mean size ($P<0.05$ for both), a drastic reduction in the proportion of dark and moderately C.O.-reactive mitochondria, and a significant decrease in the number of GABA-immunogold particles as compared to comparable cells in NPs. The densities of GABA-IR axon terminals and GABA-IR symmetric synapses in DPs were also significantly reduced ($P<0.01$), while those of GABA-IR cells and dendrites were unchanged. The total number of synapses in DPs and NPs was constant. Non-GABA-IR cells exhibited relatively minor changes in these parameters. These results suggest that: (1) metabolic activity and GABA levels in GABA-IR neurons are regulated by neuronal activity in adult monkey striate cortex; and (2) GABA-IR neurons are much more vulnerable to functional deprivation than non-GABA-IR neurons, presumably because their cell bodies are more dependent upon sustained excitatory input. (Supported by NIH EY05439 & NS18122).

MUSCIMOL AND BACLOFEN DIFFERENTLY SUPPRESS RETINOTOPIC AND NON-RETINOTOPIC CORTICAL RESPONSES. K. Mizobe, E. Schmidt and T. Kasamatsu* The Smith-Kettlewell Eye Res. Inst., San Francisco, CA 94115

The locally recorded field potentials elicited by contrast reversal of bar gratings have extremely large receptive fields beyond the usual range of the classical receptive field of single units at the same site. They have two distinct components: the retinotopic fast-local component (FLC) and the non-retinotopic slow-distributed component (SDC). The latter is thought to be a physiological correlate of the long-range lateral connections (Kitano et al., 1994). Earlier, we have shown that muscimol, a $GABA_A$ receptor agonist, suppressed the FLC more strongly than the SDC though its effects on the latter were detected earlier than those on the former (Mizobe, et.al., 1995).

In the present study, we compared the suppressive effects of muscimol with those of a $GABA_B$ receptor agonist, baclofen. Visual stimuli were contrast reversal of achromatic bar gratings in a 5-deg patch placed at either retinotopic locus or ~15 deg in the periphery. Field potentials were recorded by a pair of microelectrodes implanted in area 17 near the projection of the area centralis. Responses were extracted by a multi-input nonlinear systems analysis method (Sutter, 1992). Muscimol (10mM) or baclofen (5mM) was continuously infused for 2.3~5.6 hours at a rate of 5 µl/h through a 30-G cannula implanted ~2 mm posterior to the recording site.

Within 1 hour after the start of infusion, both muscimol and baclofen decreased the amplitude of the SDC, but not the FLC. Thereafter, however, the FLC amplitude was more strongly decreased than the SDC amplitude throughout the muscimol infusion. By contrast, the SDC was more strongly suppressed by baclofen than by muscimol. The suppressive effect of baclofen tended to be stronger on the SDC than the FLC, but the difference did not reach a significant level. The present findings suggest that : 1) the retinotopic responses are controlled more strongly by $GABA_A$ receptors than $GABA_B$ receptors, and 2) the reverse is true for the non-retinotopic responses.

SEROTONIN FACILITATES SYNAPTIC PLASTICITY IN KITTEN VISUAL CORTEX — AN IN VITRO STUDY. Q. Gu*, L. Kojic, R.M. Douglas and M.S. Cynader, Department of Ophthalmology, University of British Columbia, Vancouver, BC, Canada V5Z 3N9

We have investigated the hypothesis that serotonin is involved in activity-dependent synaptic modification in the developing visual cortex. Visual cortex slices (400 - 500 µm) were made from kittens aged between 40 - 57 days. At these ages several subtypes of serotonin receptors are found to be expressed transiently at higher level within the visual cortex. Field potentials in layer IV evoked by white-matter stimulation were recorded. Normally, low-frequency white-matter stimulation at 1 Hz for 15 minutes had no effects on field potentials in layer IV (10 out of 10 slices). However, when serotonin was present in the bath (1 µM) during the low-frequency stimulation, about half of the slices tested developed long-term depression (LTD) (5 out of 11 slices). When serotonin concentration in the bath was increased to 10 µM, the same low-frequency stimulation could induce either long-term potentiation (LTP) (3 out of 9 slices) or LTD (3 out of 9 slices). These results suggest that serotonin facilitates input-dependent synaptic modifications in kitten visual cortex. The differential effects mediated by serotonin (LTD, LTP, or no change) may depend on serotonin receptor subtypes located at the recording sites, since it has been shown that at these ages serotonin 5-HT2c receptors, for example, are localized in a columnar fashion across layer IV.

GABA iontophoresis modifies the intrinsic signal orientation map in cat area 18. L.J. Toth*, D.-S. Kim, S.C. Rao, M. Sur.
Dept. Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

While intracortical inhibition clearly has a role in generating orientation selectivity in visual cortex, how the balance of excitation and inhibition regulates orientation specificity remains unknown. To examine the issue, we injected GABA into a column of known orientation preference and imaged intrinsic signals to ascertain changes in orientation strength and preference in the surrounding cortical region. At the maximal concentration used (1.0M, 93nA) we were able to affect sites up to 1.5 mm distant from the injection. Sites with similar orientations to that at the injection showed a shift in orientation preference *away* from the injection site orientation. Orientation preference at the injection site changed up to 45°, although general activity levels were much lower in this region. These effects were reversible. Surrounding columns of orthogonal orientation, as well as more distant columns of all orientations showed no obvious changes during GABA application. Changing the amount of GABA ejected produced changes in the magnitude of the orientation shift, and the extent of cortex involved. While these results do not favor a strong role for cross-orientation inhibition, they do suggest that selective activation of inhibitory circuitry can profoundly alter the layout of orientation domains in the cortex, perhaps by selectively altering the balance of converging excitatory inputs to a region. THIP PRODUCES PROFOUND, SELECTIVE CHANGES IN FLASH EVOKED POTENTIALS OF HOODED RATS. B.E. Hetzler* and H.L. Zeisset, Dept. of Psychology, Lawrence Univ., Appleton, WI 54912.

Flash evoked potentials (FEPs) are useful in assessing the functional integrity of the visual system, although interpretation of any changes is difficult since little is known about the neuronal processes responsible for peak generation. Gamma amino butyric acid (GABA) is an inhibitory neurotransmitter believed to play a major role in information processing in the cerebral cortex, but its role in the elaboration of the rat FEP is unclear.

FEPs were recorded from the visual cortex of hooded rats at 5, 20, and 35 min. following i.p. injections of saline, and of 8, 16 and 24 mg/kg THIP on separate days. THIP is an analogue of muscimol, a GABA-A agonist. Most significant effects occurred at the 20 and 35 min recording intervals for both the 16 and 24 mg/kg doses, with effects at the 24 mg/kg dose the most pronounced. P1 amplitude remained unchanged, while N1 was reduced to such an extent that it became positive, ultimately blending into the rising phase of a novel positive component. This novel component had a latency of about 6 msec longer than N1, and became larger than P1 at the 24 mg/kg dose. P2 amplitude was drastically reduced, becoming negative. In contrast, components N2 and P3 were augmented, while the amplitude of N3 was unchanged. Latencies of most components were increased, with the late components increased to the greatest extent. A mild hypothermia of about 0.5 °C and 0.75 °C was observed at 16 and 24 mg/kg, respectively. The amplitude data suggest that the GABA-A receptor system is involved in the generation of the middle FEP components. However, the effects of THIP on the rat FEP also suggest that the role of GABAergic inhibition in FEP production is qualitatively different in the rat than in other species (e.g., cats; Zemon et al., in Evoked Potentials, Alan R. Liss, 1986).

CHARACTERIZATION OF CHLORIDE CURRENTS RECORDED FROM DISSOCIATED RAT TASTE CELLS. Xiao-Dong Sun* and M. Scott Herness, Indiana University School of Medicine, Muncie, IND. 47306.

We have characterized previously unidentified chloride currents from rat taste receptor cells using circumvallate and foliate papillae dissociated with papain using the patch clamp technique in the whole cell configuration. Chloride currents were identified as outward currents under conditions of 159 mM [Cl⁻]ext and 34 mM [Cl⁻]int by pharmacological isolation with 500 μM DIDS or 100 μM Niflumic acid. Currents reversed close to the expected Nernst potential and were on the order of a few hundred picoamperes in magnitude, increasing with more positive step potentials. When external chloride was lowered by isethionate or gluconate substitution, currents were reduced and the reversal potential shifted accordingly. Further isolation of these currents by blocking potassium currents with a combination of TEA and 4AP provided similar results. Chloride currents were additionally recorded as inward tail currents that appeared as inwardly rectifying at membrane potentials negative to the predicted chloride reversal potential. They were sensitive to both 500 μM DIDS and to 100 μM Niflumic acid as well as lowering external chloride concentration by ion substitution. Moreover they exhibited an inactivation that had temporal and voltage dependent components to it.

RESPONSES OF MUDPUPPY TASTE RECEPTOR CELLS TO DENATONIUM. T. Ogura, A. Mackay-Sim[1] and S. C. Kinnamon*, Dept. Anatomy and Neurobiology, Colorado State Univ., Fort. Collins, CO 80523, the Rocky Mountain Taste and Smell Center, Univ. of Colorado Health Science Center, Denver, CO 80262 and [1] Faculty of Science and Technology, Griffith Univ., Brisbane, QLD 4111, Australia.

Denatonium (DN) is a potent bitter substance. Responses of isolated mudpuppy taste receptor cells to DN benzoate were studied by Ca^{2+} imaging with fura-2 and whole-cell recording. We identified receptor cells by staining the apical surface with FITC-WGA prior to isolation. In 87% of receptor cells, DN (5 mM) increased $[Ca^{2+}]i$ by 56.8 ± 8.8% from a resting level of 75.5 ± 2.8 nM (n = 26). The response always began in the apical tip of the receptor cell, even though the DN was applied to the entire cell. The response to DN was present in a Ca^{2+}-free external solution, but was reduced in magnitude by approximately 75%. Thapsigargin (1 μM), a Ca^{2+}/ATPase inhibitor, induced responses of similar magnitude to DN and inhibited subsequent responses to DN. Ryanodine (10 μM) had no direct effect on $[Ca^{2+}]i$ and failed to block the DN responses. These results suggest that DN increased $[Ca^{2+}]i$ mainly from thapsigargin-sensitive, ryanodine-insensitive Ca^{2+} stores in the majority of taste cells. A small subset of DN-sensitive cells also responded to caffeine (20 mM), suggesting that caffeine-sensitive Ca^{2+} stores may also contribute to bitter transduction in some taste cells Whole-cell recording showed that DN potentiated outward currents in most taste receptor cells. In some receptor cells and in all non-receptor cells, DN either blocked, or had no effect on, outward currents. Pharmacological experiments indicated that the DN-increased outward currents were carried by K^+ and Cl^- ions. Taken together, these data suggest that DN increases $[Ca^{2+}]i$, which subsequently activates Ca^{2+}-dependent K^+ and Cl^- currents in taste receptor cells.

VERTEBRATE TASTE RECEPTOR CELLS HAVE NOVEL CATIONIC CHANNELS ACTIVATED BY QUININE. Takashi Tsunenari[1], Yukako Hayashi*[1], Manabu Orita[1], Takashi Kurahashi[2], Akimichi Kaneko[3] and Tomohiko Mori[1]. [1] Res. Ins. for Food Science, Kyoto Univ., Uji, Kyoto 611, Japan. [2] The National Ins. for physiological Sciences, Myodaiji, Okazaki 444, Japan. [3] Dep. of Physiology, Keio Univ. Sch. of Med., Shinjuku, Tokyo 160, Japan.

Quinine is known to be a bitter substance for various vertebrates. Whole-cell recordings under voltage-clamp were made from isolated taste receptor cells of bullfrog (*Rana catesbeiana*) while quinine hydrochloride was applied through a puffer pipette. Quinine stimulation elicited an inward current at the resting potential. When the blocking effect of quinine on K^+ currents was eliminated by Cs^+ pipette, the current-voltage relation was linear (the reversal potential; +16mV) and showed a clear increase in membrane conductance by quinine stimulation. The quinine-activated conductance was cation selective. The relative permeability ratio was $P_{Na} : P_{Cs} : P_K = 1 : 0.42 : 0.5$. The quinine-activated cationic conducting channel was suppressed by Ca^{2+}, sharing a common feature with quinine responses *in situ*. We therefore conclude that this novel cationic channel plays a crucial role in the bitter perception. Bitter-induced depolarization in taste cells has been explained by a blocking effect on K^+ channels. It, however, seems likely that taste receptor cells have, at least, two independent pathways for the detection of a bitter substance.

651.4

SODIUM SELF-INHIBITION IN AMILORIDE-SENSITIVE SODIUM CHANNELS: IMPLICATIONS FOR SALT TASTE TRANSDUCTION Timothy A. Gilbertson* and Huai Zhang. Pennington Biomedical Research Center, Louisiana State University, Baton Rouge LA 70808.

The role of amiloride-sensitive sodium channels (ASSCs) in salt taste transduction has been well-established. Recent experiments in fungiform taste buds have revealed that sodium transport into taste receptor cells (TRCs) is saturable, highly selective, regulated by hormones and inhibitable by amiloride and a number of its analogs. Thus, ASSCs in fungiform TRCs apparently respond to the same regulatory cues which govern their function in other transporting epithelia. In the present study, we are investigating the regulation of ASSCs in rat TRCs by extracellular sodium ions using patch-clamp and transepithelial current recording techniques. In isolated fungiform TRCs which contain ASSCs, we have recorded the current through ASSCs in response to voltage ramps using the perforated patch recording configuration while varying extracellular sodium concentrations. In most cells, currents through ASSCs are larger in 35 mM NaCl than in 70 mM NaCl, consistent with an inhibitory effect of extracellular sodium. This process, termed sodium self-inhibition, takes on the order of seconds to develop. Isolated TRCs which lack ASSCs do not demonstrate the sodium self-inhibition phenomenon. In both isolated TRCs and intact lingual epithelia, the sulfhydryl reagent, *p*-hydroxymercuribenzoate (*p*-HMB; 200 μM), removes inhibition by extracellular sodium, effectively increasing sodium currents. The effect of *p*-HMB is partially reversible by treatment with cysteine (10 mM). These results, taken together with the fact that in rats salivary sodium concentrations are ~60 mM, would imply that sodium self-inhibition may be an important regulatory process in fungiform TRCs and, hence, in the transduction of salty taste stimuli.

651.5

ELECTROPHYSIOLOGICAL ACTIONS OF QUININE ON DISSOCIATED RAT TASTE RECEPTOR CELLS. Yushe Chen* and M. Scott Herness, Indiana University School of Medicine, Muncie, IND. 47306.

The electrophysiological actions of quinine, a classic bitter stimulus, were studied on dissociated rat taste receptor cells from foliate and circumvallate papillae using patch-clamp techniques in the whole cell recording configuration. Its most profound action was a dramatic inhibition of outward potassium currents. Inhibitions could be measured from 10^{-6} to 10^{-3} M, a concentration range that coincides well with behavioral observations in rats. At the higher range inhibition of potassium currents was both complete and reversible (97% inhibition at 10^{-4} M). At lower concentrations inhibition was more profound on the sustained portions of the current, leaving a transient voltage-dependent current. This may suggest a site of action on delayed rectifiers. Input membrane resistance, on the order of 10 GΩ was increased by quinine by 10 - 20%. We tested for the presence of a quinine-induced current but none could be measured. Actions on sodium and calcium currents could also be measured. Quinine inhibited sodium current by 20 - 30% but increased calcium currents (measured with barium as a current carrier). Under current clamp conditions, some broadening of the action potential was noted in the presence of quinine. The action potential amplitude was decreased but the threshold was not changed.

RESPONSES TO GLUTAMATE IN ISOLATED RAT TASTE CELLS. A. Bigiani, R. J. Delay, N. Chaudhari, S. C. Kinnamon and S. D. Roper.* Rocky Mt. Taste & Smell Center, Denver, CO 80262, and Dipt. Scienze Biomediche, Università di Modena, 41100 Modena, Italy.

Glutamate is an important taste stimulus for humans and animals alike. A metabotropic glutamate receptor, mGluR4, is selectively expressed in rat taste buds and may be responsible, in part, for transducing glutamate taste (Chaudhari, *et al.* '94). Yet, the mechanism of chemosensory transduction for glutamate is still unknown. We have recorded responses from single cells in isolated rat taste buds, using perforated patches. 20 mM L-glutamate was dissolved in a modified Tyrode solution (maintaining iso-osmotic solutions), and bath-applied to taste cells. Applying glutamate reduced the inward holding current at -80 mV by 5.3 ± 2.9 pA, (mean ± SD; n=3). The glutamate response decreased upon depolarization, with an apparent reversal potential of -11 ± 3 mV (n=2), close to the equilibrium potential for Cl^- (-15 mV). An increase in cell input resistance was observed during the glutamate response (4.7 → 10.1 GΩ, n=1). Glutamate had no effects on voltage-gated inward Na^+ and outward K^+ currents. Applying 0.85 mM L-AP4, a selective agonist for mGluR4, mimicked the effects of glutamate. However, at this concentration, the responses were much smaller. These data suggest that the activation of mGluR4 and the consequent modulation of a Cl conductance may be key events in taste transduction for glutamate.

CHARACTERIZATION OF BITTER RECEPTORS THAT ACTIVATE α-GUSTDUCIN AND TRANSDUCIN IN TASTE MEMBRANES. L. Ruiz-Avila* and R.F. Margolskee,Roche Institute of Molecular Biology, 340 Kingsland Street, Nutley, NJ 07110.

Bitter and sweet tastes are believed to be transduced through heterotrimeric G proteins, which couple taste cell membrane receptors to intracellular effector enzymes. The taste receptors have not yet been functionally characterized nor molecularly cloned. Taste cells preferentially express a few G protein alpha subunits; notably transducin and gustducin (which is absolutely taste specific). These two proteins are closely related at the amino acid level, and have been shown to activate a taste-specific phosphodiesterase (Ruiz-Avila et al. 1995), thereby regulating the concentration of cyclic nucleotides inside the taste cells and consequently modifying the activity of taste cell cyclic nucleotide-regulated channels (Kolesnikov and Margolskee, 1995). We have reconstituted a taste responsive system using bovine or murine circumvallate papillae membrane preparations and purified bovine rod transducin or recombinant gustducin as exogenously added reporters. Both transducin and gustducin are specifically activated by receptors present in taste membranes and this activation is enhanced by the bitter compound denatonium (100 μM to 10 mM). Transducin/gustducin activation by denatonium-responsive receptors can be competitively inhibited with a peptide derived from the receptor interaction domain of transducin. The denatonium receptor-G protein interaction also requires βγ subunits. Mutations in the C-terminus of gustducin affect its interaction with rhodopsin and modify its interaction with the denatonium responsive taste receptor. L. R-A is a Fulbright scholar from the Spanish MEC-Fulbright postdoctoral program.

MULTIVARIATE CLASSIFICATION OF RAT TASTE RECEPTOR CELLS BASED ON ULTRASTRUCTURAL MEASURES OF NUCLEAR MORPHOLOGY. D. W. Pumplin, C. Yu, A. Z. Murphy*, and D. V. Smith, Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1559.

Mammalian taste receptor cells are organized within taste buds on the tongue and other oral, pharyngeal, and laryngeal epithelia. These cells have been classified into light, dark, or intermediate cells on the basis of several ultrastructural criteria. Light cells are said to have large, round or ovoid, smooth nuclei with little heterochromatin and a relatively electron-lucent cytoplasm. Dark cells are characterized as having elongated, invaginated, heterochromatic nuclei and electron-dense cytoplasm. Intermediate cells lie between these extremes. Both the occurrence of large numbers of intermediate cells and the dependence of the light/dark categorization on the parameters of fixation suggest that such a classification may be somewhat arbitrary. Rats were perfused with 1% paraformaldehyde/2.5% glutaraldehyde in 0.05 M sodium cacodylate buffer; tongues were removed, and semi-serial thin sections were cut transverse to the longitudinal axis of the vallate taste buds. To develop objective criteria for cell classification, the nuclear morphology of 95 cells was quantified with several measures that are purported to correlate with the light/dark cell classification (nuclear area, eccentricity, irregularity, and heterochromaticity). These measures discriminated well among taste cells. The resulting matrix of measurements was analyzed with both hierarchical cluster analysis (SPSS CLUSTER) and multidimensional scaling (SPSS ALSCAL). The multivariate distributions of the cell nuclei were continuous, suggesting that the light/dark cell dichotomy may represent points along a continuum of morphological types.

AMILORIDE TREATMENT ELIMINATES THE SOURNESS BUT NOT THE SALTINESS OF SODIUM CHLORIDE AND LITHIUM CHLORIDE. C. A. Ossebaard, K. J. Ciombor, and D. V. Smith*. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1559.

Taste receptor transduction of Na^+ salts has been shown in many species to be largely mediated by amiloride-sensitive ion channels on the apical receptor membrane. The residual response to these salts is mediated by a paracellular pathway that is insensitive to amiloride. These biophysical and additional electrophysiological data in rodents have led to the speculation that saltiness arises from this amiloride-sensitive component. We have previously shown that in humans the taste of NaCl is less suppressed by amiloride than the taste of Na-gluconate, which is consistent with the effects of amiloride in the rat. However, amiloride affects only the sour side taste of these salts and produces no effect on their saltiness. This suggests a correlation between stimulation of the apical ion channels and the sourness of Na^+ salts. These apical ion channels have been shown to be more permeable to Li^+ than to Na^+; LiCl also has a larger sour component than NaCl. Therefore, we hypothesized that the taste of LiCl would be more greatly suppressed by amiloride than the taste of NaCl. Human subjects estimated the taste intensity and qualities of several concentrations of NaCl, LiCl, and KCl. Amiloride suppressed the sourness of LiCl more than that of NaCl; there was no effect on the taste of KCl. Estimates of the saltiness of these stimuli were unaffected by amiloride treatment. We propose that Na^+ and Li^+ stimulation of amiloride-sensitive ion channels elicits a sour taste; saltiness may arise via the paracellular pathway.

CHORDA TYMPANI SINGLE-UNIT STUDIES ADDRESSING TASTE CODING OF SODIUM SALTS AND SWEETENERS IN HAMSTERS. B.K Formaker, B.I. MacKinnon, T.P. Hettinger and M.E. Frank*. BioStructure & Function, University of Connecticut Health Ctr., Farmington CT 06030.

We are recording responses of single units in the *chorda tympani* (CT) nerve of golden hamsters (*Mesocricetus auratus*). Stimuli include sodium salts, sweeteners, the saccharide mixture: Polycose, deionized Polycose, and the binary mixture of sucrose plus quinine.HCl (QHCl). Our response measure is the total number of spikes during the initial 5 s of response minus the average spontaneous rate for the unit. Preliminary results show that all tested 0.1 M sodium salts are effective for NaCl-best units. They have the following relative effects: NaCl = NaBr > sodium acetate = sodium benzoate > sodium gluconate. This result demonstrates an effect of anion size on sodium salt transduction in NaCl-best units (Rehnberg *et al.*, 1993). Also, the reliable effect of 10% Polycose on NaCl-best units is eliminated by deionization, indicating that much of the CT response to Polycose is due to its ionic contaminants. The sweeteners 0.04 M sucrose, 0.4 M fructose, and 0.1 M glycine, tested at EC50 concentrations for whole nerve responses (Myers *et al.*, 1993), are all effective stimuli for sucrose-best units. Consistent with the weak behavioral generalization between sucrose and Polycose, deionized Polycose has a very small effect on sucrose-best units. Finally, 0.05 M sucrose is more effective stimulus than sucrose mixed with 0.03 M QHCl for sucrose-best units. This is consistent with the suppression of whole-nerve responses to sucrose by QHCl (Formaker & Frank, 1995). [Supported by NIH R01 DC00058]

EMERGENCE OF AFFERENT FIBER TERMINAL FIELD ALTERATIONS IN SODIUM RESTRICTED RATS.
B.R. Walker* and D.L. Hill, University of Virginia, Charlottesville, Va 22903

Previous work from our lab has shown that dietary sodium restriction instituted early in prenatal development produces anatomical and functional changes in the developing gustatory system. In particular, neurophysiological recordings from the chorda tympani nerve (CT) demonstrate that whole nerve responses to NaCl are reduced in restricted rats while responses to non-salt stimuli are unaffected. Furthermore, early sodium restriction causes a rearrangement of the CT terminal fields within the nucleus of the solitary tract (NTS) in restricted rats, while glossopharyngeal (IX) terminal fields remain similar to controls. Developmental sodium restriction also produces postsynaptic changes in the NTS. For example, neurophysiological NTS recordings of restricted rats repleted with sodium show hyper-responsive activity to only sodium salts, while Golgi techniques have revealed dendritic alterations of the presumptive projection neurons from the NTS.

To examine the developmental time course of the alterations seen in the NTS in response to the NaCl restriction paradigm, the chorda tympani nerve was labelled in a developmental series with a 3KD biotinylated dextran amine neuronal tracer just peripheral to the geniculate ganglion in sodium restricted and control rats. Results show that the alterations begin at early postnatal time points, and continue through until adulthood. These results suggest that developmental dietary sodium restriction could alter the pathway which the afferent fibers follow to their target.

MULTIVARIATE ANALYSES REVEAL POTENTIAL RELATIONSHPS BETWEEN THE STRUCTURE AND FUNCTION OF GUSTATORY NEURONS. W.E. Renehan*, Z. Jin, X. Zhang and L. Schweitzer Henry Ford Hospital, Detroit, MI 48202 and Univ. Louisville Sch. Medicine, Louisville, KY 40292.

We have recently shown that a neuron's most effective stimulus ("best response") is a relatively poor predictor of neuronal morphology. The present investigation was conducted to test the hypothesis that individual "best response" groups may be comprised of physiologically-distinct neuronal subsets that do exhibit unique morphologies. Glass micropipettes filled with 2.0% Neurobiotin were used to test the response of NST neurons to 0.1M NaCl (N), 0.01N HCl (H), 0.01M quinine (Q) and 1.0 M sucrose (S). Seventy-one neurons that responded to one or more tastants were injected with Neurobiotin and reconstructed in three dimensions using the Eutectic Neuron Tracing System. Each response was corrected for spontaneous activity and the Pearson correlation coefficients of all possible stimulus-response pairs were calculated. These coefficients were used to perform a cluster analysis (SPSS) and the results of the cluster analysis were used to define physiological subsets. Analyses of variance were then performed to investigate relationships between morphologic features and physiological response properties. We were able to identify a number of trends that appear to deserve further examination with a larger data set. There was a trend ($F=2.2$, d.f.=4,61; $p=0.08$) between mediolateral extent and response category, with a subset of the neurons that responded best to NaCl (N>H>S or Q) more widespread than the S-best or Q-best neurons. This N-best subset was also more broadly tuned than all other groups ($F=4.2$, d.f.=4,61; $p<0.01$) except the Q-best neurons and there was a trend ($F=1.9$, d.f.=4,61; $p=0.12$) that indicated that this group had a larger soma-dendritic receptive field (in the coronal plane) than all other groups. These data indicate that physiologically-defined subsets of the traditional N-, H-, Q- and S- 'best' categories may provide important insights into structure-function relationships in the NST.

MORPHOLOGICAL AND FUNCTIONAL PROPERTIES OF ACUTELY ISOLATED NEURONS FROM THE GUSTATORY NUCLEUS OF THE SOLITARY TRACT. R.M. Bradley* and J Du. Dept. Biologic and Materials Sciences, Sch. of Dentistry, Univ. of Michigan, Ann Arbor, MI 48109-1078.

To study the functional properties of identified neurons in the rostral (gustatory) nucleus of the solitary tract (rNST), we have acutely isolated the cells so that direct comparisons can be made between structure and biophysical properties of the neurons. Neurons were isolated from 300 μm thick horizontal brainstem slices from rats aged 6-20 days. The rNST was dissected from the slices, placed in HEPES buffer containing 0.5% protease type 23 and then triturated with a series of different diameter, fire-polished Pasteur pipettes. The dissociated neurons were then placed on a poly-L-lysine coated coverslip in a plastic petri dish and superfused with oxygenated saline. Viewed with an inverted microscope, elongate, multipolar and ovoid neurons could easily be distinguished. These same neuron morphologies have been described in rNST by us and other investigators using a variety of morphological techniques. We recorded from the neurons using the whole cell configuration of the patch clamp technique. The isolated neurons had mean resting membrane potentials of -69 ± 14 mV, a mean input resistance of 308 ± 66 MΩ and overshooting action potentials. When depolarized the neurons either fired a regular train of action potentials or a short burst of action potentials that then accomodated. For some neurons the initiation of the regular train of action potentials was delayed by a brief membrane hyperpolarization. These intrinsic properties are similar to those we have previously reported in whole cell recordings from rNST neurons in brain slices (J.Neurophysiol. 67:1659, 1992). This study shows that neurons acutely isolated from the rNST maintain both their morphological and biophysical properties. (Supported by NIDCD grant DC00288 to R.M.B.)

CLASSIFICATION OF TERMINALS THAT CONTACT DENDRITIC SWELLINGS ON GUSTATORY NEURONS IN THE NUCLEUS OF THE SOLITARY TRACT (NST). L. Schweitzer, Z. Jin*, T. Cecil, B.M. Wetherton and W.E. Renehan. Univ. of Louisville Sch. Med., Louisville, KY 40292 and Henry Ford Hospital, Detroit, MI 48202.

We have recently established that there are eight morphologically-defined gustatory cells types in the NST. Cells in one of these cell types have small somata (<125 μm^2) and a high density of dendritic swellings (>.05/μm). To investigate the ultrastructural characteristics of terminals that contact the dendritic swellings, cells of this type were processed for electron microscopy. These cells were tested for their responses to an array of tastants, filled with Neurobiotin, reacted with DAB and flat embedded in resin. We were able to verify that dendritic swellings receive synapses. These terminals are of the "primary-like", "SP" and "MP" (small and medium pleomorphic) types as defined by Whitehead (JCN, 332, 1993). We have classified the responses of these cells. A disproportionate number of them are NH4Cl-best and HCl-best. One cell of this type only responded to two (HCl and NH4Cl) of the eight tastants and was NH4Cl-best. This cell receives terminals onto dendritic swellings and the terminals contacting the swellings have rounded or pleomorphic vesicles. We have verified that synapses of all morphological types defined by Whitehead are found in the area in which our gustatory cells are labelled, yet several synaptic types do not appear to contact dendritic swellings.

FOREBRAIN PROJECTIONS TO THE ROSTRAL NUCLEUS OF THE SOLITARY TRACT IN THE HAMSTER. M.C. Whitehead*, A. Bergula and K. Holliday. UCSD, La Jolla, CA 92093

The nucleus of the solitary tract (NST) is the first central site of taste information processing. Specific subdivisions of the NST receive taste afferent input and contain interneurons and projection neurons that engage ascending or premotor taste pathways. The forebrain projects to the NST and can influence taste responses, but the anatomical relationship between forebrain inputs, primary inputs and NST cell types is not understood. To evaluate this cholera toxin B (CTb) was injected into the rostral NST to retrogradely label the sources of forebrain inputs. Cells were labelled bilaterally in the hypothalamus, bed nucleus of the stria terminalis, amygdala, and insular (gustatory) cortex. Injections of Ctb into gustatory cortex, the site of most forebrain-NST cells, labelled axon endings confined to the rostral NST. These endings were concentrated in the rostral central and ventral subdivisions. In the rostral central subdivision corticofugal endings are positioned influence microcircuits that include taste afferent synapses, synapses of presumed inhibitory interneurons, and neurons that project to the parabrachial nucleus. In the ventral subdivision corticofugal endings synapse among premotor neurons that ultimately influence salivatory and oromotor outflow.

EXPRESSION OF c-FOS IN THE RAT .PARABRACHIAL NUCLEUS FOLLOWING INGESTION OF MONOSODIUM GLUTAMATE AND OTHER TASTANT STIMULI. S. M. Royer*[1,2], J. C. Kinnamon[1] and S. D. Roper[2]. [1]Dept. of Biological Sciences, Univ. of Denver, Denver, CO 80208 and [2]Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523.

In rodents, the pontine parabrachial nucleus (PBN) includes the second order gustatory relay in the CNS. In order to compare the localization of PBN responses to monosodium glutamate (MSG) with that of responses to other taste stimuli, we used immunocytochemistry to detect Fos protein expression in PBN neurons following ingestion of tastants. Adult rats were water-deprived and trained to drink during a one-hour period each day. On the experimental day, rats were given either distilled water or a tastant solution during the drinking period. Brains were subsequently fixed by perfusion and the pontine regions sectioned at 50μm on a Vibratome. Fos-like immunoreactivity (Fos-ir) was visualized using a rabbit polyclonal antibody (Santa Cruz Biotechnology, 1:6000). Although sparse Fos-ir appeared throughout the PBN, the location of the greatest concentration of Fos-ir cells occurred in different PBN subnuclei, depending upon the tastant solution ingested. In animals that received distilled water, a distinct cluster of Fos-ir neurons appeared in the dorsal subnucleus (dls) of the lateral PBN. Fos-ir was similarly localized following ingestion of 500mM sucrose. Rats that were given 3mM quinine HCl showed the greatest Fos-ir in the ventral region of the external lateral subnucleus (els) and the external medial subnucleus (ems). In animals that received 500mM MSG plus 30μm amiloride, Fos-ir was concentrated in the els in an area more dorsal than that observed in animals receiving quinine HCl. The region of greatest Fos-ir in response to 500mM MSG appeared to correspond to the zone in which Fos-ir has been observed following intraperitoneal injection of LiCl (Yamamoto et al., NeuroReport 3:1049, 1992).

CENTRAL CONSEQUENCES OF GUSTATORY AXOTOMY IN THE RAT: TIME COURSE OF TRANSGANGLIONIC DEGENERATION. M. B. Vogt*, C. Yu, and D. V. Smith. Department of Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201-1559.

Numerous studies have documented the peripheral gustatory system's remarkable capacity for anatomical regeneration and functional recovery following gustatory nerve lesions. However, little is known of the central consequences of gustatory nerve damage. We examined the time course of transganglionic degeneration in the rostral portion of the nucleus of the solitary tract (NST) following combined lesions of the chorda tympani and glossopharyngeal nerves, which innervate taste buds on the anterior and posterior tongue, respectively. In 12 rats a 2-5 mm section of nerve was excised on the right side, distal to the ganglion, from both the lingual-tonsillar branch of the glossopharyngeal nerve and the chorda tympani nerve; animals then survived for 2, 7, 12, 17 or 22 days. Controls included the intact contralateral side in each experimental rat and 3 additional rats that underwent sham surgeries. Brains were sectioned at 40 μm and processed simultaneously with the amino-cupric silver degeneration method. Degenerating fibers were observed ipsilaterally, consistent with the demonstrated projections of these nerves into the rostral NST. Sham-operated and 2-day survival rats showed little or no degeneration. By 7 days there was considerable degeneration which continued to increase through 22 days. Thus peripheral taste nerve section results in transganglionic degeneration which may alter synaptic organization in the NST and provide the opportunity for plasticity during regeneration.

DOPAMINE INHIBITION OF NUCLEUS ACCUMBENS CELL ACTIVITY OCCURS VIA TWO INDEPENDENT MECHANISMS: EVIDENCE FROM *IN VIVO* AND *IN VITRO* INTRACELLULAR RECORDINGS. A.A. Grace* and P. O'Donnell. *Depts. Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.*

The excitatory or inhibitory nature of dopamine (DA) receptor activation has been a topic of controversy for years. This study analyzes the effects of DA-related drugs on indices of cell excitability *in vitro*, and on the pattern of spontaneous firing observed *in vivo*. Forty-five cells were recorded from slices containing the nucleus accumbens. Perfusion with the D1/D2 agonist apomorphine (10-150 μM) caused the membrane to depolarize from -68.8 ± 8.3 mV to -57.3 ± 10.5 mV without concurrent changes in input resistance or the time constant. The amplitude of current injection required to trigger spike firing was increased from 0.28 ± 0.18 nA to 0.49 ± 0.32 nA ($p<0.005$) following apomorphine, and the membrane potential at which the cells fired was shifted from -44.2 ± 8.2 mV to -33.6 ± 13.1 mV ($p<0.0001$). This decrease in excitability was also obtained with the combined perfusion with a D1 agonist (SKF38393; 3 μM) and a D2 agonist (quinpirole, 10 μM), but not by administration of either drug alone.

Intracellular recordings were made *in vivo* from 2 accumbens cells that exhibited a bistable membrane potential. Systemic administration of a combination of SKF38393 (10 mg/kg, i.v.) and quinpirole (10 mg/kg i.v.) reduced the frequency at which the membrane switched to the depolarized, active state from 1 Hz to 0.5 Hz in both cells tested. Since we have previously shown that responses to prefrontal cortical inputs can be elicited only during the depolarized state (J.Neurosci,1995,15:3622-3639), a decrease in the frequency of depolarizing periods would result in a functional blockade of cortical throughput in the nucleus accumbens. Furthermore, both *in vivo* and *in vitro* actions appear to be mediated by coactivation of D1 and D2 receptors. Thus, despite the DA-mediated depolarization of accumbens cell membranes, the combined effects of a decrease in cell excitability and the reduction in transitions to the depolarized state would independently produce an inhibitory influence on nucleus accumbens neuron activity. THE VENTRAL PALLIDUM → ACCUMBENS FEEDBACK PATHWAY: ANATOMICAL AND ELECTROPHYSIOLOGICAL STUDIES.

M. Wu, A. W. Hrycyshyn S. M. Brudzynski*. Dept. of Physiology and Dept. of Anatomy, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Earlier evidence has suggested that a feedback loop may exist from the nucleus accumbens to the ventral pallidum (VP), to the ventral tegmental area (VTA), and back to the nucleus accumbens. Recent anatomical studies have also shown that a reciprocal projection between VP and the accumbens exists. In the present study, anatomical and electrophysiological techniques were used to investigate the functional organization of these feedback loops.

The anterograde tracer dextran conjugated rhodamine was injected into the VP of rats. Labelled terminals were found in both the nucleus accumbens and the VTA. In standard extracellular recording studies, electrical stimulation of the VP evoked mostly inhibitory responses of the accumbens and VTA neurons. 75% of the responded neurons had a latency of less than 10 ms. Furthermore, the injection of the glutamate into the VP not only altered the firing pattern of the accumbens neurons but also attenuated the excitatory responses of these neurons elicited by electrical stimulation of the hippocampus.

Since the feedback loop of VP→VTA→accumbens would likely take a longer time to complete than the more direct loop of VP→accumbens, the results from present study suggest that a direct VP→accumbens pathway may influence the limbic input to the nucleus accumbens. (Supported by MRC of Canada)

IMPAIRED ACQUISITION OF INTRACRANIAL SELF-STIMULATION IN RATS WITH BILATERAL KAINIC ACID-INDUCED LESIONS OF NUCLEUS ACCUMBENS SEPTI. A.Yu.Bespalov* and E.E.Zvartau. Dept. of Pharmacology, Pavlov Med. Univ., St.-Petersburg 197089, Russia.

Excitotoxic lesions of nucleus accumbens septi (NAS) were previously shown to have a delayed effect on the intracranial self-stimulation (ICSS) responding in rats. The present study addressed the ability of kainic acid-induced lesions of NAS to affect acquisition of ICSS. Male Wistar rats were implanted with a unilateral bipolar electrode into the ventral tegmental area and bilateral cannulas were implanted into the NAS. Seven days postoperatively two groups of animals - lesioned and sham-lesioned - were trained to respond for the response contingent electrical stimulation (continuous reinforcement schedule). Fourteen 28-min training sessions were performed once a day by an experimenter blind to the grouping factor. Percent of animals responding for electrical stimulation by the end of the training period were calculated after histological verification of cannula/electrode placement and evaluation of the size of lesions. The kainic acid-induced damage was generally restricted to the NAS and minor damage to caudatus-putamen was consistently present. Only 2 out of 10 kainic acid-lesioned animals responded more than 200 times a session by the last training session, whereas 5 out 6 control sham-lesioned successfully acquired the SS responding ($p<0.05$, chi-square test). These data suggest that NAS is necessary for the acquisition of ICSS. (Supported in part by grant NWO 07-13-087 of Dutch Medical Council).

REGULATION OF PREPULSE INHIBITION IN THE RAT BY VENTRAL PALLIDAL PROJECTIONS. M.H. Kodsi*, N. Taaid, H.I. Hartston, D. Zisook, F.I. Wan, N.R. Swerdlow. UCSD Dept. Neurosci., La Jolla, CA 92093.

Prepulse inhibition (PPI) of the acoustic startle reflex is the reduction of startle amplitude by weak prestimuli delivered 30-500 msec prior to the startling stimulus. Since PPI is significantly reduced in specific neuropsychiatric disorders, studies have attempted to elucidate the neural substrates that regulate PPI. Previous observations have shown that PPI is regulated by GABAergic projections from the ventral striatum to the ventral pallidum (VP). The GABA-A antagonist picrotoxin activates VP neurons and dose-dependently reduces PPI. In order to determine which VP projections carry modulatory signals to the primary startle circuit, we measured PPI after quinolinic acid lesions of the subthalamic nucleus (STN), mediodorsal thalamus (MD), and pedunculopontine tegmental nucleus (PPTg). We also determined the effects of these lesions on apomorphine reduction of PPI and on amphetamine-stimulated locomotion. Since VP efferents include GABAergic fibers, we also measured PPI after infusion of the GABA-A agonist, muscimol, into relevant VP targets. Of the three excitotoxic lesion sites, only PPTg damage significantly reduced PPI, and only STN lesions significantly disrupted amphetamine-stimulated locomotion. Apomorphine-induced reduction of PPI was not significantly altered by any of the lesions. Muscimol infusion into the PPTg dose-dependently reduced PPI. PPI thus appears to be regulated by ventral pallidal projections to the PPTg, but not to the STN or to the MD. Furthermore, activation of PPTg GABA-A receptors mimics the PPI disruption that follows activation of the VP. These findings collectively support the notion that PPI is regulated by a GABAergic projection from the VP to the PPTg.

652.5

CORTICO-STRIATAL SUBSTRATES OF PREPULSE INHIBITION OF ACOUSTIC STARTLE IN THE RAT F.I. Wan*, M.H. Kodsi, S.B. Caine and N.R. Swerdlow. Depts. of Neuroscience and Psychiatry, Univ. of California San Diego, La Jolla, CA 92037-0804.

Inhibition of the acoustic startle reflex by a weak "prepulse" is an operational measure of sensorimotor gating that can be studied in both humans and rats. Since deficits in prepulse inhibition (PPI) are characteristic of several neuropsychiatric disorders including schizophrenia, it is of interest to elucidate the neural substrates underlying PPI. Importantly, recent studies using neuroimaging and neuropathological methods have identified abnormalities within limbic cortico-striatal circuitries in schizophrenia patients. In the present experiment, we examine limbic cortico-striatal substrates of PPI in the rat. Preliminary data shows that PPI is disrupted after infusion of the non-NMDA agonist AMPA into the nucleus accumbens (NAc) core and shell subregions. This effect of AMPA in the core can be blocked by systemic pretreatment with the D2 antagonist haloperidol (0.1mg/kg), whereas that of AMPA in the shell appears not to be blocked by haloperidol. Infusion of NMDA (0.8μg) into the ventral subiculum of the hippocampus significantly reduces PPI. This effect of NMDA on PPI is not prevented by the non-NMDA antagonist CNQX (2.5μg) infusion into the NAc core or shell subregion, or by systemic injection of haloperidol. PPI is reduced after infusion of either NMDA or the NMDA antagonist AP5 into the basolateral amygdala, but not after quinolinic acid (0.15M/0.3μl) lesions of the basolateral amygdala. We are now studying the potential contribution of the prefrontal cortex and its connection with the NAc to the modulation of PPI. Our results suggest that glutamatergic limbic cortico-ventral striatal circuitries play an important and complex role in the regulation of sensorimotor gating in the rat.

652.6

DOPAMINE RECEPTOR MODULATION OF WHOLE CELL SODIUM CURRENT IN ACUTELY DISSOCIATED RAT NUCLEUS ACCUMBENS NEURONS. X.-F. Zhang* and F. J. White Dept. Of Neuroscience, FUHS/ The Chicago Medical School, 3333 Green Bay Road, North Chicago, IL 60064-3095

The nucleus accumbens (NAc) is a ventral striatal region that serves as an interface between limbic and motor systems and thereby plays essential roles in motivational aspects of behavior. Therefore, NAc neurons and their dopaminergic (DA) innervation have become the subject of considerable interest and their physiological properties are currently being studied under a variety of conditions. In the present studies, we used intracellular current clamp and whole-cell voltage clamp techniques to investigate dopamine receptor-mediated modulation of TTX-sensitive sodium current (I_{Na}). In adult rat NAc slices, bath application of DA (25 μM, n=6) significantly hyperpolarized NAc neurons, increased the amount of intracellular current injection required to generate action potentials, increased the spike threshold and decreased spike amplitude. Similar results were observed in two neurons with application of the DA D_1 receptor-class agonist SKF 38393. For whole-cell recordings, NAc neurons from 1-4 weeks old rats were acutely dissociated. Only medium-sized neurons (6-12 μm) were used. Application of DA (10-25 μM) reduced peak I_{Na} (3/3). SKF 38393 (1-5 μM) also reduced peak I_{Na} (10/12), an effect that was completely blocked by the DA D_1-class receptor antagonist SCH 23390 (5 μM). The degree of inhibition produced by SKF 38393 was 6.5-30.8%. This agonist reduced peak I_{Na} without affecting the activation pattern. Instead, the steady-state inactivation curve was shifted about 5 mV in the negative direction. The DA D_2-class receptor agonist quinpirole (1-5 μM) exerted diverse effects on I_{Na}, in that two (of 8) neurons responded with increased current, whereas four responded with decreased I_{Na}. Both of the effects were completely blocked by DA D_2-class receptor antagonist eticlopride (5 μM). These results indicate that DA D_1 receptor activation reduces I_{Na}, results in hyperpolarization of NAc neurons and decreased excitability. The effects of DA D_2-class receptor activation appear more complex and variable, perhaps indicating multiple receptor involvement. (Supported by DA04093 and DA00207 to FJW).

CHOLECYSTOKININ-MEDIATED INCREASES IN AXONAL TERMINAL EXCITABILITY OF DOPAMINERGIC AFFERENTS TO ACCUMBENS. M. Garcia-Munoz*, P. Patino, S.J. Young and P.M. Groves. Department of Psychiatry, School of Medicine, University of California, San Diego. La Jolla, CA 92093-0603.

The nucleus accumbens (NA) receives afferents that contain both dopamine (DA) and cholecystokinin (CCK). It has been proposed that CCK can modify the release of DA by acting on presynaptic autoreceptors located on DA-CCK afferents. Electrical excitability testing of terminal axons was employed to study the consequences of increased impulse flow in DA-NA afferents on presynaptic effects of CCK in urethane anesthetized rats. Excitability was measured as the probability of antidromic firing of DA neurons after stimulation of NA. Throughout the experiment, the stimulus current was maintained at a constant value, determined during the baseline period, that elicited antidromic responses on approximately 50% of the stimulus presentations. To increase impulse activity, the medial forebrain bundle (MFB) was stimulated with three pulses at 20 Hz, 100ms prior to the NA test stimulus. This sequence was repeated at 1 Hz for 5 min. The increase in impulse activity resulted in an enhancement in terminal excitability. Intra-NA infusion of the CCK-A or CCK-B receptor antagonists devazepide (10nM) or L-365-260 (20nM), respectively, just prior to the MFB conditioning trains prevented the stimulus-induced increase in excitability. Instead, MFB stimulation produced a decrease in DA-NA afferent terminal excitability. This decrease in excitability was abolished by impairing DA transmission with α-methyl-*p*-tyrosine (250 mg/kg, i.p., 12 and 2 h before recording). We conclude that during higher rates of impulse activity, CCK released from DA-CCK containing afferents can stimulate presynaptic receptors to increase excitability and DA release.

DISTINCTIVE ROLES OF GLUTAMATE RECEPTOR SUBTYPES OF THE STRIATUM *IN MOVEMENT* SELECTION: A HYPOTHESIS FOR SERIAL ORGANIZATION. M. Pisa*. Dept. Biomed. Sci., McMaster Univ., Hamilton, Ont., Canada, L8N 3Z5.

In support of the hypothesis of distinctive motor roles of NMDA and AMPA receptors of the striatum, we previously reported that blockade of NMDA receptors of the ventrolateral striatum (VLS) of male Wistar rats by injections of CPP (1-10 nmole) significantly increased chewing in vacuo, a nonexternally directed oral movement, while decreasing grooming, an externally directed oral movement toward the animal's own fur. In contrast, blockade of AMPA receptors by injections of NBQX (1-10 nmole) into the VLS significantly reduced grooming, but did not increase chewing in vacuo. The trend for NBQX actually to reduce chewing in vacuo was not statistically significant, apparently owing to a floor effect, i.e. a low baseline level of chewing in vacuo in vehicle treated animals. The hypothesis that AMPA-receptor blockade depresses both directed and nondirected oral movements was tested by examining the motor effects of NBQX injections (1-10 nmole/0.5 μL) into the VLS against a background high level of chewing in vacuo induced by CPP injections (5 nmole/0.5 μL) into the VLS. Injections of CPP alone replicated the motor effects found previously. Co-injections of NBQX with CPP virtually abolished the high levels of chewing in vacuo induced by CPP alone. The co-injections also significantly reduced grooming relative to vehicle controls, but not compared with CPP alone, owing to a ceiling depressant effect of CPP on grooming. These results are consistent with the hypothesis that AMPA and NMDA receptors of the VLS play distinctive roles in the initiation of reaching and chewing components of appetitive-consummatory oral motor sequences. More specifically, I propose that co-activation of both receptor subtypes mediates the initiation of oral reaching, whereas hypoactivity specifically of NMDA receptors mediates the initiation of (transition to) chewing. *Hypoactivity of AMPA receptors suppresses all movements.* (Supported by NSERC. M. Pisa is a Research Associate of the Ontario Mental Health Foundation).

BASAL GANGLIA: NIGRA AND RELATED SYSTEMS

MODULATION OF SUBSTANTIA NIGRA DOPAMINE NEURON ACTIVITY BY MUSCARINIC ANTAGONIST ADMINISTRATION. C.L. Todd, W. Cameron* and A.A. Grace. Depts. of Neuroscience and Psychiatry, Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Benztropine (Benz) is a muscarinic antagonist that is used clinically to treat acute dystonia, an extrapyramidal side effect induced by antipsychotic drugs (APDs). Acute dystonia typically occurs within the first four days of treatment with APDs, and is more common when high-potency APDs (e.g. Haloperidol (HAL)) are used. Although the effects of APDs on the firing rate of substantia nigra (SN) DA cells have been well characterized, little data regarding the effects of Benz on these cells has been reported. Therefore, in this study we examined the effects of Benz on SN DA cell firing using *in vivo* extracellular single unit recordings from male Sprague-Dawley rats anesthetized with chloral hydrate, 400 mg/kg, i.p. Recordings of baseline activity were made from identified DA cells for at least five minutes prior to and following administration of each drug. In one group of animals, the effects of Benz administered alone was tested. Benz administered in a dose-response manner (initial dose 0.01 mg/kg i.v.) caused a significant dose-dependent decrease in mean firing rate in 4/5 cells tested. In this group, the mean cumulative dose of Benz required to cause a decrease in firing rate of 10% was 0.55 ± 0.30 mg/kg. In another group of rats, the effects of HAL pretreatment on the response to Benz was tested. Hal administration resulted in a significant increase in firing rate in 4/5 DA cells tested. Subsequent administration of Benz also caused a significant dose-dependent decrease in firing rate in 4/5 cells tested. The mean cumulative dose of Benz required to cause a 10% decrease in firing rate from that present after HAL was 0.06 ± 0.04 mg/kg. In a third group of rats, Benz was given in a single bolus dose of 15 mg/kg i.v., either with (n=2) or without (n=1) previous treatment with Hal (0.1 mg/kg i.v.). In all three cases, Benz caused a 100 % inhibition of firing. Therefore DA cells were found to be more sensitive to Benz-induced inhibition following HAL pretreatment. This interaction may account for the effects of Benz in treating neuroleptic-induced acute dystonia in humans. Supported by MH42217, MH01055, NS19608.

HIPPOCAMPAL ACTIVATION SUPPRESSES VTA DOPAMINE CELL FIRING. A POTENTIAL ROLE FOR HIPPOCAMPAL REGULATION OF PHASIC DA RELEASE. D.G. Harden* and A.A. Grace. Depts. Of Neuroscience and Psychiatry, Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Post-mortem studies of the brains of schizophrenics suggest that hippocampal damage may play an important role in the etiology of this disorder. Although several studies have examined the impact of hippocampal lesion on dopamine (DA) function in striatal targets, the influence of hippocampal activity on DA cell firing has not been reported. This study examines the effects of hippocampal activation on VTA DA cells recorded in rats. In one set of experiments, electrical stimulation consisting of single pulses with a duration of 0.5 msec and intensity ranging from 0.5-1.0 mA were delivered to the fornix. Activation of the fornix potently inhibited 27/31 (87%) of VTA DA cells tested. The mean onset latency of the inhibition was 33.0 ± 4.2 msec (1◡-90 msec) and the mean duration was 198.9 ± 28.3 msec (40-515 msec). To address the possibility that the observed suppression was due to inadvertent activation of non-hippocampal projections, direct stimulation of the CA1/subicular region was performed in a second set of experiments. Similar to fornix stimulation, direct activation of the hippocampus also resulted in inhibition of VTA DA cell firing in 15/32 (47%) of the neurons examined. The mean onset latency of the response was 44.7 ± 6.5 msec (10-95 msec) and the mean duration was 127.8 ± 49.5 msec (35-705 msec). Because there are no direct projections from the hippocampus to the DA cells of the VTA, the observed inhibition is likely to be mediated by polysynaptic pathways involving the nucleus accumbens or prefrontal cortex or both.

The finding that hippocampal activation suppresses DA cell firing, suggests that hippocampal damage reported to be present in schizophrenia could potentially disrupt subcortical DA systems by reducing an inhibitory influence at the level of the cell body. ACTIONS OF SEROTONIN ON SUBSTANTIA NIGRA PARS RETICULATA NEURONS IN VITRO. I.M. Stanford* and M.G. Lacey. Dept of Pharmacology, Univ. of Birmingham, Birmingham, B15 2TT. U.K.

The GABA containing neurons of the substantia nigra pars reticulata (SNr) constitute a major relay of basal ganglia output projecting to the thalamus, superior colliculus and brainstem. The SNr appears to have a role in controlling eye movement, promoting voluntary movement and has been implicated in the generation of seizure activity. SNr neurons receive inputs from GABA-containing pallidal and striatal neurons, glutamate-containing subthalamic nucleus neurons as well as a serotonin input from the dosal raphe. Whole-cell patch clamp recordings were made from SNr neurons from 300μm parasaggital slices of midbrain from rats 9-12 days of age. Individual neurons were visualized and recordings made using a Nomarski optical system (Zeiss Axioskop, x40 water immersion objective). SNr neurons were easily identified as they fired spontaneous action potentials at a fast rate (range 5-38Hz, mean 15.6 ± 7.9Hz, n=39), showed no evidence of I_h and were insensitive to quinpirole (10μM) and met-enkephalin (10μM), pharmacologically distinguishing them from dopamine cells and interneurons of the pars compacta. Serotonin (10μM) caused an inward current accompanied by an increase in membrane conductance (5/5 cells). The inward current or depolarization was insensitive to TTX (1μM, n=2) indicating a direct action on SNr neurons, possibly through action at a 5-HT_{2C} receptor (Rick & Lacey, B.J.Pharm. 112, 490P, 1994). Single shock stimulation of the descending inputs, in the presence of CNQX (10μM) and D-APV (50μM) elicited a picrotoxin sensitive IPSC which reversed around E_{Cl}. Serotonin (3-10μM) reduced this evoked IPSC (7/7 cells) whereas spontaneous GABA IPSCs (sIPSCs) were enhanced (3/3 cells). Evoked and sIPSCs were sensitive to TTX (1μM). The increase in frequency of sIPSCs may be a direct consequence of the SNr neuron depolarization and increased GABA release from axon collaterals, while depression of the evoked IPSC may be due to the presynaptic modulation by 5-HT receptors found on striato-nigral terminals.

INHIBITION BY METABOTROPIC GLUTAMATE RECEPTORS OF EXCITATORY SYNAPTIC INPUT TO RAT MIDBRAIN DOPAMINE NEURONS *IN VITRO*. M.A. Wigmore and M.G. Lacey*. Dept of Pharmacology, Univ. of Birmingham, B15 2TT. U.K.

Dopamine plays a critical role in the control of voluntary movement and is released within the basal ganglia from the terminals of dopamine-containing substantia nigra pars compacta (SNc) dopamine cells in the midbrain. One likely source of excitatory drive to the SNc is the glutamate-containing projection from the subthalamic nucleus (SThN). Descending synaptic input to SNc has been examined here using intracellular microelectrode recording from SNc neurones in 400 μm thick parasagittal slices of rat midbrain, maintained at 33-34°C and superfused with a standard medium. SNc dopamine neurons were recognised by pacemaker firing of action potentials at up to 6 Hz and a large I_h current on hyperpolarization under voltage clamp.

Synaptic potentials were evoked by stimulating a region 200-500 μm rostral to the substantia nigra using a focal bipolar stimulating electrode, while holding membrane potential at between -70 and -80 mV with constant hyperpolarizing current (10-30 pA). In the presence of picrotoxin (50 μM) to block $GABA_A$ receptors, the residual synaptic potentials (EPSPs) were blocked by CNQX and APV, indicating that they were glutamate mediated. The broad spectrum metabotropic glutamate receptor (mGluR) agonist 1-aminocyclopentane-1S,3R-dicarboxylate (1S,3R-ACPD; 30 μM) caused a reversible depression of 38 ± 4 % of this glutamate receptor- mediated EPSP (6/6 cells). A reversible membrane depolarisation of 3 - 10 mV was also observed. Both the depression of the EPSP and the depolarization caused by ACPD was reversed by the mGluR antagonist α-methyl-4-carboxyphenylglycine (MCPG; 500 μM; 3/3 cells).

These data suggest that excitatory afferents to dopamine cells possess mGluR receptors that act to reduce glutamate release from the terminals.

ELECTROPHYSIOLOGY OF ANTISENSE KNOCKOUT OF D_2 AND D_3 DOPAMINE RECEPTORS IN NIGROSTRIATAL DOPAMINE NEURONS. B.-C. Sun*, Ian Creese, and J.M. Tepper. Center for Molecular & Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

We have shown that infusion into substantia nigra of a 19-mer antisense (AS) oligodeoxynucleotide corresponding to codons 2-8 of the mRNA for the dopamine (DA) D_2 receptor for 6 days greatly attenuates apomorphine-induced inhibition of firing of nigral DA neurons (*Soc. Neurosci. Abstr. 20*:908, 1994).

Very similar effects were obtained following treatment with a D_3 receptor AS. Treatment with D_2 and D_3 AS appeared to be additive, suggesting a role for both D_2 and D_3 receptors in the inhibition of firing of DA neurons in response to DA agonists. Three days of AS infusion produced effects similar to those after 6 days, suggesting a relatively rapid rate of DA receptor turnover and transport. Only D_2 AS knockout increased spontaneous firing rates ($F=5.1$, $df=3,96$, $p<0.01$); Control (C): 3.4±0.3 spikes/s, D_2 AS: 4.7±0.5, D_3 AS: 3.3±0.3, D_2+D_3 AS: 2.7±0.4. Measurements of the proportion of striatal-evoked antidromic responses consisting of the full spike, an index of somatodendritic excitability, revealed a significant increase in full spike responses in all groups: C: 17.9±3.6%, D_2 AS: 41.1±7%, D_3 AS: 37.3±7.1%, D_2+D_3 AS: 45.0+9.1%. Terminal excitability as measured by antidromic threshold currents was increased following AS treatment ($F=2.9$, $df=3,60$, $p<0.05$); C: 1.7±0.3 mA, D_2 AS: 1.1±0.17 mA, D_3 AS: 1.0±0.2mA, D_2+D_3 AS: 0.9±0.2 mA.

These data suggest that functional D_2 and D_3 autoreceptors are present at the somatodendritic and terminal regions of nigrostriatal neurons. Differences in the effects of D_2 and D_3 AS knockout on spontaneous firing suggest that D_2 receptors may be preferentially located relatively close to the spike-generating region of the neuron while D_3 receptors may located more distally where they modulate local dendritic excitability without affecting overall firing rate. Supported by MH52383, and Rutgers grants from Hoechst-Celanese, and Johnson & Johnson.

DIFFERENTIAL GABA RECEPTOR MEDIATED INHIBITION OF SUBSTANTIA NIGRA DOPAMINERGIC NEURONS FROM NEOSTRIATUM AND GLOBUS PALLIDUS C. A. Paladini*, P. Celada, T. M. Tran, and J. M. Tepper. Center for Molecular and Behavioral Neuroscience, Rutgers, The State University of New Jersey, Newark, NJ USA 07102

Substantia nigra (SN) pars compacta dopaminergic (DA) neurons are inhibited by pars reticulata axon collaterals acting exclusively at $GABA_A$ receptors (Tepper et al., *J. Neurosci. 15*:3092-3103, 1995). The receptors mediating the inhibition of SN DA neurons from globus pallidus (GP) and striatum have been inferred to be $GABA_B$ and $GABA_A$ respectively, but this remains to be conclusively demonstrated.

Adult male Sprague-Dawley rats were anesthetized with urethane and bipolar stimulating electrodes were implanted in the anterior-lateral striatum and GP. Single unit responses following stimulation of striatum and GP (0.5 - 2.0 mA, 0.25 - 0.5 ms duration at 0.67 Hz) were recorded extracellularly in SN pars compacta and the effects of systemic application of the $GABA_A$ antagonist, bicuculline, (0.2 - 1.0 mg/kg i.v.), on evoked responses were examined. All responses were analyzed using peristimulus time histograms and cumulative sum histograms.

Striatal stimulation inhibited SN DA neuron firing by an average of 69.6% in all of the neurons selected ($n = 7$) for bicuculline administration for a duration of 95.2 ± 29.7 ms (mean ± SEM). Stimulation of GP ($n = 11$) produced a 76.9% inhibition for a duration of 30.2 ± 12.5 ms. The onset latencies for inhibition from both GP (2.3 ± 0.9 ms) and striatum (11.4 ± 1.7 ms) were consistent with values previously reported for monosynaptic responses in SN evoked from these nuclei. After administration of bicuculline, striatal-evoked inhibition was significantly blocked or attenuated ($t = 3.94$, $p < 0.01$), but GP-evoked inhibition was not affected (72.1% inhibition). These data suggest that monosynaptic inhibition of SN DA neurons from striatal stimulation, but not from GP stimulation, is $GABA_A$ receptor mediated and support the previous suggestion that GP-evoked inhibition of SN DA neurons may be $GABA_B$ receptor mediated. Supported by MH45286 and NS30679. P. Celada was supported through a Spanish Government Fellowship.

INWARD AND OUTWARD RECTIFICATION IN NEOSTRIATAL NEURONS DURING THE EARLY POSTNATAL PERIOD. T. Kogs, F. Trent* & J.M. Tepper. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

Previously, we have shown that about 1/3 of rat striatal medium spiny neurons *in vivo* exhibit a slowly developing outward rectification (OR) at strongly hyperpolarized membrane potentials and a fast outward rectification in the depolarizing direction during the first two postnatal weeks (Tepper and Trent, *Prog. Brain Res. 99*:35, 1993) with the remainder exhibiting relatively linear I-V curves. In contrast, adult medium spiny neuron I-V curves are dominated by a fast inward rectification.

400 µm neostriatal slices from Sprague-Dawley rats (3 to 11 days of age) were cut in a modified horizontal plane. Intracellular recordings were obtained from submerged slices at 32° C with glass micropipettes filled with 1.5 M KAc and 3-8% neurobiotin possessing 60-100 MΩ resistance.

Hyperpolarizing current pulses (150-300 ms) revealed a modest OR that became very pronounced at membrane potentials negative to -110 mV, resulting in a hyperpolarizing ramp. After application of 2 mM Cs^+ the activation range for the ramp potential and the OR shifted in the positive direction and could be initiated at potentials more negative than -80 mV. 10 mM TEA or 300 µM Ba^+ (with or without Cs^+) blocked the ramp potential and the OR and linearized the neuron's response to hyperpolarizing current pulses. These drugs also increased the input resistance approximately to the value measured at the end of the most hyperpolarized potentials in the absence of any channel blockers (200-250 MΩ). In some neurons 2-10 mM TEA revealed a Cs^+ sensitive time dependent inward rectification. The outward rectification in the depolarizing direction could be blocked by 3 mM, but not 300 µM Ba^+.

These data suggest that the hyperpolarizing ramp is due to the slow deactivation of a TEA and Ba^+-sensitive potassium conductance. We suggest that the time course of opening of the Cs^+-sensitive inward rectifier channel and the closing of the TEA/Ba^+-sensitive outward rectifier are similar and their sum remains constant over time and linearizes the neuron in the negative voltage range close to rest. Supported by NS30679.

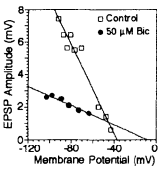
SUBTHALAMIC STIMULATION-INDUCED SYNAPTIC RESPONSES IN NIGRAL DOPAMINERGIC NEURONS *IN VITRO* K. Moore, K. Pang & J.M. Tepper* Center for Molecular and Behavioral Neuroscience, Rutgers, The State University of New Jersey, Newark, NJ USA 07102

Although the efferent projections from the subthalamic nucleus (STN) contain an excitatory amino acid, dopaminergic (DA) substantia nigra neurons *in vivo* usually respond to STN stimulation with an initial inhibition of firing (Smith and Grace, *Synapse 12*:287, 1992). Since 90% of STN-nigral fibers terminate on non-DA neurons, activation of which inhibits DA neurons via $GABA_A$ synapses (Tepper et al., *J. Neurosci. 15*:3092, 1995), we hypothesized that the STN-evoked inhibition of DA neurons arises through activation of pars reticulata axon collaterals.

Parasagittal 400 µm slices containing STN and substantia nigra were prepared from adult male Sprague-Dawley rats. Intracellular recordings were obtained from submerged slices at 32° C with glass micropipettes filled with 1.5 M KAc and 3% biocytin possessing 60-100 MΩ resistance.

Stimulation of STN produced depolarizing responses in electrophysiologically identified nigral DA neurons (n=5, max. amplitude=6.3±1.6 mV at rest; E_m = -69.2±6.7mV, onset latency=2.9±0.3ms, duration= 26.9 ±3.2ms). These responses appeared to be depolarizing synaptic responses since they increased with membrane hyperpolarization and decreased with membrane depolarization (see Figure). However, the response had an unusually negative reversal potential of -35 to -40 mV. Bath application of the GABAA antagonist, bicuculline (50 µM), shifted the reversal potential to -5 to -10 mV.



We suggest that STN stimulation produces a near simultaneous EPSP and IPSP in DA neurons. The EPSP appears to be monosynaptic, from STN, and the IPSP disynaptic, mediated through $GABA_A$ receptors activated by the axon collaterals of pars reticulata GABAergic neurons. Supported by MH-45286 and NS30679.

STIMULATION OF STRIATAL D1 AND D2 RECEPTORS IS NECESSARY BUT NOT SUFFICIENT FOR SYNERGISTIC EFFECTS OF SYSTEMICALLY ADMINISTERED DOPAMINE AGONISTS ON SUBSTANTIA NIGRA PARS RETICULATA NEURONS. **M. J. Twery*, D. A. Bergstrom and J. R. Walters. ETB, NINDS, Bethesda, MD 20892.**

Concurrent intravenous (i.v.) administration of the dopamine D1 agonist SKF 38393 and the D2/D3 agonist quinpirole inhibits the activity of substantia nigra pars reticulata (SNpr) neurons in rats with 6-hydroxydopamine (6OHDA)-induced lesions of midbrain dopamine cells. In order to investigate the role of striatal D1 and D2 receptors, agonists were administered locally in striatum while the activity of individual SNpr neurons was recorded extracellularly in gallamine-paralyzed rats with 6OHDA lesions. Striatal infusion (0.5 µl/10 min) of either SKF 38393 (17 nmols, n=14), quinpirole (19 nmols, n=9), or the combination of both agonists (n=6) produced no change in SNpr firing rate. However, striatal infusion of quinpirole and i.v. SKF 38393 (3.4 mg/kg) decreased SNpr neuronal activity to 49 ± 19% (n=10) of baseline. The i.v. SKF 38393 alone produced no change in firing rate. Striatal infusion of the D1 antagonist SCH 23390 (6 nmols) blocked the inhibitory response to concurrent i.v. administration of SKF 38393 and quinpirole (0.3 mg/kg) in 7 of 15 neurons. These results indicate a requirement for concurrent stimulation of striatal D1 and D2 receptors in the mechanism underlying synergistic inhibitory effects of i.v. dopamine agonists on SNpr neuronal activity. However, local stimulation of striatal dopamine receptors did not inhibit SNpr neurons. The findings suggest that the inhibitory mechanism can be activated if additional D1 sites are stimulated as was evident with i.v. SKF 38393. Systemically administered dopamine agonists acting principally at D1 and D2 receptors in striatum and D1 receptors at other sites could decrease SNpr neuronal activity either through convergent pathways or through multiple sites associated with a single pathway.

SIMULATION OF THE INTRINSIC MEMBRANE PROPERTIES OF GUINEA-PIG AND RAT MIDBRAIN DOPAMINE NEURONE. W.H.Yung. (SPON: The Hong Kong Society of Neurosciences). Department of Physiology, Faculty of Medicine, The Chinese University of Hong Kong, Shatin, Hong Kong

A biophysical model capable of exhibiting some of the characteristic properties of midbrain dopamine neurones of the guinea-pig and rat is described and simulated in the computer. The active membrane properties are reconstructed by simulating the following ionic conductances: a fast sodium conductance, a delayed potassium conductance, a hyperpolarisation-activated potassium conductance, a fast transient outward potassium conductance, a low threshold calcium conductance, a high threshold calcium conductance and a slow calcium-activated potassium conductance (gKCa).

The kinetic parameters of these ionic channels were obtained from voltage-clamp data of both dopamine and non-dopamine neurones. The model is capable of exhibiting the following characteristics of dopamine cells: slow pace-maker firing, a prominent slow after-hyperpolarisation (AHP) and a strong inward rectification.

A critical component of the model is the modelling of the slow AHP by combining a simple first-order calcium buffering model and a three-state kinetic model of the gKCa. Calcium influx through the high-threshold calcium channel activates the gKCa. The time course of the AHP is determined by the kinetics of the gKCa rather than the intracellular calcium concentration.

HISTAMINE H_3-RECEPTOR ACTIVATION INHIBITS K+-EVOKED GABA RELEASE IN RAT SUBSTANTIA NIGRA PARS RETICULATA SLICES. J.A. Arias-Montaño[1]*, M. García[1], J. Aceves[1], B. Florán[1], and J.M. Young[2], [1]Departamento de Neurociencias, CINVESTAV-IPN., México, D.F., México and [2]Department of Pharmacology, University of Cambridge, England.

The substantia nigra pars reticulata (SNr) plays an important role in the regulation of basal ganglia motor functions. The spontaneous activity of SNr neurones is controlled by striatal GABAergic projections and by dopamine (DA) released from dendrites of neurones located in the substantia nigra pars compacta (SNc). There is evidence that histamine is also involved in the control of locomotor activity and high levels of H_3-receptors have been found in SNr (Pollard *et al.*, Neuroscience, 52:169-189, 1993). Therefore we set out to study whether H_3-receptor activation modulates GABA or dopamine release in SNr. Coronal slices (300 μm thick) from SNr were labelled in Krebs-Henseleit (K-H) buffer with either [^{3}H]-GABA (glial uptake prevented by 10 μM β-alanine) or [^{3}H]-DA. After washing out the excess of radioactivity, slices (6-8 per chamber) were perfused with KH buffer (1 ml min^{-1}) and perfusates (collected every 4 min) were analysed by liquid scintillation spectrometry. High K+ (15 mM)-induced depolarisation resulted in increased [3H]-GABA efflux (2.8 ± 0.2 fold of basal release) and [3H]-DA efflux (1.83 ± 0.08 fold of basal), as estimated at the peak of tritium release. The selective H_3 agonist immepip (1 μM) decreased (by 53 ± 8%) K+-evoked [3H]-GABA release. This effect was fully reverted by thioperamide (1 μM), a selective H_3 antagonist. Depolarisation-induced [3H]-DA release was slightly reduced by immepip, but the inhibition failed to yield statistical significance. These results suggest that histamine may regulate SNr function by inhibiting GABA release via H_3-receptors mainly located on striatonigral terminals.

MUSCLE: CELLULAR AND MOLECULAR PHYSIOLOGY

ALTERED MYOSIN mRNA AND PROTEIN CONTENT IN RAT SOLEUS AND TIBIALIS ANTERIOR MUSCLE FOLLOWING FOREIGN REINNERVATION. K.A. Huey and S.C. Bodine-Fowler*. Dept Orthopaedics and Biomedical Sciences Group, UCSD and VA Medical Center, San Diego, CA 92161-6002.

Reinnervation by a foreign motoneuron may strongly influence myosin heavy chain (MHC) expression. MHC content may be controlled by both gene transcription and translation, thus MHC mRNA and protein were examined in the tibialis anterior (TA) and soleus (Sol) following denervation and reinnervation. The sciatic nerve of adult rats was transected and repaired by either epineurial sutures or a silicone tube (10/group). Following 8 or 32 wks of recovery, the muscles were excised, weighed, and frozen. MHC protein content was quantified by SDS-PAGE and mRNA levels with the RNase Protection Assay which allows comparison of relative levels of the 4 adult MHCs within the same sample. Control Sol contains predominately type I MHC, however, 8 wks following nerve injury, there were increases in IIa and IIx MHC mRNAs without corresponding increases in the proteins. However, by 32 wks, increases in both fast MHC mRNA and protein, especially IIx, were found with concomitant decreases in slow MHC. The relative amounts (% of total) of IIx MHC mRNA and protein increased from ~5% in control Sol to ~45% at 32 wks with tube repair. Similarly, 32 wks after tube repair in the TA, IIx MHC mRNA and protein increased primarily at the expense of IIb MHC. In control TA, IIb mRNA content was ~77% while 32 wks following tube repair, IIb mRNA ranged from 4 to 16%. These findings emphasize the role that motoneurons play in regulating MHC expression. The timing of these changes indicates that isoform switching can be detected at the mRNA level considerably before detection of the new protein. This work was supported by the Research Service of the VA.

654.2

MHC PROTEIN AND mRNA EXPRESSION IN RAT SOLEUS MOTOR UNITS AFTER SCIATIC NERVE INJURY. D.J. Pierotti*, and S.C. Bodine-Fowler. Dept. of Orthopaedics, UCSD and VA Medical Center, San Diego, California 92161-6002.

Although the nerve has been shown to affect the myosin heavy chain (MHC) isoform expressed in a muscle, little is known about the expression of the MHC mRNA transcripts. We chose to examine the influence of the nerve by studying MHC protein and mRNA expression in motor units of the rat soleus (Sol). Sciatic nerves of adult female rats were transected followed by epineurial suture repair. After a period of 16 weeks, motor units from the Sol were functionally isolated, physiologically tested, and glycogen depleted. Motor unit fibers were identified in serial cross-sections that had been labeled with MHC antibodies and mRNA probes. Previously, we demonstrated that only 10% of the neurons reinnervating the Sol were from the original motor pool and that the Sol was reinnervated by twice as many motoneurons (Bodine-Fowler et al., Neurosci. Abstr. 20: 256, 1994). Whole muscle tetanic force was reduced from normal, as was the average fiber size. Motor units (n=6: 2 slow, 2 IIa, and 2 IIx) ranged in force production from ~15 to 180 mN, in contrast to the 28 to 100mN range in control motor units. Contraction time ranged from 12 to 30 msec, as opposed to 25 to 88 msec in control motor units. Only 3 of the 6 motor units were fatigue resistant. Type 2x MHC, normally not found in rat Sol, was abundant in all muscles tested. The fibers in each of the motor units were composed of one type of MHC. Interestingly, each of the visualized units expressed only one mRNA transcript, though a large number of non-motor unit fibers contained two or more transcripts. These results indicate that after nerve injury motor unit fibers have acquired a similar degree of homogeneity with respect to protein and mRNA expression. This work was supported by the Research Service of the VA.

654.3

MYOSIN HEAVY CHAIN COMPOSITION OF SOLEUS MUSCLES IN SPINAL CORD INJURED AND CONTROL HUMANS. R.J. Talmadge, S. Harkema, K. Day, D. Lowry, B. Dobkin, and V.R. Edgerton*. Departments of Physiological Science and Neurology, UCLA, Los Angeles, CA 90024.

Several studies have demonstrated in humans that following a spinal cord injury (SCI) the muscles innervated by motoneurons below the level of the lesion become composed almost entirely of type II fibers, as assayed by myofibrillar ATPase histochemistry. It is now known that each of the three fiber types (types I, IIA, and IIB), as defined by the pH sensitivity of the myofibrillar ATPase histochemical stain in normal muscle, corresponds to a specific myosin heavy chain (MHC) isoform (types I, IIa, and IIb, respectively). However, there have been no previous studies documenting the effects of SCI on MHC composition in humans. We have determined the MHC composition of the soleus muscle in 4 spinal cord injured (from 1 to 3 years post injury) and 4 adult control subjects by using a high resolution SDS-PAGE technique that allows for the quantitative determination of types I, IIa, and IIb MHCs. The proportion of the MHC isoforms in the soleus of control subjects was 68% type I, 25% type IIa, and 7% type IIb MHCs. In contrast, the SCI subjects contained 55% type I, 25% type IIa, and 20% type IIb MHCs. The decrease in type I and the increase in type IIb MHCs after SCI were statistically significant ($p < 0.05$). These data are consistent with a shift from the slower (type I) to the faster (type IIb) MHC isoform, but these changes are not as dramatic as those previously reported for the ATPase based fiber type analysis. These data suggest that the myofibrillar ATPase reaction may overestimate the amount of fast myosin in SCI humans. Supported by NIH Grant NS 16333.

RHABDOMYOSARCOMMA CELLS TRANSFECTED WITH CONNEXIN-43 SHOW AN INCREASE IN MYOGENIC DIFFERENTIATION. A. Proulx[1], Y.C. Zhang[1], Z.X. Lin[2], J.F. Bechberger[1], P.A. Merrifield[1], and C.C.G. Naus[1]*. [1]Department of Anatomy, Univ. of Western Ontario, London, Canada. [2]Beijing Institute for Cancer Research, Beijing, China.

Gap junctional communication (GJC) has been implicated in many cell physiological processes. Although absent in mature skeletal muscle, studies have shown gap junctions to be present during early stages of myogenesis, indicating their possible role in myogenic processes. Previous reports have shown that communication deficient tumorigenic cells transfected with a gap junction protein gene exhibit an increase in cell differentiation and a decrease in cell proliferation. Rhabdomyosarcomma is a highly malignant tumor of embryonic origin. In our present study, human rhabdomyosarcomma cells were transfected with the cDNA encoding the gap junction protein connexin-43 (Cx43), and clones of varying expression were isolated. Dye-coupling attributable to GJC was proportional to the level of connexin expressed. Furthermore, expression of Cx43 also correlated with increased cell fusion and myosin expression. These results lend further evidence to the possible role of gap junctions during developmental processes such as myogenesis and cell differentiation.

EXPRESSION OF BASIC FIBROBLAST GROWTH FACTOR AND ITS RECEPTORS IN THE HUMAN FETAL MUSCLE. L.Balaci, M.Presta, V.Sogos, M.G.Ennas, P. Dell'Era and F.Gremo*. Sch. of Med., Cagliari, Brescia (Italy)

Basic fibroblast growth factor (bFGF) has been shown to stimulate proliferation and to depress differentiation of myogenic cells. Moreover, it has been proposed to stimulate rigeneration of dystrophic muscle. In order to elucidate its role in the development of the human muscle, we investigated its expression as well as the expression of the four types of FGF receptors (FGF- Rs). In brief, muscles have been dissected out from 10 - 18 week old human embryos and tissues processed for Northern and Western blot analyses. Results demontrated a progressive decrease in bFGF and FGF-Rs content in correlation with age. Immunocytochemical staining of human fetal muscles apparently showed an association between FGF-Rs and satellite cells, further suggesting that bFGF might play a key role in the development of human muscle.

TISSUE-ASSOCIATED COUNTERPARTS OF α-2-MACROGLOBULIN AND INTER-α-TRYPSIN INHIBITOR IN MOUSE SKELETAL MUSCLE. De Renzis G.*, Businaro R., Nori S., Toesca A., De Santis E., Evangelisti E., Fumagalli L.. Institute of Anatomy, Catholic University, 00168 Rome, Italy.

Proteinase inhibitors normally regulate proteolysis in numerous tissues and cells. However relatively few data are available in literature about protease inhibitors in normal and diseased muscle. The present experiments deal with the immunohistochemical and immunochemical detection of α-2-macroglobulin (α2M) and inter-α-trypsin inhibitor (ITI), two major protease inhibitors in mouse skeletal muscle. Immunoperoxidase histochemistry (ABC method) was done on cryostat sections fixed with a mixture of 4% paraformaldheyde plus 0.5 monomeric glutaraldheyde. In all muscles examined (mm. soleus, plantaris and extensor digitorum longus) α2M-related immunoreactivity occurred widespreadly in extracellular structures (peri-endomysium, blood vessel wall) as well as inside about a half of the muscle fibers. This localization pattern did not change following extensive *in vivo* perfusion (with PBS) of deeply anesthetized mice to remove serum contamination. Western blotting experiments were negative on homogenates of perfused muscles (soluble fraction), but three specific bands (180,165,35 KDa) resulted in detergent-solubilized extracts (0.3% Triton X-100). These results indicate that i) our perfusion procedure was effective in removing serum (soluble) α2M from muscle, and ii) skeletal muscle contains tissue-associated α2M. In contrast to the above results, ITI localization was restricted to the extracellular matrix both in normal and perfused muscle, with two typical bands of 220 and 180 KDa detected by immunoblotting experiments. The present results suggest that in skeletal muscle some proteinase inhibitors may have a tissue-associated counterpart with different localization and physiological roles.

IMMUNOSTAINING OF ISOLATED ADULT RAT SKELETAL MUSCLE FIBERS WITH ANTI-NA PUMP ANTIBODIES. S. Corey Specht* and M. Santiago-Sanchez. Dept. Pharmacology and Inst. Neurobiology., Univ. PR Sch. Med, San Juan, PR 00936.

The organization of Na pump molecules on the surface of adult skeletal muscle was examined in fibers of the rat *digitorum brevis* muscle. Individual fibers were isolated with dispase and collagenase at 37°C for 2 h, relaxed in 30 mM KCL followed by 2M formamide, fixed in 2% paraformaldehyde, and finally immobilized on poly-l-lysine-coated slides under microscopic observation. Tetramethylrhodamine-α-bungarotoxin was used to identify the motor endplate. Myonuclei were identified with Hoechst 33258. Na pump α1 and α2 subunits were tagged with monoclonal antibodies developed by K. Sweadner (Mass. General Hospital), and goat-anti mouse IgG conjugated with rhodamine. Both isoforms of the Na pump were present diffusely on the surface, but absent from large circular areas directly over the bulging sub-sarcolemmal nuclei. When expression was up-regulated by administration of high doses of insulin, Na pump was also seen in fine lines with occasional clumping. [NIGMS grant SS RR 08224]

ION-DEPENDENT ALTERATIONS IN METABOLIC GENE EXPRESSION IN SKELETAL MUSCLE: S.A. Vali, P. C. Tennant, R. C. Carlsen, R. C. Tait, F. A. Gorin*. Dept. of Neurology, Univ. of California, Davis, CA 95616.

It is well established that metabolic properties of the skeletal muscle fibers are modulated by neurally imposed patterns of contractile activity. Previously we have demonstrated that either denervation, inhibition of neural impulses or blockade of neuromuscular transmission reduce steady state mRNA transcript levels of muscle glycogen phosphorylase (mgp) to 40-60% of controls. These *in vivo* manipulations are associated with increased sarcolemmal permeability to sodium and resulting depolarization. Recently, we have utilized a spontaneously contracting skeletal muscle cell line as an *in vitro* model to examine the cellular mechanisms that modulate mgp levels with inhibition of neuromuscular activity. Myotubes were depolarized by manipulating sodium permeability or potassium gradients. Depolarization altered mgp steady state transcript levels as observed *in vivo*. Calcium influx has been shown to regulate the mRNA levels of the subunits of AChR in myotube cultures. But in our system, increasing calcium influx with ionomycin did not alter mgp steady state RNA levels in contrast to α AChR. From this data, it is likely that neural activity regulates mgp by different mechanisms than observed for AChR subunit genes in skeletal muscle.

EQUATORIAL MORPHOLOGY OF SLOW AND FAST INTRAFUSAL FIBERS IN CHICKEN LEG MUSCLE SPINDLES. Alfred Maier*Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL 35294.

Equatorial regions of chicken leg muscle spindles were examined to review the notion that at midequator their intrafusal fibers present a uniform structure, regardless of fiber type. Based on myosin heavy chain composition, intrafusal fibers were either classified as slow (S and M fibers) or fast (U fibers) (Maier and Zak, Am. J. Anat., 187:338-346. 1990). Staining for α-bungarotoxin was exceedingly rare at the equator; indicating that neither fiber type received a significant motor innervation at the sensory region. Immunostaining for acetylcholinesterase , on the other hand, was present as a continuous or occasionally interrupted layer throughout the equator in either fiber group, but only on the non-synaptic side, away from myosensory junctions. Sensory terminals making contact with fast U fibers were frequently claw-shaped, while those connecting to the slow M and S fibers were typically less curved. The perifibral sheath was shortest in M fibers, and on average, there were fewer myosensory contacts on slow than on fast fibers. In sections which were immunostained for filamentous actin by the phalloidin toxin reaction, at the point where the perifibral sheath was most prominent, actin was restricted to a narrow crescent on the synaptic side. This paucity of actin extended along the equator for a greater distance in slow than in fast fibers, despite a more extensive distribution of slow MHC. As seen in cross sections, slow MHC was concentrated on the periphery of fibers. There are then at the equator of chicken intrafusal muscle fibers some fiber type-specific structural elements, but they are much less pronounced than in mammalian spindles. Physiological experiments are required to determine if these morphological differences relate to unique mechanical properties which can induce distinct and separate components into the afferent discharge.

MORPHOLOGICAL ADAPTATIONS OF DIAPHRAGM NEUROMUSCULAR JUNCTION TO PROLONGED INACTIVITY. W.Z. Zhan*, Y.S. Prakash, H. Miyata and G.C. Sieck. Depts. of Anesthesiology, and Physiology & Biophysics. Mayo Foundation, Rochester, MN 55905.

Previous models of muscle disuse vary in the extent of nerve versus muscle inactivation, making it difficult to assess inactivity-induced adaptations of the neuromuscular junction (NMJ). We induced inactivation of both phrenic motoneurons and diaphragm muscle in the rat via spinal isolation (SI) at the C2 level. We then combined a three-color fluorescent immunocytochemical technique with 3D confocal microscopy to simultaneously visualize nerve terminals, motor endplates and muscle fiber type in SI diaphragm fibers. Compared to controls, both nerve terminal and endplate planar (2D) and surface (3D) areas were increased on type II fibers, but not on type I fibers. The extent of overlap of pre- and postsynaptic elements of the NMJ increased on type II fibers. Terminal and endplate branch lengths on type II fibers also increased. Endplate gutter depth was unchenged. These results suggest that NMJ inactivation at both pre- and postsynaptic levels leads to a phenotype-dependent expansion of the NMJ on type II fibers, perhaps in an effort to improve neuromuscular transmission. Supported by NIH grants HL34817 and HL37680.

EFFECT OF AGING ON DIAPHRAGM NEUROMUSCULAR JUNCTION MORPHOLOGY. L.E. Gosselin, Y.S. Prakash, D.B. Masters*, and G.C. Sieck. Depts. of Anesthesiology, and Physiology & Biophysics. Mayo Foundation, Rochester, MN 55905.

Previous studies reported fiber-type differences in morphological adaptations of neuromuscular junctions (NMJs) to aging by comparing limb muscles consisting of predominantly type I or II fibers. Differences in age-related change in activity of these muscles may be a confounding factor in these studies. In the present study, we assessed age-related changes of the NMJ in type I and II fibers of the rat diaphragm muscle which maintains consistent inspiratory-related activation throughout life. In 6- and 24-month old rats, nerve terminals were labelled with an antibody to protein gene product 9.5, and motor endplates were labelled with α-bungarotoxin. Fiber type was identified using an anti-fast myosin antibody. Labelled NMJs were imaged in 3D using confocal microscopy. When corrected for fiber diameter, only type II fiber NMJs showed significant changes with aging. Nerve terminal and endplate planar (2D) and surface (3D) areas expanded, and the number of nerve terminal and endplate branches increased. In older animals, the number of axon collaterals also increased. These morphological adaptations may relate to changes in neuromuscular transmission with aging. Supported by NIH grants HL34817 and HL37680.

CHARACTERIZATION OF A PROGRESSIVE MUSCLE DEGENERATION MUTATION IN *DROSOPHILA*. B.Clendening*, T. Tubon, J. E. Allen and G. L. Harris. Department of Biology, San Diego State University, San Diego, CA 92182.

We are using an enhancer trap analysis to identify and characterize mutations in *Drosophila* which disrupt the function of the indirect flight muscles (IFMs) of adult flies. One enhancer trap line has been used to generate a single complementation group of recessive mutations on the second chromosome which cause a progressive degeneration of the IFMs. Upon eclosion, flies homozygous for the mutation, have a normal appearance and exhibit normal walking, jumping and flying behavior. Soon after eclosion, the mutant flies become progressively impaired in their flight ability such that by four weeks most mutant flies are unable to sustain normal flight. The ultrastructure of the IFM fibers becomes progressively disrupted over the same time period. Severe fraying of the myofibrillar lattice and extensive vacuolization within the sarcoplasm are observed. Other skeletal muscles of the thorax, such as the jump muscle, appear unaffected by the mutations. There is no apparent loss of any major muscle protein band on a single dimensional gel analysis of the mutant flies. In addition to the muscular degeneration, the lifespan of the mutant flies is decreased by several weeks compared to control flies. We have undertaken a molecular analysis in order to isolate the gene(s) which underlie the mutant phenotype. Overlapping genomic and one class of cDNA clones have been isolated which identify transcripts of 1.1 and 2.1 kb on Northern blots of poly A^+ RNA from wild type flies. INTERCELLULAR COMMUNICATION MONITORED BY PROPAGATION OF CALCIUM WAVES IN CULTURED COLONIC SMOOTH MUSCLE CELLS. S.H. Young*, H.S. Ennes, and E. Mayer. CURE: VA/UCLA Gastroenteric Biology Center, Neuroenteric Biology Group; Depts. of Physiology and Medicine, UCLA and West Los Angeles VA Med Ctr., Los Angeles, CA 90073.

Single muscle cells respond to a light mechanical stimulus with a local increase in intracellular calcium which can propagate throughout the cell and into several adjacent cells. Smooth muscle cells were isolated from the circular and longitudinal layers of the rabbit distal colon, and placed into culture. Stimulus was delivered by a fire polished glass pipette (2-4 μm diameter) connected to an electronically controlled micropositoner (Eppendorf) used to displace the plasma membrane (2μm depression, 0.5 sec duration). The calcium increase starts local to the stimulation point, but if the response exceeds 100 nM above resting levels, the increase will propagate as a wave throughout the cell (intracellular velocity 13.2 μm/sec). Recovery rates to resting levels are highly variable, showing both single double time constants in the range τ= 7-300 sec. When multiple cells are in contact, the wave continues to propagate into as many as 5 adjacent cells (intracellular velocity 17 μm/sec) without large degradation in amplitude. The propagation is likely the result of diffusion of a "message" substance which releases calcium from intracellular stores, and not calcium itself: The wave can propagate through cells which do not respond, and into adjacent cells which do exhibit an increase in calcium. Propagation occurs in zero calcium external solution (21 μm/sec). After treatment with thapsigargin (2μM), a Ca2+-ATPase inhibitor which should deplete intracellular calcium stores, the stimulated cell responds, but intercellular propagation is blocked. Treatment with U-73122, an inhibitor of phospholipase C dependent processes, including production of IP_3, prevents intracellular propagation, indicating that IP_3 may be the messenger molecule. Supported by NIH Grant DK40919-05

NITRIC OXIDE SIGNALING AT THE NEUROMUSCULAR JUNCTION. D.S. Chao, J.E. Brenman, G.L. Yount*, and D.S. Bredt. Dept. of Physiology, UCSF, San Francisco, CA 94143.

Nitric oxide (NO) is synthesized in skeletal muscle by neuronal NO synthase (nNOS), which is localized beneath the sacrolemma of fast twitch muscle fibers. We now show by immunohistochemistry that nNOS is enriched at the mammalian neuromuscular junction (NMJ). NOS is tethered to the NMJ by a glycoprotein complex formed around dystrophin, the gene mutated in Duchenne muscular dystrophy, and utrophin, an autosomal homolog of dystrophin localized specifically at NMJs in skeletal muscle. We also find that a downstream effector of NO, cGMP-dependent-protein kinase Iα (cGKIα), is localized exclusively at the NMJ in rat skeletal muscle. Both nNOS and cGKIα staining persists two weeks after denervation demonstrating that both are localized in the muscle and not the nerve terminal. nNOS staining at the NMJ is reduced in *mdx* mice and absent in nNOS knockout mice while cGKIα staining persists in both of these animal models. While nNOS has previously been found only on sarcolemma of fast twitch muscle fibers, we find nNOS staining at the NMJ in both fast and slow twitch fibers. These data suggest roles for NO and cGMP as modulators of transmission at the NMJ.

LIMBIC SYSTEM AND HYPOTHALAMUS: AMYGDALA AND HYPOTHALAMUS

655.1

IONIC MECHANISMS OF METABOTROPIC GLUTAMATE RECEPTOR ACTIVATION IN MAGNOCELLULAR NEURONS OF THE HYPOTHALAMIC SUPRAOPTIC NUCLEUS. L.A. Schrader* and J.G. Tasker. Neuroscience Program and Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118.

Activation of metabotropic glutamate receptors in magnocellular neurons of the hypothalamic supraoptic nucleus (SON) results in a depolarization and a decrease in membrane conductance (Schrader and Tasker, Soc. Neurosci. Abstr. 20: 347, 1994). We have investigated the ionic mechanisms of these effects with whole-cell recordings in coronal slices (400 μm) of rat hypothalamus using the metabotropic glutamate receptor agonist *trans*-(+)-1-amino-1,3-cyclopentane-dicarboxylic acid (*trans*-ACPD) and selective ion channel blockers. Bath application of the Na^+-channel blocker tetrodotoxin (1-3μM) had no effect on the inward current or on the decrease in conductance evoked by *trans*-ACPD. However, when K^+ channels were blocked by replacing K^+ in the patch pipette with an equimolar concentration of Cs^+ and by including tetraethylammonium (10-20 mM) in the bath perfusion the decrease in conductance was attenuated or blocked completely. In some cases, when K^+ channels were blocked, *trans*-ACPD caused an increase in membrane conductance, which was attenuated by adding the Ca^{2+} channel blocker Cd^{2+} (200-250 μM) to the bath. These results indicate that metabotropic-receptor activation causes a decrease in membrane conductance and an inward current in SON magnocellular neurons by closing K^+ channels and by activation of a separate cationic current which has a Ca^{2+} component. This work is supported in part by NIH NS31187.

655.2

RESPONSES OF MEDIAL AMYGDALA (MeA) NEURONS TO ELECTRICAL STIMULATION OF THE SUPRAOPTIC NUCLEUS (SON) AND LATERAL OLFACTORY TRACT (LOT). Q.Z. Yang* and G.I. Hatton. Dept. of Neuroscience, Univ. of California, Riverside, CA 92521

Previous extracellular recording studies have suggested the existence of connections (perhaps reciprocal) between the MeA and the SON including its perinuclear zone (PNZ). Our intracellular recording experiments investigated this potential local circuit involving the MeA, the SON and the PNZ. Also studied was the nature of the input from the olfactory bulbs to MeA neurons, connections for which there is long-standing anatomical evidence. In horizontally cut slices that preserve the ventral amygdalo-hypothalamic pathway, electrical stimulation of the SON/PNZ produced short latency EPSPs or IPSPs in MeA neurons. Five MeA neurons were also antidromically activated by SON/PNZ stimulation, suggesting reciprocal connections between the two regions. Three MeA neurons were synaptically excited by both SON/PNZ and LOT stimulation, indicating convergent inputs. In three MeA neurons, stimulation of the SON elicited EPSPs that were blocked by the oxytocin antagonist, [d(CH_2)$_5$,Tyr(Me)^2,Orn^8]-vasotocin, consistent with recent findings of oxytocin receptors in the MeA. LOT stimulation consistently evoked EPSPs in MeA neurons. These ESPSs were blocked by the non-NMDA receptor antagonist, CNQX (5 μM). In five MeA neurons displaying IPSPs in response to SON/PNZ stimulation, these synaptic responses were abolished by the $GABA_A$ receptor blocker, bicuculline. These results suggest that MeA neurons receive inputs from and project to the SON and its PNZ, and that some of these inputs from the SON are oxytocinergic, probably arising from SON axon collaterals. Also MeA, like SON, neurons receive excitatory input form the olfactory system via the LOT. Supported by NINDS grant NS 16942.

ACTIVATION OF HISTAMINERGIC INPUTS TO PHASICALLY FIRING SUPRAOPTIC NUCLEUS (SON) NEURONS INCREASES DYE COUPLING: EFFECTS OF H_1-ANTAGONISTS AND cGMP. G.I. Hatton* and Q.Z. Yang Dept. of Neuroscience, Univ. of California, Riverside, CA 92521

Activation of direct olfactory inputs (glutamatergic) to the SON has been shown to increase the incidence of interneuronal coupling in slices from lactating, but not virgin or male rats. Here we studied the influence on coupling of activating another monosynaptic input to the SON, the histaminergic tuberomammillary nucleus (TM) projection, which is maintained intact in our horizontally cut slices. Stimulation of the TM selectively excites phasically firing (vasopressin) cells, an effect which is blocked by H_1-antagonists. In this study, we investigated the effects of TM stimulation and its possible downstream second messenger consequences on Lucifer Yellow (LY) dye coupling among phasically firing cells in male rat SONs. In unstimulated slices, LY injections into 27 cells (1 cell/SON) yielded 18 single and 18 coupled neurons. In slices in which TM was stimulated for 10 min at 10 Hz, 13 injections yielded 4 single and 28 coupled cells, a 185% increase in number of dye filled cells/injection ($p< .02$). LY injections into 19 cells in unstimulated and 21 injections in stimulated slices, both bathed in medium containing 10 μM pyrilamine (H_1-antagonist), yielded similar numbers of coupled neurons. That this coupling effect was blocked by an H_1-antagonist suggested that it might be mediated by guanylate cyclase-cGMP to which H_1 receptors are often linked. In a parallel study, slices were bathed in control medium or medium containing 0.5 mM 8-bromo-cGMP. In control medium, 15 LY injections yielded 10 single and 10 coupled cells whereas, in medium containing cGMP, 19 injections yielded 6 single and 32 coupled neurons, a 142% increase ($p< .02$) over control. Taken together, these results suggest that one mechanism mediating synaptic enhancement of interneuronal coupling involves connexon channel protein phosphorylation via cGMP-related actions. Supported by NINDS grant NS16942.

655.4

CHARACTERIZATIONS OF BURST FIRING PATTERNS IN RAT SUPRAOPTIC NEURONS PERIFUSED WITH CALCIUM-FREE MEDIUM. Z. Li* and G.I. Hatton. *Dept. of Neuroscience, University of California, Riverside, CA 92521.*

The present experiments were to investigate ionic mechanisms underlying burst activities of hypothalamic supraoptic (SON) neurons during perifusion of Ca^{2+}-free medium. Whole-cell recordings were obtained from SON neurons in horizontal brain slices from adult rats. Using electrodes filled with K gluconate solution containing no Ca^{2+} buffers or Ca^{2+}, either phasic or regular firing patterns were seen in SON cells. Following perifusion of a medium containing 0 Ca^{2+} with or without 2 mM EGTA, all 33 SON cells recorded displayed bursting activity. Such bursting was characterized by fast, periodic changes in membrane potential with superimposed spike activity. Membrane potential fluctuations were as much as 20 mV when resting membrane potentials were -70 to -55 mV. Further hyperpolarization (more negative than -70) inhibited burst firing. SON cells displaying phasic firing and depolarizing afterpotentials following spikes in Ca^{2+}-containing medium had more prominent burst activities in Ca^{2+}-free medium. Bath application of TTX (1-2 μM, n=6) or replacement of 83% Na^+ in perifusion medium with Li^+ (n=5) cancelled or reduced membrane potential fluctuations. Abolition of burst by perifusion with Na^+-Ca^{2+} exchanger inhibitors, Ni^{2+} (5 mM, n=7) and Mg^{2+} (10 mM, n=6) was accompanied by a decrease in membrane input resistance. Following intracelluar diffusion of 11 mM BAPTA, bursting patterns were abolished or greatly reduced (n=10). Intracellular or extracellular application of ryanodine receptor blockers, ryanodine (20 μM, 8/8 cells) or ruthenium red (20-40 μM, 4/7 cells) prevented or reduced such activities. These experiments suggest that both enhanced Na^+ influx and Ca^{2+} release from internal stores are involved in formation of bursting patterns in Ca^{2+}-free perifusion medium and provide further evidence for functional roles of releasable Ca^{2+} from internal stores in SON neurons. Supported by NINDS grant NS16942.

655.5

HISTAMINERGIC SUPPRESSION OF K^+ LEAKAGE CONDUCTANCE IN HYPOTHALAMIC SUPRAOPTIC NEURONS: ROLES OF G-PROTEIN AND PROTEIN KINASE. C. Decavel*, Z. Li and G.I. Hatton. *Dept. of Neuroscience, University of California, Riverside, CA 92521.*

Histamine (HA) has been suggested to function as a neuromodulator and/or neurotransmitter in the rat supraoptic nucleus (SON). Our previous studies have shown that HA can directly depolarize SON neurons by activating membrane H_1 receptors and this action involves Ca^{2+}-independent intracellular processes and a reduction in membrane conductance. Here we investigated ionic mechanisms and intracellular signal transduction involved in HA-induced prolonged depolarization.

Whole-cell recordings were obtained from SON neurons in horizontal brain slices from adult male rats. In medium containing 0 mM Ca^{2+}, 2 mM Co^{2+} and 1-2 μM TTX, with internal Ca^{2+} chelation (11 mM BAPTA), bath application of HA induced an apparent inward current in 15/20 cells tested. The peak of inward current evoked by 1-10 μM HA at holding potentials around -50 mV was 27.3±0.3 pA (Mean±SEM). Ramp voltage tests revealed that this inward current had a reversal potential of -90.1±3.8 mV (n=10). Current subtraction resulted in a current which showed little voltage dependence. Increased $[K^+]_i$ or introduction of K^+ channel blockers in the medium attenuated or abolished HA-induced inward current at membrane potentials close to -50 mV. When external Cl^- concentration was reduced, HA-induced inward current was still seen in 5/7 cells tested. Neither inward current nor change in conductance was observed following bath application of HA in 11/12 cells recorded using patch pipettes containing GDP-βs, and in 7/8 cells using pipettes containing GTP-γs. When electrodes containing the protein kinase inhibitor, H_7 (0.5 mM) were used, inward current with a reversal potential close to -90 mV was seen only in 1 of 11 cells tested. These results suggest that HA depolarizes SON neurons, in part at least, by inhibiting a K^+ leakage current mediated by G-protein and protein kinase. Supported by NINDS grant NS16942.

655.6

PHYSIOLOGICAL MAPPING OF LOCAL INHIBITORY NEURONS WHICH PROJECT TO THE PARAVENTRICULAR NUCLEUS IN RAT HYPOTHALAMIC SLICES. **C. Boudaba, K. Szabo and J.G. Tasker*. Dept. of Cell & Molecular Biology, Tulane University, New Orleans, LA 70118.**

Local circuit interactions may play an important role in the generation of the rhythmic bursting patterns of hypothalamic neurosecretory neurons. Neurons of the paraventricular nucleus (PVN) receive local synaptic inputs from GABA neurons outside the PVN (Tasker and Dudek, J. Physiol. 469: 179, 1993). The aim of the present study was to determine the origin of the local inhibitory inputs to PVN magnocellular and parvocellular neurons. Postsynaptic potentials were recorded in PVN cells in coronal, horizontal and parasagittal hypothalamic slices (400-500 μm) with sharp electrodes; local neurons were selectively stimulated by focal drop application of glutamate (10-50 mM). Cells were classified as magnocellular or parvocellular neurons during on the basis of electrophysiological criteria (Tasker and Dudek, J. Physiol. 434: 271, 1991), and were injected with biocytin (1%) for subsequent immuno-identification with a neurophysin antibody (generously provided by Dr. A.G. Robinson). As in the previous study, we found that both magnocellular and parvocellular neurons of the PVN received local synaptic inputs from cells outside the PVN. The synaptic responses were caused by GABA release since they were blocked by bicuculline (10-50 μM). The main sources of local inhibitory inputs to the PVN were the region surrounding the fornix, including the bed nucleus of the stria terminalis, and the dorsomedial hypothalamus. Other regions which provided weaker inhibitory inputs to PVN cells were located in the anterior hypothalamus. These local GABA neurons may serve as an inhibitory relay to neurosecretory cells from limbic structures, since the limbic system has an inhibitory influence on neurosecretion and afferent projections from limbic structures terminate outside the PVN. This study was supported by NIH-NS31187, NSF IBN-9315308, and a grant from the LA Board of Regents.

SYNAPTIC INTERACTIONS BETWEEN AMYGDALO-STRIATAL AFFERENTS AND PARVALBUMIN AND CALRETININ INTERNEURONS WITHIN THE RAT VENTRAL STRIATUM. T.Rudkin[1], A.Sadikot[1], Y.Smith[2] and A.J.Morin[1]*, *1.Dept.Neurology/Neurosurgery, MNI, McGill University, Montreal, PC; 2. Laboratoire de Neurobiologie, Hôpital Enfant-Jésus, Laval University, Quebec City, PC.*

Afferent input from the basolateral amygdala (BLA) to the ventral striatum is thought to influence voluntary responses to novel and reinforcing stimuli *(Everitt and Robbins, 1992)*. Evidence has suggested that dopamine can modulate this response and that this is effected via synaptic convergence of nigral and amygdalar input upon striatal projection neurons *(Johnson, et al, 1994)*. Interneuron populations within the striatum may represent another substrate for modulation of amygdalar input. Two distinct populations of interneurons, identified by their immunoreactivity to the calcium binding proteins parvalbumin (Pv) and calretinin (Cr), have been localized within the rat ventral striatum. Both of these populations have been shown to receive asymmetric synapses *(Lapper, et al, 1992* and *Bennet and Bolam, 1993)* and are GABAergic *(Kubota, et al, 1993)* This study examines whether Pv and Cr interneurons are targets of the amygdalo-striatal projection.

Injections of the anterograde tracer biotinylated dextranamine were made into the BLA. Areas of overlap between the amygdalo-striatal projection and Pv and Cr positive cells were analyzed by electron microscopy. Preliminary results indicate the presence of asymmetric synapses between amygdala terminals and the dendrites of Pv neurons. Synaptic input to Cr neurons has yet to be identified. Positive results from this study will support the hypothesis that these neurons mediate feed-forward inhibition of the excitatory signals arising from the amygdala.

655.8

LOCALIZATION OF VASOPRESSIN-IMMUNOREACTIVITY AND VASOPRESSIN mRNA LABELING IN THE EXTENDED AMYGDALA. G.J. De Vries*, M.A. Miller, W.C.J. Chung. Program in Neuroscience and Behavior, Univ. of Massachusetts, Amherst, MA 01003-7710 and Dept. of Psychiatry and Behav. Sciences, Univ. of Washington, Seattle, WA 98195.

The bed nucleus of the stria terminalis (BST) and the centromedial amygdala show striking similarities in cytoarchitecture, neurochemistry, and neuronal connections and have, therefore, been proposed to belong to one anatomical unit, the extended amygdala (*Alheid et al., 1995*). The vasopressin (AVP) cells of the BST and amygdala illustrate these similarities. They are similar in size and morphology; immunoreactive for estrogen and androgen receptors and for galanin. In addition, AVP expression in both areas depends entirely on gonadal hormones. Here we test whether AVP-immunoreactive (AVP-ir) and AVP mRNA expressing neurons are indeed found in homologous divisions of the BST and amygdala according to the percolation of the extended amygdala proposed by Alheid et al., (1995). In the BST, the majority of the AVP cells were found in the anterior medial BST (BSTMA), the lateral part of the posterior medial BST (BSTMPl), and the intermediate part of the lateral BST (BSTLI). In the amygdala, AVP cells were found in the intraamygdaloid bed nucleus of the stria terminalis (BSTIA), the anterodorsal part of the medial amygdaloid nucleus (MeAD), and the medial part of the central nucleus (CeM). These areas are indeed each others counterparts. The distribution of AVP cells over neurochemically distinct areas within the extended amygdala suggests that these cells may have been exposed to different microenvironments during development. This may explain differences between those cells, such as the AVP neurons in the medial BST being more abundant in males than in females, whereas AVP cells in the lateral BST do not differ in number. *Funded by NSF grant, IBN 9421658 to GJD, and NIA grant AG-10917 to MAM.*

655.9

LOCALIZATION OF BENZODIAZEPINE/GABA$_A$ RECEPTORS IN THE BASOLATERAL AMYGDALA OF THE RAT AND MONKEY: AN IMMUNOHISTOCHEMICAL STUDY. A.J. McDonald* and F. Mascagni. Dept. of Cell Biology and Neuroscience, Univ. of South Carolina School of Medicine, Columbia, SC 29208.

The basolateral amygdala (ABL) has a strong intrinsic inhibitory system mediated by GABA$_A$ receptors and is the main site of the anxiolytic actions of benzodiazepines. In an effort to identify the anatomical substrates for these transmitter and drug actions, immunohistochemical techniques were used to analyse the neuronal localization of the GABA$_A$/benzodiazepine receptor complex (GABAR/BZR) in the rat and monkey ABL.

The overall pattern of GABAR/BZR immunoreactivity was very similar in both species. The neuropil of the lateral nucleus exhibited the most robust staining. GABAR/BZR immunoreactivity was also seen in neuronal perikarya and dendrites where it was localized to the cytoplasm and/or surface membrane. The cell type with the strongest GABAR/BZR immunoreactivity was a subpopulation of small nonpyramidal neurons that had numerous thin dendrites. Other larger nonpyramidal neurons were also stained. Pyramidal neurons in the rat and monkey ABL exhibited light to moderate perikaryal staining that varied in different nuclei.

The results of this study indicate that the pattern of GABAR/BZR immunoreactivity in the neuropil of the rat and monkey ABL closely resemble the distribution of benzodiazepine receptors localized in previous radioligand autoradiographic studies. The finding of intense immunoreactivity in subpopulations of nonpyramidal neurons suggests the existence of disinhibitory mechanisms which may be important for the activation of ABL projection neurons in response to behaviorally significant stimuli. (Supported by NIH Grant NS19733).

ARE THE PROJECTIONS FROM THE CENTRAL NUCLEUS OF THE MACAQUE MONKEY AMYGDALA TO THE BRAINSTEM GABAERGIC? M.H. Mesches*, A.L. Jongen-Rêlo & D.G. Amaral Ctr Behav Neurosci, SUNY Stony Brook, Stony Brook NY 11794-2575.

The central nucleus of the monkey amygdala (Ce) gives rise to prominent subcortical connections that innervate sensory, endocrine, autonomic, and visceral regions of the brainstem such as the parabrachial nuclei, the dorsal motor nucleus of the vagus and the nucleus of the solitary tract (NTS). While there have been several attempts to determine the chemical anatomy of these projections, relatively little is known concerning their transmitter(s). The present study was prompted by the recent finding in our laboratory that many neurons of the Ce express mRNA for GAD65 and GAD67 and may be GABAergic. Supporting this, Pickel and colleagues (Soc. Neurosci. Abs, 1993) have demonstrated that Ce efferents to the NTS form symmetrical synapses. The present study examined whether cells in Ce, labeled following retrograde tracer injections into the brainstem, were also positive for expression of GAD65 or GAD67. The retrograde markers Fast blue (FB) or WGA-apoHRP-gold (WAHG) were injected into the parabrachial region in Macaca fascicularis monkeys. Tissue was processed by in situ hybridization with probes for GAD65 or GAD67 and with silver intensification of the WAHG. Based on the distributions of FB and GAD positive cells, it appears that some Ce cells which project to the brainstem may be GABAergic. We are currently attempting to confirm this finding quantitatively using double labeled WAHG/in situ preparations. Given that a substantial proportion of the subcortically projecting Ce neurons do express GAD mRNA, it raises the possibility that the amygdala may modulate visceral and autonomic function through an inhibitory GABAergic mechanism.

AMYGDALOID MODULATION OF MESOPONTINE PERIBRACHIAL (PB) NEURONAL ACTIVITY: IMPLICATIONS FOR AROUSAL A.J.Silvestri and B.S.Kapp*. Dept.Psychol.,Univ. of Vermont,Burlington,VT 05405.

Amygdaloid electrical stimulation in the rabbit produces short-latency activation of auditory responsive neurons located within the mesopontine peribrachial (PB) region (Pascoe and Kapp, 1993). Given the importance of the amygdala and PB region in arousal (Kapp et al.,1992; Steriade et al., 1990), the present study was conducted to determine (1) if the activity of PB auditory responsive neurons in the awake rabbit correlates with the state of arousal as reflected in the cortical EEG and (2) if such neurons are influenced by amygdaloid stimulation. To date, we have been investigating two types of extracellularly recorded auditory responsive neurons. The first, with a spontaneous firing rate of <0.5Hz, responded with a phasic burst of 1-4 spikes to the onset of auditory stimuli. The response of this type of neuron is similar to that of a PGO-on burst neuron (Steriade et al. 1990) which may contribute to thalamic arousal in response to novel stimuli. Neither the stimulus-evoked nor spontaneous activity of these neurons showed any obvious relationship with the state of EEG arousal. Consistent with our previous findings, amygdaloid stimulation produced a short latency (4-13 msec) activation of these neurons. The second type, with a spontaneous firing rate of 2.0Hz, responded with a train of spikes which outlasted the duration of auditory stimuli and continued to respond at an enhanced rate throughout the stimulus-induced EEG desynchronization period. In the absence of stimulus presentations, the spontaneous firing rate of these neurons was greater during periods of EEG desynchronization than during periods of EEG synchronization. Current experiments are investigating whether amygdaloid stimulation influences this type of neuron. The results suggest an amygdaloid influence on PB neurons, some of which may contribute to thalamic arousal. (Supported by NSF 9319699).

PROJECTION CELLS AND INTERNEURONS OF THE BASOLATERAL (BL) AMYGDALOID COMPLEX HAVE DISTINCT DISCHARGE PATTERNS IN CONSCIOUS BEHAVING CATS J. Dong*, H. Gaudreau and D. Paré Dept. Physiol., Fac. Medicine, Univ. Laval QUÉ. CANADA

Recently (Paré at al., J. Neurophysiol, in press), we correlated the physiological and morphological properties of BL neurons and identified two types of spiny projection neurons (by antidromic invasion). The first cell type prevailed in the BL nucleus and generated spike bursts upon depolarization. The second cell type prevailed in the lateral nucleus and generated slow membrane potential oscillations when steadily depolarized. In contrast to projection cells, aspiny interneurons had a higher spontaneous discharge rate (DR) and generated non-accommodating spike trains during depolarizing current pulses. Here, we verified if these physiological properties translate into discharge patterns that can be recognized extracellularly in behaving cats.

The majority of the cells encountered in the BL nucleus had a low DR but were most active during slow-wave sleep (SWS). These cells generated stereotyped spike doublets or bursts and a high proportion of them were formally identified as projection cells by antidromic invasion from the parahippocampal cortices. A second cell type discharged tonically in waking (W) and REM sleep (10-25 Hz) but displayed phasic DR accelerations (up to 385 Hz) in SWS. Because none of them could be antidromically invaded from the parahippocampal cortices, they are presumed to be interneurons.

In the lateral nucleus, two cell types were recognized. The first behaved like the presumed interneurons of the BL nucleus. In spontaneous conditions, neurons of the second type were silent in all states (W, SWS and REM sleep) but generated antidromic spikes in response to cortical shocks. These findings suggest that in previous extracellular studies of the lateral nucleus, most spontaneously active cells were interneurons. Thus, these data must be re-interpreted. RHYTHMIC ELECTRICAL ACTIVITY IN THE AMYGDALA: OBSERVATIONS *IN VITRO* AND *IN VIVO*. H.-C. Pape*[1] and D. Paré[2]. [1]Inst. Physiologie, Otto-von-Guericke Universität, Magdeburg, Germany; [2]Dépt. Physiologie, Université Laval, Québec, Canada.

Despite recent advantages, the operations carried out by the basolateral complex of the amygdala (BLA) remain poorly understood, partly due to the rarity of data on the intrinsic properties of the neuronal constituents. In an attempt to correlate morphological cell types and membrane characteristics, we have combined electrophysiological and staining methods in the BLA of guinea pig and cat *in vivo* and in a slice preparation *in vitro*. The major type of projection neuron in the lateral nucleus, as identified upon antidromic invasion from basal forebrain or ento-perirhinal cortices, possessed a heterogeneous, modified pyramid or stellate morphology with spiny dendrites. The unifying characteristic of these neurons was the propensity to generate slow oscillatory activity, evident as rhythmic deflections of the membrane potential at 2-10 Hz that sculptured spike patterns. Two types of oscillations were distinguished. Both were of an intrinsic, non-synaptic origin, but differed in voltage-dependence, ionic mechanisms and site of generation. A *low-threshold oscillation* occured in a range subthreshold to spike generation, was dependent on a Na-current, and presumably originated at or close to the soma. A *high-threshold oscillation* at the same predominant frequency occured in the suprathreshold range, was primarily mediated through a Ca-conductance, and presumably of a dendritic origin.

Two sets of membrane conductances thus seem to cooperate to produce resonant oscillatory activity at 2-10 Hz in projection neurons of the lateral amygdala, thereby supporting the synchronization of synaptic inputs and action potential output into coherent network oscillations.

SLOW INHIBITORY SYNAPTIC RESPONSES IN AMYGDALOID NUCLEI. L. Danober* and H.-C. Pape. Institut für Physiologie, Otto-von-Guericke Universität, D-39120 Magdeburg, Germany.

Besides GABA, glycine is the main inhibitory transmitter in the nervous system. In order to investigate the contribution of glycine to synaptic transmission in the amygdala, we combined immunohistochemical and intracellular recording techniques in slices of the guinea pig amygdala *in vitro*. A dense to moderate immunoreactive staining for gephyrin and the α- and ß-subunits of the glycine receptor was observed throughout the amygdala. Local application of glycine to neurons in lateral (LA) and, as previously described[1], central (CE) amygdaloid nuclei evoked a membrane hyperpolarization from rest that reversed at -80 mV. The glycine response persisted during blocked synaptic transmission, was antagonized by strychnine, and injection of K-nitrate positively shifted the reversal potential. Local high-frequent electrical stimulation evoked a slow IPSP in CE neurons, which reversed at -80 mV and was blocked by strychnine[1]. In LA neurons, repetitive stimulation of the external capsule evoked a slow IPSP with similar reversal potential, but of a significantly longer duration and insensitivity to strychnine. This IPSP was substantially increased during blockade of GABA$_A$ and GABA$_B$ receptors, thereby effectively inhibiting burst discharges generally observed during blocked GABAergic transmission.

The results provide evidence for the existence of strychnine-sensitive glycinergic transmission throughout the amygdala and of an additional slow IPSP in the LA nucleus with as yet undefined pharmacological characteristics. Both types of inhibitory synaptic processes may contribute to prevent epileptiform activity during reduced GABAergic transmission. 1, Nose et al., *J. Neurophysiol.* 65, 1227-1241 (1991)

MICROINJECTION OF TRH ANALOGUE INTO THE CENTRAL NUCLEUS OF THE AMYGDALA STIMULATES GASTRIC CONTRACTILITY IN RATS. N.S. Morrow,*[1] D. Hodgson[2] and T. Garrick.[1,2] CURE/UCLA Gastroenteric Biology Center, Dept. of Veteran Affairs Medical Center,[1] Los Angeles CA 90073, Dept. of Psychiatry and Biobehavioral Sciences,[2] UCLA, Los Angeles, CA 90024.

Changes in gastric contractility following microinjection of thyrotropin-releasing hormone (TRH) analog, RX 77368, into the central nucleus of the amygdala were examined in fasted, urethane-anesthetized rats. Gastric contractility was measured with extraluminal force transducers and analyzed by a computer. Bilateral microinjection of RX 77368 (0.5 μg, 1.0 μg, n= 6 each) dose-dependently stimulated gastric contractility for 10-120 min post-injection when compared to rats microinjected with 0.1 μg RX 77368, 0.1% BSA or RX 77368 into sites adjacent to the central nucleus, p's <.05. Peak responses (0.5 μg, 1.0 μg) occurred 30-40 min post-injection and represented a 15- to 30-fold increase over basal values. In the remaining groups, the gastric contractility force index was not significantly altered from pre-injection values. These results suggests that the central amygdala participates in modulating gastric function during stress-induced challenges. *Supported by a Pilot and Feasibility Award from NIH Center Grant DK 41301 (Animal Core), by VA Merit Review funds and by the UCLA Pyschoneuroimmunology Fellowship Program.

DISSOCIABLE EFFECTS OF SELECTIVE EXCITOTOXIC LESIONS OF THE AMYGDALA ON INSTRUMENTAL AND PAVLOVIAN COMPONENTS OF A NOVEL CONDITIONED PUNISHMENT PROCEDURE. A.S.Killcross, B.J.Everitt and T.W.Robbins. Department of Experimental Psychology, University of Cambridge, Cambridge, England, CB2 3EB.

SPON: European Neuroscience Association.

It has been widely reported that lesions of either the basolateral (blA) or central (cnA) nuclei of the amygdala will abolish Pavlovian aversive conditioning in rats. A novel conditioned punishment procedure is reported in which rats maintained baseline lever pressing on two levers for pellets whilst superimposed on this food schedule was a second schedule delivering on one lever a response-contingent 10-sec auditory conditioned stimulus (CS) that was terminated by a 0.5-sec, 0.3 mA footshock, and on the other lever a matched neutral auditory CS. Control animals learnt over several sessions to avoid the lever producing the response-contingent aversive CS (CS+ lever), but more rapidly came to show a selective conditioned suppression of lever pressing on both the CS+ lever and the alternative lever only during occurrences of the aversive CS. Responding during the neutral CS was always maintained at the same rate as responding during ITI periods. These two behaviours are due to conditioned punishment of instrumental responding and acquisition of a Pavlovian CS-shock association, respectively. A similar pattern of effects was produced in extinction, demonstrating the importance of the CS-shock association in both of these responses. Quinolinate lesions of the blA produced a slight retardation in the acquisition of the Pavlovian conditioned suppression, but a persistent deficit in the acquisition of instrumental conditioned punishment. Ibotenate lesions of the cnA produced the reverse pattern of effects - a persistent deficit in conditioned suppression, but only a slight retardation in the acquisition of conditioned punishment. The implications of this finding for the role of the central and basolateral nuclei of the amygdala in aversive conditioning are discussed.

INDUCTION OF RUNNING ACTIVITY AND METABOLIC CHANGE BY THE VENTROMEDIAL HYPOTHALAMUS IN THE RAT. K. Narita[1], M. Nishihara[2], Y. Mori[3]* and M. Takahashi[2]. [1] Dept. of Physiology, Fukui Medical School, Fukui 910-11, [2] Dept. of Vet. Physiology and [3] Dept. of Vet. Ethology, Univ. of Tokyo, Tokyo 113, JAPAN.

We have revealed that injection of kainic acid (KA) into the ventromedial nucleus of the hypothalamus (VMH) exclusively elicited running activity. In this study, first we investigated the involvement of KA type glutamate receptors in the VMH in the metabolic changes during running activity originating in the VMH. Next, efferent pathways of these KA-sensitive neurons in the VMH were examined by means of multiunit activity (MUA) recording technique.

Injection of KA into the VMH of conscious rats resulted in an increase in plasma glucose, norepinephrine (NE) and epinephrine (E), as well as running activity. Then to prevent the occurrence of exercise, rat was anesthetized by urethane and KA was injected into the VMH. In this condition, KA also increased plasma glucose, NE and E. A transient increase in MUA of subthalamic (SLR) and mesencephalic (MLR) locomotor regions were also observed.

From these results we conclude that KA type glutamate receptors in the VMH are involved in inducing running activity and, simultaneously, in activating the sympathetic nervous system with a resultant increase in blood glucose to supply energy substrate during running activity. It was also suggested that both SLR and MLR are involved in running activity originating in the VMH.

CHANGES IN LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) FOLLOWING INJECTIONS OF A $GABA_A$ ANTAGONIST INTO THE DORSOMEDIAL HYPOTHALAMUS OF RATS. T.J. Sajdyk*, A.Shekhar, J.S. Katner, W.J. McBride and E. Chernet Dept. of Psychiatry, Indiana Univ. Med. Center, Indianapolis, Indiana 46202.

Previous studies have shown that rats injected with a $GABA_A$ antagonist into the dorsomedial hypothalamus (DMH) exhibit panic-like responses (Shekhar, Biol. Psychiatry, 36:748-58;1994). The purpose of this study was to identify other neuroanatomical sites possibly involved in mediating this panic-like response using the [^{14}C] 2-deoxyglucose (2-DG) autoradiographic method (Sokoloff et al., J. Neurochem.,28:897-916;1977). Rats were fitted with femoral arterial and venous catheters as well as unilateral, chronic injection cannulae into the DMH. They were injected with either 20 pmol/100 nl of BMI or artificial cerebrospinal fluid (a-CSF, 100 nl) into the DMH along with intravenous injection of 2-DG (125 uCi/Kg). The ensuing physiological response was recorded and series of blood samples were taken to determine plasma glucose and [^{14}C] concentrations. Rats were sacrificed, their brains serially sectioned and regional LCGU values were determined. A significant increase in LCGU on the BMI injected side were seen in the DMH; lateral, paraventricular, arcuate and posterior hypothalamic nuclei; CA1 region; and central gray. A significant decrease in LCGU was observed in the basolateral amygdala. These results indicate that activity in several discrete nuclei are altered during the panic-like response induced by BMI injections into the DMH of rats (Supported by MH 45362).

NOREPINEPHRINE RELEASE FOLLOWING $GABA_A$ RECEPTOR BLOCKADE IN THE DORSOMEDIAL HYPOTHALAMUS OF CONSCIOUS RATS: AN IN-VIVO MICRODIALYSIS STUDY. J.S.Katner* A.Shekhar, Sajdyk, T.J., R.R.Kohl, Dept. of Psychiatry, Indiana University Medical Center, Indianapolis, Indiana 46202.

Blockade of $GABA_A$ receptors by locally injecting the antagonist bicuculline methiodide (BMI) into the dorsomedial hypothalamus (DMH) causes a panic-like response which includes increases in heart rate (HR), blood pressure (BP), respiratory rate, as well as "anxiety". Rats experiencing "anxiety" in a fear-potentiated startle test have shown increases in norepinephrine (NE) tissue levels in the DMH. Using in-vivo microdialysis, the present study sought to determine changes in extracellular NE levels following superfusion of different concentrations of BMI into the DMH. Rats were implanted with femoral arterial catheters and microdialysis probes into the DMH. After 24 hours, the DMH of conscious rats were perfused with either 100, 150 or 200 mM BMI solutions via the microdialysis probe. HR and BP responses were recorded and the extracellular levels of NE in the DMH were determined from the perfusates by using high pressure liquid chromatography. Rats receiving BMI injections showed dose-dependent increases in extracellular NE levels in the DMH. These results suggest that in the DMH, increased NE release may be closely connected with $GABA_A$ receptor blockade and the associated panic-like response. (Supported by MH 45362)

SELECTIVE DISTRIBUTION OF LACTATE DEHYDROGENASE ISOENZYMES IN NEURONS AND ASTROCYTES: EVIDENCE FOR ACTIVITY-DEPENDENT METABOLIC TRAFFICKING

P. Bittar[1], Y. Charnay[1], M. Kiraly[2]*, L. Pellerin[2], C. Bouras[1] and P.J. Magistretti[2]. [1]Département de Psychiatrie, Université de Genève and [2]Institut de Physiologie, Université de Lausanne, Switzerland.

We have observed that glutamate stimulates in a concentration-dependent manner (EC_{50} = 78 μM) glucose uptake into and lactate efflux from mouse cortical astrocytes by a mechanism involving a Na^+-dependent glutamate transporter [LP & PJM (1994) *PNAS* **91**:10625-10629]. Lactate was shown to originate from extracellular glucose. Glutamate uptake did not affect glucose uptake or lactate release in neurons however. Since glutamate is the main excitatory neurotransmitter released by activated neurons, we postulated that lactate produced by astrocytes could serve as an energy fuel for neurons during period of activation. Production and utilization of lactate require the presence of the enzyme lactate dehydrogenase (LDH). Five major LDH isoenzymes have been described. At one end, the LDH-1 (heart type) isoenzyme favors the formation of pyruvate from lactate, while the LDH-5 (muscle type) isoenzyme preferentially catalyzes the reaction in the opposite direction. We have developed and characterized two antisera (Abs) raised against the LDH-1 and -5 subunits from rabbit. The specificity of each antiserum was verified by immunohistochemistry , immunoblot and western blot analysis. Immunohistochemistry on 10 post-mortem control human cases revealed a differential cellular distribution in the hippocampus: neurons were exclusively stained with the anti-LDH-1 Ab while astrocytes were stained by both Abs. These observations are consistent with the idea that neurons process lactate to pyruvate which can then enter the TCA cycle, while astrocytes can glycolytically produce lactate from glucose; the data also support the view of a metabolic exchange between astrocytes and neurons *in vivo* especially during activation.

THE DIRECT EFFECTS OF ALTERED GLUCOSE CONCENTRATION ON THE ISOLATED RAT MIDDLE CEREBRAL ARTERY (MCA). M.W.G. Swafford, M.Y. Eichler, R.M. Bryan, Jr.* Dept. of Anesthesiology, Baylor College of Medicine, Houston, TX 77030

The direct effects of altered glucose concentration was studied in cerebral arteries. Rat MCAs were isolated, immersed in a bath (37° C) containing physiological saline solution, pressurized to 85 mm Hg, and luminally perfused. Each MCA was magnified with an inverted microscope and the image displayed on a video monitor. Changes in the diameter were measured after altering the luminal and abluminal glucose concentrations.

Decreasing the glucose from 5.5 mM to 1.5, 1.0, and 0.5 mM for 1.5 hours each had no effect on the diameter of the arteries. When all the glucose was removed for 1.5 hours, the MCAs dilated by 23% [252 ± 9 μm to 311 ± 3 μm ($p<0.05$, n=7)]. When all Ca^{+2} was removed from the bath, the MCAs further dilated to 35 ± 5 % of control indicating that maximum dilation did not occur as a result of hypoglycemia alone. When glucose was restored (100 mg/dl), the MCA diameters returned to control. Removal of the endothelium did not alter the response of the isolated MCAs to reductions in glucose. Furthermore, inhibition of the ATP sensitive K^+ channels with 10^{-4} M glibenclimide did not alter the response to glucose.

We conclude that isolated MCAs were relatively resistant to hypoglycemia since all glucose had to be removed before dilations occurred. This is in contrast to cerebral blood flow in intact rats which shows a dramatic increase when plasma glucose falls below 2.5 mM. The direct effects of hypoglycemia on the MCA did not involve endothelial vasodilatory mechanisms or ATP sensitive K^+ channels. (PHS PO1 NS 27616).

HYPERGLYCEMIA DOES NOT ALTER REGIONAL CEREBRAL BLOOD FLOW (rCBF) OR REGIONAL CEREBRAL BLOOD OXYGENATION (rCBO) CHANGES IN CORTICAL SPREADING DEPRESSION (CSD) IN RATS. U.Lindauer*, T.Wolf, A.Villringer, U.Dirnagl. Dept. of Neurology, Humboldt University Berlin, Germany.

Cortical spreading depression may play a role in the pathology of migraine and cerebral ischemia. The event of CSD, as an intense stimulus of energy metabolism, is in the normal brain followed by marked increases in rCBF, rCBO and tissue lactate concentration. Glucose is the main substrate of energy production in the brain. We tested the hypothesis as to whether glucose may be involved in the mediation of CSD related changes in rCBF and rCBO under normoglycemic and hyperglycemic conditions. In parietal cortex of α-chloralose anesthetized, ventilated rats under full physiological control, we measured rCBF with laser Doppler flowmetry (LDF) through the thinned bone. rCBO (oxyhemoglobin: HbO_2, deoxyhemoglobin: Hb) and oxidized mitochondrial cytochrome aa_3 (CytO) were measured through the intact skull with near infrared spectroscopy (NIRS). The DC potential was monitored epidurally. CSD was induced every 15min by topical application of KCl 10mm anterior from the measuring site. After 1h of normoglycemic CSD recording, hyperglycemia was induced by i.v. glucose application (1ml of 20% glucose solution as a bolus, followed by infusion of 2ml/h 40% glucose solution). A drop in blood pH due to hyperglycemia was balanced by mild hyperventilation. During hyperglycemia CSD was induced every 15min for 1h. Results are summarized in the table:

n=4, *p<0,05 mean ± SD	blood glucose (mmol/l)	bas. rCBF (%)	Δ rCBF (%)	Δ HbO_2 (arb.units)	Δ Hb (arb.units)	Δ CytO (arb.units)
normoglycemia	5.1 ± 0.7	100	+524 ± 98	+35 ± 3	-11 ± 5	-6.2 ± 0.2
hyperglycemia	18.4 ± 3.3*	91 ± 12	+540 ± 95	+35 ± 6	-10 ± 4	-6.6 ± 1.6

rCBF and rCBO responses to CSD were not affected by hyperglycemia, which points against a role of glucose in the coupling of metabolism and rCBF during CSD. (Supported by the Deutsche Forschungsgemeinschaft).

RELATIVE CONTRIBUTIONS OF GLYCOLYSIS AND OXIDATIVE PHOSPHORYLATION TO METABOLISM OF PRIMARY HIPPOCAMPAL CULTURES, AS ASSESSED BY MICROPHYSIOMETRY. J.A. Trafton, O.A. Ajilore and R.M. Sapolsky.* Biology Dept. Stanford University, Stanford, CA 94305.

Microphysiometry is a technique which measures real time changes in proton efflux rate in cultured cells or tissue slices. It is generally interpreted as measuring metabolic rate, based on the idea that metabolic processes produce hydrogen ions as lactic and carbonic acid in proportion to activity. A problem in interpretation occurs, in that glycolysis contributes 6 times as many protons/ATP as does oxidative phosphorylation. Thus, shifts in the balance between oxidative and glycolytic metabolism would change acid production, which might be wrongly interpreted as an altered metabolic rate. To distinguish between the glycolytic and oxidative contributions, we compared proton efflux rates measured in cultures given glucose and pyruvate as substrate versus pyruvate alone. At pH 7.4, approximately 90% of total metabolism was attributable to glycolysis with only 10% due to oxidative phosphorylation. Acidosis has been shown to inhibit NMDA receptor currents and to protect cultured neurons from excitotoxic insults; commensurate with that, we found that acidosis decreased proton efflux rates in cultures. We explored whether this decrease represented a true metabolic decline. While significant declines in proton efflux rate at lower pH's were still obvious in cultures restricted to oxidative metabolism, a shift toward oxidative metabolism was seen following acidification. At pH 6.4, glycolysis contributed less than 60% of total metabolism. Acidity still decreased the rate of proton production under conditions bypassing glycolysis, with a decline to < 50% of pH 7.4 levels at pH 6.4. This suggests that while acidity indeed decreases metabolic rate, it also shifts energy production towards oxidative metabolism. While the implications of this are unclear, it hints at the complexity of acid's metabolic effects and highlights the need for caution in interpretating microphysiometric data.

AUTOREGULATION OF CHOROID PLEXUS BLOOD FLOW DURING ACUTE HYPERTENSION. C. A. Hathaway, R. Du, S. B. Waller*, J. L. Williams. Univ. of South Dakota School of Medicine, Vermillion, SD 57069

Autoregulation of cerebral blood flow (CBF) has been well characterized. In contrast, autoregulation of choroid plexus (CP) blood flow (BF) has not been examined. The goal of this study was to determine whether BF to CP autoregulates during moderate increases in mean arterial pressure (MAP).

BF was measured with radioactive microspheres in anesthetized rabbits. In 5 animals, MAP to the head was increased 39 ± 10 mmHg (mean ± SD) by aortic occlusion. BF to CP of the lateral ventricle was unchanged by occlusion (347 ± 148 to 388 ± 85 ml/min/100g). In contrast, occlusion increased BF to the fourth ventricle (216 ± 37 to 428 ± 163 ml/min/100g, p=0.054). CBF was unchanged (78 ± 35 to 95 ± 34 ml/min/100g).

In other rabbits, MAP was increased 36 ± 8 mmHg by IV norepinephrine. BF to CP of the lateral ventricles was similar during control and norepinephrine (288 ± 173 to 259 ± 98 ml/min/100g). BF to CP of the fourth ventricle also was not changed (276 ± 112 to 307 ± 256 ml/min/110g) by norepinephrine.

In 3 rabbits, we measured the rate of autoregulation of BF of CP of lateral ventricle with laser Doppler flowmetry during aortic occlusion, which increased MAP 59 ± 17 mmHg. During aortic occlusion, CPBF and CBF increased 20 ± 7% and 45 ± 8% initially, and autoregulated 50% in 5.3 ± 6.3 s and 3.5 ± 1.8 s, respectively. Final autoregulation of CPBF and CBF occured in 13.8 ± 18.4 and 16.7 ± 8.8 s.

Our findings indicate that CPBF autoregulates rapidly during moderate increases in MAP.

COMPARISON OF THE ONTOGENY OF BRAIN OXIDATIVE METABOLISM *IN VIVO* VS *IN VITRO*: AN NMR SPECTROSCOPY STUDY E. J. Novotny, Jr., C. Ariyan, Y. Akiyama*, J.P. O'Reilly, K.L. Behar, G.G. Haddad Depts of Pediatrics and Neurology, Yale Univ., Sch. of Med., New Haven,CT 06510

It has been shown by indirect measurements that oxidative metabolism of brain glucose increases during development. Because the high chemical specificity of NMR spectroscopy permits direct determination of particular metabolic fluxes, we chose to study brain oxidative metabolism in the rat. We also chose to determine whether we can study such questions not only *in vivo* but also in slices in order to probe at mechanisms. A comparison of neocortical glucose oxidative metabolism between slices (400-micron thick) and *in vivo* brain tissue was therefore performed in 10 d vs. 30 d rats using 1-^{13}C glucose combined with proton-observe, ^{13}C-edited NMR spectroscopy. The ^{13}C enrichment of specific carbon positions of glutamate were measured at various time points in perchloric acid extracts of frontoparietal cortex from *in vivo* and slice experiments following administration of ^{13}C labeled glucose. Both the rate of ^{13}C label incorporation into and steady-state isotopic fraction of the C4 carbon of glutamate (glu-C4) were significantly smaller in the 10 d vs 30 d rats *in vivo* ($T_{1/2} \simeq$ 22 vs 10 min; FE=0.2 vs 0.3). In contrast, the difference in the rate of label incorporation into glu-C4 was less in the slices of immature than mature brains ($T_{1/2} \simeq$ 28 vs 22 min) and there was no difference in the isotopic fractions at 120 min (FE=0.34 vs. 0.35). Our results show for the first time that glucose oxidation can be measured directly in as little as two 400 micron slices using this technique. Our conclusions so far indicate that: 1) the lower glu-C4 FE of the immature brain compared to the mature one indicates that sources other than glucose can be used for oxidative metabolism and 2) although differences in glucose oxidation between *in vivo* and *in vitro* conditions are present at both ages, our data suggest that glucose oxidation is more closely correlated with connectivity in the mature than immature brain. (Supported by NS32578, HD32573).

SPATIAL DISTRIBUTION OF LDH ISOFORMS IN RAT BRAIN IN COMPARISON WITH SDH AND INTRACELLULAR pH. K. L. Lauro, W. D. Lust, J. C. LaManna*, Case Western Reserve University and School of Medicine, Cleveland, OH; 44106

As part of a larger study on adaptation to chronic hypobaric (.5 ATM) hypoxia, we measured micro regional succinate dehydrogenase (SDH) and lactate dehydrogenase isoenzymes (total LDH, LDH-M inhibited and LDH-H inhibited) in the normoxic rat brain through histochemical staining. Activity of the mitochondrial SDH and cytosolic LDH-H is indicative of oxidative capacity, while LDH-M is indicative of glycolytic metabolism. Additionally, pH, was measured via neutral red histophotometry to determine whether pH, is indicative of type of metabolism verses level of metabolic activity. Animals were frozen in situ after neutral red infusion. The frozen block face was photographed for pH analysis prior to removing 6 consecutive 20 or 6 micron sections. Tissue stained for LDH was defatted prior to staining.

LDH-M was most prevalent in regions of highest glycogen content, ie. the hippocampal regions of the oriens, radiatum, and astrocytic layer adjacent to the granular layer of the dentate gyrus. The marked exception to this was the oxidative region in the proximal radiatum of CA3.

The oxidative profile depicted by SDH was similar to LDH-H, yet there were distinct differences, possibly indicating as unique functional role for LDH-H. LDH-H was prominent in the pyramidal cell bodies of the hippocampus, yet SDH was nearly absent. The cerebellar purkinje cells had higher amounts of all LDH isoenzymes than the granular cells, but comparable amounts of SDH. While SDH and LDH-M was virtually absent in the corpus callosum, LDH-H was present in the in low amounts. Capillaries stained heavily for LDH-H. In the regions studied, pH, correlated with degree of oxidative metabolism. Regions of high oxidative enzyme activity, are slightly more acidic than the cortex, while regions with high glycolytic capacity tend to be alkaline. The exception to this was the columnar acidic pattern in the glycolytic radiatum, possibly indicative of activation.

656.8

NON-CLASSICAL PATTERN OF CEREBRAL BLOOD FLOW (CBF)–PRESSURE AUTOREGULATION. S.C. Jones*, C.R. Radinsky, A.D. Perez-Trepichio, Cerebrovascular Res. Lab, Cleveland Clinic Foundation, Cleveland OH 44195.

CBF–pressure autoregulation has been typically characterized by a plateau until the lower limit (LL) is reached, when CBF becomes linearly related to pressure. We have investigated variations in this classical pattern.

Thirty-five Sprague-Dawley rats (389±8 g, SEM) were anesthetized (halothane, N_2O, O_2, body temperature 37°C). The first day a plastic cranial window was implanted and the animal was allowed to recover. The second day, animals were anesthetized, tracheotomized, ventilated, and catheters were placed. Physiologic variables (MABP, $PaCO_2$, PaO_2, and pH) were stabilized. CBF was determined using laser Doppler flowmetry. Animals with low CO_2 and ADP reactivity were excluded. MABP was sequentially lowered by exsanguination to 100, 85, 70, 55, and 40 mm Hg. The LL of autoregulation and patterns were visually identified from the CBF vs MABP plots as either "classical" (n=18), "peak" (n=11) or "none" (n=6). The classical pattern exhibited a plateau followed by a pressure-passive drop. The peak pattern was characterized by a rise in CBF from control as pressure decreased, followed by a fall. No autoregulation (none) consisted of a linear fall of CBF from 100 to 40 mm Hg.

A clear difference between the classical, peak, and none patterns is evident (RM-ANOVA, $p<0.001$; *,**: $p<0.05$, 0.01, Scheffe). The classical and peak lower limits were similar (75±4 and 69±3 mm Hg). The peak pattern has been observed previously by Chen et al (Stroke 15, 343) and indicates that vessels are over-dilating in response to the pressure decrease. Almost a third (31%) exhibited no autoregulatory plateau up to a MABP of 100 mm Hg in spite of acceptable CO_2 and ADP responses. (Support: NSF IBN 90-22190)

CEREBRAL VASOMOTION: 0.1Hz OSCILLATION IN IMAGING OF NEURAL ACTIVITY. J. E.W. Mayhew, S. Askew, Y. Zheng, J. Porrill, G.W.M. Westby, P. Redgrave, D. M. Rector, R.K. Harper* and R. M. Harper. AIVRU, University of Sheffield, Sheffield, S10 2TP, U.K.; Dept. Anatomy and Cell Biology, UCLA, Los Angeles, CA, 90095-1763, U.S.A.

Reflected light from the surface of neural structures can reveal the functional architecture within large populations of neurons. The signals are derived from multiple sources, including cerebral microcirculation, light scattering properties of active neurons, and possibly glia. We collected image sequences of reflected light at video frame rates (25Hz), using a miniaturized camera and fiber optic probe, and determined that a principal component of intrinsic signals is a modulation of a pervasive low frequency oscillation in the local microvasculature. This oscillation, of approximately 0.1Hz, is present in many structures; the rat cerebral cortex, striatum, thalamus, superior and inferior colliculus, and cerebellum, and cat hippocampus, together with faster (100Hz) and slower components. Although the mechanisms producing the 0.1Hz signal are uncertain, a similar vasomotion oscillation occurs in the peripheral circulation. Concurrent laser doppler flowmeter measures find comparable low frequency signals; however, the image analyses additionally revealed a complex spatio-temporal structure to the 0.1Hz signal, with stimulation-specific patterns. Coherence analyses indicated that the signals cannot be attributed to simple motion artifacts associated with the cardiac or respiratory cycles. Significant regional modulation of the phase structure and amplitude of the 0.1Hz signal emerged in transitions between sleep states, following visual, auditory and noxious stimulation, and following electrical stimulation of the imaged tissue. Reflected light imaging provides a means to assess modulation of microcirculation spatio-temporal dynamics by populations of active neurons. *(Supported by HL-22418, NIDR DE-07212, and Wellcome Trust 038011/Z/93.)*

CAPILLARY MODULES IN MOUSE CORTICAL BARRELS. J. Sui, C.M. Rovainen*, T.A. Woolsey, Departments of Neurology & Neurological Surgery and Cell Biology & Physiology, Washington University School of Medicine, St. Louis, MO 63110.

A penetrating arteriole which is injected with dye and the surface venules from which dye emerges is an *arteriolar domain* which approximates the area of but does not coincide with a cytochrome oxidase stained barrel in layer IV (Sui et al, '94). To test the hypothesis that an internal terminal arteriole and its capillary "module" is matched to a barrel, adult mice were fixed with mixed aldehydes. Penetrating arterioles and their terminal branches were stained by perfused Rose Bengal. The cortex was cut vertically or tangentially at 200μm with a vibratome and barrels visualized with oblique lighting. In tangential sections 1-2 terminal arterioles supplied each layer IV barrel. Arteriolar branches in layer III were impaled with 3μm glass micropipetes; injected dye was recorded by videomicroscopy progressing from arterioles into capillaries and then venules. Side branches from a vertical arteriole supplied modules of capillaries within the barrels. The capillary modules matched to neural modules, manifest as barrels, are a substrate for control of LCBF to a single cortical column during neural stimulation.

WHISKER EVOKED LCBF IN DIFFERENT LAYERS OF RAT BARREL CORTEX. **Yu. Moskalenko, C.M. Rovainen, T.A. Woolsey, D.Liu, V. Sememia, N. Malisheva, W.M. Landau*, Sechenov Institute of/for Evolutionary Physiology and Biochemistry, Russian Academy of Science(s), St.Petersburg, Russia and Departments of Neurology & Neurological Surgery and Cell Biology & Physiology, Washington University School of Medicine, St.Louis, MO 63110.**

Dynamic changes in local cerebral blood flow (LCBF) were monitored simultaneously in cortical layers I-III and IV-V by H_2 clearance. Three Pt electrodes with diameters of 40-60μm and 150-200μm exposed lengths were inserted at 25-30° to the pia in whisker barrel cortex targeted by intrinsic signals in rats anesthetized with 1g/kg urethane. H_2 was generated steadily from the middle electrode; the changes in PH_2 were recorded at the upper and lower electrodes. Resting LCBF levels determined by clearance after H_2 inhalation were 20-30% higher in the middle than superficial layers. Single, rows, or all contralateral whiskers were stimulated mechanically at 3 Hz for 1 min for 5 trials which were averaged. In many cases there was an initial decrease in apparent LCBF. Increases in LCBF up to 30-35% were larger in middle layers. These results are consistent with a model for blood flow regulation in which layer IV afferent stimulation initiates LCBF increases.

SYNCHRONIZATION OF EEG ACTIVITY IN CEREBRAL CORTEX BY STIMULATION OF NUCLEUS TRACTUS SOLITARII (NTS) IN RAT: COUPLING TO CEREBRAL BLOOD FLOW AND MEDIATION BY ROSTRAL VENTROLATERAL MEDULLA (RVL). E.V. Golanov* & D.J. Reis. Dept. Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

Electrical stimulation of NTS in cat synchronizes EEG activity (Magnes et al., *Arch. Ital. Biol.* 99:33, 1961). We investigated whether NTS stimulation in rat elicits a comparable response, if it is mediated through RVL and is coupled to the changes in cerebral blood flow (rCBF) mediated by that nucleus (Golanov & Reis, *J. Cereb. Blood Flow Metab.* 14:492, 1994). Rats were anesthetized, spinalized and ventilated while monitoring electrocorticographic activity (ECoG). rCBF was recorded by laser-Doppler flowmetry. Electrical stimulation of NTS (50 Hz, 5 sec, 50 mA) globally synchronized ECoG activity within 1 sec and increased, for 30-60 sec, the powers of the 4-5 Hz and 8 Hz components by >100% ($p<0.01$) (as assessed by fast-Fourier transformation, FFT). rCBF was increased within 1 sec, reached maximum (8±1%; $p<0.05$) by 4-5 sec and declined with ECoG recovery. The stimulus-response characteristics of ECoG and rCBF were comparable (optimal frequency at ~50 Hz and threshold currents at ~20 mA) with active sites located in commissural NTS. Electrical or chemical stimulation of RVL elicited comparable but more potent effects: ECoG synchronization was accompanied by increases in the 4-6 Hz and decreases in the 1-3 Hz-components ($p<0.01$) and rCBF was elevated by 18±3% ($p<0.01$). The active zone in RVL was caudal to the sympathoexcitatory region and bilateral electrolytic lesions therein blocked the synchronization of ECoG and elevation of rCBF elicited from NTS. We conclude: (a) excitation of commissural NTS synchronizes the ECoG and coordinately elevates rCBF; (b) the responses result from excitation of neurons in a subzone of RVL; (c) the pathway may be relevant to some behaviors elicited by natural stimulations of visceral afferents and intrinsic neurons of RVL.

PRACTICAL INTRACRANIAL ANEURYSM HEMODYNAMICS D.J. Vincent* and J.A. Horton. Department of Radiology, Med. Univ. of S. Carloina, Charleston, SC 29425

To identify the basic underlying principles governing aneurysm hemodynamics, we examined flow patterns in viscoelastic aneurysm models. A pulsatile pump provided realistic flow, and injected food coloring marked flow streams. Each model has several aneurysms in series, and they differ by a single variable--either diameter of aneurysm or relative width of neck. This permitted us to make direct comparisons. We found that angular flow velocity varies inversely with aneurysm diameter; we also found that in aneurysms of similar size, the one with the wider neck will have more rapid angular flow. These results suggest roughly quantitative rules that govern the speed and turbulence of flow within aneurysms. They also have implications regarding aneurysm hemorrhage and growth.

REGIONAL CEREBRAL DEOXYGLUCOSE UPTAKE IN PREWEANLING RATS UNDER CONDITIONS OF BEHAVIORAL ACTIVATION. M. W. Lilliquist*, F. Gonzalez-Lima, & A. Amsel. Dept. of Psychology & Institute for Neuroscience, University of Texas at Austin, Austin, TX 78712.

A previous report of regional deoxyglucose (2DG) autoradiography in freely moving rats (Nehlig et al., 1988) revealed a developmental pattern from low and uniform rates of 2DG utilization in preweanling animals to higher and more heterogeneous rates in adult animals. Importantly, animals in this previous study were maintained in a small holding box throughout the 2DG uptake period. We report ^{14}C(U)-fluorodeoxyglucose (FDG) uptake values in preweanling animals under conditions of behavioral activation: appetitive learning in a straight-alley runway under different schedules of reinforcement. Under these conditions, we find significant heterogeneity of FDG uptake, revealing far greater differentiation of metabolic indices from low-activity regions to high activity regions. Methodological differences between the present and previous studies, which may contribute to the different findings, will be presented. It is suggested, however, that the relationship between regional cerebral metabolic activity and behavioral maturation may be better reflected under conditions of behavioral activation. Similar findings concerning resting vs. active state in human brain imaging studies will be discussed. (Supported by NIH grants RO1MH43353 and AA07052.)

656.15

POTENTIATION OF INTERSTITIAL ADENOSINE WITH NITROBENZYLTHIOINOSINE (NBTI) AMERLIORATES DELAYED CORTICAL HYPOPERFUSION FOLLOWING GLOBAL CEREBRAL ISCHEMIA IN THE PIGLET. Y.B. Kim, T.S. Park, E.R. Gonzales, A.R. Shah, M.J. Noetzel*, J.M. Gidday. Departments of Neurology and Neurological Surgery, Washington University School of Medicine, St. Louis, MO 63110

A period of delayed hypoperfusion characterizes reperfusion (RP) following transient global cerebral ischemia. Concomitantly, reactivity of the cerebral vasculature to many physiologic and pharmacologic stimuli is impaired. We tested the hypothesis that increases in cerebral blood flow (CBF) during RP could be realized by augmenting endogenous adenosine (ADO), a potent cerebral vasodilator. Microdialysis probes containing platinum wires for measurement of local CBF by hydrogen clearance were inserted bilaterally into the cortex of 9 isoflurane-anesthetized newborn pigs. One probe was perfused with the ADO transport inhibitor NBTI (100μM in mock CSF at 2 μl/min), the other with mock CSF alone. Measurements of [ADO] (μM) and CBF (ml/min/100g) were determined at 20-min intervals during RP following 10-min of global cerebral ischemia induced by ligation of brachiocephalic and subclavian arteries. The table shows that both ADO and CBF were reduced during post-ischemic RP, but [ADO] elevation by NBTI lessened the extent of delayed hypoperfusion. (*p<0.05 vs baseline; †p<0.05 vs control side).

	Baseline	20-40 min RP	40-60 min RP
[ADO] (control)	1.44±0.17	0.83±0.11 *	0.74±0.08 *
[ADO] (NBTI)	3.45±0.67 †	2.67±0.74 †	1.89±0.24 *†
CBF (control)	39±3	19±3 * (-51%)	22±2 * (-42%)
CBF (NBTI)	60±4 †	43±3 *† (-28%)	45±3 *† (-24%)

These results suggest that adenosine can improve post-ischemic tissue perfusion, and, in so doing, may contribute to its neuroprotective effect.

656.16

ELEVATION OF CYTOKINES IN THE CSF OF THE PATIENT WITH VASOSPASM AFTER SUBARACHNOID HEMORRHAGE. M Suzuki*, T Mase, M Sohma, K Miura, M Doi, A Kudo, N Kubo, K Kuroda, A Ogawa, S Endo and K Inada Depts Neurosurg, Bacteriology, and Crit care & Emreg Center, Iwate Med. Univ., Morioka 020 Japan

It has been focused that inflammation occurs in the CSF space after subarachnoid hemorrhage (SAH), and causes delayed vasospasm (VS). To clarify the detail of this mechanism, we analyzed cytokines (TNF, IL-6, IL-8, IL-1β, IL-1 RA) and soluble component of the adhesion molecules (ICAM-1, VCAM-1, ELAM-1) in the CSF and blood. Clinical materials were ten patients of severe SAH. CSF and blood were obtained 3 times simultaneously (day 3-5, 7-9, 12-14) after the onset. VS was diagnosed with angiography and neurological symptoms.

IL-6, IL-8, IL-1β, IL-1 RA were significantly higher in the CSF than in the blood ($p<0.05$). IL-6 and IL-1 RA was higher in the CSF of the patients with VS ($p<0.05$) during day 7-9 than the VS negative patients. Besides, IL-1 RA was also higher in the blood of the VS patients in the same period ($p<0.05$). The value of the adhesion molecules were significantly higher in the blood than in the CSF at any sampling points, but no relation was found to VS. Unique behavior of cytokines, especially IL-6 and IL-1RA, indicates the presence of specific inflammation in the CSF milieu. Elevation of the adhesion molecules in the blood may not contribute provocation of the inflammation in the CSF. Although the sources of IL-6 and IL-1 RA in the CSF are still unknown, understanding of the initiation of the inflammation in the CSF following SAH may open the therapeutic window for the prevention of VS.

ANGIOGENESIS ACCOMPANIES MAST CELL PROLIFERATION IN EXPERIMENTAL NEUROMAS. **C. Nguyen, T.E. Feasby*, D.W. Zochodne University of Calgary, Calgary, Canada T2N 4N1**

We studied changes in local blood flow, mast cells and blood vessel anatomy in experimental sciatic nerve 'neuromas' of rats (created by sectioning of the midsciatic nerve and resection of the distal nerve and its branches to prevent regeneration). In previous work, we reported that rises in blood flow of early (48 hour) sciatic neuromas were mediated by local CGRP (calcitonin gene-related peptide) accumulation with vasodilation whereas persistent rises in blood flow at later time points (14 days) were not associated with CGRP. In this work, we studied the vascular anatomy of experimental neuromas by infusing, through a femoral catheter, anaesthetized rats with gelatinized India ink prior to euthanasia. Neuromas and intact contralateral nerves were then removed, frozen and sectioned unfixed. Numbers and areas of individual perfused vessels in transverse section were measured using a computerized image analysis setup. Starting at 7 days following neuroma creation, multiple thin walled perfused microvessels were noted, most prominently in the loose connective tissue around the outside of the neuroma. The size and multiplicity of these perfused vessels indicated angiogenesis with vascular proliferation. Similar findings were not observed in contralateral intact nerves, sham-exposed nerves, or 'neuromas' at earlier time points. These microvascular changes paralleled rises in transverse nerve area, and mast cell numbers, density and degranulation from previous work.

Persistent rises in local blood flow of experimental neuromas are associated with a proliferative cellular response involving microvessels, mast cells and likely other tissue elements.

•LOCAL CEREBRAL GLUCOSE USE IN RETINOFUGAL TARGETS AFTER PARTIAL AND TOTAL RETINAL DEAFFERENTATION: A 2-DG STUDY. •U.Schmitt†, B.A. Sabel†, R. Cross♦, F.E. Samson♦ and T. Pazdernik†* †Inst. Med. Psychol., Univ. Magdeburg, Germany. ♦R.L. Smith Res. Cent. Univ. Kansas Med. Ctr., Kansas City, KS 66160.

• Rats given an optic nerve crush partially regain metabolic activity in retinofugal targets despite a 90% loss of retinal ganglion cells. Thus, there is either some restoration of information transfer from retina to brain or there is an adaptation such that visual function occurs with less information transfer. The 2-[^{14}C]deoxy-glucose technique was used to determine local cerebral glucose use (LCGU) as an assessment of information transfer from retina to brain visual centers. Male adult Long Evans rats were given a mild crush (6/group) or cut (3/group) to the right optic nerve and LCGU was assessed 2, 9 or 8 (cut) days later. The LCGU procedure was determined during stimulation with a flasing strobe-light and rotating bar pattern with or without physostigmine (300μg/Kg; i.m.), a cholinesterase inhibitor known to activate retinocollicular pathways. Quantitative analysis of LCGU autoradiograms according to the Sokoloff equation from rats 2 days after crush revealed a marked reduction in LCGU in all retinofugal targets. There was some restoration of LCGU at 9 days after crush and at this time there was not a statistically significant difference from values 8 days after the cut. Physostigmine treatment enhanced suppression of retinal driven metabolic activity and, therefore, the increase in glucose metabolism between day 2 and 9 was greater. These results provide evidence that LCGU in retinfugal targets is partially restored due to relief of an early lesion dependent depression of neuronal activity (Diaschisis).

ISCHEMIA ALTERS CEREBROVASCULAR K^+ CHANNEL FUNCTION IN PIGLETS. D. W. Busija*, and T. M. Louis. Dept. of Physiol./Pharmacol., Bowman Gray School of Medicine, Winston-Salem, NC 27157, and Dept. of Anat./Cell Biology, East Carolina University, Greenville, NC 27858.

Previous studies have shown that ischemia alters ion channel function in cortical neurons in piglets (AJP: 265; H389). The purpose of this study was to examine the effects of ischemia on ATP-sensitive K^+ channels in cerebral arterioles. In anesthetized piglets equipped with cranial windows, we examined arteriolar responses to aprikalim (APK) (an ATP-sensitive K^+ channel agonist) prior to and following 10 minutes of total global ischemia. Ischemia was induced by increasing intracranial pressure. Under control conditions, APK dilated arterioles by $7\pm1\%$ and $24\pm4\%$ at 10^{-8}M and 10^{-6}M, respectively (n=6). Coapplication of glibenclamide (10^{-5}M; n=9) blocked dilation to APK. Following ischemia (n=6), arteriolar dilation to 10^{-6}M APK was reduced to $8\pm4\%$ ($P<0.05$) at 1 hr and $16\pm3\%$ ($P<0.05$) at 2 hrs post-ischemia. In other animals, pretreatment with indomethacin (5mg/kg, iv), which blocks superoxide anion production in cortex, prevented attenuation by ischemia of arteriolar dilation to APK. We conclude that ischemia alters function of vascular K^+ channels probably via effects of oxygen radicals. Supported by HL 30260, HL 46558, & HL 50587.

DECREASED SENSITIVITY OF CEREBRAL CELLULAR ENERGY STATE TO HYPOXIA IN MICE FED A CREATINE ANALOGUE. D Holtzman*, R Meyers, E O'Gorman, T Wallimann. Children's Hospital, Boston, MA and Swiss Federal Inst. of Technology (ETH), Zurich, Switzerland.

The maturational increase in brain creatine kinase (CK) catalyzed reaction rate in vivo is temporally associated with the appearance of close coupling of the phosphocreatine (PCr) and ATP losses in the hypoxic mouse or rat brain (Holtzman et al., Dev. Neurosci., 1993;15: 261-270). Feeding the creatine transport inhibitor, B-guanidinopropionic acid (GPA), reduces brain CK catalyzed fluxes to the rates seen in the immature mouse (Holtzman et al., Brain Res 1989 483: 68-77) and doubles the brain cytosolic CK isozyme. Therefore, brain CK catalyzed reaction rates and isoenzyme activities were measured in mice fed GPA (2% by weight in standard chow) for at least three weeks starting at age 35 days. Controls received the chow without GPA. 31P NMR spectra and saturation transfer measures of CK catalyzed flux from PCr to ATP were acquired before, during, and after 7 min of hypoxia (6%, 4%, or 2% inspired O2). Brain PCr/nucleoside triphosphate (NTP) ratios and pH values were the same in control and GPA fed mice. Brain CK catalyzed reaction rate constants were about 40% lower in GPA fed mice than in controls ($p<.05$). Total brain CK activity doubled in mice fed GPA for 12 weeks. At each degree of hypoxia, deaths were higher in control than in GPA fed mice (6% O2, no deaths; 4%, GPA 0/6 died, controls 2/6 died; 2%, GPA 1/6 died, controls 3/6 died). AT 4% O2 GPA fed mice showed no losses of PCr or NTP while surviving control animals showed 40-60% losses of PCr. In conclusion, feeding GPA reduces sensitivity to hypoxic death and to losses of brain high energy phosphates. Two hypotheses for these effects are: (1) the additional phosphagen represented by PCr plus GPAP provides more effective coupling of+ ATP synthesis and demand or (2) metabolic adaptations to the Cr analogue also is adaptive to hypoxia. (Supported by NINDS NS26371).

RELATIONSHIP BETWEEN FUNCTIONAL AND STRUCTURAL ABNORMALITIES IN GERTSMANN-STRAEUSSLER-SCHEINKER DISEASE, INDIANA KINDRED (GSS-IK). G. D.Hutchins, M.R. Farlow, S. R. Dlouhy, P. Piccardo, B. Ghetti*, Indiana University School of Medicine, Indianapolis, IN 46202

The relationship between functional and neuropathologic abnormalities in a patient with GSS-IK and a mutation at codon 198 of *PRNP* was studied. The patient was a 60 year old female with a twelve year history of progressive dementia, ataxia and Parkinsonism. A quantitative Positron Emission Tomographic (PET) study of brain glucose metabolism was performed, using 2-[F-18]Fluoro-2-Deoxy-D-Glucose (FDG), seven weeks prior to the patient's death. For neuropathologic studies, serial sections of the left cerebral and cerebellar hemispheres were immunolabeled with antibodies to prion protein (PrP) and Tau protein to assess PrP and PrP-amyloid deposits as well as presence of neurofibrillary tangles. Serial 10 µm thick sections were stained with haematoxylin-eosin and automatically aligned (using a 2-D registration algorithm) with adjacent 10 µm anti-PrP immunostained sections. The ratio of the area of immunostained PrP (exceeding 25% threshold of the maximum PrP accumulation in a brain slice) to the area of the cortical or subcortical structures determined on the H&E stained slices was used as an index of PrP deposition. Glucose metabolism was dramatically decreased relative to control subjects throughout the brain. The highest metabolic rates were observed in the calcarine cortex and basal ganglia (4.6 and 4.3 mg/100g/min, respectively). The remainder of the cortical structures and cerebellum had uniformly depressed metabolic rates (range 3.0-3.5 mg/100g/min). The PrP index was highest in the basal ganglia (PrP index range 0.60-0.99) and frontal and parietal lobes (PrP index range 0.4-0.74) with lower levels of accumulation in the temporal and occipital lobes (PrP index range 0.08-0.45). All metabolically impaired regions of the brain demonstrate severe PrP and PrP-amyloid deposits, suggesting a relationship between the functional and structural abnormalities. (Supported by PHS Grant NS 29822).

MOTIVATION AND EMOTION: BIOCHEMISTRY AND PHARMACOLOGY

657.1

CLOMIPRIMINE PRETREATMENT BLOCKS THE DEVELOPMENT OF SCHEDULE-INDUCED POLYDIPSIA IN RATS. B. Knutson and J. Panksepp*. Department of Psychology, Bowling Green Univ., Bowling Green, OH 43402.

In schedule-induced polydipsia (SIP), hungry rats drink excessive amounts of water when administered small food pellets on a fixed interval schedule. Because of its' strong motivational component and excessive nature, SIP has been proposed as an animal model of obsessive-compulsive disorder (OCD). In Experiment 1, we tested whether acute administration of the antiobsessional drug clomiprimine (CMI) could block the development of SIP over seven days. Two experimental groups of rats participated in daily SIP trials, during which they received 60 mg Noyes pellets at fixed intervals of 180 s over the course of an hour. A third control group did not undergo the SIP procedure, but their water intake was monitored. The first experimental group (n = 6) received an intraparietal injection of 5 mg/kg CMI 30 minutes prior to each SIP trial (the CMI-SIP group), while the second experimental group (n = 6) received an injection of vehicle 30 minutes prior to each SIP trial (the VEH-SIP group). The control group also recceived an injection of VEH 30 minutes prior to the hour-long measurement period (the VEH-CONT group). Water intake of all groups during the experimental procedure was measured. While the VEH-SIP group consumed increasing quantities of water over the course of the week, the CMI-SIP group remained at the same low levels of water intake as the VEH-CONT group. In a follow-up experiment two weeks later, the CMI-SIP and VEH-SIP groups participated in fourteen more days of the SIP procedure, this time without any pharmacological pretreatment. The CMI-SIP group took a full 10 days for drinking levels to rise to that of the VEH-SIP group. We are presently analyzing SIP as a function of central serotonin. These findings implicate a serotonergic mechanism in compulsive behaviors and suggest that CMI may prove a viable alternative to neuroleptics in the treatment of polydipsia secondary to schizophrenia in humans.

DISSOCIATIONS IN HIPPOCAMPAL 5-HYDROXYTRYPTAMINE RELEASE FOLLOWING PAVLOVIAN AVERSIVE CONDITIONING TO DISCRETE AND CONTEXTUAL STIMULI. L.S. Wilkinson, T. Humby, A.S. Killcross, T.W. Robbins and B.J. Everitt. **SPON: Brain Research Association.** Department of Experimental Psychology, University of Cambridge, Cambridge CB2 3EB, U.K.

The experiments examined the release of 5-hydroxytryptamine (5HT) in the hippocampus of freely-moving rats following pavlovian aversive conditioning to discrete and contextual stimuli. Differential conditioning was achieved by manipulating the interval between the offset of a discrete auditory "clicker" stimulus (CS+) and the onset of a footshock reinforcer. Footshock occurred either simultaneously with the last second of the CS+ (in short trace subjects) or 60 seconds later (long trace subjects). In this way, subjects were conditioned to the discrete stimulus or background "contextual" stimuli, respectively. During conditioning subjects also received two unpaired visual stimuli (CS-). At test, dialysates were collected as all animals experienced: (i) the aversive and two other "neutral" environments and (ii) the CS- and CS+, presented in both aversive and neutral environments. Exposure to the aversive (but not either of the two neutral environments) increased hippocampal 5HT release in both short and long-trace subjects, but to a significantly greater extent in the latter. In contrast, hippocampal 5HT release was unaffected by presentation of the CS+ or CS- under all conditions. These data do not agree with the hypothesis that aversive cues generally activate 5HT function. Instead, they suggest a degree of specificity whereby 5HT afferents terminating in particular target structures are differentially activated depending on the nature of, and the extent of conditioning to, the aversive stimulus - in the case of the hippocampus, by contextual and not discrete cues predictive of aversion.

657.3

INTRA-LATERAL HYPOTHALAMIC INJECTIONS OF LOW DOSES OF KAINIC ACID ELICIT LOCOMOTOR ACTIVITY. M.R. Pitzer* and D. Wirtshafter. Department of Psychology, University of Illinois at Chicago, Chicago, Il 60607.

Injections of L-glutamate into the lateral hypothalamus (LH) has been shown to elicit coordinated locomotor activity in the rat. The present study assessed the efficacy of infusing low doses of the L-glutamate analogue kainic acid (KA) into the LH of the awake freely moving adult rat.

Bilateral injections of stimulatory doses of KA (0, 5, 10, 20 or 40ng/0.5ul) produced dose dependent increases in locomotor activity which lasted for more than an hour. Moreover, locomotor activity counts, as measured in locomotor photocell boxes, did not differ when KA was injected at one of three separate rostro-caudal LH levels.

These results, which are similar to those following L-glutamate injections, suggest that the activation of KA receptors throughout the rostro-caudal extent of the LH is capable of inducing hypermotility in a dose-dependent fashion in the awake adult rat.

THE ROLE OF GALANIN IN THE VENTRAL TEGMENTUM FOR THE EXPRESSION OF DEPRESSION. M.K. Demetrikopoulos*, A. J. Turner, R.W. Bonsall, C.H.K. West, & J.M. Weiss. Dept. of Psychiatry, Emory University, Atlanta, GA 30306.

Burst firing of locus coeruleus (LC) neurons, as occurs during stress, causes release of galanin from terminals in the ventral tegmental area (VTA). It is hypothesized that galanin plays a role in depressive symptomatology by inhibiting activity of VTA dopaminergic (DA) neurons. The present study examined motor activity in a novel environment and a swim test following galanin infusion into the VTA. Experiment 1 utilized male Sprague-Dawley rats which had been selectively bred to struggle during a swim test. Awake subjects received a bilateral infusion (3.0 µg in 3.0 µl/side over 6 min) of galanin, heat-inactivated galanin, or artificial CSF vehicle. Following infusion, subjects were placed in a novel environment (plexiglas box 16 x 20 in) equipped with infrared beam sensors which recorded spontaneous locomotor activity and rearing for 40 min. Galanin reduced ambulation ($p<.01$) and rearing behavior ($p<.01$) compared to controls. Immediately following the exploratory task, subjects were exposed to a 15 min swim test. Galanin did not affect struggling activity of experimentally naive subjects, but reduced struggling in a sub-set of the subjects that had been swim-tested previously ($p<.01$). Experiment 2 tested non-struggle-selected male Sprague-Dawley rats in the swim-test immediately following galanin infusion. Infusion of galanin into VTA resulted in increased floating behavior in these subjects ($p<.04$). Overall, these data suggest that galanin infusion into VTA results in decreased motor activity and suggest a mechanism for mediation of depressive symptomatology through interaction of the LC with the VTA DA system.

ACTIVATION OF CHOLINERGIC CELLS IN THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS PRODUCES AVERSION, NOT REWARD. R. Mehta and K.B.J. Franklin* Department of Psychology, McGill University, Montreal, Quebec, Canada, H3A 1B1.

The pedunculopontine tegmental nucleus (PPTg) has been found to play a critical role in the rewarding effects of morphine and amphetamine, as demonstrated in the conditioned place preference (CPP) paradigm. This nucleus is a major source of cholinergic projections to the substantia nigra and is believed to mediate activity of dopamine neurons. The firing rate of cholinergic neurons in the PPTg is regulated by autoreceptors that can be blocked by muscarinic antagonists to increase cell firing. Thus, microinjection of muscarinic antagonists into the PPTg elicits behaviours characteristic of dopamine cell activity, such as circling. If the role of the PPTg in reward is to modulate dopamine neurons involved in reward, a muscarinic antagonist injected into the PPTg should be rewarding. To test this hypothesis, scopolamine methyl bromide (5 µg/µL to 20 µg/µL) or 0.9% saline, intra-cranially injected into the PPTg, were used as reward treatments in a balanced CPP paradigm (3 pairings). On the test day, rats treated with scopolamine methyl bromide showed a significant conditioned place aversion, suggesting that activation of cholinergic cells in the PPTg is not involved in reward.

THE NEUROCHEMICAL ORGANIZATION OF EMOTIONAL TOLERANCE IN AN AVIAN MODEL.

G. Bernroider *, M. Waldhör and B. Minnich, Institute for Zoology, University of Salzburg, Austria

Various forms of emotionally guided learning behaviour carry an intense steroidal and peptidergic-opioid component. In addition, evidence from chronic opiate application studies suggests a behavioural equivalence to some neural mechanisms inducing states of tolerance and dependence. Using a precocial avian model (naive, day-old quail chicks), we show that visually guided social learning is reflected by a gradual return of aversive behavioural reactions such as distress vocalizations, to a pre-disposed level of discomfort in course of chronic 'comforting' exposures. This parallels neural mechanisms underlaying the acquisition of tolerance to chronic drug exposure. Acute 'withdrawal effects' are behaviourally reflected by isolation induced protest vocalizations (DV) following social isolation. These findings are accompanied by a close association of opiate receptor organization with levels of behavioural expressions. [^{3}H]-etorphin binding to quail brainstem tissue is identified as the neural substrate responsive to steroid driven organizational differences in the expression of deprivation effects. In addition, the major noradrenergic sources such as locus coeruleus neurons, show congruent changes in NA turnover rates with respect to different levels of behavioural tolerance. Our model of early social learning addresses substrates of psychotropic drug addiction as adaptive components within a system facilitating social orientation.

MESOLIMBIC DOPAMINERGIC NEURONS AND AFFECTIVE PERCEPTION : INVOLVEMENT OF AMYGDALA- NUCLEUS ACCUMBENS INTERACTIONS. A. Louilot* and C. Besson. INSERM U. 259 - Université de Bordeaux II - Domaine de Carreire - 33077 Bordeaux Cedex - France.

We demonstrated previously that the responses of mesolimbic dopaminergic (DAergic) neurons to an appetitive or to an aversive stimulus are opposite in the left *core* part of the nucleus accumbens (ACC). Anatomical and functional relationships between the amygdala and the ventral striatum have been reported. In the present work, we tested the hypothesis that the DA responses to the affective value of a stimulus are dependent on the basolateral nucleus of the amygdala (BLA).

The DAergic reactivity was studied using the voltammetric measurements of DA in the ACC of freely moving male rats. Selective detection of the DA signal was obtained by the computed numerical analysis of the catechol signal. Experimental procedure was as following: animals were placed during one hour in the experimental cage; they were thus exposed for one hour to an appetitive olfactory stimulus (banana) and received consecutively either an injection of saline (NaCl 0.9%) (control group) or an injection of LiCl (0.15M) (experimental group) and stayed one more hour in the experimental cage; 72 h later animals were again exposed for one hour to the conditional olfactory stimulus (CS). Two hours before the second exposition to the CS animals received either a microinjection of phosphate buffered saline (PBS) or a microinjection of tetrodotoxin (TTX) in BLA.

The following results were obtained : during the 2nd presentation of the CS an increase of about 120% above the baseline was observed in the control group+PBS whereas DA signal decreased rapidly of about 25% in the experimental group+PBS; in the control group+TTX no significant change in DA release was observed whereas in the experimental group+TTX the olfactory stimulus induced a rapid increase of about 50% above the basal level.

The results of the present study strongly suggest that BLA is directly involved in the perception of stimulus presenting an appetitive value and that other structures interact with the BLA for the perception of the stimulus as aversive.

BLOCKADE OF NON-NMDA RECEPTORS IN THE NUCLEUS ACCUMBENS SHELL AND VENTROMEDIAL STRIATUM ELICITS INTENSE FEEDING IN RATS. C.S. Maldonado-Irizarry*, C.J. Swanson, A.E. KELLEY. Dept. of Psychiatry, University of Wisconsin-Madison Medical School, Madison, WI 53705

The present studies investigated the role of glutamatergic inputs within the ventromedial striatum in ingestive behavior. Local microinfusion of the AMPA/kainate antagonists DNQX, CNQX and NBQX (0, 0.25, 0.75 µg bilaterally) into the shell subregion of accumbens resulted in an immediate, pronounced feeding response (in sated rats) that was dose-dependent. Infusion of equimolar doses of DNQX into the core subregion, 0.8 mm lateral to the shell site, did not induce feeding. The feeding response proved to be pharmacologically selective in that infusion of NMDA antagonists AP-5 and MK-801 into the accumbens shell did not affect feeding behavior. Systemic pre-treatment with naloxone did not affect the feeding response to DNQX infusion into the shell; however, feeding was reduced upon systemic administration of D1 and D2 antagonists. Furthermore, concurrent injection of the GABA agonist muscimol into the lateral hypothalamus, a major target of shell efferents, abolished the response. A mapping study of further striatal sites indicated that no feeding was elicited from ventrolateral, posterior dorsal, anterior dorsal, and dorsomedial sites following DNQX infusion. However, a significant feeding response was obtained from the ventromedial caudate, just posterior to the accumbens. The most sensitive site thus far examined was the posterior accumbens shell. Animals infused with a low dose of DNQX (50 ng) into this region showed a striking feeding response. These data suggest that AMPA/kainate receptors in the accumbens shell, and perhaps neighboring ventromedial striatal regions, play a critical role in ingestive behavior, perhaps via the lateral hypothalamus.

NMDA ANTAGONIST AP5 BLOCKS THE ANXIOGENIC EFFECT AND LACTATE INDUCED PHYSIOLOGICAL AROUSAL CAUSED BY CHRONIC GABA DYSFUNCTION IN THE DORSOMEDIAL HYPOTHALAMUS OF RATS. A.Shekhar* and S.R.Keim Dept. of Psychiatry, Indiana Univ. Med. Center, Indianapolis, Indiana 46202.

The present study was conducted to test if the panic-like state caused by chronic dysfunction of GABA inhibition in the dorsomedial hypothalamus (DMH) is due in part to increased N-methyl-D-aspartate (NMDA) receptor mediated excitatory tone and therefore can be blocked by acute injection of the NMDA antagonist AP5. Rats were fitted with femoral arterial and venous catheters and baseline response in the social interaction (SI) test of anxiety as well as heart rate (HR) and blood pressure (BP) responses to sodium lactate infusions (10 ml/Kg i.v.) were obtained. Unilateral, chronic injection cannulae connected to a detachable Alzet infusion pump filled with the GABA synthesis inhibitor l-allylglycine (l-AG; 3.5 nmoles/0.5ul/hr) were implanted into the DMH. After 4 days, rats were tested in SI and with i.v. lactate infusions to establish the development of anxiety and increased HR and BP responses to lactate. On days 6 and 7 of l-AG infusions into the DMH, after injection of either artificial cerebrospinal fluid (a-CSF) or the NMDA antagonist AP5 (100 pmoles/ 100 nl) into l-AG infusion site in the DMH in random order, rats were once again tested in SI and with i.v. lactate infusions. Injecting AP5 and not a-CSF into the DMH significantly blocked the chronic GABA dysfunction induced anxiogenic effect and lactate response, suggesting an increased NMDA mediated excitatory neurotransmission in this region (Supported by MH 45362).

MUSCARINIC RECEPTORS IN THE NUCLEUS ACCUMBENS MEDIATE A REINFORCING EFFECT. S. Ikemoto*, B. S. Glazier, J. M. Murphy, & W. J. McBride. Dept. of Psychiatry, Inst. of Psychiatric Res., Indiana Univ. Sch. of Med. and Dept. of Psychology, Purdue Sch. of Sci., IUPUI, Indianapolis, IN 46202.

The nucleus accumbens (NAC) has been known to be an important brain region for participating in reinforcement processes. Thus far, few studies have examined the possible involvement of the cholinergic NAC system in reinforcement processes. Therefore, the present study was undertaken to determine, using an intracranial self-administration technique, if activation of NAC muscarinic receptors produces reinforcing effects. A unilateral 22-ga guide cannula was stereotaxically implanted in adult female Wistar rats and aimed at the NAC. After at least one week of recovery, animals were given the opportunity to self-administer a carbachol solution (n = 6) or its vehicle (n = 5) into the NAC. The testing chamber was equipped with two levers; the depression of one lever (active) delivered 100 nl of a 3.28 mM carbachol solution or artificial cerebral-spinal fluid (aCSF), while the depression of the other lever (inactive) had no programed consequence. No cue or shaping method was employed. During the 3-hour test period, the animals receiving the carbachol solution had significantly more self-infusions ($p = 0.002$) than did the aCSF group (27.8 ± 3.6 v.s. 10.0 ± 1.6 total infusions for carbachol and vehicle animals, respectively). The number of responses on both the active and inactive levers for the carbachol subjects was significantly higher ($p = 0.03$) than that for vehicle animals. Carbachol subjects responded on the active lever significantly more ($p < 0.001$) than they did on the inactive lever (88.7 ± 15.9 v.s. 48.5 ± 15.4 total responses for active and inactive levers, respectively). Vehicle animals did not discriminate between the two levers (27.4 ± 7.1 v.s. 22.6 ± 6.4 total responses for active and inactive levers, respectively). The present results suggest that activation of muscarinic receptors in the NAC produces a reinforcing effect (AA 09619, AA 08553).

BOVINE GROWTH HORMONE (bGH) TRANSGENIC MICE DISPLAY INCREASED SPONTANEOUS LOCOMOTOR ACTIVITY AND LOCOMOTOR STIMULATORY RESPONSE TO d-AMPHETAMINE B Söderpalm*, R. Seiberlich, J.A. Engel and J. Törnell. Inst. of Physiol. and Pharmacol., Dept. of Pharmacol., Göteborg University, Medicinaregatan 7, 413 90 Göteborg, Sweden.

Recent clinical and animal data indicate a role for growth hormone (GH) in mechanisms related to anhedonia/hedonia, psychic energy and reward. Thus, GH substitution in GH-deficient patients has marked positive effects on the general well-being, psychic energy and drive. Moreover, GH-deficient patients are less frequent smokers than age-matched controls, whereas bovine growth hormone (bGH) transgenic mice show increased preference for ethanol and nicotine over water in free-choice models.

In the present experiments we have investigated whether bGH transgenes and controls differ in spontaneous locomotor activity (LMA), a behavioral response related to brain dopamine (DA) and reward mechanisms, as well as in LMA response to drugs of abuse known to interfere with brain DA systems.

The mice were tested for LMA in activity boxes once a week for five weeks. When first exposed to the test-apparatus bGH animals displayed significantly more LMA during the entire registration period (1 h). One week later the animals received an acute saline injection before being placed into the apparatus. Again bGH transgenes displayed more LMA, but only during the first 30 minutes of the recording period. At the third test occassion all animals received d-amphetamine (1 mg/kg, i.p.). bGH transgenic mice were significantly more stimulated by d-amphetamine than non-transgenes during the entire test-period (1 h). At the fourth and fifth test occassions the animals received ethanol (2.5 g/kg, i.p.) and nicotine-di-tartrate (0.5 mg/kg, s.c.), respectively, and tendencies for larger LMA responses in the bGH transgenes were observed.

In conclusion, bGH transgenic mice display more spontaneous LMA than non-transgenic controls, and, possibly, also a disturbed habituation process. The finding that bGH mice were also more sensitive to d-amphetamine-induced LMA may suggest that the behavioral differences observed are related to differences in brain DA systems; indicating a hyperresponsiveness of these systems in bGH transgenes. These findings may be of relevance for the reported psychic effects of GH in humans.

657.12

FACILITATED ACQUISITION OF SEXUAL BEHAVIOR IN MALE RATS FOLLOWING *d*-AMPHETAMINE-INDUCED BEHAVIORAL SENSITIZATION Dennis F. Fiorino* and Anthony G. Phillips Dept.of Psychology, University of British Columbia, Vancouver, B.C., V6T 1Z4

Drugs of abuse appear to activate neural systems mediating goal-directed behavior towards natural rewards such as food and sex. The mesocorticolimbic dopamine system plays a key role in this respect and repeated administration of psychostimulants leads to sensitization of this system. The present study investigated the effect of sensitization induced by repeated injections of *d*-amphetamine on subsequent sexual behavior in the male rat tested in a drug-free state.

Male rats were given one injection of *d*-amphetamine (1.5 mg/kg, i.p.) every other day for a total of 10 injections, a regimen sufficient to induce behavioral sensitization as measured by increased stereotypy in response to a fixed dose of *d*-amphetamine. After a three-week post-drug withdrawal period, rats were tested for sexual behavior. On day 1, sensitized rats exhibited facilitated sexual behavior in the presence of a receptive female as indicated by a significantly shorter mount latency (x = 123.9 ± 47.4 sec) as compared to controls (x = 272.0 ± 53.7 sec). Further, based on a set of criteria selected to reflect sexual proficiency (i.e. intromission latency ≤ 10 min; ejaculation latency ≤ 15 min; and post-ejaculatory interval ≤ 10 min), sensitized rats showed facilitated acquisition of sexual behavior, reaching the criteria after only 4 test days compared to 6 test days for control rats.

SULPIRIDE ATTENUATES CONDITIONED PLACE PREFERENCE FOLLOWING SEXUAL BEHAVIOR IN FEMALE SYRIAN HAMSTERS. R.L. Meisel* and M.A. Ioppa. Dept. of Psychological Sciences, Purdue Univ., West Lafayette, IN 47907.

The ability of the dopamine D_2 antagonist, sulpiride, to prevent the acquisition of a conditioned place preference was examined in female hamsters. Females were treated with one of several doses of sulpiride ip (12, 18, or 24 mg/kg body weight) prior to sexual encounters with a male in a conditioned place preference apparatus. Preliminary results indicate that sulpiride-treated females, like vehicle-treated females, exhibited near maximal levels of sexual behavior (lordosis) throughout the conditioning sessions. Despite showing high levels of lordosis, the sulpiride-treated females did not show evidence of conditioned place preference. Vehicle-treated females replicated our earlier findings of conditioned place preference induced by sexual behavior in female hamsters. These results suggest that conditioned place preference is a useful means for probing the appetitive components of female sexual behavior, and that D_2 receptors are involved in this appetitive process.

ROLE OF GLYCINE/NMDA RECEPTORS IN THE DORSAL PERIAQUEDUCTAL GRAY OF RATS UNDER THE INFLUENCE OF ANXIOSELECTIVE DRUGS. **A.P. Carobrez*, and M.M. De-Souza. Depto. de Farmacologia, CCB, UFSC, Florianópolis, SC, 88040-900, Brazil.**

The midbrain periaqueductal gray (PAG) coordinates responses of an animal facing aversive stimulus. Excitatory amino acid (EAA) neurotransmission at the dorsal PAG (DPAG), may mediate distinct behavioral performance in animal models of anxiety. The purpose of this investigation was to explore the effects of DPAG-EAA on the behavioral performance of rats under anxioselective drugs effects. Assessment of anxiety-related behavior was performed in male hooded rats with chronically implanted cannula, aimed to DPAG. Fifteen min after receiving an IP injection (1 ml/kg) of diazepam (DZP; 0.375, 0.75 mg/kg), pentylenetetrazol (PTZ; 15, 30 mg/kg) or vehicle, the rats received a microinjection (0.4 μl) of ACSF, glycine (GLY 80 nmol) or 7-Cl-kynurenic acid (7CIKYN) into DPAG. Five min after receiving both treatments the animals were placed in the elevated plus-maze test for a 5 min observation. In experiment 1, DZP increased ($p<0.05$) both, the %entries (OAE; 60 ± 5.8) and the %time spent (TSO; 36 ± 8.9) on open arms when compared to baseline levels (OAE= 31 ± 8.2; TSO= 6.3 ± 2.0), . These DZP anxiolytic effects were blocked after DPAG microinjection of GLY (OAE= 30 ± 9.7; TSO= 19.8 ± 8.3). In experiment 2, the treatment with PTZ decreased the OAE (10 ± 6.9) and the TSO (2.6 ± 2.0). These PTZ anxiogenic effects were reversed after DPAG microinjection of 7CIKYN (OAE= 53 ± 4.1; TSO= 23 ± 6.6). The results suggest that the behavioral effects of anxioselective compounds depend on baseline glutamatergic DPAG activation. Also these results strengthens the hypothesis of a modulatory role for DPAG/EAA system in anxiety. ***Supported by: CNPq and CAPES***

COMPARISON OF THE EFFECTS OF D_1 AND D_2 DOPAMINE RECEPTOR ANTAGONISTS ON THE RESPONSE-REINSTATING PROPERTIES OF FOOD REINFORCEMENT. A. L. Chausmer*, C. M. Reals and A. Ettenberg. Behavioral Pharmacology Laboratory, Dept. of Psychology, Univ. of California, Santa Barbara, 93106.

The current experiment examined the ability of selective dopamine D_1 and D_2 receptor antagonists to prevent the reinstatement in operant responding produced by a single reinforced trial in the midst of extinction. Hungry rats were trained to run a straight-alley for food reward during single daily trials. After 12 reinforced trials, the operant was extinguished during consecutive daily non-reinforced trials. Ss were then injected 30 min prior to a single Treatment trial with one of four doses of either the D_2 antagonist, raclopride (0.0, 1.0, 0.5 and 0.25 mg/kg IP) or the D_1 antagonist SCH 39166 (0.0, 0.02, 0.01, 0.005 mg/kg IP). Twenty-four hours later, a Test trial was conducted in an unbaited runway. On Treatment day, a single reinforced trial was sufficient to reinstate operant running 24 hrs later (i.e. on Test day). While raclopride on Treatment day dose-dependently attenuated the response-reinstating effects of food as measured on the next trial/day, interpretation of SCH 39166 data was made difficult because it produced no consistent dose-response effects and it attenuated performance of a motor control group. In a separate experiment, neither drug produced reliable reductions in spontaneous locomotor activity measured 24 hrs post-injection. Together these data suggest a clear role for D_2 receptor subtype in food reinforcement, but the role of the D_1 receptor remains unclear.

SOCIAL MODULATORY INFLUENCES ON CROWING AND AGGRESSION IN TESTOSTERONE-TREATED CHICKS. L. Normansell* and E. Craven, Program in Neuroscience, Muskingum College, New Concord, OH 43762.

Following chronic testosterone (T) administration, young chicks crow regularly and become very aggressive. In the present series of studies, the ability of varying social contexts to influence these behaviors in T-treated chicks was investigated. Chicks were obtained at one day post hatch, housed in like-treated flocks of 7-9 chicks, and administered either .1ml oil or 2.5mg testosterone in oil per day. When tested at 3-4 weeks of age, in both paired round-robin and group testing with animals from their own flock, T-treated animals were more aggressive and crowed more than control chicks. When who was dominant over whom was determined, the resulting dominance hierarchies were less linear in the T-treated chicks which might indicate a disruption in the development of normal social processes. In paired contests with animals from a different but like-treated flock, T-treated chicks crowed over 3 times more than when they were with an animal from their own flock but did not differ in level of aggression. Next, 2 chicks of one flock were grouped with 2 from a like-treated but different flock. T-treated animals displayed over 7 times as many aggressive acts as controls, but in both groups, these acts were directed equally to the other animals regardless of what group they were from. In this social situation, however, none of the T-treated animals emitted any crows. In summary, while testosterone treatment induces many adult-like patterns of behavior in young chicks, these behaviors are modulated to some extent within the ongoing social environment of the animals.

657.17

THE EFFECT OF SEROTONIN AND DOPAMINE REUPTAKE INHIBITORS ON DORSAL RAPHE SELF-STIMULATION THRESHOLDS. P.Tzvetkov*, S.Khan, E.Miliaressis, G.Fouriezos. University of Ottawa. Ottawa, Canada K1N 6N5.

Male Sprague-Dawley rats were implanted with monopolar electrodes in the dorsal raphe nucleus (DR). Using a descending method of limits, self-stimulation frequency thresholds were obtained before and after acute intraperitoneal injections of cocaine HCl (20mg/kg), paroxetine (10mg/kg), and paroxetine (10 mg/kg or 20 mg/kg) plus cocaine (20 mg/kg). Injection of cocaine, a mixed serotonin/dopamine reuptake inhibitor, led to a 37% drop in frequency threshold. Injection of paroxetine, a selective serotonin reuptake inhibitor, did not decrease threshold. However, paroxetine (20mg/kg) injected 30 min prior to cocaine led to a 69% drop in threshold. Results suggest that increasing serotonin levels may enhance the ability of dopamine agonists to facilitate self-stimulation in the DR.

DISSOCIATION OF REWARD AND PERFORMANCE CHANGES FOLLOWING ICV MICROINJECTIONS OF NEUROTENSIN. P.-P. Rompré* Département de psychiatrie, Université de Montréal, Montréal (Québec), Canada, H3C 3J7.

Several lines of evidence show that neurotensin (NT) modulates central dopamine (DA) functions. When microinjected into the ventricle, for instance, NT produces neuroleptic-like effects and inhibits the increase in locomotion produced by DA receptor activation in the nucleus accumbens. Such an inhibitory effect of NT on DA-induced locomotion contrasts with its stimulatory effect on DA cell firing and on DA metabolism and release and implies that this postsnyaptic action of NT is strong enough to counteract its action on DA impulse flow. Another possibilty is that the inhibitory effect of ICV NT on DA-induced locomotion results from, or is potentiated by, its non-specific effects as NT is known to induce hypotension, muscle relaxation and hypothermia. In this study, we used the curve-shift method as applied to brain stimulation reward to determine whether the suppressant effect of ICV NT on a DA-dependent behavior is specific or is due to a general decrease in motor capability. Male rats implanted with a stimulating electrode in the central gray and a guide cannula above the lateral ventricle were trained to lever press for trains of 200 msec cathodal pulses of fixed intensity and variable frequency. Once responding was stable, the effects of three doses of ICV NT (3, 10 and 30 µg/10 µl) on the function relating the rate of responding to the stimulation frequency was determined, just before, and for 95 min after the injection. Results obtained demonstrate a clear dissociation between performance and reward changes. At every dose tested, NT produced a significant suppression of maximal responding, reflecting a decrease in motor capability. At the highest dose, a decrease in reward threshold occurred 30 min later than the onset of the suppression of responding and outlasted the later effect by at least 30 min. These results suggest that ICV NT suppresses motor capability, an effect that may interfere with the behavioral expression of an increase in DA-dependent functions. Supported by a grant from the Medical Reseach Council of Canada.

657.19

STRESS-INDUCED SENSITIZATION, BUT NOT FACILITATED LEARNING, IS CHOLINERGICALLY-MEDIATED. **T.J. Shors*, G.P. Mark, J.C. Selcher, and R.J. Servatius. Dept. Psychol. and Prog. in Neurosci., Princeton University, Princeton, NJ 08544.**

Acute exposure to an inescapable stressor of restraint and intermittent tail-shock enhances sensory reactivity and independently facilitates acquisition of the classically conditioned eyeblink response in the freely-moving rat. Because the same stressor increases acetylcholine (ACh) release into the hippocampus, amygdala, and prefrontal cortex, we tested the hypothesis that either one or both of the stress-induced behaviors was cholinergically mediated. Rats (6/group) were treated with the muscarinic antagonist scopolamine (5 mg/kg) or vehicle 30 min prior to the stress and no stress condition. 24 hrs later, they were exposed to 10 white noise stimuli (85 dB) and trained with paired and unpaired stimuli consisting of a white noise conditioned stimulus overlapping and coterminating with a periorbital shock unconditioned stimulus to the eyelid. Preventing activation of muscarinic receptors during the stressor prevented the sensitization ($p = 0.02$) but not the facilitated learning ($p = 0.99$). Additional data suggest that the effective ACh is not originating in the septum; severing the fornix ($n = 12$) did not prevent the enhanced reactivity to auditory cues. These results suggest that the sensitization effect is cholinergically-mediated, although not via septal inputs to the hippocampus. Moreover, these results pharmacologically dissociate the stress-induced sensitization from the facilitation of associative learning. **[Whitehall and McDonnell-Pew Foundations and ONR support to TJS]**

EFFECTS OF PHASE-SHIFTING TREATMENTS ON THE mRNA LEVELS OF PUTATIVE OSCILLATOR PROTEINS, BiP AND PORIN, IN *APLYSIA*. M. Sloan*, C. Koumenis, and A. Eskin, Dept. of Biochem. & Biophys. Sci., Univ. of Houston, TX 77204.

A circadian pacemaker in the eye of *Aplysia* generates a rhythm of spontaneous nerve impulses. A model of this system predicts that the phase shifting agents light and 5-HT modify the synthesis of oscillator proteins at the level of translation and perhaps transcription as well. Using 2-D gel electrophoresis, we previously searched for putative oscillator proteins in the eye whose synthesis was modified by treatments with light and 5-HT. We found that light treatments to isolated eyes at CT 18-24 increased incorporation of ^{3}H-leucine into BiP (a molecular chaperone in the endoplasmic reticulum), while decreasing incorporation of label into porin (a large conductance channel in mitochondrial and other membranes). 5-HT treatments to eyes at CT 6-12 increased incorporation of label into BiP and porin.

To investigate the effects of phase shifting treatments on BiP and porin at the transcriptional level, we first obtained their cDNAs. Clones of *Aplysia* BiP were obtained from Kuhl, et al., and clones of porin were obtained by screening an *Aplysia* ganglia cDNA library using a clone from human porin. A full-length cDNA of 282 amino acids, obtained from the *Aplysia* library, was 67% identical to human porin. Riboprobes complementary to coding regions of BiP and porin were used in ribonuclease protection assays to measure their mRNA levels. Light and 5-HT administered to isolated eyes had opposite effects on the levels of mRNAs of BiP and porin. The effects of light and 5-HT on BiP and porin mRNAs correlated with their effects on proteins except for the action of light on BiP mRNA and protein. Light at CT 18-24 decreased levels of mRNAs of BiP (-68±2%, n=4) and porin (-67±6%, n=4), while 5-HT at CT 6-12 increased levels of mRNAs of BiP (50±20%, n=7) and porin (45±14%, n=6). These results indicate that light and 5-HT may phase shift the ocular circadian oscillator by regulating levels of BiP and/or porin mRNAs.

NMDAR1 SPLICE VARIANTS IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF THE SIBERIAN HAMSTER. Francis J P Ebling*, Iona H M Alexander and Jens D Mikkelsen, Dept. Anatomy, University of Cambridge, UK and Institute of Medical Anatomy, The Panum Institute, University of Copenhagen, Denmark.

Glutamate is implicated in mediating the phase-shifting effects of light on circadian rhythms, and our previous studies have revealed the presence of mRNAs encoding glutamate receptors in the rat suprachiasmatic nucleus (NMDAR1/NMDAR2C *Brain Res* 1993, 632: 329-333). The common subunit gene NMDAR1 can be alternatively spliced in three regions to generate functionally-different products, so the aim of the current study was to investigate which mRNA species are present in the SCN. *In situ* hybridization was carried out on series of 12µm coronal sections from the Siberian hamster (*Phodopus sungorus*), using ^{35}S-labelled oligonucleotide probes complementary to common and variable regions of the rat gene (*J Comp Neurol* 1994, 313:1-16, from which terminology is adopted). Probes complementary to VIP mRNA and AVP mRNA defined the ventrolateral and dorsomedial regions of the hamster SCN in adjacent sections. Hybridization of the common probe occurred ubiquitously in the hamster brain, including the SCN. A probe complementary to deletion II/exon 22 was also abundant throughout the SCN. In contrast, no hybridization of a probe complementary to insertion I/exon 5 was detected in the SCN or other hypothalamic nuclei, despite a highly characteristic pattern of expression restricted to the thalamus. Background on sections hybridized with a probe complementary to deletion I/exon 21 was high, but no clear evidence of hybridization in the SCN was obtained. These observations suggest that the predominant isoform in the SCN is NMDAR1C, and provide further evidence that glutamate is an important regulator of SCN function. *[Supported by The Wellcome Trust grant 037667/Z/93 and by The Royal Society]*

AN ALTERED CIRCADIAN CLOCK IN NCAM-180 DEFICIENT MICE. H. Shen[1], M. Watanabe[2], H. Tomasiewicz[3], U. Rutishauser[3], T. Magnuson[3] & J. D. Glass*[1], [1]Dept. of Biological Sciences, Kent State Univ., Kent, OH 44242, [2]Division of Pediatric Cardiology, Dept. of Pediatrics, Rainbow Babies & Children Hospital, Case Western Reserve Univ., Cleveland, OH 44106, and [3]Dept. of Genetics, Case Western Reserve Univ., Cleveland, OH 44106.

The basis of the circadian pacemaker in the suprachiasmatic nuclei (SCN) remains speculative. Our previous study confirmed robust expression of highly polysialylated neural cell adhesion molecule (PSA-NCAM) in adult rodent SCN. PSA-NCAM, capable of modulating contact-dependent cell-cell interactions, is involved in a variety of developmental events and in adult neuroplasticity. To explore the role of PSA-NCAM in the SCN circadian clock, we assessed circadian locomotor activity rhythms under various photoperiod regimens in the mice with genetic deletion of the major PSA-associated NCAM isoform, NCAM-180. The results showed that NCAM-180 deficient mice (n=15), with total loss of NCAM-180 and PSA in the SCN had a shorter endogenous free-running period (τ; 23.5±0.09 h) and a longer activity time (α; 18.2±0.42 h) under constant darkness (DD) than wildtypes (n=12; τ=23.9±0.05 h [$P<0.05$]; α=15.8±0.87 h [$P<0.05$]). By 2 wk of DD the majority of mutant mice exhibited a desynchronous activity rhythm. Also, the photoentrainment of locomotor activity in NCAM-180 deficient mice which was unimpaired under the initial 12L:12D photoperiod (LD), was (in contrast to the wildtypes) disrupted after return to LD following DD exposure. Collectively, these findings are evidence that PSA-NCAM, and possibly NCAM-180, are important to the generation of circadian rhythms and may help maintain the coherence of these rhythms.

CHARACTERIZATION OF THE CIRCADIAN SYSTEM OF NGFI-A AND NGFI-A/NGFI-B KNOCKOUT MICE. T.S. Kilduff* (1), C. Vugrinic (1), S.L. Lee (2), J.D. Milbrandt (2), J.D. Mikkelsen (3), B.F. O'Hara (1), and H.C. Heller(1). (1) Center for Sleep & Circadian Neurobiology, Depts. of Psychiatry and Biological Sciences, Stanford Univ., Stanford, CA 94305, (2) Dept. of Pathology, Washington Univ., St. Louis, MO 63110, (3) Inst. of Med. Anatomy, Univ. of Copenhagen, Denmark.

The genes NGFI-A and NGFI-B have previously been shown to be induced in the suprachiasmatic nuclei by photic stimulation during the subjective night. The purpose of this study was to characterize the circadian system of mice in which either NGFI-A or both NGFI-A and NGFI-B were eliminated by homologous recombination. Wheel running activity was recorded from null mutants and wild type controls under LD 12:12 , DD, and LL conditions. All mice appear to entrain normally to a 12:12 cycle and could re-entrain to both phase advances and phase delays of the light cycle. The response of the pacemaker to acute light pulses is being assessed at the present time. These results, along with neuroanatomical information about the structure of the SCN in NGFI-A minus and NGFI-A/B minus mice, will be presented. (Supported by NIH grant AG11084).

IDENTIFICATION OF PINEAL-SPECIFIC GENES IN RAT BY DIFFERENTIAL DISPLAY PCR.

X. Wang* Michael J. Brownstein, and W. S. Young, III. Lab. Cell Biology, NIMH, NIH, Bethesda, MD 20892

In the mammalian pineal, the circadian production of melatonin is controlled by the rhythmic expression of acetyl-CoA: serotonin N-acetyltransferase (SNAT). Acetylation of serotonin by SNAT is the rate-limiting step in melatonin synthesis. Isoproterenol injections in intact rats stimulate the expression of SNAT or SNAT regulator(s) transcriptionally or translationally. Various cloning methodologies have failed to find the SNAT cDNA. In order to screen for pineal-specific mRNAs that may be crucial for the circadian regulation of melatonin synthesis, differential display PCR was employed. Pineal, retinal and cerebellar tissues were dissected from Sprague-Dawley rats (male, 200-250 each, Taconic Farms) two and half hours after intraperitoneal injections of 10 mg/kg isoproterenol. The same tissues were collected from uninjected rats as well. $T_{12}N_2$ oligos were used for cDNA synthesis using total RNA isolated from above tissue samples as templates. The same $T_{12}N_2$ oligos plus arbitrary 10-mers of random sequence were used to amplify the cDNAs by PCR in the presence of ^{35}S-dATP. The PCR products were displayed on a 6 % polyacrylamide gel. Clone PG10.2 is expressed in both the pineal gland and retina; the 8 kb mRNA is much more abundant in retina where it is expressed in the outer nuclear layer (especially at the outer edge) and over the photoreceptor cell bodies. *In situ* hybridization revealed that the clones PG23 and PG25 are pineal specific. Preliminary sequence analysis of cloned fragments shows no significant homologies to known genes. Full length cDNAs are being isolated from an isoproterenol-induced pineal cDNA library to see if they code for proteins with roles in the circadian regulation of melatonin synthesis.

CLONING OF THE MOUSE MEL$_{1a}$-MELATONIN RECEPTOR GENE. Alfred L. Roca* and Steven M. Reppert, Laboratory of Developmental Chronobiology, Mass. General Hospital, and Program in Neuroscience, Harvard Medical School, Boston MA 02114

Recently a high-affinity melatonin receptor, designated the Mel$_{1a}$-melatonin receptor, was cloned from mammals (Reppert et al. 1994; Neuron 13:1177). Defining the structure of the murine receptor gene is a necessary step for generating transgenic animals. Degenerate primers were designed using regions conserved among other mammalian Mel$_{1a}$-receptor cDNAs. PCR of mouse genomic DNA yielded a 466 bp fragment that was 94% identical at the amino acid level to the rat and Djungarian hamster Mel$_{1a}$-receptor cDNAs. In situ hybridization of adult C57BL/6J mouse brain using the PCR-generated fragment produced a hybridization pattern consistent with that expected for the Mel$_{1a}$-melatonin receptor; hybridization signal was most intense in the hypophyseal pars tuberalis. Southern blot analysis of genomic DNA indicated a single-copy gene. RNA was isolated from a murine cell line (RT2-2) which expresses the Mel$_{1a}$-receptor. Northern analysis of poly(A)+ RNA indicated a transcript length of ca. 1.9 kb. RT-PCR was used to generate the full-length coding region (1059 bp) of the receptor, which showed 84% amino acid identity to the human Mel$_{1a}$-receptor. RNase protection analysis, 5' and 3' RACE, and screening of a BALB/c mouse EMBL3 SP6/T7 genomic library revealed that the receptor gene consists of 2 exons divided by a large (>8 kb) intron. The 3' untranslated region is 444 bp long, and includes the polyadenylation signal AUUAAA. RNase protection assays suggest that a major transcription start site is located ca. 100 bp upstream of the initiation codon.

MELATONIN ACTION VIA PROTEIN KINASE C IN THE SCN OF THE RAT. A.E. Hunt, A.J. McArthur, M.U. Gillette*. Neuroscience Program and Depts. of Physiology and Cellular and Structural Biology. University of Illinois at Urbana-Champaign, Urbana, IL 61801.

Production of the pineal hormone melatonin occurs only at night, or during the dark phase of the subjective lighting cycle, and is controlled via a multisynaptic pathway from the suprachiasmatic nucleus (SCN) to the pineal gland. There are high-affinity melatonin receptors within the SCN itself, suggesting a feedback function for melatonin. Indeed, melatonin (10-9 M), when bath applied for 1 hr to a hypothalamic brain slice preparation, has been shown to advance the phase of circadian rhythm extracellular firing rate in the ensemble of SCN neurons. The SCN shows temporal sensitivity in that melatonin application during mid-day or mid-night is without effect, while application at subjective dusk (CT 10) or subjective dawn (CT 23) causes phase advances of about 4 hr. To study the signalling mechanisms responsible for melatonin's effects, the phorbol ester 12-O-tetradecanoyl phorbol 13-acetate (TPA), a potent protein kinase C activator, was bath applied to brain slices (10-8 M, 10 min) and was found to reset the SCN firing rate with a profile similar to that of melatonin. The specific protein kinase C inhibitor, Calphostin C, which binds and blocks the diacylglycerol site on PKC, blocks melatonin phase shifts when bath applied 45 min prior to melatonin treatment at CT 10 and CT 23. Calphostin C induces no phase shift of its own when applied alone. Our data indicate that melatonin can phase shift circadian timing within two windows of sensitivity and that melatonin exerts its effects at both dusk and dawn via a protein kinase C pathway. (Supported by PHS grant NS22155).

PONTINE CHOLINERGIC NEURONS SHOW FOS-LI IN ASSOCIATION WITH CHOLINERGICALLY-INDUCED REM SLEEP. P. Shiromani*, S. Winston, R.W. McCarley. *Brockton VA-Harvard Med School, MA 02401.*

We (Brain Res, 1992; J Neurosci,1995) and others (Yamuy et al., J Neurosci, 1993) have shown that Fos-LI occurs in pontine areas in response to cholinergically-induced REM sleep (REMc). Since pontine cholinergic mechanisms have been implicated in REM sleep generation, in the present study we examined whether pontine cholinergic neurons show Fos-LI in association with REMc.

Sleep was recorded from cats given pontine microinjections of either saline (n=2; 0.25μl) or carbachol (n=3; 2 ug/0.25μl). Carbachol treated animals had REMc (27-40 min) and were sacrificed (nembutal) at end of REMc. In saline treated animals, very few Fos-LI cells were found in the pons. None of these cells were colocalized in LDT-PPT cholinergic neurons. On the other hand, the animals with REMc showed a consistent pattern of Fos-LI cells in the dorsolateral pons. In the REMc animals, a subpopulation of the LDT-PPT cholinergic cells were also Fos-LI positive (contralateral= 10.17%; ipsilateral=11.1%).

We found that only a subpopulation (10.64%) of LDT-PPT cholinergic neurons were also Fos-LI positive. It is interesting that single-unit studies have also found that only a subpopulation of neurons recorded in the LDT-PPT are "REM-on". Thus, even in a phenotypically similar population (i.e., cholinergic) only a subset are differentially affected during REM sleep, as assessed by electrophysiological or molecular techniques.

CHANGES IN c-FOS, PPE AND DYN mRNA LEVELS ASSOCIATED WITH THE PLATFORM TECHNIQUE OF REM SLEEP DEPRIVATION. L.Ramanathan*, R.Basheer, R.W. McCarley and P.Shiromani. *VA-Harvard Medical School, West Roxbury, MA 02132.*

Immobilization stress, cold water swim, and chronic or acute drug treatments alter c-fos, preproenkephalin (PPE) and dynorphin (DYN) mRNA levels. c-Fos is known to induce the expression of both PPE and DYN. In the present study, changes in the expression of these messages were investigated using the platform technique of REM sleep deprivation. Rats were placed on either large platforms (LP) or small platforms (SP) for 1 and 5 days, while control animals were kept in dry cages throughout the experimental period.

Northern blot analysis showed decreased levels of c-fos mRNA in the cortex and striatum of platform animals compared to rats maintained in dry cages. In contrast, PPE mRNA levels were increased in the cortex and striatum of platform animals. DYN mRNA levels were unaltered.

The differential expression of messages whose protein products have been associated with various aspects of the transcriptional cascade described in other systems, suggests that a similar series of events may play a role in this experimental paradigm.

658.10

CHANGES IN c-FOS AND ChAT mRNA LEVELS IN SPECIFIC RAT BRAIN REGIONS DURING NORMAL SLEEP. M. A. Greco[1], G. Perides[2*], R.W. McCarley[1], and P. Shiromani[1]. Harvard Medical School, VA Medical Center, West Roxbury, MA 02132, and New England Medical Center, Boston, MA 02111

Studies in this laboratory have investigated neuronal mechanisms underlying sleep-wake states. These studies have also shown an increased number of c-fos immunoreactive cells in a subpopulation of pontine cholinergic neurons in response to drug-induced REM sleep. We have new begun to examine molecular events associated with physiological sleep. Initial experiments using northern blot analysis indicated a more sensitive assay was required to investigate possible transcriptional regulation mechanisms of gene expression in this system. In the studies described here, c-fos and ChAt mRNA levels from discreet brain regions were analyzed across normal sleep states. Rats were sacrificed during waking, slow wave sleep or REM sleep. Total RNA was extracted from punch biopsies of the medial PRF, DRN, LC and LDT regions of the pons as well as hypothalamic areas. Messenger RNA levels were analyzed by quantitative RT/PCR. The results indicate that c-fos and ChAT messages are differentially and variably expressed. These studies show the utility of RT/PCR to analyze low abundance messages in specific areas of the brain.

658.11

CHANGES IN TYROSINE HYDROXYLASE mRNA LEVELS ASSOCIATED WITH THE PLATFORM TECHNIQUE OF REM SLEEP DEPRIVATION R.Basheer*,R.W.McCarley and P.Shiromani. *Dept Psychiatry, Harvard Medical School- VA Medical Center, West Roxbury, MA 02132.*

A number of experimental techniques have been shown to induce the expression of tyrosine hydroxylase mRNA in locus coeruleus. We studied alterations in TH mRNA using a paradigm that also produces REM sleep deprivation in rats.

Rats were placed on large platform (LP) and small platform (SP) for one and five days and compared with controls kept in dry cages. Changes in TH mRNA were analysed by northern analysis of total RNA isolated from pons, locus coeruleus and ventral tegmental area. Preliminary results showed that compared to dry cage controls there was no significant change in TH mRNA in LP rats. Whereas in SP animals there was a significant increase in TH mRNA after one day which drops to control levels after five days. It will be important to examine the changes in TH mRNA in discrete pontine nuclei using *in situ* hybridization.

These data indicate that TH mRNA levels are changed with the pedestal treatment.

ULTRAVIOLET-SENSITIVE RETINAL PHOTORECEPTORS MEDIATE LIGHT-INDUCED PHASE-SHIFTS AND FOS EXPRESSION IN RAT SUPRACHIASMATIC NUCLEUS. S. Amir* and B. Robinson. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Quebec, Canada.

Mammalian circadian rhythms are generated by a pacemaker located in the hypothalamic suprachiasmatic nucleus (SCN) and are entrained by photic stimuli that are carried to the SCN in a direct retinal projection, the retinohypothalamic tract (RHT), and in an indirect projection from the intergeniculate leaflet (IGL), the geniculohypothalamic tract (GHT). The retinal photoreceptors underlying entrainment, and that are thought to be distinct from those involved in vision, have not been identified. In rodents, photic stimuli that entrain circadian rhythms induce expression of the transcription factor Fos in SCN cells innervated by the RHT and GHT. Here we report that in rats ultraviolet light pulses known to excite the retina electrophysiologically induce a pattern of Fos expression in the SCN that corresponds to the known pattern of distribution of RHT and GHT terminals in the SCN region. The effect of ultraviolet light on Fos expression is phase dependent and appears to be mediated by a retinal mechanism bearing characteristics of a specific ultraviolet receptor. Because we find in addition that ultraviolet light pulses that induce Fos expression in the SCN are sufficient to induce phase shifts in circadian rhythms, we conclude that the retinal photoreceptors that mediate the effect of light on rodent circadian pacemaker are ultraviolet sensitive.

DAY-NIGHT DIFFERENCE IN THE NUMBER OF FOS-IMMUNOREACTIVE NEURONS IN THE SUPRACHIASMATIC NUCLEUS OF FETAL SHEEP.
S.Breen[1], S.Rees[1], L.Wise[3]* & D.Walker[2]. [1]Department of Anatomy & Cell Biology, University of Melbourne, Parkville, Victoria 3052, Australia; [2]Department of Physiology & [3]Department of Psychology, Monash University, Clayton, Victoria 3168, Australia.

Fetal sheep exhibit several behavioural and hormonal diurnal rhythms in late gestation. It is unclear whether these rhythms are controlled directly by the fetal suprachiasmatic nucleus (SCN) or result from diurnal changes in maternal hormones. FOS immunoreactivity (FOS-ir) was utilised as a marker of neuronal activation to determine if SCN neurons are active during gestation. Pregnant ewes (n=28) were maintained under a 12 hour (h) light-dark cycle prior to administration of an overdose of sodium pentobarbitone at either 1200 h or 0300 h. At 1200 h in the 75 d fetus (term=146 d) a few FOS-ir neurons were observed while in the 90, 105, 117 and 138 d fetuses many FOS-ir neurons were present throughout the nucleus. However fetuses killed at 0300 h at 90 and 138 d gestation showed only a few FOS-ir neurons in the SCN. To determine whether the activity of the fetal SCN was due to direct light stimulation of the fetal retina through the maternal body wall, 1 fetus from each of 2 sets of twins was optically enucleated a 100 d. The unoperated twin acted as a control. Counts of FOS-ir neurons in the SCN of these animals at 1200h at 133 d showed no difference between operated and control animals, indicating that retinal input is not essential for entraining the fetal SCN. Another possibility is that a chemical messenger which undergoes diurnal fluctuation in the mother may communicate time of day information to the fetus. Two ewes each with twin fetuses of 133 d were exposed to constant light conditions for 5 days. Analysis of these fetuses indicated that the day-night difference in FOS-ir neuron number had now been abolished, suggesting that a messenger such as melatonin may be important in entraining the fetal SCN.

658.14

LIGHT-INDUCED AND CIRCADIAN EXPRESSION OF *fosB, c-fos, junB* AND *c-jun* IN THE HAMSTER SUPRACHIASMATIC NUCLEUS.
M. E. Guido*, B. Rusak and H. A. Robertson. Departments of Psychology and Pharmacology, Dalhousie University, Halifax NS, Canada B3H 4J1.

The mammalian suprachiasmatic nucleus (SCN) of the anterior hypothalamus is the site of an endogenous pacemaker that is responsible for the timing and overt expression of daily rhythms. The circadian rhythmicity of this pacemaker is synchronized by light, and a molecular correlate of photic entrainment is the rapid and transient induction of various immediate early genes (IEGs) in SCN cells. These IEGs encode for, among other things, transcription regulatory factors such as Fos and Jun family proteins. The anatomical pattern of cFos induced by light is similar to the pattern of retinohypothalamic fiber terminals in the SCN. Fos and Jun proteins could be regulating transcriptionally the expression of genes responsible for the timing of the intracellular circadian pacemaker.

To study the role that other IEGs could be playing in the SCN, we have characterized the photic and circadian expression of *fosB* as well as *c-fos, c-jun* and *junB* by *in situ* hybridization in hamsters. *fosB* mRNA exhibits a typical IEG kinetic of induction in response to a pulse (30 min) of light (during the dark phase of an LD 14:10 schedule) in cells of SCN, and mRNA levels are elevated for up to 150 min after the light pulse. When we assessed the spontaneous and light-evoked expression of these genes at different circadian phases, we found light-induced expression for all these genes during the subjective night, but *c-fos,* and especially *junB* also showed increased expression either spontaneously or after a light pulse at the beginning of the subjective day. These results suggest that induction of some IEGs in the SCN occurs spontaneously as well as in response to light stimuli at selected circadian phases.

FOS IMMUNOREACTIVITY IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF THE DIURNAL RODENT ARVICANTHIS NILOTICUS.
Catherine Katona, Cheryl Sisk* & Laura Smale. Department of Psychology/Neuroscience Program, Michigan State University, East Lansing, MI 48824

The suprachiasmatic nucleus (SCN) regulates circadian rhythms in all mammals examined to date and has been studied extensively in nocturnal species. Little is currently known about differences in the neural mechanisms controlling rhythms in nocturnal and diurnal animals. These functional differences may exist either within the SCN or in response to SCN signals. We used Fos as an index of SCN function to explore the hypothesis that mechanisms within the SCN are coupled in one way to the LD cyle in nocturnal animals and are coupled oppositely in diurnal animals.

Fos is a phosphoprotein which interacts with DNA to regulate gene transcription. The number of Fos immunoreactive (Fos-IR) cells in the SCN of a nocturnal rodent, the rat, peaks during the light phase of a 12:12 light-dark (LD) cycle. We examined Fos-IR in the SCN of a diurnal rodent, Arvicanthis niloticus.

Our study included 36 adult males sacrificed at 6 time points around a 12:12 LD cycle. There was the suggestion of a 24h rhythm of Fos-IR within the SCN of A.niloticus. During the light part of the cycle there was an increase in the number of cells expressing Fos-IR, whereas during the night, levels of Fos-IR were lower.

Thus, the rhythm of Fos-IR in the SCN is similar in the nocturnal laboratory rat and the diurnal species A.niloticus in a 12:12 LD cycle; however, it remains possible that temporal differences of Fos-IR occur in different subsets of SCN cells.

MICROINJECTION OF DOUBLE-STRANDED DNA OLIGONUCLEOTIDE CONTAINING AP-1 SEQUENCE BLOCKS LIGHT-INDUCED PHASE ADVANCE OF HAMSTER CIRCADIAN RHYTHMS
J. Takeuchi, D. Golombek and M. Ralph* Dept.of Psychology, University of Toronto , Toronto, ON, Canada M5S 1A1

Expression levels of a variety of AP-1 transcription factor proteins including C-Fos, Fos B, C-Jun, Jun B and Jun D in the suprachiasmatic nucleus (SCN) are reported to change in response to a phase-shifting light pulse . Although a role for these proteins in the phase shift mechanisms is suggested, few data are available to directly prove their involvement. A clear interpretation of results from a gene knock-out (c-fos) remains difficult partly because of the diversity of these protein complexes. One way to assess the direct involvement of these factors is to reduce their bindings to AP-1 DNA sequences in the SCN *in vivo* by competitively adding double-stranded(ds) DNA oligonucleotide containing AP-1 sequences. After implantation with a guide cannula aimed at the bottom of the third ventricle near the SCN, hamsters were housed in constant darkness and their wheel running activities were monitored. One ul of 36-mer ds AP-1 oligo (50 uM or picomoles/ul) or control oligo with shuffled AP-1 sequence in artificial cerebrospinal fluid was injected through the cannula under dim safe-light conditions 10-15 minutes before light exposure at circadian time 18 (250-350 lux for 15 minutes). The animals remained active after injections. AP-1 oligo pretreatment significantly reduced light-induced phase advances (13.2±13.5 min. n=10) while control oligo pretreatment did not (93.9±47.8 min. n=8).

These results suggest that binding of the AP-1 transcriptional complexes to AP-1 sequences is an essential part of light-induced phase advances in the mammalian circadian clock.

658.17

CIRCADIAN REGULATION OF CREB PHOSPHORYLATION IN THE SUPRACHIASMATIC NUCLEUS BY LIGHT, GLUTAMATE, AND NITRIC OXIDE.
J. M. Ding*, W. J. Hurst, L. E. Faiman, L. R. Kuriashkina, and M. U. Gillette. Dept. of Cell & Structural Biology, Physiology, and Neuroscience Program. University of Illinois, Urbana, IL 61801.

Circadian rhythms of mammals are timed by an endogenous clock with a period of about 24 hours located in the suprachiasmatic nucleus (SCN) of the hypothalamus. Light synchronizes this clock to the external environment by daily adjustment in the phase of the circadian oscillation. The SCN receives direct visual input via the retino-hypothalamic tract (RHT) which is thought to release the excitatory neurotransmitter glutamate (Glu). We tested the hypothesis that light adjusts the SCN clock through activation of N-methyl-D-aspartate (NMDA) receptor, and subsequently induces calcium dependent activation of nitric oxide synthase (NOS) in the SCN resulting the release of nitric oxide (NO). Brief exposure of rats to light only at the night-phase of the circadian cycle, induces phosphorylation of the transcription factor cAMP response element binding protein (CREB) in the SCN on the transcriptional regulatory site (Ser 133). Brief treatment of SCN *in vitro* with Glu produced light-like phase shifts and phosphorylation of CREB. Furthermore, antagonists of NMDA or NOS blocked Glu induced phase shifts as well as CREB phosphorylation. Moreover, DNA mobility assay of SCN tissue demonstrated CRE binding ability of phospho-CREB after light and Glu treatment at night. These results suggest the following signal transduction pathway linking environmental light stimulus to molecular changes in the SCN that reset the phase of the biological clock: Glu release--NMDA receptor activation--NOS stimulation--NO production--CREB phosphorylation--target gene activation--phase shift.

CYCLIC-GMP-DEPENDENT PROTEIN KINASE INHIBITORS BLOCK LIGHT-INDUCED PHASE ADVANCES OF CIRCADIAN RHYTHMS IN VIVO.
A. Mathur *, D. A. Golombek and M. R. Ralph. Dept. of Psychology, University of Toronto, Canada, M5S 1A1.

Biological rhythms in nature and in the laboratory can be synchronized by 24 hr. cycles of light and dark. Synchronization is thought to be accomplished primarily through daily phase delays and advances of the endogenous circadian rhythm which in mammals is generated by the hypothalamic suprachiasmatic nucleus (SCN). Pulses of light are known to shift the phase of activity rhythms of nocturnal animals but only during the time of their cycle (Circadian Time or CT) when they are active (subjective night). In the SCN, a number of second messenger pathways may participate in photic signal transduction. *In vitro,* pulses of both c-AMP and c-GMP analogs induce CT-dependent phase advances of electrical activity in SCN slices (Prosser, McArthur and Gillette, 1989). The involvement of cyclic nucleotide -dependent protein kinases was examined *in vivo* using inhibitors of c-AMP-dependent kinase (PKA) and c-GMP-dependent kinase (PKG) microinjected near the SCN of hamsters. In a constant dark, aperiodic environment, selective (KT-5823, 20 μM) and non-selective (H-8, 20 μM) inhibitors of PKG had no effect on phase delays of wheel-running activity rhythms produced by 15 min. light pulses given in the early subjective night, but significantly attenuated (70 %) phase advances induced late in the subjective night (CT 18). A selective inhibitor of PKA (H-89, 1 μM) had no effect at either time point. The results suggest that PKG activity is necessary but not sufficient for normal photic responsiveness, and that PKA is not required. The phase dependence of the effect of PKG supports the notion that photic responsiveness at different phases of the circadian cycle are mediated by different biochemical pathways. (Supported by the AFOSR grant to M. R. R.)

CALMODULIN-DEPENDENT PROTEIN KINASE II EXPRESSION DURING WAKEFULNESS AND SLEEP. M.Pompeiano*, P.Arrighi, C.Cirelli and G.Tononi. Inst. Biol. Chem. and Dept. Physiol. Biochem., Univ. of Pisa, Italy, I-56100.

There is strong evidence that wakefulness (W) and sleep (S) are associated with changes in the expression of certain genes, including transcription factors, in specific brain areas. Among potential target genes are those coding for the subunits of calmodulin-dependent protein kinase II (CaM-K II), which has been implicated in synaptic plasticity. We examined the expression of CaM-KII mRNA in the brain of rats sacrificed after spontaneous W or S and after sleep deprivation (SD).

Two groups of rats were killed at 2PM either after a long period of S(n=6) or at least 30min of W(n=6). A third group of rats was sacrificed at 2AM after a long period of spontaneous W(n=6). 3 animals from each group were used for in situ hybridization (ISH) and 3 for Northern blot (NB) analysis. Rats underwent manual SD for 3h(n=6), 6h(n=4), 12h(n=5), and 24h(n=6) starting at 8AM, and for 12h(n=6) starting at 8PM. Controls were sacrificed at the same phase of the 24h cycle.

The expression of CaM-K II is strongly and differentially modulated during spontaneous S-W states, as shown with both ISH and NB: the α subunit mRNA increases during spontaneous W in the cerebral cortex and hippocampal formation, while in the same areas CaM-K II ß mRNA decreases during W with respect to S. After SD, the changes in the expression of both subunits of CaMK-II in the cerebral cortex and hippocampus were less marked than after spontaneous W.

Given the involvement of CaM-K II in long-term potentiation, kindling and learning, the observation of changes in its expression in specific brain areas during spontaneous and forced W suggests potential differences in synaptic functioning during different arousal states.

LONG-TERM IMAGING OF INTRACELLULAR CALCIUM IN CELLS OF THE SUPRACHIASMATIC NUCLEUS. Michael E. Geusz* and Gene D. Block. NSF Center for Biological Timing, Department of Biology, Univ. of Virginia, Gilmer Hall, Charlottesville, VA 22903.

The use of Ca^{2+}-sensitive fluorescent dyes such as Fura-2 to measure intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) is often limited by time-dependent loss of dye from the cell and its gradual compartmentalization into regions that are not representative of cytosolic Ca^{2+}. Dextran-conjugates of Fura-2 circumvent these restrictions but require microinjection, limiting their usefulness with small neurons such as those of the suprachiasmatic nucleus (SCN). Because the SCN is the principal mammalian circadian pacemaker we wished to monitor $[Ca^{2+}]_i$ in SCN cells for at least 24 hours. Such a capability would provide $[Ca^{2+}]_i$ measurements in individual SCN cells throughout the circadian cycle and would allow the effects of phase-shifting agents on $[Ca^{2+}]_i$ to be measured at different circadian phases.

For long-term Ca^{2+} imaging, primary cell cultures of neonatal rat SCN were loaded with the dye Fura-PE3 AM, a modified form of the membrane-permeable Fura-2 AM which is reported to show less compartmentalization and leakage than Fura-2. Cells were loaded for 1 to 2 hours with 10 μg/ml Fura-PE3 AM and then left at room temperature (22°C) in a HEPES-buffered medium. The emission at 510 nm was imaged during alternating 340 and 380 nm light pulses. The cells showed a diffuse cytoplasmic fluorescence for at least 50 hours after loading and elevated K^+ treatments caused repeatable $[Ca^{2+}]_i$ increases in neurons and astrocytes during this time. This approach can be used to measure $[Ca^{2+}]_i$ in SCN cells during the circadian cycle. *Supported by NIH NS15264 and the NSF Center for Biological Timing.*

TTX AND Mg^{2+} RESISTANT SLOW FLUCTUATIONS OF THE MEMBRANE POTENTIAL IN SUPRACHIASMATIC NUCLEI NEURONS *IN VITRO*. L. Trachsel*, K. Kampe, H.U. Dodt, and W. Zieglgänsberger, Max Planck Institute of Psychiatry, Clinical Institute, Clinical Neuropharmacology, 80804 Munich, FRG.

We used spontaneous fluctuations of the membrane potential of SCN neurons as an integral measure to assess neuron ensemble activity as a function of synaptic mechanisms and circadian control. Neurons in cell clusters in rat SCN slices (300 μm; at 35-37 °C, pH 7.4) were visually identified by IR videomicroscopy[a], and voltage clamped at -50mV. Power spectra (0.016-1000 Hz) of the holding current (r.m.s. ~50 pA) were decomposed into Lorentzian components[b]. Oscillations below 10 Hz prevailed in terms of spectral power in both the day and night SCN, and with TTX and Mg^{2+} perfusion. The spectral distributions were fitted (r^2>0.9) with Lorentzian functions. In the SCN corresponding to subjective day, the corner frequencies (f_0) of two Lorentzian components were 9 Hz and 180 Hz. In the nighttime SCN, the f_0 were estimated at 11 Hz and 22 Hz. Power between 1-3 Hz was significantly lower, and power between 70-630 Hz was significantly higher in neurons of the day SCN than of the nighttime SCN ($p<0.05$). TTX significantly suppressed power between 50-500 Hz. Only one Lorentzian component was found (f_0 at 10 Hz) in both circadian preparations under TTX. High Mg^{2+} and zero Ca^{2+} perfusion evoked similar effects. We conclude that SCN neurons held below spiking threshold operate electrophysiologically in a wide frequency range of 1 ms - 64 s periodicity, where slow frequencies of <10 Hz clearly predominate. The TTX and Mg^{2+} sensitive high frequency Lorentzian (200 Hz) suggests fast synaptic sources. The TTX and Mg^{2+} resistant low frequency Lorentzian (<10 Hz), suggests either non-synaptic input, or intrinsic slow rhythm generators in SCN neurons.

CONSTANT LIGHT HOUSING INDUCES FOS PROTEIN IN RAT INTERGENICULATE LEAFLET. K. Edelstein* and S. Amir. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Canada H3G 1M8.

Exposure to prolonged constant light (LL) disrupts circadian rhythms in nocturnal rodents. This disruption may be manifested as a loss of circadian rhythmicity, desynchrony of individual rhythms, or splitting of circadian activity rhythms into two or more components. The neural mechanisms underlying these effects are not well defined, although previous research has demonstrated that ablation of the intergeniculate leaflet (IGL) prevents splitting of circadian activity rhythms in the hamster. We examined the effects of LL on the circadian system of Wistar rats previously housed under a normal light-dark cycle, using a telemetry system to measure temperature and activity rhythms, and the immunocytochemical expression of Fos protein as a marker of light-induced activation of cells in the IGL. Results indicate that LL induces Fos expression in the IGL independent of circadian time. Furthermore, we found a correlation between the disruption of circadian temperature and activity rhythms observed in rats housed in LL for 30 days, and attenuation of Fos immunoreactivity in the IGL of those animals. Whereas Fos expression was observed in the IGL of rats sacrificed during the LL period prior to the loss of circadian rhythmicity, rats sacrificed after this disruption occurred tended to exhibit fewer Fos immunoreactive cells in this region. Results support the idea that the IGL mediates the disruption of circadian rhythms during exposure to prolonged LL. These data also suggest that Fos expression in the IGL may be a marker of the integrity of the circadian system in rats housed under prolonged LL.

Fluorocitrate Affects Circadian Rhythms in Rats. A.S. Elliott* and A.A. Nunez. Dept. of Psych., Neuroscience Program, Michigan State University, East Lansing, MI 48824.

The glial metabolic inhibitor fluorocitrate was used to probe the role of astrocytes in the generation and expression of circadian running wheel and drinking rhythms. Rats (≈180 g) received implants of double cannulae such that the tips of the cannulae were aimed to end immediately dorsal to the suprachiasmatic nucleus (SCN). Animals were placed in running wheels with food and water available ad lib. under dim red illumination. After rhythms were established, animals received an injection of 2 nmol fluorocitrate in each cannula at either the beginning or end of their active phase, and rhythms were subsequently monitored. Wheel running and drinking were subdued for about 24 hr and, upon resumption, showed various changes from previous patterns. A large proportion of animals showed a phase advance regardless of the time of injection. A subset of the animals showed no phase shift but a lengthening of tau, and a small proportion of the animals became "arrhythmic". This arrhythmic pattern persisted even when the animals were placed under a light:dark cycle. Lower doses (1nmol fluorocitrate / cannula) consistently produced a lengthening of *tau*. Taken together, these results support the hypothesis that astrocytes in the SCN play an intimate role in the generation and maintenance of circadian rhythms.

CIRCADIAN CHANGE IN THE INTENSITY OF ULTRAWEAK BIOCHEMILUMINESCENCE FROM RAT SUPRACHIASMATIC NUCLEUS SLICE. Y. Isojima*[1,2], T. Isoshima[3], K. Nagai[1], K. Kikuchi[4] and H. Nakagawa[1]. [1]Division of Protein Metabolism, Institute for Protein Research, Osaka Univ., Suita, Osaka 565, Japan. [2]Photodynamics Research Center, The Institute of Physical and Chemical Research (RIKEN). [3]Frontier Reasearch Program, The Institute of Physical and Chemical Research (RIKEN). [4]Faculty of Engineering, Univ. of Tokyo.

Two classes of light emission related to biological phenomena are known. One is the well-known bioluminescence visible to human eyes which is associated with reactions such as the luciferin-luciferase system. The other is ultraweak biochemiluminescence in the order of 10^{-17}W/mm^2 or less, which is spontaneously emitted from all kinds of living organisms without excitation light. In the previous work, we developed ultrahigh sensitivity photodetection system using a silicon avalanche photodiode and succeeded to detect ultraweak biochemiluminescence from rat hippocampal slice. It was shown that the intensity of biochemiluminescence is at the order of 10^{-18}W/mm^2 and related with neural activity. In the present work, to study the oscillation mechanism of circadian clock in the suprachiasmatic nucleus (SCN), we applied this phtodetection system to the SCN slice culture and succeeded to detect ultraweak biochemiluminesence for as long as 72 hours. The intensity of biochemiluminescence showed circadian change, though its pattern was quite different from electrical or metabolic activity of the SCN. The intensity showed peaks in the middle of subjective night as well as subjective day, and troughs in the transition periods of the day and night. This result suggests that ultraweak biochemiluminescence from the SCN reflects not only neural activity but also other cellular activity.

VARIOUS TYPES OF SLEEP DEPRIVATION HAVE DIFFERENT EFFECTS ON CEREBRAL PROTEIN SYNTHESIS IN THE RAT. P. Ramm and R.K. Zoltoski, Dept. of Psychology, Brock University, St. Catherines, ON L2S 3A1, Canada

We investigate possible restorative functions of sleep by mapping cerebral protein synthesis (CPS) during sleep-wake states. In this study, we compared CPS during post-deprivation recovery sleep under three conditions: a) a short period of manual total sleep deprivation; 24 hr of island platform mixed sleep deprivation, and computer-controlled total sleep deprivation.

Rats received electrodes for recording of EEG and EMG, and cannulae allowing external access to the femoral artery and vein. A 3 day period was then allowed for recovery from surgery. Control animals (n=16) were manually prevented from entering sleep for 4-6 hr. This condition represents minimal deprivation and a uniform high level of sleep need. A 24 hr platform condition (n=11) used medium-sized islands over water. This condition replicates classic REM sleep deprivation. A final deprivation condition (n=9) used 24 hr in a computer-driven rocking cage, which was produced total sleep deprivation (> 99%). Following the deprivation period, the animals were allowed to sleep. L-1[14C]leucine was injected, timed plasma samples were taken for LSC and analyses of free amino acids, and the EEG/EMG were recorded for state monitoring. After 45 min, the brains were extracted, cut in a cryostat, and processed for quantitative autoradiographic analysis of CPS.

In the minimal deprivation (tired) and platform (some SWS deprivation, total REM deprivation) conditions, we failed to observe a relation between recovery SWS and rates of CPS. In contrast, the rocker deprivation group (total sleep deprivation) exhibited a strong ($p < 0.01$) negative relation between CPS and SWS. These data suggest that the metabolic consequences of classic REM sleep deprivation are different from those of total sleep deprivation.

Recovery sleep in Fos-LacZ mice leads to a rapid decline of the elevated Fos and ß-gal levels which result from forced waking. J.E. Sherin, P. Shiromani, J. Morgan and C.B. Saper, Harvard Med. School, Boston MA 02115 & Roche Inst. of Molecular Biology, Nutley N.J. 07110.

Previously we reported that sleep-deprivation (SD) increases the level of Fos-protein in the rat and cat brain, and that recovery sleep (RS) following SD leads to its rapid decline. Using transgenic Fos-LacZ mice (n=6), we examined the effects of SD and RS on Fos and ß-gal levels in brain. Mice were sleep-deprived for 3 hrs. Three mice were sacrificed for analysis immediately after deprivation while remaining animals (n=3) were allowed to sleep or wake spontaneously for 1.0,1.5 and 2.0 hours, at which point they were sacrificed for analysis.

Brains from animals not allowed recovery sleep contained high levels of ß-gal and Fos which were particularly prominent in cingulate and piriform cortices. In contrast, brains from animals which slept spontaneously following deprivation showed a dramatic decrease in ß-gal and Fos.

These preliminary results in Fos-LacZ mice corroborate findings in rat and cat that Fos and now ß-gal protein degradation is enhanced during sleep. We propose that an increase in degradative processes at the cellular level during sleep may be central to the functions of sleep. Thus, the efficient elimination of gene products that accumulate during waking may serve a restorative function at the cellular and ultimately the organismal level.

INVERTEBRATE LEARNING AND BEHAVIOR V

659.1

PHOSPHORYLATION OF THE CONDITIONING-ASSOCIATED GTP-BINDING PROTEIN CP20 BY PROTEIN KINASE C. T. J. Nelson*, C.-L. Yi and D. L. Alkon. Laboratory of Adaptive Systems, NINDS, National Institutes of Health, Bethesda, MD 20892.

The phosphorylation state of cp20, a low-MW membrane-associated GTP-binding protein, was previously shown to increase 2- to 3-fold in *Hermissenda* 24h after associative conditioning. Iontophoretic injection of either cp20 or protein kinase C (PKC) reproduces the biophysical and structural modifications that accompany memory acquisition. Associative conditioning causes translocation of PKC from the cytosol to membrane. Here, cp20 is shown to be phosphorylated by PKC. Marked differences in activity were observed with the three major isoforms of PKC, while casein kinase, CaM-kinase II, and cyclic AMP-dependent protein kinase produced no detectable phosphorylation of cp20, suggesting that the increase in phosphorylation of cp20 after conditioning is due to PKC. Phosphorylation of cp20 had no effect on its GTPase or GTP binding activity, but caused a translocation of cp20 from cytosol to the nuclei / mitochondrial fraction.

659.2

GABA-INDUCED FACILITATION AT TYPE B TO A PHOTORECEPTOR SYNAPSES IN *HERMISSENDA*. L.M. Schultz* and G.A. Clark. Program in Neuroscience, Psych. Dept., Princeton University, Princeton, NJ 08544.

Enhanced type B photoreceptor excitability is a well-documented neuronal correlate of associative learning in *Hermissenda*. However, recent evidence suggests that facilitation at type B to A cell synapses may also contribute to learning in this system. Serotonin (5-HT) has been implicated in both type B cell excitability and synaptic strength changes, and γ-aminobutyric acid (GABA) has more recently been linked to type B cell excitability changes. Here we examined whether GABA would also promote facilitation at type B to A cell synapses.

Rapid bath perfusion with 100 μM GABA followed by a seawater rinse (GABA + RINSE) enhanced the amplitude of inhibitory postsynaptic potentials (IPSPs) elicited in type A cells by type B cell stimulation (mean change ± SEM: +0.99 ± 0.18 mV; $t_9 = 5.56$, $p < .0005$), as did 10 μM 5-HT (+0.53 ± 0.18 mV; $t_9 = 2.92$, $p < .01$), in confirmation of previous results. By contrast, preparations continually perfused with either seawater (-0.33 ± 0.18 mV; $t_9 = 1.85$, NS) or 100 μM GABA (-0.24 ± 0.21 mV; $t_9 = 1.13$, NS) showed no significant changes. An ANOVA ($F_{3,36} = 11.86$, $p < .0001$) followed by Duncan pairwise comparisons revealed that the changes in IPSP amplitude observed in the GABA + RINSE and 5-HT conditions were both significantly greater than the changes in the other two conditions (p's < .01), which did not differ. The observation that GABA + RINSE, but not sustained GABA exposure, promotes synaptic facilitation suggests that when GABA is present, its slow, modulatory effects on synaptic strength may be counteracted by its faster shunting actions; hence, removal of GABA from the bathing medium may have revealed its more sustained modulatory actions. Because the GABA + RINSE condition approximates the transient US-mediated activation of GABAergic hair cells which occurs during associative training of the intact animal, these findings suggest a straightforward means by which behavioral training could promote synaptic facilitation in this system.

VOLTAGE-SENSITIVE DYE RECORDING FROM THE *APLYSIA* ABDOMINAL GANGLION INDICATES MODEST LE CELL RESPONSE TO A LIGHT SIPHON TOUCH. C. Hickie*, L.B. Cohen, and P.M. Balaban. Dept. of Physiol., Yale Univ. Sch. of Med., New Haven, CT 06520, and Inst. of Higher Nervous Activity and Neurophysiol., Moscow.

Recent reports suggest that the LE sensory neurons may not be activated by a light touch that initiates a gill-withdrawal reflex. We have used voltage-sensitive dye recordings to evaluate the role of LE sensory neurons in the generation of gill withdrawals. In recordings made with the abdominal ganglion in sea water, we detected action potentials in about 100 neurons in response to a 1 or 2 g touch. The gill withdrawal in response to this stimulus was vigorous and often seemed to be more than half as large as the response to a 5 g touch. Additional recordings were made in a low calcium or a high divalent sea water. This suppressed the activity of interneurons and motor neurons but presumably did not affect the response of sensory neurons. In experiments on five animals we estimated the number of cells meeting LE-cell criteria (i.e. small, no spontaneous activity, activated by touch in altered divalency sea water, located in the LE region). In response to a light touch a median of 5 cells (range 0 to 8) fired a median of 1.6 spikes/cell (range 0 to 2.9). Given the small PSP size in gill motor neurons from LE spikes relative to the overall PSP size in responses to siphon touch (Byrne et al., *J.Neurophysiol*, 1978), this low activity level is consistent with the existence of other sensory cells responsive to light touch. We estimate that the LE contribution to the motorneuron PSP for light to moderate touches ranges from 0 to 10% depending on the strength of the touch and the behavioral state of the preparation. We are presently recording from other regions of the abdominal ganglion and from other ganglia to search for cells briskly activated by siphon touch in altered divalency sea water. Supported by NSF grant IBN-9222214, and NIH grants NS08437 and NS07102.

NOCICEPTIVE RESPONSES AND SENSITIZATION OF LE SIPHON SENSORY NEURONS IN *APLYSIA*. P.A. Illich* and E.T. Walters. Dept. of Integrative Biology, Univ. Texas - Houston Medical School, TX 77030.

Responses of LE sensory cells to mechanical stimulation were compared in 1) a semi-intact preparation that allows unrestricted siphon movements and 2) a pinned out preparation like that originally used to characterize the LE cell response properties (Byrne, Castellucci, & Kandel, *J. Neurophysiol.*37:1041, 1974). In both preparations LE cells showed maximal activation (including afterdischarge for up to 15 sec) by strong siphon pinch. LE cells displayed a very wide dynamic range to von Frey hair stimuli, sometimes responding weakly to light pressure, and showing graded activation to increasing pressures. Significant depression of mechanosensory threshold was produced by either pinching the unrestrained siphon or by testing the siphon in the pinned out preparation. Siphon pinch or siphon pinning also dramatically increased soma excitability. Water jets that activated LE cells in the pinned out preparation rarely evoked responses in the unrestrained siphon. Weak vibratory stimuli applied several cm away from the siphon never activated LE cells, while reliably activating a set of unidentified neurons in the abdominal ganglion. These results indicate 1) that LE cells can encode nociceptive information, as well as information about innocuous mechanical stimuli, 2) that receptive field injury greatly enhances peripheral and central excitability of the LE cells, and 3) in an extension of previous observations (see Cohen *et al. Soc. Neurosci. Abstr.* 17:1302, 1991), that *Aplysia* has unidentified siphon mechanoreceptors that are far more sensitive to weak mechanical stimuli than the LE cells are.

OCTOPAMINE MAKES LOCUSTS PAY ATTENTION

JP Bacon[1] M Stern[2] JM Blagburn[1]* KSJ Thompson[1]
[1]Sussex Centre for Neuroscience, University of Sussex, Brighton BN1 9QG, U.K.
[2]Universität Hamburg, Zoologisches Institut, D-20146 Hamburg, Germany

Like schoolchildren, insects experience boredom, showing declining responsiveness to repetitive stimulation. However, both can be made more alert and attentive (or aroused) by suddenly presenting an additional, novel stimulus. A clear example of arousal in the locust is provided by the visual system: the habituated response of the descending contralateral movement detector (DCMD) interneuron to repetitive visual stimuli can be dishabituated (aroused) by a variety of other visual and tactile stimuli[1].

We believe octopamine mediates arousal in this system because we find its exogenous application to the locust brain and optic lobes dishabituates the DCMD, much like tactile stimuli do. The locust CNS contains 4 octopamine-immunoreactive neurons, the protocerebral medulla 4 (PM4) neurons[2], that could potentially mediate this effect. PM4 neurons project from the deutocerebrum, through the protocerebrum, and into the optic lobe. Mass spectrometry has confirmed that each PM4 cell body contains approximately 25pg octopamine[2]. Activity in PM4 neurons is increased by tactile stimulation of the locust's head or body, by auditory stimuli or by light on/off visual stimuli[2]. To provide categorical evidence that PM4 neurons can dishabituate the DCMD, we recorded extracellularly from the DCMD and intracellularly from one of the PM4 neurons. When PM4 action potentials were suppressed with hyperpolarising current, the DCMD habituated to a moving visual stimulus. However, depolarising a PM4 neuron, to produce action potentials at approximately 20Hz, significantly increased the number of DCMD action potentials per stimulus. The PM4 neurons therefore play an important role, presumably by the release of endogenous octopamine within the optic lobe, in dishabituation of DCMD by novel stimuli.

CELLULAR ANALYSIS OF HABITUATION OF THE PROLEG WITHDRAWAL REFLEX OF LARVAL *MANDUCA SEXTA*.

D.E. Wiel*, E.R. Wood and J.C. Weeks. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Stimulation of planta hairs on an abdominal proleg of larval *Manduca sexta* evokes withdrawal of the proleg toward the body wall. The proleg withdrawal reflex (PWR) habituates with repeated deflection of one or more planta hairs (Wiel & Weeks, 1992, *Soc. Neurosci. Abstr.* **18**:942). In semi-intact preparations consisting of a proleg and the associated segmental ganglion, repeated deflection of a planta hair or electrical stimulation of its sensory neuron results in a decrease in the number of spikes evoked in the proleg motor nerve (Wood, Wiel & Weeks, 1994, *Soc. Neurosci. Abstr.* **20**:582). This decrease in evoked motor neuron activity is a neural correlate of habituation of the PWR.

Using the same preparation, we recorded intracellularly from the principal planta retractor (PPR) motor neuron during habituation training (20 brief trains of electrical stimuli delivered to a planta hair sensory neuron, at 60 s intervals). The number of spikes evoked in PPR decreased significantly over training, representing a neural correlate of habituation in a single motor neuron. Several possible underlying mechanisms were examined. The amplitude of monosynaptic EPSPs evoked in PPR by the stimulated sensory neuron did not differ significantly before and after training. PPR's resting membrane potential, input resistance and spike threshold were also measured before and after training. There were no differences between the habituation group and a control group which received only trials 1 and 20 during training. These results suggest that other mechanisms, such as changes in polysynaptic pathways in the reflex circuit, may underlie habituation of the *Manduca* PWR. Supported by NIH T32 GM07257 (DEW), R01 NS23208, K04 NS01473, the Murdock Trust and an NSF Presidential Young Investigator award (JCW).

659.7

CHARACTERIZATION OF A MORPHOLOGICALLY DISTINCT SUBSET OF SENSORY NEURONS IN THE PLEURAL GANGLION OF *APLYSIA*.

H. Zhang,* J.H. Byrne and L.J. Cleary, Dept. of Neurobiology and Anatomy, Univ. Texas Houston Medical School, Houston, TX 77225.

The tail-siphon withdrawal reflex of *Aplysia* is a useful model system for studying simple forms of learning and memory. The sensory neurons mediating the reflex are located in a cluster on the ventrolateral surface of the ganglion. Most of these neurons project to the periphery through pedal nerves, including those to the head (Zhang et al. 1993). A small number projected through the cerebral-pleural connective. Because of their unusual projection, we wanted to confirm that these neurons were sensory in function. Members of this subset (n=20) were identified by stimulating ipsilateral cerebral nerves. Their location on the rostral edge of the cluster corresponded to the subset of sensory neurons labeled by backfilling the cerebral-pleural connective. Tactile stimulation of the head skin elicited action potentials without prepotentials. Hyperpolarization of the cell body reduced the amplitude of the action potentials. Most of these sensory neurons had receptive fields on the anterior tentacle (n=17), and a few had receptive fields on the posterior tentacle (n=2) and lips (n=1). Physiologically-identified cells were injected iontophoretically with 2% dextran tetramethylrhodamine. All of these neurons projected out both the cerebral-pleural and pleural-pedal connectives. Some of these neurons were bipolar (n=8). In 10 preparations, axons could be traced out cerebral nerves (C1=1, C2=7, C4=2). In 2 preparations, a contralateral branch arose within the cerebral ganglion.

Our results suggest that a subset of sensory neurons located on the rostral edge of the pleural sensory cluster are primary mechanoreceptors for the head. These neurons are morphologically distinct in that they are either bipolar or bifurcate within the pleural ganglion. Functionally, they may be more closely related to sensory neurons in the J and K clusters of the cerebral ganglion, which also project to the pedal and pleural ganglia, than to other sensory neurons in the pleural cluster.

659.8

CELLULAR CORRELATES OF LONG-TERM SENSITIZATION IN *APLYSIA*.

W.L. Lee*, M.Aguirre, L.J. Cleary, J.H. Byrne. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston TX 77225.

Long-term sensitization is an important form of learning exhibited by the tail-siphon withdrawal reflex. Previous work demonstrated that long-term sensitization was lateralized, and was correlated with changes in the membrane properties of tail sensory neurons (Scholz and Byrne, 1987). In this study, we extended these observations to include properties of both sensory and motor neurons innervating the tail, as well as the synaptic connections between them.

Animals were trained as described previously (Scholz and Byrne, 1987). Enhancement of siphon withdrawal was greater on the sensitized side of the animal than on the contralateral control side (186 ± 14% vs. 121 ± 7%, $P < 0.0001$). Training increased the excitability of sensory neurons from the sensitized side of the animal. A depolarizing current pulse (2 nA, 1 sec) elicited 14.3 ± 1.4 spikes on the sensitized side compared with 7.5 ± 1.2 spikes on the control side ($P < 0.001$). Moreover, the afterdepolarization following the pulse was enhanced in sensitized ganglia compared with controls (2.7 ± 0.8 mV vs. 0.7 ± 0.3 mV, $P < 0.03$). Resting membrane potential and input resistance were unaffected. Training had no significant effects on properties of tail motor neurons, including resting membrane potential, input resistance and spike threshold. Synaptic currents elicited by a single action potential in a sensory neuron were calculated by dividing the amplitude of the evoked EPSP by the input resistance of the motor neuron. Training enhanced the calculated synaptic current (1.85 ± 0.33 nA vs. 0.92 ± 0.23 nA, $P < 0.03$).

In these experiments, long-term behavioral training produced a lateralized enhancement of sensory neuron excitability, which is consistent with the change in net outward currents described previously (Scholz and Byrne, 1987). Synaptic transmission between sensory and motor neurons mediating tail withdrawal was also enhanced in the trained side of the animal. Therefore, these experiments confirm that the same cellular changes induced *in vitro* (Zhang et al, 1994) are correlated with long-term sensitization *in vivo*.

659.9

CHANGES IN CALMODULIN (CAM) AND ROLE OF CA^{2+}/CAM-DEPENDENT PROTEIN KINASE II IN SYNAPTIC FACILITATION IN *APLYSIA*.

F.Zhang*, K.Nakanishi, D.A.Baxter, S.Hattar, Q.R.Liu, K.Macphee, A.Eskin, and J.H.Byrne. Dept. of Neurobiology & Anatomy, Univ. of Texas Med. Sch., Houston, TX 77030, and Dept. of Biochem. and Biophys. Sci., Univ. of Houston, Houston, TX 77204.

Experiments using *in vitro* translation of mRNA indicated that the level of mRNA for calmodulin (CaM) was increased by an *in vitro* analogue of sensitization training in *Aplysia* (Zwartjes, et al., 1992). This raised the possibility that CaM and Ca^{2+}/calmodulin-dependent protein kinase II (CaMK) may play a role in the induction and maintenance of short- and/or long-term facilitation (STF and LTF). Indeed, we previously found that KN62, an inhibitor of CaMK, reduced 5-HT-induced STF in sensorimotor synapses in the pleural-pedal ganglia (Nakanishi *et al.*, 1994). The present studies have extended these findings. First, using ribonuclease protection assays, we confirmed the increase of CaM mRNA in sensory neurons (SN) induced by 5-HT, and also by behavioral training, which induced long-term sensitization (see Lee et al., this volume). Second, we examined LTF in isolated pleural-pedal ganglia. The amplitudes of EPSPs at identified sensorimotor connections were measured before and 24 hr after nerve stimulation, an analogue of long-term sensitization training. Neither KN62 nor KN04 (an inactive form of KN62), applied during stimulation, blocked the induction of LTF. Third, to test the possible role of CaMK in the maintenance of LTF, we continued the experiment by applying KN62 after the 24 hr tests, and testing the EPSPs again 15 min later. KN62 did not block the expression of LTF. Finally, we examined the effects of KN62 on 5-HT-induced spike broadening and increases in excitability in SN. KN62 was applied to isolated SN soma after 3 baseline tests (ISI=5 min) and 15 min before the application of 5-HT. KN62 by itself induced a slight increase in the duration of the action potentials relative to KN04, but did not block 5-HT-induced broadening. In addition, KN62 had *no effect* on either basal excitability or the 5-HT-induced increases in excitability. These data suggest that a spike duration independent (SDI) process contributes to STF and that CaMK plays a role in this SDI process. Although CaMK does not appear to be necessary for LTF, calmodulin may act through mechanisms other than CaMK.

659.10

A *TOLLOID*-LIKE GENE IS REGULATED IN *APLYSIA* NEURONS BY TREATMENTS THAT INDUCE LONG-TERM MEMORY.

Q. R. Liu*, S. Hattar, K. MacPhee, J. H. Byrne#, and A. Eskin. Dept. Biochem. & Biophys. Sci., Univ. of Houston, TX 77204. #Dept. Neurobiol. & Anat., Univ. of Texas Med. Sch., Houston, TX 77030.

Long-term facilitation of sensory-motor connections of *Aplysia* is produced by long-term sensitization training or procedures that mimic that training. The long-term effects are dependent on protein and mRNA synthesis (Montarolo et al., 1986). Recently, we began to use differential display reverse transcription PCR (DDRT-PCR) to identify genes whose expression is regulated by long-term training procedures. We found several mRNAs whose levels appeared to be regulated immediately after treatment of isolated pleural-pedal ganglia with 5-HT for 1.5 hr. One of these mRNAs was selected for further study. The labelled PCR fragment affected by 5-HT was reamplified and cloned. To confirm the change in mRNA of this clone observed using DDRT-PCR, ribonuclease protection assays (RPA) were performed to examine mRNA from pleural-pedal ganglia treated with 5-HT for 1.5 hr. 5-HT significantly increased the levels of mRNA for this clone in the ganglia. Moreover, this mRNA was also increased in tail sensory neurons isolated from the ganglia. Finally, we found that this mRNA level in sensory neurons was also increased by long-term behavioral training.

Aplysia head ganglia cDNA libraries were screened to identify the gene affected by 5-HT. Eight separate positive clones were isolated with different insert sizes (1.5–4.0 kb). Sequence analysis showed that the *Aplysia* gene affected by 5-HT is 41-45% identical to a developmentally regulated gene family including *Drosophila tolloid* gene and human bone morphogenetic protein 1 (BMP-1). Both *tolloid* and BMP-1 appear to function as zinc proteases to activate TGF-β like molecules. The finding that a *tolloid*-like gene is regulated by 5-HT is important because a large number of studies have shown that synaptic morphological changes accompany the formation of memory in *Aplysia* and in other animals. The *Aplysia tolloid*-like protein could be involved in regulating the morphological changes that are associated with long-term facilitation and other examples of synaptic plasticity.

659.11

CLONING AND CHARACTERIZATION OF A NOVEL GENE REGULATED BY TREATMENTS PRODUCING LONG-TERM FACILITATION IN *APLYSIA* SENSORY NEURONS. K.MacPhee, R.Homayouni, X.Ren, H.West, J.H.Byrne#, and A.Eskin*. Dept. of Biochem. and Biophysical Sci., Univ. of Houston,77204. Dept. of Neurobiology and Anatomy#, Univ. of Texas Med. School, Houston, TX 77225.

Long-term memory in *Aplysia* requires protein and RNA synthesis and can be induced by exposing neural tissue to serotonin (5-HT) (Montarolo, 1986). Using in vitro translation of mRNA and two-dimensional polyacrylamide gel electrophoresis of the protein products, we previously found three proteins, calmodulin, phosphoglycerate kinase and an unidentified one (protein 3) whose mRNA levels were increased in response to treatments that mimic sensitization training (Zwartjes et al, 1992; Eskin et al, 1993). To identify protein 3, we screened a Lambda Zap library of *Aplysia* ganglia with a 132 bp PCR probe amplified using degenerate oligonucleotides designed from the peptide sequence. A 1750 bp cDNA clone, which contained the DNA sequence that codes for the original peptide (58 amino acids), was isolated. An amino acid sequence of 210 residues deduced from the middle of the cDNA clone of protein 3 yielded no similar sequences in a search of Genbank. Approximately 90% of the cDNA clone has been sequenced in one direction. We are currently sequencing the opposite strand. To confirm the change in levels of mRNA we initially observed, ribonuclease protection assays have been used to measure mRNAs. Levels of protein 3 mRNA in pleural sensory neurons were increased by 88±30%, n=5 when ganglia were exposed to 5-HT for 1.5h. Moreover, long-term behavioral training also increased protein 3 mRNA (48±11%, n=6) in sensory neurons.

659.12

ACQUISITION AND RETENTION OF HABITUATION OF THE OLFACTO-CARDIAC RESPONSE IN *PROTOPHORMIA TERRAENOVAE*. A.M. Angioy*, P. Casula, P. Muroni, N. Piroddi, C. Reali, I. Tomassini Barbarossa. Department of Experimental Biology, General Physiology, University of Cagliari, Viale Poetto 1, 09126 Cagliari, Italy.

Olfactory stimulation of antennal receptors can release the cardiac response of premature heart-beat reversal in the blowfly. Repeated stimulation with 1-hexanol vapors can iteratively evoke the response or lead to response habituation depending on the efficacy of the chemical concentration in inducing behavioral responses of rejection as well.

By simultaneously recording heart activity and sensory input on intact flies, we examined the dynamics of acquisition and retention of response habituation as a function of stimulus intensity and interstimulus interval (ISI). The response habituates faster to low intensity stimulation repeated at the shortest and longest ISI. Duration of habituation retention is directly related to stimulus intensities adopted, and it ranges between 30' and 120' mean values. The response to olfactory stimulation is promptly restored in habituated flies, i.e. dishabituation takes place, following intense stimulation of mechano-taste receptors on the labellar area.

LONG-TERM HYPEREXCITABILITY OF *APLYSIA* SENSORY NEURONS: INTERACTIONS OF AXOTOMY AND 5-HT. X. Liao, J. D. Gunstream, T. M. Grogean, and E.T. Walters*. Department of Integrative Biology, Univ. of Texas - Houston Medical School, TX 77030.

Both repeated 5-HT application to sensory neurons (SNs) in dissociated cell culture (Dale & Kandel, *J. Neurosci.* 7:2232, 1987) and close axotomy of SNs in organ culture (Gunstream *et al., J. Neurosci.* 15:439, 1995) enhances soma excitability 1 day later. To begin to explore potential interactions between signal pathways activated by axon injury and by 5-HT, we have examined the effects of 5 applications of 5-10 μM 5-HT on SNs axotomized different distances from the soma 1-2 hr earlier. 5-HT treatment enhanced the excitability (tested 20-30 hr later) of SNs whose axons had been crushed 10-20 mm from the soma (8.6 ± 0.7 spikes after 5-HT vs. 6.0 ± 1.1 spikes in contralateral controls, p=0.02; n=7 animals). This distance is short enough to allow retrograde transport of axonal injury signals to the soma within 20 hr. In contrast, 5-HT application had little effect on the excitability of SNs in which the distance to the axonal crush was too long (>40 mm) for such signals to reach the soma by this time (4.5 ± 1.2 vs. 4.2 ± 0.7 spikes, n=5). [However, 1 of these 5 "long nerve" preparations did show a significant within-animal effect of 5-HT.] Repeated application of 50 μM 5-HT had no obvious effect in the "long nerve" preparation (3.5 vs. 3.5 spikes, n=2 animals). These results suggest that axonal injury signals may permit 5-HT-induced long-term hyperexcitabilty to be expressed. Injury signals produced by extremely close axotomy (excising the SN somata) were not sufficient to permit 5-HT-dependent soma hyperexcitability (5.9 ± 1.3 after 5-HT vs. 6.8 ± 0.7 spikes, n=5 animals), indicating that interactions between 5-HT and axotomy signals are complex and depend upon the site of axonal injury.

659.14

AXOTOMY-INDUCED HYPEREXCITABILITY OF *APLYSIA* SENSORY NEURONS REQUIRES PERIPHERAL CALCIUM. J. D. Gunstream*, G.A. Castro and E.T. Walters. Department of Integrative Biology, Univ. Texas - Houston Medical School, TX 77030.

Nerve injury in *Aplysia* leads to long-term hyperexcitability of the central somata of sensory neurons (SNs), which is triggered (at least in part) by retrograde transport of axonal injury signals to the soma (Gunstream *et al., J. Neurosci.* 15:439, 1995). To begin to define initial cellular signals of axonal injury we used an *in vitro* preparation in which peripheral nerves containing axons of VC SNs could be treated selectively. 24-30 hr after proximal nerve crush, a 1 sec depolarizing pulse at 2.5x threshold elicited 6.8 ± 0.8 spikes in axotomized SNs, whereas paired, contralateral SNs whose axons were left in 0 Ca^{2+} (nominally) or 0 Ca^{2+} and EGTA displayed only 3.8 ± 0.3 spikes ($p<0.001$, n=29 cell pairs). A solution containing 100 μM Ca^{2+} did not prevent hyperexcitability (7 spikes vs. 6.5 spikes in normal Ca^{2+}, n=8 cell pairs). Elevation of Ca^{2+} alone does not appear sufficient to trigger hyperexcitability since calcium ionophores (100 μM ionomycin or calcimycin) applied to long nerves (which do not exhibit hyperexcitability within 30 hr) had no significant effect (4.0 spikes vs. 4.4 spikes without ionophores, n=24 cell pairs). However, an initial study using 100 μM BAPTA-AM (which is membrane permeant) suggests that an elevation of intracellular Ca^{2+} may be necessary for triggering long-term hyperexcitability. How Ca^{2+} exerts its necessary role(s) is not known. Preliminary experiments have revealed no consistent effects on hyperexcitability of bathing the nerve crush site with several nonspecific inhibitors protein kinases (K-252a, staurosporine, and KN-62; 5-20 μM each).

ACETYLCHOLINE INDUCES INK SECRETION FROM ISOLATED INK VESICLES IN *APLYSIA*. T.L. Ross*, J. Prince and T.G. Nolen Dept. of Biology, University of Miami, P.O. Box 249118, Coral Gables, FL 33124.

The secretion of ink provides *Aplysia* with an active chemical defense against predators (Nolen *et al*, ICP 176:239-254). Ink pigments are extracted from the phycobilisomes of red algal rhodoplasts. An ultrastructural analysis combined with immuno-gold labeling of phycoerythrin (the main ink pigment) suggests that it is released by rhodoplast catabalism in the hepatopancreas. Soluble pigments are taken up by granulate cells within the ink gland via coated vesicles and then packaged in large (50-1000μm) secretory vesicles that develop from single uni-nucleate cells. Activation of muscles surrounding each vesicle forces ink through a valved duct to the gland's surface.

Ink secretion is centrally mediated by a neural circuit within the Abdominal ganglion (Abd. g.) [Carew and Kandel, 1977]. We present evidence that the peripheral control of vesicle activation is cholinergic: Isolated individual ink vesicles were dissected from undisturbed ink glands and assayed using an ascending conc. series of ACh dissolved in high divalent cation ASW. ACh induced ink release from 33 of 38 vesicles compared to 1 of 9 controls ($p<0.0005$) (N=3 animals). At least 75% of the vesicles released ink at ACh concentrations ≤ 0.5mM (median = 0.25mM). Koester & Kandel (1977) report that the identified neurons in the Abd. g. thought to be responsible for generating the inking response ($L14_{A-C}$) are non-cholinergic. Our evidence for cholinergic activation of individual ink vesicles implies the existence of yet unidentified cholinergic central and/or peripheral ink motoneurons. This is further indicated by experiments where the peripheral nerves containing the axons of $L14_{A-C}$ were cut. Following recovery, ink secretion was still observed if other peripheral nerves were left intact (N=5). These results suggest that other neurons in addition to $L14_{A-C}$ are sufficient for inking. Currently we are employing intracellular staining, tract tracing, immunohistochemical and pharmacological techniques to identify central and peripheral neurons of the ink circuit. RAPID CONDITIONED CHANGES IN TASTE REACTIVITY RESPONSES: COMPARING TASTE AND ODOR CUES. K.-P. Ossenkopp*, B. Navarro, L. A. Eckel and S. N. D. A. Clarke. Neuroscience Program and Department of Psychology, University of Western Ontario, London, Ontario, Canada, N6A 5C2.

Conditioned flavour aversions (CFAs) can be produced by pairing ingestion of a novel food with exposure to a toxin, such as LiCl. Using a rapid, within session, conditioning paradigm, the effects of pairing a novel taste (saccharin), odor (almond), or taste-odor mixture (saccharin-almond) with LiCl treatment, on conditioned changes in taste reactivity responses (TRRs) were examined. On 2 occasions male rats were injected with NaCl or LiCl (3 meq/kg, i.p.) placed in an observation box for 30 min, and given 7 brief (30 sec) intraoral infusions (0.78 ml/min) of a sodium saccharin (0.2%), almond odor (2%), or saccharin-almond mixture dissolved in distilled water, at 5 min intervals. Relative to the NaCl control rats, the LiCl treated subjects exhibited significant ($ps < 0.01$) conditioned reductions in ingestive TRRs and increased levels of passive drip. When tested with saccharin or almond alone in a CFA test phase (no injections), conditioning to the taste or odor cue was found to be equally strong. The present results provided no evidence for a taste-potentiated odor conditioning effect. (Supported by NSERC and MRC of Canada).

660.2

EXCITOTOXIC LESIONS OF THE RAT LATERAL HYPOTHALAMUS: EFFECTS ON TASTE AVERSION. J.M. Scollon, M.P. Latimer and P. Winn (SPON: Brain Research Association) School of Psychology, Univ. St Andrews, Fife, Scotland KY16 9JU.

Excitotoxic lesions of lateral hypothalamus (LH) produce small reductions in intake; no motor impairments; continued ability to regulate intake after addition of glucose or salt to the diet; normal responding to food and water deprivation (including prandial drinking). LH lesioned rats also show normal motivation measured by responding for food on progressive ratio schedules. There are though always impairments in responding to physiological challenges such as hypertonic saline. Excitotoxic lesioned LH rats also respond as controls to adulteration of the diet with quinine or saccharin, indicating normal taste processing. Taste aversion conditioning (the association of a specific taste with experimentally produced malaise) has not been investigated. To examine this, bilateral LH (2.0 µl 0.09M NMDA in phosphate buffer) and control (2.0 µl phosphate buffer) rats were water deprived for 19h/day for 3 days. On the fourth day rats were given 0.15% saccharin solution instead of water for 30 min. Intake did not differ between lesioned and control rats. Immediately after, half the LH and half the controls were given 20ml/kg 0.15M LiCl; the remainder had an equal volume of NaCl. Behavior was observed for 30 min post-injection. All LiCl treated rats showed a characteristic "lying-on-belly" reaction. 3 days after this rats had a two-bottle drinking test: one bottle contained 0.15% saccharin solution, the other tap water. Intake of saccharin solution was suppressed in both LH and control rats which had previously had LiCl injections; injection of NaCl had no effect. In further tests, drinking in response to hypertonic saline was significantly suppressed in LH rats compared to controls. These data indicate that LH lesioned rats which characteristically fail to respond as controls to injections of hypertonic saline perform normally in tests of taste aversion.

660.3

AMYGDALA LESIONS ATTENUATE PICA ELICITED BY LITHIUM CHLORIDE INJECTIONS BUT NOT BY FOOD DEPRIVATION IN RATS. D. Mitchell*[1] and [2]S. Maren. [1]Dept. of Psychol., Univ. of So. Calif., Los Angeles, CA 90089, [2]Dept. of Psychol., Univ. of. Calif., Los Angeles, CA 90024.

The amygdala is known to modulate a wide spectrum of visceral phenomena including gastric motility, secretions, pathology, and gastrointestinal malaise. In previous research, we have demonstrated that pica, the consumption of non-nutritive substances, is a useful animal model for quantifying unpleasant visceral sensations produced by a variety of treatments such as food deprivation and lithium chloride injections. We here report two experiments investigating the effects of bilateral electrolytic (Experiment 1) and ibotenic acid (Experiment 2) amygdala lesions on food deprivation- and illness-elicited pica. In Experiment 1, lesioned and sham-operated rats were maintained with food, water, and kaolin (non-nutritive clay) continuously available throughout the testing sequence, except for the initial food deprivation test during which the food was removed from all rats for 24 h. Two weeks following surgery and three days following the food deprivation test, half of the sham rats and rats with amygdala lesions were administered lithium chloride (0.15 M, 20 ml/kg, i.p.) every third day for a total of five treatments. The remaining sham rats were treated identically except that they were administered an equivalent volume of isotonic saline (0.15 M) on each of the five treatment days. Though all three groups engaged in comparable amounts of deprivation-elicited pica, amygdala lesions eliminated the robust increase in illness-elicited pica apparent in shams given repeated lithium chloride treatments. Saline controls did not engage in pica on any treatment day. A similar pattern of results was obtained in Experiment 2 with ibotenic acid lesions in the amygdala. These results reveal that neurons in the amygdala mediate behavioral responses to the visceral malaise induced by lithium chloride, but not by food deprivation, and they further demonstrate the utility of pica as an effective tool in studying the psychophysics of subjective visceral sensation.

660.4

THE EFFECT OF INSULAR CORTEX LESIONS ON LITHIUM CHLORIDE INDUCED BEHAVIORAL RESPONSES AND CONDITIONED TASTE AVERSION. P. A. Bryant*, M. A. Norris and I. S. McGregor Dept. Psychology, University of Sydney, NSW, 2006, Australia.

Lithium chloride (LiCl) produces nausea and emesis in humans and is frequently used to induce conditioned taste aversions (CTA) in animals. In rats, LiCl induces a series of unconditioned responses including reduced food intake, hypothermia and decreased motor activity as well as "lying on belly" (LOB), believed to be a postural index of malaise.

The insular cortex (IC) receives taste and visceral afferents from thalamic and brainstem nuclei and has been implicated in the acquisition and retention of CTAs. Previous research from our laboratory has demonstrated increased expression of the c-fos gene in the IC of rats following LiCl injection and following exposure to conditioned and unconditioned taste stimuli.

Water-deprived IC lesioned and sham lesioned rats were given 30min access to 0.1% saccharin solution and then immediately injected (i.p.) with LiCl (0.15M, 20 mg/kg). They were assessed for unconditioned effects of LiCl (hypothermia, anorexia and LOB) for one hour. Starting two days later, they were given four daily one-bottle test sessions (30min) where intake of saccharin was measured. IC lesions had no effect on any of the unconditioned responses to LiCl, with sham and lesioned animals exhibiting a similar level of LOB, aphagia and hypothermia. IC lesions also had no effect on neophobia to the 0.1% saccharin. However, IC lesioned animals showed significantly faster extinction of a CTA to saccharin.

This suggests that although the insular cortex is clearly activated by LiCl (as shown by c-fos expression) it does not mediate the unconditioned effects of LiCl. Rather it may be that the insular cortex is involved in the associational mechanism whereby taste and illness are paired.

660.5

ALTERED INDUCTION OF c-FOS IN THE CENTRAL NUCLEUS OF THE AMYGDALA (CeN) CORRELATED WITH CONDITIONED TASTE AVERSION EXPRESSION. T.A.Houpt*, R.A. Berlin, and G.P. Smith E.W.Bourne Behav. Res.Lab.,Dept.Psychiatry, Cornell Univ.Med.Coll., White Plains, NY 10605.

The induction of c-Fos-like immunoreactivity (c-FLI) in the intermediate nucleus of the solitary tract (iNTS) is a neuronal correlate of conditioned taste aversion (CTA) expression (Houpt et al., 1994; Swank et al., 1994). Decerebrate preparations have demonstrated that intact connections between the hindbrain and forebrain are required for behavioral expression of a CTA. The CeN is a candidate forebrain site required for CTA expression. We quantified c-FLI induction after CTA expression in the CeN as a marker of neuronal activation during CTA expression.

Adult male rats were implanted with sublingual intraoral catheters. Conditioned rats received intraoral infusions of 5% sucrose (6ml/6min) paired with a LiCl injection (12ml/kg, 0.15M ip) 3 times over 1 week. Unconditioned controls received LiCl and sucrose on alternate days (non-contingently) so that no CTA against sucrose was acquired. Two days after the last pairing, rats recieved an unpaired infusion of 5% sucrose (6ml/6min). One hr later, rats were sacrificed and processed for c-FLI. Positive cells were counted within a 0.25 mm radius circle centered on the CeN in conditioned and unconditioned rats. An intraoral infusion of sucrose induced more c-FLI-positive cells in the CeN of conditioned rats (68.3 ± 13.1, n=3) than a sucrose infusion did in unconditioned rats (21.0 ± 2.6, n=3). An acute LiCl injection (0.15M, 12ml/kg) also induced large numbers of c-FLI positive neurons in the CeN (155.0 ± 9.7, n=3). All 3 groups were significantly different from each other (p's <0.005).

Thus the CeN responds differently to an intraoral sucrose infusion at the level of gene expression after acquisition of a CTA against sucrose. The observation of altered c-FLI induction in the CeN complements and parallels our observation of altered c-FLI induction in the iNTS. The CeN has reciprocal connections with many brain regions, including the medial iNTS. This raises the possibility that the induction of c-FLI in the iNTS during CTA expression is causally linked to activation of the CeN.

VARIATION IN AVOIDANCE OF BITTER COMPOUNDS BY RODENTS AND BIRDS. S.A. Wager-Pagé* and J.R. Mason, USDA/APHIS/ADC/DWRC, c/o Monell Chemical Senses Center, Philadelphia, PA 19104.

Quinine hydrochloride (QH) and denatonium benzoate (DB) are non-toxic, chemically dissimilar, bitter tasting compounds. The perceived toxicity of bitter compounds can modify dietary selection by rodents and birds. We evaluated responses of two rodent species, deer mice, Peromyscus maniculatus and, prairie voles, Microtus ochrogaster, and an avian species, European starlings, Sturnis vulgaris to the bitter taste of QH and DB. The effect of adulteration of a preferred food, apples, by soaking in QH or DB (0.01 & 0.1% v/v) solutions was evaluated during 2 hr, 2 choice feeding trials. Both DB and QH (0.01 & 0.1% v/v) decreased apple intake in mice, voles, and starlings $P<0.05$. Voles exhibited greater avoidance of QH (0.1%) than DB (0.1%) selecting 27.8% of their intake from the QH adulterated apples compared to 39.8% from DB treated apple pieces in separate trials, $P<0.05$. Voles avoided QH to a greater extent than either mice or starlings, $P>0.05$. European starlings were less sensitive than either deer mice or prairie voles to these bitter substances requiring higher concentrations of QH and DB to inhibit intake. Despite intraspecies variation in responsiveness, both rodents and birds avoided QH and DB adulterated apples. Therefore, these compounds may be useful in wildlife management of a diverse number of vertebrate species. (This work was supported by a cooperative agreement between USDA/APHIS/ADC/ DWRC and Monell Chemical Senses Center.)

FOREBRAIN CONTRIBUTION TO THE CONDITIONED EXPRESSION OF c-FOS IN NTS FOLLOWING TASTE AVERSION LEARNING. Glenn E. Schafe, Randy J. Seeley, & Ilene L. Bernstein*. Department of Psychology, University of Washington, Seattle, WA 98195

The induction of c-Fos-like immunoreactivity (c-FLI) in intermediate NTS following re-exposure to a taste (CS) which has been paired with LiCl appears to be a reliable cellular correlate of the behavioral expression of a conditioned taste aversion (CTA). This pattern of c-FLI is similar to that seen following administration of the US drug (LiCl). The present studies employed a variant of the chronic decerebrate rat preparation to explore whether circuitry intrinsic to the brainstem is sufficient to support the induction of c-FLI in NTS following both administration of the US drug and re-exposure to the CS taste. In the first experiment, chronic hemidecerebrate rats, which have a unilateral supracollicular brain transection, were injected with either LiCl or NaCl. Hemidecerebrates in the second study were re-exposed to a saccharin CS which had been either paired or unpaired with LiCl. Results indicated that the bilateral induction of c-FLI following LiCl administration was unaltered by the transection, while expression of c-FLI following exposure to the CS taste was evident only on the side of the brain which retained neural connections with the forebrain. These findings indicate that forebrain connections are necessary for the induction of c-FLI in NTS during the behavioral expression of a CTA, but not for that following administration of LiCl. Thus, in the CTA paradigm, two distinct neural pathways appear to mediate the response to the US (LiCl) and CS (taste).

660.8

ROLE OF THE AREA POSTREMA IN CISPLATIN-INDUCED TASTE AVERSION LEARNING IN RATS. B. M. Rabin*. Dept. of Psychology, Univ. of Maryland Baltimore County, Baltimore, MD 21228.

A conditioned taste aversion (CTA) is produced when ingestion of a novel food is paired with a toxin, such that the organism avoids ingestion of the food at a subsequent presentation. CTA learning following treatment with many toxins in dependent upon the integrity of the area postrema (AP), the chemoreceptive trigger zone for emesis. Two sets of experiments examined the role of the AP in the acquisition of a cisplatin-induced CTA and its relationship to a CTA produced by lithium chloride (LiCl).

Injection of cisplatin (3-5 mg/kg, ip) produced a significant test day reduction in the intake of the conditioned stimulus (10% sucrose solution) using a two-bottle test. However, interpretation of these results was confounded by the observation that the injection of cisplatin also produced a reduction in total fluid intake. AP lesions prevented both the acquisition of the cisplatin-induced CTA and the reduction in fluid intake. Preexposing rats to 3 unpaired injections of LiCl (3 mEq/kg, ip) prevented cisplatin-induced CTA learning. Preexposure also prevented the cisplatin-induced reduction in fluid intake.

The results support the hypothesis that the integrity of the AP is necessary for the acquisition of a cisplatin-induced CTA, and that the mechanisms by which cisplatin leads to the acquisition of a CTA are similar to those of LiCl.

660.9

TASTE AND OTHER ORAL RESPONSES ASSOCIATED WITH OVEREATING. P.J.Geiselman*, C.F.Smith, D.A.Williamson, V.Broussard, R.Plum, L.Womble, V.Nguyen, C.Carlton, N.Baker, G.A.Bray, C.Champagne, and D.H.Ryan. Dept. Psychol. & Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA 70808.

Caloric intake can be largely determined by the palatability of food and many highly palatable foods are high in sugar and fat content. The present study was conducted to determine how taste and other oral responses to a high sugar/high fat preload may account for overeating. The Three-Factor Eating Questionnaire was used to identify four groups of women according to history of dieting (High or Low Restraint) and tendency to binge eat (High or Low Disinhibition). Half of the subjects were given a high sugar/high fat preload of chocolate pudding to eat and then were presented with a standard pasta product and told that they could eat as much or as little as they wished. Control subjects were given the pasta only. Regardless of patterns of Restraint or Disinhibition, subjects in the Preload condition ate twice as many calories as did subjects in the control condition. Data will be presented to show how taste and other oral responsivity to the high sugar/high fat chocolate preload are associated with overeating in each of the four groups.

660.10

FAT PAD-SPECIFIC RESPONSES TO HIGH-FAT OR HIGH-CARBOHYDRATE DIET IN DIABETIC RATS. M.F. Wiater*, C.A. Matson, M. Chavez, and S.C. Woods. Department of Psychology, University of Washington, Seattle, WA 98195.

Retroperitoneal white adipose tissue (RWAT) and mesenteric white adipose tissue (MWAT) are more responsive than epididymal white adipose tissue (EWAT) to changes of food intake. Neural and/or humoral factors could be involved. To differentiate these possibilities, we changed the humoral environment by use of streptozotocin (STZ). Diabetic rats (STZ 60 mg/kg; glucose> 400 mg/dl) were divided into two weight- matched groups and fed a high-fat diet (HF; n=15; fat = 43%, carb=19% by weight of diet) or a high-carbohydrate diet (HC; n=13; fat=6%, carb=70% by weight of diet). Non-diabetic controls (n=6) weighed 339 ± 6 g. Diabetes resulted in hyperphagia on the HC diet, but normophagia on the HF diet. Beginning body weights of HF (348 ± 8 g) and HC (345 ± 9 g) were not different. At sacrifice, 4 wks, body weights of HF (347 ± 12 g) and HC (345 ± 11) were also not different, nor were they different from beginning body weights. HC combined fat pad mean weight (5.0 ± 0.6 g) was reduced significantly ($p<0.05$) compared to HF combined fat pad mean weight (9.5 ± 0.8 g). HF rats had comparable EWAT (3.4 ± 0.3 g) and RWAT (3.7 ± 0.5 g) weights. However, HC rats had smaller RWAT (1.4 ± 0.3 g) than EWAT (2.2 ± 0.3 g). In controls, RWAT (4.4 ± 0.3 g) was heavier than EWAT (3.4 ± 0.2 g). Thus, in non-diabetic controls RWAT weighs more than EWAT; in HF, RWAT weighs the same as EWAT; and, in HC, RWAT weighs less than EWAT. MWAT weighs less than EWAT. MWAT mean weight in HC rats was 1.3 ± 0.1 g and in HF rats was 2.1 ± 0.2 g. These results suggest that RWAT is more responsive to dietary differences in diabetic rats than MWAT or EWAT, and that humoral factors are probably important in its control.

660.11

HYPERINSULINEMIA IN HYPERPHAGIC RATS WITH POSTERODORSAL AMYGDALOID LESIONS. B. M. King*, J. T. Cook, and M. F. Dallman. Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148, and Dept. of Physiology, Univ. of California, San Francisco, CA 94143.

Recent studies have found that lesions of the posterodorsal amygdala in female rats result in hyperphagia and excessive weight gain (King et al., 1993, 1994). The animals gain as much as 100 g in 20 days. In the present study, female rats with either sham or posterodorsal amygdaloid lesions were maintained on a restricted feeding schedule for five days and then were given food ad libitum for 15 days. The rats with amygdaloid lesions gained a mean of 52 g during the final 15 days, compared to 14 g for controls. Plasma insulin levels were significantly elevated ($p < .001$) in the rats with amygdaloid lesions both during food restriction and at the end of the ad libitum feeding period. Basal corticosterone and ACTH levels were unaffected by the lesions. These results suggest that the effects of posterodorsal amygdaloid lesions on feeding behavior and body weight may be mediated, in part, by a change in metabolic responses.

660.12

TEMPORAL, BUT NOT SENSORY, LEARNED SIGNALS FOR MEAL INITIATION ARE ASSOCIATED WITH TRANSIENT DECLINES OF BLOOD GLUCOSE IN THE RAT. H.P. Weingarten*, F.J. Smith, L.A. Campfield and D. Elston. Department of Psychology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1.

Rats that have learned to associate cues with food delivery reliably initiate meals upon subsequent exposure to these learned signals for meal initiation. We explored whether the transient decline of blood glucose that is causally related to *spontaneous* meal initiation was also evident in cases of *conditioned* meal initiation. Over a 12 day period, male rats were conditioned to associate a tone-light CS+, presented at 3 hr intervals, with food and the opportunity for ingestion by providing six such signalled meals per day. After conditioning, rats were maintained ad libitum except for approximately 3 hr food deprivation imposed before tests examining the effects of the CS+ on meal initiation and blood glucose. Although the CS+ reliably elicited food anticipatory behavior and meal initiation, its presentation did not result in any systematic change of blood glucose, as measured with continuous withdrawal on-line blood glucose monitoring. However, measurement of blood glucose during the intermeal interval revealed the presence of a transient decline of blood glucose at times that, as a result of the conditioning schedule, rats had learned to anticipate a meal. The parameters of this blood glucose dynamic were similar to the premeal decline of blood glucose associated with the initiation of spontaneous meals. Control rats that had not been provided with an opportunity to learn that meals were provided every 3 hr showed no analogous changes in blood glucose concentration during the intermeal interval. These studies further define the occasions under which meal initiation is associated with transient declines of blood glucose and suggest that this dynamic may be related to meals initiated in response to endogenous signals as opposed to meals instigated by external signals such as exteroceptive CS+'s or the presence of palatable foods.

LATERAL PARABRACHIAL NUCLEUS (lPBN) BLOCKADE ATTENUATES SALINE INTAKE BY RATS WITH LESIONS OF THE AREA POSTREMA AND ADJACENT NUCLEUS OF THE SOLITARY TRACT (AP/mNTS-lesion). T. Wang* and G.L. Edwards. Dept. of Physiol. & Pharmacol., Coll. of Vet. Med., Univ. of Georgia, Athens, GA 30602

Previous studies indicate that 3 h ad libitum saline intake as well as intake after sodium depletion by rats with AP/mNTS-lesions is greater than sham-lesioned rats (Am. J. Physiol. 264:R1242, 1993). Additionally, rats with AP/mNTS-lesions consume increased amounts of highly palatable food (Physiol. & Behav. 32:923, 1984). Electrolytic lesions of the lPBN block or reverse the overingestion of palatable food observed in AP/mNTS-lesioned rats if the lPBN-lesion precedes the AP/mNTS-lesion (Am. J. Physiol. 256:R306, 1989). The present study examined the effect of lidocaine blockade of the lPBN on saline intake in AP/mNTS-lesioned and sham-lesioned rats. All animals were implanted with bilateral cannulae in the lPBN. Bilateral injection of lidocaine into the lPBN significantly attenuated 2% saline intake in AP/mNTS-lesioned rats after sodium depletion. There was no effect of lPBN lidocaine on depletion-induced intake in sham-lesioned rats. This study suggest that lPBN plays an important role in the enhanced sodium appetite observed in rats with AP/mNTS lesions. (Supported by NIH DK 42533)

WATER LOADS DURING SODIUM DEPLETION FACILITATE SALT APPETITE IN SFO-LESIONED RATS. E. M. Starbuck, J. R. Lane, & D. A. Fitts*. Dept. of Psychology, University of Washington, Seattle, WA, 98195.

Reports from this laboratory suggest that the subfornical organ (SFO) is not important for angiotensin II (ANG II) -mediated salt appetite. However, two recent reports by others show that SFO lesions do acutely reduce salt intake after sodium depletion. One concluded, in apparent contradiction to our findings, that blood-borne ANG II may activate receptors in the SFO to elicit salt appetite. These reports also noted that the SFO-lesioned rats drank much less water acutely in response to the diuresis than sham-lesioned rats. The present study examined salt appetite in SFO-lesioned rats after water gavage to determine whether the lesion or the underhydration caused the decreased salt appetite. Male rats with SFO lesions or sham lesions were given a 10 mg/kg dose of furosemide sc followed by either 2- or 10-ml/kg loads of tap water 2, 4 and 18 hr later (6 or 30 ml/kg total load) in different groups. No other food or fluids were available. Two hours after the last load, the rats were given access to water and 0.3 M NaCl for 2 hr. The results (below) showed that: (1) Water intake during the test depended on the lesion condition; and (2) saline intake depended on the amount of water loaded during the depletion. Thus, SFO-lesioned rats can express a robust salt appetite after sodium depletion if they are hydrated equivalently to control rats. This supports our view that the SFO is not necessary for the expression of ANG II-induced salt appetite.

AREA POSTREMA MODULATION OF FLUID INTAKE AND NEUROHYPOPHYSEAL HORMONE SECRETION AFTER HYPERTONIC NaCl ADMINISTRATION. K.S. Curtis*, J.G. Verbalis, and E.M. Stricker. Depts. of Neuroscience and Medicine, U. of Pittsburgh, Pittsburgh, PA 15260

The area postrema is a caudal brainstem circumventricular organ thought to be involved in body fluid homeostasis. Rats with area postrema lesions (APX) show enhanced spontaneous salt intakes and reduced urinary excretion of salt loads. The present studies examined drinking and neurohypophyseal responses to systemic administration of hypertonic saline (HS) in rats with APX. When water was available after HS (2 ml 2 M NaCl, iv), intake by rats with APX (10.4 ± 0.8 ml; n=7) was greater than that by control rats (6.6 ± 0.8 ml; n=17) during a 30-min drinking test, while excretion of the salt load was reduced. In contrast, when only 0.5 M NaCl was available, the enhanced NaCl intake by rats with APX (n=6) was unaffected by iv HS in a 30-min drinking test (7.5 ± 0.7 ml). Baseline plasma oxytocin levels (pOT) in rats with APX (4.4 ± 0.8 pg/ml; n=6) were not different from those in control rats (3.1 ± 0.9 pg/ml; n=11). Although iv administration of HS stimulated pituitary release of oxytocin in both groups, pOT in rats with APX were blunted 30 min after HS (13.5 ± 1.6 pg/ml) compared to those in control rats (21.4 ± 3.2 pg/ml). These results suggest some anatomical segregation of HS-induced drinking and neurohypophyseal responses, and are consistent with our previous proposal that the robust spontaneous salt intake of rats with APX may reflect reduced inhibition by central oxytocin neurons.

MINERALOCORTICOID INDUCED SODIUM APPETITE IN GROUP HOUSED MALE MICE. **K.K. Henricks*, Z.A. Rodd, B.C. Dudek, & N.B. McCutcheon. Dept. of Psychology, University at Albany: SUNY, Albany, NY 12222.**

Up to now, research investigating sodium hunger in mice has failed to produce evidence that mineralocorticoids are involved in sodium appetite. In our own laboratory, doses of deoxycorticosterone acetate (DOCA) ranging from 1mg/kg to 20mg/kg have failed to induce a sodium appetite. However, recent research with fludrocortisone suggests that the mouse, like the rat, does possess mineralocorticoid reactivity for sodium appetite, but, unlike the rat, appears to have a strong dependency on an accompanying glucocorticoid action. Previous experiments were conducted with singly housed, socially isolated mice, a condition which may have altered neural modulating factors that interact with mineralocorticoid control of sodium appetite. Two such factors associated with housing condition and sodium appetite control are corticosterone and serotonin. Therefore, the present experiment was conducted in order to study the effect of DOCA on sodium appetite in mice under housing conditions that attempted to eliminate the reduction of corticosterone and the alteration of the serotonergic system associated with social isolation. Male GHSC mice were group housed and given two counterbalanced treatment conditions - a single daily injection of either 10 mg/kg DOCA or oil vehicle for two consecutive days. Group housed male GHSC mice drank, over 24-h of continuous access to water and 3% NaCl, a significantly larger amount of NaCl after injections of DOCA than after injections of the vehicle. This degree of DOCA effect in mice is comparable, on a ml/kg basis, to that reported in rats with high dose DOCA injections.

DISSECTION OF MEAL CONTROLS IN COLITIS-INDUCED ANOREXIA. E.D. Kustra*, S.Amarelo, S.M. Collins and H.P. Weingarten. Dept. of Psychology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1.

Acute inflammation of the colon (ie, colitis) results in a large but transient anorexia of approximately 3 days duration. Studies indicate that the anorexia is caused by a specific reduction of meal size, not meal frequency, leading to the hypothesis that the suppression of eating reflects an exaggerated response to cues that normally signal meal termination. In order to obtain the greatest stimulus control over meals, we compared meal sizes in colitic and control rats using the intraoral feeding preparation. Male Sprague-Dawley rats were maintained on powder chow and habituated to one intraoral feeding session per day using liquid diet. Then, colitis was induced by infusing 25 mg trinitrobenzenesulfonic acid (TNB) in .25 ml 50% ethanol directly into the colon (N=11). Control rats (N=10) received equivolume infusions of 50% ethanol. Meal sizes were approximately 2.5 times larger when intraoral, compared to real, feeding. TNB-treated rats demonstrated a much attenuated and smaller inhibition of intake on these intraoral meals even though they displayed the expected pattern of anorexia in home cage intake. In a second study, we specifically compared the satiety response of TNB and control rats to intragastric loads. Rats were adapted to a 4 hr/day feeding schedule. Then, half the rats were treated with TNB; the other half with the ethanol vehicle. On Days 1-5 post-treatment, half of the animals in each treatment group received a 5 ml liquid diet preload 20 min prior to the 4 hr feeding period. The other half received no preload. TNB-treated rats displayed the expected pattern of anorexia across days. However, the 5 ml preload had no differential effect on the amount eaten by TNB or control groups. These data suggest that some aspect of the preparatory feeding responses that are eliminated by intraoral feeding may be necessary for the complete expression of TNB-induced anorexia and that differences in postingestive satiety alone may be insufficient to explain fully the small meals associated with colitis. Collectively, these observations suggest that elucidation of the mechanisms accounting for the anorexia of colitic rats will not be simple.

THE USE OF MULTIDIMENSIONAL SCALING IN THE APPRAISAL OF THE RELATIONSHIP BETWEEN BRAINSTEM ELECTRODE PLACEMENT, WEIGHT GAIN, AND FOOD INTAKE. J. Stenger*, S. Jordan and C. Bielajew. School of Psychology, Univ. of Ottawa, Ottawa, Ont., K1N 6N5, Canada.

A multidimensional scaling analysis was used to examine inter-element proximity data from rats that had received chronic electrical stimulation to the brainstem region. The variables were the three histological planes, weight gain, and food intake. The results of the principle components analysis yielded four factors, two of which, weight gain and food intake, were combined into one (mass) factor. The proximity matrix was generated for 45 rats based on the histological data and the factorial scores from the principle components analysis. The multidimensional scaling analysis yielded an $r^2=0.938$ and a stress value of 0.118. Visual inspection of the two dimensional stimulus map revealed that cases formed two clusters on one dimension. The separation along this dimension was influenced by weight gain, food intake, and electrode placement. Not surprisingly, one cluster largely consisted of rats with ventromedial hypothalamic electrode placements, whereas the second cluster contained animals with extra-VMH placements. It appears that weight gain and food intake also differs for these two groups; this theory is born out by previous work from this laboratory.

660.19

A RETROSPECTIVE STUDY OF THE EFFECTS OF CHRONIC SMOKING ON REGIONAL CEREBRAL BLOOD FLOW DURING COGNITIVE PROCESSING. J.L. Austin-Lane*, B.S. Kirkby, J.D. Van Horn, G. Esposito, D.R. Weinberger, K.F. Berman. Unit on PET, Clinical Brain Disorders Branch, NIMH, Bethesda, MD 20892-1384.

Previous studies on nicotine and regional cerebral blood flow (rCBF) have focused on acute effects of cigarette smoking, but very little work on chronic effects of smoking has been done. Using the oxygen-15 water positron emission tomography (PET) method, we retrospectively examined global and regional CBF in 10 chronic smokers (mean age 31.2+9.6) and 10 subjects who had never smoked (mean age 29.9+7.8) while they performed the Wisconsin Card Sorting Test and a sensorimotor control task. Subjects had no caffeine or nicotine for four hours prior to the study, and all subjects were right-handed. Absolute rCBF was calculated on a pixel-by-pixel basis with a least squares method. Data were normalized, pixel-by-pixel, as a ratio of the global mean for regional analyses and regions of interest were drawn on co-planar MRIs for each subject. There was a trend (t=-2.09, p=.052) for the smokers to have higher global CBF (51.3+8.58 ml/100g/min) than the non-smokers (44.6+5.41 ml/100g/min), while their normalized rCBF in the left superior frontal gyrus was lower during both task (t=3.58, p=.002) and control (t=2.54, p=.02). For the smokers, Spearman rank order correlations between smoking index (#cigarettes per day x #years) and rCBF revealed a negative relationship between smoking history and rCBF in the left superior temporal gyrus during the control task (r=-.77, p=.009). These data, although preliminary, suggest that effects of chronic smoking on brain activity can be seen, even in the absence of acute nicotine effects. These results should be interpreted with caution since this study has a small sample size and is retrospective instead of prospective in nature, and many comparisons were made.

STRESS: PRECLINICAL AND CLINICAL STUDIES

661.1

STRESS AND PENTYLENETETRAZOL INCREASE THE RELEASE OF DOPAMINE IN THE PREFRONTAL CORTEX OF ROMAN HIGH-AVOIDANCE (RHA) BUT NOT LOW-AVOIDANCE (RLA) RATS. O. Giorgi, D. Lecca, G. Carboni, V. Frau, V. Valentini, A. Fernandez*[1], G. Di Chiara and M.G. Corda. Dept. Toxicol., Univ. of Cagliari, Italy and [1]Dept. Pharmacol. and Psych., Autonomous Univ. of Barcelona, Spain.

RHA and RLA rats are selected and bred for rapid versus poor acquisition of two-way avoidance behavior in a shuttle box. They also show many other behavioral differences related to emotional factors, RLA rats being emotionally more sensitive. To delineate further the functional factors underlying the different emotivity levels of RHA and RLA rats, we used brain microdialysis to compare the effects of tail pinch (TP, 40 min) and subconvulsant, anxiogenic doses of pentylenetetrazol (PTZ, 15 mg/kg, i.p.) on the release of dopamine (DA) in the prefrontal cortex (PFCX) and nucleus accumbens (NA) in both rat lines. The basal release of DA (fmol/20 µl) was higher in the PFCX of RHA rats (12.6 ± 0.7) than in RLA rats (8.1 ± 0.4, $n = 21$, $p < 0.05$) but no line-related differences were observed in the basal DA release in the NA (RHA: 73 ± 4, RLA: 67 ± 3). TP caused a significant increase in DA release in the PFCX of RHA rats (net release above basal value in 2 h after beginning of TP, fmol: 10.9 ± 1.9, $p < 0.05$) but not in RLA rats (net release: 3.2 ± 2.6, n.s.). Similarly, PTZ increased significantly DA release only in the PFCX of RHA rats (net release, fmol/2 h after PTZ: RHA, 43 ± 7, $p < 0.05$; RLA, 8 ± 5, n.s.). In contrast, TP and PTZ failed to affect DA release in the NA of either line. It is proposed that the activation of the mesocorticolimbic DAergic pathway induced by TP and anxiogenic doses of PTZ may reflect an increased attention of the animal and/or the activation of cognitive mechanisms in an attempt to actively cope with the stressor. These mechanisms appear to be lacking in RLA rats, which are "passive" copers.

661.2

DIFFERENTIAL EFFECTS OF RESTRAINT, IMMERSION AND ELECTRIC FOOT SHOCKS. S. Retana-Marquez, A. Ferreira Nuño, E. Dominguez Salazar and J. Velazquez-Moctezuma*. Lab. of Psychobiology, Universidad Autonoma Metropolitana-Iztapalapa, Mexico city, C.P. 09340.

Previous results have shown that stress response depends on the nature of the stressor. To further analyze this notion, male rats were submitted either to immobilization during 2 (IMB2) hrs, immobilization during 6 (IMB6) hrs, electric foot shocks (EFS) during 5 mins or immersion in cold water (WIM) during 15 min, for 1 day or daily during 15 and 20 days. To assess stress effect, male sexual behavior was evaluated when the stress period had ended, thereafter blood was collected to determine corticosterone titers. Spleen, thymus, liver, testicles, adrenal and seminal glands were also obtained. WIM decreased sexual behavior performance during all periods tested. EFS deteriorated sexual behavior only in days 15 and 20. IMB2 had no effect and IMB6 stimulated sexual performance. All the stressors produced significant increases in costicosterone titers during days 15 and 20, but not in the first day. WIM induced the higher elevation, whereas EFS elicited only slight increases. Only IMB6 induced noticeable changes in total weight of organs. Spleen increased its weight after 20 days of stress and testicles increased their weight after 15 days of stress. This results support the notion that the stress response will depend on the characteristics of the stressful situation.

661.3

STRESS-INDUCED HYPERTHERMIA IN INDIVIDUALLY HOUSED MICE. J.A.M. van der Heyden *, T.J.J. Zethof and B. Olivier Dept. Pharmacology, Solvay Duphar BV, PO Box 900, 1380 DA Weesp, The Netherlands

Measurement of stress-induced hyperthermia (SIH) in group-housed mice requires a large number of animals and is time-consuming. We adapted this method for use in individually housed mice. The effect of various stressors on the rectal temperature of individually housed mice was tested. Repeated temperature measurement at a 10 min interval was chosen as stressor since this enabled measurement of basal temperature and hyperthermic response in each animal. The maximal hyperthermia is reached after 30 min, but 70 % of the response is reached after 10 min. Prior injection of the animals also results in a modest hyperthermia, that is no longer observed if the animals are treated 60 min prior to the first temperature measurement. Various benzodiazepines (diazepam, oxazepam, alpidem) dose-dependently suppressed the stress-induced hyperthermia. Similar effects were found for alcohol and the 5-HT_{1A} agonists buspirone, ipsapirone, flesinoxan and 8-OH-DPAT. Of the various 5-HT drugs tested, TFMPP and eltoprazine were active in this model. No effect was found after administration of ondansetron, ketanserin, fenfluramine, DOI or m-CPP. Of the antidepressant drugs tested, only mianserine showed an anxiolytic effect, but not imipramine, amitriptyline, chlorimipramine and fluoxetine. At high doses also the neuroleptic drugs haloperidol and chlorpromazine attenuated the stress-induced hyperthermia. No effects were found after administration of the glutamate antagonist MK 801 and the CCK_B antagonist CI-988.

In conclusion, the stress-induced hyperthermia model in individually housed mice is a fast and reproducible screening test for anxiolytic activity. The major advantages of this model compared to that described in group-housed mice are the reduction in time and animals needed for an experiment.

661.4

EFFECTS OF CHLORDIAZEPOXIDE ON SOCIAL SEPARATION STRESS IN YOUNG DOMESTIC FOWL; A NOVEL MODEL FOR SCREENING ANXIOLYTIC DRUG EFFICACY. G. S. Watson, M. J. Mark, E. S. Carlson and K. J. Sufka* Departments of Psychology and Pharmacology, University of Mississippi, Oxford, MS 38677.

In response to concerns over issues of validity and utility of traditional procedures for screening anxiolytic drugs, the present study sought to determine whether a relatively inexpensive social separation stress biobehavioral assay, possessing both face and construct validity, would demonstrate predictive validity by screening for the anxiolytic effects of the benzodiazepine agonist chlordiazepoxide (CDP). Thirty min after IM injections of CDP (Exp. 1: 0.0, 3.0, and 10.0 mg/kg; Exp. 2: 0.0, 1.0, & 3.0 mg/kg), eight-day-old cockerels were placed into observation chambers in isolation or with two social companions for a formalin (0.10%) nociceptive test. At the highest dose, CDP produced a sedative effect, independent of the stress manipulation, as indexed by a decrease in ventral recumbency latency. Isolated chicks exhibited distress vocalizations; CDP reversed this separation stress effect in a dose-dependent fashion. Isolated chicks displayed hypoalgesia on the formalin test. CDP (1.0 and 3.0 mg/kg) attenuated this separation stress hypoalgesic effect. Chicks treated with 10 mg/kg CDP exhibited few pain-related behaviors. However, this specious hypoalgesic effect was likely due to CDP's potent sedative effects at this dose. Finally, CDP did not affect respiration rate, but did produce a dose-dependent hypothermic effect. The demonstration of this paradigm's predictive validity suggests that the chick social separation stress model may serve as a useful assay for screening anxiolytic drug effects.

661.5

SEXUALLY DIMORPHIC EFFECTS OF NEONATAL ENVIRONMENTAL DISRUPTIONS ON DEPRESSIVE BEHAVIOR AND PITUITARY-ADRENAL HORMONE FUNCTIONING OF THE ADULT RAT E.P. Zorrilla*, S. Shah, J. Kessler, H. Lieberman, E. Redei. Depts.of Psychology and Pharmacology, U.Pennsylvania, Philadelphia, PA 19104.

Many studies have documented changes in emotional behavior and functioning of the hypothalamic-pituitary-adrenal axis in adult male rats subjected to handling or maternal separation as neonates. However, many of these did not control adequately for litter effects (e.g., genetic differences in parents, gestational/rearing differences), nor did they test for sex differences in their effects. Therefore, we subjected 40 litters derived from Sprague-Dawley dams mated in our colony, to 1 of 5 postnatal conditions: cage-cleaning control (C), daily, 1-hour maternal/litter separations through the 1st or 2nd postnatal week (S1,S2), or a daily handling control for the separation groups (H1,H2). At 60 days of age, analyses of pups' (n=457) behavior in the Porsolt forced swim test (FST) and HPA-responses were performed at the unit of litter, rather than at the unit of pup. Females exhibited more immobility in the FST than males ($p<.0005$). This difference was reduced by both early separation and handling (Sex X Treatment, $p<.005$), as both S and, especially, H males, showed female C levels of 'behavioral despair.' Only H females showed significantly more immobility than C females ($p<.05$). Furthermore, week 2 females, but not males, showed greater increases in immobility than their week 1 counterparts ($p<.05$). Sexually dimorphic effects of the treatments also were observed on basal levels of corticosterone (H=S>C in females, but not males) and ACTH (H=S<C in males, H1>H2 and S2>S1 in females). The present study provides further evidence that adult affective behavior can be altered by early life experiences, reinforces the need to address litter effects, and suggests that some imprinting effects are maternally-mediated.

661.6

STRESSOR EXPOSURE PRODUCES LASTING EFFECTS ON SLEEP/WAKING STATE RELATED CELL ACTIVATION OF THE CAT PARAVENTRICULAR HYPOTHALAMUS. M.P. Kristensen*, D.M. Rector, G.R. Poe and R.M. Harper. Interdepartmental Program in Neuroscience and Department of Anatomy and Cell Biology, UCLA School of Medicine, Los Angeles, CA, 90095.

The paraventricular hypothalamus (PVH) mediates hypothalamo-pituitary-adrenocortical (HPA) axis activation and is subject to multi-level feedback-regulation. Stressors increase PVH discharge acutely, but stress, particularly when repeated or prolonged, can introduce enduring modifications of neural function.

Our purpose was to examine whether PVH neuronal responsivity to perturbations by endogenous, non-stressors can be influenced by stress. We assessed whether PVH activity patterns characteristic of specific sleep/waking states were altered by an auditory stressor. Activity changes were indexed by quantifying tissue light reflectivity, which is inversely proportional to cell discharge.

A coherent image conduit, directly coupled to a CCD camera, was stereotaxically positioned in the PVH of 4 cats. Electrodes were placed for measuring neck EMG, EOG, and cortical EEG to monitor behavioral state. After surgical recovery, multiple video-recordings of scattered light were obtained from freely behaving cats during spontaneously varying sleep/waking states before and after 5 minute exposure to an auditory stressor (white noise > 90 dB). Video-images were grouped by state, and normalized overall, as well as subarea, activity changes were calculated.

Prior to stress, overall PVH activity increased during quiet and active sleep compared to waking states. Activity levels did not change significantly between states after stress, though a blunted variation similar to control patterns was apparent. Activity changes accompanying awakening from quiet or active sleep were reduced by 2/3 after noise exposure.

The results demonstrate state-specific PVH activity patterns, and suggest lasting effects of stress at the cellular level on PVH function. We speculate that a blunted response of state-changes after stress may arise as a result of altered state control and/or HPA feedback effects on the PVH.

661.7

ENHANCEMENT OF HIPPOCAMPAL PRIMED BURST (PB) POTENTIATION BY DEHYDROEPIANDROSTERONE SULFATE (DHEAS). D.M. Diamond[1]*, B.J. Branch[1], M. Fleshner[2], and G.M. Rose[1]. Dept. of Pharmacology, Univ. of Colorado Health Sci. Ctr. and VAMC[1], Dept. of Psychology, Univ. of Colo. Boulder[2].

The neurosteroid DHEAS is produced in the brain and is the major secretory product of the human adrenal cortex. Functionally, DHEAS is described as an anti-glucocorticoid (*Mol. Cell. Biochem.*, 131:99, 1994). However, little is known concerning the effects of DHEAS on hippocampal function. We have provided the first analysis of the effects of DHEAS on hippocampal primed burst (PB) potentiation, an electrophysiological model of memory.

Male rats were administered DHEAS (12-96 mg/kg, sc), then anesthetized with urethane, and the CA1 region of the hippocampus was electrically stimulated (see *Hippocampus*, 2:421-430, 1992). ***There was an inverted-U relationship between the dose of DHEAS and PB in non-stressed rats: whereas 24 and 48 mg/kg enhanced PB, 12 and 96 mg/kg were without effect. Further study revealed that: 1) DHEAS (24 mg/kg) was effective at enhancing PB when given before the rats were stressed; and 2) DHEAS (24 mg/kg) was ineffective at enhancing PB when given after the rats were stressed.*** These findings indicate that DHEAS could protect the hippocampus against the inhibitory effects of stress on synaptic plasticity, but only when the neurosteroid was administered in advance of the stressful event.

661.8

METYRAPONE-INDUCED ENHANCEMENT OF HIPPOCAMPAL PB POTENTIATION CORRELATES WITH TYPE I RECEPTOR BINDING, BUT NOT WITH PERIPHERAL CORTICOSTERONE. B.J. Branch[1]*, M. Fleshner[2], M.J. Meaney[3] and D.M. Diamond[1]. Dept. of Pharmacology, Univ. of Colorado Health Sci. Ctr. and VA Medical Center[1], Dept. of Psychology, Univ. of Colorado, Boulder[2], Douglas Hosp. Res. Ctr., Montreal, Quebec[3].

Corticosterone modulates electrophysiological models of memory, including long-term (LTP) and primed burst (PB) potentiation. We have tested the hypothesis that a dose-dependent reduction of endogenous corticosterone by metyrapone would correlate with the magnitude of PB. Rats were given metyrapone (25, 50, 100 or 200 mg/kg, sc) prior to being anesthetized with urethane, and the hippocampus was electrically stimulated (*Hippocampus*, 2:421-430, 1992). ***All 4 doses of metyrapone were equally effective at reducing serum corticosterone levels to 10-15 μg/dl; however, only the 50 mg/kg dose enhanced PB and reduced the number of available hippocampal Type I receptors.*** Also, doses ≥ 50 mg/kg increased available Type II receptors, independent of serum corticosterone levels. Corticosterone (20 mg/kg, sc) blocked metyrapone effects on PB and Type I binding. This work suggests that metyrapone can affect hippocampal plasticity and glucocorticoid receptors by means other than a reduction in serum corticosterone levels, possibly via its capacity to increase levels of ACTH, DHEA and deoxycorticosterone.

661.9

PSYCHOLOGICAL DISTRESS IN HIV-1 DISEASE: RELATIONSHIP TO HYPOCHOLESTEROLEMIA. G. Shor-Posner*, D. Feaster, T. Baldewicz, N. T. Blaney, M. Miguez-Burbano, K. Goodkin, C. Eisdorfer, M.K. Baum. Departments of Epidemiology and Psychiatry, University of Miami School of Medicine, Miami, Florida.

Disturbances in serum lipid concentrations have been associated with behavioral abnormalities, possibly mediated by serotonin pathways that are altered in HIV-1 infected individuals. The present study evaluated serum cholesterol levels and psychosocial status in 118 HIV-1 seropositive (CDC Stages II, III n= 96; CDC Stage IV 2A n=22) and 52 seronegative homosexual men aged 20-55. Levels of cholesterol were obtained from serum extracts after reaction with Lieberman-Buchard color reagent. Psychological distress was measured with the total mood disturbance score from the Profile of Mood States. Hypocholesterolemia (<150 mg/dl) was significantly related to increased distress ($p=.03$) in both the seropositives and seronegatives. As compared to distress levels of 20.73 ± 31.42 in the seronegatives, distress tended to be higher in the seropositive men (32.81 ± 32.97, $p<0.06$), who had widespread hypocholesterolemia (41% vs 25% in seronegatives, $p<0.05$). Clinical distress (score >60) occurred more frequently among those with hypocholesterolemia (26%), relative to 13% with normal range cholesterol levels ($p=0.03$). These findings demonstrate an important influence of lipid status on psychological function.

661.10

STARTLE AND NEUROENDOCRINE RESPONSES IN SHY CHILDREN L.A.Schmidt, N.A. Fox, E.M. Sternberg, P.W. Gold, C.C. Smith and J.Schulkin* Inst. for Child Study, Univ. of Maryland, College Park, MD 20742.

The relations among behavioral inhibition, morning salivary cortisol, and the acoustic startle response in a sample of 4-year-old children were examined. Analyses revealed a significant relation between morning cortisol level and acoustic startle amplitude. Children who had elevated morning cortisol levels exhibited an augmented startle response. Analyses also revealed a significant relation between 14-month behavioral inhibition and morning cortisol at 4-years. Children who displayed fear and wariness in response to novel stimuli at 14-months of age had elevated morning cortisol at 4-years. These findings are consistent with recent studies of fear responses in animals in which CORT can potentiate fear, and CRH expression in the central nucleus of the amygdala, and are consistent with work on neuroendocrine responses in fearful children. High levels of cortisol in inhibited children may induce CRH in the central nucleus of the amygdala, exacerbating their fearfulness.

661.11

HUMAN RESPONSE TO UNCONTROLLABLE STRESS AND HIGH DOSE NALOXONE J. Fertig*, R. Peters, J. Leu. Walter Reed Army Institute of Research, Washington, D.C. 20307

Forty healthy male subjects were exposed to bursts of 95 dB noise while attempting to solve a visual-spatial task under either controllable stress (CS) or uncontrollable stress (UCS) conditions. CS subjects could terminate both stressors while their yoked UCS partners could not. Measures of physiologic reactivity, biochemical response and mood were monitored throughout the study. Stress induction was followed by a double blind infusion of the opiate antagonist naloxone (1.5 mg/kg) or placebo. A muscle ischemia pain tolerance test was given following drug administration. Physiologic response and several biochemical markers of the stress response were differentially elevated in the two conditions. UCS subjects also reported increased helplessness, lack of control and total mood disturbance. Naloxone administration augmented the stress induced rises in cortisol, heart rate, negative mood and physical symptoms but did not affect diastolic or systolic blood pressure. In addition, naloxone had a differential effect on pain tolerance depending upon subject's prior exposure to CS or UCS. Pain intensity ratings were highest for CS exposed subjects and lowest for UCS subjects. Results suggest that lack of control over psychological stressors can produce differential responses in physiological, biochemical and behavioral systems.

661.12

CORTISOL RESPONSE AND MEMORY FUNCTION FOLLOWING A PSYCHOLOGICAL STRESS IN HEALTHY ELDERLIES : RELATIONSHIP WITH PAST CORTISOL HISTORY.

M.J. Meaney*, S. Gaudreau, S. Sharma, N.P.V. Nair, R.L. Hauger and S. Lupien. Douglas Hospital Research Centre, McGill University, Montreal, Canada, 6875 Bld. Lasalle, Verdun, Québec, H4H-1R3; Research Centre, Centre Hospitalier Côte-des-Neiges, 4565 Queen Mary, Montréal, Québec, Canada, H3W-1W5.

Saliva cortisol responses to the psychological stress of public speaking was investigated in 18 healthy elderly subjects previously shown to present different patterns of cortisol secretion over a period of 3 to 6 years. A test of explicit (cued recall) and implicit (word-stem completion) memory was given to subjects before and after a non-stressfull condition (attention task) and before and after the stressful condition. Correlational analyses performed between memory scores and cortisol responses showed that the explicit recall during the non-stressful condition was negatively correlated with post-recall cortisol levels (r=-0.72) and not with pre-recall cortisol levels (r=-0.24). This correlation lasted for 10 minutes and disappeared for the next cortisol sample. No correlation coefficient reached significance level for the implicit memory task. The explicit recall during the stressful condition was significantly and negatively correlated with both pre-recall/post-stress cortisol levels (r=-0.59) and post-recall/post-stress cortisol levels (r=-0.52), showing that the subjects who reacted to the stress with increases in cortisol levels presented the greater memory impairment as tested after the stressor. This correlation lasted 21 minutes and disappeared for the next cortisol sample. No correlation coefficient reached significance level for the implicit memory task. Finally, the cortisol slope of subjects as measured over a period of 3 to 6 years was negatively correlated with changes in explicit and implicit memory performance after the stressful condition (r=-0.33 & -0.31) but not with explicit and implicit performance after the non-stressful condition (r=-0.11 & 0.09). These results show that aged subjects with a history of increasing cortisol levels over the years present a stronger cortisol response to a psychological stressor and a greater memory decline after a stress than aged subjects showing moderate increase or decrease in cortisol levels with years.

STRESSING THE STRESS CONCEPT: QUANTITY MAKES QUALITY

L. Angelucci*. Farmacologia 2, La Sapienza Univ. Medical Faculty, Rome 00185, Italy.

Contrary to the Selye's concept of stress as a basic hormonal mechanism of adaptation, this physiological phenomenon is often considered in medicine, and presented through the media as a ravaging event resulting, directly or indirectly, in various diseases. This conceptual distortion originates from the well documented deleterious effects of high doses of glucocorticoid hormone, or of chronic fierce stress exposure. On these bases it has been postulated that a high glucocorticoid milieu can damage the hippocampus and exacerbate neurotoxic lesions. We have found that the hippocampal injury by kainic acid is accrued neither by aging nor by repeated stress exposures, two conditions accompanied by or causing large, albeit physiological, increases in plasma glucocorticoid level. A potentiation of the neurotoxic action was encountered only in some strains of rats following injection of corticosterone in doses producing in the periphery and in the brain concentrations of the hormone a hundred times greater than normal. The brain glucocorticoid receptor (GR) binding capacity is controlled by neurotransmitters: dysfunction of the hypothalamo-pituitary-adrenocortical axis during depression, as well of the negative feedback function of the GR, and the relief by antidepressants are operated through loss and reinstatement, respectively, of neurotransmitter action. A totally different image emerges when physiological increases of the hormone are considered. For instance, we have found that rats lactated by a mother with a moderate hypercorticosteronemia (of the same degree as following low-intensity stress exposure), in adulthood show "better" adaptive behaviors and a reduced stress responsiveness. In conclusion, in spite of the principle that quality is more fundamental than quantity, in stress related phenomena quantity appears more momentous than quality. BRAIN CHEMISTRY OF LEARNED HELPLESSNESS: NEURAL NETWORK FOR DEPRESSION MODEL. F. Petty* and G. Kramer. Department of Veterans Affairs Medical Center and Department of Psychiatry, University of Texas Southwestern Medical School, Dallas, Texas 75216.

For many years, the biochemical theories of mood disorders featured one or another of the biogenic amines as key players in the development of depressive symptoms, and in their amelioration by pharmacological treatments. By default, these monoamine theories focused on locus ceruleus or dorsal raphe as anatomical loci for biochemical changes. We have developed a new, multi-transmitter, multi-brain region model for learned helplessness which incorporates the traditional biogenic amine theories, and also explicates the roles of the amino acid neurotransmitters including GABA, glutamate, and glycine. This neuronal model incorporates regions of the limbic system known to regulate mood, and accounts for complex neurotransmitter interactions, particularly in the medial prefrontal cortex, where the cascade of events leading from inescapable stress to behavioral depression begins. Other brain regions considered in the model include entorhinal cortex, hippocampus, lateral septum, hypothalamus, amygdala, and nucleus accumbens. This model will be compared to the neuronal maps being developed for clinical depression using brain imaging. Additionally, new data from *in vivo* microdialysis experiments in progress will be presented.

MONOAMINES AND BEHAVIOR: DOPAMINE I

662.1

EFFECTS OF SELECTIVE AND NON-SELECTIVE DOPAMINE ANTAGONIST ADMINISTRATION IN PREFRONTAL CORTEX ON DRL RESPONDING IN THE RAT. J.D. Sokolowski* and J.D. Salamone. Dept. of Psychlogy, University of Connecticut, Storrs, CT 06269-1020 USA

Previous research utilizing dopamine depletions in the medial prefrontal cortex of the rat demonstrated substantial deficits in operant responding on the differential-reinforcement-of-low-rates 30 sec schedule. In the present experiments, rats were locally injected with one of four dopamine antagonists: the non-selective drug cis-flupenthixol, the moderately D2 selective drug haloperidol, the highly D1 selective antagonist SCH23390, the highly D2 selective antagonist sulpiride. Doses of 5-20 nanomoles per side were injected bilaterally in 1.0 ul total volume, and control injections consisted of lactic acid vehicle. Local injections of flupenthixol increased total number of responses, with the most effective dose being 10 nanomoles. Analysis of interresponse times demonstrated that, at the 10 nanomole dose, there was a 3-4 fold increase in interresponse times in the range of 0-1.0 sec. This indicates that much of the increase in responding produced by flupenthixol was in the form of increased "bursts" of responses that closely followed one another. Local injections of haloperidol in the prefrontal cortex produced effects similar to those observed with flupenthixol. However, preliminary data indicate that the effects of intra-prefrontal SCH23390 and sulpiride were less robust than the effects of flupenthixol or haloperidol in the dose range tested.

662.2

PREFRONTAL CORTICAL GABA RECEPTORS MODULATE STRESS-INDUCED DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS. M. D. Doherty* and A. Gratton, McGill Univ., Douglas Hosp. Res. Ctr., Montreal, Canada, H4H 1R3.

We have recently reported that local D1-, but not D2-, receptor blockade in medial prefrontal cortex (PFC) potentiates stress-induced dopamine (DA) release in nucleus accumbens (NAcc). This finding is consistent with several other lines of evidence indicating that meso-PFC DA neurons exert an indirect inhibitory influence on the NAcc DA response to various stimuli including stress. The PFC also contains GABA interneurons and these too may be involved in modulating the DA stress response in NAcc. We examined this possibility by monitoring restraint-induced increases in NAcc DA-dependent electrochemical signals following bilateral intra-PFC injections (1 nmole/side) of GABA-A and GABA-B agonists (muscimol and baclofen) and antagonists (bicuculline and phaclofen). Intra-PFC baclofen significantly attenuated the peak amplitude and the duration of the NAcc DA response to stress; the GABA-A agonist muscimol produced a similar but less potent and non-significant inhibitory effect. In contrast, PFC GABA-A receptor blockade with bicuculline elicited seizures, whereas the GABA-B blocker phaclofen had no effect. However, intra-PFC phaclofen was found to potentiate the NAcc DA response to stress when it was co-injected with the D2 receptor antagonist sulpiride at a dose we have shown previously to have no effect (Doherty & Gratton, 1994). These findings indicate that PFC projection neurons that modulate the DA stress response in NAcc are regulated in part by GABA acting primarily, but not exclusively at the GABA-B site. They also suggest that, unlike D1 receptors, an involvement of PFC D2 receptors in modulating the NAcc DA response to stress may depend on the activity of cortical GABA interneurons. *Supported by the Medical Research Council of Canada.*

662.3

CHANGES IN NUCLEUS ACCUMBENS DOPAMINE EFFLUX ELICITED BY SCHEDULED AND UNSCHEDULED FOOD PRESENTATION. N.R. Richardson* and A. Gratton, McGill Univ., Douglas Hosp. Res. Ctr., Montreal, Canada, H4H 1R3.

We have recently reported evidence that dopamine (DA) release in nucleus accumbens (NAcc) increases during the moments leading to an operant response (lever-press) reinforced with food (condensed milk) and that consumption of the earned reward is associated with a cessation or inhibition of NAcc DA transmission (Richardson & Gratton, 1994). These and similar other findings are generally consistent with the idea that NAcc DA transmission increases in response to the incentive, behavioral activating properties of rewards. In order to test this idea further, we used voltammetry to monitor the changes in NAcc DA efflux associated with non-contingent presentations of a 0.2 ml meal of condensed milk delivered over 30 sec. Animals received meals either at fixed intervals of 52 secs (FI 52) or on a variable interval (VI 52) schedule of 32,35,40,45,53,64 and 95 secs. Meals presented on the FI schedule were preceded by pronounced signal increases that peaked within a few secs of receiving the anticipated milk reward before decreasing as the animals consumed the milk. These biphasic changes were remarkbly similar to those we have observed previously in animals lever-pressing for food. Similar decreases in signal were observed when animals consumed meals presented on the VI schedule. Under this condition, however, each meal was followed by an increase in signal that peaked rapidly and remained elevated until the next milk presentation. These findings reinforce the idea that DA transmission in NAcc increases in anticipation of a positive outcome. They also suggest that such anticipatory elevations in meso-NAcc DA activity increase as a function of reducing the predictability of the outcome. *Supported by the Medical Research Council of Canada.*

662.4

DOPAMINE AND PLAY BEHAVIOR IN JUVENILE RATS: RELATIVE INVOLVEMENT OF D2 AND D3 RECEPTORS. S.M. Siviy* and A.L. Milburn. Department of Psychology, Gettysburg College, Gettysburg, PA 17325.

Previous work from this lab has suggested that dopamine might be involved in the normal elaboration of playfulness among juvenile rats. Specifically, low doses of the D2/D3 agonist quinpirole tend to increase pinning, an index of play in the rat, while higher doses reduce pinning. Since quinpirole acts at both D2 and D3 receptors, it is not clear from these data which receptor subtype might be responsible for these effects. In the present study, the effects of quinelorane, a more selective D2 agonist, and 7-OH-DPAT, a selective D3 agonist, on play were assessed. Male rats (25-35 days old) were housed individually and given daily 5 minute opportunities to play. One group of rats were injected SC with either vehicle or one of four doses of quinelorane (0.003, 0.01, 0.03, 0.1 mg/kg) 30 minutes prior to a play session. Another group of rats were injected SC with either vehicle or one of four doses of 7-OH-DPAT (0.003, 0.01, 0.03, 0.1). The frequency of pinning was recorded and play bouts were also videotaped for later analysis. 7-OH-DPAT had no significant effect on pinning at any of the doses. Quinelorane significantly increased pinning at the lowest dose (0.003 mg/kg) and decreased pinning at the higher doses, with play being completely abolished at 0.1 mg/kg. These data suggest that dopamine, acting at D2 receptors, can have biphasic effects on play. On the other hand, D3 receptors, which are localized preferentially in limbic structures, do not appear to be involved in play behavior.

662.5

CHOLERA TOXIN INFUSION INTO NUCLEUS ACCUMBENS: INTERACTIONS WITH MOTOR ACTIVITY, DOPAMINE AGONISTS, AND CONDITIONED REINFORCEMENT. A.E. Kelley,* M. Holahan, M. Finn. Dept. of Psychiatry, Univ. of Wisconsin Medical School, Madison, WI 53706

Cholera toxin (CTX) is known to cause long-lasting stimulation of the cyclic AMP second messenger system via activation of the Gs protein. We have previously shown that CTX in the dose range of 50-500 ng, infused bilaterally into the nucleus accumbens (N.Acc.), causes locomotor activation in rats. The present experiments extended this work. First, the behavioral effects of low doses of CTX (0, 5, 15 ng) infused bilaterally into the N.Acc., were examined. Both doses of CTX elicited a small but significant hyperactivity response (locomotion and rearing), which was apparent 2-5 days following infusion. In separate groups of rats, the motor response to intra-accumbens SKF 38393 (0.1, 1.0 μg) or quinpirole (1, 5 μg) was examined 2 days following intra-accumbens CTX (0, 5, 15 ng). The response to quinpirole was completely suppressed in CTX-treated rats. The response to SKF 38393 was affected in a more complex manner; the response to the high dose was suppressed, whereas the response to the low dose was first enhanced and then inhibited. In a second experiment, rats were trained to associate a stimulus (light-click) with food reward. Subsequently, they learned to lever-press for presentation of the stimulus (responding for conditioned reinforcement). Bilateral intra-accumbens infusion of CTX (100 ng/1 μl) induced a significant increase in lever pressing that lasted approximately 5 days, compared with both their own baseline and a control group infused with saline. As a positive control, the same groups of animals were administered the stimulants pripradrol (2.5, 5 mg/kg) and cocaine (10, 25 mg/kg) at later time points; these compounds also enhanced responding for CR. These results suggest that the cyclic AMP system with nucleus accumbens neurons modulates spontaneous and drug-induced locomotor activity, as well as reward-related processes.

662.6

PARAMETRIC ANALYSIS OF IN VIVO STIMULATED NUCLEUS ACCUMBENS DOPAMINE EFFLUX MEASURED BY FAST CYCLIC VOLTAMMETRY AT LEVELS TYPICALLY USED IN RAT SELF-STIMULATION PROCEDURES.
J.E.G. Williams*, Department of Psychology, Eastern Illinois University, Charleston, IL 61920.

Extracellular nucleus accumbens (NAcc) dopamine (DA) levels are increased by electrical stimulation of the ventral tegmental area (VTA). VTA self-stimulation is routinely used to maintain responding in behavioral procedures. Fast cyclic voltammetry (FCV) at carbon fibre electrodes measured the effect of electrically stimulated NAcc DA efflux in anesthetized rats with a time resolution of 10 ms (Millar et al 1992). FCV has advantages in terms of time and spatial resolution over other methods of measuring transmitter release. Single fibre microelectrodes (active surface 7μm dia.; length 20-30 μm) were implanted into the NAcc, and bipolar wire stimulating electrodes implanted into the VTA. Prior to implant, FCV electrodes were electrochemically calibrated *in vitro* with 1 μmol DA relative to a Ag/AgCl reference electrode, in 0.1 Molar phosphate buffered 0.9% w/v NaCl solution, pH 7.4. The FCV potential consisted of a 1.5 cycle, 100 Hz triangular ramp scanning between -1.0 and +1.4V relative to the Ag/AgCl reference with a scan rate of 480 v/s applied at 2 Hz. Signals were fed into a Nicolet 310 storage oscilloscope, and measurement made from hard copies of signals. FCV signals were recorded following VTA constant current stimulation presented at levels typically used in self-stimulation procedures. Results show that stimuli presented to the VTA at levels around those used in self-stimulation are correlated with DA efflux in the NAcc. Therefore, this FCV technique is useful for functional analysis of real-time neurochemical events that maintain motivated responding.

662.7

DOPAMINE RELEASE WITHIN THE NUCLEUS ACCUMBENS ELICITED BY SEX-RELATED OLFACTORY CUES: EFFECTS OF SEXUAL EXPERIENCE. J.B. Mitchell*. Dept. of Psychology, Boston College, Chestnut Hill, MA 02167.

Exposure to primary incentive stimuli, such as food or sex-related cues, leads to an increase in extracellular dopamine (DA) concentrations within the nucleus Accumbens. The current experiments investigated the effect of sexual experience on the neurochemical response to sex-related olfactory cues (bedding from cages that housed estrus female rats). Male rats were tested with each of two primary incentive stimuli, a highly palatable food and sex-related olfactory cues while sexually naive and again after a test for sexual behaviors. During presentation of these stimuli, extracellular DA concentrations were measured within the nucleus Accumbens using high speed chronoamperometry. The electrochemical signal was obtained by applying a +0.55 V pulse, relative to a Ag/AgCl reference electrode, to a carbon fiber electrode, at a rate of 5 Hz. While sexually naive, presentation of either food or sex-related olfactory cues reliably elicited an increase in the electrochemical signal. After sexual experience, the response to sex-related olfactory cues was significantly enhanced, whereas the response to food did not differ from that obtained on the earlier test. These results indicate that naturally rewarding stimuli increase activity within the mesolimbic DA system. Furthermore, the augmented response to sex-related olfactory cues after sexual experience suggests that changes in DA release within the nucleus Accumbens are stimulus specific and depend, at least in part, on the animal's previous experience.

662.8

INDIVIDUAL DIFFERENCES IN SUGAR CONSUMPTION PREDICT INDIVIDUAL DIFFERENCES IN AMPHETAMINE-STIMULATED DOPAMINE OVERFLOW IN THE POSTERIOR-MEDIAL ACCUMBENS. T.L. Sills* and J.N. Crawley, Section on Behavioral Neuropharmacology, NIMH, Bethesda, MD 20892

Rats exhibit significant individual differences in their consumption of sugar and in their response to amphetamine (AMP) treatments. Intrinsic variation in the functioning of the mesolimbic dopamine (DA) system is one potential mechanism underlying the expression of these individual differences. The present experiment examined the relationship between sugar consumption and the DAergic and locomotor responses to AMP (1.75 mg/kg, i.p.). Rats were divided into LOW and HIGH sugar feeders based on a median split of their sugar consumption in response to a saline injection. *In vivo* microdialysis was used to assess AMP-stimulated DA overflow in the posterior-medial nucleus accumbens (Acc) in LOW and HIGH rats, and concomitant measures of locomotor activity were obtained. There was a significant correlation between sugar consumption and AMP-stimulated DA overflow in the posterior-medial Acc. HIGH rats exhibited significantly larger increases in AMP-stimulated DA overflow than LOW rats. HIGH rats also exhibited significantly higher levels of Acc-DA overflow immediately after handling and entry into the novel test chamber, suggesting a possible difference between LOW and HIGH rats in the Acc-DAergic response to mild stress. LOW and HIGH rats did not exhibit differences in locomotor activity either in response to being handled or in response to AMP. These results indicate that the propensity to ingest sugar is a predictor of the Acc-DAergic response to AMP treatment and mild stress.

662.9

EFFECTS OF D-AMPHETAMINE AND PHENCYCLIDINE ON BEHAVIOR AND EXTRACELLULAR CONCENTRATIONS OF NEUROTENSIN AND DOPAMINE IN THE VENTRAL STRIATUM AND MEDIAL PREFRONTAL CORTEX OF THE RAT. T.H. Svensson, P. Hertel, J.M. Mathé, G.G. Nomikos, M. Iurlo, B. Ulfhake* and A.A. Mathé, Dept Physiol & Pharmacol, Div Pharmacol, Karolinska Institutet, 171 77 Stockholm, SWEDEN

The effects of phencyclidine (PCP; 2.5 mg/kg, s.c.) and d-amphetamine (AMPH; 1.5 mg/kg, s.c.) on neurotensin-like immunoreactivity (NT-LI) and dopamine (DA) in the ventral striatum (vSTR) and the medial prefrontal cortex (mPFC) were studied in freely moving rats using microdialysis. The effects of PCP and AMPH on locomotor activity were also analyzed. PCP, but not AMPH, caused a significant 156% increase of NT-LI levels in the vSTR which was relatively short lasting (< 2 h.) In contrast, both drugs significantly increased NT-LI levels in the mPFC by almost 100% during the same period. PCP and AMPH also significantly increased DA levels in the vSTR by 83% and 364%, respectively. However, the peak effect of PCP on DA appeared later than that of AMPH, i.e. at 150 min and 60 min, respectively, after drug administration. Also in the mPFC both PCP and AMPH significantly increased DA levels by 98% and 284%, respectively. Generally, effects on DA levels of both PCP and AMPH were, in contrast to their effects on NT-LI levels, more long-lasting, i.e. of 3-4 hours duration. Behaviorally, AMPH produced a more pronounced, general activation than PCP, with a faster onset of action, i.e. within 30 vs. 90 minutes after administration. However, both drugs produced long-lasting effects on the spatial organization of behavioral activity, which lasted for 3-4 hours. Thus, the more pronounced behavioral stimulation by d-amphetamine vs. PCP in the rat may largely be explained by its more potent DA releasing effect in brain. Initial behavioral suppression by PCP, e.g. of rearing, as well as its rather poor locomotor stimulant action might relate to release of NT in the vSTR. The long-lasting, behavioral disorganization by both PCP and AMPH may, however be related to increased release of DA rather than NT in the mesolimbocortical areas.

662.10

D2 ANTAGONISTS INDUCE STRIATAL FOS-LIKE IMMUNOREACTIVITY IN RATS DEPLETED OF STRIATAL DOPAMINE AS WEANLINGS, BUT NOT AS ADULTS.

M. Sandstrom*, M. Sarter, and J.P. Bruno, Dept of Psychology and Neuroscience Program, Ohio State University, Columbus OH 43210

Rats depleted of striatal dopamine (DA) with 6-OHDA as adults exhibit profound motoric deficits for several weeks after the lesion. Once recovered, these rats are supersensitive to the motoric effects of low doses of D1 or D2 antagonists. Administration of D2 antagonists to rats unilaterally depleted of DA as adults induces Fos-like immunoreactivity (FLI) in the intact, but not in the depleted striatum. In contrast, rats depleted of striatal DA as weanlings (Day 20) exhibit modest motoric deficits for only days after the lesion. As adults, these rats are not supersensitive to the motoric effects of low doses of DA antagonists. We have found that D2 antagonists induce FLI in both the intact and the depleted striata in rats treated with 6-OHDA on Day 20. We interpret this lack of behavioral supersensitivity to low doses of DA antagonists, and the retention of D2 antagonist-induced FLI following the depletion in weanlings as suggesting that extracellular levels of DA remain high in the lesioned striata of these animals. Such increased extracellular DA may also account for the fact that rats depleted of DA as weanlings exhibit only modest deficits and recover from them within several days.

662.11

THE LOCOMOTOR EFFECTS OF QUINPIROLE IN THE NUCLEUS ACCUMBENS OF DEVELOPING RATS. C. Van Hartesveldt* and K. J. Frantz, Department of Psychology, University of Florida, Gainesville, FL 32611 U. S. A.

The purpose of the present experiment was to analyze the locomotor activity of developing rats in response to various doses of the dopamine D2 subfamily agonist, quinpirole, injected directly into the nucleus accumbens. Ten-, 20-, and 30-day-old rats were implanted bilaterally with guide cannulae in the cortex above the nucleus accumbens. On the next day, rats were injected with 0.25ul of distilled water containing one of several doses of quinpirole (0.00, 0.01, 0.1, 1.0, 10.0, 20.0, 40.0 ug). Immediately after the injection, locomotor behavior was recorded for 2 hr.

The responses of 10-day-old pups were highly variable, but generally all doses of quinpirole increased activity throughout the test session. In 20-day-old pups, low doses of intra-accumbens quinpirole did not alter locomotion. However, the high doses decreased activity early in the test session and increased activity later in the session; this pattern is known as the biphasic locomotor response. The finding that high doses of quinpirole were required to decrease activity in 20-day-old rats indicates that, at this age in the nucleus accumbens, locomotor suppression is not a "low dose phenomenon" and therefore is not likely to be mediated by autoreceptors. In contrast, a low dose of quinpirole given to 30-day-old rats did decrease activity early in the test session, thereby inducing the classic low dose agonist-induced locomotor suppression. High doses induced the biphasic response in 30-day-olds. Dopamine autoreceptor function, D2 and D3 receptor activation, and drug diffusion are possible determinants of these behaviors.

662.12

PAW PREFERENCE, TURNING BEHAVIOR AND DOPAMINE FUNCTION IN THE COLLINS HI AND LO LATERALIZED MOUSE STRAINS. D.M. Nielsen,* J.N. Carlson, K.E. Visker, R.W. Keller, Jr. and S.D. Glick, Dept. of Pharmacology and Neuroscience, Albany Medical College, Albany, NY 12208

Mice exhibit a paw preference that is not task specific and is consistent upon repeated measurement. The Collins HI and LO lines are two populations of mice that have been selectively bred to differ markedly in the degree of paw preference. They represent a unique genetic model of functional cerebral lateralization. Rotation (or circling) behavior in normal unlesioned animals reflects an endogenous lateralization of the functioning of brain dopamine (DA) systems. In the present studies rotational behavior and lateralized brain DA neurochemistry were assessed in the Collins HI and LO lines of mice. Confirming Collins' data, HI strain mice exhibited a stronger paw preference than LO strain mice. HI strain mice also showed more net turns and a stronger percent directional preference during nocturnal tests of spontaneous rotation. As a population, HI mice also had a predominantly leftward turning preference. Neurochemical differences were also apparent between the strains. DA and its metabolites were measured in the medial prefrontal cortex (PFC), nucleus accumbens (NAS) and striatum. The lines differed on certain measures of DA utilization in the PFC and NAS. Side, paw preference, turning preference, sex and strain interacted in a complex way to determine measures of DA utilization in the striatum. (supported by MH 45539)

662.13

RELATION BETWEEN ELECTRICALLY EVOKED ROTATIONAL BEHAVIOR AND DOPAMINE OVERFLOW IN THE CAUDATE NUCLEUS AND NUCLEUS ACCUMBENS. L. T. L. Tran-Nguyen* and E. Castañeda. Arizona State University, Tempe, AZ 85287-1104.

Male Sprague-Dawley rats received a unilateral bipolar electrode in the medial forebrain bundle and bilateral microdialysis probes in the caudate nucleus (CN) or nucleus accumbens (NAc) and 24 hr later were tested for 2 days. On day 1, rats received monopolar electrical stimulation at 100μA or 200μA (50 Hz, 10s trains, 1-min ISI) for a 20-min period. On day 2, rats received stimulation at the other intensity. Next, electrical stimulation (200μA) was applied in the presence of tetrodotoxin (TTX; 5μM) infused through the microdialysis probe ipsilateral to the electrode. Extracellular overflow of dopamine (DA), 3,4-dihydroxyindoleacetic acid (DOPAC), homovanillic acid (HVA), and 5-hydroxyindoleacetic acid (5-HIAA) were measured during resting state and electrical stimulation. Quarter turns contralateral and ipsilateral to the stimulated side were measured throughout microdialysis testing. Contralateral turns occurred during electrical stimulation and were intensity-dependent. TTX infusion attenuated this behavioral response. DA and DOPAC overflow were enhanced bilaterally during electrical stimulation in the CN in an intensity-insensitive manner and only at the higher intensity in the NAc. HVA and 5-HIAA levels showed a delayed increase in response to the electrical stimulation that peaked 20 to 40 min following stimulation. TTX infusion decreased monoamine overflow in the treated hemisphere. The ability to use this technique to study functional changes in DA metabolism will be discussed.

662.14

ROTATIONAL BEHAVIOR IN INTACT RATS FOLLOWING INTRA-STRIATAL INJECTIONS OF DOPAMINERGIC DRUGS. I.D. Smith* and R.J. Beninger. Dept. Psychology, Queen's Univ., Kingston, Canada.

Imbalances in striatal dopamine (DA) following unilateral 6-OHDA lesions produces rotational behavior as a result of receptor supersensitivity. Motor asymmetry due to manipulation of DA receptors in rats without DA depletions is rarely studied. Rotation caused by glutamate (GLU) receptor agonists (NMDA, kainate, AMPA and ACPD) has been studied in normosensitive rats and is dependent on DA receptor tone. It is unclear however, whether the behavioral effects of DA agonists depend on GLU receptor stimulation.

Cannulated rats received 0.5μl injections into the dorsal striatum. The direct DA agonist apomorphine (0.67, 6.7, 66.7mM) failed to caused rotation. In addition, neither the D1 agonist SKF 81297 (1, 10, 100mM), the cAMP-analogue Sp-cAMPS (0.11, 1.1, 11.2mM), nor the D2 agonist quinpirole (0.78, 7.8, 78.2mM) affected turning. In contrast, the DA releaser amphetamine (AMPH) (1.1, 10.9, 108.7mM) caused contralateral circling. This effect was reversed by co-injection of the D1 antagonist SCH 23390 (3.1mM), but was not significantly reduced by the D2 antagonist eticlopride (5.3mM). Finally, AMPH-induced rotation was reversed by TTX co-injections (100μM) but was not blocked by the NMDA receptor antagonist AP7 (0.88μM) or the kainate/AMPA antagonist CNQX (500μM).

These data suggest that post-synaptic stimulation of striatal DA receptors by exogenous drugs (apomorphine, SKF 81297, quinpirole) does not cause behavioral asymmetry, whereas releasing endogenous stores of DA (AMPH) will result in turning away from the injection. This rotation appears to depend on D1 receptors (SCH 23390 block) and may occur through an increase in striatal discharge (TTX block), but does not seem to require intact GLU neurotransmission (AP7, CNQX failure to block). (Supported by NSERC)

662.15

A COMPARISON OF THE LOCOMOTOR STIMULANT EFFECTS OF D1-LIKE AGONISTS IN MICE. P. Terry* and J.L. Katz[1]. [1]Psychobiology Section, NIDA Addiction Research Center, P.O. Box 5180, Baltimore, MD, USA, and School of Psychology, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK

Agonists at D1-like receptors are often reported to produce only mild stimulation of locomotor activity in rodents. However, a recent study described a profound, long-lasting locomotor stimulant effect of the prototypical D1-like agonist SKF 38393 in C57/Bl6J mice (Tirelli and Terry, 1993, *Psychopharmacol.*, **110**: 69). The present study compared effects of five D1-like agonists on locomotor activity in non-habituated, Swiss-Webster mice. Each drug was injected IP (0.1 - 100 mg/kg and vehicle; independent groups) and locomotor activity was monitored in photobeam arenas for 3 hours post-injection. Four of the drugs (SKF 82958, SKF 81297, SKF 77434 and SKF 75670) produced strong stimulant effects over the dose range 0.1 - 10 mg/kg, and these persisted for at least two hours. At 100 mg/kg, each drug produced a biphasic effect: locomotor inhibition followed by enhanced activity. The fifth drug, SKF 38393, only produced the high-dose biphasic effect; there was negligible locomotor stimulation at the lower doses. However, SC injection of SKF 38393 produced stimulant effects across the dose range, and these continued beyond three hours. For the five agonists, there was no relationship between reported efficacy in stimulating adenylyl cyclase activity and efficacy in stimulation of behavior, nor was there any clear association between reported receptor affinity and behavioral potency. The results confirm the stimulant profile of D1-like agonists and further demonstrate a dissociation between certain pharmacological characteristics of these drugs and their behavioral effects. The results also indicate that effects of SKF 38393 are not always characteristic of other D1-like agonists.

662.16

A NOVEL SYSTEM FOR SIMULTANEOUS MEASUREMENT OF LOCOMOTOR ACTIVITY DURING MICRODIALYSIS EXPERIMENTS IN FREELY-MOVING RATS. D.L. Alexoff, S.L. Dewey, C. -E. Chen, D. L. Tedeschi, R. Straughter-Moore, D. D'Emilia, J.S. Fowler* and S.J. Gatley. Chem and Med Dep'ts, Brookhaven National Laboratory, Upton, NY 11973

Microdialysis can accelerate the biological characterization of new drugs or neuroactive chemicals by measuring changes in extracelluar neurotransmitter concentrations following pharmacologic challenge. Behavioral data on freely moving animals during microdialysis, however, is often not collected due to the complication and expense of interfacing standard commercial behavioral systems to new microdialysis equipment. We describe an inexpensive system for monitoring rat locomotor activity simultaneously during microdialysis experiments. The system is based on the gimbaled tethering arm in Bioanalytical Systems CMA/120 Awake Animal System. An optical proximity detector (SmartEye, TRITRONICS, Tampa, FL) was mounted opposite the end of the gimbaled arm so that excursions of the arm caused by the animal's movements would alternatively reflect or let pass the detector's infra-red beam. The digital output of the detector was interfaced to an IBM PC programmed to count both positive and negative arm deflections during the experiment. Locomotor counts were summed over 5 min. intervals and stored. Data was collected using 4 time windows (0, 1, 3 and 5 sec.) to evaluate the detector's selectivity to rat head movements, such as grooming or sniffing, compared to gross movements. Locomotor data collected after amphetamine was consistent with the well-characterized amphetamine-induced locomotor response. This system is suitable for assaying locomotor responses to drug challenges during microdialysis experiments. We have applied this system to potential new radiopharmaceuticals including novel monoamine uptake inhibitors (Pan, et al., Eur. J. Pharm., 1994) and new serotonergic ligands. Supported by DOE/OHER, NINDS, NIMH 49165, NARSAD and BNL-LDRD.

QUINPIROLE MODULATION OF ACTIVITY LEVELS AND EXPLORATORY BEHAVIOR IN RATS WITH FORNIX TRANSECTIONS. B. Osborne*, A.C. Dukowicz, D.A. Hutcheson, W. I. Maris and L.G. Adams. Dept. of Psychology, Middlebury College, Middlebury, VT 05753.

The ability of the dopamine agonist, quinpirole, to modulate the exploratory behavior and activity levels of control rats and rats with fornix transections was examined under different dose levels and basal activity levels. Control rats and rats with fornix transections were given either saline, 0.03 mg/kg quinpirole, or 0.5 mg/kg quinpirole, i.p., 15 mins. prior to exploration of an enriched novel environment. Following this first experience, rats were habituated to the environment and tested again under the same drug conditions. Under both conditions, latency to move, activity levels and the frequency and duration of rearing and object interactions were recorded. With saline injections, fornix transected rats were more active, had more frequent object interactions, less rearing, and the durations of behaviors were shorter. At the .03 mg/kg dose level, quinpirole reduced activity of all groups and returned the activity levels of fornix transected rats back to normal levels. At 0.5 mg/kg, quinpirole reduced the levels of fornix transected rats but to a lesser extent. Controls were not affected on initial exposure, but both control and fornix transected rats failed to habituate under the higher dose level. Exploratory behavior was also affected but to a lesser extent. The results are discussed in terms of pre-and post-synaptic effects at different dose levels, and dopamine and glutamate actions at nucleus accumbens.

STIMULATION OF DOPAMINE RECEPTORS IN THE MEDIAL PREFRONTAL CORTEX MEDIATES INHIBITION OF SPONTANEOUS LOCOMOTOR ACTIVITY. R. A. Radcliffe and V. G. Erwin*. School of Pharmacy, University of Colorado Health Sciences Center, Denver, CO 80262

It is well established that stimulation of dopamine receptors (DAR) in the nucleus accumbens (Acb), a major limbic DA terminal field, initiates increases in locomotor activity. The medial prefrontal cortex (mPFC), also an important DA terminal field, is thought to regulate DA functions in the Acb. The locomotor response to DA stimulation in the mPFC, however, has not been well characterized. We have previously demonstrated that application of the selective DA uptake blocker GBR-12909 into the mPFC of LSP/IBG mice causes a dose-dependent decrease in locomotion followed by a return to control values. The intent of the present study was to determine which DAR subtype(s) is responsible for the observed biphasic response and if application of GBR into the mPFC mediates altered DA activity in the mPFC or in the Acb. Bilateral cannula guides were implanted into the mPFC of LSP/IBG mice. 24 hours post surgery, the subjects were injected bilaterally with either GBR, the DAR-D_1 antagonist R(+)-SCH-23390, the DAR-D_2 antagonist epidepride, or a combination of drugs. Distance traveled was monitored in an automated open field apparatus. Doses of SCH (1-100 pmol) alone had no effect on locomotor activity but simultaneous injection (10 pmol) with GBR (0.1-1000 pmol) attenuated GBR-induced inhibition. Epidepride (0.1-100 fmol) alone produced a dose-dependent decrease in locomotor activity, but simultaneous injection with GBR had no effect on the response to GBR. Alteration of DA metabolism was estimated from tissue levels of DA and DA metabolites, determined with HPLC coupled to EC detection, in the mPFC and Acb after unilateral injections of doses of GBR. Preliminary evidence indicates that 5 min post injection, GBR caused the ipsilateral mPFC HVA/DA ratio to increase above contralateral values at low doses and return to control at high doses. Ipsi- and contralateral DOPAC and DA levels were not different in the mPFC. In contrast, at this same time point, GBR had no effect on DA, HVA, or DOPAC levels on either side of the Acb. The results of these studies suggest that an increase in synaptic DA in the mPFC is responsible for depressed locomotion and that this response is mediated by DAR-D_1. Furthermore, while blockade of DAR-D_2 is able to suppress locomotion, this effect is not additive to the GBR response. (This work was supported, in part, by USPHS grants DA01717 and AA07330.)

CHANGES OF THE ACOUSTIC STARTLE RESPONSE IN RATS AFTER LOCAL INJECTION OF PERTUSSIS TOXIN INTO THE VENTRAL TEGMENTAL AREA. J. Zhang, J. A. Engel, S. Hjorth and L. Svensson*. Dept. Pharmacol., Göteborg Univ., Göteborg, Sweden.

The effect of local injection of pertussis toxin (PTX) into the ventral tegmental area (VTA) on the acoustic startle response (ASR) in rats was investigated. The PTX treatment caused only minor effects of its own on ASR magnitude or prepulse inhibition (PPI) of ASR magnitude. However, systemic treatment with the indirect DA receptor agonist, amphetamine (2 mg/kg, s.c.), caused a significant increase of ASR magnitude and a significant disruption of PPI in PTX-treated rats while no such effects were observed in sham-treated rats. Treatment with the direct DA receptor agonist, apomorphine (2 mg/kg, s.c.), caused a significant disruption of PPI, an effect that was observed in both PTX- and sham-treated rats. Treatment with the 5-HT_{1A} receptor agonist, 8-OH-DPAT (0.5 mg/kg, s.c.), did not affect PPI in either group but caused a marked increase of ASR magnitude in sham-treated rats. Interestingly, this effect was blocked in PTX-treated rats. The present results suggest that local injection of PTX into the VTA causes an increased sensitivity to the behavioural effects of psychostimulants on acoustic startle and may also suggest that intact midbrain 5-HT_{1A} receptors are essential for the effect of 5-HT_{1A} agonists on acoustic startle.

EFFECTS OF REWARD AND STRESS ON IN VIVO HYDROXYLATION OF TYROSINE AND TRYPTOPHAN IN RAT NUCLEUS ACCUMBENS: A MICRODIALYSIS STUDY. D. Nakahara* and M. Nakamura. Department of Psychology, Hamamatsu University School of Medicine, 3600 Handa-cho, Hamamatsu 431-31, Japan

Microdialysis studies have recently shown that serotonin metabolism in the nucleus accumbens is equally enhanced by rewarding and stressful stimuli, while the release and metabolism of dopamine in this region is differentially affected by these two stimuli, with a larger enhancement in rewarding than stressful situations. In the present study, we applied the microdialysis technique to assess the changes in the synthesis of dopamine and serotonin in response to rewarding and stressful manipulations by measuring accumulation of 3,4-dihydroxyphenylalanine (DOPA) and 5-hydroxytryptophan (5-HTP) after the local infusion of an aromatic L-amino acid decarboxylase inhibitor, NSD-1015 (3-hydroxybenzylhydrazine dihydrochloride), through the dialysis membrane. The rate of accumulation of DOPA and 5-HTP was utilized as an index of the in vivo hydroxylation of tyrosine and tryptophan, respectively. Self-stimulation of the medial forebrain bundle was used as a rewarding manipulation and immobilization as a stressful manipulation consisted of taping their limbs to a wood board with adhesive tape.

Self-stimulation caused a significant increase in both DOPA and 5-HTP accumulations. On the other hand, immobilization stress increased 5-HTP accumulation without affecting DOPA accumulation.

Taken together with previous data, our results suggest that dopamine activity in the nucleus accumbens may be more responsive to reward rather than stress, and that serotonin activity in this region may be responsive to stress as well as reward.

THE SEROTONIN SYNDROME IN THE MOUSE. R.J.Blanchard*, G. Griebel, M.M.R. Brush, Jennet Lee, and D.C. Blanchard, Pacific Biomedical Research Center, Univ. of Hawaii, Honolulu, HI 96822

The effects of selective activation of central 5-HT_{1A} receptors on the behavior of mice have not been clearly defined. Yamada et al. (1988) found that the 5-HT_{1A} receptor full agonist 8-OH-DPAT induced a distinct 5-HT syndrome, whereas Goodwin and Green (1985) reported that in mice the drug did not induce any distinct behavioral alteration.

Behavioral effects of 8-OH-DPAT (0.5-10m g/kg, i.p.) were examined in mice in a home cage setting. Vehicle controls displayed an initial activity that declined gradually over the observation period, providing a shifting baseline for evaluation of 8-OH-DPAT effects. During initial segments of the test period, 1 and 10 mg/kg blocked rearing and hanging on the wire mesh. Eating was increased at 10 mg/kg. Grooming was inhibited and Straub tail response increased at all doses. In the earliest post injection period (10 min) 8-OH-DPAT, at low and moderate doses only, produced rapid, ballistic-type forelimb movements ending near the sides of the mouse's head. Also, in an oval runway permitting limitless forward progression, moderate and high doses produced a distinct suppression of forward locomotion which exhibited itself as periods of immobility, tight rotating and circling.

These data provide some puzzling differences from the effects of 8-OH-DPAT in rats, which include continuous forward locomotion and forepaw treading when forward locomotion was interrupted. The present finding of opposite patterns in the mouse suggests the value of investigation of species differences in response to compounds which act at the 5-HT_{1A} receptor.

663.2

THE EFFECT OF EXERCISE AND L-TRYPTOPHAN ADMINISTRATION ON EXTRACELLULAR SEROTONIN METABOLISM IN RAT HIPPOCAMPUS. R. Meeusen*, K. Thorré, S. Sarre, K. De Meirleir, G. Ebinger and Y. Michotte, Dept. Human Physiology and Sportsmedicine, Vrije Universiteit Brussel, Laarbeeklaan 101, 1090 Brussels, Belgium

The purpose of this study was to examine the effects of L-TRP administration in combination with exercise on extracellular concentrations of 5-HT and 5-HIAA in rat hippocampus using microdialysis. The day before the experiment, after the microdialysis probe was implanted, male albino wistar rats were placed on the treadmill and stayed there until the end of the experiment. The following day, after stable baseline values were obtained. L-TRP (50 mg/kg i.p.) or saline was administered in a single dose. One hour later the animals ran for 60 min at a moderate speed (12 m/min) on a treadmill. Administration of L-TRP slightly increased extracellular concentrations of 5-HT and 5-HIAA. During and following exercise the 5-HT and 5-HIAA concentrations significantly increased (+ 120 %) and stayed above baseline during the following two hours. Extracellular 5-HT and 5-HIAA concentrations were significantly different between the saline-exercise and the L-TRP-exercise animals. Our results suggest that after precursor loading 5-HT metabolism and release is increased due to exercise.

663.3

CHANGES IN EXTRACELLULAR BRAIN SEROTONIN DURING THE LIGHT/DARK TRANSITION:RELEASE IS CORRELATED WITH BEHAVIORAL ACTIVITY RATHER THAN THE CIRCADIAN CYCLE B.L. Jacobs* and L.E. Rueter Prog. Neurosci.,Dept. Psychology, Princeton Univ., Princeton, NJ 08544

The degree of site specificity with which serotonin is released in the forebrain and the physiological conditions under which release is altered are still unclear. The present study was designed to address these issues in the context of changes across the daily transition from light to dark, by employing in vivo microdialysis in the freely moving rat. Cannulae were implanted in the anterior dorsolateral hippocampus, the corpus striatum, the amygdaloid complex, and the frontal cortex in male Sprague-Dawley derived rats (two different sites per animal, all six site combinations used). After one week of recovery, concentric microdialysis probes were inserted in both sites and perfused simultaneously. Sampling began three hours prior to lights off and at least twelve hours after probe insertion. Samples were taken every half hour for three hours of light and then two hours of dark. Each session was videotaped and scored for time spent in alert waking. Results indicate that serotonin release increases significantly during the first half hour of dark phase in all areas tested (hippocampus 43.7%, striatum 11.3%, amygdala 16.8%, frontal cortex 19.5%). The increase in hippocampus is significantly greater than the other sites. Release was positively correlated with alert waking time (hippocampus r=.87, striatum r=.61, amygdala r=.88, frontal cortex r=.91). When matched for activity levels within subjects, serotonin release in the light essentially equaled release in the dark (activity> 15 min: light 121% of baseline,dark 119%; activity< 5 min: light 97% of baseline, dark 89%). These results show that, in agreement with electrophysiological studies, serotonin release is correlated with behavioral activation rather than the light-dark cycle per se, and that there can be specificity of degree of release in target areas of the serotonergic system (i.e. greater release in the hippocampus). Supported by grants from AFOSR and NIMH.

663.4

SEROTONIN RELEASE DURING STRESSFUL AND NON-STRESSFUL CONDITIONS: IS THE SEROTONERGIC SYSTEM SPECIFICALLY STRESS-ACTIVATABLE? L.E. Rueter* and B.L. Jacobs Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Neurochemical studies indicate that stressors increase release and/or turnover of serotonin while electrophysiological studies indicate that stressors do not increase serotonergic neuronal activity above levels seen during spontaneous active waking. The present study was designed as an attempt to reconcile these apparently disparate literatures using in vivo microdialysis to measure serotonin in various forebrain sites. We also employed two important experimental design controls: stress exposure during the rat's dark or active phase and direct comparison of the stress response to a non-stressful condition containing somewhat similar behavioral/activational components. (See previous abstract for experimental details.) Sampling began a half hour into dark phase; sample time was 30 minutes. The baseline or control condition was taken as the 90 minutes prior to manipulation. Each rat was exposed to two conditions of the following manipulation sets: 1. tail pinch(tp), tp with food, and food; and 2. swimming and floating. Order of presentation was varied. Results indicate that

CONDITIONS (% increase from baseline; all n's > or = 10)

SITE	tp	tp w/food	food	swim	float
hippocampus	50.6%	41.0%	37.5%	20.3%	26.8%
striatum	28.0%	32.2%	26.1%	15.2%	12.8%
amygdala	36.3%	55.7%	43.3%	36.0%	40.4%
frontal cortex	33.2%	44.8%	27.0%	57.1%	35.7%

serotonin release during tp, tp with food, and food was increased in each area to approximately the same degree. Serotonin release was also increased during swimming and floating in each area to approximately the same degree. These results suggest that under these conditions serotonin is released in the forebrain in a fairly nonspecific manner and that the serotonergic system is not specifically stress activatable but rather that serotonin release is best correlated with behavioral activation/motor activity. Supported by grants from AFOSR and NIMH.

CLONING THE ECDYSONE-RECEPTOR FROM THE AMERICAN LOBSTER, *Homarus americanus*. A. Quinones-Hinojosa* & E. A. Kravitz, Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

The steroid ecdysone is the molting hormone in crustaceans and insects. Ecdysone has been shown in insects to serve important roles in the transformation of the larval CNS to that of the adult. Ecdysone acts by binding to a cellular receptor protein, which is translocated to the nucleus where it binds to multiple target genes. Ecdysone levels fluctuate over the molt cycle in lobsters with a large peek seen in the D2-D3 period (Snyder and Chang, 1991). Aggressive behavior also varies over the molt cycle in lobsters (Tamm and Cobb, 1978). Early in the cycle (post molt period) animals show little aggression, while shortly before the next molt (premolt) animals become highly aggressive. Our studies suggest that serotonin is involved in aggressive behavior in lobsters. Certain serotonergic neurons show elevated levels of the amine in the premolt period. In beginning to explore the possibility that ecdysone, serotonin and aggression are linked in lobsters, we are attempting to clone the lobster ecdysone receptor.

First stage larval lobster were used for these studies. mRNA was isolated from whole animals and cDNA was synthesized. Oligonucleotides were designed from highly conserved regions of the cDNA sequences of Drosophila ecdysone-receptor genes. Using a PCR strategy, amplified pieces of DNA were cloned and later sequenced by the Sanger method. A 535 bp fragment was isolated that showed 70% sequence homology to the ecdysone-inducible genes E75A and B from D. melanogaster. We are attempting to isolate and characterize the full length cDNAs for these transcription factors and will continue a search for the ecdysone receptors themselves. As the various molecular entities are isolated we will design probes to ask whether ecdysone-receptors or related genes are expressed in nerve cells containing the neurotransmitter serotonin.

IN-VIVO VOLTAMMETRY IN THE NERVOUS SYSTEM OF INVERTEBRATES M. Hörner, F.W. Schürmann* and E.A. Kravitz, Harvard Medical School, Dept. of Neurobiology, 220 Longwood Ave., Boston 02115, MA,

There is growing evidence that biogenic amines like serotonin (5HT) after release from neuronal terminals can have both synaptic and non-synaptic influences (Fuxe & Agnati, 1991; Volume Transmission In The Brain; Novel Mechanisms For Neural Transmission). In the latter case diffusion through extracellular space allows neuroactive substances to affect a wide target area and not only immediate adjacent post-synaptic sites. 5HT has been shown to exert strong influences on behavior in insects and lobsters. In these species possible paracrine release sites have been identified by immunocytochemistry.

In order to measure dynamic changes of extracellular 5HT levels with high temporal and spatial resolution we have been using chronoampèrometry (0.5 V, 5-10 Hz, IVEC, Medical Systems Corp.) with fine diameter carbon-fibre glass electrodes coated with Nafion™. Recordings are made in regions shown by immunocytochemistry to be high in 5HT. The identification of electroactive species is based on the substance-specific ratios of redox-currents.

In the cricket brain, site-specific release of serotonin-like signals is observed in the region of the central body during aversive behavior. The time course of the voltammetric signals, when related to the ongoing behavior, suggests diffusion of 5HT from terminals within the central body, a neuropil area containing high amounts of 5HT. In lobsters we have compared signals generated in physiologically identified serotonergic, octopaminergic, GABAergic and glutamatergic neurons. In preliminary experiments we have measured the clearance of injected 5HT from the circulation using carbon electrodes chronically implanted into the heart. Our future goals are to measure the release of serotonin into known neurohemal areas during aggressive behavior.

PROZAC, SEROTONIN UPTAKE AND AGGRESSION IN LOBSTERS. M. M. Orzeszyna, R. Huber[1], and E.A. Kravitz*. Dept. of Neurobiology, Harvard Med. School, Boston 02115, [1]Dept. of Neurobiology, Institute of Zoology, University of Graz, Universitatsplatz 2, Graz 8010, Austria.

Our previous studies suggest that serotonin serves important roles in aggression in lobsters. Fluoxetine (Prozac), a valuable therapeutic agent in the treatment of depression, is an effective blocker of serotonin uptake in vertebrates. With the aim of possibly using this substance in studies of aggression in lobsters, we first examined the effects of Prozac on serotonin (5-HT) uptake in lobster nervous tissue. Incubations were performed using pairs of second thoracic roots, which contain dense plexuses of serotonergic and octopaminergic neurosecretory terminals. Nerves from one side acted as controls for the other side, and 5-HT and octopamine levels were measured using HPLC with electrochemical detection. Incubation in 10^{-5}-10^{-6} M 5-HT increased the levels of 5-HT in tissues by 60% with no effect on octopamine levels. Prozac effectively blocked this increased uptake of 5-HT.

Further experiments, using ^{3}H-5-HT, supported an earlier finding (Livingstone et al., 1980) that there are likely to be two forms of 5-HT uptake: a high-affinity, saturable uptake into serotonergic neurons, and a second low-affinity, non-saturable uptake, possibly into surrounding tissues. Prozac appears to act as a competitive inhibitor of the former form of uptake alone.

When injected into living animals, Prozac (10^{-4} M) was not toxic. We also saw no immediate behavioral effect of acute Prozac treatment. 5-HT injections cause subordinate animals to be significantly more likely to engage in fights with dominants (Huber *et al.*, unpubl.). We are now testing the effects of Prozac on the 5-HT-mediated enhancement of aggressive behavior of subordinate animals and examining the effect of chronic Prozac treatment.

CLONING OF AMINE HYDROXYLASE GENES FROM THE LOBSTER. X.-S. Chen, L.N. Geller, A. Kopp, R. Hawley, C. DeFranco*, and H. Potter. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

The amine hydroxylases are of particular interest because of their roles as the rate-limiting enzymes on the pathway for serotonin and catecholamine synthesis which have been shown to induce posture and behavior changes in lobster. We have isolated five independent amine hydroxylase cDNA clones including two 5'-end and three 3'-end RACE clones. Sequence analysis demonstrated that (1) The two 5'-end RACE clones are totally different from each other at their 5' untranslated regions, partially different at the beginning of the translated regions, and identical in the remainder of the translated region. (2) All of the 3'-end clones terminate at known polyA sites and are identical in their translated regions. They have identical 3' untranslated regions for a short stretch, followed by different sequences. (3) The three 3'-end clones overlapped the 5'-end clones, thus identifying a contiguous coding sequence. (4) Alignment of deduced lobster TRH with *Drosophila* TRH/PAH, rat TRH, rat PAH, and rat TH proteins showed >76% identity. Northern blot analysis of lobster polyA+ mRNA revealed three transcripts of 1.6 to 2.2 kb. The exact identity of the protein encoded by the single large open reading frame is not apparent from the sequence data, although it is clearly of an amine hydroxylase. *In situ* hybridization with the different untranslated sequences reveals different patterns of hybridization, raising the possibility that more than one enzyme is encoded by a single gene.

663.9

EXPRESSION OF THE SHAB GENE IN THE CNS OF THE AMERICAN LOBSTER. H. Schneider*, D.J. Baro, R.M. Harris - Warrick, & E.A. Kravitz, Neurobiology Dept. Harvard Med. Sch., Boston, MA 02115, Dept. Neurobiol. & Behav., Cornell Univ., Ithaca, NY 14850.

Serotonin (5HT) and octopamine (OA) appear to participate in the regulation of agonistic behavior in the American lobster, *Homarus americanus* (Kravitz, '88). Serotonin injections into the hemolymph trigger postures simlar to those seen in dominant lobsters while OA injections elicit postures similar to those seen in subordinate animals. In addition, 5HT injections into subordinate lobsters shortly after a hierarchy has been established, can alter the behavioral status of these animals and dramatically increase their fighting activity (Huber et al., unpubl.). In isolated nerve cords, 5HT and OA have opposing effects on flexion and extension motor circuits (Harris-Warrick & Kravitz, '84).

We have begun searching for long term physiological and molecular changes in the lobster ventral nerve cord that maybe correlated with dominant or subordinate status. Here we present the pattern of expression of the Homarus shab K^+-channel gene in 5HT- and OA neurosecretory cells and in postural motoneurons (MNs). Applying PCR methods we have partially cloned a Homarus shab gene that is 92% identical at the nucleotide level to the shab gene of the spiny lobster, Panulirus interruptus, and 82% identical to with the Drosophila shab gene. The mRNA for this gene is found in inhibitory and excitatory flexor abdominal MNs but not in 5HT- neurosecretory cells as demonstrated by single cell PCR. The expression pattern correlates with the physiological activities of these cells. Serotonin neurons are spontaneously active while the studied MNs are not. We plan to compare the shab expression pattern with those of the shal, shaw, and shaker forms of K^+-channels and ask how the patterns correlate with the intrinsic properties of 5HT- and OA cells in lobsters of different behavioral status. Supported by NINDS.

SEROTONERGIC MODULATION FOLLOWS CHANGES IN SOCIAL STATUS. S.-R. Yeh* and D.H. Edwards Department of Biology, Georgia State University, Atlanta, GA, 30302-4010.

Social relationships among animals influence their behavior by affecting the neural circuits and responses that control behavior. We have found that the effect of bath-applied serotonin on the responsiveness of the crayfish lateral giant (LG) tailflip command neuron changes with changes in the animal's social status. We recorded LG responses in socially isolate, dominant and subordinate crayfish before, during and after bath-application of 5-HT and 5-HT agonists. 5-HT reversibly enhanced the LG EPSPs and lowered the stimulus threshold in dominant crayfish, and reversibly inhibited the cell and raised threshold in subordinates. Tests with different vertebrate 5-HT agonists suggest that the LG neurons have at least three populations of 5-HT receptors that differ in their relative number or efficacy in dominant, subordinate, and isolate crayfish.

Dominant/subordinate social status is determined within half an hour of pairing isolated animals; 5-HT's effect on LG changed much more slowly following pairing. 5-HT-induced enhancement of LG's response in isolates decreased linearly in the new subordinates, crossed zero at 7 days pairing and became strongly inhibitory by 12 days. 8 days re-isolation restored the enhanced responses.

663.11

OPPOSITE EFFECTS OF SEROTONIN ON THE DENDRITES AND AXON OF A COMMAND NEURON M.J. Weissburg, B.E. Musolf, S.-R. Yeh and D.H. Edwards* Department of Biology, Georgia State University, Atlanta, GA, 30302-4010.

A neuromodulator usually has a suite of effects on a neuron that act together to increase or decrease excitability. The identification of many kinds of serotonin (5-HT) receptors, some of which have opposing effects on excitability, raises the possibility that 5-HT could have opposing actions at different locations in the same neuron. We report here such a case, where bath-applied $5x10^{-5}$M 5-HT increases the excitability of the lateral giant (LG) neuron of crayfish but also causes conduction failure in the cell's axon. 5-HT causes EPSPs in LG's initial axon segment to increase and the stimulus threshold of the spike to decrease, whereas the mid-axonal spike becomes smaller, briefer, and then fails. All these effects are reversible with saline wash. These opposing effects are seen in socially dominant crayfish, but not in social isolates, where 5-HT irreversibly enhances LG EPSPs and reduces threshold while axonal conduction is maintained. We suppose that the different effects of 5-HT on LG result from different distributions of two or more 5-HT receptors in the cell, and that this receptor pattern is specific to socially dominant crayfish.

663.12

DO SEROTONIN 1A OR 1B RECEPTORS INFLUENCE OFFENSIVE AGGRESSION IN FEMALE HAMSTERS? M. A. Ioppa*, R. L. Meisel and K. Bunting. Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907.

Selective 5-HT_{1A} receptor agonists and mixed agonists of the 5-HT_{1A} and 5-HT_{1B} receptors have been reported to decrease both intermale and maternal aggression in rats. In this experiment, we tested the effects of the specific 5-HT_{1B} receptor agonist, CGS 12066A, and the specific 5-HT_{1A} receptor agonist, 8-OH-DPAT, on interfemale aggression. For 3 weeks, ovariectomized hamsters received icv vehicle injections and an aggression pretest followed 2 days later by one of 3 icv doses (5, 10, and 20 µg) of either 8-OH-DPAT or CGS 12066A and an aggression test. Latency to attack, number of attacks, and number of uprights did not differ following any of the 3 doses of CGS 12066A or 8-OH-DPAT, nor were any side effects consistently observed. However, when 8-OH-DPAT was given ip, side effects significantly increased and latency to attack, number of uprights, and number of attacks significantly decreased. The neurochemical mechanisms underlying interfemale aggression in hamsters may be different from those regulating intermale aggression in rats and mice.

This research was supported by a grant from the National Science Foundation (IBN-9412543).

SEROTONIN CONTROLS FIGHTING BEHAVIOR IN CRAYFISH. Robert Huber, Edward A. Kravitz and Simone Helluy* Dept. Zoology, Univ. Graz; Dept Neurobiology, Harvard Medical School; Dept. Biology, Wellesley College.

When the amines, serotonin and octopamine are injected into the hemolymph of lobsters and crayfish, they trigger postures resembling those seen in dominant (serotonin) and subordinate (octopamine) animals. These initial observations led to detailed studies in crustaceans on the role of amine neurons in fighting behavior. The recent development of analytical methods for quantification of fighting behavior (Huber and Kravitz, 1995) now allows us to carry out pharmacological interventions and ask whether any important changes in behavior result.

Using crayfish (*Astacus astacus*), we first tested the effects of serotonin. Ten pairs of animals differing 30% in size were selected. Indwelling fused silica cannulae were glued into the pericardial sinus of the smaller animals. In all cases, when placed together the larger animal quickly assumed the dominant position (pre-inj). Using a syringe pump, saline was infused into the subordinate animal (control inj) resulting in little or no qualitative or quantitative changes in behavior. When the infusion solution was switched to saline containing serotonin at 3=B5g/min. (5-HT inj), fighting activity increased greatly. This slowly decayed back to the pre-injection levels after the serotonin infusion was turned off (post-inj). A multivariate statistical analysis identified the parameters of fighting that were changed by the amine injection. The likelihood that the smaller, serotonin-treated animal would withdraw, was significantly reduced, resulting in fights of increased duration. No other characteristics of fighting behavior were altered. Behavioral studies with serotonin uptake and receptor blockers are planned along with mapping studies of the nervous system for amine neuron distribution to ask whether amine neuron systems are similar in lobsters and crayfish. Supported by Austrian Science Foundation P10165-BIO and NINDS.

SOCIAL REPRODUCTIVE ROLES AFFECT CENTRAL MONOAMINES IN FEMALE *Anolis carolinensis*. Tangi R. Summers,* Amy L. Hunter, and Cliff H. Summers. Dept. of Biology, University of South Dakota, Vermillion, SD 57069.

Groups of 5 female *A. carolinensis* were housed with 1 male, but only 1 or 2 females exhibited recrudescing ovaries. These reproductively dominant females were above threshold weight (≥2.7g) at the end of 1 month; subordinate females were not. Final controls, 1 female housed with 1 male for one month, all exhibited ovarian growth; initial controls had quiescent ovaries. Brain monoamines and metabolites were quantified using HPLC coupled with electrochemical detection. Reproductively dominant females had significantly greater telencephalic 5-HIAA, and serotonergic turnover, as indicated by the ratio of 5-HIAA to 5-HT. Telencephalic DOPAC as well as the DOPAC/DA ratio are also significantly greater in dominant females compared to all other groups. The activation of serotonergic systems in reproductively dominant females is similar to subordinate males. However, DA system activation in dominant females is similar to dominant males. Activation of serotonergic systems in females may be related to submissive behaviors toward the male during competition for access to that male, whereas activation of the dopaminergic system may be associated with aggressive interactions with other females.

SEROTONIN DEPLETION INCREASES IMPULSIVE BEHAVIOR IN RATS. J.B. Richards*, L.S. Seiden. University of Chicago, Department of Pharm/Phys Sci., Chicago, Il. 60637.

Rats were required to choose between small immediate rewards and large delayed rewards. Preference for an immediate small reward over a large delayed reward is an operational definition of impulsivity (Logue, Behav Brain Sci, 11, 665-709, 1988). Rats received either whole brain 5HT lesions (LES) induced by intraventricular injection of the neurotoxin 5,7-DHT (100 ug/side, pre treatment with 30 mg/kg desipramine) (N = 8) or intraventricular injection of vehicle (CNT)(N = 11). Previously we have found that this treatment causes depletion of 5HT to less than 15% of control levels in all of the areas assayed (frontal cortex, nucleus accumbens/olfactory tubercle, striatum, septum, somatosensory cortex, amygdala, hypothalamus, and hippocampus). Dopamine and norepinephrine levels were not affected. Thirsty rats were given a choice between 200 ul of water presented after a delay or a smaller amount of water presented immediately. The amount of water available immediately was adjusted until each rat chose the small immediate amount of water and the large delayed amount of water with equal frequency (i.e. indifference point). We found the indifference points for delays of 0, 2, 4, 8, and 16 seconds in LES and CNT rats. At 0 s (no delay to the large amount) the there was no significant difference between the LES and CNT groups. At delays of 2, 4, 8, 16 s the LES rats chose smaller immediate amounts then the CNT rats. These results are consistent with the hypothesis that low serotonin is associated with increased impulsivity. (Supported by: MH-11191; RSA-10562, L. Seiden)

IMPULSIVE BEHAVIOUR IN RATS: THE EFFECTS OF DRUGS ON RESPONSE CHOICE WITH VARYING DELAYS OF REWARD. Christine Natasha Ryan and John Leslie Evenden* Dept of Behavioural and Biochemical Pharmacology, Astra Arcus, S-113 53, Södertälje, Sweden.

Impulsive behaviour is seen as a clinical symptom in several psychiatric disorders, particularly the personality disorders. To act impulsively may be (a) to act despite knowing the consequences may not be beneficial, (b) to choose between two actions without proper consideration of the consequences, or (c) to choose an action which has an immediate moderate effect, rather than one which has a delayed but potentially more beneficial effect. In man, impulsivity has been associated with low levels of serotonin (5-HT). Compatible with this finding, in rats, increased waiting capacity has been associated with increased levels of 5-HT. In the present study, hungry rats were trained in an operant chamber to choose between 1 pellet or 5 pellets. As the test session progressed, the reward of 5 pellets was progressively delayed up to a maximum of 60 seconds. Under baseline conditions the rats preferred five pellets if the delay was short, but chose 1 pellet if the delay was long. If, once the rats were trained, the delay was not increased, they preferred 5 pellets throughout the session, indicating that they were sensitive to delay of reward. Treatment with 10 & 30 mg/kg citalopram or 3 & 10 mg/kg imipramine did not affect reward choice, while treatment with 0.3 or 1.0 mg/kg amphetamine increased preference for the small reward. In contrast, the 5-HT antagonist, metergoline, enhanced selection of the large reward. These preliminary results indicate that 5-HT may have a more dynamic role than first supposed in different types of impulse behaviour. Prolonged training resulted in the adoption of a rigid strategy, which was insensitive to delay. By varying the variations in delay, flexible behaviour could be maintained for longer periods. Treatment with the 5-HT_{1A} antagonist, WAY 100635 (0.01, 0.03, 0.1 mg/kg) or with low doses of haloperidol (0.01 or 0.03 mg/kg) or carbemazepine (40 or 100 mg/kg) both of which are used for the pharmacotherapy of personality disorders, had no significant effects under these circumstances.

663.17

CHARACTERIZATION OF SEROTONIN 1B RECEPTOR CONTRIBUTION TO STARTLE AMPLITUDE AND PREPULSE INHIBITION IN WILD TYPE AND SEROTONIN 1B MINUS MICE. S.C. Dulawa [1], R. Hen [3], K. Sccarce[3], and M.A. Geyer[1,2] *. Departments of Neuroscience[1] and Psychiatry[2], University of California San Diego, La Jolla, CA 92093. Center for Neurobiology and Behavior[3], Columbia University, New York, NY 10032.

The present experiments explored the possible involvement of the serotonin 1B (5HT-1B) receptor in modulating two behaviors in mice: startle amplitude, and pre-pulse inhibition (PPI). PPI is an operational measure of sensorimotor gating, and is defined as the percent decrease in startle amplitude when a weak prepulse precedes a startling pulse. In rats, the direct 5HT-1A/1B agonist RU24969 reduces both startle amplitude and PPI. As yet, no highly specific 5HT-1A or 5HT-1B antagonists are available to explore the individual contribution of each receptor to these behaviors. We compared PPI in wild-type 129sV and homozygous 5HT-1B-minus 129sV mice in a startle response paradigm in which some 120 dB acoustic pulses were preceded by 2, 4, or 8 dB prepulses, above a 65 dB background. A potentiation of PPI was found in 5HT-1B-minus mice relative to wild types, suggesting that the 5HT-1B receptor modulates PPI ($p<.001$). In addition, startle amplitude was greater in wild-type than in 5HT-1B-minus mice. In subsequent studies, mice received 0 or 10 mg/kg BW intraperitoneal injections of RU24969. Analysis revealed a main effect on startle amplitude, with higher startle amplitudes observed in wild-type than in 5HT-1B-minus mice. There was also a group by drug interaction, as RU24969 reduced startle amplitude in wild-type mice, but did not alter startle amplitude in 5HT-1B-minus mice. 5HT-1B-minus mice demonstrated more PPI than wild-type mice at the 0mg/kg BW dose ($p<.001$). A group by drug interaction was observed at the 10mg/kg BW dose, with RU24969 diminishing PPI in wild-type mice but not in 5HT-1B-minus mice. Results suggest that activation of 5HT-1B receptors is responsible for startle amplitude reduction and deficits in PPI induced by RU24969 in mice. Further, activation of 5HT-1B receptors by endogenous serotonin may decrease PPI.

663.18

CHARACTERIZATION OF THE DISRUPTIONS OF PREPULSE INHIBITION AND HABITUATION OF STARTLE INDUCED BY α-ETHYLTRYPTAMINE. D.L. Martinez[1], M.A. Geyer[1,2], and V. Lehmann-Masten[2]*. Departments of Neuroscience[1] and Psychiatry[2], University of California San Diego, La Jolla, CA 92093-0804.

α-ethyltryptamine (AET), a monoamine oxidase inhibitor and potent monoamine releasing agent, is the first example of an indolealkylamine analog demonstrated to substitute in MDMA-trained animals. (Glennon, 1993). Previous studies have demonstrated that the substituted amphetamine/entactogen 3,4-methylenedioxymethamphetamine (MDMA) and AET have similar effects on unconditioned motor behavior in rats (Krebs and Geyer, 1993). Furthermore, the locomotor activating effects of both MDMA and AET are blocked by pretreatment with fluoxetine (Callaway and Geyer, 1990; Krebs and Geyer, 1993), a serotonin (5-HT) uptake inhibitor, suggesting that the two compounds may share a presynaptic mechanism of action. This study examined the effects of AET using measures of startle plasticity, specifically prepulse inhibition (PPI) and habituation. PPI, a measure of sensorimotor gating, is reduced in rats treated with hallucinogens, serotonin releasers, and dopamine agonists. In contrast, startle habituation is reduced in rats treated with hallucinogens and serotonin releasers. AET (2.5, 5.0 and 10.0 mg/kg) decreased PPI of acoustic startle and reduced the habituation of tactile startle. To determine whether AET produces these effects via pre- or post-synaptic actions, fluoxetine (2.5 and 10.0 mg/kg) was used as a pretreatment. Fluoxetine did not disrupt PPI, but did reduce startle habituation. Fluoxetine pretreatment prevented the AET-induced disruption of PPI, and reduced the AET-induced disruption of startle habituation. Combined with previous findings, these results confirm that the effects of AET on startle plasticity are due to the release of presynaptic 5-HT.

DISSOCIATION OF HIPPOCAMPAL SEROTONIN RELEASE AND LOCOMOTOR ACTIVITY FOLLOWING DRUG INJECTIONS INTO THE MEDIAN RAPHE NUCLEUS. I. Shim* and D.Wirtshafter. Dept. Psychology., Univ. Ill. at Chicago, Chicago, IL 60607-7137.

In vivo microdialysis was used to investigate the role of 5-HT in mediating the locomotor hyperactivity produced by injections of 8-OHDPAT, muscimol and baclofen into the median raphe nucleus (MR).

Intra-MR injections of muscimol produced a pronounced increase in locomotor activity and a concomitant decrease in hippocampal 5-HT release to 58% of baseline during the first hour post injection. 8-OHDPAT resulted in a much smaller effect on activity which was accompanied by a remarkable reduction of hippocampal 5-HT output to 49.1% of baseline. In addition, even though intra-MR injections of baclofen resulted in marked activity, the maximal magnitude of which was similar to that produced by muscimol, these injections were without effect on extracellular 5-HT release in the hippocampus. No injections altered 5-HIAA release.

These findings demonstrate that the effects of intra-MR injections of these drugs on activity and hippocampal 5-HT release can be clearly dissociated, and strongly suggest both that serotonin does not play an essential role in the production of the hyperactivity by muscimol or baclofen, and that the hyperactivity produced by intra-MR injections of different drugs is mediated through at least partially distinct cell populations within the MR.

5-HT_1, BUT NOT β-ADRENERGIC, ANTAGONISM, REDUCES THE EFFECTS OF A 5-HT_2 AGONIST K.M. Krebs* and M.A. Geyer Dept. of Psychiatry, UCSD, La Jolla, CA 92093-0804.

The existence of functional interactions between serotonin (5-HT) 1A and 2 receptors has been suggested. For example, chronic pretreatments with the 5-HT_{1A} agonist 8-OH-DPAT produced cross-tolerance to the effects of the selective 5-HT_2 agonist DOI on rat locomotor activity. The current experiments tested this putative interaction using the Behavioral Pattern Monitor (BPM), which measures amounts and patterns of locomotor and investigatory behavior. In a series of studies, male rats (n=10-11) received pretreatments of either vehicle or one of the nonselective 5-HT_1 and β-adrenergic antagonists, propranolol (10 mg/kg SC) or (+/-)pindolol (20 mg/kg SC) before receiving treatments of either saline or 1.0 mg/kg DOI (SC). Acutely, DOI reduced measures of locomotor activity. Both propranolol and pindolol pretreatment blocked the attenuation of locomotor activity produced by DOI. Thus, antagonism of either 5-HT_{1A}, 5-HT_{1B}, or β-adrenergic receptors, produced by propranolol and pindolol, decreases the expression of DOI-induced behavior. Because 5-HT_{1B} agonists increase locomotion, it is unlikely that the 5-HT_{1B} antagonist effects of propranolol or pindolol were responsible. To assess the relevance of β-adrenergic receptors to the effect of DOI, the selective β-adrenergic antagonist betaxolol was used as a pretreatment. Rats (n=10) received either saline or betaxolol (10 mg/kg SC) before treatments with saline or DOI (1.0 mg/kg SC). DOI again reduced locomotion, but this effect was insensitive to betaxolol, indicating that β-adrenergic antagonism was not responsible for the ability of pindolol and propranolol to block the effects of DOI. Thus, it is likely that propranolol and pindolol attenuated the effects of DOI on locomotor activity through 5-HT_{1A} antagonism. As DOI is reputed to be a selective 5-HT_2 agonist, this antagonism may reflect a functional interaction between 5-HT_{1A} and 5-HT_2 receptors in the expression of the effects of DOI on locomotor activity.

FLUOXETINE INCREASES STEADY-STATE LEVELS OF PREPROENKEPHALIN mRNA IN RAT STRIATUM AND AMYGDALA. P. Rossby, C. Perrin, A. Burt, I. Nalepa, S. Spector*, F. Sulser. Vanderbilt Univ., Sch. of Med., Nashville, TN 37232.

Fluoxetine and other selective serotonin reuptake inhibitors (SSRIs) are being prescribed extensively for a broad range of psychopathologies, including depression, obsessive-compulsive disorder, and post-traumatic stress disorder. Yet aside from the knowledge that SSRIs increase the synaptic availability of serotonin, little is known about the mechanism(s) of their actions in the CNS. We are therefore studying the effects of fluoxetine on the steady-state mRNA levels of genes putatively involved in the modulation of cognitive/emotional states. In this experiment we focused on the preproenkephalin (PPE) gene, which encodes two opiate peptides i.e., met- and leu-enkephalin. Male Sprague Dawley rats (250-300 g) were treated with fluoxetine (10 mg/kg, i.p.) or normal saline for 10 days. Total RNA was prepared from frozen tissues by the method of Chomczynski, and PPE mRNA levels were determined by quantitative slot blot or Northern blot analysis. The cDNA probe contained the entire rat PPE coding region. Chronic fluoxetine treatment induced a 2-fold increase in PPE mRNA in the amygdala and a 1.7- to 2-fold increase in the striatum versus saline treated controls. This is the first report implicating fluoxetine (and possibly serotonin) in the regulation of an opiate mRNA in vivo. (USPHS grant MH-29228).

5-HT1A AND OPIOID RECEPTORS HAVE DIFFERENT ROLES IN THE INHIBITION OF VOMITING. J.B. Lucot*. Dept. Pharmacology, Wright State Univ., Dayton, OH 45435

The 5-HT_{1A} receptors inhibitory to vomiting are postsynaptic, implying a physiologically relevant role in preventing vomiting. Endogenous opioids have been implicated in both eliciting and inhibiting vomiting. Antagonists were used to evaluate the role of these receptors in the regulation of vomiting elicited by motion in cats.

The dose of 1.0 mg/kg of the prototype 5-HT_{1A} antagonist LY 297996 completely reversed the antiemetic effect of the agonists 8-OH-DPAT, flesinoxan and LY 301317. Given alone, it had no effect on the number vomiting, the latency to the first retch, the duration of a bout of retch/vomits or the number of multiple bouts of retch/vomits. The highest dose of naloxone tested, 0.1 mg/kg (1/100th the emetic dose) did not alter the latency to the first retch but did increase the incidence and the number with multiple bouts and significantly increased the duration of the first bout of retch/vomits. These results suggest that stimulation of 5-HT_{1A} receptors decreases the probability of vomiting while endogenous opioids end a vomiting sequence and produce a relatively refractory period.

SEROTONERGIC MODULATION OF AVIAN COMPULSIVE PECKING. L.J. Goodman*, P.D. Skosnik, L.J. Beeler & C.F. Gaskill. Dept. of Psychology, West Virginia Univ., Morgantown, WV 26506.

Compulsive pecking is a stereotyped, species-specific behavior that may be induced in birds by a variety of stimuli. DAergic mechanisms of this behavior have been previously established in pigeons. Compulsive behaviors in mammals have also implicated serotonin, as in humans (e.g., in OCD patients) where a serotonin reuptake inhibitor (e.g., clomipramine (CLO) reduces compulsive behavior. The present study assessed and compared acute and chronic effects of CLO on apomorphine (APO) induced pecking (AIP) and restricted feeding induced pecking (FIP) in Columba livia..

Under FIP conditions, acute testing of pre-feeding injection of CLO demonstrated a negative dose (5-15 mg/kg, ip)-FIP response relationship, the higher the CLO dose the greater the FIP suppression compared to saline injection. TFMPP (2 mg/kg, ip), another 5-HT agonist, also acutely reduced FIP. Chronic CLO injections (21 days, 15 mg/kg/day), aside from a first day effect, did not produce a sustained reduction in FIP until day 19. Reduced FIP was often accompanied by marked pacing. Seven days of saline were required for recovery to elevated pre-chronic CLO FIP. Under AIP testing, a first day reduction in pecking occurred with CLO but acute TFMPP produced no change from APO alone. Chronic CLO (24 days), unlike in FIP, did not alter AIP scores.

Differential results from such assessments may provide useful insight into interactive mechanisms of DA and 5-HT systems in stereotypy.

SEROTONIN INNERVATION OF DOPAMINE NEURONS IN RAT VENTRAL TEGMENTUM. C.F. Phelix[1], M.J. Russell[1], P. Kumar*[1], P.A. Broderick[2] 1 - Div. Life Sci., Univ. Texas, San Antonio, TX 78249-0662; 2 - Dept. Pharm., CUNY Medical School, New York, NY 10031

There are two sights of presynaptic interaction proposed for serotonin (5HT) to affect tegmental dopamine (DA) neurons, i.e., proximal and distal. One sight of distal interaction is at the convergence of their terminals, e.g., nucleus accumbens (NAcc; Phelix and Broderick, Brain Res. Bull. 37:37-40, 1995). Our present objective was to determine the degree of overlap between 5HT axons and DA somatodendrites in the ventral tegmental area (VTA) and substantia nigra, the proximal sights. In addition, tract tracing studies were performed to identify mesoaccumbens DA neurons innervated by 5HT axons. The first part of this study utilized a double label light microscopic immunocytochemical procedure to stain for 5HT first with silver-diaminobenzidine (DAB) and second for tyrosine hydroxylase (TH) with DAB alone. With this approach 5HT axons were seen to inundate DA neurons forming axodendritic and axosomatic contacts. These contacts extended from DA neuron populations in the midline VTA to the dorsolateral substantia nigra pars compacta. The second part of this study included retrograde transport of horse radish peroxidase from the ventrolateral NAcc to the VTA before staining with 5HT, that is both were visualized with silver intensified DAB. Then TH was visualized with DAB. Most mesoaccumbens DA neurons received axodendritic and axosomatic 5HT innervation. These results show the pervasive character of the presynaptic influence of 5HT on DA neurons within reward and motor circuits. Supported by HHMI and HL02914-01 to CFP.

CORTICOSTERONE DETERMINES SPECIFIC 5-HT$_{1A}$ RECEPTOR-MEDIATED RESPONSES IN A WATER MAZE LEARNING TASK.
O.C. Meijer*, R. Kortekaas, M.S. Oitzl and E.R. de Kloet. Div. of Medical Pharmacology, LACDR, P.O.B. 9503, 2300 RA Leiden, The Netherlands

We have tested the effects of the specific 5-HT$_{1A}$ receptor agonist 8-OH-DPAT in animals with different plasma levels of corticosterone (B) in the free swim trial of the Morris water maze. Sham operated male Wistar rats with normal circadian rhythmicity were compared to rats with defined exogenous levels of B. Rats were adrenalectomized and implanted with a 20% corticosterone pellet, to obtain constant low levels of circulating B. One week after surgery the animals were trained for 4 days to find a submerged platform in a pool. On the 5th day the platform was removed and the behaviour of the animals was monitored during a 1-minute swim session. 90 Min before this free swim trial an s.c. injection of 1 mg/kg B (High B) or vehicle (Low B) was given; 30 min before the trial 0 or 100 μg/kg 8-OH-DPAT was injected i.p.

8-OH-DPAT had a stimulatory effect on the distance swum by the animals of all 3 groups. There were no effects of 8-OH-DPAT on initial memory retrieval, measured as the distance swum upto the first crossing of the previous platform location. As a measure for search strategy in the free swim trial the number of crossings of the previous platform location was used. Rats with high B, but no 8-OH-DPAT had significantly more crossings than sham or Low B rats. In response to 8-OH-DPAT, both sham and High B rats showed a decrease in the number of crossings. Low B rats were completely unresponsive to the effect of 8-OH-DPAT on this parameter.

These results show two different effects of B on the behaviour of rats in the free swim trial of the Morris water maze: 1) High B per se increases use of the knowledge of the previous platform location compared to sham and Low B rats. 2) The 5-HT$_{1A}$ receptor-mediated response to 8-OH-DPAT in the hippocampus is blocked by low levels of B; high levels of B can override this effect. This last point provides a striking parallel between the hormonal dependency of the activity of single CA1 neurons and a parameter in a spatial memory task in response to 5-HT$_{1A}$ receptor stimulation by 8-OH-DPAT.

NEUROPEPTIDES AND BEHAVIOR II

664.1

DIFFERENTIAL REGULATION OF VASOPRESSIN RECEPTORS IN THE HYPOTHALAMUS OF GOLDEN HAMSTERS.
Y. Delville* and C.F. Ferris. Behavioral Neuroscience Program, Psychiatry Dept., Univ. of Mass. Med. Ctr., 55 Lake Ave. N., Worcester, MA 01655.

In female golden hamsters, ovariectomy results in a loss of vasopressin (AVP) binding from the ventrolateral hypothalamus (VLH). It is likely that periods of the reproductive cycle associated with low plasma levels of gonadal steroids, such as lactation, coincide with low density of AVP receptor binding within the VLH. This possibility was tested by comparing the density of AVP receptor binding in the VLH of lactating and cycling females. As predicted, lactation was associated with a total loss of AVP receptor binding from the VLH. Interestingly, lactation was also associated with a dramatic increase in AVP receptor binding density within another hypothalamic site, the dorsomedial nucleus (DMN). Our data support the hypothesis AVP receptor binding within the VLH is dependent upon gonadal steroids. In contrast, AVP receptor binding within the DMN may be responsive to other neurobiological changes associated with lactation. The function of increased AVP receptor binding within the DMN during lactation is currently being tested in the context of behavioral modifications associated with lactation. (Supported by NSF BNS-9121097 awarded to C.F.F.)

BEHAVIORAL AND NEUROBIOLOGICAL CONSEQUENCES OF ADOLESCENT ABUSE IN GOLDEN HAMSTERS.
C.F. Ferris*, R.H. Melloni, M.A. Abbott and Y. Delville. Behavioral Neuroscience Program, Psychiatry Dept., Univ. Mass Med. Ctr., 55 Lake Ave N., Worcester, MA 01655.

Physical and emotional abuse in human adolescence is associated with changes in context dependent aggression. We hypothesize that environmental and emotional insult during this developmental period have behavioral and neurobiological consequences into adulthood. In golden hamsters, a similar period to adolescence can be identified in sub adult animals. Between postnatal days P28-P42, sub-adult hamsters were subjected to daily attacks and threats by aggressive adults for 30 min periods. Following the cessation of abuse, animals were tested for context-dependent aggression as young adults on P45 in a resident/intruder model. When exposed to younger and smaller males placed into their home cage, abused animals were significantly more aggressive than controls. However, when confronted by animals of equal age and size, abused hamsters were submissive. Since vasopressin and serotonin are involved in the control of aggression, brains are being analyzed for changes in these neurotransmitters. (Supported by NSF BNS-9121097)

664.3

VASOPRESSIN/SEROTONIN INTERACTIONS IN THE ANTERIOR HYPOTHALAMUS CONTROL AGGRESSIVE BEHAVIOR IN GOLDEN HAMSTERS.
R.H. Melloni, Jr.*, Y. Delville, and C.F. Ferris, Behavioral Neuroscience Program, Psychiatry Dept., University of Massachusetts Medical Center, Worcester, MA 01655

This study examines the specific anatomic and pharmacologic nature of the AVP/5-HT neural systems in the anterior hypothalamus (AH) of golden hamsters, their involvement in the control of aggressive behavior, and their interactions with fluoxetine, a 5-HT uptake inhibitor shown to decrease aggressive behavior in many species. We hypothesized that AVP facilitates aggression by enhancing the activity of AH neural network controlling offensive aggression that is normally restrained by 5-HT. To test this hypothesis, we first employed receptor binding and immunohistochemistry to examine whether AVP and 5-HT and their receptors were colocalized in the AH. These studies showed high density of both AVP and 5-HT receptor binding in this brain region and revealed the presence of putative 5-HT synapses on AVP neurons in particular regions of the AH. Next, we tested whether AVP microinjections in the AH could stimulate offensive aggression, and if this behavior could be selectively inhibited by 5-HT or fluoxetine. AVP microinjection in the AH resulted in a marked increase in offensive aggression that could be blocked by the co-injection of 5-HT or the peripheral administration of fluoxetine. Finally, *in vivo* microdialysis was used to measure directly AVP and 5-HT levels in the AH following fluoxetine treatment. Fluoxetine treatment caused an approximate 4-fold increase in 5-HT levels in the AH, and a coincident with a 3-fold decrease in AVP levels. In summary, we provide anatomical, behavioral and pharmacological evidence supporting a functional relationship between the AVP/5-HT neural systems in the AH and the control offensive aggression.

664.4

IBOTENIC LESIONS OF CENTRAL AMYGDALA INHIBITS VASOPRESSIN-INDUCED FLANK MARKING.
M. Bamshad* and H.E. Albers. Lab. Neuroendocrinol & Behav., Depts. Biol. & Psychol., Georgia State Univ., Atlanta, GA 30303.

Syrian hamsters communicate social information by a form of scent marking called flank marking. Flank marking can be stimulated by microinjection of arginine vasopressin (AVP) into either the medial preoptic-anterior hypothalamus continuum (MPOA-AH), the lateral septum-bed nucleus of stria terminalis (LS-BNST) or the periaqueductal gray (PAG). Previously, we reported increases in Fos-like immunoreactivity in the BNST, PAG and central amygdala (Ce) of hamsters microinjected with AVP into the MPOA-AH. To investigate whether the Ce is involved in AVP-induced flank marking the Ce of hamsters was lesioned with ibotenic acid. Hamsters were injected bilaterally with either saline or ibotenic acid in the Ce and then implanted with a guide cannula aimed at the MPOA-AH. A week later, hamsters were microinjected with AVP into the MPOA-AH and tested for flank marking. The frequency of flank marking was significantly reduced in hamsters with Ce lesions ($p<0.05$). The ibotenic acid injected animals flank marked 4.8 ± 3.60 during the 10 min. test whereas the saline injected animals marked 36.6 ± 11.37. These data suggest that signals from the MPOA-AH to the Ce are important for flank marking and that Ce is yet another component of the neural circuit that regulates AVP-induced flank marking. (Supported by NSF IBN 9222099).

664.5

FLANK MARKING STIMULATED BY VASOPRESSIN (AVP) INJECTED INTO THE MEDIAL PREOPTIC AREA-ANTERIOR HYPOTHALAMUS (MPOA-AH) IS INHIBITED BY AVP AND NMDA ANTAGONISTS INJECTED INTO THE PERIAQUEDUCTAL GRAY (PAG). T.T.Cooper*, M. Bamshad, and H.E. Albers. Laboratory of Neuroendocrinology and Behavior, Depts. of Biology & Psychology, Georgia State University, Atlanta, GA 30303

The MPOA-AH and PAG are components of the neural circuit controlling flank marking in Syrian hamsters. Microinjection of AVP into the MPOA-AH or PAG elicits high levels of flank marking and microinjection of AVP combined with a NMDA antagonist into the MPOA-AH inhibits flank marking. The purpose of the present study was to examine the effects of an AVP antagonist (AVP-A) and a Glu antagonist (AP5) microinjected into the PAG on flank marking stimulated by AVP microinjection into the MPOA-AH. Hamsters (n=8) were injected with either AVP-A (1.0mM), AP5 (1.0mM), metergoline (5-HTa, 10.0μM), or saline into the PAG followed by microinjection of AVP (9.0μM) into the MPOA-AH (counterbalanced across test days). Hamsters exhibited high levels of flank marking following injection of saline (27.38$\pm$4.82) or 5-HTa (19.63$\pm$5.20) into the PAG, but exhibited significantly ($p<.01$) lower levels of flank marking when either AVPA (6.75$\pm$6.06) or AP5 (6.88$\pm$2.89) was injected into the PAG. These data indicate that activation of both AVP and NMDA receptors in the PAG are important for eliciting flank marking following microinjection of AVP into the MPOA-AH.

664.6

FOS-LIKE IMMUNOREACTIVITY ASSOCIATED WITH MATING-INDUCED AGGRESSION IN MALE PRAIRIE VOLES (*MICROTUS OCHROGASTER*). T.J. Hulihan, Z.X. Wang* and T.R. Insel. Department of Psychiatry and Behav. Sci., Emory Univ., Atlanta, GA 30322, USA

We have been studying monogamous prairie voles (*Microtus ochrogaster)* to investigate the neural substrates of pair bonding. After mating, male prairie voles develop a pair bond with selective affiliation and aggression. Selective aggression is defined as attack of a novel conspecific while defending the mate. This behavior is associated with monogamy (non-monogamous voles do not show selective aggression) and appears to be induced by mating (cohabitation with a female does not induce aggression). In this study, we examined regional brain Fos induction associated with selective aggression. In Experiment 1, male prairie voles that mated with a female for 24 hrs (MT) showed aggression in a resident-intruder test (RI; Winslow et al., 1993), as well as increased Fos-like immunoreactivity (Fos-ir) in the lateral septum (LS), the bed nucleus of the stria terminalis (BST), medial amygdaloid nucleus (MA), and the ventromedial hypothalamus (VMH), in comparison to the mated voles without RI test. In Experiment 2, MT males showed more aggression than the males that cohabited with a female for 24 hrs without mating (CH) or that had no exposure to a female (NF). MT males also had increased Fos-ir staining in the accessory olfactory bulb (AOB), dorsomedial hypothalamus (DMH), and MA than CH and NF males, and the males that had neither exposure to a female nor RI test (control). In addition, MT and CH males had increased Fos-ir staining in the LS and BST than NF and control males. In Experiment 3, MT males showed more aggression and Fos-ir staining when tested by a male intruder than by a female intruder or a female partner. These data indicate distinct brain areas that may be involved in the induction or regulation of mating-induced selective aggression in male prairie voles.

Enkephalinergic Immunoreactivity is Distributed throughout the Social Behavior Pathways of the Male Syrian Hamster Brain. A. G. Holt* and S. W. Newman. Neuroscience Program and Department of Anatomy and Cell Biology, University of Michigan, Ann Arbor, MI 48109-0616

The objectives of this study were (1) to determine whether methionine enkephalin (met-E) and/or leucine enkephalin (leu-E) are distributed within neural pathways implicated in mating and aggression in the male Syrian Hamster and (2) to compare and contrast the distribution of met-E and leu-E immunoreactivity (ir). Twenty-two behaviorally naive male hamsters received 50-360μg of colchicine, a compound which disrupts axonal transport, administered intracerebroventricularly under anesthesia 48 hours prior to perfusion. Hamsters were perfused transcardially with 4% paraformaldehyde and 40μm brain sections were processed for met-E or leu-E ir using one of several polyclonal antibodies, rabbit anti-met-E or anti-Leu-E antibody from Incstar Inc., or one of several rabbit anti-met-E antibodies from Dr. S.J. Watson, at a dilution of 1:1000. The ABC method (Vectastain Elite) was utilized with NiCl enhanced DAB. To determine the specificity of the primary antibodies, preabsorption and cross-reactivity studies were done with met-E, leu-E and other peptides. The olfactory bulbs (OB), preoptic area, and bed nucleus of the stria terminalis (BNST), regions that play a role in copulatory behavior, contained both met-E and leu-E ir as did regions implicated in aggressive behavior, including the central amygdaloid nucleus, paraventricular nucleus of the hypothalamus, arcuate nucleus, periaqueductal gray, and ventromedial nucleus of the hypothalamus. The distribution pattern of met-E and leu-E ir differed from that of dynorphin and beta endorphin reported previously. The results of the preabsorption and cross-reactivity control studies suggested that the specificity of the leu-E antibody was less than that of the met-E antibodies. The distribution of met-E and leu-E ir overlapped in all areas studied with the exception of the OB and BNST, where only met-E or Leu-E ir, respectively, was found. The quality and amount of immunostaining was greater with the met-E antibodies than with the leu-E antibody. (Supported by NIH, GM13553 and NS20629)

BEHAVIORAL EFFECTS OF INTRACEREBROVENTRICULAR INJECTION OF SELECTIVE TACHYKININ AGONISTS AND ANTAGONISTS. **T.C.M. de Lima*, R.M. Teixeira, A.R.S. Santos, G.A. Rae and J.B. Calixto. Depto. de Farmacologia, CCB, UFSC, Florianópolis, SC, 88040-900, Brazil.**

Tachykinins promote several biological effects by activation of NK_1, NK_2 and NK_3 receptors (Maggi et al., 1993, J.Auton.Pharmacol. 13:23-93). Stimulation of NK_1 and NK_2 receptors induces an anxiolytic behavior in the mouse light-dark box (Zernig et al., 1992, Neurosci.Lett. 143:169-172; Stratton et al., Eur.J.Pharmacol. 250:R11-R12). In the present study mice were injected (5 µl) intracerebroventricularly with 0.1, 1, 10, 100 or 500 pmol of substance P (SP), SP methyl ester (SPME), [ß-Ala^8] neurokinin A_{4-10} (ßALA), senktide (SENK), NK_1, NK_2 and NK_3 receptor agonists, respectively; FK888 (FK) or SR48968 (SR), NK_1 and NK_2 receptor antagonists, or vehicle (PBS). Immediately after drug injection they were placed in an open-field for habituation. After 5 min they were tested on an elevated plus-maze (EPM) for an additional 5 min session. SP did not modify any of EPM parameters, but SPME caused a reduction in frequency of open arm (OAE) and a decrease in enclosed arm (EAE) entries ($p<0.05$). ßALA just increased EAE in the highest dose, while SENK enhanced OAE and percent open arm time (OAT; $p<0.05$). FK increased OAT and SR enhanced OAE and OAT ($P<0.05$). None of these compounds changed percent enclosed arm time or motor coordination in a rota rod test. These results suggest that tachykinins play a modulator role in anxiety evaluated on EPM test in mice : NK_1 and NK_2 receptors activation inducing an anxiogenic whereas NK_3 stimulation producing an anxiolytic action.

TREATMENT WITH SUBSTANCE P IN AN ANIMAL MODEL OF HEMI-PARKINSONISM: INDICES FOR PROTECTIVE AND RECOVERY-PROMOTING EFFECTS

R.K.W. Schwarting*, S. Nikolaus, C. Thiel, B. Körber, J. Fornaguera, and J.P. Huston. Institute of Physiological Psychology I, University of Düsseldorf, Universitätsstr. 1, 40225 Düsseldorf, FRG

The neuropeptide substance P (SP) is known to act as a neurotransmitter or neuromodulator in various parts of the nervous system. Apart from its enhancing effects on reinforcement and memory, found after central and peripheral administration, there is evidence that SP can also have neurotrophic effects. Since SP is anatomically and functionally related with the nigrostriatal dopamine (DA) system, such neurotrophic effects of SP may play a role in cases of experimental damage of DA neurons, and in relevant neurodegenerative disorders, especially in Parkinson's disease. Thus, in a previous experiment (Mattioli et al., Neuroscience 48'92, 595-605), we administered SP daily (50μg/kg, ip) starting with the day after unilateral 6-OHDA injection into the rat substantia nigra and found that such post-lesion treatment with SP not only promoted recovery from the lesion-dependent deficit in thigmotactic scanning, but also prevented the ipsiversive asymmetry in turning in animals with subtotal depletions of neostriatal DA. These results indicated that SP might have acted also in a protective way. Thus, a subsequent experiment was conducted where rats received the unilateral 6-OHDA injection after 1 week of daily treatment with SP (50μg/kg, ip). An additional group was treated with cholecystokinin (CCK, 1μg/kg, ip), another neuropeptide also closely associated to DA in the forebrain. The analysis of behavioral asymmetries during 2 weeks after 6-OHDA injection showed that animals with pre-lesion SP treatment showed less behavioral asymmetry than vehicle- or non-treated controls, whereas the asymmetries were even stronger in CCK-treated animals. Thus, these results strengthen our hypothesis that SP can act in a protective way.

BEHAVIORAL EFFECT OF THE NK 2 ANTAGONIST SR 48968 BUT NOT OF THE NK 1 ANTAGONIST SR 140333 IN THE MOUSE BLACK AND WHITE BOX MODEL. G. Bematzky*, A. Saria *Central Animal Facility, Univ. of Salzburg, Austria; Neurochemical Laboratory, Univ. of Innsbruck, Austria

Previous reports have suggested the envolvement of neurokinin (NK) receptors in anxiety as tested in the black and white box (BWB) behavioral paradigm. We studied the new antagonists of NK1, SR 140333 and of NK 2, SR 48968 in the BWB. Swiss albino mice were kept in groups of 10 - 12 mice under conventional housing conditions and controlled reversed lighting. Diazepam, SR 140333 and SR 48968 or vehicle were injected ip30 min (10 ml/kg) before testing in the BWB. The experimenter was blind to the treatment until after the evaluation of the videotapes. Briefly, mice were placed in the center of the brightly lit (60 W white light) compartment of a two-compartment high-walled open-topped box. Like diazepam, the NK 2 antagonist SR 48968 increased time in the white, crossings in the white and rearings in the white, suggesting an anxiolytic effect. The NK 1 antagonist SR 140333 did not change the time spent in the light or dark compartment. The observed increase of crossings in the white and rearings in the white as well as the increase of the same behavioral parameter in the dark compartment, suggest higher activity of these animals compared with the solvent controls. However since also the number of transitions was higher than in the controls and comparable with different solvent groups we believe that such differences may result from normal variations in basic activity of this strain of mice. It is concluded that blockade of NK 2 receptors in mouse brain leads to an effect comparable with that of anxiolytic drugs. No NK 1 specific behavioral effect could be detected in the black and white box paradigm. (This study was supported by the Mundipharma Company.)

Neuropeptide Y (NPY) and D-Trp^{32}-NPY increase monoaminergic neurotransmission in rat hypothalamic dialysates during feeding behavior. F. F. Matos*, V. Guss and C. Urban. CNS Drug Discovery, Bristol-Myers Squibb Pharmaceutical Research Institute, 5 Research Parkway, Wallingford CT, USA

Administration of NPY into the hypothalamus or ventricles induces marked increases in food consumption in satiated rats. It has been suggested that the brain monoamines are involved in NPY-induced feeding. This study investigated the effects of NPY and the proposed NPY antagonist, D-Trp^{32}-NPY, on extracellular norepinephrine (NE), dopamine (DA), serotonin (5-HT), and metabolites 5-HIAA, DOPAC and HVA in the rat hypothalamus. Microdialysis probes were implanted in the vicinity of the periventricular hypothalamic nuclei (PVN) and a guide cannula in the lateral ventricle for intracerebroventricular (icv) administration of NPY and D-Trp^{32}-NPY. Dialysate levels of NE, DA, 5-HT, 5-HIAA, DOPAC and HVA were determined by HPLC-ECD. Feeding behavior was measured for 2 hours while animals were continuously dialyzed. NPY (20 µg, icv) significantly increased extracellular levels of NE (1.5 fold), DA (2.5 fold), DOPAC (1.5 fold) and HVA (3 fold), but did not change 5-HT or 5-HIAA levels. While NPY increased neurotransmitters and metabolites, food intake increased to 3.5±0.3 g (n=26). Food intake in control animals was 0.13±0.05 g (n=22). The putative NPY antagonist, D-Trp^{32}-NPY (40 µg, icv) produced similar increases in extracellular levels of NE (1.7 fold), DA (2.5 fold), DOPAC (3.5 fold) and HVA (2 fold) as NPY but did not change 5-HT or 5-HIAA levels. D-Trp^{32}-NPY also significantly increased food intake to 1.8±0.4 g (n=10). Administration of D-Trp^{32}-NPY (40 µg, icv) 5 min before NPY did not significantly change the increases in NE and DA produced by NPY alone. In contrast, D-Trp^{32}-NPY attenuated the later increase in DOPAC and HVA induced by NPY. In these animals, food intake increased to 3.7±1.2 g (n=7). These data indicate that activation of the hypothalamic monoaminergic system is involved in NPY-induced feeding and that D-Trp^{32}-NPY is a partial agonist at NPY receptors.

THE ROLE OF ANGIOTENSIN II IN THE MOTIVATIONAL AND PREFERENTIAL FACTORS OF DRINKING. L. Stubley-Weatherly*, J.N. Weatherly, and J.W. Wright. Dept. of Psychology, Washington State University, Pullman, WA 99164-4820

While it is well established that an intracerebroventricular (icv) infusion of Angiotensin II (AngII) induces a drinking response in an organism, the functional motivation underlying this drinking is unknown. The present study examined an animal's preference for drinking different liquids (H_2O versus a 16% sucrose solution) over a 24 hour period following an infusion of either AngII or aCSF. Male Sprague-Dawley rats were implanted with an icv cannula through which AngII (100 pmol in 2 ul aCSF) or aCSF was delivered. After an infusion, an animal's fluid intake of either H_2O, 16% H_2O/sucrose solution, or H_2O and 16% H_2O/sucrose solution was measured. Thus, factors involved in AngII-induced drinking, such as whether drinking was motivated by a biological need for a fluid or whether fluid preference controlled fluid intake, could be assessed. Furthermore, monitoring drinking over a 24 hour period allowed for the assessment of any interaction between these variables. Preliminary data suggests that an interaction exists between total fluid intake and fluid preference. Although AngII infusions mediate simple generalized drinking responses, it also appears that other motivational factors still exert control over an animal's drinking behavior.

DEVAZEPIDE, A CCK_A RECEPTOR ANTAGONIST, BLOCKS THE ACQUISITION OF CONDITIONED REWARD. F.J. Vaccarino [1], P. Li[1]*, V.P. Franco and S.A. Josselyn, **Dept. of Psychology and Psychiatry[1], University of Toronto, Toronto, Canada M5S 1A1.**

Cholecystokinin (CCK) is co-localized with dopamine (DA) in portions of the mesolimbic system, where it may facilitate the function of DA through the CCK_A receptor subtype. DA has been implicated in the acquisition of conditioned reward (CR), raising the possibility of a role for endogenous CCK in this process. Exp. 1 examined the effects of systemic administration of the CCK_A receptor selective antagonist, devazepide (0, 0.001, 0.01, 0.1 mg/kg, ip) on the acquisition of CR. Two novel levers were presented to drug-free animals in a test session; depression of the CR lever produced a light-tone stimulus previously paired with food delivery while depression of the non-CR lever produced no programmed consequence. Animals receiving vehicle treatments prior to the food-CS conditioned sessions responded more frequently on the CR lever during the test session. However, pre-treatment with devazepide (0.1 but not 0, 0.001, 0.01 mg/kg) in the conditioning sessions blocked the acquisition of CR. The possibilities that devazepide (0.1 mg/kg) impaired the development of CR by decreasing the amount of food consumed or by inducing a conditioned taste aversion to the food were ruled out in Exps. 2 and 3. Together, these results suggest that intact CCK_A function may be necessary for the development of CR.

664.14

INTRA-AMYGDALA INFUSION OF PENTAGASTRIN, A CCK_B AGONIST, PRODUCES A FACILITATION OF THE ACOUSTIC STARTLE REFLEX. S. A. Josselyn*, P. W. Frankland, F. J. Vaccarino, and J. S. Yeomans, **Dept. of Psychology, University of Toronto, Toronto, Canada M5S 1A1.**

The startle reflex is enhanced by both conditioned and unconditioned "fear". The amygdala appears to play a critical role in the mediation of these effects since lesions of various amygdala nuclei abolish increased startle responding, while electrical stimulation of the amygdala and its output pathways increase startle amplitudes (e.g., Davis, 1992). Several lines of evidence suggest that activation of cholecystokinin$_B$ (CCK_B) receptors produces anxiety and panic in laboratory animals and humans. CCK is found in the basolateral nucleus of the amygdala. Systemic administration of CCK-4 or pentagastrin, which are selective for the CCK_B receptor, increases anxiety-like behaviors measured in a number of different behavioral paradigms. Here we test whether the central infusion of CCK, either intracerebroventricularly (icv) or into the amygdala, increases startle amplitudes. Following icv infusion of the CCK_B agonist pentagastrin (0, 1.0, 10.0 nM in 5.0 µl), we recorded startle amplitudes for a period of 2 hours. No increases in startle amplitudes occurred over this period compared to pre-infusion baseline levels. In contrast, infusion of pentagastrin into the amygdala (0, 0.01, 0.1, 1.0, 10.0 nM in 0.5 µl) produced large increases in startle amplitudes at the three highest doses compared to pre-infusion baselines. These increases occurred 5-10 minutes following the drug infusion, and persisted for the remainder of the 30-minute test.

664.15

THE EFFECT OF CORTICOTROPIN RELEASING HORMONE ON THE ACOUSTIC STARTLE REFLEX. S.G. Birnbaum, M.S. Lidow* and M. Davis. Dept. of Psychiatry and Section of Neurobiology*, Yale Univ. Sch. Med., New Haven, CT 06508

Stimulation and lesion studies have implicated the amygdala in modulation of the acoustic startle reflex. The amygdala projects directly to the nucleus reticularis pontis caudalis (PnC), an obligatory synapse in the acoustic startle pathway, and contains a high level of corticotropin releasing hormone (CRH) neurons. The present study evaluated the effect of local infusion of CRH into the PnC on startle amplitude .

Eighteen rats were implanted with a cannula unilaterally in the PnC. One week following surgery all rats received a 5-min acclimation period followed by 60 startle stimuli (105-dB bursts of white noise, 50-msec duration, 30-sec interstimulus interval) to establish a stable baseline. They were then removed from the startle chamber and infused with artificial cerebral spinal fluid (ACSF) or CRH (10, 20, and 40 ng) according to a Latin square design. They were immediately replaced into the startle chambers and tested with 120 startle stimuli. Testing occurred every other day until each rat had received all doses. Two days following the last test session, all animals received the same testing procedure with either ACSF or a 80-ng CRH dose in a cross-over design.

CRH produced a dose-dependent increase in the startle amplitude which was significant at all doses. This effect began immediately after infusion and peaked at approximately 25 min. The facilitation of startle amplitude persisted for the 60-min test session. These results suggest that modulation of startle amplitude may occur by CRH release at the level of the PnC, perhaps following activation of the amygdala.

664.16

ROLE OF THE BED NUCLEUS OF THE STRIA TERMINALIS AND THE AMYGDALA IN THE EXCITATORY EFFECT OF CRH ON THE ACOUSTIC STARTLE REFLEX. Y. Lee* and M. Davis. Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06508.

Corticotropin releasing hormone (CRH) is known to markedly increase the amplitude of the acoustic startle reflex after intraventricular (i.c.v.) infusion (CRH-enhanced startle; Swerdlow et. al. '86, Liang et. al. '92). Although intra-amygdala infusion of CRH did not mimic CRH-enhanced startle, we found that large electrolytic lesions of the amygdala complex blocked this effect. This suggested that the amygdala may play an obligatory role in the expression of this effect but may not be the primary receptor site for CRH given i.c.v. Subsequently, we reported that electrolytic lesions of the medial septum, but not the lateral septum, blocked CRH-enhanced startle, and intra-medial septum injection of CRH induced a small but significant enhancement of startle amplitude (Lee & Davis, '93). However, kainic acid lesions of the medial septum failed to block CRH-enhanced startle, which suggested that the blockade of CRH-enhanced startle by electrolytic lesions of the medial septum was due to damage of fibers of passage, presumably the fornix. In the present studies, we investigated the role of the bed nucleus of the stria terminalis (BNST) and the sub-nuclei of the amygdala in CRH-enhanced startle.

Electrolytic lesions, as well as NMDA lesions, of the BNST blocked CRH-enhanced startle. However, neither ibotenic acid lesions of the central nucleus nor NMDA lesions of the basolateral nucleus of the amygdala appeared to block CRH-enhanced startle, even though both amygdala lesions completely blocked fear-potentiated startle, another behavioral measurement sensitive to amygdala manipulation. These data suggest that the blockade seen with electrolytic lesions of the amygdala complex was due to damage of fibers of passage, perhaps afferent or efferent fibers of the BNST.

At the present time, it is not clear whether the BNST is the primary receptor site which mediates CRH-enhanced startle, or whether it is an important relay station for expressing this effect. Currently we are testing both possibilities by infusing CRH directly into the BNST and by investigating the role of various other structures which are close to the ventricles and project to the BNST via the fornix, such as the ventral hippocampus, in CRH-enhanced startle.

BEHAVIORAL PROFILE OF PUTATIVE ANTICRAVING DRUGS IN AA RATS, AN ANIMAL MODEL OF ALCOHOLISM. J. De Vry, R. de Beun and T. Glaser*. Institute for Neurobiology, Troponwerke, Berliner Strasse 156, D-51063, FRG

Alcohol preferring AA rats, selectively bred for a high daily consumption of ethanol (EtOH, > 5 g/kg, 10 % V/V) and preference (> 70 %) for EtOH over water, were tested with a variety of putative anticraving drugs, injected shortly before the 12 h test session. Absolute and relative (preference) EtOH intake, as well as total fluid and food consumption were assessed. In general, drugs could be categorized according to the particular profile of drug effect. One typical profile was obtained with (cis)-flupenthixol, with a clear suppression of consummatory behavior (both food and fluid). Although EtOH intake was reduced by this compound, the effect was completely nonselective (consequently, EtOH preference was not affected). A different profile was obtained with imipramine and fenfluramine, as these compounds reduced both EtOH intake *and* preference. However, both compounds also reduced food intake and this effect was already present at doses below the doses which affected EtOH intake. The largest group contained compounds which were able to reduce EtOH intake and preference, but this effect occurred at similar doses which suppressed food intake (fluoxetine, lisuride, nifedipine, nitrendipine, verapamil, buspirone). In the case of 8-OH-DPAT and nimodipine, there appeared to be a slightly more selective profile (i.e., small ratio between EtOH and food intake reduction). The most selective profile was obtained by diazepam and ipsapirone. In both cases, clear reduction of EtOH intake and preference was obtained at doses which did not suppress food intake. The last group (ritanserin, ondansetron, diltiazem and naltrexone) consisted of compounds which were without effect on any parameter. These data suggest that the AA rat model offers the opportunity to find drugs which suppress EtOH intake and preference in a selective manner, but it remains unclear to what extent such profile reflects specific anticraving properties.

665.2

INTRAVENOUS HEROIN AND ALCOHOL SELF-ADMINISTRATION BY ALCOHOL-PREFERRING AA AND ALCOHOL-AVOIDING ANA RATS. P.Hyytiä*, G. Schulteis and G.F. Koob. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

The AA (Alko, Alcohol) rat line, selected for high alcohol drinking, has previously been shown to drink more solution containing the opiate etonitazene than its counterpart, the alcohol non-preferring ANA (Alko, Non-Alcohol) rat line (Hyytiä and Sinclair, *Psychopharmacology* 111:409,1993). The present experiments were conducted to see whether the relationship between ethanol and opiate intake by these lines would persist if an intravenous route of administration is used. Naive AA and ANA rats (n=6 per line) were trained to lever press using food as a reinforcer. Rats were then implanted with a silastic catheter into the external jugular vein. After recovery, animals were trained to respond for a 0.1 ml i.v. infusion of heroin (0.03 mg/kg/infusion) on a fixed-ratio (FR) 1 schedule with a 20-sec timeout (TO) during 3-h sessions. Once stable baselines were achieved, rats were given 3 within-session dose-response sessions during which rats were allowed to respond for ascending heroin doses (0.0075, 0.015, 0.03, and 0.06 mg/kg). The ratio requirement was then gradually increased to FR5 and the subjects were tested during one 6-h progressive-ratio session. There were no significant differences between AA and ANA rats either during the baseline heroin sessions, across the ascending within-session doses, or on the progressive-ratio probe. However, when after additional heroin baseline sessions, the rats were given ethanol intravenously (1.0 mg/kg/infusion) substituted for heroin on an FR1 TO 10-sec schedule, AA rats initially increased their responding, while ANAs fell below their heroin baseline. AA rats maintained stable responding and were significantly higher than ANAs also at higher ethanol doses, 2.0 and 4.0 mg/kg. These findings do not give evidence for a line difference in i.v. opiate self-administration but suggest that at least some factors contributing to the line difference in alcohol drinking are present when a non-oral route of administration is used. Supported by grants AA08459, AA06420, and AA07456.

665.3

NALTREXONE EFFECTS ON ORAL SUCROSE AND ETHANOL-REINFORCED RESPONDING IN RHESUS MONKEYS. E.D. Pakarinen[1], K.L. Williams[2] and J.H. Woods*[1,2] Departments of Pharmacology[1] and Psychology[2], University of Michigan, Ann Arbor, MI 48109-0632.

Twelve rhesus monkeys were given opportunities to respond to obtain either sucrose [3.2 - 320 mg/ml] or ethanol and water; most of the monkeys had histories of exposure to opioids (e.g., etonitazene) or phencyclidine (PCP)-like drugs. Eight of the twelve reliably self-administered ethanol relative to water over a 3-hour period. Ethanol concentration [0.25 - 32 gm/L] was altered; increases in concentration produced a bitonic preference in drug-reinforced responding relative to water and increases in ethanol intake. Individual differences in ethanol intake were considerable, and were representative of individual differences of other studies of oral ethanol intake in rhesus monkeys. Naltrexone (0.032 - 0.32 mg/kg i.m.) reduced both ethanol and water responding across monkeys, and, in some cases, reduced ethanol-reinforced responding more than water responding. At doses that reduced ethanol-reinforced drinking, naltrexone had little or no effect on sucrose-reinforced drinking. This type of study in primates may be appropriate to begin to examine parallels to the studies in humans in which naltrexone decreases certain ethanol-related behaviors. (Supported by USPHS Grants DA 00254, DA 05325, DA 07268, and DA 08568).

GENETIC DIFFERENCES IN NALOXONE ENHANCEMENT OF ETHANOL-INDUCED CONDITIONED TASTE AVERSION. J. Broadbent*, H. V. Linder, C. L. Cunningham. Medical Psychology, Oregon Health Sciences University, Portland, Oregon 97201

The influence of opioid systems on the aversive hedonic effects of ethanol was examined in alcohol-preferring (C57BL/6J) and avoiding (DBA/2J) strains of mice using the conditioned taste aversion paradigm. Naloxone (1 or 3 mg/kg) or ethanol (3 g/kg) given alone did not produce an aversion to a novel tasting fluid in C57BL/6J mice. Administration of both naloxone and ethanol, however, produced a significant taste aversion in this strain. Naloxone alone did not produce an aversion and also failed to potentiate the moderate aversion produced by ethanol (1.5 g/kg) alone in DBA/2J mice. A second experiment addressed the possibility that naloxone failed to enhance the aversion to ethanol in DBA/2J mice due to a 'floor' effect on consumption. A lower dose of ethanol (1 g/kg) produced a modest taste aversion in DBA/2J mice that, again, was not potentiated by naloxone. Additional conditioning with a high ethanol dose, however, significantly suppressed consumption indicating that naloxone's failure to enhance the effects of ethanol was not due to a 'floor' effect. These results reveal a selective enhancement of the aversive effects of ethanol in C57BL/6J mice by naloxone, suggesting that genetically determined differences in endogenous opioid systems in alcohol-preferring mice may mitigate ethanol's aversive effects.

665.5

NALTREXONE EFFECTS ON ACQUISITION AND REDUCTION OF ETHANOL CONSUMPTION IN C57BL/6J MICE. T.J. Phillips*, C.D. Wenger, and J.D. Dorow. V.A. Med. Cntr. and Dept. of Medical Psychology, OR Health Sci. Univ., Portland, OR 97201.

Opiate receptor antagonists, such as naloxone and naltrexone, have been shown to reduce ethanol (EtOH) consumption in EtOH preferring rodent lines and strains. Most studies have concentrated on antagonist effects in animals that have already acquired high levels of EtOH drinking. We have performed three two-bottle choice studies (water vs. 10% EtOH) using the EtOH preferring C57BL/6J mouse strain. The first was designed to replicate earlier findings of naltrexone's effects on reducing established EtOH consumption. An increasing i.p. dosing regimen was used, and significant effects of naltrexone on EtOH preference and consumption were found at lower doses; these effects waned at higher doses. The second study examined the effects of chronic naltrexone on the acquisition of EtOH consumption. Time-release naltrexone pelleted mice drank more EtOH and showed greater EtOH preference than did placebo pelleted mice. The third study examined the effects of i.p. injected naltrexone on acquisition of EtOH drinking. Naltrexone injected mice consumed less and exhibited lower preferences than did saline treated mice. There appear to be important consequences of dosing parameters and possibly EtOH experience on the effects of naltrexone on EtOH consumption. Supported by grants from the Dept. of Veterans Affairs and the Alcoholic Bev. Med. Res. Found.

665.6

CENTRAL ADMINISTRATION OF AN OPIATE ANTAGONIST DECREASES ORAL ETHANOL SELF-ADMINISTRATION IN RATS. C.J. Heyser*, A.J. Roberts, G. Schulteis, P. Hyytiä, and G.F. Koob. Dept. Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Opioid peptides have been implicated in various behavioral actions of alcohol, including the reinforcing effects, however the role of specific brain sites remains to be explored. The present study examined the effects of intracerebroventricular (ICV) or intracerebral (IC) injections of an opiate antagonist on ethanol self-administration. The nucleus accumbens and central nucleus of the amygdala were selected as IC sites given that these regions have been implicated in the behavioral effects of opiate drugs. Male Wistar rats were trained in a limited access paradigm (30 min/day) to respond for ethanol (10% w/v) or water in a two-lever free-choice condition using a saccharin fading procedure. Following the establishment of stable baseline responding for ethanol (± 20%), animals were implanted stereotaxically with a guide cannula above the lateral ventricle (ICV) or with bilateral guide cannulae either above the nucleus accumbens or amygdala. Following postoperative recovery of stable baseline responding, the rats were tested 15 min after ICV or IC microinjections of an opiate antagonist methylnaloxonium (0 - 2µg). Methylnaloxonium injections dose-dependently reduced ethanol responding. Injections into the amygdala significantly reduced responding for ethanol at doses of 0.25 - 0.50 µg, whereas higher doses were required in the nucleus accumbens (0.50 - 1.0 µg) and still higher doses were needed ICV (1.0 - 2.0 µg). These results provide evidence that opioids, particularly in the amygdala, may be involved in the regulation of ethanol self-administration. Supported by grants AA08459, AA06420 and NRSA AA05403.

DECREASED VOLUNTARY ETHANOL CONSUMPTION IN TRANSGENIC MICE LACKING β-ENDORPHIN

J.E. Grisel*, N.J. Grahame, J.S. Mogil, J.K. Belknap and M.J. Low
Department of Veterans Affairs Medical Center and Oregon Health Sciences University, Portland OR 97201

The opioid peptide, β-endorphin, has been purported to play a role in the voluntary consumption of ethanol. We tested this hypothesis in mice lacking β-endorphin (POMCX*4 -/- mice) due to transgenic alteration of its precursor, the proopiomelanocortin (POMC) gene. Introduction of a premature translational stop-codon into the POMC gene resulted in a truncated prohormone lacking the carboxyl-terminal region coding βendorphin, but normal expression and regulation of other peptide products of the POMC gene. We have previously demonstrated that POMCX*4-/- mice display deficient opioid stress-induced analgesia, but are not impaired in their analgesic responses to exogenously administered opiates (Rubenstein et al., submitted). In the present study, these adult male POMCX*4 -/- mice and their wild-type littermates (129/B6 hybrids) were given home-cage, two bottle choice access to either water and solutions containing either ethanol (7% vol/vol) or the selective μ-agonist, etonitazine (3mg/ml). POMCX*4 -/- mice demonstrated both a decreased preference for and consumption of ethanol compared to wild-type mice, but no differences in etonitazine self-administation were apparent. These data support the idea that β-endorphin plays a role in mediating ethanol consumption, and extend previous findings suggesting that mice lacking β-endorphin do not have altered opiate responsivity. Supported by grants from the NIH and the Markey Charitable Trust (MJL), and a VA Merit Review (JKB).

DELTA AND KAPPA OPIATE RECEPTORS MODULATE VOLITIONAL ETHANOL INTAKE IN THE RAT

J. Franck[1] and G. Örnung*[2] Departments of Physiology and Pharmacology[1], and Neuroscience[2], Karolinska Institute, S-171 77 Stockholm, Sweden.

The effect of opioid antagonists on volitional ethanol intake was studied in normal Sprague-Dawley rats using a free-choice paradigm. Rats were habituated to drinking solutions with increasing concentration of ethanol, reaching a final concentration of 5% within 12 days. The rats had free access to food and water. During a four day's baseline period, the rats were deprived of water and ethanol solution for the last 4 h of the light period. The average total daily intake of ethanol during this period was 1.70±0.22 g/kg/d (n=24). An i.p. saline injection was given 30 min before the beginning of the dark period, and water and ethanol solution were reinstalled when lights went off. The average intake of ethanol during the first hour after reinstallation of water and ethanol was 0.32±0.02 g/kg/h (n=24). A four day's treatment period was initiated by i.p administration of the opioid antagonists, naltrexone (0.1 and 1 mg/kg), ICI-174,864 (0.1 mg/kg), nor-binaltorphimine (nor-BNI; 0.1 mg/kg) or saline (4 ml/kg) 30 min before water and ethanol solution were reinstalled. Naltrexone (0.1 and 1 mg/kg; unselective antagonist) reduced the ethanol intake during the one hour test sessions by 45% and 65%, respectively, compared to the baseline values. ICI-174,864 (0.1 mg/kg; δ antagonist) and nor-BNI (0.1 mg/kg: *k* antagonist) reduced ethanol intake by 47% ($p<0.01$, n=8) and 32% ($p<0.05$, n=8), respectively. Naloxonazine (0.1 mg/kg; μ_1 antagonist) had no effect on ethanol intake (n=8). The total daily intake of ethanol was unaffected by the drugs studied. Food and water intake did not differ between treatment groups and controls. Ethanol intake during the test sessions was restituted to baseline values when drugs were replaced by saline injections. The results suggest that opiate receptors of the δ and *k* subtypes modulate volitional ethanol intake in the rat, and that selective opioid antagonists may have a therapeutic potential in the treatment of alcohol dependence.

CONTENT OF PROENKEPHALIN AND PRODYNORPHIN mRNAs IN DISTINCT BRAIN REGIONS OF THE ALCOHOL-PREFERRING (AA) AND THE ALCOHOL-AVOIDING (ANA) RATS.

N. T. Jamensky, K. Kianmmaa, M. Thakur* and C. Gianoulakis. Douglas Hospital Research Centre, McGill University, Verdun, PQ, H4H 1R3, Canada and Research Laboratories, Alko Ltd., Helsinki, Finland.

A number of studies have indicated that the reinforcing effects of ethanol are mediated, at least in part, by its effects on the activity of the endogenous opioid system. Genetically determined differences in the activity of the endogenous opioid system, under basal conditions or following exposure to alcohol, may be important in controlling alcohol consumption. Indeed, previous studies have demonstrated a higher content of pro-opiomelanocortin (the precursor to beta-endorphin) mRNA in the arcuate nucleus of the AA than of the ANA lines of rats. The objective of the present studies was to investigate the presence of differences in the contents of proenkephalin and prodynorphin mRNAs in distinct regions of the brain between AA and ANA rats under basal conditions, using ^{35}S-labelled oligonucleotide probes for proenkephalin and prodynorphin and in situ hybridization techniques. Results indicated that in the arcuate nucleus and septum the content of proenkephalin mRNA was significantly higher in the AA than ANA rats. On the other hand a lower content of prodynorphin mRNA was observed in some brain regions of the AA than of the ANA rat. In conclusion, such differences in the content of mRNAs of the endogenous opioid peptides between the AA and ANA rats may be important in controlling voluntary alcohol consumption by these lines of rats.

THE EFFECT OF AN ACUTE ETHANOL EXPOSURE ON THE RAT BRAIN POMC OPIOPEPTIDE SYSTEM.

R. L. Popp.* and C. K. Erickson. Div. Pharmacol. and Toxicol., Col. Pharm., U. T. Austin, Austin TX 78712.

The discovery of endogenous opiopeptides in the central nervous system has stimulated numerous questions concerning their function. It has been suggested that they play a role in the etiology of alcoholism or other addictive diseases. Beta-endorphin 1-31 (β-end) is one of these endogenous opiopeptides. It is post-translationally processed from the inactive peptide pro-opiomelanocortin (POMC). We have previously reported that a single ethanol exposure (0.5, 1.0, and 3.0 g/kg BW, 20% w/v ethanol) resulted in an increase in β-EPLP levels in the hypothalamus and a decrease in the hindbrain, regardless of dose. Biological significance could not be attached to any individual group differences seen at several time points. In order to identify the molecular action of ethanol on this peptide system we conducted another series of experiments using male Sprague Dawley rats to study the effects of different doses of ethanol (same as before) at different time points post-ethanol administration (15, 30, 60 and 240 minutes) on changes in POMC synthesis in the hypothalamus. We measured changes in both the POMC primary transcript and the POMC mature mRNA by hybridizing hypothalamic total RNA with a POMC intron/exon junction, *in vitro* -synthesized riboprobe. No changes in primary transcript were detected. We also did not see any changes in mature POMC hypothalamic mRNA up to 4 hours post-administration at any dose. Based on the results from these two experiments we conclude that an acute ethanol exposure affects the rat hypothalamic POMC opiopeptide system by increasing levels of β-EPLP. The increase in levels appears not to be caused by an increase in POMC synthesis but rather by an increase in the post-translational processing (PTP) of the pro-peptide POMC. (Funded by DA07355)

INVOLVEMENT OF THE PEDUNCULOPONTINE NUCLEUS IN REGULATING ALCOHOL DRINKING.

S.N. Katner, W.J. McBride, L. Lumeng, T.-K. Li, J.M. Murphy*. Depts. of Psychi. and Med., Indiana Univ. Sch. of Med., VA Med. Ctr., and Dept. of Psychol., Purdue Sch. of Sci., IUPUI, Indianapolis, IN 46202.

Experiments were conducted to determine if the pedunculopontine nucleus (PPN) is involved in mediating ethanol drinking behavior in the alcohol-preferring P line of rats. Female P rats were given limited access (2h/day) to 10% (v/v) ethanol and 0.0125% (g/100ml) saccharin solutions. During limited access, P rats consumed 10.4 ± 0.6 ml of ethanol and 7.3 ± 1.6 ml of saccharin. Food and water were available *ad libitum*. Cholinergic agents were microinjected unilaterally into the PPN immediately prior to ethanol access. Carbachol (1-4μg/0.5μl), which inhibits cholinergic neuronal activity within the PPN, dose-dependently decreased ethanol intake within the first 30 min (70% decrease at the highest dose; $p<0.05$). However, by the end of the 2 hr period, the actions of carbachol had begun to diminish with only the highest dose being effective. Carbachol also dose-dependently reduced saccharin intake within the first 30 minutes (90% decrease at the highest dose; $p<0.05$). The results with carbachol suggest that normal activity of the cholinergic PPN system is required for maintaining drinking behaviors in general. Scopolamine (5-15μg/0.5μl), which stimulates cholinergic neuronal activity within the PPN, dose-dependently decreased ethanol intake within the first 30 min (65% decrease at the highest dose; $p<0.05$); ethanol consumption had partially recovered by the end of the 2 hr period. On the other hand, microinfusion of scopolamine into the PPN did not alter saccharin intake after 30 minutes. The findings with scopolamine suggest that increased activity of the cholinergic PPN system selectively reduces ethanol intake, possibly by mimicking the actions of alcohol itself and consequently requiring less ethanol consumption to produce the same CNS effect. Overall, these results support an involvement of the cholinergic PPN system in regulating alcohol drinking behavior of the P line of rats. (supported in part by AA 08553, AA 07462, AA 07611).

ARE SOME OF THE EFFECTS OF ETHANOL MEDIATED THROUGH NPY?

C.L. Ehlers*, C. Somes, C. Garcia-Andrade, S. Lopez, J. Rivier. Clayton Fnd. Labs, Salk Institute, and Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Central administration of NPY in low concentrations has been shown to produce anxiolysis in several anxiety models and to produce some suppression of locomotor activity at higher doses, a behavioral profile which is similar to that of ethanol. In addition, recent studies have demonstrated that ethanol can potentiate some of the behavioral effects of NPY such as NPY-stimulated food ingestion. The present study was conducted to ascertain whether NPY and ethanol have a similar electrophysiological profile and to determine if potentiation of NPY's actions can also be detected in neurophysiological measurements. Thirty-two Wistar rats were stereotaxically implanted with electrodes aimed at dorsal hippocampus (DHPC), amygdala (AMYG), and frontal cortex (CTX). Rats received the following drug regimes: saline ICV , 1 and 3 μg NPY ICV, Saline ICV plus saline IP, Saline ICV plus ethanol (0.75 g/kg) IP, NPY ICV (1 μg) plus ethanol (0.75 g/kg) IP. Forty minutes of EEG was collected and event related potentials (ERPs) recorded in response to an auditory "oddball" paradigm . Spectral analysis revealed that the higher dose of NPY produced significant ($p<.006$) overall decreases in spectral power except in the higher frequency bands (10-50 Hz) specifically in frontal cortical areas. Ethanol (0.75 g/kg) and the lower doses of NPY also decreased spectral power but not to a significant degree. The combined administration of EtOH and NPY (1μg) produced significant effects similar to those found at the 3 μg dose of NPY. Evaluation of ERPs revealed that NPY (3μg) produced reductions in the N1 component in frontal cortex ($p<.001$) and decreases in the P3 component in amygdala ($p<.05$). Low doses of ethanol were found to significantly potentiate the effects of low doses of NPY on the N1 component. These studies suggest that NPY produces electrophysiological effects similar to low doses of ethanol. In addition ethanol appears to potentiate some of the electrophysiological effects of NPY. Dose-dependent effects of α-melanocyte-stimulating hormone (α-MSH) on the acquisition of a preference for ethanol in Sprague-Dawley rats. W. L. Nores, R. L. Bell, R. D. Olson, G. A. Olson*, and A. J. Kastin. Department of Psychology, University of New Orleans, New Orleans, LA 70148.

We studied the effects of α-MSH on the acquisition of a preference for ethanol. Thirty-six Sprague-Dawley male rats had access to a 3% v/v solution of ethanol for the first six days, followed by six days of 6% v/v solution of ethanol and six days of 12% v/v solution of ethanol in a limited access paradigm. The solutions of ethanol were available for one hour a day starting at 1600h, and intake of ethanol and water were measured at the end of this period. Food and water were freely available throughout the study, and were measured daily prior to the presentation of the solutions of ethanol. Rats were injected IP with either 0.0, 0.0001, 0.001, 0.01, 0.1, or 1.0 mg/kg α-MSH 20 minutes before the presentation of the solution of ethanol. A 6 X 3 X 6 (dose X concentration X days) mixed analysis of variance, with concentration and days as the repeated measures, yielded a significant two-way (dose X ethanol) interaction, $p < .05$. All doses of α-MSH increased intake of ethanol as the concentration of ethanol increased except the 1.0 mg/kg dose of α-MSH which decreased intake of ethanol as the concentration of ethanol increased. A significant main effect for ethanol was obtained, $p < .05$, with a higher overall intake of ethanol for the 6% and 12% v/v solutions of ethanol. There was also a significant main effect for dose, $p < .05$. An overall trend analysis on the doses of α-MSH yielded a significant quadratic trend, $p < .05$, indicating an inverted-U shaped dose-response relationship among the doses of α-MSH. The results suggest that α-MSH influences the acquisition of a preference for ethanol in rats.

TIME COURSE OF CORTICAL NMDA RECEPTOR ELEVATION AND SEIZURES IN MICE FOLLOWING WITHDRAWAL FROM CHRONIC PHENOBARBITAL. K. R. Short* and B. Tabakoff Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262, *Dept. of Psychology, Creighton Univ., Omaha, NE 68178.

The authors previously reported increased numbers of NMDA receptors in mouse cortex following chronic phenobarbital (PhB) treatment, suggesting a possible mechanism for withdrawal (W/D) seizures. We report the duration of NMDA receptor elevation following PhB W/D, and the corresponding rates of W/D seizures and levels of serum PhB.

C57BL/6 mice (N=85) ate normal chow or chow containing 2.0 g PhB/kg food (increased to 2.5 g/kg after 5 days) for 7 days, after which all mice received drug-free chow. All mice were tested for susceptibility to auditory seizures at 0, 8, 12, 24, 36, 48, and 72 hrs post-W/D. PhB-treated mice were sacrificed at either 0, 12, 24, 36, or 72 hrs post-W/D, and control mice at 24 hrs and 72 hrs. At sacrifice, trunk blood was assayed for serum PhB and cortical tissue was prepared for NMDA receptor quantification. [^{3}H]MK-801 binding (0.25 to 25 nM) to crude synaptic membranes was determined in the presence of 10 mM glutamate, 1 mM glycine, and 100 μM $MgSO_4$ in the presence or absence of 1 mM MK-801.

No PhB-treated mice displayed seizures at 0 or 8 hrs post W/D, while 67% at 12 hrs and 64% at 24 hrs showed W/D seizures, after which time seizure rates dropped sharply. Serum PhB at 0 hrs was 102μg/ml but dropped to 3 μg/ml at 12 hrs W/D. B_{max} for MK-801 binding was 49% higher than controls at 0 hrs W/D (K_d unchanged) and was still elevated 24% at 24 hrs, but dropped to control levels at 36 hrs post-W/D. These results suggest PhB W/D seizures are associated with increased NMDA receptor number and low serum PhB. (AA-09014, AA-09005, AA-07464)

NITRIC OXIDE SYNTHASE INHIBITION REDUCES ALCOHOL WITHDRAWAL HYPERMOTILITY, ALCOHOL PREFERENCE AND CORTICAL HYPERVASCULARIZATION. Ph. De Witte*, C. Verheyden and F. Lallemand. Lab. Psychobiology, Univ. of Louvain, Belgium.

Nitric oxide (NO) modulates the vascular system and also interacts with alcohol. L-NNA, a stereoselective NO synthase inhibitor, was mixed with water in the drinking bottle at 5mg/kg/day during pulmonary chronic alcoholization. Rats were kept for 30 days in the alcoholization chamber before recording of 1)the motility during the withdrawal syndrome 2) the preference for ethanol in a free choice water versus 10% (v/v) ethanol solutions and finally 3) the microvascular morphometric quantification of the vessels length in the fronto-parietal cortex. Results showed that 1) the hypermotility observed during the withdrawal syndrome was significantly decreased in L-NNA rats 2) the alcohol preference cut-off, i.e. the moment when rats failed to drink preferentially alcohol, was significantly decreased in the L-NNA treated rats, while no difference occured in the global liquid consumption between treated and untreated rats and 3) the hypervascularization of the cortical area observed after chronic alcoholization was significantly decreased in L-NNA treated rats. L-NNA, a NO synthase inhibitor, reduced thus the behavioral dependence after alcoholization, the behavioral preference for alcohol as well as the microvasculature length of the cortex supporting thus the direct implication of NO in alcohol abuse and its withdrawal.

INDOMETHACIN INCREASES ALLOPREGNANOLONE PLASMA LEVELS AND REVERTS ETHANOL PSYCHOPATHOLOGY IN ALCOHOLICS WITHDRAWAL. E.Romeo*, F.Pompili°, F. di Michele°, G.Spalletta°, P.Fucci°, C.Fumari°, M.Pace°°, L.Masala°°, G.Vaccarella°°and A. Pasini.°, Dept. Med. Sperimentale and °Dept. San. Pubblica, "Tor Vergata" Univ., Rome; °°"S. Giuseppe" Hosp. ,Albano, Rome , Italy 00133

We previously reported (Neuroscience 1994, Abst.215.26) a large decrease of plasma allopregnanolone (ALLO) levels in alcoholics in the early phase of ethanol withdrawal that negatively correlated with symptoms of anxiety and depression. Here we treated a group of alcoholics during withdrawal, with indomethacin (100mg/day) that inhibits a 3α-hydroxysteroid-oxidoreductase (HSOR), responsible for the conversion of ALLO to 5α-dihydroprogesterone (DHP). The plasma levels of progesterone (PROG), ALLO and DHP were measured by gas chromatography-mass spectrometry. Blood samples were taken on the first day of withdrawal (just before the beginning of treatment with indomethacin), each of the next 4 days of treatement and on day 15th (treatment free). On the same days patients were administered psychometric tests to measure depression, anxiety and agressiveness. On the first day of indomethacin treatment plasma ALLO increased 10 fold compared to control subjects. On the following 3 days and on day 15th ALLO levels were as in control subjects but higher than in alcoholics untreated. Since the plasma levels of PROG were unchanged the data support the hypothesis that indomethacin reverts the decrease of ALLO plasma content observed in not treated patients by acting on the HSOR. Although all subjects met the DSM-IV criteria for alcohol dependence, measurements of anxiety and depression in the indomethacin treated patients were within normal values. These findings raise the possibility that pharmacological interventions aimed to increase ALLO content could be beneficial in the treatment of the withdrawal syndrome in alcoholic patients.

RELATIONSHIP BETWEEN SPONTANEOUS SEIZURE OCCURRENCE AND SALICYLATE SPIN-TRAP ADDUCTS FROM WHOLE RAT BRAIN HOMOGENATES AFTER SINGLE AND REPEATED ETOH DEPENDENCE EPISODES. M. Vallett[1],* D.V. Gauvin[1], W.W. Beatty[1], T. Tabatabaie[2] & R.A. Floyd[2], Dept. Psychiatry & Behavioral Sciences, University of Oklahoma Health Sciences Ctr., [1], Dept. of Free Radical Biology & Aging, Oklahoma Medical Research Foundation[2], Oklahoma City, OK 73190

ETOH exposure increases free-radical generation, lipid peroxidation (LP), and [GSSG] with concomitant decreases in [SOD] and [GSH] in rat brain. The increase in LP is independent of acetaldehyde production by both alcohol dehydrogenase and catalase (Montoliu *et al.*, 1994, *J Neurochem*, 63, 1855-1862). The present study examined the relationship between the occurrence of ETOH-withdrawal-associated spontaneous convulsive behaviors and the level of CNS hydroxyl-radical species in rats exposed to either single or multiple (11) cycles of ethanol vapor exposure-induced dependency. HPLC assays of salicylate hydroxylation products (catechol, 2,3 Dihydroxybenzoate [2,3 DHBA], and 2,3 Dihydroxybenzoate [2,5 DHBA]) were used to quantify levels of brain homogenate hydroxyl-radical concentrations 12 hours after removal from the ETOH chambers. Water control and ethanol treated rats (terminal BAC's of ≥ 300 mg/dl for >24 hrs) were injected with 100 mg/kg salicylate, as a trapping agent, one hour before rapid decapitation, tissue harvesting, and liquid nitrogen tissue immersion. Significant group differences ($F[1,22]=22.7$, $p<.001$) were found in 2,3 DHBA concentrations after a single exposure cycle. Significant group-dependent differences were also found for both 2,5 DHBA concentrations and the total DHBA:salicylate ratio after both single and multiple exposures. Point biserial correlations between the occurrence of spontaneous withdrawal seizures and the concentration levels of 2,5 DHBA and the total DHBA:salicylate ratios were 0.82 ($t_{calc}(15)=7.4$, $p<.001$) and 0.75 ($t_{calc}(15)=5.9$, $p<.001$), respectively.

665.18

CALCIUM CHANNEL BLOCKERS REDUCE ETHANOL WITHDRAWAL-INDUCED ANXIETY IN MALE RATS. C.J. Wallis*, and H. Lal. Department of Pharmacology and SAINT, University of North Texas Health Science Center, Fort Worth, TX 76107.

Ethanol modifies the activity of a variety of ligand gated and voltage regulated ion channels. If increased calcium channel activity contributes to the ethanol withdrawal (EW) syndrome, then reducing calcium channel activity during EW should ameliorate some of the symptoms of ethanol withdrawal. In the present studies, we investigated the efficacy of nitrendipine and nimodipine, calcium channel blockers, to modify an EW symptom in an animal model of anxiety: male rat behavior in elevated plus-maze (EPM). Long-Evans hooded male rats were given a nutritionally balanced liquid diet containing 4.5% ETOH for 10 d (Lal et al., JPET 247:508, 1988). Twelve h after removal of the ETOH diet, rats were tested. We observed a significant reduction in the open-arm activity and the number of total arm entries indicative of EW. Single pretreatment (1h) with nitrendipine or nimodipine (0.08-5.0 mg/kg) resulted in a dose related increase in open arm activity at doses of 1.25-5.0 mg/kg. Acute pretreatment did not improve the total number of arm entries. Repeated injections of nitrendipine or nimodipine (1.25-5 mg/kg, 2/day, 3 or 5 days) increased open arm activity and total arm entries during EW. These data support a role for increased Ca^{2+} channel activity in EW. Supported by NIAAA grants AA06890 and AA09567

EFFECTS OF CHLORDIAZEPOXIDE AND ACAMPROSATE ON THE CONDITIONED PLACE AVERSION INDUCED BY ETHANOL WITHDRAWAL. B.A.Baldo*, C.J. Heyser, P.Griffin, G. Schulteis, L. Stinus#, and G.F. Koob. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA. 92037 and #Universite de Bordeaux II, Bordeaux, France..

Ethanol withdrawal is associated with irritability, anhedonia, anxiety, and other affective symptoms. In rats, ethanol withdrawal has been found to produce elevated brain stimulation-reward thresholds, locomotor hyperactivity, hypothermia, reduced seizure threshold, and conditioned place aversion. In the present study, an attempt was made to reverse ethanol withdrawal-induced conditioned place aversion by the classic benzodiazepine anxiolytic chlordiazepoxide (5 mg/kg, 10 mg/kg), and the novel anti-craving drug, acamprosate (400 mg/kg). Male Wistar rats were maintained on an ethanol-containing liquid diet (10% ethanol). After 20-24 days of exposure to the ethanol liquid diet, animals were tested in the place conditioning apparatus, which consisted of three distinct rectangular compartments separated by a triagular central region. During this initial exposure, animals freely explored all three compartments of the apparatus. One to three days later, animals were confined to one of the compartments while not undergoing withdrawal. On the following day, liquid diet was removed and the rats were exposed to a second compartment 8 hrs into withdrawal (mean BAL at withdrawal: 218 mg%), following injection with vehicle, chlordiazepoxide, or acamprosate. When subsequently allowed to re-explore all compartments, animals showed a significant place aversion to the compartment associated with ethanol withdrawal; both doses of chlordiazepoxide reversed this effect. In an initial attempt to characterize the effect of acamprosate on ethanol withdrawal-induced place aversion,five out of eight vehicle-treated rats displayed a reduction in the withdrawal-paired compartment, whereas none of the acamprosate-treated animals demonstrated such an effect. Thus, both chlordiazepoxide and acamprosate appear to reverse the place aversion elicited by ethanol withdrawal.

REPEATED EPISODES OF ETHANOL WITHDRAWAL LOWER PENTYLENETETRAZOL (PTZ) SEIZURE THRESHOLD DOSE IN MICE. J.L. Diaz-Granados*, R.R. Reich, K.G. Fernandes, and H.C. Becker. Med. Univ. of S. Carolina and VAMC, Charleston, S.C. 29425.

We have established a model in which multiple episodes of EtOH withdrawal result in an exacerbation of handling-induced convulsions (HIC) in adult C3H mice compared to mice that have been withdrawn a single time. The present experiment was designed to examine whether repeated EtOH withdrawals alters sensitivity to the proconvulsant effects of the GABAa receptor antagonist PTZ, as assessed by the tail vein infusion method. Mice were divided into three treatment groups: a multiple withdrawal (MW) group received 4 cycles of 16 hr EtOH vapor separated by 8 hr periods of abstinence; a single withdrawal (SW) group received a single 16 hr bout of EtOH; and controls (C) received no EtOH. At withdrawal, blood ethanol levels did not differ among the ethanol-exposed groups (150-175 mg/dl). Separate groups of animals were administered PTZ (4 mg/ml) i.v. either 8 or 24 hr post-withdrawal. At the 8 hr timepoint, threshold doses for tonic/clonic (TC) and tonic hindlimb extension (THE) were significantly lower in the MW group as compared to the SW and C groups (TC: 17.9 ± 1.3, 40.5 ± 7.7, 38.6 ± 7.2 mg/kg, respectively; THE: 20.5 ± 1.3, 50.9 ± 10.8, 80.7 ± 11.8 mg/kg, respectively). In addition, these treatment groups differed in the development of the seizure where the time between the myoclonic jerk (MJ) and TC was significantly less in the MW as compared to SW and C groups (6.2 ± 1.1, 35.9 ± 10.1, 33.0 ± 9.6 sec, respectively). At the 24 hr timepoint, preliminary results indicate a lower seizure threshold dose to MJ in the MW group. The latter endpoints are currently being evaluated. These results suggest that modifications at the GABAa receptor complex may underlie the potentiated seizure activity resulting from repeated ethanol withdrawals. Supported by NIAAA and VAMC.

ß-CARBOLINES DURING DETOXICATION AND ABSTINENCE IN CHRONIC ALCOHOLICS - A LONGITUDINAL STUDY N. Wodarz*, H. Rommelspacher[1], G.A. Wiesbeck, P. Riederer, J. Böning Department of Psychiatry, University of Würzburg, Füchsleinstr. 15, 97080 Würzburg, Germany; [1]Dept. of Neuropsychopharmacology, Free University of Berlin, Ulmenallee 30, 14050 Berlin, Germany

ß-carbolines (BC) could be formed by condensation of indolealkylamine and catecholamine transmitters with aldehydes or pyruvate. It was hypothesised that BCs might contribute to the pathogenesis and manifestation of at least some phenomena of addictive alcohol drinking. Chronic intraventricular infusion of BCs have repeatedly been shown to increase voluntary alcohol ingestion in rats and monkeys. Moreover, ethanol-preferring rats exhibit an increased formation, increased levels in brain, and increased excretion of BCs. However, few studies investigating the role of neurotransmitter condensation products in alcoholism of man have been conducted. Therefore, we investigated 12 men (age 23 - 58 years), fulfilling at least 6 of 8 diagnostic ICD-10 criteria of alcohol dependence, lasting for at least 5 years. Relevant psychiatric and/or somatic comorbidity was excluded. Levels of BCs Harmane and Norharmane were measured repeatedly in plasma and 24h-urine. Moreover, possible correlations of BC kinetics to life events, incl. history of alcoholism, personality traits, and actual psychopathology were evaluated. Compared to 12 age-matched healthy men without any history of dependence Harmane- and Norharmane-levels in 24h-urine were significantly increased. Harmane decreased during abstention without reaching values of healthy subjects. Norharmane exhibited an additional increase after alcohol withdrawal and remained elevated even 8 weeks after detoxication. Preliminary results indicate correlations of BC-levels with some demographic, clinical, and neuropsychological data.

DRUGS OF ABUSE: ALCOHOL V

ALCOHOL-ILLNESS ASSOCIATIONS IN THE SELECTIVELY BRED AA AND ANA RATS. Richard L. Elder*, Illinois State University, Campus Box 4620, Normal, IL 61790-4620 and Nancy Badia-Elder, and Stephen W. Kiefer. Department of Psychology, Kansas State University, Manhattan, KS 66506-5302.

Selectively bred AA and ANA rats were used to examine the acquisition and extinction of an alcohol-illness association. Each animal was given one pairing of a 6% (v/v) alcohol solution followed by intubation of a 0.15 M LiCl solution. On the day following the acquisition trial, animals were tested for taste reactivity to 6% alcohol. The animals then received seven extinction trials with the alcohol solution, each trial given every other day. Analysis of the taste reactivity data showed that AA rats produced significantly more ingestive responses and fewer aversive responses than ANA rats. Although both AA and ANA rats showed alcohol avoidance on the initial extinction test, the AA rats consumed significantly more alcohol over the course of the seven extinction trials. These results suggest that, while AA rats acquired an avoidance of alcohol when it was paired with illness, the avoidance did not appear to entail a shift in palatability nor was it as durable as that found in ANA rats.

666.2

TASTE REACTIVITY TO ALCOHOL IN RATS SELECTIVELY BRED FOR SENSITIVITY TO A SEROTONIN-1A AGONIST. N.E. Badia-Elder*, S.W. Kiefer, D.H. Overstreet, and A.H. Rezvani. Kansas State University, Manhattan, KS 66506-5302, University of North Carolina School of Medicine, Chapel Hill, NC 27599-7178.

Rats selectively bred for high (HI) and low (LO) hypothermic responses to the serotonin-1A agonist 8-hydroxy-(2-amino)-tetralin (8-OH-DPAT) were tested for taste reactivity to five concentrations of alcohol (5%, 10%, 20%, 30%, and 40%), sucrose, quinine, and water both prior to and following 21 days of two-bottle consumption testing with 10% alcohol and water. Both groups showed similar increases in ingestive and decreases in aversive responding to alcohol from the first to second set of taste reactivity tests. However, HI and LO rats did not differ in taste reactivity responding in either pre- or post-consumption tests. During consumption testing, HI rats consumed only slightly more alcohol than LO rats. The results indicated that HI and LO rats do not differ greatly in alcohol reactivity or consumption. However, after experience with alcohol, both rat lines showed a hedonic shift in alcohol palatability as shown by taste reactivity tests. Because these lines differ greatly in hypothermic responses to 8-OH-DPAT it seems unlikely that serotonin-1A receptors play a major role in modulating alcohol reactivity or consumption. (Supported by Training Grant T 32 MH 19547 from NIMH to the Society for Neuroscience).

ALCOHOL RESPONSES IN NULL MUTANT MICE MISSING THE SEROTONIN $5HT_{1B}$ RECEPTOR. J.C. Crabbe*, T.J. Phillips, D.J. Feller, N. Castanon and R. Hen. VA Med. Ctr. and Oregon Hlth. Sci. Univ., Portland, OR 97201 and Columbia Univ. P&S, NY, NY 10032.

Quantitative Trait Loci analyses suggest that the $5HT_{1B}$ serotonin receptor subtype may be a candidate gene that influences several responses to ethanol (EtOH). Mutant mice have been developed that lack the gene coding for the $5HT_{1B}$ receptor. Pharmacological evidence suggests that these mice might show reduced sensitivity to several EtOH effects. Homozygous knockouts ($5HT_{1B}^{-/-}$) were compared with heterozygotes ($5HT_{1B}^{+/-}$) and wild-type ($5HT_{1B}^{+/+}$) controls for EtOH-induced hypothermia and tolerance. (-/-) and (+/-) mice had diminished response to an acute 3 g/kg EtOH injection as compared with (+/+) mice. With 3 daily injections, tolerance developed in all genotypes to an equivalent extent. Because the hypothermia data suggested partial loss of response in heterozygotes even though they are thought to have normal $5HT_{1B}$ receptor levels, we tested additional animals after 10 mg/kg RU 24969, a $5HT_{1B}$ receptor agonist. (+/+) animals had a large, and (-/-) mice a very small hypothermic response: heterozygotes had an intermediate response. One week later, these mice were tested for their acute withdrawal response following a single 4 g/kg dose of EtOH, but the three genotypes did not differ. Other effects of EtOH were also tested. These studies are consistent with a role for serotonergic systems in modulating responsiveness to some, but not all, effects of EtOH. Support by NIAAA, NIDA, & Dept. of Veterans Affairs.

666.4

POTENTIATION OF ETHANOL-INDUCED EXCITATION OF VENTRAL TEGMENTAL AREA NEURONS BY SEROTONIN IS MEDIATED BY $5\text{-}HT_2$ RECEPTORS. M.S. Brodie* and R.D. Trifunović, Dept. of Physiology and Biophysics, University of Illinois at Chicago, Chicago, IL 60612-7342.

The dopamine-containing neurons of the ventral tegmental area (VTA) may be important in mediating the rewarding properties of drugs of abuse. We have previously shown that serotonin enhances ethanol-induced excitation of putative dopaminergic neurons of the VTA. Serotonin receptors have been classified into a number of different subtypes, therefore, we further characterized serotonin potentiation of ethanol-induced excitation with selective agonists and antagonists. Brain slices containing the VTA were prepared from male Fischer 344 rats, and all drugs were administered in the superfusate. Ethanol (40 - 160 mM) produced a concentration-dependent increase in the spontaneous firing rate, and serotonin (5 - 10 μM) enhanced this excitation. Two serotonin $5\text{-}HT_2$ agonists, DOI (0.1 - 1 μM) and α-methylserotonin (0.5 - 5 μM) also enhanced ethanol-induced excitation. The enhancement of ethanol-induced excitation was completely reversed by the administration of ketanserin (0.5 - 2 μM), a selective serotonin $5\text{-}HT_2$ antagonist. In some experiments, ethanol-induced excitation was reduced by ketanserin, suggesting that endogenous serotonin may contribute to the magnitude of ethanol-induced excitation seen in this preparation. These experiments indicate that potentiation of ethanol-induced excitation of VTA neurons is produced by serotonin acting at $5\text{-}HT_2$ receptors. Support: PHS grant AA-09125-03.

ETHANOL- AND NICOTINE-PREFERRING TRANSGENIC MICE DISPLAY REDUCED SEROTONIN CONTENT IN NUCLEUS ACCUMBENS. R.W. Steger*, C.J. Meliska, C.T. Fadden and A. Bartke. Dept. of Physiology, SIU School of Medicine, Carbondale, IL 62901.

Male transgenic (T) mice overexpressing the bovine growth hormone gene consume more and exhibit greater preferences for ethanol (EtOH) and nicotine solutions than non-transgenic litter mate controls (Pharmacol. Biochem. Behav. 50:563,1995). Since mesolimbic forebrain monoamines may modulate drug-induced reinforcement, we examined indices of content and turnover of serotonin (5-HT) and dopamine (DA) in various brain regions in male T and non-T mice, one hour after i.p. injection of either saline or 1.5 g/kg EtOH. Results showed that 5-HT content in nucleus accumbens (Nacc), but not corpus striatum was lower in T than in non-T mice (1.7 ± 0.5 vs. 4.6 ± 1.0 ng/mg tissue, $P < 0.01$), one hour after i.p. saline. In contrast, one hour after i.p. EtOH, T and non-T mice did not differ in Nacc 5-HT content (4.4 ± 1.3 vs. 4.7 ± 1.4 ng/mg tissue, $P > 0.05$), suggesting that EtOH normalized 5-HT levels in T mice, while having no effect in non-T controls. Levels of 5-hydroxyindole acetic acid after saline and EtOH showed a similar pattern of results. T and non-T mice did not differ in DA content in Nacc or corpus striatum after saline or EtOH. Reduced 5-HT function in reward-relevant brain regions may be associated with increased vulnerability to drug-induced reinforcement. (Supported by NIAA Grant 1-R03-AA09457.)

DIFFERENTIAL IMPACT OF ETHANOL ON EXTRACELLULAR LEVELS OF SEROTONIN AND GLUTAMATE: A COMPARATIVE STUDY IN LEWIS AND FISCHER 344 RAT STRAINS. M. Selim* and C. W. Bradberry. Yale Univ. Sch. of Med., Depts. of Psychiatry and Laboratory Medicine, and the West Haven Veterans Administration Hospital, Box 116/A2,West Haven, CT 06516.

The present study investigated the impact of systemic ethanol administration on extracellular levels of 5-HT and Glutamate (Glu) in the prefrontal cortex (PFC) and the nucleus accumbens (NA) in Lewis (LEW) and Fischer (F/344) inbred rat strains using microdialysis in awake animals. Lewis rats self-administer alcohol at higher rates than F/344 rats and are thought to be genetically predisposed to drug abuse. The extracellular levels of 5-HT and Glu in the PFC of either strain were not significantly altered by i.p. ethanol at 0.5, 1.0 or 2.0 g/kg; $p>0.05$ in all cases. Similarly, injections of ethanol at 0.5 or 2.0 g/kg did not result in any significant change ($p>0.05$) in NA dialysate concentrations of 5-HT or GLU in either strain. At 1 g/kg, ethanol caused a 44%±16 increase in NA-dialysate 5-HT levels in LEW rats ($p=0.006$). Again, no significant change was observed in F/344 rats ($p=0.66$). Preliminary data indicate that ethanol (at 1g/kg) causes a non-significant trend toward an increase in extracellular Glu in NA in both strains. Basal levels of Glu in both the NA and PFC of LEW rats were significantly lower than in F/344 rats ($p=0.05$ and 0.04, respectively). Basal levels of 5-HT were also lower in LEW rats, but the levels of statistical significance were marginal ($p=0.06$ and 0.08). These findings indicate that responsiveness of 5-HT to ethanol, or basal levels of Glu may be important in strain differences between F344 and Lewis rats in response to acute ethanol administration. Supported by DA 08073, DA 08227, The Yale VA Alcoholism Research Center, and the West Haven VA Center for the study of PTSD.

ETHANOL EFFECTS ON EXTRACELLULAR DOPAMINE IN NUCLEUS ACCUMBENS: COMPARISON BETWEEN FISCHER AND LEWIS RAT STRAINS. Z. Mocsary and C.W. Bradberry*, Yale Univ. Sch. of Med., Depts. of Psychiatry and Laboratory Medicine, and the West Haven Veterans Administration Hospital, West Haven, CT 06516.

Increasing attention has focused upon comparisons between strains of animals with differing propensities to consume alcohol and other drugs of abuse in order to gain insight into potential biochemical bases for drug abuse vulnerabilities. This includes the Fischer and Lewis rat strains, with the Lewis rats exhibiting greater ease of self-administration of ethanol, cocaine and opiates. The neurochemical basis of ethanol reward is unclear, without the same dependence upon intact dopamine (DA) innervation of the nucleus accumbens as is seen with psychostimulants. We have made a microdialysis comparison of the effects of ethanol upon both extracellular DA, and serotonin (accompanying poster) in awake animals of the Fischer and Lewis rat strains. In the nucleus accumbens, there was no significant increase in DA in either strain at 0.5 g/kg (i.p.). A 1.0 g/kg dose caused a significant increase only in the Fischer strain (180 % of baseline at 60 min post-ethanol), with a significant difference in response between the two strains (by two-way repeated measures ANOVA). The 2.0 g/kg dose caused a nearly significant increase in the Fischer strain, no significant increase in the Lewis, and no significant difference in responsiveness between the two strains. Basal extracellular DA levels were not different between the two strains. Our results are not consistent with an elevated mesoaccumbens DA response to ethanol as a basis for the enhanced preference of Lewis rats for ethanol. Supported by DA 08073, DA 08227, DA 04060, The Yale VA Alcoholism Research Center, and a NARSAD Young Investigator Award to CWB.

ALCOHOL SELF-ADMINISTRATION AND AGGRESSION IN RATS: DOPAMINE AND SEROTONIN IN N. ACCUMBENS. A.M.M. van Erp* and K.A. Miczek. Department of Psychology, Tufts University, Medford, MA 02155

Ethanol, when self-administered orally, enhances aggression in a subpopulation of resident rats confronting an intruder. These residents were characterized neurochemically, using *in vivo* microdialysis of dopamine and serotonin in the n. accumbens. Male Long-Evans rats, housed with a female, attacked a smaller male intruder in their home cage during 5 min tests. Rats which consistently attacked were trained to drink a 10% ethanol solution during 15 min access in their home cage, using a sucrose-fading technique. After ethanol intake stabilized, intruder tests were conducted 2/wk, starting 5 min after the ethanol session. Blood samples were taken directly after the fight from the orbital sinus, under isoflurane anesthesia. Under these conditions, rats drank up to 1.0 g/kg, resulting in BAC levels in a range of 10-80 mg/dl, but mostly 20-40 mg/dl. Aggressive behavior after ethanol self-administration was enhanced in some animals (n=5) and unchanged in others (n=3), similar to previously reported results from tests with experimenter-administered ethanol. In a second experiment changes in catecholamines in the nucleus accumbens were monitored during ethanol drinking and subsequent intruder tests. Ten min samples were taken during 60 min baseline, 10 min ethanol exposure, 10 min intruder test and 120 min recovery. During the intruder test the residents displayed circa 15 bites and threats, for a total duration of 140 seconds. Dopamine release was increased during ethanol self-administration and the subsequent intruder confrontation; no change or even a decrease in dopamine is observed during and after intruder confrontations without ethanol. Preliminary results suggest that serotonin levels follow a similar pattern. Individual differences in neurochemical measurements are evaluated in relation to ethanol's aggression enhancing effects.

COMPARISON OF THE EFFECTS OF INTRAPERITONEAL, INTRAGASTRIC, AND DIRECTLY PERFUSED ETHANOL ON EXTRACELLULAR DOPAMINE LEVELS IN NUCLEUS ACCUMBENS OF LEWIS RATS. J. Chen*, J. Li and E.L. Gardner, Departments of Psychiatry and Neuroscience, Albert Einstein College of Medicine, New York, NY 10461

Enhancement of synaptic activity in the nucleus accumbens (Acc) terminal projections of the mesolimbic dopamine (DA) system is one of the few neuropharmacological commonalities among drugs of abuse (Chen, *Sem Neurosci* 5:315-320, 1993), and drug action on this system is hypothesized to be an essential neurobiological substrate for addiction (Wise, *Pharmacol Biochem Behav* 13[suppl.1]:213-223, 1980; Wise & Bozarth, *Brain Res Bull* 12:203-208, 1984). However, ethanol's actions on these brain systems are less clear. Even the effect of different routes of ethanol administration on extracellular Acc DA levels remains unclear, as does interaction between route of administration and self-administration versus exogenous administration. We studied the effect of three routes of ethanol administration on behavior and Acc DA overflow (by *in vivo* brain microdialysis) in ethanol-preferring Lewis rats. Intraperitoneal (i.p.) ethanol injection (0.5, 1.0 g/kg) and intragastric ethanol gavage (0.5, 1.0, 2.5, 10.0 g/kg) produced significant motor effects (ataxia, etc.), but direct Acc ethanol perfusion (0.01, 0.1, 1.0, 5.0% v/v) did not. Acc ethanol perfusion and i.p. ethanol injection produced significant increases in Acc DA overflow, but intragastric ethanol gavage did not. Intragastric ethanol consumption may require volitional self-administration to activate Acc reward synapses (Moolten & Kornetsky, *Alcohol* 7:221-225, 1990). (Supported by NIAAA grant AA 09547, NIDA grant DA 03622, and the Aaron Diamond Foundation).

666.10

THE EFFECT OF REPEATED ADMINISTRATION OF ETHANOL ON THE RELEASE OF DOPAMINE IN THE NUCLEUS ACCUMBENS OF THE ALCOHOL-PREFERRING AA AND ALCOHOL-AVOIDING ANA RATS. K. Kiianmaa*, M. Nurmi[1], T. Ashizawa and J.D. Sinclair. Biomedical Research Center, Alko Group Ltd, and [1]Department of Biosciences, University of Helsinki, Helsinki, Finland.

The aim of the study was to investigate the effect of repeated administration of ethanol on the release of dopamine in the nucleus accumbens of the alcohol-preferring AA (Alko Alcohol) and alcohol-avoiding ANA (Alko Nonalcohol) rats with *in vivo* microdialysis. One group of AA rats self-administering ethanol (group AA-SA) was offered a two bottle choice between ethanol (10% v/v) and water. A yoked group of AA rats (group AA-IG) and another of ANA rats (group ANA-IG) received intragastrigally at 8:00, 13:00 and 17:00 daily the amount of ethanol (g/kg) drunk by their matched pair. After two weeks of continual access, the AA-SA group was switched to daily 30 min limited access to ethanol at 13:00, while the yoked groups were intubated once daily. After three weeks of limited access to ethanol the rats were implanted with a guide cannula for *in vivo* microdialysis, and the effect of a challenge dose (1 g/kg, IP) of ethanol on the release of dopamine in the nucleus accumbens was studied. Samples were collected from freely moving animals every 10 minutes, and concentrations of the monoamines and their metabolites were determined in the dialysate with small bore HPLC. Ethanol increased the release of dopamine in a similar manner in the AA-IG and the ANA-IG groups, while the effect of ethanol on the release of dopamine in the AA-SA group was significantly smaller than in the AA-IG group. The results show that there was no difference between the AA and ANA rat lines in the effect of prior intragastric ethanol treatment on the subsequent release of dopamine by ethanol. In contrast, prior self-administration of ethanol decreased the response to ethanol suggesting that the manner of exposure to ethanol can alter the neurochemical reaction.

666.11

TIME-DEPENDENT EFFECTS OF ACUTE ETHANOL ADMINISTRATION ON REGIONAL CEREBRAL BLOOD FLOW IN THE RAT. D. Lyons*, M.D. Miller, A.M. Crane, A.A. Hedgecock, S.L. Hart & L.J. Porrino. Dept. of Physiology & Pharmacology, Bowman Gray School of Medicine of Wake Forest University, Medical Center Blvd., Winston-Salem, NC 27157.

The present study tested the hypothesis that the effects of ethanol administration on brain activity depend upon the length of time following administration. A number of reports, for example, support the assertion that the rewarding effects of alcohol intake coincide with the ascending limb of the blood alcohol curve (BAC) and the depressant effects coincide with the descending limb. To understand better the neurobiology of ethanol intake, we evaluated the functional consequences of acute administration in awake rats at 5 and 15 minutes after treatment (1.0 g/kg ethanol or saline, ip), using the quantitative [^{14}C]iodoantipyrine method for measurement of regional cerebral blood flow. These time-points were chosen because, although the 5 min point is on the ascending limb and the 15 min point is on the descending limb of the BAC, the same blood ethanol levels exist at each point, thus reducing potential differences related to the bioavailability of ethanol. Findings indicate that blood flow increased at 5 min compared to controls in the olfactory tubercle, basolateral amygdala and motor cortex, and these values returned to baseline at the 15 min time-point. Blood flow was altered at 15 min, however, in the caudate, nucleus accumbens and hippocampus. Other brain regions were unaffected by treatment. These data are consistent with work from this laboratory measuring the effects of ethanol on cerebral metabolism and demonstrate that the pattern of brain activity is different on the ascending and descending limbs of the BAC despite similar blood levels of ethanol. *(Supported by NIAAA grant AA09291)*

666.12

A STRATEGY FOR ASSESSMENT OF THE CONTRIBUTION OF DOPAMINE TO THE CHANGES IN CEREBRAL METABOLISM FOLLOWING ETHANOL ADMINISTRATION L. Williams-Hemby* and L.J. Porrino. Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

The administration of methylphenidate (3.0 mg/kg/IV), an indirect dopaminergic agonist, altered rates of local cerebral glucose metabolism as measured by the 2-[^{14}C] deoxyglucose (2DG) method in structures of the mesocorticolimbic and nigrostriatal dopamine systems including the nucleus accumbens, olfactory tubercle, globus pallidus, entopeduncular nucleus, and subthalamic nucleus. Although these changes occur in regions that receive dopaminergic innervation, they cannot be directly attributed to increased dopaminergic activity because the 2-DG method is not specific to a given neurotransmitter system. In order to determine whether the increases in glucose metabolism in these structures are due to increases in dopaminergic activity, the non-specific dopamine antagonist flupenthixol was administered in conjunction with methylphenidate to block dopaminergic activity. The administration of flupenthixol (0.1 mg/kg/IP) 2.5 hours prior to the administration of methylphenidate blocked these regional alterations in cerebral metabolism. These data demonstrate the feasibility of this pharmacological approach for the identification of neurotransmitter-specific changes in functional activity. This strategy is also being used to examine the neurochemical nature of the increases in glucose metabolism in the mesocorticolimbic dopamine system observed following the oral administration of ethanol. Supported by grants AA09346 (LJP) and AA05400-01 (LWH).

666.13

DOPAMINERGIC DYSFUNCTION AS RESIDUAL MARKER OF ALCOHOLISM. A. Heinz*, S. Kuhn, T. Sander, H. Harms, L.G. Schmidt, H. Rommelspacher. Dept. of Psychiatry, Free University of Berlin, 14050, Germany.

Alcoholics with poor treatment outcome display reduced sensitivity of dopamine receptors before detoxification, compared to patients with good treatment outcome and healthy controls (Heinz et al., Alc. Clin. Exp. Res. 19, 62-65, 1995). Therefore, we tested the hypothesis that the sensitivity of central dopamine receptors (apomorphine-induced Growth Hormone (GH) release) corresponds to the allelic constitution of DNA-polymorphisms of the dopamine D1 (D1.7) and D2 (TaqA) receptor genes and allows to predict treatment outcome. Forty-seven alcohol-dependent patients were observed for six months after detoxification. Patients with poor treatment outcome displayed blunted GH response compared to subsequent abstainers. In these patients, a strong correlation between dopamine receptor sensitivity and the amount of chronic ethanol consumption was found. On the other hand, GH release and treatment outcome did not differ in patients carrying different alleles of the examined dopamine D1 and D2 receptor gene polymorphisms. We conclude that dopamine receptor dysfunction in alcoholics is a residual, not a trait marker of alcoholism.

INVOLVEMENT OF D_2 RECEPTORS IN THE SUPPRESSIVE EFFECT OF THE TRH ANALOG TA-0910 ON ALCOHOL INTAKE. Amir H. Rezvani*, J.C. Garbutt and G.A. Mason. Skipper Bowles Center for Alcohol Studies and Dept. of Psychiatry, UNC Sch. of Med., Chapel Hill, NC 27599.

Previously, we showed that the thyrotropin-releasing hormone analog TA-0910 dose-dependently reduces alcohol intake in alcohol preferring (P) rats. Further, we observed cross-tolerance between TA-0910 and bromocriptine in reducing alcohol intake, suggesting the involvement of dopaminergic systems. In the present study, experiments were conducted to determine the neuronal mechanisms underlying the attenuating effect of TA-0910 on alcohol intake. P rats were injected IP with vehicle or different doses of the selective D_2 antagonist S(-)-Eticlopride or the selective D_1 antagonist R(+)-SCH-23390 and 20 min. later with a dose of 0.75 mg/kg TA-0910 or vehicle. Alcohol and water intake were measured every two hr. up to six hr. and then at 24 hr. Food intake was measured at 24 hr. Neither S(-)-Eticlopride nor R(+)-SCH-23390 altered alcohol intake alone, however, S(-)-Eticlopride, but not R(+)-SCH-23390, dose-dependently diminished the suppressive effect of TA-0910 on alcohol intake in P rats. These data suggest involvement of D_2 receptors in the attenuating effect of TA-0910 on alcohol consumption (Supported in part by NIAAA Grant AA07809).

666.15

EFFECTS OF CHRONIC ALCOHOL CONSUMPTION AND AGING ON DOPAMINE, SEROTONIN AND METABOLITE LEVELS.

M.J. Druse-Manteuffel* and J. M. Woods. Mol. Cell. Biochemistry Dept., Loyola U Chicago, Stritch Sch. of Med., Maywood, IL 60153

The present study investigated the combined effects of chronic alcohol consumption and aging on the concentrations of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), serotonin (5-HT), and 5-hydroxyindoleacetic acid (5-HIAA). These monoamines and metabolites were quantitated in nigrostriatal and mesocorticolimbic brain areas of 5-, 14- and 24-month-old male Fischer 344 rats.

The results of these experiments demonstrated that there were both significant age- and alcohol-related changes in mesocorticolimbic brain areas. There was a significant age-associated decline of dopamine, and an alcohol-associated reduction of 5-HT and 5-HIAA in the ventral tegmental area. In contrast, there was an age-related increase of 5-HT in the ventral pallidum (VP) and of 5-HIAA in the frontal cortex, striatum, nucleus accumbens and VP. The ratio of 5-HIAA/5-HT was increased in aged rats in several brain areas. The noted dopaminergic and serotonergic abnormalities are of particular interest in light of the involvement of these neurotransmitter systems in alcohol use and abuse.

This research was supported by a grant from the USPHS - AA08451-04. J.M. Woods is the recipient of a USPHS fellowship - F31 AA05378.

666.16

STRAIN-DEPENDENT SUPPRESSANT EFFECTS OF DOPAMINERGIC, SEROTONERGIC AND OPIOIDERGIC AGENTS ON ALCOHOL INTAKE.

D.H. Overstreet*, A.H. Rezvani, and A.B. Kampov-Polevoy, Skipper Bowles Center for Alcohol Studies, UNC, Chapel Hill, NC 27599-7178.

Several strains of rats are known to consume large amounts of alcohol voluntarily, including the Fawn-Hooded (FH) rats and the selectively bred alcohol-preferring (P) and alcohol-accepting (AA) rats. Neurochemical differences have been reported for these strains, so it was predicted that they might respond differently to agents interacting with neurotransmitter systems known to modulate alcohol intake. Adult male FH, P, and AA rats were obtained from their respective breeding colonies in Chapel Hill, Indianapolis, and Helsinki and housed individually in wire mesh cages under standard laboratory conditions. The rats had free, continous access to food, water, and alcohol (10%, v/v). After establishment of stable baselines, rats were injected subcutaneously with either the dopamine agonist bromocriptine (5 mg/kg), the serotonin-1A agonist 8-OH-DPAT (0.125 mg/kg), the serotonin releaser fenfluramine (0.25-1.0 mg/kg), the opiate antagonist naltrexone (3-9 mg/kg), or vehicle at 4-day intervals. The P rats exhibited a significantly greater suppression of alcohol intake after bromocriptine, while the FH rats exhibited a significantly greater suppression after 8-OH-DPAT. In contrast, the AA rats were comparatively resistant to each compound. These findings indicate that alcohol-preferring rat strains are differentially sensitive to several drugs which suppress alcohol intake, making it unlikely that a single pharmacological treatment will be beneficial in all human alcoholics.

666.17

ETHANOL-INDUCED CHANGES IN ACTIVITY OF ALCOHOL-PREFERRING (P) & NONPREFERRING (NP) RATS: EFFECTS OF DOPAMINE (DA) AND 5-HT RECEPTOR ANTAGONISTS.

M.J. Lewis* T. Smith, J. Bryant, M. J. Cichelli and H.L. June. Neurobehavior Lab, Dept of Psych, Temple Univ. Phila. PA 19119/Howard University, Wash., D.C. 20059 & IUPUI, Ind., IN 46202

P rats, in comparison to NP and untrained randomly bred rats, orally self-administer ethanol (E) at high concentrations (>10%) and increase locomotor activity after parenteral and oral E. The present study examined the effects of intraperitoneal (IP) E on open field activity in both P and NP rats. Animals were injected with saline or E (0.25-1.0 gm/kg) and open field (Digiscan) activity was measured at 10 and 60 min. Animals then were injected with the DA antagonist haloperidol (0.1 - 0.5 mg/kg, ip), the 5-HT_3 antagonist MDL72222 (0.5 - 2.0 mg/kg ip), or saline prior to measurement of activity. NP rats showed lower activity at all E doses. P rats showed increased activity after low doses of E at 10 min. and depression at higher doses. Both pimozide and MDL72222 blocked the increase in activity in P rats. Both antagonists increased the depressant effects of E in both lines. These data support the putative role of dopamine and 5-HT_3 receptor mechanisms in E effects on activity.

666.18

INCREASES IN VOLUNTARY ALCOHOL CONSUMPTION IN RATS FOLLOWING A SINGLE LARGE DOSE OF DMI.

W. J. Shoemaker*, A.W. Deckel, V. Scranton & L. Arky, Dept of Psychiatry, Neuroscience Program & Alcohol Res. Ctr.,Univ. of Connecticut Health Center, Farmington, CT 06030

In the course of a series of studies to examine the relationship between lesions of the prefrontal cortex (PFC) in Wistar rats and voluntary alcohol consumption, we report the following phenomenon. Male Wistar rats were subjected to either bilateral aspiration lesions of the PFC, injections of 5,-7-Dihydroxy-tryptamine (5,7DHT) or sham lesions. The 5,7DHT treatment required pre-treatment with 25 mg/kg i.p. desmethyl-imipramine (DMI), a catecholamine uptake blocker that is commonly given to enhance the 5,7DHT exposure to serotonergic neurons The controls for the aspiration lesion group were not given DMI. All lesions and pre-treatments were given during deep anesthesia induced by 65 mg/kg i.p. pentobarbital. After the lesions, rats were placed on a 6-week, modified sucrose-fading procedure during which they were exposed to increasing concentrations of alcohol-containing solutions. At each concentration of sucrose (Suc) and ethanol (ETOH) including 10% Suc: 5%ETOH, 15% Suc: 5% ETOH, 3% Suc: 5% ETOH and 5% Suc: 10% ETOH the control rats that had received the DMI drank significantly more ethanol (in g/kg body weight) than the control group without DMI. The incresed drinking was not generalized since the DMI group drank less than the controls without DMI when a 20% sucrose alone solution was tested. The rats had food and tap water available at all times. An unusual aspect of the finding is that the increased consumption of ethanol solutions lasted throughout the length of the study. Following the final solution presentation, all animals were decapitated and the brains rapidly dissected. Brain regions are analyzed for norepinephrine, dopamine and serotonin and their metabolites to determine whether the single dose of DMI produced a measurable change in transmitter level. (supported by NIAA P50-AA3510)

666.19

ACUTE SUPPRESSION OF ETHANOL WITHDRAWAL SEIZURES AND CHRONIC ATTENUATION OF ETHANOL INTAKE BY AMPHETAMINE AND FENFLURAMINE COMBINATION.

L.Yu, H.Fisher, and G.C.Wagner*. Depts. of Psychology and Nutritional Sciences, Rutgers Univ., New Brunswick, NJ 08903.

Rats were rendered physically dependent on ethanol by semivoluntary consumption of a 4.5% ethanol-containing liquid diet. Approximately 60% of ethanol-dependent rats underwent audio-stimulation-induced seizures nine hours after ethanol was withdrawn. Rats exhibiting seizures had higher dopamine and lower serotonin levels in the striatum compared to rats not exhibiting seizures. Treatment with amphetamine (2 mg/kg) plus fenfluramine (8 mg/kg) in combination resulted in a significantly lower seizure rate (about 18%) in ethanol-withdrawn rats. The dependent rats treated with amphetamine plus fenfluramine and not exhibiting seizures had striatal dopamine and serotonin concentrations in parallel with control diet rats and dependent rats not exhibiting seizures. Thus, the amphetamine plus fenfluramine combination seemed to exert seizure-suppressing effects by decreasing striatal dopamine while increasing serotonin levels. Finally, this same treatment of amphetamine (2 mg/kg) plus fenfluramine (8 mg/kg), administered chronically, reduced consumption of a 5% ethanol solution while sparing the water intake during two-bottle choice tests in both ethanol-dependent and -nondependent rats. This drug combination may be beneficial for both the treatment of ethanol consumption and withdrawal.

ETHANOL/SUCROSE AND SUCROSE REINFORCEMENT IN MULTIPLE SCHEDULE COMPONENTS: EFFECTS OF AMPHETAMINE AND HALOPERIDOL.

C. Slawecki, C.W. Hodge and H.H. Samson*. The Neuroscience Program and the Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157-1083

It is of interest to examine whether ethanol-reinforcement involves the same neurobiological control mechanisms as are other reinforcers. A multiple schedule may provide advantages over concurrent schedules when exploring this question. Because multiple schedules limit responding to the duration of each component, the actions of various agonists and antagonists on behavior maintained by different reinforcers can be evaluated at similar times periods of drug action.

Six, male Long-Evans rats were trained to lever press during a 30 min daily session for a 5% sucrose/10% ethanol mixture presented in one 2 min component and 5% sucrose presented in the other 2 min component of a Multiple FR4 FR4 schedule. When responding was stable, dose effect curves were determined twice for amphetamine (0.0, 0.1, 0.3, 1.0 and 3.0 mg/kg) and then twice for haloperidol (0.0, 0.1, 0.25, 0.5 and 1.0 mg/kg). Responding in the sucrose/ethanol components was approximately 50% greater than during sucrose components. Amphetamine, at 1.0 mg/kg or greater reduced responding in both components, with a greater effect during the second determination. Haloperidol had an equal effect on responding in both schedule components, reducing responding at 0.3 mg/kg or greater. Tolerance to haloperidol was observed on the second determination of the dose effect curve. Dopaminergic processes appear to be involved for both reinforcers and tolerance to the antagonist resulted from multiple injections.

666.21

INVOLVEMENT OF CENTRAL BUT NOT PERIPHERAL NICOTINIC ACETYLCHOLINE RECEPTORS IN THE DOPAMINE ACTIVATING AND REINFORCING EFFECTS OF ETHANOL. Q. Blomqvist*, J.A. Engel and B. Söderpalm. Inst. of Physiology and Pharmacology, Dept. of Pharmacology, Göteborg University, Medicinaregatan 7, S-413 90 Göteborg, Sweden.

We have previously shown that mecamylamine (1.0 mg/kg i.p.), a blood brain barrier penetrating antagonist at the nicotinic acetylcholine receptor (nAChR), completely blocks ethanol-induced (2.5 g/kg i.p.) dopamine (DA) overflow in the nucleus accumbens in Wistar rats, as measured by *in vivo* microdialysis. Mecamylamine also decreased voluntary ethanol intake in high-preferring but not low-preferring rats, classified after a pre-experimental screening period in a free choice situation between an ethanol solution (6% v/v) and water. Hence, we hypothesized that ethanol's DA releasing effect, which may be of importance for its reinforcing effect, is mediated via activation of central nAChR, perhaps through a direct ethanol-nAChR interaction. Involvement of peripheral nAChR could, however, not be excluded.

In the present study, hexamethonium, a nAChR antagonist which does not penetrate the blood brain barrier was used in order to elucidate the possible involvement of peripheral nAChR in the previous findings. Hexamethonium-chloride was administered (10 mg/kg i.p.) 20 minutes prior to ethanol (2.5 g/kg i.p.), and DA overflow in the rat nucleus accumbens was measured by *in vivo* microdialysis. Although dialysis probe insertion might cause a discrete blood brain barrier defect resulting in hexamethonium diffusion into the brain, no antagonism of ethanol-induced DA overflow was observed. Furthermore, hexamethonium treatment did not alter ethanol drinking behavior in high-preferring or low-preferring rats. In conclusion, unless mecamylamine and hexamethonium display significant pharmacodynamic differences in addition to their pharmacokinetic differences, peripheral nAChR are not likely involved in the DA activating and reinforcing effects of ethanol.

PSYCHOTHERAPEUTIC DRUGS: ANTIPSYCHOTICS II

667.1

ANTIPSYCHOTIC DRUGS' MECHANISMS OF ACTION: INTERACTIONS AT THE NMDA RECEPTOR. T.J.Lidsky*, E.Yablonsky-Alter, L.Zuck, S.P. Banerjee. Inst. for Basic Research, Staten Island, New York 10314.

Glutamatergic dysfunctions have long been implicated in psychosis. Based on this consideration, the present study of antipsychotic drug interactions with the NMDA receptor was undertaken. In cortical tissue extensively washed to reduce residual levels of glutamate and glycine, [^{3}H]MK-801 binding is minimal. However, addition of either ligand at non-saturating concentrations increases ionophore opening resulting in a two- to threefold enhancement of [^{3}H]MK-801 binding and is thus commonly used as a functional assay of NMDA activity. Addition of either chlorpromazine, thioridazine, haloperidol or clozapine all further increased the already elevated [^{3}H]MK-801 binding caused by either glutamate and/or glycine. This effect was prominent at drug concentrations similar to that found in schizophrenic patients' plasma water or CSF when antipsychotic efficacy is achieved. At higher concentrations inhibition of NMDA activity was seen for all drugs. Augmentation at low and inhibition at higher concentrations was confirmed in electrophysiogical studies of glutamatergic transmission in the striatal slice preparation. These data, consistent with partial agonism, suggest that a unique action at glutamate synapses contributes to antipsychotic efficacy and further implicate glutamatergic dysfunction in the etiology of schizophrenia.

667.2

CHANGES IN STARTLE, EVOKED POTENTIALS, SPEM, SUSTAINED ATTENTION AND NEGATIVE SYMPTOMS FRAME A "THERAPEUTIC WINDOW" FOR NEUROLEPTICS K.A. Young*, M.D. Brady, C. Poche and P.B. Hicks. Department of Psychiatry and Behavioral Science, Texas A&M University Health Science Center, Scott & White Clinic and the Waco VAMC Neuroscience Laboratory, Waco, Texas 76711.

The influences of different doses of chronic neuroleptic medication on multiple information processing behaviors and on clinical symptoms were determined in long-term schizophrenic subjects with a cross-sectional design. A multidimensional information processing battery and standard CPT and WCST exams were administered in a one hour session. Inverted U-shaped neuroleptic dose-response curves were observed for startle prepulse inhibition deficit, N100/P200 evoked potential gating deficit and P200 evoked potential latency. U-shaped curves with minima corresponding to the peaks of the inverted curves were observed for negative symptoms and PANSS symptoms of anergia. Similarly shaped curves may also be present for the Continuous Performance Task, smooth pursuit eye movement and delta EEG activity. Dose-related changes in positive symptoms occurred only at low chronic neuroleptic doses. The dose-related correlation of low levels of negative symptoms and maximal changes in information processing suggestive of dopaminergic hyperactivity provides indirect evidence that moderate doses of neuroleptics may have an action to increase the availability of forebrain dopamine. The low dose suppression of positive symptoms, and the high dose reversal of moderate dose improvements in negative symptoms lends support to the concept that classical neuroleptics have a "therapeutic window" that is framed by positive symptom remediation at low doses and deterioration of negative symptoms and information processing behaviors at high doses.

667.3

CLOZAPINE INCREASES EXTRACELLULAR DOPAMINE IN THE RHESUS MONKEY PREFRONTAL CORTEX. K.D. Youngren*, F.M. Inglis, H.P. Jedema, P.J. Pivirotto, J. Bagley, C.W. Bradberry, B.S. Bunney, P.S. Goldman-Rakic, R.H. Roth and B. Moghaddam. Neuroscience Program, Depts. of Psychiatry and Pharmacology, and Sect. of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510, and VA Med. Center, West Haven, CT 06516.

The effects of clozapine and haloperidol on extracellular levels of dopamine were examined in cortical and subcortical regions of the rhesus monkey brain using intracerebral microdialysis. MRI-directed stereotaxic surgery was used to implant guide cannulae in three young adult male animals. Microdialysis probes were lowered into discrete brain regions through the guide cannulae while animals were under isoflurane gas anesthesia. Several dopamine-terminal-containing cortical regions were examined. These include: dorsolateral prefrontal cortex (Brodmann's area 46), medial prefrontal cortex (areas 8 and 9), and premotor cortex (area 6). Subcortical regions examined include the caudate and putamen. Basal extracellular levels of dopamine were reliably measured in all of these discrete brain regions. A stable baseline in extracellular dopamine was established for a minimum of one hour before drug administration. Clozapine (2 mg/kg i.v.) produced a significant increase in extracellular levels of dopamine in all brain regions examined, both cortical and subcortical. Haloperidol (0.2 mg/kg i.v.), in contrast, produced little or no change in extracellular dopamine levels in cortical regions or in the caudate. These results provide evidence in the non-human primate that acute administration of the atypical antipsychotic drug clozapine exerts a potent effect on cortical dopamine systems in comparison to the typical drug haloperidol. Supported in part by USPHS Award MH-44866.

667.4

MODIFICATION OF CLOZAPINE-ELICITED FOS EXPRESSION IN THE PREFRONTAL CORTEX AFTER BASOLATERAL AMYGDALA LESIONS. D. S. Cameron*, C. D. Young, and A. Y. Deutch. Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508 and the VA Medical Center, West Haven, CT 06516.

Administration to rats of the atypical antipsychotic drug clozapine results in a marked increase in the expression of the immediate-early gene c-*fos* or its protein product Fos in the medial prefrontal cortex (PFC). Administration of other antipsychotic drugs (APDs) does not induce Fos expression in the PFC. The mechanisms underlying the selective effect of clozapine on PFC Fos expression is not well understood, but D_2-like, D_1-like, 5-$HT_{2a/2c}$, α_1, and muscarinic cholinergic receptors do not appear to be critical factors. We attempted to determine if lesions of key afferents to the PFC modify the cortical Fos response to clozapine. Lesions of the thalamic paraventricular nucleus, which projects to the deep layers of the infralimbic and prelimbic cortices, did not modify the clozapine-elicited increase in PFC Fos expression, as assessed by immunoblots. However, lesions directed at the basolateral nucleus of the amygdala enhanced Fos expression in the PFC in response to clozapine challenge. The mechanisms subserving the modification of the cortical Fos response to clozapine are currently being examined. Supported in part by MH-45124, the VA Schizophrenia and Post-Traumatic Disorder Research Centers, and the National Parkinson Foundation Center of Excellence at Yale University.

667.5

DISCRIMINATIVE STIMULUS PROFILE OF CLOZAPINE, OLANZAPINE AND CHLORPROMAZINE IN MIANSERIN AND SCOPOLAMINE TRAINED RATS. B. M. Kelley, J. H. Porter* and S. A. Varvel. Dept. of Psychology, Virginia Commonwealth University, Richmond, VA 23184-2018.

The atypical antipsychotic clozapine (CLZ), the typical antipsychotic chlorpromazine (CPZ), and the putative atypical antipsychotic olanzapine (OLZ) were tested in rats trained to discriminate the serotonergic (5-HT) antagonist mianserin (MIA, 4.0 mg/kg) from saline and in rats trained to discriminate the muscarinic antagonist scopolamine (SCP, 0.25 mg/kg) from saline. CLZ produced full substitution in the MIA-trained rats with 87.5% drug-lever responding (DLR, 1.25 mg/kg dose) and partial substitution in the SCP-trained rats with 60.9% DLR (5.0 mg/kg dose). The 2.0 mg/kg dose of CPZ produced partial substitution in the MIA-trained rats (58.5% DLR), but did not substitute for SCP (18.9% DLR). OLZ produced a substitution profile intermediate between CLZ and CPZ. The 1.25 mg/kg dose of OLZ produced 66.8% DLR in the MIA-trained rats and 36.0% DLR in the SCP-trained rats.

The selective 5-$HT_{2A/2C}$ antagonist ritanserin produced complete substitution in the MIA-trained rats (98.4% DLR, 5.0 mg/kg dose) but did not substitute for SCP (25.0% DLR, 2.5 mg/kg dose). Interestingly, there was an asymmetrical cross-generalization between MIA and SCP. While MIA failed to produce SCP-appropriate responding,SCP produced 88.0% DLR in the MIA-trained rats. The present results demonstrated that the two-lever drug discrimination paradigm reveals different profiles for the atypical antipsychotic clozapine and the typical antipsychotic chlorpromazine in both MIA- and SCP-trained rats. The putative atypical drug olanzapine produced a discriminative stimulus profile intermediate between that of CLZ and CPZ. Testing with other typical and putative atypical antipsychotics will be necessary to establish the predictive validity of this behavioral screen for atypical antipsychotics.

667.6

THE INFLUENCE OF HALOPERIDOL ON THE PEAK VELOCITY OF HORIZONTAL AND VERTICAL SACCADES. B. Guldin , J. Heermann and W. Poewe (Spon: European Neuroscience Association). Virchow-Klinikum der Humboldt-Universität, Neurologie, 13353 Berlin, Germany.

Metoclopramide and haloperidol may cause oculogyric crises in susceptible patients. We were interested in their influence on horizontal and vertical saccades in order to determine the qualitative or quantitative nature of such crises.In a pilot study (open design) three healthy male volunteers (23-28 years old) received metoclo-pramide 10 mg tid. Eye movement registration with infrared oculography was done before the application of the test substance, seven hours, and 22 hours after the first dose (six hours past the third dose). In two of the subjects the horizontal and vertical saccades were all slower at the third measurement compared to baseline. In the second pilot study five healthy male volunteers received haloperidol 2 mg tid in a double-blind placebo-controlled design. The protocol of eye movement registration is described above. Four of the volunteers had slower saccadic peak velocities for horizontal and vertical saccades after the ingestion of haloperidol compared to placebo.
D2-antagonists probably decrease the peak velocity of saccades unspecifically through their sedating effects. Regarding the oculogyric crises our suggestion is that there is no specific path of action of d2-antagonists on vertical eye movements and that the tendency of some patients to develop oculogyric crises on these drugs is due to differences in density and proportion of receptor-subtypes.

667.7

ATYPICAL BEHAVIORAL EFFECTS OF CHRONIC CLOZAPINE TREATMENT IN THE RAT ARE NOT ELIMINATED BY SEROTONIN DEPLETION G.E. Jaskiw*, B. Yrtunski Psychiatry Service, Cleveland VAMC (541), Brecksville, OH 44141 and Dept of Psychiatry, Case Western Reserve University, Cleveland, OH 44106.

Rats withdrawn from chronic treatment with clozapine (CLOZ) (in contrast to haloperidol (HAL)) do not show an augmentation of higher order stereotypies (gnawing, biting) after apomorphine (APO) challenge. It has been postulated that some of CLOZ's atypical effects are mediated via serotonin (5HT) systems. To test the latter, 5HT depletion was achieved in rats by infusing 5,7-dihydroxytryptamine icv, after pretreatment with nomifensine and desipramine. After a 28d recovery period, groups of SHAM and 5HT depleted animals were assigned to a 21d course of treatment with VEH, HAL 1 mg/kg/d or CLOZ 20 mg/kg/d in drinking water. After a 3d withdrawal period, animals were challenged with APO 0.75 mg/kg SC and monitored for 90 min. Brain regions were assayed for monoamines. As anticipated HAL but not CLOZ pretreated animals showed an increase in biting behaviors and a reduction in time spent being stationary. Differences between HAL and CLOZ treated rats persisted despite a high and selective degree of 5HT depletion. Our data suggest that at least some of CLOZ's preferential actions on mesolimbic DA systems do not depend on an intact central 5HT system. Supported by VAMC grant.

REFLEX COMPONENTS IN WRIST ROTATION OF CLOZAPINE-TREATED SCHIZOPHRENICS. P.B. Vrtunski*, P.E. Konicki, G.E.Jaskiw, M.Simon and K.Y. Kwon. Cleveland VAMC and Department of Psychiatry, CWRU School of Medicine, Cleveland, OH 44141.

Several reports have suggested that the atypical antipsychotic drug clozapine (CLOZ) may have an adverse effect on various motor tasks including eye-movements, reaction time response or submaximal force maintenance. In all of these studies, tasks relied on voluntary movements and considerable attentional effort on the part of the subject. The intent of this study was to establish whether similar clozapine-induced deficits in motor control can be observed in outputs with minimized voluntary, and maximized unpredictable aspects of response. Ten chronic schizophrenics, tested before and after initiation of clozapine treatment, were compared to seven normal controls. The method included subject's holding a handle in vertical position and "matching" a target light with the handle-position light. At random intervals, supinating or pronating stimuli, 0.5 s long, of two different intensities, were applied to the handle. Handle movement was controlled by a torque motor and its position was read by an optical (5 pulses/degree) encoder. Resistance to handle movement was obtained from tracings during torque-stimuli (time-integral-of-force). Three findings were made: (a) Reflex response to handle movement readily discriminates normal subjects from those with schizophrenia (most likely due to medication induced rigidity). (b) Initiation of clozapine does not abolish the observed rigidity. (c) Clozapine attenuates resistance to torque-stimuli several-fold ($F(1,6) = 16.75$, $p < 0.01$). We conclude that reflex response to kinetic stimuli may provide important information regarding the motor mechanisms and antipsychotic medication. (Supported by the Veterans Administration and USPHS grant MH-46630)

667.9

CLOZAPINE AND FORCE CONTROL DECLINE AT TREATMENT INITIATION OF SCHIZOPHRENICS. P.E. Konicki*, G.E. Jaskiw, K.Y.Kwon, M.Simon and P.B. Vrtunski. Cleveland VAMC and Department of Psychiatry, CWRU School of Medicine, Cleveland, OH 44141.

In evaluating the effects of antipsychotic drugs on force control (FC) we recently demonstrated that clozapine (CLOZ) treatment is associated with a reduction in voluntary movement control; this effect did not appear to be related to pre-existing patient characteristics, but rather to clozapine treatment *per se* (Soc.Neurosci.Abstr., 20: 854, 1994; submitted). Since CLOZ treatment is usually initiated by a titration from 12.5 mg/d to about 450 mg/d over 3-4 weeks, we now present a study of the relationship between CLOZ dose and the decline in force control. The FC task consisted of 42 10-second long trials in which the patient was instructed to match a target light with a response light. The response consisted of patients' index-finger pressure on a force-sensitive button. There were 7 targets of increasing force (20 to 480 centiNewtons), each presented 6 times. The steadiness of force maintenance was the dependent variable. In seven cases studied so far, force control variability increased in all patients, from the pre-treatment mean of 2.51 (±0.53) to 3.10 (±0.69) reached at the mean daily dose of 410 mg/day. The paired t-test indicated the difference to be significant ($t = 3.40$, $p < 0.02$). The dose - response relationship, however, was not linear: in two patients the FC decline was a positively accelerated function of dose increase; in another patient a maximum FC decline was recorded at lower dose (150 mg/day), probably due to a strong sedative effect. We conclude that force control analysis may be useful both for establishing dose-response function of clozapine, and for more precise understanding of individual differences in response to this antipsychotic agent. (Supported by the Veterans Administration and USPHS grant MH-46630)

667.10

THE EFFECT OF CLOZAPINE ON FOS PROTEIN IMMUNOREACTIVITY IS NOT MIMICKED BY THE ADDITION OF α1-ADRENERGIC OR 5HT RECEPTOR BLOCKADE TO HALOPERIDOL. T. Specht Ludvigsen, Niels Korsgaard, Peter Kristensen* and A. Fink-Jensen. Health Care Discovery, Novo Nordisk A/S, Novo Nordisk Park, DK-2760 Måløv, Denmark

The involvement of α1-adrenergic or 5HT2-receptor blockade in the atypical profile of clozapine was investigated in the rat by use of Fos protein immunoreactivity, a technique, which has been used to identify the anatomical substrate underlying the effects of typical and atypical neuroleptics. Clozapine (20 mg/kg) induced a significantly higher Fos protein immunoreactivity response in the prefrontal cortex and significantly lower response in the dorsolateral striatum compared to the effect of haloperidol (1 mg/kg). Prazosin (0.3 and 1 mg/kg) and ritanserin (1 and 3 mg/kg) did not increase Fos protein immunoreactivity by themselves and did not mimic the clozapine response when co-administered with haloperidol (1mg/kg). Consequently, the present study does not suggest, that the α1-adrenergic receptor blockade or the 5HT2-receptor blockade exclusively accounts for the atypical profile of clozapine compared to haloperidol.

667.11

LOW-DOSE SLOWING OF RATS' LAPPING RHYTHM AS A POTENTIAL MARKER FOR ATYPICAL NEUROLEPTICS. S.C. Fowler* and S. Das. Dept. of Human Development, Univ. of Kansas, Lawrence, KS 66045.

The acute behavioral effects of the atypical neuroleptic clozapine (0.5-4.0 mg/kg), were compared with those of olanzapine (0.25-2.0 mg/kg) and risperidone (0.04-0.08 mg/kg). As thirsty rats (n=29) lapped water from a force-sensing disk, the force of tongue contact was continuously recorded and then Fourier analyzed to yield estimates of the lick rhythm (in Hertz). All three drugs significantly, and dose dependently reduced the lick rhythm, and the lowest dose of each drug had this effect even when the total number of licks per 2-min session was not significantly reduced. Neither the typical neuroleptic haloperidol nor the selective D2 dopamine receptor antagonist raclopride produced this slowing effect. The doses producing half the maximal effect on rhythm slowing for risperidone, olanzapine, and clozapine were 0.06, 0.55, and 1.16 mg/kg, respectively. The rank order of potencies suggested a serotonin-2 receptor involvement in the slowing of lick rhythm. Supported by MH43429.

667.12

ATYPICAL PROFILE OF THE ANTIPSYCHOTIC CANDIDATE BW1205U90 IN A PRIMATE SOCIAL COLONY MODEL FOR SCREENING ANTIPSYCHOTIC AGENTS. R.F. Schlemmer*, J.E. Young, C.K. Fleming, D.J. McGinness-Grimes, and J.M. Davis. University of Illinois at Chicago, Chicago, IL 60612.

BW1205U90, ((+/-)-cis-2-(4-(4-(1,2-benzisothiazol-3-yl)-1-piperazinyl)butyl)-4A,5,6,7,8,8A-hexahydro-1(2H)-phthalazinone HCl), has been identified as a potential atypical antipsychotic drug (AP) (Rigdon and Norman, Neurosci.Abs. 20:1639, 1994). It binds to 5-HT_2 sites with greater affinity than to D_2 and has appreciable affinity for the 5-HT_{1A} and α_1-NE sites. This study assessed the behavioral effects of BW1205 alone and with apomorphine (Apo) in a non-human primate screening model for AP. Four females from a colony of 5 stumptail macaques (Macaca arctoides) were assigned to 2 treatment groups of 2 females each. After determining baseline behavior, each group received drug treatment for 2 days/week in a cross-over design. First, Apo was given alone, 1 mg/kg, i.m. at 1045 for 2 days. Then, 5 escalating doses of BW1205, 0.1-3.0 mg/kg n.g. were given at 0800 and 1630 on Day 1 and at 0800 on Day 2. Two 1 hr observation sessions were conducted at 0930 and 1100 each day to observe the effects of BW1205 alone and with Apo respectively. On Day 2 of treatment BW1205 produced a dose-dependent antagonism of the Apo-induced increase in submissive gestures given by treated monkeys and checking (visual scanning). However, BW1205 failed to robustly antagonize Apo-induced stereotypy and produced only low levels of movement abnormalities at doses $\geq$ 1 mg/kg when given alone. Antagonism of increased submissiveness and checking is similar to known AP. The more than 10-fold separation between antagonist dose vs. movement disturbance threshold dose and weak antagonism of stereotypy is comparable to clozapine. Thus, the behavioral profile of BW1205 in primates is consistent with that of an atypical AP. (Funded by a gift from Burroughs-Wellcome, Research Triangle Park, NC).

667.13

DOPAMINE D3 RECEPTORS MEDIATE CLOZAPINE-INDUCED C-FOS EXPRESSION IN THE FOREBRAIN. N. Guo*, S.R. Vincent and H.C. Fibiger. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1Z3

The atypical antipsychotic clozapine produces a unique pattern of c-*fos* expression in the forebrain. While the receptor mechanisms by which this occurs are not well understood, there is some evidence to suggest that D2-like receptors may be involved. To determine if D3 receptors contribute to clozapine's effects on regional c-*fos* expression, in situ hybridization histochemistry with a cDNA oligonucleotide probe was used to identify cells that synthesize D3 receptor mRNA.

Consistent with previous studies, D3 receptor mRNA was enriched in the islands of Calleja (IC). In addition, a moderate density of D3 mRNA signal was observed in the lateral septum (LS). Fos-immunostaining combined with in situ hybridization histochemistry demonstrated that most clozapine-induced Fos-positive neurons in the IC express mRNA encoding D3 receptors, and that the majority of Fos-positive neurons in the LS and nucleus accumbens (NAc) contain D3 receptor mRNA. Further studies with oligonucleotide probes for enkephalin and dynorphin mRNA demonstrated that in the NAc and LS, some Fos-positive neurons express enkephalin mRNA and some contain dynorphin mRNA. In the IC, many Fos-positive neurons express dynorphin while very few express enkephalin mRNA.

A previous study has demonstrated that clozapine-induced c-*fos* expression in the NAc, IC and LS is blocked by D3 receptor agonists, suggesting that clozapine's effects in these regions are due to its antagonist actions at D3 receptors (Neurosci. 65, 3: 747). The co-localization of D3 receptor mRNA and Fos protein following clozapine administration in limbic brain neurons is consistent with this hypothesis.

667.14

MUSCARINIC m4 RECEPTOR AGONISM BY ATYPICAL BUT NOT TYPICAL ANTIPSYCHOTICS. X.P. Zeng , F. Le, I. Scarisbrick, and E. Richelson. Neuropharmacology Laboratory, Mayo Clinic Jacksonville, Jacksonville, FL 32224

The muscarinic m4 receptor agonist effects of clozapine as recently reported by Zorn et al., 1994, may be related to its therapeutic and side effects as an antipsychotic drug (Tandon & Kane, 1993). We have further examined the effect of a group of neuroleptics on forskolin-stimulated cyclic AMP accumulation in Chinese hamster ovary cells (CHO) expressing human m4 receptors to determine the possible relationship between m4 agonism and their pharmacological efficacy. Comparable to carbachol, at 1 μM, all the atypical neuroleptics tested - clozapine, olanzapine, fluperlapine, rilapine and tenilapine - caused a 20 to 50% inhibition of forskolin (500 μM)-stimulated increase of cAMP. These effects were totally reversed by pretreatment with 10 μM atropine. In contrast, a series of typical neuroleptics - chlopromazine, flupherazine, molindone and thiothixene - did not show the inhibition. In addition, none of the drugs tested caused a significant change in the basal concentration of cAMP. Therefore, m4 receptor agonism appears to be a common mechanism for atypical antipsychotic drugs, which may explain differences in the therapeutic efficacy and side effects between atypical and typical drugs. (Supported by Mayo Fdn. And USPHS Grant MH27692)

CLOZAPINE (CLOZ) PLUS SKF38393 STIMULATES THE ACTIVITY OF DOPAMINE (DA)-DEPLETED RATS. D. M. Jackson, N. Mohell, A. Bengtsson, C. Wallsten* and Å. Malmberg. Depts of Behavioural and Biochemical Pharmacology, and Molecular Pharmacology, Astra Arcus AB, Preclinical R & D, S-151 85, Södertälje, Sweden.

The aim of the present experiments was to investigate the locomotor stimulant effects of the atypical antipsychotic agent CLOZ in rats depleted of their DA by reserpine and α-methyl-p-tyrosine pretreatment. CLOZ itself induced a slight but non-significant activation which was enhanced by the addition of the selective D_1 agonist SKF38393 but not by the selective D_2 agonist quinpirole. The activation produced by CLOZ plus SKF38393 was partially blocked by the D_1 antagonist SCH23390, while the D_2 antagonist, haloperidol, was ineffective. A combination of SCH23390 and haloperidol completely blocked the CLOZ plus SKF38393 induced locomotion. Unlike the effect seen with CLOZ, neither the 5-HT_2 antagonist ritanserin nor the D_2 antagonists haloperidol and remoxipride caused locomotor activation when given alone or in combination with SK-F38393. d-Amphetamine was inactive in the monoamine depleted rats indicating that no DA was available for release by d-amphetamine. The muscarinic antagonist scopolamine was inactive, but produced marked stimulation when combined with SKF38393 but not with quinpirole. This stimulation was not affected by haloperidol, nor was it completely blocked by SCH23390 alone or by the combination of haloperidol and SCH23390. The data indicate that CLOZ, in rats depleted of their DA stores, exhibits properties like those of a DA agonist. The pharmacology of this behavioural stimulation was similar, but not identical, to that seen with the muscarinic antagonist scopolamine. The DA agonist like behavioural effects of CLOZ reported here may therefore be due in part to a muscarinic receptor antagonist like effect.

667.16

ANTAGONISM OF PCP-INDUCED DEFICITS IN PREPULSE INHIBITION BY OLANZAPINE. V.P. Bakshi* and M.A. Geyer. Dept. of Neuroscience, UCSD, La Jolla, CA 92093.

Presentation of a weak stimulus (the prepulse) immediately prior to an intense startling stimulus (the pulse) results in an attenuation of the startle response to the pulse. This phenomenon of prepulse inhibition (PPI) is thought to be a measure of sensorimotor gating mechanisms, which are deficient in schizophrenia patients. PPI is disrupted in schizophrenia patients and in rats, PPI is disrupted by the psychotogenic noncompetitive NMDA antagonists phencyclidine (PCP) and dizocilpine (MK-801). Reversal of PCP- and MK-801-induced deficits in PPI is produced by the atypical antipsychotic clozapine, but not by traditional neuroleptics. Olanzapine is a putative atypical antipsychotic that shares many pharmacological and pre-clinical behavioral characteristics with clozapine. The purpose of the present investigation was to determine if olanzapine would also reverse PCP- and MK-801-induced disruptions in PPI. Rats were treated with either 1.25, 2.5, 5.0 or 10.0 mg/kg of olanzapine (i.p.) or saline and then treated with PCP (0 or 1.5 mg/kg, s.c.). In a second study, separate groups of rats were given either saline or olanzapine (10.0 mg/kg, i.p.) followed by MK-801 (0 or 0.1 mg/kg, s.c.). After drug administration, animals were placed into startle chambers. PCP and MK-801 dramatically reduced PPI. Olanzapine by itself did not affect PPI, but did antagonize both the PCP- and MK-801-induced deficits. Effects on PPI were independent of changes in baseline startle amplitude. Finally, olanzapine accelerated habituation of the startle response to repeated tactile stimuli. These results provide further evidence for the functional homogeneity of olanzapine and clozapine. Studies to determine the mechanisms underlying these effects are in progress.

INTRA - ACCUMBENS CLOZAPINE AND HALOPERIDOL ENHANCE LATENT INHIBITION IN RATS. L.A. Dunn* and R.J. Scibilia. Department of Psychiatry, Duke University Medical Center, Durham, North Carolina 27710.

Latent inhibition (LI) is an indirect behavioral measure of selective attention that is sensitive to dopaminergic and serotonergic receptor modulation. Haloperidol enhances LI across a broad dose range. Clozapine enhances LI only at very low doses (0.1 and 0.3 mg/kg) and reduces LI at moderate (3.0 mg/kg) doses (Dunn and Scibilia, Soc. Neurosci. Abstr., 20:1, 226, 1994). The anatomic locus of these effects is being explored. Sprague-Dawley rats weighing 150-175 grams were fitted with bilateral chronically indwelling canulae located just above either the nucleus accumbens (coordinates from bregma: A=2.2 mm, L=±1.5 mm, V=-7.2 mm, head 5° above intraaural line), or the amygdala (coordinates from bregma: P=-0.3mm, L=±4.3 mm, V=-8.1mm, head 5° above intraaural line). Six days following surgery rats were started in a LI measurement procedure published previously (Dunn et al., 1993, Psychopharmacology, 112:315-323). This consisted of 4 days of lick training, 1 day of preexposure (20 or 0 light stimuli) and conditioning (2 light, shock pairings), and 1 day of testing. Haloperidol, 50 ng in 1 µl, or clozapine 1 µg in 1 µl was administered once 2 minutes prior to preexposure. Vehicle was 0.3% w/v tartaric acid pH adjusted to 6.8. Haloperidol enhanced LI in both the nucleus accumbens ($p<0.02$) and the amygdala ($p<0.025$). Clozapine enhanced LI in the nucleus accumbens ($p<0.05$), but reduced LI in the amygdala ($p<0.05$). The divergent effects of clozapine in these nuclei is likely due to a differential sensitivity to 5-HT2a/c antagonism. (Supported by NIMH #47503)

CONTRASTING EFFECTS OF CHRONIC CLOZAPINE, SEROQUEL AND HALOPERIDOL ADMINISTRATION ON ΔFosB EXPRESSION IN THE FOREBRAIN F. Ansari*[1], Y. Nakabeppu[2] and G.S. Robertson[1] Dept. of Pharmacology[1], University of Ottawa, Ottawa, Ontario, Canada, K1H 8M5. Dept. of Biochemistry[2], Medical Institute of Bioregulation, Kuyshu University 69, Fukuoka 812, Japan.

We have recently demonstrated that specific neuroanatomical patterns of increased Fos-like immunoreactivity (FLI) are predictive of atypical antipsychotic activity. However, the fact that neuroleptics must be administered chronically in order to generate both extrapyramidal side effects (EPS) and an optimal therapeutic response calls into question the relevance of acute changes in FLI for these slowly developing events. In resolution of this problem, we have discovered that the immediate-early gene product ΔFosB is expressed in neurons activated by chronic alterations in dopaminergic neurotransmission. Chronic administration of typical and atypical neuroleptics may therefore produce distinct patterns of ΔFosB expression that can be used to identify such compounds and their neuronal targets. To test this hypothesis, we compared the effects of chronic haloperidol, clozapine and seroquel administration on ΔFosB-like immunoreactivity (ΔFosB-LI) in the rodent forebrain. Administration of haloperidol (2 mg/kg/day) for 19 days dramatically elevated ΔFosB-LI in both the dorsolateral and ventral striatum. In contrast, administration of either clozapine (20 mg/kg/day) or seroquel (10, 20 mg/kg) for 19 days elevated ΔFosB-LI primarily in limbic regions such as the prefrontal cortex, ventral striatum and lateral septal nucleus. These patterns of chronically increased ΔFosB-LI are similar to those observed acutely for FLI suggesting that ΔFosB may be a relevant maker for neuronal populations activated by prolonged neuroleptic administration.

AGING: PRIMATES INCLUDING HUMANS

668.1

VARYING THE TRACE INTERVAL IN EYEBLINK CONDITIONING IN YOUNG AND AGING HUMANS. M.C. Carrillo*, C.T. Fitzpatrick & J.F. Disterhoft. CM Biology, Northwestern University Med. Sch, Chicago, IL.

Eyeblink conditioning has been used extensively to investigate the neural substrates of associative learning. Recent studies have found the effects of age and interstimulus interval in delay conditioning to change over life span (Solomon, et al., 1991). Other studies of trace conditioning have found nonoptimal interstimulus intervals (Woodruff-Pak et al., 1991). Our goal was to determine an optimal trace interval in the eyeblink conditioning paradigm for young and aging subjects, and subsequently test medial temporal lobe amnesics and Korsakoff amnesics with the optimal interval.

Younger (n=32, 20-38 yrs) and older (n=32, 60-75 yrs) humans were randomly assigned to one of four trace intervals: 250, 500, 750, and 1000 ms. Eyeblink conditioning involved the presentation of an 85 db, 100 ms, 3 kHz tone, followed after a silent trace interval by a 100 ms, 3–6 psi corneal airpuff sufficient to elicit reliable unconditioned responses. Sessions consisted of 30 pseudoconditioning trials (unpaired tone and puff presentations), 60 conditioning trials, and 30 tone-alone extinction trials. A correction method was used to eliminate responses that could contaminate data, including voluntary or alpha responses and random blinks.

No aging difference in mean percent conditioned responses was observed for the 250 ms ISI, Young=32.6%, Aging=32.1%. Significant aging differences were found for the remaining three intervals: 500 Young=55.8%, Aging=29.3; 750 Young=34.6%, Aging=16%; 1000 Young=21.8%, Aging=10.7 ($p<.05$). These data suggest that the trace eyeblink conditioning interval which resulted in the highest conditioning performance for young and aging humans was 500 ms. Having an optimal trace interval for young, as well as aging subjects is relevant when testing patient populations which vary in age. Currently, medial temporal lobe and Korsakoff amnesics are being tested using the 500 ms trace eyeblink conditioning paradigm. Supported by AG 08796 to JFD, GM 17223-01 to MCC, RR-00048 to CRC NMH.

A COMPARISON OF CLASSICAL EYEBLINK AND HEART RATE CONDITIONING IN YOUNG AND OLD HUMAN SUBJECTS AND THIER RELATIONSHIP TO OTHER COGNITIVE TASKS. Samantha Walker, Janet Hunt, S.L. Buchanan* & D.A. Powell. VA Medical Center and the University of South Carolina, Columbia, SC 29208.

Young (28-35 yrs.) and old (60-80 yrs.) human subjects received a single session of Pavlovian conditioning using a 500 msec tone as the conditioned stimulus and a 100 msec corneal airpuff as the unconditioned stimulus. Eyeblink and heart rate conditioned responses were recorded. A number of other cognitive tests were also administered to determine the relationship between Pavlovian conditioned EB and HR responses and other kinds of cognitive tasks. Age-related deficits in both EB and HR conditioning occurred. In addition, it was found that various aspects of EB conditioning were correlated with performance on several declarative but not nondeclarative tasks. Significant correlations were obtained, for example, between total EB CRs and performance on paired associate and verbal recall tests. Both HR and EB conditioning were also correlated with scores on the WAIS vocabulary subtest. These correlations may reflect a declarative component to classical conditioning that is at least partially responsible for the large age-related deficits in classical conditioning found in this and other experiments.

MRI DETECTED CEREBELLAR ATROPHY DURING AGING. Michael P. Sullivan, Leyla deToledo-Morrell, Frank Morrell*, and Sandra Spencer. Departments of Neurological Sciences, Psychology and Diagnostic Radiology, Rush Medical College, Chicago, IL. 60612.

Classical, delay conditioning of the eyeblink response has been shown to be impaired in aged individuals, thus implicating cerebellar dysfunction. With the use of high resolution, quantitative, magnetic resonance imaging (MRI) protocols, it is now possible to detect and quantify, *in vivo*, the extent of age or disease induced alterations in given brain regions of interest. In the present study, the presence of cerebellar atrophy was assessed in healthy, aged individuals as part of a larger investigation designed to examine the effects of aging on brain anatomy *in vivo*. 37 aged (mean age=70, range=61-84) and 27 young (mean age=27, range=22-34) subjects were studied with a high resolution MRI protocol. An interactive, 3-D reconstruction program was used to compute the volume of regions of interest. Cerebellar volume was derived from 18 gapless, 5mm sagittal slices, 9 on each side of the midline. To correct for individual differences in brain size, each person's absolute cerebellar volume was divided by total intracranial volume computed from sagittal slices spanning the whole brain. Cerebellar volume was found to be significantly reduced in aged subjects compared to young ones when either absolute or normalized values were considered ($t=5.414$, $df=62$, $p<0.001$ for absolute cerebellar volume and $t=4.044$, $df=62$, $p<0.001$ for normalized volume). There were no gender differences in the extent of cerebellar atrophy with age. Since cerebellar integrity is crucial for eyeblink conditioning, this age-dependent volume loss may explain the behavioral deficit.

668.4

GENDER DIFFERENCES IN THE VULNERABILITY OF THE HIPPOCAMPAL FORMATION DURING AGING. Leyla deToledo-Morrell*, M.P. Sullivan, F. Morrell, C. Spanovic and S. Spencer. Depts. of Neurological Sciences, Psychology and Diagnostic Radiology, Rush Medical College, Chicago, IL. 60612

The hippocampal formation (HF), which is critically involved in the acquisition of certain types of new information, is especially vulnerable to the aging process. Until recently, it has been difficult to directly document such vulnerability in humans and to relate anatomical alterations to behavioral deficits. With the advent of high resolution, quantitative, magnetic resonance imaging (MRI) protocols, it has been possible to visualize detailed brain anatomy *in vivo* and to quantify age or disease induced alterations in regions of interest. Using this technology, we now report that there are ***gender*** differences in age induced changes in hippocampal anatomy. 37 healthy, aged individuals (15 males and 22 females; mean age=70, range=61-84) and 27 young subjects 13 males and 14 females; mean age=27, range=22-34) were studied with a high resolution MRI protocol, as well as the verbal and spatial versions of the Buschke "Enhanced Cued Recall" test (Buschke & Grober, *Dev. Neuropsychol.*, 1986, 19:287-307). A 3-D reconstruction program was used to compute hippocampal volume from coronal slices taken perpendicular to the long axis of the hippocampus. Left and right hippocampal volumes were derived separately. Individual differences in brain size were corrected for by dividing each person's hippocampal volume by total intracranial volume computed from sagittal slices spanning the entire brain. The right HF, but nor the left, was significantly smaller in aged males compared to their young counterparts ($F=23.62$, $p<0.001$ for the age x hemisphere interaction). This difference did not hold for females. Furthermore, aged males had a deficit in spatial, but not verbal memory. Aged females did not show any memory deficits. The differential vulnerability of the right HF in aged males fits well with the nature of the behavioral results.

Supported by NIA grants PO1 AG9466 and P30 AG10161.

EFFECTS OF AGE ON EVENT-RELATED POTENTIALS EVOKED BY WORD REPETITION IN DIRECT AND INDIRECT MEMORY TESTS. R.E. Mark, M.D. Rugg*, R.C. Roberts and J. Gilchrist. Wellcome Brain Research Group, Sch. of Psychology, Univ. of St Andrews, UK, and Dept. of Medicine, Univ. of Dundee, UK.

Event-related potentials (ERPs) were recorded to visually presented words from 13 scalp sites in samples of young (age range 19-29) and elderly (range 62-74) subjects while they performed two tasks. In the indirect task, subjects monitored a series of words in order to detect and respond to target items (animal names), which occurred on 16% of trials. 19% of non-targets repeated after a single intervening item (lag 1 repeats), and 19% repeated after a mean lag of 10 trials (range 8-12). The same trial structure was employed in the direct task, but now subjects responded to every item, discriminating between words presented for the first and the second time.

Compared to ERPs elicited by unrepeated words, words repeated in the indirect task after either lag were significantly more positive-going in both groups of subjects. This ERP repetition effect was of comparable magnitude in the two groups, but onset approximately 50 msec earlier in the young subjects. The size of the effect did not differ significantly with lag in the young group, whereas the effect of lag was highly reliable in the elderly subjects, who showed smaller effects for lag 10 repeats. In the direct task, repeated words once again elicited a positive-going shift in the ERPs of the young subjects. In contrast to the indirect task, this effect was reliably smaller for the words repeated at the longer lag. In the elderly subjects, lag 1 repeats in the direct task elicited a significant effect, which was smaller than the lag 1 effect in the young subjects. Lag 10 repeats in the direct task failed to elicit a repetition effect in the elderly subjects.

The findings show that the effects of word repetition on ERPs reflect age-related differences in brain activity associated with memory for words. In keeping with previous behavioral work, these differences are more in evidence when memory is tested directly than when it is tested indirectly.

Aging-related deficit in implicit perceptuomotor learning.
E. C. McNay* & D. B. Willingham, Neuroscience Program, University of Virginia, Charlottesville, VA 22903.

A widely-held view of the basis of age-related deficits in learning and memory has been that deficits are caused by a reduction in the level of resources available for working memory, self-initiated processing, or as part of some other model. This has been offered as an explanation for the observed reduction in performance with aging on explicit tasks and spared performance on implicit tasks.

We investigated the effect on aging on both explicit and implicit measures of perceptuomotor learning. Subjects were tested using a task which required them to trace a line presented on a computer screen using a pen held out of their sight. Baseline measurements were taken, followed by two experimental phases. In the training phase, the feedback on the screen of the subjects' movements was transformed (a constant 90 degree rotation). Subjects were told that there was a transformation, but not of the identity of the transformation. After each block of training trials, both transformation and feedback were removed for a block of test trials in which subjects were asked to directly trace the line presented. The primary measures of performance were deviation from target line (training phase, explicit measure) and signed deviation from target line (test phase, implicit measure of space recalibration).

Contrary to expectations, aged subjects showed impaired performance (after correction for age-related changes in drawing ability) in both phases, with greater deviation from the target line in the training phase and lower recalibration of their perceptuomotor space in the test phase.

SPATIAL MEMORY AS MEASURED BY A HUMAN MAZE IN AGED SUBJECTS SHOWING VARIOUS PATTERNS OF CORTISOL SECRETION AND MEMORY FUNCTION.
S. Lupien, T. Ngô, C. Rainville, N.P.V. Nair*, R.L. Hauger, M.J. Meaney
Research Centre, Centre Hospitalier Côte-des-Neiges, 4565 Queen Mary, Montréal, Québec, Canada, H3W-1W5; Douglas Hospital Research Centre, McGill University, Montreal, Canada, 6875 Bld. Lasalle, Verdun, Québec, H4H-1R3;.

Studies have shown that hypersecretion of corticosteroids result in hippocampal dysfunction and spatial memory deficit in the aged rat. We have recently shown in a group of elderly subjects that those who present a significant increase of cortisol levels over a period of 3 to 6 years present an amnesic profile as revealed by a poor declarative memory performance while aged subjects showing a moderate increase or a decrease of cortisol levels with years perform normally on these tasks. We have tested spatial memory performance in this aged population using a human maze. Three types of encoding of spatial information were measured; a spatial encoding for which the subject was shown a path by following the experimentaor through the maze and was then required to do it on his/her own; a verbal encoding for which the subject was given verbal instructions to follow in order to find his/her way in the maze; a contextual encoding for which the subject had to create a cognitive map of the maze in order to perform the path. Correlational analyses were performed between the cortisol slope of subjects as measured over a period of 3 to 6 years and their performance on the three types of encoding. The results showed significant positive correlations between the cortisol slope and the time taken to do the path in the spatial (r=0.75) and verbal encoding (r=0.45) conditions, with no significant correlation between the cortisol slopes and the contextual encoding condition (r=0.08). Since this last encoding condition did not involve any memory processing while the spatial and verbal encoding did, these results suggest that the amnesic profile described in aged subjects showing a significant increase of cortisol levels with years applies to both spatial and non-spatial information. This further confirm the animal data literature which reports a significant relationship between prolonged exposure to corticosteroids in later life and spatial memory dysfunction.

668.8

A LONGITUDINAL STUDY OF DEHYDROEPIANDROSTERONE SULFATE (DHEA-S) LEVELS, CORTISOL LEVELS AND COGNITIVE FUNCTION IN ELDERLY HUMAN SUBJECTS. S. Sharma*, A. Turken, G. Schwartz, N.P.V. Nair, M. De Leon, M.J. Meaney, R.L. Hauger and S. Lupien.
Dpt Psychiatry, VA Medical Center, UCSD, 9500 Gilman Drive, La Jolla, Ca, 92093-0603&Douglas Hospital Research Centre, McGill University, Montreal, Canada, 6875 Bld. Lasalle, Verdun, Québec, H4H-1R3

It has been postulated that dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S) are markers of successful aging and life expectancy while cortisol levels may be discriminators of pathological brain aging. We have previously shown in a longitudinal study of elderly volunteers that the slope of the increase in cortisol secretion over years predicts the nature and the magnitude of the cognitive decline. We have retrospectively analyzed DHEA-S levels in this population of aged individuals for the years 1990-91, 1991-92 and 1992-93 in order to determine if DHEA-S secretion is negatively associated with cortisol hypersecretion and cognitive deficits. Subjects were retested in year 1992-93 for 24-hour cortisol secretion as well as memory function and we replicated the cortisol/memory impairment relationship previously reported. The results of the analysis of DHEA-S levels revealed decreasing DHEA-S levels in all subjects. Consistent with the hypothesis that DHEA-S may have a protective effect on the aging system, we have shown that subjects showing a significant increase in cortisol levels with years and memory impairment had the greatest decrease in DHEA-S levels. However, the reverse pattern was not observed in individuals showing decreasing cortisol levels and highly efficient cognitive function. These individuals consistently presented lower DHEA-S levels than the other subjects. Finally, although cortisol levels were significantly correlated with cognitive function, DHEA-S levels were not significantly correlated with cognitive efficiency. These results suggest that cortisol secretion during aging may be a better biological marker of cognitive decline than DHEA-S secretion.

668.9

DEMENTIA AND RESPONSE TO PAIN IN THE ELDERLY. F Porter, M Smith, JP Miller, J Morris*. Washington Univ School of Medicine, St Louis, MO 63110

To study relations among dementia, pain response and perception, heart rate and facial expression were continuously recorded during undisturbed BASEline (13±3min), PREParation (tourniquet/cleansing/needle visualized) (1±1min), VENIpuncture (2± .3min), and undisturbed RECovery (10±3min) from 44 (24 female) adults (mean age=73± 9 years) during a standard unanesthetized venipuncture. Clinical dementia ratings (0=normal, 3=severe dementia) were 14=0, 8=0.5, 12=1, 5=2, and 5=3. General anxiety and pain sensitivity were rated by subjects on 10-point visual analog scales prior to study; anticipatory and experienced anxiety and pain were rated just before or after VENI. Ratings were correlated with HR responses and dementia. HR increased from BASE to PREP and decreased from PREP to VENI (p's<.001), returning to BASE levels during VENI. A lower magnitude HR response to PREP and VENI was associated with dementia but not age or gender. Higher general pain sensitivity and higher anticipatory anxiety were positively correlated with the magnitude of HR response to VENI and negatively correlated with dementia but <40% of demented subjects were able to provide ratings. Demented subjects exhibited more facial movements to PREP (p=.06) and VENI (p=.02) than normals. More facial movements during BASE were associated with less HR increase to PREP. We conclude that the elderly exhibit a larger HR increase to stress(PREP) than pain (VENI) and that dementia may 1) decrease HR response to stress and pain; 2) minimize the magnitude of anxiety and pain ratings but self-report was limited among the demented; and 3) increase facial expression to pain. Thus, there is an apparent discordance among behavioral, physiologic and self-reported reactions to stress and pain among the demented. (NIA P50 AGO5681)

668.10

EFFECTS OF NORMAL AGING ON THE SPATIAL DISTRIBUTION OF VISUOSPATIAL ATTENTION IN VISUAL SEARCH. P.M. Greenwood*, R. Parasuraman & G.E. Alexander. Cognitive Science Lab., Catholic Univ., Washington, DC and Lab. of Neurosciences, NIA, Bethesda, MD.

Healthy elderly experience "pop-out" in visual search as readily as do young subjects when the target is easily discriminable from distracters. However, search for a poorly discriminable target, believed to require the movement of visuospatial attention from one display element to the other, proceeds more slowly in elderly compared to young subjects (Plude & Doussard-Roosevelt, 1989; Greenwood et al. 1992). Does this arise from a different spatial distribution of visuospatial attention in aging? Young subjects and two groups of elderly (aged 65-74 and 75-85) screened to exclude memory loss and dementia searched a display of 15 letters for a target defined by a conjunction of color and letter (a pink "R") and surrounded by 3,5,7 or 9 target color (pink) items, the remaining distracters being blue and green. In this type of search, subjects confine their attention to the target color items. Although RT slowed in all groups as the number of target color distracters increased, the increase was greatest in the two elderly groups. More eccentric target locations heightened the slowing of RT with increased numbers of target color distracters. This effect of eccentricity in slowing RT was greater in the elderly than in the young. However, when the target was centered in the display the young were unaffected by the number of target color distracters while the elderly were additionally slowed with each increase in target color distracters. These results suggest the spatial distribution of visuospatial attention is more diffuse in the elderly than in the young. A broader focus of visuospatial attention may contribute to age-related (1) slowing in search speed and (2) increased vulnerability of search to the presence of distracters.

668.11

SPATIAL LEARNING AND MEMORY IN FREELY MOVING MONKEYS. P.R. Rapp*1, M.T. Kansky, C.T. Stanko, and J.A. Roberts. 1Cntr. for Behavioral. Neurosci., SUNY Stony Brook, Stony Brook, NY 11794-2575, Behav. and Neurobiol. Unit, Calif. Regional Primate Res. Cntr., UC Davis, Davis, CA 95616-8542.

Tests of spatial learning and memory are among the most sensitive tasks for characterizing the effects of hippocampal dysfunction in the rat, and the present studies were intended to develop comparable procedures for monkeys. Six normal rhesus macaques (4-6 years) were tested on an octagonal platform maze (10 ft. diameter) that contained 8 hidden reward locations distributed evenly around the perimeter. A tether system confined animals to the surface of the maze, but exploration was otherwise unrestricted. Spatial working memory procedures required subjects to visit each reward location once per trial. With the exception of one monkey that failed to learn, acquisition was rapid, and subjects averaged 19.8 (±8.0) trials to achieve a criterion of 87.5% correct. Forgetting rates for spatial information were examined by imposing a delay between the 4 initial choices on each trial and the opportunity to make 4 additional choices. Accuracy declined by an average of only 12.8% (±4.3) across retention intervals ranging from 5 minutes to 4 hours, and performance remained significantly above chance at the longest delay ($p<0.005$). Rearranging the abundant extramaze cues during a 30 minute retention interval substantially impaired accuracy, implying that performance is supported by memory for the spatial relationships between these stimuli. Finally, ongoing studies of cognitive aging revealed significant learning deficits in at least a subgroup of aged rhesus monkeys. In combination, these findings are consistent with the expectation that tests of spatial learning and memory, adapted from research in rats, can provide valuable procedures for exploring hippocampal memory function in nonhuman primates. Supported by NIH grant AG10606, the CRPRC Base Grant RR00169, and a HFSPO award.

668.12

COGNITIVE CORRELATES OF TEMPORAL LOBE VOLUME AND CALLOSAL ATROPHY IN HEALTHY ELDERLY AND INCIPIENT DEMENTIA J.A. Kaye, J.S. Janowsky* and D. Howieson, Dept. of Neurology, Oregon Health Sciences Univ., VA Med. Ctr, Portland, OR. 97201

We examined the size of the corpus callosum (CC), temporal cortex, parahippocampal gyrus, and hippocampus using quantitative MRI in 26 healthy elderly (HE) "oldest-old" subjects (mean age 87). We examined the relationship between structure size and cognition. 12 of the subjects showed cognitive decline (e.g. CDR=.5-1) in the subsequent four years of follow up (Incipient Dementia, ID). Therefore, we examined structure size in HE and ID subjects when ID subjects were cognitively normal. The hippocampus was smaller in the ID subjects ($p< .05$). Temporal cortex correlated with CC size ($R=.44$, $p=.03$). The middle and posterior sectors of the CC were correlated with temporal cortex in the ID ($R's> .55$, $p's< .05$) but not the HE subjects. Significant relationships were found between memory and the hippocampal volume, and midsector of the CC over all subjects ($R's> .45$, $p's< .03$). These data suggest that atrophy precedes clinical signs of dementia. We are currently examining MRI and cognitive assessment data during subsequent years of cognitive decline in these subjects. SHIFTING ATTENTION BETWEEN SENSORY MODALITIES IN HEALTHY AGING. A. Berardi*, J.V. Haxby, Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

Age-related changes in attention shifting were investigated by measuring reaction times to visual and auditory stimuli in three task conditions: a visual baseline task in which visual stimuli (rectangles) were presented to the right or left of fixation, an auditory baseline task in which auditory stimuli (tones) were presented to the right or left ear, and a shifting task in which visual and auditory stimuli were presented on alternating trials. Twenty-one young (mean age ± SD = 29.5 ± 5; range: 20-39), 20 middle-aged (mean age ± SD = 51.2 ± 6.6; range: 40-59), and 20 old subjects (mean age ± SD = 67.1 ± 4.4; range: 60-73), matched on sex and education, participated in this study. All subjects were right-handed and screened for optimal health. Reaction times were slower on the shifting task than on the baseline tasks for both auditory and visual stimuli ($p < 0.0005$, in both cases). Significant condition X group interactions revealed that slowing due to shifting was greater for both middle-aged and older subjects as compared to young subjects ($p < 0.05$, for both visual and auditory interactions). Whereas young subjects slowed 4 and 34 msec on the shifting task for visual and auditory stimuli, respectively, middle aged subjects slowed 87 and 46 msec and old subjects slowed 114 and 58 msec relative to baseline ($p < 0.05$ for all comparisons between young subjects and other groups). When reaction times on the shifting task were expressed as percent increases relative to the baseline tasks, the main group effects remained significant, indicating that age-related slowing on the shifting task was greater than would be predicted by generalized slowing. These results demonstrate that age-related inefficiency in shifting attention between sensory modalities is evident in middle aged as well as in old subjects and is not attributable to generalized slowing.

SEX AND HANDEDNESS DIFFERENCES IN CHANGE OF SIZE OF THE CORPUS CALLOSUM DURING NORMAL AGING. A. Unsal, S.F. Witelson, D.L. Kigar, M. Steiner*, Dept. of Psychiatry, McMaster Univ., Hamilton, ON, L8N 3Z5.

Advancing age is associated with a small decline in brain size. We previously reported that midsagittal area of the corpus callosum (CC) decreases sharply with age, but in men only (Witelson, NEJM, 1991). The aim of the present study was to assess, in a larger group of postmortem brain specimens from subjects varying in age from 25 to 70 yr, what the quantitative model may be between CC size, age and hand preference in men and women. A sample of 46 women and 32 men were studied, all documented to be of normal neurologic and cognitive status. Mean CC areas for men and women were 688 and 662 mm^2, respectively. For men, CC area is greater in non consistent-right-handed (nonCRH) than CRH men (725 mm^2 vs 656 mm^2, $p = .02$). For each group of men, there was a negative relationship with age [nonCRH ($r = -0.69$, $p < .01$) and CRH ($r = -0.46$, $p = .05$)]. The slopes of the regresssion lines differed significantly, indicating that the decline in CC area per year is greater in nonCRH than CRH men (R^2 change, $p < .05$). For women, no relationship was observed ($r = 0.02$): this was true whether linear or quadratic models were considered. The best predictor of CC area in women was the group mean. By age 70, all three groups approached a similar CC size, a point of callosal equality. The results suggest that CC size may have theoretical implications as well as diagnostic utility (using in vivo imaging) for cortical changes that occur with normal aging; that some sex hormonal factors influence brain aging; and in men, hemispheric lateralization affects brain change with age. Funded in part by grants NS18954 and MRC (CA) MA-10610.

THE EFFECTS OF ODORANT AND NUMBER OF TRIALS ON THE OLFACTORY EVENT-RELATED POTENTIAL IN YOUNG AND OLDER ADULTS. C.D. Morgan, J.W. Covington, C. Quiñonez, D. Ellison, D. Wester, D.L. Kalinoski*, J. Polich, C. Murphy(UCSD Medical Center, Naval Medical Center, The Scripps Research Institute, San Diego State University, San Diego, CA 92120, Monell Chemical Senses Center, Phila. PA 19104)

Olfactory event-related potentials (OERP) are currently used to differentiate groups of individuals based on peak amplitude and latency and show considerable promise as a diagnostic tool in clinical settings. In an effort toward determining clinical utility in an individual participant, the present study was designed to find the optimal parameters for recording the most robust OERPs in both young and older adults. Using three different stimulus odors (amyl acetate, geraniol, phenylethyl alcohol) the clearest and most consistent OERP waveforms were produced by amyl acetate. The average of 20 stimulus trials recorded from each participant produced a robust waveform, however, a distinct wave is also present in the average of as few as 10 trials; fewer trials result in shorter administration time, a factor which is desirable in clinical settings. Furthermore, peak amplitudes and peak latencies were found to differentiate young and older adults such that the amplitudes were smaller and latencies were longer for the older participants, indicating that age is an important factor in OERP responses. These findings will help guide future research and clinical application in olfactory assessment.

PRE-MOVEMENT AND AUDITORY EVENT-RELATED POTENTIALS IN HEALTHY AGED SUBJECTS. M. Roe*, W. J. Evans, H. J. Michalewski and A. Starr. Departments of Psychobiology and Neurology, University of California, Irvine, CA 92717.

Pre- and post-stimulus event-related potentials were studied to examine the effects of "normal" human aging. A healthy "Old" group (mean = 80 yrs.) and "Young" group (mean = 38 yrs.) of subjects were tested. The "Old" group did not show the usual memory changes associated with age, suggesting that these subjects represent a healthy, normal aged population. Brain potentials were recorded at scalp sites Fz, Cz, Pz, C3', and C4' during an auditory target detection task and during self-paced movements. To targets, measures of accuracy, reaction time (RT), a pre-stimulus negative potential (readiness potential [RP]) and post-stimulus event-related potentials (P50, N100, P200, N200, P300) were analyzed. To self-paced movements, the average amplitude of a self-initiated RP was analyzed. No significant differences were found for accuracy or RTs between the two age groups. No significant differences for age group were found for the self-initiated RP. In contrast, pre-stimulus RP amplitudes decreased significantly with age. The post-stimulus P300 latency was significantly delayed (80 msec) and P300 amplitude was reduced (50%) for the "Old" group as compared to the "Young" group. In spite of normal performance measures, the "Old" group showed age-related changes in both latency and amplitude of several event-related components, indicating a dissociation of behavioral performance and cerebral processing of auditory signals with aging.

CORTICAL SYNAPTOGENESIS IN HEMIMEGALENCEPHALY. J.R. O'Kusky[1]* and H.V. Vinters[2]. Dept. of Pathology and Laboratory Medicine, [1]University of British Columbia, Vancouver, B.C., Canada V5Z 1M9 and [2]UCLA Medical Center, Los Angeles, CA 90024.

Histological specimens for electron microscopy were prepared from cortical resections, performed for the treatment of intractable childhood epilepsy, in 4 cases of hemimegalencephaly (HME) and 4 control cases (Rasmussen's encephalitis) ranging in age from 1 to 7 years. Stereological analyses were used to determine postnatal changes in the numerical density (N_V, contacts per mm^3) of asymmetric and symmetric synapses in the cerebral cortex. Samples included frontal, parietal and temporal cortices. In control cases the N_V of asymmetric synapses decreased after 1 year of age due to a loss of axospinous contacts with no change in the density of axodendritic or axosomatic contacts. The N_V of symmetric synapses increased gradually up to 7 years of age. In HME cases the N_V of asymmetric and symmetric synapses did not differ significantly from controls. Given the increased cortical thickness in HME, the number of synapses in a column of cerebral cortex beneath 1 mm^2 of pial surface was substantially greater than in controls. (Supported by the B.C. Health Research Foundation)

SACCADIC VARIABLES IN ADULTS WITH CEREBRAL PALSY. M.LeGare*, S.Gu, H.Zhang and S.Lee. Biomedical Engineering Program, California State University, Sacramento, CA 95819-6019.

Aimed movements require visual localization. The slow and inaccurate aimed movements in cerebral palsy (CP) may be partly due to the saccadic system which provides visuomotor support for localization. The right and left eye positions of 6 CP and 4 normal (N) adults were measured by the 7000S (Micromeasurements, Inc., Farmington, CT). Square-wave stimuli at three frequencies (0.3,0.5,0.7Hz), three amplitudes (±4,±6,±8°), horizontal and vertical dimensions were used for 18, 10s tests in a J-saccade paradigm. The right and left eye positions were pooled for this analysis of five saccadic variables. The CP group had greater than normal means for: saccadic latency (M_{CP}=0.367±0.207s; M_N=0.268±0.088s), RMS error (M_{CP}=3.588±2.693°; M_N=0.268±0.088), and fixation (M_{CP}=0.299±0.09s; M_N=0.266±0.053s). The CP group made more low velocity saccades than the N group but the acceleration profiles were comparable indicating similar organization. Therefore, the system should also exhibit motor learning. Such training may improve aimed movement in CP. Supported by: NSF-BCS9107276, CSUS-RA to ML.

DUPLICATION OF THE EYE AND CEREBRAL HEMISPHERE IN A HUMAN. T. A. Woolsey*, E. J. Stelnicki, J. L. Marsh, B.C.P. Lee, and M. J. Noetzel. Divisions of Experimental Neurology & Neurological Surgery, Plastic & Reconstructive Surgery, Neuroradiology, and Pediatric Neurology, Washington University School of Medicine, St. Louis, MO 63110.

We describe a unique case of complex craniofacial and CNS anomalies. The focus here is on aspects that relate to the nervous system. The child's skull was asymmetric (plagiocephalic) with the axis displaced to the right. However, her most overt and distinguishing feature was that the left orbit contained two eyes while the right orbit contained one normal appearing and functioning eye. Accordingly the anomaly was termed TRIOPIA. Computer assisted medical imaging was used to define intra- and extracranial structures *in vivo*. There were two left cerebral hemispheres: the anterior was gyrencephalic; the posterior lissencephalic. Other abnormalities included duplication of extraocular muscles excepting the lateral lateral rectus on the left; two left ophthalmic arteries; two left middle cerebral arteries; agenesis of the corpus callosum; duplication of the falx cerebri, sagittal dural venous sinuses and confluens of sinuses. The circle of Willis was incomplete. The brain stem was nearly symmetrical with slight reduction in the left cerebellar hemisphere and an attenuated left medullary pyramid. We propose that the embryological basis for this unprecedented anomaly was duplication, in the neural plate, of primordia for the eye and secondary prosencephalon.

Murine Platelet Activating Factor Acetylhydrolase: Expression Pattern and Enzymatic Activity in the Developing Brain Correlate with the Timing of Neuronal Migration

U. Albrecht, R. Abu-Issa, L. Colquhoun*, K. Inoue* and G. Eichele. Dept. of Biochemistry and *Div. of Neuroscience, Baylor College of Medicine, Houston TX 77030, USA, *Faculty of Pharmaceutical Sciences, University of Tokyo, Tokyo Japan.

Miller-Dieker lissencephaly, a human brain malformation associated with a hemizygous deletion in the *LIS 1* gene, is a defect in cell migration leading to an abnormal cerebral cortex. Bovine platelet-activating factor acetylhydrolase (PAF-AH) has been purified previously. PAF-AH deacylates and thereby inactivates platelet activating factor, an alkyl-ether phospholipid implicated in various aspects of neuronal development and in neuronal function. Purification studies suggest that PAF-AH consists of three subunits (29kD, 30kD and 45kD) and the 45kD subunit is identical with the coding sequence of the *LIS 1* gene. In order to study the spatial and temporal expression of the PAF-AH subunits, we cloned the cDNAs for the mouse 29kD and 30kD subunits. Both subunits are highly conserved between mouse, bovine and human. We find that the mRNAs encoding the the 29kD, 30kD and 45kD subunits are coexpressed in the cerebral cortex and in the hippocampus. Coexpression is also observed in the migrating granule cells of the developing cerebellum. PAF-AH activity measurements in cytosolic extracts show that in the cerebellum activity is highest between postnatal day 5 and 16, the time-span of granule cell migration. Correlation between elevated enzymatic activity and high levels of expression in the developing cerebellum substantiate the notion that 29kD, 30kD and 45kD subunits are associated in vivo.

SPECIFIC CORRECTION OF "ANTI-BRAIN" AUTOIMMUNITY. E.F.Bakunenko, B.B.Gnedenko, A.B.Poletaev*. Chernobyl-Test Ctr., 10 Rimskogo-Korsakova St., 127577 Moscow, Russia.

As it was found earlier, most of children, which have been born from mothers with elevated serum anti-S100 immunoreactivity, have revealed a different forms of the brain malfunctioning (mental retardations, cerebral palsy, seizure syndroms). Ability to abnormal production of anti-S100 antibodies (AB) has epygenetically transferred from mother (not from father) to offsprings and could be related to aggravation of the brain dysfunctions. It was found that maternal "tunning" of the offspring immune system based on a combination of AB-dependent modulation of specific lymphocyte repertoires, and direct transfer, and persistention of maternal "memory" lymphocytes into fetus. In experiments (rats were preliminary immunized to S100) it was found that parenteral administration of antiidiotypic AB could inhibit specific serum' anti-S100 reactivity. Also there were found two immunomodulatoric S100 fragments. The first one had at least equal efficient compared with antiidiotypic AB (selective stimulator of specific T-suppressors?). The second one significantly increased anti-S100 immunity (probably due to stimulation of a specific T-helpers). These findings may explain some aspects of pathologic anti-S100 autoimmunity as well as to be used for elaboration of a prophilactic measures.

INDUCED MICROGYRIA AND ITS EFFECTS ON CELL SIZE, CELL NUMBER, AND CELL PACKING DENSITY IN THE MEDIAL GENICULATE NUCLEUS. A.E. Herman, R.H. Fitch, A.M.Galaburda*, and G.D. Rosen. Beth Israel Hospital and Harvard Medical School, Boston, MA 02215 and CMBN, Rutgers Univ., Newark, NJ 07102.

Microgyria can be induced in otherwise normal rat neocortex by neonatal freezing injury (Humphreys et al., *J. Neuropath. Exp. Neurol.* **50**:145,1991). Adult animals with microgyria located in frontal and somatosensory cortices show deficits in fast auditory temporal processing (Fitch et al., *Cereb. Cortex* **4**:260,1994). It is not understood why damage to cortical areas far from auditory input would disrupt auditory discrimination. We have hypothesized that the developmental cortical injury results in changes in connectionally related areas, and that some of these changes involve areas important for auditory processing.

To test this hypothesis we measured cross sectional cell areas, cell packing densities, and total cell numbers in the medial geniculate nuclei (MGN) of rats who had received neonatal cortical freezing or sham injury and who had been behaviorally tested for auditory temporal processing in adulthood. Measures of cross-sectional neuronal area and cell packing density of ventral, dorsal, and medial regions of the MGN were derived using a variation of the dissector method (Williams and Rakic, *J. Comp. Neurol.* **278**:344,1988), and MGN volumes were computed based on estimates from serial sections.

Preliminary analysis has shown changes in the patterns of asymmetry in cell size between microgyric and control rats — control rats have larger neurons in the left hemisphere while microgyric animals show no asymmetry. Continued analysis will concentrate on gender differences, differences based on lesion location, and the relationship of the anatomic measures to auditory temporal processing

NEOCORTICAL DYSPLASIA, MICROGYRIA, AND PORENCEPHALY: COMMON ETIOLOGIES? G.D. Rosen* and A.M. Galaburda. Beth Israel Hospital and Harvard Medical School, Boston, MA 02215.

Injury to the developing cortical plate before the end of neuronal migration is generally believed to be the underlying cause of neocortical migration disorders such as molecular layer ectopias, microgyria, and porencephaly (Sarnat, *Amer. J. Dis. Children* **141**: 969,1987). It has been hypothesized that these different forms of developmental pathology result from distinct mechanisms of injury. Alternatively, they may result from a single mechanism, but only the severity of the injury varies among them.

Molecular layer ectopias and microgyria have been induced in otherwise normal neocortex by focal damage to the developing cortical plate in rats (Rosen et al., *Dev. Brain Res.* **67**:285,1992; Humphreys et al., *J. Neuropath. Exp. Neurol.* **50**:145. 1991). In the present experiment, we placed a freezing probe on one side of the skull during the first day of life (P1) for durations ranging from 2 to 20 seconds. In some rats, the procedure was repeated a second time at a location adjacent to the first. The animals were sacrificed on either P2, P4, P7, P10, P21, or P60 and brains examined with standard and immunohistochemical stains for the presence of neuropathology.

Single injury 5 seconds or longer resulted in the formation of microgyria, with the depth of the microsulcus and the volume of the lesion increasing with longer freezing times. Two-second freezing injury rarely resulted in microgyria, and instead most often led to molecular layer ectopias and/or minor laminar dysplasia. As expected, injury at two adjacent sites led to more severe disturbances than single injury, culminating in the formation of porencephalic cysts following 20 second injury. These findings indicate that a common mechanism can underlie the formation of molecular layer ectopias, microgyria, and porencephaly.

NEURONAL AREA IS INCREASED IN THE VENTROBASAL COMPLEX IN AUTOIMMUNE NZB MICE WITH CORTICAL ECTOPIAS G. F. Sherman*, L.V. Stone, and A.M. Galaburda. Dyslexia Research Laboratory, Beth Israel Hospital; Harvard Medical School, Boston, MA 02215.

Neuronal cell size differs in both the LGN and MGN of dyslexics in comparison to controls (Livingstone et al., PNAS 88:7943,1991; Galaburda et al., PNAS 91:8010,1994). Neurons of the magnocellular division of the LGN and of the left MGN are smaller in area. These differences may play a role in the perceptual deficits seen in dyslexia and may be the result of changes in cortical targets produced by the presence of the neocortical ectopias in layer I seen in dyslexia (Galaburda et al., PNAS 91:8010,1994). Because thalamic cell size has been measured only in dyslexics with neocortical ectopias it was not possible to directly test this relationship. We used an animal model, the New Zealand Black mouse (NZB/BINJ), that develops similar malformations in about 40% of the cases to test the relationship of molecular ectopias to neuronal size in related thalamic nuclei. Because most ectopias in NZB mice occur in the somatosensory barrel field we measured neuronal size in the ventrobasal complex nuclei VPM and VPL.

Mice were transcardially perfused with 0.9% saline followed by 10% formalin. The brains were embedded in celloidin, cut in 30 µm coronal sections, stained with cresyl violet, and mounted. Neuronal cell size was measured blind in the right and left VPL and VPM in 8 adult NZB mice with barrel field ectopias and 11 adult NZB mice without ectopias. Two sections (150 µm apart) per brain which contained VPM and VPL were selected. Cross-sectional neuronal areas in one field per section for each nucleus on both sides were measured using a stereology-derived system (Williams and Rakic, J. Comp. Neurol. 278:344,1988). The counting grid was 85 µm high, 95 µm wide and 25 µm deep. Neurons were grouped according to area into bins and X^2 values were calculated. The distribution of neuronal size differed between mice with and without ectopias for both VPL ($p< 0.001$) and VPM ($p< 0.001$). In both nuclei there were fewer small neurons and more large neurons in mice with ectopias. We suggest that the prenatal generation of molecular layer ectopias in somatosensory cortex subsequently affects the organization of related thalamic nuclei. Supported by NIH grant HD 20806.

CONNECTIVITY OF CORTICAL ECTOPIAS IN AUTOIMMUNE MICE. A. R. Jenner*, A. M. Galaburda, and G. F. Sherman. Dyslexia Research Laboratory, Beth Israel Hospital and Harvard Medical School, Boston, MA 02215.

New Zealand Black mice (NZB/BINJ) and NXSM-D/Ei mice develop minor neocortical anomalies and are used as a model for the similar pathology present in the brains of dyslexics. Approximately 40% of the NZB and 80% of NXSM-D mice prenatally develop clusters of ectopic neurons in cortical layer I. Neurofilament staining of these ectopias provided preliminary evidence that the connections of these cells were aberrant. The present study was designed to look more specifically at the cortical and subcortical connections the ectopias.

Adult mice were perfused with 2% paraformaldehyde/0.1% glutaraldehyde and the brains removed from the skull. The brains were stained with methyl-green in order to visualize the surface of the brain more clearly and viewed under the dissecting microscope for ectopias. Large ectopias appear as small bumps on the surface of the brain. Ectopias were visualized in seven brains. A small crystal of DiI which labels cell membranes by passive diffusion was then placed in the middle of the ectopia just under the pial surface. The brains were stored in fixative at 37°C for up to 4 months. The brains were cut with a vibratome into 100 µm coronal sections and viewed under using a rhodamine filter set in order to visualize the DiI.

DiI brightly labeled the ectopias and in all cases there was a distinctive bundle of labeled fibers extending from the ectopic cells through the deeper layers of the cortex. This bundle of fibers then either entered the corpus callosum or the internal capsule. Six ectopias were in the somatosensory barrel cortex and one was in the hindlimb sensorimotor cortex. Depending on the location of the ectopia within the barrel cortex labeling was seen in thalamic nuclei VPM, and/or Po. The hindlimb ectopia was connected with VPL. Cortico-cortical connections were also seen between ectopias in barrel cortex and both secondary somatosensory and primary motor cortices. These DiI studies provide the first conclusive evidence that the neurons within the ectopias are connected both to other cortical architectonic areas and thalamic nuclei. Supported by NIH grant HD 20806 & the Sackler Scholarship

ULTRASTRUCTURAL ANALYSIS OF NEOCORTICAL ECTOPIAS IN NXSM-D RECOMBINANT INBRED MICE. G.W. Boehm*, M.W. Goss, A.J. Seaman, A.M. Galaburda, V.H. Denenberg and G.F. Sherman. Biobehavioral Sciences Graduate Degree Program, Univ. of Connecticut, Storrs, CT 06269; Central EM Facility, Univ. of Connecticut Health Center, Farmington, CT 06032; and Beth Israel Hospital and Harvard Medical School, Boston, MA 02215.

Focal disruptions of the laminar organization of the cortex, similar to those found in post-mortem analyses of human dyslexic cortices, have been reported in autoimmune NZB and BXSB inbred mice (Sherman *et al.*, *Acta Neuropath.*, 74:239, 1987). These strains have since become useful animal models of this pathology. The small abnormalities produced by a breach in the pial-glial membrane have been shown to form in utero, and be associated with highly specific learning deficits (Sherman *et al.*, *Neurosci. Abs.*, 18: 1446; Denenberg *et al.*, *Brain Res.*, 562:98, 1991).

This study complements prior work done at the light microscopic level by reporting findings from transmission electron microscopic analysis of the cellular structure of neurons and glia residing in and around the apex of ectopias, in a recombinant inbred strain derived from progenitor NZB and SM mouse strains, the NXSM-D (Eicher & Lee, *Genetics*, 125: 431, 1990). Six ectopias from four NXSM-D males (2 weanlings, 2 adults) were examined. In addition to being out of position, cells inside ectopic clusters had multiple ultrastructural abnormalities. The most striking abnormality was the large, apparently ballooned dendrites noted in nearly all of the ectopias. The vacuous nature of many of these dendrites, without any similar cytoskeletal damage to neurons on either side of the ectopia, was suggestive of localized excitotoxic damage. Abnormal numbers of lysosomes frequently observed inside ectopias also argue for ongoing cellular damage. Additionally, unusual deposits of extracellular protein and extended basal laminae were seen between ectopic cell processes. Approximately half of the ectopias had what appear to be either thin extensions of the pia or rather extensive pericyte septa bordering the edges of the ectopia. Ultrastructural abnormalities appear to be more severe in adult mice. Supported in part by NIH grant H-20806.

HIPPOCAMPAL DEGENERATION IN APP-C100 MICE IS ASSOCIATED WITH EXTRAMEDULLARY HEMOPOIESIS. M. L. Oster-Granite*, J. R. Greenan, D. McPhie, and R. L. Neve. Div. Biomed. Sci., Univ. CA, Riverside, CA 92521-0121 and Depart. Genetics, Harvard Univ. Sch. Med., Boston, MA 02178.

We have previously described the pathogenesis of massive pyramidal and granule cell loss in the hippocampi of mice transgenic for an amyloid precursor protein construct (APP-C100) driven by a neuron specific dystrophin promoter. When the reporter sequence FLAG is added to the construct, we have observed extensive degeneration as early as one year of age in some these new transgenic lines. Lysosome-like inclusions, immunoreactive for the antibodies that recognize epitopes in the C-100 construct, appear in increasing numbers of cells and increasing numbers appear in individual neurons in many regions of the CNS as the animals age. Examination of cerebellum, cerebral cortices, spinal cord, hypothalamus, and striatum have revealed no significant neuronal cell loss relative to that significant neuronal destruction observed in the hippocampal formation of individual transgenic animals. In addition, many of the APP-C100 mice exhibit cardiomegaly, hepatosplenomegaly, and extramedullary hemopoiesis reminiscent of that occurring in human beings with anaplastic anemia or in individuals with Down Syndrome. The earlier and more rapid degeneration of the hippocampus in the FLAG construct is accompanied more frequently by megakaryocytic abnormalities which may be associated with the platelet abnormalities observed in individuals with DS and some individuals with AD. Supported by HD19932 (MLOG) and NS28695 (RLN).

DEVELOPMENTAL EXPRESSION OF THE AMYLOID PRECURSOR PROTEIN AND TAU IN A MOUSE MODEL OF DOWN SYNDROME. M.L. Lacey-Casem*, C.B. Kuo, and M.L. Oster-Granite. Div. of Biomedical Sciences, University of California, Riverside, CA 92521.

The amyloid precursor protein (APP) and the microtubule associated protein, tau, are both key components in the Alzheimer's-like neuropathology of Down Syndrome (DS). A correlation has recently been found between the expression of these two important proteins in DS, suggesting either that APP and tau are under similar transcriptional regulation or that the overexpression of APP influences the expression of tau. In order to study the interaction of APP and tau gene expression, we have made use of an animal model of DS, the Trisomy 16 (Ts16) mouse.

The levels of APP and tau gene expression were determined by quantitation of the respective mRNAs by the method of reverse transcription-PCR. Total RNA was isolated from normal and Ts16 fetuses from 13 to 17 days gestation and cDNAs for all APP and tau isoforms were amplified and quantitated by digital image analysis of ethidium bromide stained gels. All reactions were standardized relative to GAPDH, a constitutively expressed protein.

We have found that the expression of both APP and tau follow a similar developmental pattern in the normal mouse. This result is consistent with APP and tau being under similar transcriptional control. We have also confirmed the observation that APP expression is elevated two fold in the Ts16 fetus when compared to its normal littermate. Interestingly, the level of tau expression in the Ts16 fetus is also elevated, but only from day 15 on. This latter observation argues that increased tau expression is not due to triplication of the tau gene. The pattern of tau expression in the Ts16 mouse suggests that Ts16 neurons are more sensitive to some event or signal, occurring at 15 days gestation, which influences tau gene expression. Supported by NIH1F32NS09496.

ALZEIMER'S TYPE NEUROFIBRILLARY DEGENERATION IN BRAIN WARTS M. A. Morán* and P. Gómez-Ramos Morphology Dep., Autonomous Univ. Sch. of Med., Madrid. Spain

Verrucose dysplasias (VD) of the cerebral cortex are developmental abnormalities characterized by a nodular shape and a disrupted cytoarchitecture of upper layers. In three autopsied elderly individuals (two without neurologic disorders and one with motor neuron disease), VD presented abundant Alzheimer's type neurofibrillary degeneration (ND), which immunoreacted with 5E2 and AT8 Abs, disclosed cholinesterase activity, and were thioflavin-S positive. This ND was conspicuous in layers II and III abutting the external borders of the dysplasia, as well as in layers V, VI, and in the underlying white matter. All VD contained cell-sparse areas within them, around which a peak of ND was seen. We suggest that alterations in the neuropil around neurons disturbed in their migration make them vulnerable to undergo cytoskeletal changes. Additional micro-environmental anomalies related to hypoxia-ischemia in these lesions are proposed as contributing factors for ND, pointing to the potential of VD as a source of material to study unresolved issues such as the way ND may be related to ischemia. *Supported by F.I.S. 93/0198 Spain.*

STEARYL-NLE^{17}-VIP PROTECTS AGAINST DEVELOPMENTAL RETARDATION IN APOE-DEFICIENT MICE AND AGAINST NEURODEGENERATION IN ALZHEIMER'S DISEASE-RELATED MODELS. I. Gozes*, M. Bachar, A. Bardea, A. Reshef, S. Rubinrout, M. Fridkin and D.E.Brenneman. Dept. Clin. Biochem. Sackler Med. Sch. Tel Aviv Univ. Israel, 69978; Dept. Organic Chem. Weizmann Inst. Rehovot, Israel, 76100; Sect. Develop. and Molec. Pharmacol. LDN, NIH, Bethesda, MD, USA 20892.

Stearyl-Nle^{17}-VIP is a novel agonist of vasoactive intestinal peptide (VIP) exhibiting a 100-fold greater potency than the parent molecule and specificity for a VIP receptor associated with neuronal survival (J. Pharmacol. Exp. Therap. 273:161,1995). The new molecule contains two chemical modifications in VIP, the addition of an N-terminal long chain fatty acid and the substitution of the methionine in position 17 with norleucine (Nle). In the present study, the developmental and protective effects of stearyl-Nle^{17}-VIP were investigated *in vivo* using mice deficient in apolipoprotein E (apoE) (Cell 71: 343,1992). The ApoE-deficient mice were tested for the development of behavioral milestones and were found to be significantly retarded in their acquisition of forelimb placing behavior (postnatal day 11-13) as compared to control animals (postnatal day 2-5). A two day delay in the acquisition of cliff aversion behavior also was observed in these mice. Chronic daily injections (s.c.) of stearyl-Nle^{17}-VIP to apoE-deficient new born pups resulted in a significant improvement and acquisition of behavioral milestones, similar to the development of control animals. Similarly, in Alzheimer's-related models (e.g. beta amyloid toxicity *in vitro* and cholinotoxicity *in vivo*), stearyl-Nle^{17}-VIP protected against accelerated cortical neuron death and impairments in learning and memory. Stearyl-Nle^{17}-VIP in particular and lipophilic neuropeptides in general may provide a novel route to drug design for neurodegenerative diseases. *Dedicated to the memory of the late Prof. Shlomo Eisenberg.* Supported by: Fujimoto Pharmaceutical Corp.

ALTERED MEMBRANE RESISTANCE AND REDUCED OUTWARD CONDUCTANCE IN CULTURED TRISOMY 16 MOUSE TONGUE MUSCLE CELLS SUGGEST A MECHANISM FOR THE HYPOTONIA IN HUMAN DOWN SYNDROME S. Peng, Z. Galdzicki*, and S. I. Rapoport. Lab of Neuroscience, NIA. NIH. Bethesda, MD 20892

Trisomy 16 (Ts16) mouse is a genetic animal model of Down syndrome (DS; human Ts21). Young DS patients develop a characteristic hypotonia. It has been reported that the tongue muscle is abnormal in DS. A whole-cell patch-clamp method was used to study membrane properties of isolated Ts16 and diploid control tongue muscle cells.

Muscle cell cultures were prepared from diploid control and Ts16 mouse fetus tongues on the 16th day of gestation. Cells can be maintained for 21 or 23 days. Electrophysiological recordings were done in vitro in normal physiological solutions with 1 mM $CdCl_2$ on cells cultured between day 7 and 14. Before recording, cells became spherical after a few hours of exposure to 0.1 μM colcemid. Membrane resistance (R_m) and capacitance (C_m) were measured at a holding potential of -60 mV. Mean Ts16 cell R_m was 372 MΩ (±45; n=17), whereas R_m of control was 513 MΩ (±39; n=31). Thus the Ts16 cell R_m was 27.5% less than that of control. We did not detect significant difference in C_m between Ts16 and control cells. Furthermore, we applied 15 steps of depolarization voltage with 10 mV increments to elicit total membrane current at holding potential of -60 mV. The mean of normalized maximum outward conductance ($G_{max.out}/C_m$) was 497 pS/pF (±80; n=17) and 843 pS/pF (±83; n=31) for Ts16 and control cells respectively. Thus the $G_{max.out}/C_m$ of the Ts16 cells was 41% lower than that of control, but there was no significant difference in inward current or conductance. Therefore, the cause of hypotonia could be the increased Cl^- conductance.

BETA-AMYLOID: ApoE II

RATS TREATED WITH ANTISENSE OLIGONUCLEOTIDES TO APP AND APO-E RETAIN PLACE, CUE, AND MOTOR MEMORY. C.A. Marotta*[1], S. Agrawal[2], D.P. Binsack[3]. Dept. of Psychiatry and Human Behavior[1,3],and Dept. Neuroscience[1] Brown University, Providence R.I. 02912; and, Hybridon, Inc.[2], Worcester, MA 01605.

Antisense compounds can be applied to modulate the expression of gene products implicated in a variety of disorders, including Alzheimer's Disease (AD). Thus, we designed phosphorothioate oligonucleotides complementary to amyloid precursor protein (APP) mRNA and to apolipoprotein E (APO-E) mRNA. In a previous report we showed that anti-APP can modulate the expression of APP in PC12 cells (Cell. Molec. Neurobiol. 14:425-437; 1994). The most common symptom of AD involves the disruption of memory. Thus, any potential therapeutic agent requires initial assessment with respect to its impact on behavioral functions in normal animals. Male rats were injected (i.v.) with: 1) anti-APP; 2) anti-APO-E; 3) saline; or 4) an unrelated (nonsense) oligonucleotide at dosages of 2.5 or 5.0 mg/kg. All rats were trained in a multi-component water maze task which simultaneously assessed long-term and short-term place memory, cue memory, and motor memory. Antisense oligonucleotides produced no deleterious effects on normal rats when tested for place, cue, and motor memory at the dosages tested. Safety and efficacy assessments are continuing to evaluate the therapeutic potential of antisense compounds in the treatment of AD.

EXPRESSION OF THE LOW DENSITY LIPOPROTEIN RECEPTOR FAMILY MEMBER gp330 IN RESPONSE TO EXPERIMENTAL LESION MODELS OF ALZHEIMER DISEASE. G.M. Pasinetti[1*], M.Z. Kounnas[2], W.S. Argraves[2], and C.E. Finch[1]. [1]Division of Neurogerontology, Andrus Gerontology Center and Dept. of Biological Sciences, USC, Los Angeles, CA 90089, [2]J.H. Holland Lab., Dept. of Biochem., American Red Cross, Rockville, MD 20855

Alzheimer plaques contain the apolipoproteins apoJ (clusterin) and apoE in complexes with the amyloid β-peptide (Aβ), which could have roles in the metabolism of Aβ. The LDL-receptor family member gp330 contains a shared binding site for both apoJ and apoE (Kounnas et al., *J. Biol. Chem.* 1995, in press), whereas the LDL receptor related protein (LRP) binds apoE but not apoJ. ApoE-LRP, but also apoJ-gp330 complexes can be internalized through endocytosis and might be an important clearing mechanism of Aß from neuropil for lysosomal Aß degradation. This study surveyed gp330 and LRP, and the 39 kDa LDL receptor associated protein (RAP) for changes in response to brain lesions that model features of Alzheimer disease. During responses to hippocampal deafferentation by perforant pathway transection, gp330 immunoreactivity was induced in hippocampal neurons of the CA1-CA3 subdivision and subiculum. Similarly, after infusion of synthetic aggregated Aβ1-42 peptide, surviving hippocampal neurons showed elevated immunoreactivity for gp330. ApoJ was also found as immunoreactive deposits in the vicinity of the infused Aβ. Hippocampal deafferentation increased LRP immunoreactivity in glial-rich zones, but did not alter the regional distribution of RAP. The findings highlight the coexpression of gp330 and one of its ligands apoJ at sites of brain injury which is consistent with the possibility that gp330 may be functioning to mediate clearance of apoJ at these sites. This work was supported by the Nathan W. & Margaret T. Shock Aging Research Foundation to GMP by the NIA (AG-07909) to CEF and NIH (DK45598) to WSA.

APP751 (PROTEASE NEXIN 2):PROTEASE COMPLEXES ARE INTERNALIZED VIA THE LDL RECEPTOR-RELATED PROTEIN (LRP). M. F. Knauer*, R. A. Orlando, and C. G. Glabe. Dept. of Molecular Biology and Biochemistry, University of California, Irvine, CA 92717.

Protease Nexin 2 (PN2), a secreted isoform of the amyloid precursor protein (APP751), inhibits the binding protein for epidermal growth factor (EGFBP) by forming PN2:protease complexes. In the present studies we have investigated the mechanism by which PN2:EGFBP complexes are cleared by human fibroblasts. Our data indicate that the internalization of the PN2:EGFBP complex by human fibroblasts is mediated by the LDL receptor-related protein (LRP), which binds multiple ligands including ApoE. Complex binding and internalization were inhibited 50% and 80%, respectively, by the 39 kDa LRP receptor associated protein (RAP), which has been shown to block the binding of all ligands to LRP. In addition when EGFBP was added to surface labeled cells overexpressing APP751 there was a significant increase in the internalization of transmembrane APP751. More importantly, this increase was blocked by the addition of RAP. Taken together, these data demonstrate that the transmembrane bound form of APP751 acts as a protease inhibitor, and that its internalization is LRP dependent. This suggests an alternative mechanism by which amyloidogenic APP751 can be re-internalized into cells after it has been targeted to the plasma membrane, and may provide a mechanistic basis for the generation of the beta peptide which is a seminal component of senile plaques in Alzheimer's disease.

670.4

BINDING OF ß-AMYLOID PEPTIDE (Aß) TO APOLIPOPROTEINS E3 AND E4. L. M. Shaffer*, N. J. Richter-Cook, R. Gupta-Bansal and K. R. Brunden, Gliatech, Inc., Cleveland, OH 44122.

Apolipoprotein E (apoE) is found associated with senile plaques in Alzheimer's disease (AD), and relatively recent data reveal that individuals expressing the apoE4 isoform have an increased probability of developing AD. Previous studies demonstrated that apoE4 and the more common apoE3 isoform both bind Aß, the major component of senile plaques. However, only SDS and heat stable complexes were quantified, and conflicting results were obtained regarding the relative affinities of the apoE isoforms for Aß. Since there is a likelihood that apoE might form SDS-labile complexes with Aß, we have utilized a solid-phase binding assay to determine the affinity of recombinant apoE3 and apoE4 for fibrillar $A\beta_{1-40}$. The apoE isoforms were immobilized in 96-well plates, and fibrillar preparations of Aß were subsequently allowed to interact with the coated wells. Bound amyloid peptide was detected with a specific monoclonal antibody, followed by addition of a peroxidase-conjugated anti-mouse antibody. Aß showed saturable binding to both apoE3 and apoE4. There were not dramatic differences in the affinity of Aß for either apoE isoform at pH 7.4, with K_d values of approximately 100-200 nM. To ensure that immobilization of apoE did not expose artifactual Aß binding sites, experiments were performed in which increasing concentrations of apoE3 and apoE4 were added to the binding solutions to compete for Aß association with immobilized apoE. A dose-dependent inhibition of Aß binding was seen with solution-phase apoE3 and apoE4, with K_i values that were in general agreement with the K_d values mentioned above. These data suggest that both apoE3 and apoE4 are capable of relatively high-affinity interactions with fibrillar Aß. This is in agreement with previous work demonstrating that apoE immunoreactivity was comparable in plaques from AD patients homozygous for the E3 and E4 isoforms.

APOLIPOPROTEIN E AGGREGATES WITH SOLUBLE AMYLOID BETA IN ALZHEIMER'S DISEASE AND NORMAL BRAINS. G. Angelini, C. Russo, D. Zaccheo[#], X. Xu[&,*], J.K. Teller[&], P. Gambetti[&] and M. Tabaton[#]. Advanced Biotechnology Center, Genova, and [#]Institute of Anatomy, University of Genova, Italy, and [&]Division of Neuropathology, Case Western Reserve University, Cleveland, OH 44106.

Apolipoprotein E (ApoE) allele 4 is a genetic risk factor in sporadic and familial Alzheimer's disease (AD). Recent studies in vitro suggest that ApoE4 may play a role in modulating amyloid beta (Aβ) polymerization through a preferential binding. We detected and analyzed ApoE - Aβ complexes in the cerebral cortex of AD and normal subjects. An anti-ApoE antiserum was used for immunoprecipitation from buffer-soluble fraction of the brain. Immunoprecipitates were separated by gel electrophoresis, blotted, and analyzed with monoclonal antibodies against ApoE and Aβ (Mab 6E10). Apart from two free peptides (~4 and 3.7 kDa) detected with 6E10, a band migrating at ~41 kDa was detected with both anti-ApoE and anti-Aβ Mabs, indicating that the band corresponded to an ApoE - Aβ complex. Surprisingly, we also found the same 41 kDa band in the extracts from control brains in which soluble Aβ was undetectable. Our findings suggest that ApoE may sequester soluble Aβ in the normal brain. Direct analysis of the ApoE - Aβ complex and comparsion of the complex in AD cases homozygous for ApoE3 and ApoE4 are in progress. APOLIPOPROTEIN E POLYMORPHISM AND RECEPTOR INTERACTION IN ALZHEIMER DISEASE. H. Soininen*, O. Heinonen, S. Ylä-Herttuala, P. Riekkinen Sr. Dept. of Neurology and AIV-Institute, University and University Hospital, Kuopio, P.O.Box 1627, 70211 Kuopio, FINLAND.

Alzheimer disease (AD) is associated with an increased prevalence of apolipoprotein E (ApoE) ε4. ApoE is a plasma protein that binds to low-density lipoprotein (LDL) receptor and the α_2-macroglobulin receptor/LDL receptor-related protein (α_2MR/LRP). In the central nervous system, ApoE is produced and secreted by astrocytes. In AD, ApoE is bound to senile plaques (SPs), tangles as well as to cerebrovascular amyloid. Colocalization of ApoE and α_2MR/LRP to SPs suggests that these molecules may play a role in amyloid accumulation. The aim of this study was to investigate the ApoE and α_2MR/LRP interactions in AD patients with different ApoE genotypes. We determined immunopositivity for the anti-β-amyloid (Aβ), anti-ApoE and anti-α_2MR/LRP-α in the frontal cortex of 3 ApoE ε44, 1 ε34 and 2 ε33 AD patients and 2 aged ε33 controls. Immunostainings were done for adjacent 50 μm-thick free floating sections using an avidin-biotin-peroxidase system. The major results were: 1) All AD patients showed a high number of Aβ immunopositive plaques in the frontal cortex, 2) The number of ApoE immunopositive plaques was higher in AD ε44 patients compared to ε33 patients, 3) Immunopositivity for anti-α_2MR/LRP-α was increased in AD cases compared to controls, 4) The number of anti-α_2MR/LRP-α positive astrocytes was increased in AD ε44 patients compared to those with ε33. These results underlie the genetic association of ApoE alleles with the severity of AD pathology.

PROMOTION OF THE NEUROTOXICITY OF ALZHEIMER Aβ PROTEIN BY THE PATHOLOGICAL CHAPERONES ACT AND APOE4: INHIBITION BY Aβ-RELATED PEPTIDES AND APOE2. J. Ma*, [&]H. Bryan Brewer, and H Potter. Department of Neurobiology, Harvard Medical School, Boston, MA 02115; [&]National Heart and Blood Institute, National Institutes of Health, Bethesda, MD 20892.

The amyloid β-protein (Aβ) is a major component deposited in the senile plaques of Alzheimer's disease brain. We and others have previously found that two amyloid associated proteins, apolipoprotein E4 (ApoE4) and α_1-antichymotrypsin (ACT), possess strong amyloid filament-promoting activity and these proteins have been proposed as pathological chaperones for the formation of amyloid (Ma and Potter, 1994, *Nature*, 373:92-94, Sanan et al., 1994, *J. Clin. Invest.* 94:860-869 and Wisniewski et. al 1994, *Am. J. Pathol.* 145:1030-1035). Here we report the effects of the amyloid filaments promoted by ACT and apoE4 on the viability of primary human cortical neurons. ACT- and apoE4-induced amyloid filaments were more neurotoxic than amyloid filaments formed in the absence of pathological chaperones, as judged by a colometric MTT assay. Preincubation of ACT and apoE4 with Aβ-related peptide, or of apoE4 with apoE2, reduced their ability to promote the formation of neurotoxic Aβ filaments. The maximal neuroprotection effect of Aβ-related peptides and apoE2 can be observed at 100 nM concentration. These data suggest that ACT and apoE4 act as pathological chaperones—promoting the generation of amyloid filaments in Alzheimer's disease, which, in turn, lead to neuronal cell death. The ability of Aβ-related peptides and apoE2 at nM concentration to serve as "antipathological chaperones" by reducing the ACT and apoE4 neurotoxic filament-promoting function, may provide the basis for a potential therapy for Alzheimer's disease.

ASTROCYTE- APOLIPOPROTEIN E (APOE) ASSOCIATIONS IN SENILE PLAQUES IN ALZHEIMER'S DISEASE (AD) AND VASCULAR LESIONS: A REGIONAL IMMUNOHISTOCHEMICAL STUDY. Y. Shao*, M. Gearing, and S. S. Mirra. Department of Pathology and Laboratory Medicine, VA Medical Center and Emory University School of Medicine, Atlanta, GA 30322.

While ApoE and ß-amyloid (Aß) colocalize in senile plaques in cortex and cerebellum in AD, the Aß-positive, predominantly diffuse plaques in the striatum do not exhibit ApoE immunoreactivity. As astrocytes are a major source of ApoE in brain, we investigated potential regional differences in the ability of astrocytes to produce ApoE that might affect Aß processing and progression of AD pathology. Using antibodies to ApoE, glial fibrillary acidic protein (GFAP) and Aß, we compared the pattern of immunoreactivity in senile plaques in AD autopsy tissue with that of reactive astrocytes surrounding subacute and old infarcts in both AD and non-AD cases. We found GFAP and ApoE immunoreactivity but no Aß label in cell bodies and processes of reactive astrocytes in vascular lesions within cerebral cortex, striatum, and cerebellum. In contrast, while many senile plaques in AD cortex evidenced prominent GFAP-positive astrocytes, ApoE immunoreactivity was not observed within these cells but instead paralleled that of Aß. Prominent ApoE label of astrocyte cytoplasm was seen, however, in neighboring zones of infarction. Our findings suggest that, in AD and non-AD brains, reactive astrocytes are capable of upregulating ApoE regardless of the location of injury. Moreover, the apparent absence of ApoE label in senile plaque astrocytes may reflect decreased ApoE expression and/or increased release related to ApoE-Aß binding or other factors. Supported by VA Merit Award and AG10130.

BIOCHEMICAL QUANTITATION OF ALZHEIMER Aß PEPTIDE AND APOLIPOPROTEIN E AGGREGATED INTO AMYLOID FIBRILS. L. Buée*,[1] B. Permanne,[1] J. Pérez-Tur,[1] J-Ch. Lambert,[1] J.Ph. David,[1,2] P. Vermersch,[1] F. Ghozali,[2] F. Pasquier,[3] F. Lebert,[3] H. Petit,[3] C. Di Menza,[2] M.C. Chartier-Harlin,[1] A. Delacourte[1]
[1]INSERM U422, 59045 Lille Cedex, France. [2]Hôpital Emile Roux, 94456 Limeil Brévannes, France. [3]Dept of Neurology, Hôpital B, 59037 Lille Cedex, France.

Alzheimer's disease (AD) is a neurodegenerative disorder characterized by the presence of amyloid deposits and neurofibrillary tangles in the cerebral cortex. The main component of amyloid deposits is a 42 amino-acids peptide referred to as Aß. AD is associated with an increased frequency of the apolipoprotein E (ApoE) ε4 allele. ApoE is a secreted glycoprotein involved in cholesterol transport and neurite outgrowth. In AD, ApoE is also found in amyloid deposits. ApoE binding to Aß peptide could lead to their aggregation into amyloid fibrils. Conversely, ApoE ε2 allele may be neuroprotective. 101 brains were obtained at autopsy from elderly patients at different stages of amyloid deposition including 61 demented and 40 non-demented cases. For all of the cases, classical neuropathological examination was performed. Aß peptide and ApoE aggregated into amyloid fibrils was also quantified by dot-blot immunoassay. A strong correlation was found between this Aß biochemical quantitation and number of amyloid deposits (per mm^2) determined by neuropathological examination. Using this method, we are able to determine the amount of Aß within amyloid deposits in the cerebral cortex of typical AD patients. These data should allow to set up a better model of Alzheimer type amyloidosis.

ApoE detection was not proportional to Aß-immunoreactivity obtained by dot-blot immunoassay. These data suggest that ApoE binding to Aß within amyloid deposits may be related to particular ApoE variants. Thus, ApoE was genotyped in 78 out of the 101 cases. Interestingly, cases having at least one ε2 allele always demonstrated lower Aß amounts compared to other subjects. These data suggest that ApoE ε2 allele may facilitate clearance of Aß peptide.

PHYSIOLOGICAL APOLIPOPROTEIN E ε3 AND ε4 ISOFORMS PROMOTE FIBRILLOGENESIS OF Aß (1-42) IN A THIOFLAVINE T ASSAY. D. Sweeney[1], Z. Zhou[1], R. Martins[1], H. LeVine[2], J. Cheetham[3], J. Breslow[4], J. Smith[4], P. Greengard[3] and S. Gandy[1*1]Dept. of Neurology & Neuroscience, Cornell Univ. Medical College, 1300 York Ave., New York, NY 10021; [2]Dept. of Neuroscience Pharmacology, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48106; [3]Lab. of Molecular & Cellular Neuroscience, and [4]Lab. of Biochemical Genetics & Metabolism, The Rockefeller Univ., 1230 York Ave., New York, NY 10021

Genetic-neuropathological correlation has established that apoE ε4 specifies increased cerebral amyloid plaque density. Thus, an important starting point for understanding the role of apoE in Alzheimer disease is the elucidation of the relevant apoE isoform-dependent interactions with Aß. Here we report the application of a thioflavine T based assay of Aß fibrillogenesis kinetics to the study of apoE/Aß interactions, and use this assay to study modulation of Aß fibrillogenesis using metal ions, recombinant apoE isoforms, or physiological apoE isoforms from stably transfected CHO cells. Aluminum, iron and zinc promoted fibrillogenesis of synthetic Aß (1-40) and Aß (1-42) by 3-5 fold ($p<0.001$) following incubations of 1, 4 or 7 days. Recombinant baculoviral apoE isoforms had no obvious effect on fibrillogenesis of Aß (1-40) or Aß (1-42) under the conditions studied. Physiological apoE ε3 or ε4 isoforms, produced in conditioned serum- free media, stimulated fibrillogenesis of Aß(1-42) by approximately 1.8 fold ($p< 0.01$) as compared with conditioned media from CHO cells transfected with an irrelevant construct. In contrast, fibrillogenesis of Aß (1-40) was not stimulated by physiological apoE isoforms under the conditions studied. These results provide evidence that physiological apoE isoforms can demonstrate profibrillogenic activity. The similarity in the profibrillogenic activities of ε3 and ε4 isoforms raises the possibility that interactions other than (or in addition to) apoE-mediated Aß fibrillogenesis might contribute to the apoE ε4 isoform specificity associated with increased plaque density.

ISOFORM-SPECIFIC EFFECT OF APOLIPOPROTEIN E ON THE ASSOCIATION OF β-AMYLOID WITH NEURO-2A MOUSE NEUROBLASTOMA AND RAW264 MACROPHAGE CELLS. Z. Zhou[1,2], J. Smith[1], F. Plum*[2], J. Breslow[1], P. Greengard[1], and S. Gandy[1,2].
[1]Rockefeller University, and [2]Department of Neurology & Neuroscience, Cornell University Medical College, New York, NY 10021.

Alzheimer's disease is characterized by senile plaques formed mainly from β-amyloid peptide (Aβ). Genetic analyses have revealed an allele specific association of apolipoprotein E (apoE) isoforms with the relative risk for Alzheimer's disease. In order to investigate the possible existence of an apoE isoform-dependent effect on the clearance of Aβ, synthetic Aβ(1-40) was labeled by iodination and incubated with Neuro-2a or RAW264 cells in the presence of human apoE ε3- or ε4- containing conditioned medium or control conditioned medium. After a 4 hr incubation at 37°C, cells were washed and treated with trypsin to remove surface bound Aβ. The trypsin resistant, cell-associated Aβ was quantitated by measuring the radioactivity associated with the cell pellet. When Neuro-2a cells were used together with conditioned medium prepared from stably transfected CHO cells, the cell-associated Aβ in the presence of apoE ε3 was ~30% lower than that which was cell-associated in the presence of apoE ε4 ($p < 0.001$). However, when RAW264 cells were incubated with conditioned medium prepared from transfected RAW264 cells or control conditioned medium, the cell-associated Aβ in the presence of apoE ε3 conditioned medium was ~10% higher than that which was cell-associated in the presence of apoE ε4 conditioned medium ($p < 0.05$). These results suggest that apoE can have an isoform-specific effect on the association of Aβ with cells. The different patterns of Aβ association in these two cell types suggest that cell type-dependent factors are also involved in this process.

APOLIPOPROTEIN E ALLELES IN CEREBRAL AMYLOID ANGIOPATHY AND INTRACEREBRAL HEMORRHAGE ASSOCIATED WITH ALZHEIMER'S DISEASE (AD)

R.N. Kalaria*, D.L.Cohen and D.R.D. Premkumar. Departments of Neurology and Pathology, Case Western Reserve University and UH Alzheimer Center, Cleveland, Ohio 44106, USA

The presence of apolipoprotein E (*APOE*)- E4 allele has been implicated as a risk factor for AD. We examined the occurrence of *APOE* E4 alleles in AD associated with cerebral amyloid angiopathy (CAA) and other vascular lesions including intracerebral hemorrhage. We found significantly high frequency of the *APOE* E4 allele in AD subjects exhibiting moderate to severe CAA. This association was further corroborated in three other non-AD subjects with severe CAA in the absence of significant neocortical amyloid deposition, who were all homozygous for *APOE* E4 allele. Compared to all AD group, The frequency of the allele was also higher in AD cases with other vascular lesions such as multiple infarcts, ischemic white matter lesions, and petechial and subarachnoid hemorrhages. As previously reported, we confirm that the frequency of the *APOE* E4 allele in the diffuse Lewy body variant of AD is intermediate between controls and AD subjects. Our results suggest *APOE* E4 allele to be a significant factor in the development of CAA in AD. The possibility exists that *APOE* may be a specific factor in vascular abnormalities associated with AD.

Supported by grants from NIA and ADRDA.

APOLIPOPROTEIN E (APOE) FAILS TO ENHANCE THE EFFECT OF ß-AMYLOID ON PHOSPHOLIPASE C ACTIVITY AND ON CELLULAR CALCIUM SIGNALLING Henrike Hartmann*, Anne Eckert and Walter E. Müller
Central Institute of Mental Health, Dept. Psychopharmacology, J5, 68159 Mannheim, Germany

The major component of senile plaques in Alzheimer's disease is ß-amyloid (ßA) which has neurotoxic properties and may contribute to neurodegeneration in AD. Another risk factor for sporadic AD is the ε4 allele of ApoE. Colocalization of ßA and ApoE has been observed in senile plaques and ApoE complexes with ßA to form stable fibrillay complexes. Recent work has demonstrated an amplifying effect of various ßA fragments on neuronal Ca^{2+} signalling and on phosphoinositide (PI) hydrolysis. ApoE also enhances the rise in intracellular calcium ($[Ca^{2+}]_i$) following neuronal depolarization. The aim of the present study was to investigate if preincubation of ßA with ApoE affects neuronal PI-hydrolysis or $[Ca^{2+}]_i$ in a different way than ßA or ApoE alone. For the determination of the PI-hydrolysis mechanically dissociated mouse brain cells were loaded with ^{3}H-myo-inositol and depolarized with KCl. $[Ca^{2+}]_i$ was evaluated by the use of fura-2. ßA1-43, ApoE and ßA/ApoE (1/10) were dissolved in PBS and preincubated at 37°C for 2 days. ßA1-43 (≥ 1nmol/l) enhanced the KCl (10mmol/l) induced inositolphosphate (IP) accumulation in a concentration-dependent manner. In the presence of 1µmol/l ßA1-43 the amplification was about 30% above IP accumulation induced by KCl alone. This effect was restricted to submaximal depolarization of the cells with low KCl concentrations (≤20mmol/l). Incubation of the cells with ApoE (100nmol/l) enhanced the KCl-induced IP accumulation to about 20% above control. In contrast to the effect of ßA the ApoE-induced amplification was also seen at higher KCl concentrations, indicating that different mechanisms might be involved in the enhanced PI-hydrolysis induced by ßA and ApoE. Coincubation of ßA with ApoE did not result in further enhancement of the effect of ßA1-43 on PI-hydrolysis alone. Comparable effects were seen on the level of $[Ca^{2+}]_i$, where ßA1-43 and ApoE amplified the KCl-induced rise in $[Ca^{2+}]_i$ without further enhancement of this effect by ßA/ApoE. Therefore in our model no evidence was found that ApoE by enhancing ßA aggregation amplifies the effect of ßA on cellular signalling.

BINDING OF APOLIPOPROTEIN E2 TO ß-AMYLOID: COMPARISON TO APOLIPOPROTEIN E3 AND E4. T.M. Pederson, D.E. Frail*, R.E. Metzger, A.M. Manelli, C.A. Reardon, M.T. Falduto, G.S. Getz and M.J. LaDu. Neuroscience Discovery, Abbott Laboratories, Abbott Park, IL 60064 and Dept. of Pathology, University of Chicago, Chicago, IL 60637.

In humans, apolipoprotein E (apoE) has three major isoforms, E2 (Cys^{112}, Cys^{158}), E3 (Cys^{112}, Arg^{158}), and E4 (Arg^{112}, Arg^{158}). ApoE4 is a genetic risk factor for Alzheimer's disease (AD). Recent evidence suggests that apoE2 may protect against late-onset AD. We previously demonstrated that native preparations of apoE3 from conditioned media or human plasma bind to Aß with 20-fold greater avidity than apoE4. This preferential binding of Aß to apoE3 was abolished with a purification process which includes delipidation and denaturation. Here we expand these observations to include Aß binding to native apoE2, the isoform deficient in binding to the low density lipoprotein receptor. Human apoE2 cDNA was transiently and stably transfected into HEK-293 cells and the conditioned media was incubated with Aß1-40 peptide. Complex formation was analyzed by non-reducing, SDS-PAGE, followed by immunoblotting with either Aß or apoE antibodies. Under these conditions, apoE2 migrates as dimer, apoE3 as monomer (~70%) and dimer (~30%), and apoE4 as monomer. The presence of cysteine in apoE2 and apoE3 allow these isoforms to form disulfide-linked dimers. Initial results indicated that the apoE2 dimer-Aß complex was less abundant than either apoE3 monomer-Aß or apoE4-Aß complexes. We are currently purifying apoE2 to determine its Aß binding capacity relative to the native protein. These data underscore the notion that the more prevalent apoE3 isoform may provide protection from AD by binding to Aß, while apoE2 and apoE4 may lack this function.

670.15

EFFECT OF APOLIPOPROTEIN E ISOFORMS ON ß-AMYLOID INDUCED TOXICITY IN RAT PRIMARY HIPPOCAMPAL CULTURES. M. T. Falduto*, M.J. LaDu, A.M. Manelli, G.S. Getz, and P.S. Puttfarcken. Dept. of Neuroscience, Abbott Laboratories, Abbott Park, IL 60064 and Dept. of Pathology, University of Chicago, Chicago, IL 60637.

Apolipoprotein (apoE), particularly the e4 allele, is genetically linked to Alzheimer's disease. Immunostaining colocalizes apoE with ß-amyloid (Aß) to senile plaques. In vitro, Aß has been shown to be neurotoxic. While the role of apoE in the pathogenesis of the AD is unknown, one possibility is that it protects against Aß-induced neurotoxicity. As the hippocampus is the region of the brain most affected by AD, we evaluated the effect of both native and purified preparations of apoE3 and apoE4 on Aß-induced toxicity in primary cultures of rat hippocampal neurons. Morphological and biochemical changes were assessed following plating with apoE (30 µg/ml) ± 15 µM Aß(1-42). We have previously observed that apoE in conditioned media from HEK cells stably transfected with human apoE3 or apoE4 cDNA is lipid-associated. Using this native preparation as the source of apoE, both apoE isoforms protected against Aß-induced neurotoxicity in primary rat hippocampal cultures. Toxicity was assessed by neurite length and cell viability (MTT assay) measurements made 3 days after exposure to the peptide. These results correlated with microscopic examination. Using purified apoE, again both isoforms protected against Aß-induced toxicity. The addition of exogenous ß-migrating very low density lipoprotein (40 µg cholesterol/ml) alone did not provide protection against Aß-induced toxicity or enhance the protection provided by purified apoE3 and apoE4 alone. These data suggest a role for apoE in protecting against Aß- induced neurotoxicity.

670.16

EFFECT OF APOLIPOPROTEIN E ISOFORMS ON THE DEVELOPMENT OF RAT PRIMARY HIPPOCAMPAL CULTURES. P.S. Puttfarcken*, A.M. Manelli, M.T. Falduto, G.S. Getz, and M.J. LaDu. Dept. of Neuroscience, Abbott Laboratories, Abbott Park, IL 60064 and Dept. of Pathology, University of Chicago, Chicago, IL 60637.

The correlation between the e4 allele of apolipoprotein E (apoE) and Alzheimer's disease is well established. However, the role of apoE in both normal and pathological brain processes remains unknown. Previous work has demonstrated that apoE has neurotrophic effects on cultured dorsal root ganglion cells, possibly related to cholesterol delivery in the developing cultures. To begin to understand the function of apoE in CNS neurons, we treated rat primary hippocampal cultures with native or purified preparations of human apoE3 or apoE4 (30 µg/ml). Morphological changes were assessed by microscopic examination and measurements of neurite length at 1 and 3 days following plating. We have previously observed that apoE in conditioned media from HEK cells stably transfected with human apoE3 or apoE4 cDNA is lipid-associated. Using this native preparation as the source of apoE, apoE3 exhibited greater neurotrophic actions than apoE4 at 1 day in culture. This effect was attenuated by day 3. A comparable result was observed using purified apoE isoforms. Neurotrophic effects were also observed 1 day following the addition of ß-migrating very low density lipoproteins (>20 µg cholesterol/ml). None of these treatments produced significant changes in cell viability. These results demonstrate that this system is suitable for investigating the role of apoE in the CNS.

EXPRESSION AND CHARACTERIZATION OF ALL THREE APOLIPOPROTEIN E ISOFORMS (E2, E3, AND E4) IN INSECT CELLS. W.J. Checovich* and T. Burke. PanVera Corporation, Madison, WI 53711.

Apolipoprotein (Apo-) E is thought to play a role in the progression of Alzheimer's Disease by way of its lipid transport role or by virtue of its interaction with either β-amyloid protein, the microtubule protein *tau*, or both. There are three primary Apo-E isoforms, E2, E3, and E4, which differ from each other in one or two critical amino acids.

We have purified all three human Apo-E isoforms after baculovirus-mediated expression in insect cells. Human recombinant Apo-E (hrApo-E) has an apparent molecular weight of 34 kDa. Two-dimensional gel electrophoresis reveals a complicated isoform pattern which is reminiscent of the human serum Apo E pattern; along with the primary hrApo-E band, three-to-four additional bands occur at more acidic isoelectric points (pI), possibly representing sialylated and deaminated forms of Apo-E. The pI's of hrApo-E2, E3, and E4 are 6.25, 6.35, and 6.7 respectively. hrApo-E, reconstituted in DMPC (dimyristylphosphatidylcholine) liposomes, competes with ^{125}I-LDL for binding to the LDL receptor. All three isoforms also bind to β-amyloid protein and *tau*.

A PROTEIN KINASE CASCADE STIMULATED BY Aβ PEPTIDES: PKC, FAK AND FYN C. Zhang*, G. Krafft, and W.L. Klein Dept. of Neurobiol. & Physiol., Northwestern University, Evanston, IL 60208

It recently has been discovered that neuronal responses to Aβ peptides include a selective change in signal transduction associated with protein tyrosine phosphorylation (Zhang, et al, J. Biol. Chem., 1994, 269:25247). This change is most evident in FAK, an unusual protein tyrosine kinase (Clark and Brugge, 1995, Science 268:233) coupled to integrins and other receptors, to actin regulation, and to the ras signaling pathway. With respect to dose, kinetics, dependence on cell differentiation and requirement for Aβ aggregation, the evoked FAK Tyr (P) correlates with Aβ neurotoxicity, in both rat and human nerve cell lines. FAK thus provides an interesting molecular landmark to elucidate the cascade of intracellular events triggered by Aβ aggregates. We now show that aggregates of Aβ stimulate FAK-*fyn* association, indicating that the Aβ-stimulation of FAK Tyr(P) is of functional consequence, and that PKC participates upstream in the signaling pathway from Aβ to FAK Tyr(P). How the cascade is triggered is unknown, although stimulation of FAK Tyr(P) by A23187 and by mas-7 suggest that Aβ could access the cascade by promoting Ca++ leak or modifying G-protein function. While their potential down-stream consequences are extensive, the coupling of PKC, FAK and *fyn* to mitogenic pathways are especially intriguing; recent reviews (Heinz, TINS 1993, 18:157) have suggested that ectopic entry to the cell cycle in neurons could cause programmed cell death. Because *fyn* immunoreactivity is significantly increased in Alzheimer's-afflicted neurons (Shirazi, Neuroreport 1993, 4:435), this cascade could be a significant factor in Alzheimer's pathogenesis, especially if amyloid-evoked disregulation of *fyn* activity should prove to be neurodegenerative.

SECRETED FORM OF AMYLOID PRECURSOR PROTEIN PRIMES NAIVE PC12 CELLS FOR NEUROTROPHIC EFFECTS OF NERVE GROWTH FACTOR. W.C. Wallace*, W.E. Lyons, C. Akar, and V. Haroutunian. National Institute on Aging/GRC, Baltimore, MD 21224, Mount Sinai School of Medicine, New York.

Subcortical lesions of various neurotransmitter systems result in the *in vivo* induction and secretion of amyloid precursor protein (APP) in the corresponding projection fields of the cortex. In order to understand the physiological role of the secreted APP, we have studied the interaction of purified secreted human APP_{751} with NGF. APP induced a relatively modest outgrowth of neurites (approximately 25% of cells exhibited neurites) from naive PC12 cells when present at 50 to 100 ng/ml concentrations in the media. The induction was rapid (maximal effect after one day) but shortlived (decline in number of neurites after 3 days). In contrast, NGF-induced neurite outgrowth required at least 3 days and was present at maximum numbers after 7 days. Simultaneous addition of suboptimal concentrations of APP (1 ng/ml) and NGF (1-5 ng/ml) dramatically elevated neurite outgrowth, suggesting a synergistic interaction of the two factors. Similar effects were observed when APP was bound to laminin and extracellular matrix (matrigel) substrata. The ability of low levels of NGF (5 ng/ml) to induce neurites was increased 3- to 4-fold with APP present in the substrata. In addition, low concentrations of APP (which did not induce neurites) primed naive PC12 cells for subsequent neurite induction by NGF. Naive cells were treated with either 10 ng/ml APP or 50 ng/ml NGF for 4 days. The cells were triturated and replated in the presence of various concentrations of either APP or NGF. Compared to NGF primed cells, those cells primed with APP exhibited the most rapid and dramatic response to subsequent treatment by NGF, showing neurites 2 hours after exposure to NGF. APP-induced neurite outgrowth was minimal for cells initially primed with either APP or NGF. These results implicate APP as a co-growth factor in the injured cortex where it may act to make damaged neurons more responsive to the low levels of NGF.

671.3

NEURITE EXTENSION ASSAY DETECTS THE DEFECTIVE FUNCTION DUE TO SWEDISH MUTATION IN AMYLOID B/A4 PROTEIN (APP) H.L. Li,J.M. Roch, M. Pawlik*, S. Sisodia and T. Saitoh. Sch. of Med., Dept. of Neurosciences, Univ. of Ca, San Diego, La Jolla CA 92093.

Alzheimer's disease (AD) is characterized by selective loss of large neurons, decrease in presynaptic terminal density, and amyloid accumulation in the brain. The abnormal expression or processing of APP might play a critical role in these pathogenic process. To test this hypothesis, the human Swedish mutant APP695 cDNA, was stably transfected to a clonal CNS neuronal line, B103, and an African green monkey kidney cell line, COS-1, and compared with wild type APP695 tranfected cell lines. B103 cells transfected with Swedish mutant APP695 construct developed neurites significantly slower than those transfected with wild type APP695 when plated in a serum-free defined medium. Neurite outgrowth of parent B103 cells promoted by the addition of conditioned medium (CM) from wild type APP695 overproducing cells. However, neurite outgrowth was inhibited by the CM from Swedish mutant APP695 overproducing cells. The effect of Swedish mutant on neurites was not entirely due to the production of Aβ peptide. We determined that the secreted form of APP (sAPP) through α-secretase cleavage (sAPPα) could block the effect of Aβ, whereas sAPP produced by β-secretase (sAPPβ) could not under the identical condition. These results demonstrate the importance of the C-terminal cleavage site (α or β) on the trophic activity of sAPP regulating the deleterious effect of Aβ. We suggest that not only Aβ but also the secreted form of APP is critically involved in the pathogenesis of AD.

671.4

PHYSIOLOGIC LEVELS OF ß-AMYLOID (Aß) ACTIVATE PI3-KINASE AND PROMOTE NEURITE OUTGROWTH IN PC12 CELLS. Y. Luo*, T. Sunderland and B. Wolozin Section on Geriatric Psychiatry, NIMH/NIH, Bethesda, MD 20892-1264

The aß peptide plays an important role in Alzheimer's disease but is also present in blood serum and cerebrospinal fluid at 225 - 625 pM. The potential physiologic actions of low level aß have not been explored. We have found that picomolar doses of aß can stimulate tyrosine phosphorylation of neuronal cells. One of the phosphasyl proteins responding to aß is phosphatidylinositol-3 kinase (PI3 kinase). Three independent lines of evidence support the hypothesis that aß is activating PI3 kinase through a tyrosine kinase mediated mechanism. Immunoblotting studies show that aß induces tyrosine phosphorylation of p85 as well as binding of the p85 subunit of PI3 kinase to tyrosine phosphorylated proteins. Studies of glycosylated membrane proteins show that aß induces a translocation of p85 to membrane bound proteins, which are likely to be receptors. Finally, direct determination of lipid kinase products show that aß increases the activity of PI3 kinase in anti-phosphotyrosine immunoprecipitates. Activation of PI3 kinase by aß also stimulates PC12 cells to send out processes. Processes are evident within 8 hrs of application of 10 - 1000 pM aß; doses above this inhibit process outgrowth. Wortmannin, a selective inhibitor of PI3 kinase, blocks this response. Thus, physiologic levels of aß stimulate tyrosine phosphorylation which leads to the activation of PI3 kinase and stimulation of neurite outgrowth.

671.5

CONNEXIN43 (Cx43) AND GAP JUNCTIONS IN PC12 CELLS OVEREXPRESSING β/A4 AMYLOID AND Cx43 ELEVATION IN ALZHEIMER'S DISEASE. J.I. Nagy*, M.Z. Hossain, B.D. Lynn, W. Li, E.L. Hertzberg and C.A. Marotta. Dept. Physiol., Univ. of Manitoba, Winnipeg, Canada, Dept. of Neurosci., Albert Einstein College of Med., Bronx, NY and Dept. of Psych., Brown Univ., Providence, R.I.

Previous studies have shown that PC12 cells overexpressing β/A4 amyloid peptide display altered morphology characterized by extensive intercellular appositions. To determine if these features are accompanied by gap junctional communication, we examined connexin43 (Cx43) in normal and β/A4-transfected PC12 cells. Two β/A4-transfected PC12 clones exhibited induced Cx43 expression by Western blotting, intracellular and plasma membrane-associated Cx43 in some cells of cultures processed by immunofluorescence, dye-transfer between some cells microinjected with Lucifer Yellow, gap junctions between cells examined by EM, and transmission of intercellular Ca^{++} waves in cultures imaged with fura-2. Normal and vector-transfected PC12 cells exhibited none of these properties. Increased immunofluorescence in some clusters of β/A4-transfected cells was also observed with a monoclonal antibody against Cx32. Comparisons of Cx43 in normal and Alzheimer's Disease (AD) brain indicated that cortical areas with numerous β/A4 amyloid plaques contained increased levels of Cx43 and some plaques corresponded to sites of elevated Cx43 immunoreactivity. If β/A4 amyloid peptide causes aberrant gap junctional communication through induction or increased expression of connexins in cells, this may compromise cellular homeostatsis and exacerbate pathological conditions in amyloid plaques.

671.6

β-AMYLOID DECREASES ADHESION OF FIBROBLASTS IN CULTURE.

R.E. Majocha* and J. Schneider. Dept. of Psychiatry and Human Behavior, Miriam Hospital and Brown University, Providence, RI 02906

Fibroblasts from Alzheimer's Disease (AD) victims demonstrate several abnormalities. These include reduced spreading, decreased adherence on plastic culture plates and absence of a 113-pS potassium channel. The channel defect was simulated in normal fibroblasts by the addition of β-amyloid. To study the effects of β-amyloid on the adherence of cultured mouse fibroblasts, cells were exposed to the 40 residue form under a variety of conditions. By acutely or chronically administering β-amyloid to cultured cells, we were able to demonstrate that the protein interferes with normal cell adherence on a number of substrates. Rates of adhesion with acutely added β-amyloid were decreased on the laminin derived peptide IKVAV and on collagen I but not on plastic alone. The effect was concentration dependent. β-amyloid, when used as a substrate, decreased adherence . It is apparent that β-amyloid can have deleterious effects even on non-neuronal cell types.

671.7

PHYSIOLOGIC LEVELS OF ß-AMYLOID AUGMENT PLATELET AGGREGATION. B. Wolozin*, C. Jones, R. Dukoff, N. R. Shulman and T. Sunderland. Section on Geriatric Psychiatry, NIMH and Clinical Hemotology Branch, NIDDK, Bethesda, MD 20892.

ß-amyloid is constitutively secreted by many cells and is normally present in our blood and CSF at levels ranging from 225-625 pM. Although micromolar levels of aggregated aß are toxic to neurons, the functions of soluble aß is unknown. We now report that aß appears to play an important physiologic role in augmenting platelet aggregation. Addition of 1 nM $aß_{1-40}$ to gel filtered platelets in Tyrodes buffer increased the sensitivity of the platelets to ADP-induced aggregation approximately 2-fold. Addition of aß alone, however, did not induce platelet aggregation, both ADP and fibrinogen were required, and RGDS, which blocks fibrinogen-integrin binding, prevented aggregation. The aß peptide augmented ADP-induced aggregation at doses of aß beginning at 100 pM, peaking at 1 nM aß and evident up to 1 μM. The reverse $aß_{40-1}$ sequence and the $aß_{25-35}$ sequence were both inactive, while $aß_{1-16}$ showed weak (25%) enhancement of platelet aggregation. Addition of wortmannin, which inhibits PI3 kinase, reduced the effects of aß on aggregation, suggesting that PI3 kinase is involved in the aß-response. Biochemical studies show that aß induces rapid increases in tyrosine phosphorylation of a protein at 180 kDa, which occurs even in the absence of ADP or fibrinogen, suggesting that this process is directly related to binding of aß. These results show that ß-amyloid at physiological plasma levels markedly potentiates platelet aggregation possibly by activating a specific tyrosine kinase-linked cellular receptor.

671.8

UBIQUITIN-DEPENDENT PROTEIN DEGRADATION IS INHIBITED BY AMYLOID BETA-PROTEIN. L. Gregori*, M. Pereira#, and D. Goldgaber. Dept. of Psychiatry and Behavioral Science, Sch. of Medicine, SUNY at Stony Brook, Stony Brook, NY 11794.# Dept. of Pharmacology, Mt. Sinai Medical Center, New York, NY 10029.

Ubiquitin and ubiquitin conjugate immunoreactivity is typically observed in neurofibrillary tangles and inclusion bodies in the brains of individual affected by neurodegenerative disorders such as Alzheimer's disease and Down's syndrome. In addition to ubiquitin, amyloid β-protein (Aβ) immunostaining is also detected in neurofibrillary tangles. We investigated the correlation between the presence of Aβ and the accumulation of ubiquitin conjugates. In our *in vitro* studies using radiolabeled lysozyme as the substrate, we found that synthetic $Aβ_{1-40}$ inhibited ubiquitin-dependent degradation pathway. In the presence of Aβ, lysozyme-ubiquitin conjugates were normally formed and subjected to deubiquitination. However, their degradation was inhibited which is consistent with Aβ affecting the multi-subunit 26S proteasome activity. We tested the catalytic subunits of the 20S proteasome and found that $Aβ_{1-40}$ selectively inhibited the chymotrypsin-like activity within the proteolytic complex. Inhibition of ubiquitin conjugate degradation by Aβ would explain the accumulation of high levels of ubiquitin conjugates which are found in neurofibrillary tangles and inclusion bodies. Furthermore, these studies identify Aβ as an inhibitor of the 26S proteasome which, if occurs *in vivo*, has important physiological significance and consequences.

671.9

EXOGENOUS AMYLOID Aß1-42 STIMULATES THE INTRACELLULAR ACCUMULATION OF NEWLY SYNTHESIZED, 4 kDa AMYLOID PEPTIDE IN THE INSOLUBLE FRACTION OF TRANSFECTED CELLS.

A. J. Yang, T. Shu, A. Henshen and C. G. Glabe* Dept. of Molec. Bio. and Biochem., University of California, Irvine. CA 92717.

Our earlier reports have indicated that intracellular Aβ1-42 aggregates alter the turn-over of APP to cause the accumulation of insoluble APP and amyloidogenic fragments. To determine whether this accumulation ultimately gives rise to the production of more Aß, we examined the insoluble fraction of Aß1-42-treated cells for the presence of 4 kDa amyloid peptides. ^{35}S-*met* labeled 4 kDa Aβ peptides were immunoprecipitated from the detergent insoluble fraction of the cell lysate by anti-Aβ antibodies. The amyloid peptides were purified by size gel filtration and reverse phase column chromatography. Sequence analysis of purified peptide indicated that some of the newly synthesized peptides are "ragged" as previously observed for the exogenously added peptide. These peptides were eluted as a broad peak by a reverse-phase HPLC; this chromatographic properties is very similar to the Aβ1-42. In addition, the purified ^{35}S-met labeled amyloid peptides form SDS-stable high molecular weight aggregates with synthetic Aß1-42, suggesting that at least a fraction of these peptides extends to residue 42. Therefore, our results suggest the intracellular Aβ1-42 aggregates serve as a nucleus for the further accumulation of additional newly synthesized Aβ peptides. Supported by NIH AG00538 and NS31230.

PERSISTENT ACTIVATION OF MICROGLIA BY LPS INFUSED WITH Aß 1-40 PEPTIDE AND PERLECAN

S.A. Benkovic*, S.A. Fargher, M.N. Gordon, and D.G. Morgan Department of Pharmacology and Therapeutics, University of South Florida, Tampa, FL 33612-4799

Prior studies injecting LPS into rat brain to activate microglia found the inflammatory reaction resolves within two weeks of injection (Andersson et al, 1992). We have investigated the activation of microglial cells in the brain by infusion of LPS into the hippocampus in combination with the Aß 1-40 peptide and the heparan sulfate proteoglycan, perlecan. Fisher 344 rats were cannulated unilaterally in the hippocampus and infused with 200 µl of solution containing 15µg LPS, 250 µg Aß 1-40, and 70 µg perlecan in PBS delivered by an osmotic minipump at a rate of 0.5µl/h for 14 days. At eight weeks following surgery, animals were sacrificed and their brains sectioned and stained with Nissl (ribonucleoprotein particles) or Thioflavin S (amyloid), or immunostained with antibodies against GFAP (astrocytes) or the MHC II marker OX-6 (microglia).

We report a persistent activation of microglial cells following an infusion of LPS, Aß 1-40, and perlecan into the hippocampus. Eight weeks post surgery, brains contained a significantly elevated number of OX-6 immunopositive microglia in rats receiving LPS plus amyloid compared to amyloid alone ($p < 0.05$). The ipsilateral microglial response involved multiple brain regions whereas the contralateral response was confined to the hippocampus. In addition, the area of necrosis produced by the injection was significantly greater in those rats retaining amyloid deposits at the eight week time point. No effects of LPS or residual amyloid on GFAP immunoreactivity were observed. These data suggest that sustained infusion of LPS plus amyloid into the brain results in the persistent activation of microglial cells. Once activated, microglia may phagocytise deposited amyloid concomitantly initiating the neurodegeneration associated with Alzheimer's disease. Supported by the Alzheimer's Association 11RG 93-083 (DGM).

671.11

INTRAHIPPOCAMPAL AMYLOID BETA-PEPTIDE 1-42 INTERFERES TWO WEEKS LATER WITH ONE-TRIAL REWARD LEARNING.

P.G. Negrete, R.E. Plotner*, R.M. Greenwood, W.D. Moon, M. Moroney, P. Olachea, L.R. Rigsby, S. Hajmuhammad, T. Giordano[1] and D.H. Malin. Univ. of Houston-Clear Lake, Houston, Tx 77058 and [1]Symphony Pharmaceut. Inc., Malvern, Pa 19355.

Amyloid beta-peptide 1-42 (Aß) is a major plaque constituent found in Alzheimers Disease (AD). Nine Sprague-Dawley rats received 7 hippocampal microinjections per side of Aß 1-42 (Abbott Labs, 9 nmol per site) in DMSO, while 7 received equivalent injections of Aß 1-42 with a scrambled amino acid sequence in DMSO, and 7 received DMSO alone. After 14 days, all rats were trained on a one-trial discriminative reward learning task using a starburst maze. Retention of this task has previously proved to be sensitive to the effects of aging, cholinergic activity and other Aß fragments. On the retention trial one day later, the Aß 1-42 group had significantly more errors than DMSO controls (Dunnett's Test). The scrambled Aß 1-42 group did not differ significantly from controls. The Aß 1-42 group also had significantly slower speed (reciprocal of latency to reward) than DMSO controls. Again, the scrambled Aß group did not significantly differ from controls. There were no significant differences on the initial training trial. The results suggest that Aß peptides may play a causal role in the memory deficits of AD.

671.12

LEVELS OF ß-AMYLOID AND ß-AMYLOID PRECURSOR PROTEIN IN HUMAN CSF ARE LINKED TO CHOLINESTERASE ACTIVITY.

R.T. Carroll[1]*, K.S. Kim[2], C.A. Parker[1], M.R. Lust[3] and M.R. Emmerling[1]. [1]Neuroscience Therapeutics, Parke-Davis Pharmaceutical Research Division, 2800 Plymouth Road, Ann Arbor, MI 48106-1047. [2]Institute for Basic Research in Developmental Disabilities, 1050 Forest Hill Road, Staten Island, NY 10314-6399. [3]St. Vincent Medical Center, 2213 Cherry Street, Toledo, OH 43608-2691.

We have evaluated 110 human cerebrospinal fluid samples from individuals ranging in age from newborn to 82 years to determine their cholinesterase (ChE) activity, APP and ß/A4 levels. When examined, no age-related change in the average level of either APP or ß-amyloid was observed. However, a significant correlation was observed between ChE and APP content ($p>0.001$) and between ChE and ß-amyloid content ($p<0.001$). Upon closer examination, this correlation was found to be developmentally regulated. In neonates (0-1 month), ChE activity correlated with APP levels ($p<0.001$) but not with ß-amyloid levels. However, in the 1 month to 1 year age group, ChE activity correlated with ß-amyloid content ($p<0.001$) and not with APP. After 1 year of age, a significant correlation was found between ChE activity and APP or ß-amyloid content. This correlation also increased in significance with increasing age. A significant correlation between APP and ß-amyloid ($p<0.001$) was also found in CSF. Again, this relationship was found to be developmentally regulated and only existed in individuals over 25 years of age. The underlying mechanisms explaining the correlations presented here are not clear at this time, however, these data do suggest a link between cholinergic activity and APP processing.

671.13

CHOLINESTERASE ACTIVITIES AND LEVELS OF APP, sAß, AND COMPLEMENT PROTEINS C1q, C3 AND C9 IN CSF FROM NORMAL AND AD PATIENTS.

P.D. Doyle[1], R.T. Carroll[1], J. Jaen[1]*, K.S. Kim[2], H. Wisniewski,[2] T. Wisniewski[3], & M.R. Emmerling[1]. [1]Parke-Davis Pharmaceutical Research, 2800 Plymouth Rd., Ann Arbor, MI 48105. [2]New York State Institute for Basic Research, 1050 Forest Hill Rd, Staten Island, NY 10314, [3]Dept. Neurology, NYU Medical Center, 550 First Avenue, New York, N.Y. 10016.

It has been suggested that certain proteins in the cerebrospinal fluid (CSF) might change as a result of Alzheimer's Disease (AD). We measured several proteins and soluble amyloid peptide (sAß) in CSF samples from non-AD and AD patients. Samples of CSF from AD (21) and non-AD (15) patients had comparable levels of AChE, BuChE, APP, sAß, C1q and C9. Only, the complement protein C3 showed a statistically significant, but modest (40%) increase in AD versus non-AD CSF. A good correaltion existed between the APP and sAß measured in the AD ($R = 0.75$) and in the non-AD ($R = 0.70$) samples. AChE and sAß, and AChE and APP levels in the AD and non-AD samples were also correlated. In the AD samples, sAß and AChE, and APP and AChE had R values of 0.52 and 0.83, respectively. In non-AD samples, the R values for sAß and AChE (0.30) and APP and AChE (0.67) were less than in the AD samples. There was little correlation between the sAß and BuChE levels ($R = 0.19$) and APP and BuChE ($R = 0.18$) in the AD CSF. A better correlation between sAß and BuChE levels ($R = 0.56$) and APP and BuChE ($R = 0.44$) was seen in the non-AD CSF samples. In conclusion, we found little difference in the levels of different proteins and sAß in the CSF from AD and non-AD patients. We observed a good correlation between the levels of sAß, APP and AChE in the AD and non-AD CSF samples. However, there was a poor correlation for sAß and APP with BuChE n the AD samples, but not in the non-AD samples. This may imply that AD causes a disco-ordinated expression of certain proteins in the CSF relative to BuChE, but no major changes in the absolute protein levels.

671.14

CHRONIC BETA-AMYLOID TREATMENT: EFFECTS ON INCORPORATION OF FATTY ACIDS INTO RAT BRAIN.

S.K. Brining* and M. Chang. Lab. Neurosciences, NIA, NIH, Bldg. 10/Rm. 6C-103, Bethesda MD 20892-1582.

The present study evaluated the effects of chronic βA4 (1-40; Bachem, Torrance CA) administration on fatty acid incorporation into rat brain. βA4 was chronically infused intraventricularly via an osmotic mini-pump (Model 2ML1; Alza, Palo Alto CA) for 7-10 days at a concentration of 460 µM. After the infusion, fatty acid metabolism was evaluated using an *in vivo* method developed in this laboratory (Robinson et al., Brain Res. Reviews 17:187, 1992). Three radiolabeled fatty acids including [1-^{14}C]AA (Amersham, Arlington Heights IL; 170 µCi/kg), [1-^{14}C]DHA (Dupont NEN, Boston MA; 110 µCi/kg) and [9,10-^{3}H]PAM (Dupont NEN; 6.7 mCi/kg), reflecting structural and functional cellular roles, were infused i.v. in awake animals. Biochemical and histological analyses showed no effect due to the presence of βA4. However, *in vitro* tests, using the same lot (#445) of βA4, showed that it caused significant cell death in PC-12 cells. Furthermore, βA4 that had been retrieved from the pumps after the *in vivo* infusion was also toxic to PC-12 cells. A finer-grained analysis, using autoradiographic imaging, is underway. In addition, the fate of the βA4 in the rat brain is being examined using Western blotting.

BETA-AMYLOID INHIBITS PROTEOLYSIS OF TAU PROTEINS BY RABBIT RETICULOCYTE LYSATE Ronald S. Black*, Cornell Univ. Med. Coll. at Burke Medical Research Inst., White Plains, NY 10605

Neurodegeneration in Alzheimer's disease is accompanied by the accumulation of insoluble aggregates of tau proteins conjugated to ubiquitin. The DEAE-cellulose binding fraction of rabbit reticulocytes, containing enzymes of the ubiquitin degradation system (Fraction II) was used to conjugate bovine ubiquitin to tau proteins prepared from twice-cycled bovine brain microtubules. In the presence of ATP, an ATP regenerating system, and hemin, which inhibits the breakdown of ubiquitin conjugates, high molecular weight ubiquitin-conjugated tau proteins accumulated. Tau-ubiquitin conjugation did not occur in the absence of ATP. In the absence of hemin, tau-ubiquitin conjugates did not accumulate and the tau proteins were degraded in an ATP- and ubiquitin-dependent fashion. Some tau proteolysis occurred in the absence of ATP; quantitative studies using ^{125}I-labelled tau demonstrated that ATP-dependent proteolysis was 2-3 fold greater than ATP-independent proteolysis in this system. β-amyloid peptides inhibited the ATP-dependent degradation of 125-I labelled tau in the reticulocyte lysate system. Aβ(1-28) was a more potent inhibitor than was Aβ(1-40). The effect of Aβ(1-28) was dose dependent and was half maximal at 5μM peptide concentration. The degree of inhibition (40-70%) was comparable to that of 20 μM hemin. This system may provide an in-vitro model of metabolic processes relevant to the pathogenesis of AD. Supported by the NIA (AG00504)

671.16

β-AMYLOID 25-35 (βA) INDUCED TAU-IMMUNOREACTIVITY FOLLOWING INJECTIONS INTO THE AMYGDALA OF RATS *IN VIVO*. E. M. Sigurdsson*, M. J. Hejna, D. J. Magnuson, J. M. Lee and S. A. Lorens. Depts. Pharmacology and Pathology, Loyola Univ. Chicago Medical Center, Maywood IL 60153.

Alzheimer's disease (AD) is characterized histopathologically by plaques and tangles in several brain regions. To determine if βA induces tau-immunoreactivity (IR) *in vivo*, we injected βA (5.0 nmole) into the right amygdala (AMY) of rats. Control rats received vehicle (VEH) infusions. In the first experiment, βA increased tau-2-IR ipsilaterally in the AMY (βA = 226 ± 95 cells; VEH = 10 ± 7, $p < 0.001$), cingulate cortex (βA = 94 ± 30; VEH = 0, $p = 0.004$) and hippocampus (HIP) (βA = 251 ± 78; VEH = 5 ± 4, $p < 0.001$) of rats sacrificed 8 days postoperatively (PO). In the second experiment, tau-2-IR was increased in the AMY (βA = 721 ± 194; VEH = 48 ± 24, $p = 0.033$) and HIP (βA = 938 ± 84; VEH = 310 ± 161, $p = 0.013$) of rats sacrificed 32 days PO. As with tau-2 the intensity of Alz-50-IR in βA rats was greater at 32 days than 8 days. In the third experiment, immunoblots were performed on the AMY of rats sacrificed 8 days PO. Some were perfused with phosphatase inhibitors (PI), others were decapitated without perfusion. Preliminary results revealed Alz-50-IR bands of similar size in PI-perfused βA and VEH rats. Alz-50-IR bands were virtually absent in non-perfused VEH rats and normal human brain but were observed in non-perfused βA rats and AD brain. Surprisingly, no difference was seen in the density of the bands in left vs right AMY, although βA was only injected into the right AMY. No difference was observed in tau-1-IR between βA and VEH rats. These data suggest that *in vivo* βA time dependently increases tau-IR in the vicinity of the injection site as well as at distant sites, possibly by acting on nerve terminals to cause cytoskeletal alterations in axons and perikarya. Immunoblotting supports the immunohistochemical findings that βA affects the state of phosphorylation of tau proteins, suggesting an association between plaque and tangle formation in AD. The tau-1 blots indicate that βA does not induce changes in the amount of normal tau or in the proportions of its respective isoforms.

671.17

AMYLOID ß PEPTIDE (25-35) INDUCES TAU PHOSPHORYLATION AND DECREASES MICROTUBULE-FORMING ABILITY IN RAT HIPPOCAMPAL CULTURE. A. Takashima*, K. Ishiguro, K. Noguchi, G. Michel, M. Hoshi, K. Sato, M. Takahashi, T. Hoshino, T. Uchida, and K. Imahori. Mitsubishi Kasei Institute of Life Sciences, 11 Minamiooya, Machida-shi, Tokyo 194, Japan

According to the amyloid hypothesis for the pathogenesis of AD, amyloid ß peptide (Aß) directly affects neurons, leading to neurodegeneration and tau phosphorylation, followed by the production of paired helical filament (PHF) in neurofibrillary tangles (NFT). Consistent with this idea, primary cultures of embryonic rat hippocampal neurons undergo progressive degeneration as well as expression of an epitope for phosphorylated tau after exposure to Aß. However, it is unclear whether the tau is phosphorylated at the same sites as PHF-tau, and whether the phosphorylated tau causes destabilization of microtubules in hippocampal culture after treatment with Aß. These are crucial points for understanding the relationship between Aß and phosphorylation of tau in the pathogenesis of AD. To address these points, we analyzed tau phosphorylation in a rat hippocampal culture treated with Aß (25-35). By using antibodies that recognize phosphorylation sites of tau in a phosphorylation-dependent manner, we showed that the tau phosphorylation was enhanced in at least 5 sites. The phosphorylated tau accumulated in the cytoplasmic soluble fraction and showed reduced ability to support microtubule formation, as has been observed with PHF-tau. Thus, Aß exposure could modify tau to a PHF-like state in rat hippocampal culture, suggesting that this culture system may be a useful model for studying the pathogenesis of AD.

BETA-AMYLOID: CELLULAR EFFECTS II

MODIFICATION OF MACROPHAGE INFLAMMATORY RESPONSE BY ALZHEIMER β AMYLOID PEPTIDE.

A. Klegeris, D.G. Walker, E.G. McGeer and P.L. McGeer*. Kinsmen Lab. of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, B.C. Canada, V6T 1Z3.

Brain resident macrophages (microglia) have been found to be closely associated with β amyloid containing plaques in brain tissue affected by Alzheimer's disease. Immunohistochemical data suggest that these cells are activated, thus indicating that inflammatory mechanisms may be involved in the pathogenesis of Alzheimer's disease. We previously reported that activation of rat peritoneal macrophages by β amyloid peptide and its subfragment (25-35) can be readily detected in several assay systems (Klegeris et al. (1994) BBRC, 199, p.984) including respiratory burst induction.

Here we show by cytochrome c reduction that both β amyloid peptide (1-40) and its subfragment (25-35) can induce production of superoxide anion in macrophages. In addition to this short-term (minutes) response a long-term effect can be demonstrated. When macrophages are pretreated with β amyloid peptides for 1.5 hours, and subsequently stimulated with opsonized zymosan or phorbol myristate acetate, the resulting superoxide generation rate is increased significantly compared with cells not so pretreated.

It is well known that such potent macrophage activators as lipopolysaccharide, interferon γ and tumor necrosis factor α can induce (prime) macrophages into a state of enhanced respiratory burst potential. The ability of β amyloid peptides also to increase the responsiveness of macrophages to various stimulating agents, thus enhancing the cytotoxic potential of these cells, could be an important factor in the pathogenesis of slowly progressing neurodegenerative disorders, including Alzheimer's disease.

Supported by a grant from the Jack Brown and Family AD research fund.

672.2

Aβ IMPAIRS ION-MOTIVE ATPase ACTIVITIES: EVIDENCE FOR A ROLE IN LOSS OF NEURONAL Ca^{2+} HOMEOSTASIS AND CELL DEATH. R. J. Mark*[1], K. Hensley[2], D.A. Butterfield[2] and M.P. Mattson[1] [1]Dept. of Anatomy & Neurobiology and Sanders-Brown Center on Aging and [2]Dept. of Chemistry and Center of Membrane Sci, Univ of Kentucky, Lexington, KY 40536.

The amyloid β-peptide (Aβ) that accumulates as insoluble plaques in the brain in Alzheimer's disease (AD) can be directly neurotoxic and can increase neuronal vulnerability to excitotoxic insults. Exposure of cultured rat hippocampal neurons to Aβ1-40 or Aβ25-35 causes a selective reduction in Na^+/K^+-ATPase activity which precedes loss of calcium homeostasis and cell degeneration. Aβ did not impair Na^+/Ca^{2+} exchange. Experiments with ouabain, a specific inhibitor of the Na^+/K^+-ATPase, demonstrated that impairment of this enzyme was sufficient to induce an elevation of $[Ca^{2+}]_i$ and neuronal injury. Impairment of Na^+/K^+-ATPase activity was causally involved in the elevation of $[Ca^{2+}]_i$ and neurotoxicity since suppression of Na^+ influx significantly reduced Aβ- and ouabain-induced $[Ca^{2+}]_i$ elevation and neuronal death. Antioxidants prevented Aβ-induced impairment of Na^+/K^+-ATPase activity, elevation of $[Ca^{2+}]_i$ and neurotoxicity, suggesting a role for free radicals. Impairment of Na^+/K^+-ATPase appears to be mediated through an intracellular pathway, because treatment of partially purified membranes with Aβ failed to impair the pump. Some neurotrophic factors have been shown to protect neurons against Aβ toxicity. We report that bFGF attenuates Aβ-induced peroxide accumulation, impairment of the Na^+/K^+-ATPase, and neurotoxicity. We also found that Aβ impairs both the Na^+/K^+ and plasma membrane Ca^{2+}-ATPases in human synaptosomes, suggesting that impairment of the ion-motive ATPases may play a role in the pathogenesis of AD.

672.3

MODULATION OF INTRACELLULAR ATP BY Aß(1-40) IN RAT CORTICAL NEURONAL CELLS. Z. Zhang, G. J. Drzewiecki, R. E. Rydel#, S. Wright#, P. C. May and P. A. Hyslop*. Dept. CNS Research, Eli Lilly & Co., Lilly Corporate Center, Indianapolis, IN 46285. #Athena Neurociences, 800 Gateway Blvd., So. San Francisco, CA 94080.

Maintenance of intracellular ATP is critical to neuronal survival during sublethal toxic insults induced by a wide variety of mediators generated during inflammation in the CNS in Alzheimer's disease by glial activation and amyloid ß (Aß) accumulation. We sought to determine if exposure of primary cultures of rat cortical neurones to Aß(1-40) depressed intracellular ATP as an early event in the progression of the neurotoxic insult. Intracellular ATP fell in a dose-dependent manner on exposure to Aß. Previous studies from a number of labs have shown that a component of Aß toxicity may involve oxidant generation. We measured dichlorofluorescein (DCF) and dihydroethidium (DE) fluorescence as markers of intracellular H_2O_2 and O_2-. generation respectively in response to Aß. No increase in DE was observed. DCF was significantly increased up to 24 hr. Cell viability was not significantly altered up to 24 hr, but declined after 48-72 hr. The glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) activity is inhibited by exogenously added H_2O_2, but was not inhibited by Aß exposure up to 24 hr. The decline in intracellular ATP is unlikely to result from inhibition of this enzyme by Aß. We are continuing to evaluate the potential role of oxidant stress on cell metabolism and/or signal transduction.

ß-AMYLOID PEPTIDE EXERTS A RAPID INHIBITORY EFFECT UPON A NON-MITOCHONDRIAL NADPH-OXIDASE. J.B. Davis*, S. Parvathy, M.S.G. Clark, G.W. Roberts. Molecular Neuropathology, SmithKline Beecham, Harlow, CM19 5AW, UK.

βA4 is toxic to primary and clonal neuronal cells. The cytotoxic mechanism is unknown, but is associated with an increase in intracellular hydrogen peroxide and an early cellular response involving redox pathways that reduce MTT.

βA4 (0.01-10µM) has no effect upon cellular ATP production in rat neuroblastoma B12 or PC12 cells. Depletion of mitochondria by ethidium bromide pretreatment has no effect upon basal level of MTT reduction, nor upon its modulation by βA4. These data indicate that the redox pathway involved is not the respiratory chain, commonly thought to be the site of MTT reduction. Using respiratory chain and glycolytic inhibitors [rotenone (50nM), antimycin-A (128µM), 2-deoxyglucose (13mM) (DG), iodoacetate (2µM)] we demonstrate that the redox pathway inhibited is dependent upon reducing potential generated via glycolysis, most probably NADPH. Unlike DG, βA4 does not inhibit the generation of this reducing potential, suggesting that the direct or indirect effect of βA4 is to inhibit an oxidase itself.

We conclude that an early effect of βA4 is the inhibition of a non-mitochondrial NADPH-oxidase.

672.5

Depolarization of Mitochondrial Membrane Potential Accompanies ß-amyloid-induced compromise of cellular redox potential. E.J. Hunnicutt*, Jr., J.N. Davis and J.C. Chisholm , Institute for Dementia Research, Bayer Corp., West Haven, CT 06516

Neurotoxicity of the ubiquitous ß-amyloid peptide(s) (βA4), deposited in plaques characteristic of Alzheimer's disease, varies with experimental protocol, even in vitro. Compromise in dehydrogenase activity (redox state), which accompanies treatment with neurotoxic βA4 peptides, occurs rapidly (within 15 min) in a variety of cells, and precedes cell death in cultured rat hippocampal neurons. The redox compromise is associated with dose-dependent alterations in the pattern of cellular deposition of MTT product (insoluble formazan) in each cell. The subcellular distribution of the MTT product appeared to colocalize with a rhodamine mitochondrial dye in untreated cells. Since the βA4-induced alteration occurs in all cells, it suggests that each cell possesses a component of redox which is sensitive to these peptides. We now report that βA4 also produces a rapid depolarization of mitochondrial membrane potential, as measured with the fluorescent ratiometric mitochondrial membrane potential dye, JC-1, using confocal laser microscopy. This mitochondrial depolarization occurs in parallel with the compromise in MTT-reportable redox state. These data support an early mitochondrial involvement in a cellular response to βA4, at concentrations which are selectively toxic to neurons.

672.6

ß-AMYLOID INDUCED CHANGES IN THE RESPIRATORY BURST ACTIVITY OF CULTURED RAT MICROGLIA CELLS

F.L. Van Muiswinkel, B. Drukarch* and P. Eikelenboom. Research Institute Neurosciences Vrije Universiteit, Faculty of Medicine, Dept. of Psychiatry and Neurology*, Van der Boechorststraat 7, 1081 BT Amsterdam, The Netherlands.

Activated microglia, often associated with neuritic amyloid plaques in Alzheimer's disease (AD) brain, are likely to contribute to the progression of the disease process, e.g., by releasing neurotoxic reactive oxygen species (ROS). The mechanisms whereby microglia cells become activated, however, are largely unknown. Therefore, the aim of the present study was to examine the effect of the ß-amyloid peptide (Aß) on the respiratory burst activity of microglia cells. Microglia, isolated from neonatal rat cortices, were cultured for 24h in the presence of synthetic Aß-peptides (Bachem, California) before the respiratory burst activity was studied. Aß-peptides, previously stored at 500µM in ddH_2O at -70°C, were diluted in serum-free culture medium and added to the cultures at a concentration of 1-50µM. Superoxide anion (O_2^-) production was assayed by the (superoxide dismutase inhibitable-) O_2^--mediated reduction of iodonitrotetrazoliumviolet whereas the release of nitric oxide (NO) was determined with the Griess reagent. In Aß1-40 and Aß1-42 pretreated cultures, neither the survival and the spontaneous release of NO and O_2^- nor the LPS-mediated induction of NO production was altered. However, pretreatment for 24h with Aß1-40 (1-10µM), but not Aß1-42, resulted in a statistically significant increase (1.5 to 2 fold) in the phorbol 12-myristate 13-acetate (PMA; 0.01µg/ml) stimulated production of O_2^-. Phase contrast microscopy revealed that particularly those microglia cells located in the close vicinity of Aß fragments were highly responsive. It is concluded that, as far as the production of O_2^- is concerned, Aß1-40 acts as a priming rather than a triggering stimulus on the respiratory burst activity of cultured rat microglia cells under our conditions.

672.7

β-AMYLOID INTERACTS WITH THE INTEGRIN RECEPTOR MAC-1 RESULTING IN NITRIC OXIDE RELEASE FROM CULTURED MICROGLIA. J. Goodwin, C. Martens, and E. Uemura*. Department of Anatomy and Neuroscience Program, Iowa State University, Ames, IA 50011.

While the β-amyloid protein of Alzheimer's disease (AD) has been well characterized biochemically, its primary biological function and mode of action in cells of interest in AD has not been determined. In previous studies, β-amyloid (β25-35 and β1-40) with IFN-γ was shown to trigger nitric oxide release from cultured microglial cells. A potential receptor for this effect is the microglial β2 integrin, Mac-1. We examined the interaction of β-amyloid (β25-35) with Mac-1 by a) performing competitive binding studies between biotinylated β25-35 and FITC-labeled anti-Mac-1 antibodies to Mac-1 using immunofluorescence flow cytometry and b) observing the effects of anti-Mac-1 monoclonal antibodies (Mabs) on the microglial release of nitric oxide. For the competitive binding studies, microglial cells isolated from the hippocampi of P2-4 rats (Holtzman) were exposed to biotinylated β25-35 (R-PE labeled), FITC-labeled anti-Mac-1 Mabs, or β25-35 followed by FITC-labeled anti-Mac-1 Mabs, and analyzed for fluoresence intensity by flow cytometry. For the nitric oxide studies, harvested microglia were plated onto 24-well culture plates (pre-treated with β25-35) in the presence or absence of anti-Mac-1 Mabs, incubated for 72 hours and analyzed for nitrite release. Flow cytometry revealed β-amyloid binding and upregulation of anti-Mac-1 Mab binding to microglial cells. Cultured microglia showed a decrease in β-amyloid/IFN-γ induced NO release when treated with anti-Mac-1 Mabs. Our study suggests an interaction between β-amyloid and the microglial Mac-1 receptor resulting in NO release. Such an interaction may have implications in the neurodegeneration seen in Alzheimer's disease.

672.8

AMYLOID PRECURSOR PROTEIN INHIBITS ASCORBATE INDUCED LIPID PEROXIDATION IN HUMAN CORTEX. A.C. Andorn* and M.A. Pappolla. Dept. of Psychiat., St. Louis Univ. Hlth. Sci. Centr., and St. Louis VAMC, St. Louis, MO (63125) and Dept. of Pathol., Univ. of Texas Hlth. Sci. Centr., Houston, TE (77030).

Amyloid precursor protein (APP) is the progenitor of β-amyloid (βAM) which accumulates in fibrillar form in neuritic plaques and walls of blood vessels in Alzheimer's disease (AD). Lipid peroxidation (LP) is a result of increased oxidative damage which may play a role in the pathogenesis of AD. The interaction between APP and LP was not known. We now report that when ascorbate (0.1 mM) is used to stimulate LP in particulate membrane fragments derived from presumptive normal human prefrontal cortex, APP completely inhibits the stimulated LP. Computer assisted analysis of the merged dose-response data (N=3) showed an IC_{50} of 5.7 x 10^{-6}M. Similar analysis of data obtained using fragments of APP, showed the following IC_{50}: βAM_{25-35} (2.4 x 10^{-5}M), βAM_{1-28} (5.6 x 10^{-5}M) and βAM_{1-40} (1.7 x 10^{-3}M). βAM that had been incubated to produce the neurotoxic equivalent and then used in the experiments generated an IC_{50} of 3.6 x 10^{-5}M. These data suggest that APP and some of its cleavage products can prevent LP at certain concentrations. The physiologic relevance of this finding remains to be determined.

672.9

FREE RADICAL INVOLVEMENT IN ß-AMYLOID TOXICITY. [1]C. Cafè*, [1]C. Torri, [1]L. Bertorelli, [2]N. Angeretti, [2]E. Lucca, [2]G. Forloni, [1]F. Marzatico.
[1] Istituto di Farmacologia, Università di Pavia, Italy
[2] Istituto di Ricerche Farmacologiche "Mario Negri", Milano, Italy

Previous data showed that a synthetic peptide (ß 25-35) homologous to residues 25-35 of ß-protein (Aß) plays a neurotoxic action, inducing cell death by apoptosis.

There is some evidence that oxygen radical reactions play a role in Alzheimer's disease physiopathology. Furthermore oxidative stress has been shown to be able to induce neuronal death by apoptosis. The aim of this work was to investigate whether free radical reactions may play a primary role in neurodegenerative events associated with Aß deposition.

Primary cortical neurons were exposed chronically and acutely to 50 µM ß 25-35: for the acute exposure a solution of the peptide was added to the medium after 7 days of culture and the effect was observed the following day; the chronic treatment consisted of a single exposure for 3 days or repeated treatments every 2 days up to day 7 in culture.

The following parameters were evaluated: antioxidant enzymes superoxide dismutase and glutathione peroxidase, lipid peroxidation products (TBARS) and intracellular reactive oxygen species production, using a fluorescent probe, dichlorofluorescin diacetate.

ß 25-35 treatment induced a marked increase of superoxide dismutase activity only after acute exposure, while it had no effect during chronic treatment. Glutathione peroxidase showed changes only following chronic treatment. Lipid peroxidation index was unaffected during chronic treatment, while the acute exposure of neurons to ß 25-35 showed a paradoxical protective effect, being lipid peroxidation product level significantly higher in the control neurons. ROS production, measured fluorimetrically, was markedly enhanced in both chronically and acutely exposed neurons.

In conclusion, our results suggest that oxidative stress and free radical production are somehow linked to the peptide presence, and, may be, to its neurotoxicity.

672.10

POSSIBLE MECHANISMS OF APOPTOSIS INDUCED BY EXPRESSION OF MUTANT AMYLOID PRECURSOR PROTEIN IN PC12 CELLS B. Zhao[(1)]*, S. S. Sisodia[(2)], and J. W. Kusiak[(1)]. Molecular Neurobiology Unit, GRC/NIA/NIH, Baltimore, MD 21224[(1)]; Department of Pathology, Johns Hopkins University, Baltimore, MD 21205[(2)].

Mutations found in the amyloid precursor protein (APP) gene of certain familial Alzheimer's disease (AD) pedigrees provide general mechanistic implications for the disease, suggesting a crucial role for altered APP processing in developing neuropathology of AD. Several groups reported extracellular neurotoxicity of fibrillar amyloid β-peptides (Aβ). Recent evidence indicated that apoptosis is associated with AD and oxidative stress can initiate apoptosis in neurons. We previously reported increased apoptosis in PC12 cells stably transfected with constructs harboring mutant APP genes (APP692, APP693, APP717F). The present studies further investigated possible molecular and cellular mechanism(s) of mutant APP induced apoptosis in these cell lines. By Western blot analysis we showed an increased level of large carboxyl terminal fragments (CTFs) of APP within the cells expressing mutant APPs. We did not observe an increased level of Aβ by immunoprecipitation in conditioned medium from the cells expressing mutant APPs. Treatment of untransfected parental PC12 cells with conditioned medium from mutant APP transfectants did not enhance apoptosis as measured by flow cytometric analysis. When N-acetylcysteine (NAC, 25mM), a thiol antioxidant, was added to mutant cell lines prior to, but not after, the initiation of apoptosis, DNA laddering was inhibited in APP692 transfected cells. However, NAC showed no effects on apoptosis in APP717 transfected cells. These data suggest that the potentially amyloidogenic CTFs generated from mutant APPs may have neurotoxic effects on the cells intracellularly. Oxidative stress seems to be one of the mediators leading to apoptosis induced by mutant APPs, which in turn may contribute to the neuronal loss in AD.

672.11

EVIDENCE FOR DNA DAMAGE, BUT NOT APOPTOSIS, IN ALZHEIMER'S DISEASED (AD) BRAIN. L.S. Perlmutter*, A.F. Bushnell, Y.-P. Li, S. Webster, S. Wong. Institute for Dementia Research, Bayer Corp, West Haven, CT 06516.

While controversial, recent work suggests that ßA4-mediated neurotoxicity may operate via an apoptotic pathway in cultured cells. Also, a transgenic mouse line overexpressing intraneuronal ßA4 exhibits staining of neuronal nuclei with a kit designed to label the nicked ends of DNA. The present study used one such kit (Apoptag, Oncor) to label autopsy samples from AD (n = 5) and non-AD (n = 5) brains to determine the physiological relevance of apoptosis to AD Fixed samples from hippocampus, cerebellum, and Brodmann's areas (BA) 22 and 17 were vibratome-sectioned and labeled free-floating. A subset were prepared for electron microscopy. Some sections were double-labeled with thioflavine S, or immunocytochemically for ßA4 (4G8) or PHF- tau (AT8). In addition, frozen brain samples taken from an adjacent region of BA 17 (the area with the most Apoptag staining) were examined for DNA laddering.

While many more stained nuclei were evident in all AD brain regions examined as compared to non-AD, the location of labeled cells (which were overwhelmingly neurons) did not correlate with either the pattern of AD-associated neuronal loss or with the presence of AD hallmark lesions (ß-amyloid plaques, neurofibrillary tangles). At the ultrastructural level, no clear apoptotic bodies or cells with pyknotic nuclei were observed; labeled nuclei did not differ in any apparent morphologic way from unlabeled nuclei. Finally, DNA laddering was not seen in any sample from AD brain; one non-AD sample exhibited laddering that was not correlated with Apoptag staining in the fixed section. These data indicate that the AD pathogenetic process may involve fragmented or nicked DNA, but provide no evidence thus far that apoptosis is the mechanism involved.

672.12

β AMYLOID-INDUCED NEURONAL DEATH IN MURINE CORTICAL CULTURES: ATTENUATION BY PHORBOL ESTER OR HIGH K^+. J. Koh*, M. I. Behrens, S. L. Sensi, L. M. T. Canzoniero, B. J. Gwag and D. W. Choi. Dept. of Neurology and Center for the Study of Nervous System Injury, Washington Univ. School of Medicine, St. Louis, MO 63110

Aggregated β amyloid peptides induce neuronal death in cultures. Although the mechanism of this death is still unknown, proposed possibilities include i) formation of Ca^{2+} ionophores; ii) destabilization of Ca^{2+} homeostasis; and iii) generation of free radicals.

Murine cortical cell cultures exposed to 10-40 µM synthetic β amyloid (β1-42; obtained from K-biologicals) developed concentration-dependent, gradually occurring neuronal death, partly blockable by the protein synthesis inhibitor, cycloheximide. This β1-42-induced neuronal death was not associated with an increase in neuronal $[Ca^{2+}]_i$, measured at 12 and 24 hr after exposure onset. Indeed, it was potentiated by lowering extracellular Ca^{2+}, or variably by addition of glutamate antagonists (10 µM MK-801 or 50 µM CNQX), or 20 µM nimodipine. Furthermore addition of the phorbol ester PKC activator, 10 nM PMA, or 30 mM K^+, reduced β1-42-induced neuronal death. Addition of trolox, superoxide dismutase/catalase, or N-arginine, did not attenuate the β1-42 neurotoxicity.

These data are consistent with an idea that β1-42-induced neuronal death may occur at least in part via mechanisms involving intracellular Ca^{2+} insufficiency and new macromolecule synthesis, and fit with other data suggesting that this death may involve apoptosis (Loo et al., PNAS, 90:7951, 1993).

672.13

COMPARISON OF ALTERED GENE EXPRESSION DURING NEURONAL DEATH INDUCED BY NGF WITHDRAWAL, AMYLOID ß-PROTEIN TREATMENT, OR GLUCOSE DEPRIVATION. S. Estus#*, C. van Rooyen#, M. Mattson‡, E.F. Brigham§, and R.E. Rydel§. Depts. of Physiology#, Neurobiology and Anatomy‡, Sanders-Brown Center, University of Kentucky, Lexington, KY 40536, and Athena Neuroscience, Inc.§, South San Francisco, CA 94080.

We previously identified a pattern of gene expression that accompanies the neuronal apoptosis of rat sympathetic neurons induced by NGF deprivation. This temporal cascade begins with transcription factors such as *c-jun* and *c-myb*, followed by *c-fos*, *fos B*, *NGFI-A*, and *rhl*, and then two extracellular matrix proteases regulated by c-Jun and c-Fos, i.e., *transin-1* and *collagenase*. Moreover, neutralizing antibodies against the Jun family, the Fos family, or c-Jun specifically, blocked apoptosis, indicating that these gene products are necessary for apoptosis. To examine whether this genetic cascade occurs in other *in vitro* models of neuronal death, we have examined rat cortical neurons (i) treated with the Alzheimer amyloid ß-protein (Aß) or (ii) subjected to glucose deprivation. When neurons were treated with 20 µM Aß, we observed robust inductions of *c-jun*, beginning at 12 hours, followed by *c-fos* and *fos B*, beginning at 24 hours, with death (LDH release) beginning at 48 hours. Similar genetic changes were not observed after glucose deprivation. In future experimentation, we shall confirm and extend these findings. The present results suggest that the induction of *c-jun* and *c-fos* may be specific to certain types of neuronal death.

BIOLOGICAL EFFECTS OF NON-FIBRILLOGENIC β-AMYLOID AND PRP PEPTIDES. G. Forloni*, E.Lucca, N. Angeretti, L. De Gioia, L.Diomede, O.Bugiani°, F.Tagliavini° and M.Salmona, Istituto di Ricerche Farmacologiche Mario Negri, °Istituto Neurologico Besta, Milano Italy.

Cerebral amyloid-β protein deposits is a major pathological feature of Alzheimer's disease. Also in spongiform encephalopathies (SE), altered form of prion protein (PrP) aggregates in amyloid fibrils and accumulates in the brain of affected individuals. Synthetic peptides homologous to β25-35 and to PrP 106-126 fragment induced neuronal death by apoptosis *in vitro*. Furthermore, accordingly with pathological features of SE, chronic treatment with PrP 106-126 increased the proliferation rate and GFAP expression in astrocytes β 25-35 and PrP 106-126 fragments have a β-sheet structure and exhibit self-aggregation properties. Since the neurotoxicity of these peptides has been associated with their fibrillogenic activity, we synthesized amidated homologous, β 25-35-NH2 and PrP106-126-NH2, to obtain peptides with low level of amyloidogenic activity and directly test the relationship between amyloid fibrils and neuronal death or astroglial proliferation. The β-sheet conformation and the self-aggregation activity of both amidated peptides were strongly reduced as determined by circular dichroism spectroscopy analysis and electron microscopy examination. Rat hippocampal neuronal cells were chronically exposed to both amidated peptides (25-100 µM). β25-35-NH 2 compared to β 25-35 reduced its neurotoxic activity, while the neuronal cell death induced by PrP106-126-NH2 was similar to that observed by exposure to unmodified peptide. In contrast, rat astrocytes chronically exposed to PrP106-126-NH2 (25-100 µM) did not alter their proliferation rate and GFAP expression compared to control condition was unchanged. Thus, astrogliosis induced by PrP 106-126 appear associated with self-aggregation activity while toxic effect, unlike β 25-35, was independent of the peptide amyloidogenic activity.

ANALYSIS OF TRANSCRIPTIONAL CHANGES IN RESPONSE TO ß-AMYLOID INDUCED NEUROTOXICITY. T. Sunderland*, J. W. Kusiak and B. Wolozin. Section on Geriatric Psychiatry, NIMH and Molecular Neurobiology Unit, NIA, Bethesda, MD 20892.

Recent studies have shown that specific transcripts, including Jun and Fos, are upregulated during neuronal apoptosis (Freeman, et al, Neuron 12: 343-355, 1994). We have now analyzed changes in gene expression occurring during ß-amyloid (aß)-induced cell death in order to better understand the mechanism of action of aggregated aß. Cortical neurons from E18 rats were grown in culture for 10 days, transferred to serum free medium and then treated with 10 µM aged $aß_{1-42}$ for 1-72 hrs. The RNA was harvested and transcriptional changes were analyzed by semi-quantitative PCR. Several transcripts examined, including G3PDH, NGF-IA and p53, showed no changes during the course of treatment with aß. Two transcripts, Fos and Bcl X showed rapid and persistent elevation evident 4 hrs after application of aß. The levels of Jun, Bax and cyclin D1 also increased, but over a slower time course, being evident 10 - 24 hrs after treatment with aß. The levels of Bcl2 increased from 4 - 10 hrs after application of aß, but then declined as the levels of Bax increased. Such reciprocal expression of Bcl2 and Bax has been observed in other systems as well. The patterns of gene expression induced in response to aggregated aß resemble that seen during neuronal apoptosis in response to growth factor withdrawal, and set the basis of an understanding of aß-induced cell death on a molecular level.

672.16

GENERATION OF AMYLOIDOGENIC ALZHEIMER'S AMYLOID PRECURSOR PROTEIN FRAGMENTS DURING H_2O_2 INDUCED APOPTOSIS IN HUMAN NEURONAL CELLS

L. Zhang*[1], J.W. Kusiak[2], B. Zhao[2] and G. S. Roth[1] [1]Molecular Physiology & Genetics Section, Lab. of Cellular & Molecular Biology, [2]Molecular Neurobiology Unit, Lab. of Biological Chemistry, NIA/NIH, Baltimore, MD21224

A number of groups have reported apoptotic cells in Alzheimer's brain. This suggests a role for neuronal programmed cell death (apoptosis) in the development of Alzheimer's disease (AD). To explore how apoptosis may relate to AD pathophysiology, we studied the processing of amyloid precursor protein (APP) during H_2O_2 induced apoptosis in cultured human neuroblastoma cells. We found increases in amyloidogenic fragments of 12 and 16 kDa both prior to and after apparent induction of neuronal programmed cell death which was indicated by DNA laddering. The level of full length APP was dependent on the concentration of H_2O_2 used. We conclude that a neuronal apoptotic process may generate fragments containing intact βA4 peptide which is neurotoxic. Since βA4 has been recently shown to induce apoptosis, we further hypothesize that amyloidogenic fragments may induce a cycle of apoptosis which generates additional toxic fragments and such a vicious cycle may contribute to the neuronal loss during AD development.

ALZHEIMER'S DISEASE: MECHANISMS OF DEGENERATION I

673.1

DISTRIBUTION OF IL-1α-IMMUNOREACTIVE CELLS IN CORTICAL LAYERS: IMPLICATIONS FOR β-AMYLOID PRECURSOR PROTEIN-IMMUNOREACTIVE PLAQUE FORMATION. J.G. Sheng,* R.E. Mrak, and W.S.T. Griffin. Ark. Children's Hosp. Res. Inst., Dept. of Veteran's Affairs Med. Ctr., Univ. Ark. Med. Sci., Little Rock, AR 72202.

The cytokine interleukin-1 (IL-1) is a potent neurotrophic factor that is present in elevated levels in brain of Alzheimer disease. IL-1 induces excessive expression of β-amyloid precursor protein (β-APP), suggesting that IL-1 is an important pathogenic factor in plaque evolution. We used computer image analysis to determine the number, size, and immunoreactive intensity of IL-1α immunoreactive ($IL\text{-}1\alpha^+$) microglia in temporal lobe of 9 Alzheimer and 4 control patients. The number of $IL\text{-}1\alpha^+$ microglia and the average $IL\text{-}1\alpha^+$ cell soma area in cortical layers 1 and 2 were similar in Alzheimer and control patients. In contrast, in layers 3 through 6, the number of $IL\text{-}1\alpha^+$ microglia in Alzheimer's disease was significantly elevated when compared to controls (3.5-fold in layer 3 and 2-fold in layers 4, 5, and 6), as was and the IL-1α immunoreactive content of microglia (2-fold higher in layers 3, 4, and 5; and 1.2-fold higher in layer 6; $p < 0.05$). The distribution of $\beta\text{-APP}^+$ plaques in cerebral layers correlated with that of $IL\text{-}1\alpha^+$ microglia ($R = 0.99$; $P < 0.005$), as did the total immunoreactive area of these $\beta\text{-APP}^+$ plaques ($R = 0.95$; $P < 0.05$). This topographical correlation between microglial IL-1α and neuritic β-APP overexpression supports a role for IL-1 in induction of β-APP overexpression and promotion of dystrophic neurite formation in Alzheimer's disease, and thus in the evolution of diffuse amyloid deposits into neuritic β-amyloid plaques. Supported in part by NS27414, AG10208, and AG12411.

C1q IN ALZHEIMER'S DISEASE CORRELATES TO SEVERITY OF DEMENTIA AND COLOCALIZES TO MATURE PLAQUES AND NEURONS. N.C. Berchtold, B.J. Cummings, D.C. Cribbs, R. Shankle, D. McCleary, A. Afagh, J. Ulas*, A.J. Tenner, C.C. Cotman. *Institute for Brain Aging and Dementia, University of Irvine, CA 92717-4550 USA*

Numerous studies have implicated the immune system as contributing to the neuropathology present in Alzheimer's disease (AD) (See McGear et al., 1994, Eikelenbloom et al., 1994 for reviews). In particular, activation of the complement system is suspected of constituting a significant factor in AD progression. Aß is known to bind C1q. We have previously reported that levels of C1q are decreased in cerebrospinal fluid (CSF) of Alzheimer's patients, suggesting increased binding of complement proteins in the AD brain. We have expanded on this study to include a larger sample size, across a broader range of dementia scores. Further, we have increased the number of control cases. We confirmed the previous findings and report that CSF C1q levels correlate with the degree of dementia of the AD individuals. We have also investigated the localization of this inflammatory marker in brain tissue with immunohistochemical double and triple labeling techniques. Using affinity purified anti-C1q and anti ß1-42, and counter staining for ß-structure with thioflavine-S, we find that C1q colocalizes with later stage plaques, but rarely with diffuse plaques. Furthermore, numerous neurons in AD brain stained immunopositive for C1q, while minimal labeling was observed in control brain tissue. Interestingly, most C1q positive neurons were neither AT8 positive, nor PHF-1 positive. However, extracellular PHF-1 positive NFT's were C1q positive. These results implicate a complement mediated inflammatory process as an early selective event in injured or stressed neurons, in AD.

673.3

EXPRESSION OF COMPLEMENT INHIBITORS C1 INHIBITOR AND PROTECTIN (CD59) BY HUMAN NEURONS DERIVED FROM NTERA2 TERATOCARCINOMA CELLS. D.G. Walker*, J. Xiao, E.G. McGeer and P.L. McGeer. Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, B.C. Canada, V6T1Z3.

Studies of brains from Alzheimer Disease (AD) cases have shown evidence of inflammatory changes in affected tissue, as demonstrated by the presence of reactive microglia and complement proteins of the classical pathway. Activation of the complement system in brains of AD patients may be leading to the death of healthy neurons (bystander lysis). Immunohistochemical studies from this laboratory have indicated that neurons may have the ability to express certain proteins that can inhibit different stages of the complement cascade.

To explore further the potential expression by neurons of complement cascade inhibitory molecules, pure cultures of cells with the characteristics of post-mitotic human neurons were prepared from the NTERA2 teratocarcinoma cell line. Following retinoic acid treatment, purified cells were prepared for gene expression studies by short term culture in serum-free media. Cells were stimulated with ψ interferon, interleukin 1β or phorbol myristate acetate. Using the reverse transcription-polymerase chain reaction (RT-PCR) technique, C1 inhibitor gene expression was detected in a number of independent preparations of neuronal cells. C1 inhibitor expression was low or absent in unstimulated neurons, and was greatly increased by treatment of cells with ψ interferon. Protectin gene expression was detected in these cells by RT-PCR, by immunoblot analysis and by immunocytochemistry. In contrast to C1 inhibitor, protectin expression was not increased by ψ interferon stimulation. These results indicate that human neurons can express crucial complement inhibitory proteins. Understanding how these proteins can be regulated may lead to potential therapeutic strategies for affecting the progression of neurodegenerative diseases like AD.

Supported by a grant from the Jack Brown and Family AD research fund.

INFLAMMATORY MECHANISMS OF NEURODEGENERATION. THE ROLE OF THE COMPLEMENT DERIVED ANAPHYLATOXIN C5a. G. Tocco[1]*, W. Musleh[1], and G.M. Pasinetti[2]. [1]Division of Neuroscience, Hedco Neuroscience Program, USC, Los Angeles, CA 90089; [2]Division of Neurogerontology, Andrus Gerontology Center, USC, Los Angeles, CA 90089

This study addresses the role of the proinflammatory anaphylatoxin C5a in mechanisms of hippocampal neurodegeneration. We found that the pyramidal neurons in the CA3 sub-region of the hippocampal formation in congenic mice genetically deficient in complement component C5 ($C5^-$) are more susceptible to glutamate mediated neurodegeneration, relative to C5-sufficient mice ($C5^+$). Moreover, the C5 derived anaphylatoxin C5a (human recombinant) was shown to diminish glutamate-mediated neurotoxicity in vivo. Therefore, the pro-inflammatory anaphylatoxin C5a might also be a neuroprotectant. Potential mechanisms include regulation of glutamate receptors and local control of cytokine expression that may influence hippocampal responses to lesions. We found that $C5^-$ congenic mice show selective impairment of Ca^{++} dependent regulation of glutamate AMPA receptors in CA1/CA3 pyramidal neurons during response to hippocampal lesions and found that hippocampal astrocytes cultured from $C5^-$ mice have hypersecretion of the cytokines IL-6 and TNF. These data are consistent with our findings showing C5a receptor (C5aR) expression in CA1/CA3 pyramidal neurons and astrocytes of the mouse hippocampal formation. This study may lead to a better understanding of complement-mediated pathophysiology in Alzheimer disease and other neurodegenerative diseases which involve excitatory AA pathways. Ongoing studies using a C5aR knockout mouse model will clarify the role of the pro-inflammatory anaphylatoxin C5a in brain. This work was supported by the Nathan W. & Margaret T. Shock Aging Research Foundation to GMP.

COEXISTENCE OF ALZHEIMER'S DISEASE WITH HERPES VIRUS ENCEPHALITIS. P. Staub, J. Colmer, F. Denaro and D. Freed*, Texas Tech University HSC, Lubbock, TX 79430

At present there are no treatments for Alzheimer's disease but diagnostic techniques have progressed using peripheral markers and clinical tests. Problems in treatment or diagnoses can arise if Alzheimer's disease is present with other conditions that cause dementia, such as herpes virus encephalitis. In the present report we examine both the clinical progression of dementia and the histological picture of herpes virus superimposed on Alzheimer's disease. Several important points were noted: The mental status of Alzheimer's patients should be evaluated at routine intervals. If a sudden change in mental status occurs, evaluation of other medical conditions should be performed. With the advent of PCR, viral testing may be more easily done and antiviral treatment initiated if needed. Examination of the brain of this Alzheimer's patient revealed viral infection using EM, immunocytochemistry and *in situ* hybridization. In addition, the histological picture of AD was superimposed in some of the infected areas. NS31875

MERCURY VAPOR INHALATION INHIBITS BINDING OF GTP TO TUBULIN IN RAT BRAIN: A MOLECULAR LESION PRESENT IN ALZHEIMER BRAIN. F.L. Lorscheider, M.J. Vimy, J.C. Pendergrass and B.E. Haley*. Univ. of Calgary Fac. of Med., Calgary, AB T2N 4N1 CAN and Univ. of Kentucky Col. of Pharm., Lexington, KY 40536 USA.

Hg^{2+} interacts with tubulin and disassembles microtubules that maintain neurite structure. Hg vapor (Hg^0) is also continuously released from "silver" amalgam tooth fillings and is absorbed into brain (FASEB J. 9: 504-508, 1995). In the present study rats were exposed to Hg^0 4 h/day for 0,2,7,14 and 28 d at 250 μg Hg/m^3 air, a concentration present in mouth air of some humans with many amalgam fillings. Average rat brain Hg concentrations increased significantly (11-47 fold) with duration of Hg^0 exposure. By 14 d Hg^0 exposure, photoaffinity labelling of the ß-subunit of the tubulin dimer with [α^{32}P]8N_3GTP in brain homogenates was decreased 75%, upon analysis of SDS-PAGE autoradiograms. The identical neurochemical lesion of similar magnitude is evident in most Alzheimer brain homogenates when compared to human age-matched controls. Since the rate of tubulin polymerization is dependent upon binding of GTP to tubulin dimers, we conclude that chronic inhalation of low-level Hg^0 can inhibit polymerization of tubulin essential for formation of microtubules.

I "AN INHIBITOR OF THE 20S PROTEASOME INDUCES A STRESS RESPONSE IN A MOUSE NEURONAL CELL LINE, MANIFESTED BY ACCUMULATION OF UBIQUITINYLATED PROTEINS AND OF THE INDUCIBLE FORM OF HSP70." Maria E. Figueiredo-Pereira*, Sophie Kurdziel & Ronald P. Magnusson, Dept. of Pharmacology, Mount Sinai School of Medicine of CUNY, N.Y., N.Y. 10021.

Ubiquitin-protein conjugates are commonly detected in neuronal brain inclusions of patients with neurodegenerative diseases suggesting that a common molecular response involving ubiquitinylated proteins occurs in chronically degenerating neurons. The ubiquitin/ATP-dependent proteolytic system (26S proteasome) plays a major role in the removal of short lived, abnormal and denatured proteins. The catalytic core of the 26S proteasome is the multicatalytic proteinase complex (MPC) or 20S proteasome. Recently, we showed that exposure of HT4 cells (a mouse neuronal cell line) for 3 hours to 25 μM of a new potent permeable peptidyl aldehyde inhibitor of MPC [Z-IE(OtBu)AL-CHO] induced the accumulation of ubiquitinylated proteins. We now show that overnight incubations with concentrations of the same MPC-inhibitor as low as 0.25 μM also produce accumulation of ubiquitinylated proteins. The ladder-like pattern and increased intensity of the immunostaining observed in Western blots of total cells extracts probed with an antibody against ubiquitin-protein conjugates depicts an increase in the accumulation of ubiquitinylated proteins as compared with that observed after shorter (3h) incubations. Overnight incubations with the same concentrations of a calpain inhibitor (Z-LL-CHO) produced no accumulation of ubiquitin-protein conjugates. Furthermore, overnight incubations with the MPC-inhibitor but not with the calpain inhibitor, led to accumulation of the inducible form of the heat shock protein HSP70i in HT4 cells. Northern blots showed that there was a concentration dependent increase in HSP70i mRNA concomitant with the increase in protein expression detected by Western blots probed with a specific antibody for HSP70i. These results suggest that malfunction of the 26S proteasome resulting from a decrease in MPC activity, induces a stress response in the neuronal cells, accumulation of ubiquitinylated proteins, and ultimately may lead to neuronal death. This mechanism may be involved in the etiology of neurodegenerative diseases. (Supported by NIH grant NS29936).

• CULTURE OF ADULT RAT NEURONS AND THEIR AGE-DEPENDENT GLUTAMATE AND LACTATE TOXICITY. • P.J. Price[1]* and G.J. Brewer[2]. [1]GIBCO/Life Technologies, Grand Island, NY 14072 and [2]Southern Illinois University School of Medicine, Springfield, IL 62794.

• If neurons could be isolated and cultured from adult brain tissue, numerous studies on genetic regulation, development, grafting and aging could be conducted. Cultures can also provide a uniform environment to test for age-related changes or other genetic differences. Here, we describe techniques for the culture of hippocampal neurons from any age rat and apply this capability to determine whether neurons from aged rats are more susceptible to stressors such as glutamate excitotoxicity and lactate acidosis. By dissection of the hippocampus from rats from 0 to 24 months old, we have isolated by digestion with papain and separation on a density gradient an average of 500,000 neuron-like cells per brain (n=17). By linear regression, there was no significant effect of age on the cell yield. By staining with antibodies to neurofilament, greater than 70% of these cells are neuron-like and less than 30% are like glia, staining with GFAP. In three experiments, we compared hippocampal neuron viability from young (3 or 4 months) to old (19 or 24 months) rats after 4 days in culture. In our serum-free B27 in Neurobasal without fibroblast growth factor 2 (FGF), viability was 12% for neurons from young rats and 19% from old rats. The difference is not significant. In the presence of FGF, viability increased to 20 to 60% at 4 days in culture. Good survival continued for at least 3 weeks. Removal of FGF and exposure to lactic acid (1 to 3 mg/ml) for 24 hrs indicated that neurons from a 24 month old rat were significantly more susceptible to acidosis than those from a 3 month old rat. Similar studies with 24 hr treatment with glutamate (50 to 200 µM) resulted in substantial excitotoxicity for neurons from old rats compared to little effect on neurons from young rats in culture. This is the first time aged rat neurons have been cultured for extended periods and shown to exhibit increased sensitivity to stress. These techniques should facilitate studies of the age-dependence of Alzheimer's disease.

673.9

NEURODEGENERATION IN THE SEPTO-HIPPOCAMPAL SYSTEM: EFFECT OF SEPTAL QUINOLINIC ACID INJECTIONS. J.D. Brioni *, A.B. O'Neill and S.J. Morgan. Neuroscience Discovery and Pathology Department, Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, IL 60064-3500.

In many neurological and neurodegenerative disorders, neuronal death can result from the excessive release of endogenous excitatory amino acids like glutamate. As excitotoxicity may constitute a final common pathway for neuronal injury and death, we investigated the dynamics of the toxic effect of another endogenous substance, quinolinic acid, after its injection in the medial septum/diagonal band area (MS/DB) of Long-Evans male rats.

Quinolinic acid (60, 180 and 600 nmoles in 0.5 µl) was injected into the MS/DB area, and histological, biochemical as well as behavioral studies were conducted starting 3 days after the injections. Groups of radiofrequency-lesioned (RF) rats were also included for comparison. Histological evaluation after hematoxylin-eosin staining of paraffin-embedded sections revealed a differential degree of necrosis, glial proliferation and cyst formation in the MS/DB area. The loss of pyramidal neurons in the hippocampus was present only in quinolinic-injected animals and appeared to be time-dependent and dosage dependent. In the behavioral studies, quinolinic acid induced a dose-related ataxia and disinhibition to aversive stimuli in the elevated plus-maze model of anxiety. In the water maze test, an impairment in the processing of spatial information was present without any effect on cue learning. Hippocampal ChAT activity was significantly reduced only in RF-lesioned rats. The neurodegenerative process induced by quinolinic acid injections in the MS/DB area indicate the sensitivity of the septo-hippocampal neurons to this endogenous excitotoxin as demonstrated by histological and behavioral parameters.

673.10

EFFECTS OF A BILATERAL NEUROTOXIC LESION OF THE RHINAL CORTEX ON CEREBRAL GLUCOSE UTILIZATION (CMRglc) IN BABOONS: A PET STUDY. K. Meguro, C. Chavoix, X. Blaizot, C. Le Mestric, F. Hansen, E.T. MacKenzie* and J.C. Baron. INSERM U320, CNRS URA 1829, Centre Cyceron, University of Caen, BP 5229, 14074 Caen, France.

Alterations in the rhinal cortex may play a crucial role in Alzheimer's disease (AD). In AD, the entorhinal cortex (ERh) is, with the hippocampus, the area most affected by neurofibrillary tangles while the cerebral metabolic rate for glucose is most reduced in temporo-parietal associative cortices; these two features are markers for the severity of dementia. Furthermore, combined ablations of ERh and perirhinal cortex (PRh) in macaques leads to a severe declarative memory deficit. To assess the relationships between rhinal alterations and cortical hypometabolism, we studied the effects of stereotaxic ibotenic acid lesions of ERh and PRh on CMRglc in *Papio anubis* baboons. Magnetic resonance imaging (MRI) was used to 1) pre-operatively locate the target sites (n=21-22 per side, 1/2 in each rhinal area), 2) post-operatively confirm the lesion location, 3) determine internal brain landmarks for PET positioning, and 4) identify brain structures for CMRglc measurements. Coronal PET coregistered with MRI was performed under phencyclidine-$N_2$0, once before and 3-4 times after surgery (at days 10-20, 25-32, 39-50, and 74-107). In contrast to sham-operated baboons (n=2), there was a stable and diffuse post-operative decline (10 to 30%) in CMRglc following Rh lesion (n=4). The areas most affected were not only the hippocampus but also the temporal, occipital associative and insular cortices, consistent with the known anatomical connections of the rhinal areas. Declines in CMRglc more or less important than expected (e.g. in basal ganglia and cingulate, respectively) also occured. These preliminary results suggest that severe rhinal neuronal loss (histologically confirmed in two baboons) induces a long-lasting effect on brain metabolism. Relationships between these metabolic effects and memory performance are currently being investigated.

673.11

NON-Aβ COMPONENT OF ALZHEIMER'S DISEASE AMYLOID (NAC) IS AMYLOIDOGENIC. A. Iwai*, M. Yoshimoto, E. Masliah and T. Saitoh. Department of Neurosciences 0624, University of California at San Diego, La Jolla, CA92093-0624

The non-Aβ component of Alzheimer's disease (AD) amyloid (NAC) was identified biochemically as the second major component in the amyloid purified from brain tissue of AD patients. NAC, derived from its 140-amino-acid long precursor, NACP, is at least 35 amino acids long (NAC35) although its amino terminus is not definitely determined. An affinity-purified anti-NAC-X1 antibody against the amino-terminal 9-amino acid sequence of NAC35 immunostained amyloid in AD brain sections and recognized NAC35 but not NACP on Western or dot blot. In aqueous solutions, synthetic NAC35 self-aggregated in a time-, concentration-, and temperature-dependent manner. NAC35 was detected initially as a monomer with a molecular mass of 3500 Da, but became aggregated as a function of time into a higher molecular mass component that could not migrate into the gel. The aggregate of NAC35 showed green-gold birefringence after Congo-red staining when analyzed under polarized light and a fiber-like structure when analyzed ultrastructurally. These results suggest that NAC can form amyloid after it has been cleaved out of its precursor and may be a crucial factor in amyloidosis in the brain. This work has been funded by Alzheimer's Disease Research, a program of the American Health Assistance Foundation, NIH grant AG05131, and was supported by Yamanouchi Pharmaceutical Co., Ltd.

673.12

IDENTIFICATION OF THE DINUCLEOTIDE REPEAT POLYMORPHIC SEQUENCE IN THE NACP GENE. Y. Xia, H.A.R. de Silva, A. Roses, X. Chen, E. Masliah, R. De Teresa, M. Sundsmo, D. Galasko, L. Hansen, R. Katzman, L. Thal, J.M. Roch*, and T. Saitoh Dept. of Neuro-sciences, Sch. of Med., Univ of CA, San Diego, La Jolla CA 92093.

Previous studies have shown the presence of a NAC peptide in amyloid preparations from patients with Alzheimer's disease (AD). We cloned its precursor, NACP, and identified that NACP is the synaptic protein loosely bound to presynaptic vesicles. In the current study, we identified a dinucleotide repeat microsatellite in the NACP gene and its polymorphism. The microsatellite found in a NACP intron contains four clusters of the dinucleotide repeat (CT)10N5(CT)8C(AT)7(AC)12. Amplification of this region of DNA identified five different polymorphisms in Caucasians. Uneven distribution of NACP allele 2 was found among various domestic groups. One-quarter of healthy APOE ε4 carriers have NACP allele 2 whereas only 10% of AD individuals have this allele. We also quantified the NACP protein using Western blots. The result demonstrates that the concentration of NACP is higher by 80% in individuals with NACP allele 2 in AD victims. The higher levels of NACP might indicate that these individuals have higher levels of synaptic reserve, a higher degree of synaptic plasticity, or a higher buffering capacity to sequester toxic Aβ peptide.

673.13

Bax Immunoreactivity In Aged and Alzheimer's Brains. M. Primiano, D. Palm, E. G. Stopa†, R. Corona*#, P. Chan, and C. Johanson. Dept. Clin. Neurosci., Program in Neurosurg. & †Dept. of Pathology, Brown Univ. & RI Hospital, Providence, RI 02903 and #Dept. of Pathology, SUNY Health Sci. Ctr., Syracuse, NY 13210.

Alzheimer's disease (AD) is associated with the accumulation of ß-amyloid protein and the loss of specific neurons. ß-amyloid has been shown to induce neuronal apoptosis *in vitro* and it has been suggested that apoptosis may be involved in Alzheimer's related neurodegeneration. Apoptosis appears to be regulated by the ratio of bcl-2, which promotes cell survival, and bax, which accelerates cell death. Both of these genes are present in neural tissue. We sought to investigate the possibility that changes in the expression of the bax protein in the aging brain may contribute to the progression of Alzheimer's related neurodegeneration. Therefore, we examined the immunohistochemical distribution of bax protein from samples of brain tissue from control and Alzheimer's patients classified with early and severe AD. Sections were blocked with 4% normal goat serum, and incubated overnight at 4°C with a polyclonal rabbit antibody specific for bax (Santa Cruz) or antibody preincubated with the immunizing peptide. Following incubation with biotinylated goat anti-rabbit IgG, sections were incubated with avidin/biotin/peroxidase complex and diaminobenzidine was used as a chromagen. Immunoreactive bax protein was detected within the cytoplasm of a small population of neurons. Additionally bax immunoreactivity was detected within the epithelial cells of the choroid plexus. Glial cells did not appear to be immunoreactive for bax. The number of bax immunoreactive neurons appears to correlate with the severity of AD. These results suggest that the presence of bax protein may be associated with the progression and severity of AD.

673.14

TRANSPORT OF AMYLOID PRECURSOR PROTEIN (APP) IN HIPPOCAMPAL NEURONS. P.J. Tienari, E. Ikonen, B. de Strooper, M. Simons, A. Weidemann, C. Czech, T. Herdegen*, C. Dotti, and K. Beyreuther. ZMBH and Inst. Physiol., Univ. Heidelberg, Germany and Cell Biology Programme, EMBL, Heidelberg, Germany.

APP is a ubiqutously expressed transmembrane glycoprotein with an as yet unknown function and is the parent molecule of Alzheimer's disease (AD) βA4-amyloid peptide. Mutations in the APP gene have been linked to early-onset AD thus highlighting the importance of brain APP-metabolism in AD. Therefore it is of particular interest to study the transport of this protein in neurons. In order to follow the trafficking of newly synthesised APP in cultured rat hippocampal neurons we used the Semliki Forest Virus expression system and immunofluorescence microscopy. We found that APP is after its initial synthesis first transported into the axon and 30-60 min later is also found in the dendrites. APP-mutations implicated in early-onset AD did not change its initial axonal targeting. However, the axonal transport was greatly reduced when specific portions of the extracellular domain were deleted. These results suggest that the extracellular domain of APP plays an important role in the polarised (axonal vs. dendritic) transport of APP and may provide insights into the pathways and molecular interactions of amyloid formation.

673.15

PURIFICATION AND DETAILED CHARACTERIZATION OF PERLECAN ISOLATED FROM THE ENGELBRETH-HOLM-SWARM (EHS) TUMOR FOR USE IN AN ANIMAL MODEL OF Aß AMYLOID PERSISTENCE IN BRAIN. G.M. Castillo, J.D. Miller, J.A. Cummings, C. Ngo, W. Yang and A.D. Snow*. Dept. of Pathology, Neuropathology Labs, Box 356480, University of Washington, Seattle, WA 98195-6480.

Previously we have demonstrated that coinfusion of perlecan (a specific heparan sulfate proteoglycan) and beta-amyloid protein (Aß) into rat hippocampus leads to a consistent animal model to study the effects of fibrillar Aß amyloid in brain (Neuron 12:219-234, 1994). We have recently observed that the final purity of perlecan may be important to the observed effects in the animal model such that contaminating proteins produced by the EHS tumor may reduce the extent and consistency of congophilic Aß amyloid persistence in brain. In the present study, we describe our method of perlecan isolation, and the stringent testing we employ to ensure the highest possible quality of our perlecan preparations for use in the animal model. Briefly, 50 or 100 grams of EHS tumor tissue is extracted using 4M guanidine-HCl, followed by anion-exchange and gel filtration chromatography. SDS-PAGE followed by staining with silver and Coomassie blue, demonstrate no other contaminating proteins in our perlecan preparations. Western blots using a specific perlecan core protein antibody (HK-102) following heparitinase digestion show a characteristic doublet at 400 and 360 kDa indicative of intact perlecan core protein. Absence of contamination by other basement membrane components produced by the EHS tumor is confirmed by absence of immunoreactive bands on Western blots using antibodies against laminin, fibronectin or collagen type IV. Our procedures for isolation and characterization of perlecan from EHS tumor ensures perlecan of the highest quality, to maximize the potential effects of Aß amyloid deposition/persistence in brain in the animal model.

673.16

DNA FRAGMENTATION IN ALZHEIMER'S DISEASE HIPPOCAMPUS:- CORRELATION WITH TAU AND β-AMYLOID IMMUNOREACTIVITY M. Dragunow*, P. A. Lawlor, R.L.M. Faull and H. Waldvogel. Departments of Pharmacology and Anatomy, School of Medicine, Auckland Univ, Auckland, New Zealand.

A number of recent studies indicate that cells in postmortem brain tissue from Alzheimer's disease cases show in situ evidence of DNA fragmentation, suggesting that these cells are undergoing apoptosis. We have examined hippocampal sections from neurologically-normal and Alzheimer's disease post-mortem cases and compared DNA fragmentation (detected using the TUNEL method) with Tau and β-amyloid immunoreactivity. In addition, we undertook double-label studies to investigate whether TUNEL-positive cells were also Tau, calbindin, calretinin, and/or GFAP positive. Results show that most TUNEL-positive cells in Alzheimer's disease hippocampi are not neurons and there is no strong correlation between the number of TUNEL-positive cells and the number of Tau-positive cells. The implications of these results to mechanisms of cell death in Alzheimer's disease will be discussed. Supported by the NZ Health Research Council.

673.17

EVOLUTION OF β-AMYLOID PLAQUES IN ALZHEIMER'S DISEASE: ROLE OF ASTROCYTIC S100β. R.E. Mrak,* J.G. Sheng and W.S.T. Griffin. Dept. of Veterans' Affairs Med. Ctr., Ark. Children's Hospital Res. Inst., Univ. of Ark. for Med. Sci., Little Rock, AR 72202.

S100β, a neurite extension factor, is overexpressed by activated astrocytes associated with amyloid-containing plaques in Alzheimer's disease and has been implicated in dystrophic neurite formation in these plaques. We sought to correlate S100β-immunoreactive ($S100\beta^+$) astrocytes with the formation of dystrophic neurites and thus with the evolution of diffuse amyloid deposits into neuritic plaques. Dual immunohistochemical labelling was used to determine the number of $S100\beta^+$ astrocytes associated with different plaque types in temporal lobe of 12 Alzheimer patients, age 65 to 88. Amyloid-immunopositive plaques were classified into four types according to the pattern of amyloid distribution (diffuse *vs* dense core) and the presence or absence of β-amyloid precursor protein- (β-APP) immunoreactive dystrophic neurites. Diffuse non-neuritic plaques had small numbers of associated $S100\beta^+$ astrocytes (1.3 ± 0.1 cells/plaque; mean ± SEM; 80% of plaques had associated $S100\beta^+$ astrocytes). In contrast, diffuse neuritic plaques had the most associated $S100\beta^+$ astrocytes (4.2 ± 0.2; 100%), and dense-core neuritic plaques had fewer $S100\beta^+$ astrocytes (1.6 ± 0.2; 90%). Dense core non-neuritic plaque were almost devoid of $S100\beta^+$ astrocytes (0.15 ± 0.05; 12%). Computerized image analysis showed that the number of plaque-associated $S100\beta^+$ astrocytes significantly correlated with the cross-sectional area of plaque β-APP immunoreactivity, an index of the size of the plaques' dystrophic neurite shells ($R = 0.66$, $P < 0.05$). These results are consistent with a role for S100β in the induction and maintenance of dystrophic neurites in plaques in Alzheimer's disease. Supported in part by NIH AG10208, NS27414, and AG12411.

STRUCTURAL ORGANIZATION OF THE MOUSE APLP2 GENE. K. Paliga[1], H. Mechler[2*], S. Kreger[1], A. Weidemann[1], C.L. Masters[3] and K. Beyreuther[1]. 1) Center for Molecular Biology Heidelberg, INF 282, 69120 Heidelberg; 2) F: Hoffmann-La Roche Ltd, Preclinical CNS Research, Basel, Switzerland; 3) Dept. Pathology, Univ. Melbourne, Parkville, Victoria, 3052 Australia. Recent identification of APLP1 and APLP2, two novel proteins highly homologous to Amyloid Precursor Protein (APP) provides evidence for the existence of a new multigene family. The human APP encoding gene has been localized to chromosome 21 and consists of 18 exons. Tissue specific alternative splicing results in the generation of multiple transcripts differing in the length of the corresponding protein products from 677 to 770 amino acids. As a further step towards understanding the evolutionary relationships between members of the family of APP-like proteins we characterized the exon-intron organization of the mouse APLP2 gene. The 129SVJ mouse genomic library in Lambda FIXII (Stratagene) has been screened using random primed APLP2 cDNA fragments as probes. DNA from plaque purified hybridizing phages has been prepared and analyzed using standard methods. Exon-intron junctions were determined by dideoxy sequencing. As a result of three independent screening rounds we have isolated five lambda phages, which cover almost the entire gene, extending from the 1st intron to the last exon and additional 9 kb of 3'-flanking sequences. In contrary to the human APP gene, which has been estimated to be app. 400 kb long, the mouse APLP2 gene encompasses about 50 kb and consists up to 18 exons. Determination of exon-intron boundaries reveals strong conservation of the overall gene structure between APP and APLP2 underscoring the phylogenetic relatedness of both genes.

ALZHEIMER'S DISEASE: NEURONAL INJURY AND DEATH

674.1

CEREBROVASCULAR INSUFFIENCY: A RISK FACTOR FOR COGNITIVE DECLINE IN AGING AND ALZHEIMER'S DISEASE? P.G.M. Luiten*, G.I. de Jong, C.M. Stienstra, B.T. Stuiver, S. Knollema, J. Korf, K. Majtenyi. Lab. of Animal Physiology, University of Groningen, Haren, The Netherlands.

Although cognitive impairment in aging and Alzheimer's disease (AD) is mainly associated with neuronal alterations, the cerebrovascular system also undergoes prominent changes. With electronmicroscopic (EM) techniques we previously showed progressive decline of the microvascular wall in the cerebral cortex of aged rats. Aged rats show basement membrane thickening, massive perivascular collagen deposits and pericyte degeneration, which suggests a hampered transport fuction of the blood brain barrier.

The importance of the cerebral microvascular condition and blood supply for cognition was studied 1) in AD by EM analysis of the microvascular wall and 2) in adult rats exposed to mild ischemia (unilateral carotic artery occlusion combined with 5 min hypoxia of 10% O_2). Ischemia effects were assessed in spatial learning paradigms like Morris maze and hole board.

In entorhinal and prefrontal cortex in AD and controls a high incidence of microvascular anomalies was observed including basement membrane thickening, collagen deposits and pericyte degeneration. Preliminary data suggest that microvascular pathology is more severe in AD patients.

Neuronal death (after 1-7 days) was almost absent in mild experimental ischemia, but there was a prominent and significant decrease in the learning rate in the initial phase of spatial orientation learning tested 4 weeks after the ischemic episode.

In conclusion, microvascular pathology occurs with high incidence in the aging human brain and appears to be more severe in AD. Short periods of hypoperfusion in rat yield subtle but significant cognitive alterations

674.2

BRAIN LEVELS OF THIAMINE AND ITS METABOLIZING ENZYMES IN ALZHEIMER'S DISEASE. Frank Mastrogiacomo[1], Lucien Bettendorff[2], Thierry Grisar[2], Lori Dixon[1]* and Stephen J. Kish[1]. [1]Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, Toronto, Ontario, Canada, and [2]Laboratory of Neurochemistry, University of Liège, Liège, Belgium

Clinical data suggest that high dose thiamine (Vitamin B1) may have a mild beneficial effect in some patients with Alzheimer's disease (AD). Since the mechanism of this effect could be related to a brain deficiency of thiamine, we measured the levels of free thiamine and its phosphate esters thiamine monophosphate and thiamine diphosphate (TDP), and the activities of three TDP-metabolizing enzymes (thiamine pyrophosphokinase, thiamine diphosphatase, and thiamine triphosphatase) in autopsied cerebral cortex of 18 patients with AD and 20 matched controls. In the AD group mean levels of free thiamine and its monophosphate ester were normal whereas levels of TDP were significantly reduced by 18%-21% in all three cortical brain areas examined. Activities of the TDP-metabolizing enzymes were normal in the AD group, suggesting that decreased TDP is not due to altered levels of these enzymes. The TDP decrease could be explained by reduced levels in AD brain of either ATP, which is needed for TDP synthesis, or energy metabolizing enzymes which utilize TDP as a cofactor and which therefore may act as a "sink" for thiamine storage. Although the magnitude of the TDP reduction is only slight, a chronic subclinical TDP deficiency could contribute to impaired brain function in AD and might provide the basis for the modest improvement by thiamine in cognitive status of some patients with AD. (Supported by US NINDS NS 26034).

674.3

REDUCED PREVALENCE OF DIABETES IN ALZHEIMER'S DISEASE RELATIVE TO OTHER DEMENTIAS. J. H. Nolan, K. A. Nielson, R. A. Mulnard*, C. A. Sandman, and C. W. Cotman. Depts. of Cognitive Science, Psychiatry & Human Behavior, and the Brain Aging and Dementia Institute, University of California, Irvine, CA, 92717.

Diabetes mellitus and Alzheimer's disease (AD) are significant health care problems in the elderly population. The present study examines the coexistence of diabetes and AD in a large, well-characterized patient population, and examines the contribution of vascular disease history to diabetes prevalence among dementia groups.

The assessment records of 275 dementia patients were evaluated by diagnostic group for the existence of diabetes and vascular disease risk factors (hypertension, heart disease, stroke, hyperlipidemia, etc.). Diabetes occurred significantly less often in AD patients than in patients with other dementias. Vascular disease, which is closely linked to diabetes, was more prevalent in AD patients than would be expected given the exceptionally low occurrence of diabetes in this group. Further, there were no differences among the dementia groups in fasting glucose levels.

Therefore, diabetes is very rare in patients with AD. Vascular disease and fasting glucose levels did not explain the reduced prevalence of diabetes in AD. Thus, the disassociation could provide new insight about the pathogenesis of AD. Glucose, insulin sensitivity, and perhaps insulin degrading enzyme may be important factors.

674.4

GENE EXPRESSION OF ND4, A MITOCHONDRIAL DNA-ENCODED SUBUNIT OF NADH DEHYDROGENASE, IS DECREASED IN NEURONS OF ALZHEIMER'S DISEASE BRAIN. R. Fukuyama, J. Fu, K. Hatanpää, C. Jones, D.R. Brady, K. Chandrasekaran* and S.I. Rapoport. Lab. Neurosciences, NIA, NIH, Bethesda, MD 20892

We reported decreased levels of gene expression and enzyme activity of cytochrome oxidase, a mitochondrial enzyme of oxidative phosphorylation, in affected brain areas in Alzheimer's disease (AD). These findings lead us to examine the hypothesis that energy impairment in neurons of AD cause neurodegeneration observed in AD brain. We extended our observations by analyzing the level of gene expression of a subunit of another mitochondrial enzyme, NADH dehydrogenease (complex I of oxidative phosphorylation) in this report. First, we raised monoclonal antibodies (mAbs) against entorhinal cortical grey matter dissected from a normal human brain by applying a modified hybridoma technique (SOFISTIC immunization). One mAb, BG5, immunochemically detected an antigen only in the mitochondrial subcellular fraction separated from other organelles in the rat brain. We further isolated a cDNA clone immunoreactive to mAb BG5 by screening an expression cDNA library and found that the cDNA fragment is a portion of ND4, a subunit of NADH dehydrogenase. We characterized the localization and the level of expression of ND4 in adult brains and cultured cells of rat and human with immunohistochemical and molecular biological procedures. Finally, we compared the level of ND4 gene expression in normal human brains to that in AD brains. We found that ND4 is highly expressed in the cytoplasm of large neurons and that immunohistochemical staining of brain sections showed a significant decrease of ND4 in several brain areas in AD, without a significant decrease in the number of neurons. Northern blot analysis also showed a similar decrease of the expression of ND4 gene in AD. These results indicate that gene expression of mitochondrial DNA-encoded enzymes is generally decreased in AD and suggest that the energy impairment in selective neurons may be involved in neurodegeneration in AD.

674.5

MITOCHONDRIAL MEMBRANE FLUIDITY AND OXIDATIVE DAMAGE TO MITOCHONDRIAL DNA IN AGED AND AD HUMAN BRAIN. P. Mecocci[1]*, M.F. Beal[2], R. Cecchetti[1], M.C. Polidori[1], A. Cherubini[1], F. Chionne[3], L. Avellini[4], G. Romano[1], U. Senin[1]. [1]Gerontology & Geriatrics, Dept. of Clinical Medicine, Pathology and Pharmacology, Perugia University, Perugia (Italy); [2]Neurochemistry Lab, Neurology Service, Massachusetts General Hospital Harvard Medical School, Boston (USA); [3]Department of Medical Physics, Policlinico Monteluce, Perugia (Italy); [4]Institute of Biochemistry and Medical Chemistry, Perugia University, Perugia (Italy).

Oxidative damage on biological molecules has been proposed as a major cause of alterations observed in aging brain as well as in neurodegenerative diseases. In this study we measured membrane fluidity in mitochondria extracted from three cerebral regions and cerebellum of Alzheimer's disease (AD) patients and age-matched controls by means of fluorescence polarization technique. A significant reduction of mitochondrial membrane fluidity was found in AD, except in cerebellum. In controls, a decrease of membrane fluidity was observed along with age and it was also related to the contenent of the oxidized nucleoside 8-hydroxy-2'-deoxyguanosine (OH^8dG) in mitochondrial DNA (mtDNA). Alteration in membrane fluidity seems to be mainly a result of lipid peroxidation since it dramatically decreased when mitochondria were exposed to $FeCl_2$ and H_2O_2. The parallel increase of viscosity in mitochondrial membrane and amount of OH^8dG in mtDNA is suggestive of a relationship between these biological markers of oxidative stress, supporting the hypothesis of a membrane mediated oxidation of DNA. From these results in AD patients biological molecules seem to be particularly sensitive to oxidative stress suggesting that free radicals, together with aging, may play a fundamental role in the pathogenesis of the disease.

ALZHEIMER'S DISEASE: A HYPOTHESIS ON PATHOGENESIS. D. Harman[1] and J. F. Rodriquez-Sierra[2*]. Dept. of Medicine, Dept. of Cell Biology and Anatomy. College of Medicine., University of Nebraska Medical Center, 600 So. 42nd Street, Omaha, NE 68198-4635, USA.

Senile dementia of the Alzheimer's type (SDAT) is a sporadic systemic disorder whose major manifestations reflect loss of neurons involved in memory. The same pattern of neuronal loss is seen at later ages in normal individuals.

It is hypothesized that SDAT is the result of a mutation in a mtDNA molecule of a non-germ line cell (the progenitor cell) early in development; this increases the rate of cellular aging, by impairing ATP formation and increasing production of superoxide radical and H_2O_2. Clonal expansion of the progenitor cell results in a spectrum of daughter cells; some with many copies of the mutated mtDNA, others may have none. Daughter cells are distributed to the developing organism in such a manner that with advancing age cellular dysfunction and death occurs first in brain areas associated with SDAT.

SDAT incidence may be decreased by maternal antioxidant supplementation and/or increased consumption of fruits and vegetables. SDAT patients may be improved by measures employed for other mitochondrial disorders.

674.7

SUPPRESSIVE EFFECT OF A NON-PEPTIDE PROLYL ENDOPEPTIDASE (PEP) INHIBITOR, Y-29794, ON THE AMYLOIDGENESIS OF SENESCENCE-ACCELERATED MICE (SAM). A. Kato*, A. Fukunari, Y. Sakai, and T. Nakajima. Research Laboratories, Yoshitomi Pharmaceutical Industries, Ltd., 871 Fukuoka, Japan.

One of the early symptoms of Alzheimer's disease (AD) is characteristic deposition of ß-amyloid peptide (Aß) among brain regions. Although prevention of this brain amyloidgenesis is thought to be the plausible approach to halt or slow down the progression of AD, the lack of animal models hinders the progress of the research. We, however, previously reported close temporal and spatial relationships between deposited structures of PEP and Aß in SAM hippocampus, suggesting that SAM could be used as an in vivo model for testing therapeutic compounds. The purpose of this study was to estimate whether chronic treatment of SAM with a non-peptide PEP inhibitor, Y-29794, could suppress the progression of amyloidgenesis in the hippocampus.

Male SAMP8/Ta/Sea (senescence-prone) were given oral doses of Y-29794 (1, 10, and 20 mg/kg/day) in drinking water from 2.5 to 8 month-old. Paraffin-embedded coronal sections of the hippocampus were made to stain Aß with polyclonal rabbit anti-Aß(1-16). Aß-like immunoreactivity (Aß-LI) was analyzed by computerized image analyzer and NIH Image.

Deposited structures of Aß-LI which were composed of fine granules were observed in the hippocampus of SAM. After the repeated dosing of Y-29794, the number of granules per deposit, and total number of Aß granules were decreased. Moreover, Y-29794 decreased denser part of characteristic biphasic distribution of the mean density of the granules.

These results indicate that Y-29794 suppresses the amyloidgenesis in the hippocampus of SAM, providing further support of our working hypothesis that PEP is closely involved in the amyloidgenesis, and that Y-29794, an inhibitor of PEP, would be promising as a therapeutic agent for AD.

CHARACTERIZATION OF A Tc1 INSERTION MUTANT OF *apl-1* IN *CAENORHABDITIS ELEGANS*. J. Daigle* and C. Li. Dept. of Biology, Boston University, Boston, MA 02215.

The amyloid precursor protein (APP) is thought to be involved in Alzheimer's disease, but its specific function is still unknown. We are interested in investigating the function of APP by looking at *APP*-related genes in the nematode *Caenorhabditis elegans*. We have isolated an *APP*-related gene, *apl-1*, from *C. elegans*. The *apl-1* gene is approximately 4.4 kbp, has 12 exons and 11 introns, and has been positioned to the X chromosome of *C. elegans*.

To look at the function of APL-1, a Tc1 transposon insertion mutant in *apl-1* has been isolated by R. Plasterk. The insertion site of Tc1 has been located to the 12th exon, in the region corresponding to the first residue of the transmembrane domain. A strain homozygous for the insertion in *apl-1*, however, showed no phenotype. RT/PCR and Northern blot analysis suggest that the transposon is removed and is not present in the mRNA, as often observed in *C. elegans*. In addition, Western blot analysis showed no size difference between the wild-type protein and the insertion mutant protein, supporting the idea that the transposon does not disrupt gene function in *apl-1*::Tc1 animals. Excision screens are underway to isolate mutants in which Tc1 excision creates a deletion in *apl-1* and, presumably, disrupts its function.

To examine the effects of *apl-1* overexpression, we are producing transgenic animals carrying constructs of the *apl-1* cDNA under the control of a heat shock promotor and a neural-specific promotor.

BCL-2 PROTEIN IMMUNOREACTIVITY INCREASES IN ALZHEIMER'S DISEASE BRAIN WITH DISEASE SEVERITY. Takao Satou, Brian J. Cummings and Carl W. Cotman*. Institute for Brain Aging and Alzheimer's Disease. University of California, Irvine. Irvine, CA 92717-4550.

Bcl-2 protein has been suggested to be one of the proteins preventing apoptosis in a variety of cell types. Recently, apoptosis has been suggested to have an important role in the pathogenesis of Alzheimer's disease(AD). We have utilized Bcl-2 immunohistochemical methods to examine Bcl-2 in the hippocampus and entorhinal cortex of AD patients ranging in clinical and neuropathological severity from mild to severe and compared these results to those from controls. Immunoreactivity for Bcl-2 was increased relative to controls in most neurons of the entorhinal cortex, subiculum, CA1, CA2, CA3, hilus and dentate gyrus granule cells. Bcl-2 staining increased with increasing disease severity. However, neurons displaying increased immunoreactivity for markers of neurofibrillary tangle formation showed reduced staining for Bcl-2, suggesting that Bcl-2 may be downregulated in these neurons. Immunoreactivity of astrocytes and the vasculature was also increased in AD. These results suggest that Bcl-2 protein may have a role in compensation responses to AD pathology, perhaps affording to the remaining neurons a margin of protection from apoptosis.

674.10

PATTERNS OF NEURONAL DNA FRAGMENTATION DETECTED BY TUNEL IN ALZHEIMER'S DISEASE. R.R. Sukhov*[1,2], J.T. Troncoso[1,2,4], C. Kawas[4], V.E. Koliatsos[1-4]. [1]Neuropathology Laboratory, Dept. of [2]Pathology, [3]Neuroscience, and [4]Neurology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Alzheimer's disease (AD), the most common type of dementia, is characterized by cerebral atrophy, ß-amyloid protein (Aß) deposits/senile plaques, neurofibrillary tangles, and loss of synapses. Although morphometric studies of different areas of the CNS demonstrated loss of pyramidal neurons in neocortical layers III and V in AD, the precise extent and distribution of cortical neuronal loss remains undetermined. In the present study, we used terminal transferase-mediated deoxyuridine triphosphate (d-UTP)-biotin nick end labeling (TUNEL) as a method for detection of fragmented DNA to identify degenerating neurons in the cerebral cortex of individuals with autopsy-confirmed AD and to establish whether similar changes occur in age-matched nondemented individuals. In early stages of AD, we found that TUNEL-labeled neurons are restricted to lamina III of isocortex and entorhinal cortex. In late stages of AD, TUNEL-labeled neurons were found in all layers of the above cortices as well as in the hippocampus. The specificity of TUNEL labeling was supported by the absence of labeling in age-matched and young controls. In conclusion, our findings of the laminar pattern of neuronal degeneration suggest that specific neural systems are involved in the pathogenesis of AD and that the TUNEL method can be used as a method for direct demonstration of neuronal DNA fragmentation in early stages of disease.

674.11

QUANTITATIVE ASSESSEMENT OF APOPTOTIC-LIKE NUCLEI IN HIPPOCAMPAL FORMATION OF ALZHEIMER BRAIN Joseph H. Su*, Aileen J. Anderson and Carl W. Cotman. *Brain Aging and Dementia Institute. University of California, Irvine. Irvine, CA 92717-4550 USA.*

Neuronal death is a prominent feature of Alzheimer's disease (AD) and has been suggested to play a significant role in the expression of dementia in AD and perhaps other age related losses of cognitive function. Recent studies *in vitro* have suggested that apoptosis may have a role in the neuronal cell death associated with AD. We have recently demonstrated the presence and morphological features of apoptotic-like nuclei in AD brain and have shown that such apoptotic nuclei are present in a subset of neurofibrillary tangles in AD brains (NeuroReport 5, 2529-2533, 1994). In this study, we examined the hippocampal formation of AD brains using a TdT-end labeling system (ApopTag, Oncor) on vibratome sections to quantitatively assess apoptotic-like nuclei. The vast majority of apoptotic-like nuclei were located in the grey matter, and were found within neurons. 2/3 of PHF-tau positive neurons were associated with apoptotic-like nuclei. Apoptotic-like nuclei were generally not detected within extracellular neurofibrillary tangles. These results suggest that neuronal cell death may occur without neurofibrillary formation, and neurofibrillary tangle bearing neurons may die by apoptosis.

In conclusion, our data indicate that neuronal DNA damage appears to be more prominent and wide spread in AD than previously realized. This could reflect either a mechanism of cell death, DNA damage/repair mechanisms, or both. In this context, TdT labeling may be an early marker of cellular risk.

674.12

FIBROBLAST GROWTH FACTOR RECEPTORS-LIKE IMMUNOREACTIVITY IN ALZHEIMER'S DISEASE

K. Takami*, A. Matsuo, Y. Aimi, O. Yasuhara[1], I. Tooyama[1] and P.L. McGeer, Kinsmen Lab. of Neurol. Res., Univ. of British Columbia, Vancouver, Canada, V6T 1Z3; [1]Institute of Mol. Neurobiology, Shiga Univ. of Med. Sci., Otsu, Shiga, Japan.

Recent studies have revealed the localization of FGFs in astrocytes, neurons and senile plaques of Alzheimer's disease(AD), indicating their involvement in the pathogenesis of the disease. We report here the immunohistochemical localization of FGF receptors (FGFR2, 3 and 4) in AD and control brain tissue, using rabbit polyclonal antibodies (Santa Cruz Biotechnology Inc.). The epitopes recognized by these antibodies in each case mapped to the carboxy terminal region of the human FGFRs. In cerebral cortices of both AD and controls, astrocytes, especially in white matter, showed FGFR2 and FGFR4-like immunoreactivity. Some neuronal fibers also showed FGFR2 or FGFR4 immunoreactivity. Reactive astrocytes having FGFR4-like immunoreactivity were observed around senile plaques. FGFR3-like immunoreactivity was localized to tangles and dystrophic neurites in or near senile plaques.

These findings suggest that FGFs may participate in many functions associated with the pathology of AD through their various receptors, which are distinctly localized.

674.13

TRANSPLANTED SYNGENEIC RAT FIBROBLASTS GENETICALLY MODIFIED TO EXPRESS HUMAN NERVE GROWTH FACTOR ARE BIOACTIVE FOR AT LEAST 6 WEEKS AS DEMONSTRATED BY ENHANCED SURVIVAL OF MEDIAL SEPTAL CHOLINERGIC NEURONS AFTER FIMBRIA-FORNIX TRANSECTION R. J. Mandel*, D. G. Clevenger, D. Nagy, T. M. Jaret, M. Morten, and S. E. Leff. Somatix Therapy Corp. 850 Marina Village Pkwy., Alameda, CA 94501.

This experiment was designed to investigate the duration of bioactivity of intracerebrally grafted transgenic hNGF producing fibroblasts by transplanting the fibroblasts at various time-points **before** fimbria-fornix (FF) lesioning. Syngeneic Fischer dermal fibroblasts were grown in culture (≈ 8 passages) and transduced with a retroviral vector encoding the hNGF cDNA or *E. Coli lac-Z* both driven by the internal viral LTR promoter. *In vitro* hNGF production determined by an ELISA assay (257 ng/10^6 cells/24 hr) was comparable to that reported previously (Rosenberg *et al., Science* 242:1575-1578, 1988). Each rat received 2 grafts of 1 µl of 7.5 X 10^4 of hNGF (n=5-7) or lac-z producing cells (n =5-7) in the medial septum (MS). Immediately following the implantation surgery (day Ø) or following variable delay intervals (4,7, 14, 28 & 42 days), an unilateral FF lesion was performed ipsilateral to the cell implantation. The rats were sacrificed 21 days after the FF lesion. Fixed tissue was sliced at 40 µm and prepared for choline acetyltransferase (ChAT in MS) immunohistochemistry , acetylcholinesterase (AChE) histochemistry (hippocampus), and hemotoxylin and eosin staining. Some animals were removed from the study prior to ChAT+ cell counting by evaluating their FF lesion via examination of the AChE stained sections of the hippocampus. Each MS section was evaluated "blind" to treatment by counting ChAT+ cells and by noting whether the graft was innervated by ChAT+ fibers. There was no effect of surgery delay on ChAT+ cell survival in the lac-z group, therefore the lac-z data were combined into one control group for further analysis. hNGF-producing fibroblasts significantly enhanced survival of ChAT+ neurons at all FF lesion delays ($p < 0.05$) but the magnitude of the survival effect appeared to wane over time (42 day percent survival < 14 day survival, $p < 0.05$).

ISCHEMIA: ISCHEMIC TOLERANCE AND STRESS PROTEINS

675.1

BCL-2 EXPRESSION AND TOLERANCE FOR POSTISCHEMIC NEURONAL DEATH IN THE GERBIL HIPPOCAMPUS.

K. Shimazaki[1]* K. Watanabe[2], H. Hosoya[2], K. Oguro[1], T. Masuzawa[1], Y. Eguchi[3], Y. Tsujimoto[3], and N. Kawai[1] [1]Depts. Physiol. Neurosurg. Jichi Medical School, Tochigi-ken 329-04, [2]Dept. Exp. Biol. Tokyo Metropolitan Inst.for Gerontology, Tokyo, 173-2, [3]Osaka Univ. Med. School. Suita Osaka, 565, JAPAN

Pretreatment with brief (2 min) ischemia induced tolerance for subsequent ischemia (5 min) and prevented delayed neuronal death (DND). Using monoclonal antibody against bcl-2 oncoprotein we previously reported that immunoreactivity of bcl-2 greatly increased in the gerbil hippocampal CA1 sector in parallel with acquisition of tolerance for DND (Shimazaki et al. Neurosci. Res. 20:95,1994). To determine time course and locus of bcl-2 production after sublethal brief ischemia, we have studied mRNA expression in the gerbil hippocampus by *in situ* hybridization. The level of bcl-2 mRNA was markedly increased at 2 days following 2 min ischemia. Northern blot analysis supported the result showing 2-fold increase in bcl-2 mRNA after 2 min ischemia. In the gerbil treated with 5 min ischemia, no increase in the level of bcl-2 mRNA was found. The results suggest close correlation between acquisition of tolerance for DND and the expression of bcl-2, which is known to support survival of the neuronal death.

675.2

TRANSIENT FOCAL ISCHEMIA ELEVATES *bcl-2* EXPRESSION IN THE NEOCORTEX. Z.G. Huang*, A.M. Buchan and G.S Robertson[1]. National Research Council of Canada, and [1]Department of Pharmacology, Faculty of Medicine, University of Ottawa, Ottawa, Canada

Several lines of evidences suggest that apoptotic mechanisms may contribute to neuronal death following transient cerebral ischemia. Over-expression of the proto-oncogene *bcl-2* in several cell lines has recently been shown to reduce apoptotic death produced by a variety of noxious treatments. This finding suggests that there may be a positive relationship between *bcl-2* expression and resistance to ischemic cell death *in vivo*. The present study addressed this hypothesis by examining the effects of transient forebrain ischemia on *bcl-2* expression in the neocortex. Reversible focal cerebral ischemia was produced in male spontaneously hypertensive rats by 90 min of transient right cerebral artery occlusion (MCA-o) combined with permanent right common carotid artery occlusion. Six groups, composed of 4 animals each, were subjected to 90 min of MCA-o and sacrificed after 1, 4, 8, 12, 24 or 48 hr of reperfusion (RP). A seventh group served as sham-operated controls and underwent the same operative procedures except that the MCA was not occluded. Brains were rapidly removed, quickly frozen and sections 12 µm thick cut through the cortex. *bcl-2* mRNA was detected by *in situ* hybridization histochemistry and quantified by computer assisted image analysis. *bcl-2* mRNA levels were low in the neocortex of sham animals. Transient MCA-o elevated *bcl-2* mRNA levels selectively in the ischemic penumbral region of the neocortex within 8-12 hr with peak increases occurring between 12-24 hr of RP. *bcl-2* mRNA levels were still elevated in the penumbra 48 hr after RP. These results suggest that elevated *bcl-2* expression may contribute to the survival of neurons located in the penumbral region following cerebral ischemia.

675.3

The Distribution of bcl-2 Protein In The Rat Hippocampus Following Transient Forebrain Ischemia. N. Knuckey*, M. Primiano, D. Palm, M. Guglielmo, M. Epstein, and C. Johanson. Dept. Clin. Neurosci., Program in Neurosurg., Brown Univ. & RI Hospital, Providence, RI 02903

There is increasing evidence for the involvement of apoptosis in the selective, delayed neuronal death resulting from cerebral ischemia. Bcl-2 is present in the developing and adult nervous system and has been shown to prevent apoptosis and neuronal cell death under many neurotoxic conditions implicated in ischemia. To investigate the possible relationship between bcl-2 and selective ischemic neurodegeneration, we examined the distribution of bcl-2 in the rat hippocampus following transient forebrain ischemia (TFI).

TFI was induced in normothemic adult rats by bilateral carotid artery occlusion with hypotension. Animals were perfused with 4% paraformaldehyde 6, 12, 18, 24, 48, 72 hours following induction of TFI. Frozen 10 µm coronal sections were analyzed for the distribution of bcl-2 protein by immunohistochemistry. Sections were immunostained using a polyclonal rabbit antibody specific for bcl-2 (Santa Cruz) or antibody preincubated with the immunizing peptide. Following incubation with biotinylated anti-rabbit IgG, sections were incubated with avidin/biotin/peroxidase complex and DAB was used as a chromagen.

Immunoreactive bcl-2 was detected within the cytoplasm of most hippocampal neurons including the vulnerable CA1 pyramidal cells of non-ischemic animals and during the first 18 hours following TFI. At approximately 24 hours of recovery, a depletion of immunoreactive bcl-2 was observed in most vulnerable CA1 pyramidal neurons while immunoreactive bcl-2 continued to be present at all recovery times in resistant neurons of the other CA regions and dentate gyrus. These results suggest that the presence of bcl-2 protein may influence neuronal survival following TFI.

Supported by funds from Rhode Island Hospital.

675.4

BCL-2 PROTECTS NEURAL CELL MITOCHONDRIA FROM Ca^{2+} OVERLOAD AND Ca^{2+}-INDUCED RESPIRATORY INHIBITION. A.N. Murphy*, D.E. Bredesen[1], and G. Fiskum. Dept. of Biochemistry and Molec. Bio., George Washington Univ. Medical Center., Washington, D.C. 20037, and [1]La Jolla Cancer Research Foundation, La Jolla, CA 92037.

Recent data suggest that Bcl-2 expression provides neuroprotection in models of cerebral ischemia. Although evidence suggests that Bcl-2 can act as an antioxidant and may affect patterns of Ca^{2+} metabolism, the exact mechanism is unknown. The effect of Bcl-2 expression in GT1-7 neural cells on mitochondrial resistance to damage induced by high concentrations of extramitochondrial Ca^{2+} has been examined. Bcl-2 appears to have little effect on state 3, state 4, or uncoupler-stimulated rates of respiration of digitonin-permeabilized cells under control conditions. However, the addition of 7.7 nmoles of $CaCl_2/10^6$ cells inhibited uncoupler-stimulated respiratory rates of permeabilized control cells by approx. 83%, whereas this rate in Bcl-2 expressing cells was inhibited by only 30%. Measurements of maximal Ca^{2+} uptake capacity prior to Ca^{2+} release revealed that control mitochondria could sequester 600 and 500 nmoles $Ca^{2+}/4.3x10^7$ permeabilized cells respiring on glutamate/malate or succinate, respectively; whereas Bcl-2 expressors could accumulate 1013 and 800 nmoles under the same conditions. In addition, mitochondria isolated from Bcl-2 expressors were significantly less sensitive to respiratory inhibition in response to 42-167 nmoles Ca^{2+}/mg mitochondrial protein. The ability of mitochondria of Bcl-2 expressing cells to maintain function under conditions of cytotoxic levels of extramitochondrial Ca^{2+} may provide a mechanism by which Bcl-2 inhibits delayed neuronal death following cerebral ischemia. (Supported by NIH NS34152)

675.5

REGULATION OF GENE EXPRESSION BY O_2 DEPRIVATION IN *DROSOPHILA MELANOGASTER*. Enbo Ma and G. G. Haddad*. Departments of Pediatrics and Cellular & Molecular Physiology, Yale University School of Medicine, New Haven, CT 06520

We have recently shown that the adult fruit fly *Drosophila melanogaster* (DM) is very tolerant to complete lack of O_2 and can totally recover from 4 hrs of anoxia. To study the mechanisms that are activated during O_2 deprivation and which are potentially protective, we used two groups of DM: one was kept in 0% O_2 for 4 hrs and another was used as a control. Flies from both groups were immediately frozen in liquid N_2, shaken vigorously, and passed through a number of sieves of successively smaller pore sizes in order to collect heads. Poly-A RNA was isolated from both groups of DM heads and the transcripts for heat shock proteins (HSP70 and HSP26), ubiquitins (UB3 and UB4), cytochrome oxidase (COX) and superoxide dismutase (SOD) were quantitatively analyzed by Northern and slot blot analysis. Gene expression for HSP70 was up-regulated by ~3.5 times while UB4 and COX were down-regulated to about half of control during anoxia. HSP26, UB3 and SOD did not change significantly. From these results we conclude that during O_2 deprivation 1) there is differential regulation of gene expression and 2) the up-regulation of HSP70 and down-regulation of UB4 are consistent with the idea that such changes potentially protect against protein degradation. AN OPTIMIZED MODEL OF INDUCED ISCHEMIC TOLERANCE IN THE GERBIL. H. Abe and T.S. Nowak, Jr.* Dept. of Neurology, University of Tennessee, Memphis, TN 38163.

Brief insults moderate the damage seen following subsequent more severe ischemic challenges, but reported effects are highly variable. In the present study we monitored hippocampal DC potentials to determine effective durations of priming insults and test challenges, identifying threshold depolarization intervals for tolerance induction and changes in gene expression. Ischemia of varied duration was produced by bilateral carotid artery occlusion in halothane-anesthetized gerbils (n=125) fixed in a stereotaxic frame. Hippocampal DC potentials were recorded via glass microelectrodes. Induced mRNAs were evaluated by in situ hybridization at 1 h or 6 h recirculation. In other gerbils a test insult was administered 2 d after the first and consisted of depolarization for ≥385 sec, which produced maximal neuron loss in naive animals. Histological evaluation of CA1 was done 7 d after the test insult. Tolerance was first evident after ≥90 sec depolarization, with complete protection after ≥150 sec. The mRNA encoding the stress protein, hsp72, was not increased after depolarizations ≤120 sec, with consistent induction only after ≥200 sec, and was strongly expressed only after ≥240 sec, which was the threshold for histological damage. In contrast, slight increases in c-fos, junB and junD were detected after the shortest depolarizations (60 sec) and these mRNAs were reliably induced in all hippocampi after ≥120 sec. These results: 1) indicate that the stress response is not required for induced ischemic tolerance, 2) demonstrate that diverse cascades of altered gene expression must occur after insults that induce tolerance, and 3) establish a highly reproducible model in which to study neuroprotective mechanisms after repeated insults.

675.7

HSP70 AND C-FOS mRNA INDUCTION IN THE HIPPOCAMPUS FOLLOWING THE FOCAL ISCHEMIA IN GERBILS: THE RELATIONSHIP TO ISCHEMIC TOLERANCE. K. Miyashita*, T. Nakajima, H. Abe, M. Nishiura, T. Sawada and H. Naritomi. Cerebrovac. Division, Dept. Med. **National Cardiovascular Center**, Suita, Osaka 565, JAPAN.

In gerbil model of unilateral middle cerebral artery occlusion (MCAO), in which both sides of hippocampus are spared from direct ischemic insult, hsp70 and c-fos mRNA induction in the hippocampus was studied using in situ hybridization method. Ischemic tolerance of the hippocampus was also investigated inducing transient forebrain ischemia at 3-7 days after MCAO. Induction of hsp70 mRNA was faint in both hippocampal regions at 12 to 24 h after left MCAO, while c-fos message was clearly induced in the left hippocampus at 0.5 to 6 h following ischemia. Animals undergoing left MCAO displayed ischemic tolerance at 5 min bilateral carotid artery occlusion (5BCO) done at 3 days after MCAO. More than 40% of CA1 neurons survived in the left hippocampus. In contrast, less than 10% of those survived in the right. No such tolerance was observed at 5BCO done at 7 days after MCAO. The dissociation of hsp70 and c-fos mRNA induction after MCAO may be derived from the difference of threshold between these two genes. Hsp70 appears to play little role in the induction of focal ischemic tolerance in the gerbil MCAO model.

675.8

SPREADING DEPRESSION INDUCES TOLERANCE TO ISCHEMIA IN THE CEREBRAL CORTEX OF RATS. S. Kobayashi, V. A. Harris, F. A. Welsh* Div. Neurosurg., Univ. Penna. Sch. Med., Philadelphia, PA 19104.

The objective of the present study was to determine whether cortical spreading depression (CSD) induces tolerance to ischemia in the cerebral cortex of rats. CSD was evoked by applying 2 M KCl to the intact dura over the frontal cortex of one hemipshere for 2 hr. After recovery for 24 hr, bilateral forebrain ischemia was produced using carotid artery occlusion and arterial hypotension. Following ischemia for 6 min (n=7) or 10 min (n=6), animals were permitted to survive for 4-6 days prior to assessment of histopathology. In separate animals (n=5), KCl evoked 11 ± 3 DC shifts and triggered the expression of c-*fos* mRNA, but not hsp72 mRNA, in the ipsilateral cortex. Forebrain ischemia of 6-min duration caused selective neuronal necrosis in many brain areas, but the number of necrotic neurons in the cerebral cortex preconditioned with CSD was significantly lower than that in the contralateral cortex. The extent of neuronal necrosis in striatum and hippocampus was not significantly different between hemispheres. Forebrain ischemia of 10-min duration caused a severe degree of neuronal necrosis and scattered microinfarction. The extent of infarction in the cerebral cortex preconditioned with CSD was markedly diminished relative to that in the contralateral cortex. These results demonstrate that CSD induces tolerance to both mild and severe ischemia in cerebral cortex by mechanisms unrelated to hsp72.

675.9

THE EXPRESSION OF BFGF INCREASED AT TRANSCRIPTION LEVEL BUT NOT AT TRANSLATION LEVEL IN THE CA1 PYRAMIDAL CELL LAYER IN ISCHEMIA-TOLERANCE INDUCED RAT MODEL.

M.Endoh*, J.A.Wagner#, T.Yokoyama, H.Ryu, K.Uemura Dep.of Neurosurgery, Hamamatsu University School of Medicine, 3600 Handa-cho, Hamamatsu, 431-31 Japan, #Dep.of Neurology/Neuroscience, Cornell University Medical College

We previously reported that 10 minutes of transient forebrain ischemia induces bFGF mRNA but not bFGF protein in the CA1 pyramidal cells. In this study, we investigated the changes of bFGF following 2 minutes of transient forebrain ischemia, that is so called ischemia-tolerance induced rat. Transient forebrain ischemia was produced with 4 vessel-occlusion method. *In situ* hybridization demonstrated that 2 minutes of transient forebrain ischemia induced bFGF mRNA in the CA1 pyramidal cell layer by 24 hours after ischemia. But immunohistochemistry failed to show the expression of bFGF in the CA1 pyramidal cell layer. Other investigators have recently reported that ischemia induced bFGF protein in neurons shortly after ischemia *in vitro*. However, our results do not suggest that bFGF plays a key role in the protection for neurons in ischemia-tolerance induced rat.

675.10

ISCHEMIC PRECONDITIONING CONVEYS HISTOLOGICAL BUT NOT FUNCTIONAL PROTECTION.

D. Corbett*, P. Crooks, P. Dooley, S. J. Evans and S. Nurse. Basic Med.Sciences, Fac. Med., Memorial Univ., St. John's, NF, Canada A1B 3V6.

Previous studies have shown that prior exposure to brief periods (e.g. 1.5-2 min) of ischemia protects CA1 neurons from a subsequent, lethal ischemic insult several days later. It is not known if this ischemic "tolerance" translates into functional preservation since a number of treatments maintain neurons in a viable, but abnormal state.

Gerbils were exposed to 2 x 1.5 min episodes of global ischemia (24 hr apart) followed 3 days later by a 5 min occlusion that typically destroys >95% of CA1 neurons. In one experiment, animals were tested in an open field test of habituation 3, 7 and 10 days after the last ischemia. In a second experiment CA1 field potentials (fEPSP's)were recorded from hippocampal slices taken 4 days after the last ischemia.

CA1 cell counts showed that preconditioning resulted in about 70% preservation assessed 10 days after ischemia. In spite of the substantial degree of histological protection, open field activity levels in preconditioned gerbils were no different than ischemic gerbils, indicating a marked habituation deficit. Similarly, CA1 fEPSP's were less than 50% of those recorded in sham animals. These data suggest that while ischemic preconditioning protects CA1 neurons histologically, many of these neurons are functionally abnormal.

CHRONIC HYPOXIA INCREASES THE NEURONAL RESPONSE TO ACUTE HYPOXIC STRESS.

J.P. O'Reilly* and G.G. Haddad. Depts of Biology, Pediatrics, and Cellular and Molecular Physiology, Yale University and School of Medicine. New Haven, CT. 06520

Acute oxygen deprivation can have severe consequences in the central nervous system (CNS). However, much less is known about the effects of long-term (chronic) hypoxic exposure on the CNS. We hypothesized that exposure to chronic hypoxia would be detrimental to the CNS. We exposed rats (P0-P2) to FiO_2 of 9.5±1% until P21-P35 (*exposed*). Membrane potential (Vm) and input resistance (Rm) were measured during *in vitro* acute hypoxia at two levels of tissue PO_2 in neocortical neurons (NCX) and hypoglossal neurons (XII) using the brain slice technique and intracellular recordings. Age-matched normoxic animals were used as controls (*naive*). In response to acute hypoxia (15 Torr), exposed NCX (n=13) depolarized to a much greater extent (53.2±7.0 mV; ±SE) and showed a larger decrease in Rm (-76.7±8.2%) than naive NCX (n=8; ΔVm=10.6±2.1 mV; $p<0.001$; ΔRm= -17.0±4.6%, $p<0.001$). In response to anoxia (0 Torr), exposed NCX (n=18) showed anoxic depolarization (>20mV/min) much sooner (4.8±0.4 min) than naive NCX (8.8±1.0 min, n=19; $p<0.001$). Exposed (n=25) and naive (n=33) XII showed similar responses to both hypoxia and anoxia. Re-oxygenation produced a rapid recovery of both Vm and Rm in naive NCX and XII, and also in exposed XII. However, exposed NCX remained depolarized during the recovery period (10min) following both hypoxia and anoxia, and Rm showed a delayed recovery pattern. In addition, 28% of the exposed NCX failed to recover from anoxia. We conclude that chronic hypoxic exposure renders neurons in the NCX more sensitive to the effects of acute hypoxia, and possibly more vulnerable to stress-induced injury. (Supported by HD 32573, HL 28940, NS 32578)

ALTERED NEURONAL PROPERTIES IN NEOCORTEX FOLLOWING LONG-TERM EXPOSURE TO HYPOXIA.

M.L. Schwartz*, J.P. O'Reilly and G.G. Haddad. Depts. of Neurobiology, Biology, Pediatrics, and Cellular and Molecular Physiology. Yale University and School of Medicine. New Haven, CT. 06520

Neurons in the central nervous system (CNS) are extremely sensitive to oxygen availability in the environment, and oxygen deprivation can have severe physiologic and pathophysiologic consequences. Since little is known about the effects of long-term O_2 deprivation on the developing CNS, we studied neurons from animals chronically exposed to a hypoxic environment. We hypothesized that chronic hypoxic stress would be detrimental to the development of the CNS. Neonatal rats (P0-P2) were raised in a plexiglass chamber with FiO_2 of 9.5 ± 1% (*exposed*). At P21-P35, the animals were removed from the chamber, and the neocortex (NCX) was prepared for morphologic and electrophysiologic study. Golgi stained sections (100 μm) were used to count spine density on apical dendrites of pyramidal neurons in NCX. Data from 6 exposed and 6 age-matched normoxic controls (*naive*) revealed a significant decrease ($p<0.01$) in the mean # of dendritic spines in the NCX from exposed (40.7 ± 1.7; ±SEM) vs naive animals (49.4 ± 1.3). Intracellular recordings from brain slice were used to measure membrane potential (Vm) and input resistance (Rm). Baseline Vm was not different between exposed and naive NCX, while Rm was greater ($p<0.01$) in exposed (53.5 ± 3.4 MΩ, n=41) compared to naive (42.8 ± 2.3 MΩ, n=52). We conclude that 1) long-term exposure to a reduced oxygen environment alters neuronal cytoarchitecture and membrane properties in NCX, and 2) these changes may play a role in the increased response to acute hypoxia in NCX neurons from exposed animals. "ISCHEMIC TOLERANCE" IN CORTICAL CELL CULTURE.

M.C. Grabb*, and D.W. Choi. Dept. of Neurology and Center for the Study of Nervous System Injury, Washington Univ. School of Medicine, St. Louis, MO 63110.

Several studies in recent years have established the phenomenon of "ischemic tolerance" in animal models of brain ischemia, where mild ischemic insults render the brain resistant to injury induced by a subsequent, more severe insult (Kitagawa, *Br. Res.* 528:21, 1990; Kirino, *J. Cereb. Blood Flow Metab.*11:299, 1991). This phenomenon is thought to reflect protective cellular alterations induced by the first, preconditioning ischemic insult. The present study was performed to see if the phenomenon could be demonstrated in cell cultures.

Murine cortical cell cultures containing both neurons and glia (DIV 13) were exposed to sham wash, or periods of oxygen-glucose deprivation (5-20 min) too brief to induce detectable cell death. 24 hrs later, these cultures were exposed to a 50-75 min period of oxygen-glucose deprivation, sufficient to induce intermediate levels of neuronal death without glial death in control cultures (as assessed 24 hrs later by morphological examination and LDH efflux to the bathing medium). Cultures preconditioned by exposure to a 20 min period of oxygen-glucose deprivation exhibited 30-70% less neuronal death than those preconditioned by sham wash alone. These experiments support the idea that sublethal ischemic insults can render cortical cells resistant to subsequent ischemic insults, and provide encouragement for further examination of this phenomenon in the culture system.

HYPOXIA TRIGGERS NEUROPROTECTIVE ALTERATIONS IN HIPPOCAMPAL GENE EXPRESSION VIA A HEME-CONTAINING SENSOR.

A.T. Gage* and P.K. Stanton. Departments of Neuroscience & Neurology, Albert Einstein Coll. Med., Bronx, NY 10461

Pre-exposure of rat hippocampus to short periods of hypoxia increases the resistance of CA1 pyramidal neurons to longer, normally fatal hypoxic insults. We have previously shown that the induction of this neuroprotection requires ongoing RNA and protein synthesis. We hypothesized that, similar to peripheral erythropoeisis, a low [O_2] environment may convert a heme-containing sensor to its deoxygenated conformation, triggering the expression of neuroprotective gene products. Carbon monoxide (CO) can replace O_2 bound to heme iron and effectively lock the porphyrin ring in its oxygenated state. Therefore, we applied 10% CO to hippocampal slices during severe hypoxia, to determine if it could prevent the induction of neuroprotection by hypoxia.. We used a bipolar electrode to stimulate Schaffer collateral axons in area CA1 every 60 s, and recorded evoked dendritic population epsps in stratum radiatum. Naïve slices subjected to a 15 min period of severe hypoxia (95% N_2/5% CO_2) show little or no recovery of synaptic transmission. In contrast, 5 min preconditioning hypoxia markedly improved resistance to subsequent, longer hypoxic episodes. In contrast, when a 5 min preconditioning hypoxia was given in the presence of CO (85% N_2/5% CO_2/10% CO), the induction of neuroprotection was completely blocked. As a control, another group of slices were subjected to 5 min preconditioning hypoxia, followed 1 hour later by a second hypoxia in the presence of CO.. This group of slices exhibited normal resistance to hypoxia-induced loss of synaptic transmssion, indicating that the blockade of neuroprotection by CO could not be attributed to nonspecific toxicity, but are probably due to inactivation of a heme-containing O_2 sensor.

EFFECTS OF SEVERE ISCHEMIA-HYPOXIA ON GENE EXPRESSION IN YOUNG RATS. K.L. Gilby*, K.M Murphy, J.N. Armstrong, R.W. Currie and H.A. Robertson. Laboratory of Molecular Neurobiology, Depts. of Pharmacology and Anatomy & Neurobiology, Dalhousie Univ., Halifax, NS, Canada, B3H 4H7.

Ischemic brain injury leads to a destructive cascade of events that culminates in the death of certain neurons in hippocampus, striatum and cortex. The mechanism by which this occurs is poorly understood, but one of the early events following injury is a rapid increase in the expression of immediate-early genes and stress genes such as the inducible *hsp-70*. In order to understand the progression of changes initiated by ischemic insult that eventually lead to cell death, we used young rats in the Rice-Vannucci model of ischemia-hypoxia and have studied the effects of severe (60 min hypoxia) injury on the induction of *c-fos*, *c-jun* and *hsp-70* in the hippocampus. Rats (100) were divided into 4 groups (naive control, hypoxic control, ligated control and ligated hypoxic). Two animals that had seizures were excluded from the study. No cell death or increased protein expression was seen in any of the control groups. However, in the ligated hypoxic group, severe damage was observed. Such severe injury was associated with increased expression of the c-Fos and c-Jun proteins on the side ipsilateral to the injury at 12 hrs. However, at 24 hrs the expression of both c-Fos and c-Jun proteins on the ipsilateral side had returned to basal levels while their expression was increased on the contralateral side. HSP-70 levels increased on the ipsilateral side in CA1 at 24 hrs, but not at 12 hrs. At 48 hrs, the levels of c-Fos and c-Jun are at basal levels, but HSP-70 remains elevated on the ipsilateral side. At no time was HSP-70 protein expressed on the side contralateral to the insult. These findings suggest that even in this severe type of ischemic insult, expression of *c-fos*, *c-jun* and *hsp-70* may be involved in the events leading to cell death. Altering expression of these genes may therefore be expected to change the degree of injury. (supported by the MRC and SmithKline Beecham Pharma Inc.)

NEURONAL AND GLIAL EXPRESSION OF INDUCIBLE HSP70 IN FOREBRAIN ISCHEMIA. D. Xu[1], J.-C.L. Plumier[1], H.A. Robertson[2] and R.W. Currie[1]* Laboratory of Mol. Neurobiology, Depts. of Anatomy & Neurobiology[1] and Pharmacology[2], Dalhousie Univ., Halifax, N.S., Canada, B3H 4H7.

Although induction of HSP70 in neurons in the vulnerable regions in the brain after cerebral ischemia has been well documented, the relationship of the expression with neuronal death and survival remains unclear. In the present study, we examined neurons as well as glial cells for cell death using cresyl violet staining, and for expression of HSP70 by immunohistochemistry at 1.5, 3, 6, 12, 24, 48, 72, and 120 hours after 30 minutes of global ischemia. Immunoreactivity against HSP70 was first observed at 12 hours in neurons in layer V of the cortex, and at 24 hours in layers II and III. Layer VI of the cortex rarely revealed expression of HSP70. Most of the pyramidal cells in the hippocampus expressed HSP70 at 24 hours and the expression remained at high levels until 72 hours. Elevated expression of HSP70 remained until 120 hours in the CA3 region. This pattern of HSP70 expression was seen when there was only moderate cell loss in CA1 at 72 and 120 hours as revealed by cresyl violet staining. However, in some cases, cresyl violet staining revealed abrupt and massive neuronal loss due to cell death in CA1 at 24 hours and in CA3 and dentate gyrus at 72 hours. In these brains, at 24 hours, HSP70 was not observed in CA1 but CA3 had a pattern similar to brains with only moderate cell loss in CA1. Only in cases with severe cell loss, was HSP70 expression seen in layer VI of the cortex. HSP70 expression was observed in glia-like cells, often in clusters, in areas in cortex and hippocampus where neuronal HSP70 immunoreactivity was no longer detected and cresyl violet staining revealed loss of neurons. These glial-like cells were immunoreactive for OX-42. These findings suggest a relationship between neuronal expression of HSP70 and neuronal survival. Glial expression of HSP70 may be associated with activation of the glial cells in response to neuronal necrosis.

EFFECTS OF CEREBRAL INJURY ON TRANSGENIC MICE EXPRESSING THE HUMAN HSP70. J.-C.L. Plumier[1]*, J.N. Armstrong[1], H.A. Robertson[2], R.W. Currie[1], C.E. Angelidis[4], H. Kazlaris[3], G. Kollias[3], and G.N. Pagoulatos[4], Laboratory of Molecular Neurobiology, Departments of Anatomy & Neurobiology[1] and Pharmacology[2], Dalhousie University, Halifax, N.S., Canada B3H 4H7; Department of Molecular Genetics[3], Hellenic Pasteur Institute, Athens, Greece 11521; Laboratory of General Biology[4], University of Ioannina Medical School, Ioannina, Greece 45332.

In the brain, expression of the inducible HSP70 is well described following many types of injury, including ischemia and kainic acid treatment. This induced expression of HSP70 has been suggested to be associated with neuronal protection to ischemic injury. Recently, we reported that constitutive overexpression of the human inducible 70-kDa heat shock protein in mice increased the contractile recovery of isolated hearts following global ischemia. The protective effect of overexpression of the human HSP70 transgene in mouse brain has not yet been determined. Transgenic mice overexpressing the human HSP70 under the control of the human β-actin promoter were examined for neuronal protection to cellular injury. Presence of the human transgene in brain was determined by S1 nuclease mapping using a fragment derived from the PAT-HS70 plasmid as probe. Western analysis demonstrated constitutive expression of the human HSP70 in mouse brains. In preliminary experiments, kainic acid was injected intraperitoneally into control and transgenic mice. Kainic acid administration (35 mg/kg) lead to 50% death of control mice (n=6) and 89% death of transgenic mice (n=9) during epileptic seizure. This result suggests that overexpression of the human HSP70 transgene in mouse brain does not protect and may even sensitize the hHSP70 transgenic animals to kainic acid induced seizures. We are currently examining these transgenic mice for resistance to ischemic injury.

EXPRESSION OF hsp70 mRNA FOLLOWING TRANSIENT BILATERAL COMMON CAROTID ARTERY OCCLUSION IN TRANSGENIC MICE OVEREXPRESSING CuZn-SUPEROXIDE DISMUTASE. Murakami K. [1] Kondo T. [1] Honkaniemi J. [3] Mikawa S. [1] Chan T. [1] Chen S *. [1] Sharp F R. [3] Epstein C J. [2] and Chan P H. [1] (Department of Neurology, Neurosurgery[1] and Pediatrics[2], University of California, San Francisco, CA94143 and Department of Neurology[3] VA Medical Center, San Francisco, CA94121.)

Various studies have demonstrated an increase in heat shock protein 70 (HSP70) synthesis in the brain following transiently induced ischemia, suggesting a protective role for HSP70 against ischemic insult. Recently, it has been reported that HSP70 mRNA (hsp70) expression is affected by oxidative stress. However, the underlying mechanism is unclear. We used transgenic (Tg) mice which overexpress CuZn-superoxide dismutase (CuZn-SOD), to examine the amount and distribution of hsp70 expression following transient bilateral common carotid artery (CCA) occlusion. Male heterozygous Tg mice (Tg HS/SF-218-3) and nontransgenic (nTg) normal littermates (35±4 g) were anesthetized with methoxyflurane. Bilateral CCA were occluded for 3 min using small surgical clips. The mice were decapitated, and brains were frozen and sectioned 20 μm thick. The sections at 4, 24, 72, and 168 h after the surgery were processed for in situ hybridization with [^{35}S]-labeled oligonucleotide probe of hsp70 (n=3). Histological findings were examined by cresyl violet staining, and DNA fragmentation was examined by specific labeling of 3'-OH DNA ends using the TUNEL technique. In Tg mice, hsp70 was strongly expressed in cortex, caudate putamen, thalamus and whole hippocampus at 4 h, and it was still detectable within the hippocampal CA1 for up to 24 h. However, in nTg mice, hsp70 weakly appeared only CA1 from 4 to 24 h. There was no observable neuronal necrosis in either Tg or nTg by cresyl violet, and DNA fragmentation was not seen in either Tg or nTg. The present study demonstrates that increased CuZn-SOD activity induced or permitted the hsp70 expression after transient bilateral CCA occlusion without any observable cerebral injury. We speculate that upregulation of hsp70 expression may be associated with decreased production of reactive oxygen species in CuZn-SOD Tg mice after a transient cerebral ischemia. ASTROCYTE SURVIVAL AND HSP70 HEAT SHOCK PROTEIN INDUCTION FOLLOWING ACIDOSIS AND HEAT SHOCK. P.Narasimhan*, R.A.Swanson, S.Sagar, F.R.Sharp. Department of Neurology, University of Californ at San Francisco and SFVAMC, San Francisco, CA 94121.

Though severe acidosis is animportant mediator of brain infarction, recent evidence suggests that mild acidosis may also protect ischemic cells. The HSP70 heat shock protein is induced by acidosis in cultured cells and in ischemic brain, and is known to protect cells against many types of injury. Therefore, this study determined whether induction of heat shock proteins protects cultured astrocytes against acidosis. Brief exposure of cultured cortical astrocytes to acid (pH5.2 for 40 minutes) or heat shock (45^{0}C for 40 min) markedly induced hsp70 mRNA and HSP70 protein in these cells. Heat shock of the cultured cortical astrocytes completely protected the astrocytes from subsequent heat treatment (45^{0}C for 4h). In contrast, heat shock pretreatment and acid pretreatment sensitized the astrocytes to injury from acidosis 24 h later. Heat shock pretreatment did protect astrocytes against exposure to acid 48h later. These results suggest that induction of other stress proteins and acid shock proteins partially protect the astrocytes against damage produced by high concentrations hydrogen ions.

ANOXIA/AGLYCEMIA INDUCES mRNA ENCODING THE 70 KDA STRESS PROTEIN, HSP72, IN RAT HIPPOCAMPAL SLICES. Q. Zhou* and T. S. Nowak, Jr. Depts. of Anatomy & Neurobiology and Neurology, University of Tennessee, Memphis, TN 38163

In previous studies we examined changes in the expression of mRNAs and proteins that occur during preparation of hippocampal slices. Under optimal conditions hsp72 was not detected, MAP2 immunoreactivity was comparable to that of normal brain, and Fos and Jun staining were only moderately increased. We have now used slices that meet these criteria to develop an in vitro model that replicates many features of postischemic hsp72 expression observed in vivo. Vibratome slices (400 μm) were prepared from halothane anesthetized Wistar rats and incubated at 34 °C in standard artificial cerebrospinal fluid (ACSF) purged with 95% O_2, 5% CO_2 including 5 mM glucose and 1.5 mM Ca. The anoxic/aglycemic insult was produced by transfer to ACSF lacking glucose, replacing O_2 with N_2 and reducing Ca to 0.2 mM. After insults of 2-6 min slices were returned to normal ACSF for varied intervals up to 4 h. Slices were frozen or fixed in 4% paraformaldehyde and sectioned for in situ hybdridization, immunocytochemistry and histology. Insults of 2-3 min duration resulted in minimal changes in normal MAP2 immunoreactivity during the time intervals examined, while anoxia/aglycemia of 4 min or longer produced rapid loss of MAP2 staining and histologically shrunken neurons. Hsp72 mRNA was detected after reoxygenation intervals of 1 h or longer, with preferential induction in dentate granule cells and CA3 neurons. Preliminary results indicate maximal expression after 3 min in vitro ischemia. These findings demonstrate the potential utility of such preparations for studies of changes in gene expression after ischemia.

676.1

PREVALENCE OF TRAUMATIC BRAIN INJURY IN RUGBY AND LACROSSE PLAYERS. J. Liotta, P. Donovick*. Environmental Neuropsychology Lab., Dept. of Psychology, State Univ. of N.Y. at Binghamton, 13902-6000.

The present study of 59 athletes was done to see the amount of traumatic brain injury (TBI) that they have sustained while playing in their respective sports. An inventory of their sports history was also examined. The athletes currently play women's lacrosse or men's and women's rugby. The testing instrument was the Binghamton Head Injury Questionnaire. Two trends were observed. The first being that rubgy players had a higher incidence of TBI than lacrosse players. The second was that female rugby players had a higher incidence of TBI on avg. than males in both their sports history and in rugby. It was concluded that this may be due to the amount of experience that both sexes have with contact sports. Females may have reported every incident while males only reported the severe cases because they are used to the little blows. Another conclusion was that males have more developed necks and their heads are more protected as a result.

SINGLE-DAY TESTING IN THE MORRIS WATER MAZE. R.F. Cody, D.O. Maris, L.C. Costa*[1], M.S. Grady. Depts. of Neurological Surgery and Environmental Health[1], Univ. of Washington School of Medicine, Seattle, WA.

The Morris water maze has been widely used to evaluate spatial learning. Usually, sequential trials are carried out over several days to allow subjects time to acquire the task. We were interested in determining whether a series of trials in a single day would retain test specificity and sensitivity and have the benefit of reducing work effort required in analyzing spatial function. In this study, the Morris water maze was used to test spatial learning in naive adult male Sprague-Dawley rats at 7 and 14 days following either sham surgery or experimental traumatic brain injury (fluid percussion injury) (n=8 for each group). Six trials per day were used, for a total of 12 trials per rat. Escape latency, quadrant time, and cumulative platform distance were measured with a video tracking system (VP-116, HVS Image, Hampton, England). Spatial bias was assessed with free swims (probes) on the 5th and 12th trials.

Sham rats demonstrated significantly better performance than injured rats in both probe trials. Cumulative distance measures indicated task acquisition by sham but not injured animals at the end of the first day ($p<.009$ to .03); significance was approached but not obtained in quadrant time and latency measures ($p<.053$ to .147). Comparison of escape latency, quadrant time, and cumulative platform distance indicated definite acquisition of the task by sham rats at the end of the second day of testing ($p<.001$ to .017). This experiment shows that single-day testing in the Morris water maze can be used to assess spatial learning accurately.

676.3

EFFECTS OF SECONDARY INSULT ON TRAUMATIC BRAIN INJURY. D.A. Chorney*, J.S. Soblosky, L.L. Colgin, J.F. Davidson, and M.E. Carey. Dept. of Neurosurgery, LSU Medical Center, New Orleans, LA 70112

Secondary insults (eg. hypotension, hypoxia) potentiate traumatic brain injury. We quantified the effects of traumatic brain injury followed by 10 minutes of hypotension (MABP 50 mm Hg) on rodent sensory/motor behavior. Isoflurane-anesthetized rats were injured in the right sensory/motor cortex by a piston with a 4X8mm elliptical tip which depressed the dura 1mm. Impact speed was 5M/sec. Hypotension was produced by removing 5ml of blood via a jugular cannula. We reinfused the blood after the 10-min hypotensive period. Animals were placed in one of four groups: 1) Brain-injured followed by 10-min. of hypotension; 2) 10-min. hypotension only; 3) brain-injured only; and 4) control. We evaluated motor deficits using four tests: performance traversing a flat narrow beam, the number of footslips on a pegged narrow beam, the number of foot-faults on a grid platform, and a forepaw preference test. The results indicate the animals that received brain injury and were made hypotensive performed significantly poorer on the flat beam and the grid than the normotensive brain-injured rats or the rats subject to hypotension. Experimental brain injury followed by hypotension has a demonstrated deleterious effects on motor behavior, beyond that of brain-injury alone.

HYPERMETABOLIC RESPONSES TO BRAIN DAMAGE S.Y. Roe, J.K. Relton+, S. Toulmond, E. McGowan* and N.J. Rothwell School of Biological Sciences, Neuroscience Division, 1.124 Stopford Building, University of Manchester, Manchester M13 9PT, UK +Present address Amgen, 1885 33rd Street, Boulder, Colorado 80301, USA

Increases in metabolic rate have been reported in patients with traumatic or ischaemic brain damage, and can compromise neurological recovery and lead to metabolic disturbances. In order to investigate the mechanisms underlying these responses, metabolic rate has been measured after focal ischaemia (middle cerebral artery occlusion, MCAo) or traumatic brain injury (lateral fluid percussion) in the rat. Both insults lead to significant (25-30%) increases in resting oxygen consumption over the 24h period after injury. This hypermetabolism was dependent on activation of the sympathetic nervous system and was associated with reduced food intake and weight loss. Expression of corticotrophin releasing factor (CRF), which has been implicated in metabolic responses to systemic injury and infection, was induced by brain damage. Central (icv) injection of a CRF receptor antagonist, or lipocortin-1, which inhibits CRF release, significantly inhibited the increases in metabolic rate induced by MCAo. These data suggest that the marked metabolic disturbances which result from brain damage share common mechanisms with those seen after systemic injury, and depend on synthesis of CRF.

PHARMACOLOGICAL ATTENUATION OF PHOTOCHEMICALLY INDUCED APOPTOSIS IN THE RAT BRAIN. A. Kharlamov*, D.M. Armstrong and H. Maney. ASRI, Medical College of Pennsylvania and Hahnemann University, Allegheny Campus, Pittsburgh, PA, 15212.

It has recently been demonstrated that apoptotic cell death characterized by intranucleosomal DNA fragmentation can occur in a mature brain after ischemic damage (Stroke 1993, 24:2002; J Neurochem. 1993, 61:378; NeuroReport 1994, 5:493). We have shown in rats that photothrombotic focal brain injury, induced by the intravenous injection of the photosensitive dye rose bengal and skull irradiation with a beam of focused light, can initiate the apoptotic process in cells in the area surrounding the necrotic core (NeuroReport 1994, 5:2661). Apoptotic cells were identified using the immunocytochemical terminal deoxynucleotidyl transferase (TDT)-mediated dUTP-biotin nick end labeling (TUNEL) technique (ApopTag kit, Oncor). In addition, the area of the infarcted core was measured in brain slices incubated with 2% triphenyltetrazolium chloride for 15 min at 37°C. Further evidence of programmed cell death was obtained using a pharmacological approach and blocking: a) endonucleases by intracerebroventricular injection of aurintricarboxylic acid (ATA 5,10,20 µg/5µl); and b) protein synthesis by injecting cycloheximide subcutaneously (2.5 mg/kg). Both treatments significantly reduced the number of apoptotic cells in the area surrounding the necrotic core, suggesting that the apoptotic process involved de novo synthesis of proteins. In this study we also blocked glutamate receptors by injecting MK-801 intravenously (2.5 mg/kg). MK-801 reduced the size of the photothrombotic lesion and decreased the number of TUNEL-labeled cells. Our results are consistent with the hypothesis that glutamate receptor activation (probably caused by the release of glutamate from the lesion core) may trigger delayed apoptotic cell death. Treatments targeted at halting this process might provide neuroprotection in post-stroke or post-traumatic brain pathologies.

ASTROCYTE INJURY: THE ROLE OF EXTRACELLULAR CALCIUM B.A. Rzigalinski, S. Liang, and E. F. Ellis*. Dept. of Pharmacology and Toxicology, Medical College of Virginia, Richmond VA 23298.

Although considerable evidence supports a role for elevated intracellular calcium ($[Ca^{2+}]i$) in neuronal damage associated with traumatic injury, mechanisms which mediate traumatic injury in the astrocyte are less clear. Using an *in vitro* model of cell injury (Ellis et al., FASEB J. A665, 1994), we investigated the role of Ca^{2+} in astrocyte injury. Neonatal rat cortical astrocytes were cultured in silastic-bottom wells. Stretch injury was induced using a Cell Injury Controller. This device delivers a regulated pressure pulse of air to the silastic membrane, resulting in membrane deformation and stretch injury. For these experiments, silastic membranes were subjected to a 50 msec pulse, resulting in a 6.3 mm deformation of the silastic membrane (38% stretch). The extent of cell membrane injury was assessed by uptake of propidium iodide (PI) and release of lactate dehydrogenase (LDH). The highest levels of PI staining were observed in cells injured in Ca^{2+}-free or low Ca^{2+} medium (0-10 µM). Increasing concentrations of extracellular calcium (0.1-2 mM) resulted in decreased PI uptake. Release of LDH was also maximal in Ca^{2+}-free medium, and was also decreased by increasing extracellular Ca^{2+} (0.1-1mM). Thus, the extent of injury was actually reduced by elevated extracellular Ca^{2+}. Neither Ba^{2+}, Mn^{2+}, or Zn^{2+} could substitute for extracellular Ca^{2+}, suggesting that the effect on injury is specific for Ca^{2+}. Experiments conducted with $^{45}Ca^{2+}$ demonstrated that stretch injury induced an influx of extracellular Ca^{2+}. Maximal levels of $[Ca^{2+}]i$ (10 fold that of uninjured controls) were attained by 5 minutes post injury and returned to near basal levels by 2-3 hours post injury. Neither influx of $^{45}Ca^{2+}$ nor the ability of increased extracellular Ca^{2+} to protect cells from stretch injury could be inhibited by nimodipine, CNQX, MK801 or SKF96365. Thapsigargin elevates $[Ca^{2+}]i$ by activation of the capacitative calcium influx pathway, independent of receptor occupation. Pretreatment of astrocytes with 1 µM thapsigargin for 5 minutes prior to injury significantly deceased astrocyte injury. Thus, elevation of $[Ca^{2+}]i$ reduces stretch injury of astrocytes. These results may be critical to evaluation of the role of calcium in mechanical injury to the nervous system. Supported by NIH-NS 27214.

EPIDERMAL GROWTH FACTOR INDUCES PROSTAGLANDIN H SYNTHASE-2 IN CEREBRAL MICROVASCULAR SMOOTH MUSCLE. G. Rich*, L.J. Prokuski, E.J. Yoder, and S.A. Moore. Dept. of Pathology, University of Iowa, Iowa City, IA 52242-1181

Prostaglandins (PG) are likely to play an important role in regulating normal cerebral vessels and their response to injury. This response often involves proliferation of vascular cells and an inflammatory cell infiltrate. Recently an inducible form of prostaglandin H synthase (PGHS-2) has been described that may be important in inflammatory and proliferative conditions. Thus, we investigated the ability of mouse endothelium (En) and smooth muscle (SM) derived from cerebral microvessels to release PG and express PGHS-2. In routine cultures, both En and SM produce PGE_2 and I_2 and express PGHS-1 and -2 mRNA. Serum deprivation for 48h decreases PG production by > 90% in SM but does not affect En. The drop in SM PG release is accompanied by a loss of PGHS-2 mRNA and protein. Serum and epidermal growth factor (EGF) reinduce PG production in these serum-deprived cultures, while other growth factors, FGF and PDGF, are largely ineffective. Selective PGHS-2 inhibitors, NS-398 and 6-methoxy naphthalene acetic acid, block EGF and serum-induced PG production. Readdition of serum also upregulates PGHS-2 mRNA. Furthermore, EGF and serum induce PGHS-2 protein in immunoprecipitation and immunohistochemistry assays. A specific PGHS-2 antibody labels the nuclear membrane with high intensity in serum and EGF-stimulated cells. While a mechanism for serum and EGF induction of PGHS-2 is not clear, phorbol esters also induce this PGHS suggesting that protein kinase C may be involved. These results indicate that cerebrovascular SM may be a significant source of PG in brain injury. Supported by NS-27914, NS-24621 and NS-09858.

THE FEASIBILITY OF SPINAL CORD STIMULATION FOR CONTROL OF LOWER EXTREMITIES. V. K. Mushahwar, K. W. Horch and P. R. Burgess*. Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT 84112

The goal of this project is to assess the feasibility of controlling muscles in the hindlimb of cats by electrically stimulating the spinal cord, ultimately as a method for restoring mobility to paralyzed individuals. Earlier work in our lab has shown that the lumbo-sacral portion of the spinal cord contains regions in which stimulation activates specific muscle groups in the leg in isolation. We refer to these regions as "activation pools." We report here on the activation pools for the quadriceps muscle group.

For the experiments, the lumbo-sacral portion of the spinal cord was exposed. The patella was dislocated and the patellar tendon was transected and attached to a transducer to measure quadriceps force. Activities in the remaining main muscle groups were monitored using a combination of force transducers and EMG electrodes. Electrical stimulation through penetrating needle electrodes was used to map the quadriceps activation pools in the ventral horn of the cord.

The results show that the quadriceps muscle group has two activation pools. The rostral pool spreads from mid L5 to mid L6, while the caudal pool is contained within L7. Current thresholds in the quadriceps pool for force production were as low as 3 μA for 600 μs pulses. Stimulus levels could be increased several fold beyond threshold before activity in other muscle groups was detected. Peak twitch forces as high as 17 N were generated by single point stimulation.

These results indicate that the quadriceps muscle group can be selectively recruited by electrically stimulating activation pools in the lumbo-sacral portion of the spinal cord, and that good control of force can be achieved. If, as expected on the basis of preliminary work we have completed, these results can be extended to the remaining muscle groups in the leg, it would be feasible to utilize spinal cord stimulation for restoring mobility to paralyzed individuals.

PERSISTENT SLEEP ABNORMALITIES AND CLINICAL COURSE IN PRIMARY ALCOHOLICS WITH SECONDARY DEPRESSION **CPClark,JCGillin,SGolshan,ADemodena,TLSmith,SDanowski,SLFoote* Mlrwin,MASchuckit Dept. of Psychiatry, UCSD, La Jolla CA 90048.**

23 male primary alcoholics with secondary depression (PASD) were compared retrospectively with 23 age-matched males with alcoholism alone. Polysomnography (PSG) and Hamilton Rating Scale for Depression (HRSD) scores at admission & discharge were analyzed (mixed design ANOVA, BMDP). Subjects were diagnosed by Schuckit's $1^{o}/2^{o}$ classification system & were excluded for alcohol withdrawal, other Axis I diagnoses, recent drug use, recent delirium tremens, serious medical problems, or sleep disorders. All remained medication-free throughout their admission.

HRSD-17 was significantly worse in PASD than in pure alcoholics. HRSD-24, HRSD-17, sleep latency, and % sleep efficiency improved by discharge in both groups. REM duration displayed a trend toward interaction, decreasing slightly in the pure alcoholics as compared to little or no increase in PASD. Delta sleep abnormalities were severe in both groups at admission; like some other sleep abnormalities, they persisted despite clinical improvement.

Studies in primary depression suggest that short REM latency and decreased delta sleep may be persistent trait markers.

BINDING TO 5-HT_{1D} SITES IS REDUCED IN PREFRONTAL CORTEX OF ALCOHOLICS. *V. Arango*, V.D. Khait and J.J. Mann.* Dep. of Neuroscience, NYS Psychiatric Institute and the College of Physicians & Surgeons of Columbia University, New York, NY 10032.

Alterations in the serotonergic system have been implicated in suicidal behavior and in chronic alcohol consumption. We sought to determine whether binding to 5-HT_{1D}, a presynaptic serotonin receptor, differed between alcoholics who died by suicide (SA, n=12) or other means (CA, n=12), compared to normal controls (C, n=12) in homogenates from dorsal prefrontal cortex. Each SA and CA were carefully matched to a control based on age, sex and postmortem delay (PMI) and assayed together as a triplet. Demographic variables did not differ between groups, including age (SA=37.5±4.0y [20-61]; CA=39.2±4.3y [19-66]; C=38.3±4.1y [17-66], p=0.96) and PMI (SA=11.3±1.1h; CA=12.3±1.2h; C=13.2±1.1h; p=0.51). The ratio of men to women was 10:2 in each group. P_2 pellets were resuspended in 50mM Tris-HCl buffer (pH 7.7) and preincubated (37°C) for 10 min. The incubation (30 min, 20°C) contained six concentrations of ^{3}H-5HT (0.25 to 4nM) with 100nM 8-OH DPAT and 10μM pargyline. Specific binding was defined by 5μM sumatriptan. The levels of 5-HT, its precursor (TRP) and metabolite (5-HIAA) were determined by HPLC.

Both alcoholic groups had lower B_{max} than controls (CA=60.9±9.1, p=0.027; SA=56.4±4.9, p=0.009, C=79.1±8.0 fmol/mg protein), but K_D did not differ between groups. Neither B_{max} nor K_D correlated with age. B_{max} correlated positively with PMI when all groups were examined together (r=0.37 p=0.03, n=36). K_D did not correlate with PMI in any group. The levels of 5-HT, 5-HIAA and TRP did not differ between groups (p>0.05). B_{max} correlated with 5-HIAA only in the control group (r=0.75, p=0.01). K_D did not correlate with 5-HT, 5-HIAA or TRP. The data suggest that alcoholism is associated with damage to serotonergic nerve terminals independent of the serotonergic deficit related to suicide (MH46745, AA09004).

INCREASED ABUNDANCE OF MONOAMINE OXIDASE-A CATALYTIC SITES AND ACTIVITY IN BRAINS OF HUMANS WITH HEPATIC ENCEPHALOPATHY D.D. Mousseau[1]*, G.B. Baker[2] and R.F. Butterworth[1] [1]Neurosci. Res. Unit, Hôp. Saint-Luc, Univ. of Montreal, Montreal and [2]Neurochem. Res. Unit, Dept. of Psychiatry, Univ. of Alberta Hospital, Edmonton, Canada.

Hepatic encephalopathy (HE) is a neuropsychiatric complication of chronic liver disease which presents an altered biogenic amine function. Monoamine oxidase (MAO) is the main degradative enzyme in amine metabolism. We investigated the binding parameters of [^{3}H]Ro 41-1049 and [^{3}H]Ro 19-6327, ligands having a high-affinity for the catalytic sites of MAO-A and -B, respectively, in autopsied brain tissue from cirrhotic patients with HE. The binding density of [^{3}H]Ro 41-1049 was increased in both frontal cortex (by ~86%) and cerebellum (by ~223%) of HE patients. An increase in MAO activity in the frontal cortex (by ~47%) and in the cerebellum (by ~145%) was also limited to MAO-A. Except for a slight increase in cerebellar activity, MAO-B parameters (*eg.* specific binding of [^{3}H]Ro 19-6327 and activity) in patient tissue were not significantly different from those in control tissue. Analysis of putative neurotransmitter amines in both regions indicated increased levels of 3,4-dihydroxyphenylacetic acid and 5-hydroxyindoleacetic acid, the predominant MAO-mediated metabolites of dopamine and serotonin, respectively. These findings suggest a pathogenic role for the MAO-A isozyme in human HE. (Funded by MRC, Canada)

THETA SLOWING AS A RELIABLE, EEG-BASED INDICATOR OF 5-HT_2 ANTAGONISM. D.F. Sisson*, D.H. Snyder, J.M. Goldstein. Zeneca Pharmaceuticals Group, Wilmington, DE 19897.

Several putative, antipsychotic compounds were administered to rats *per os* as a suspension in HPMC. EEG was recorded from screw electrodes chronically implanted, bilaterally, in the skull over frontal and parietal cortices. The EEG signal was quantitatively analyzed in the frequency domain by estimating the power spectrum of one minute epochs of EEG before drug administration and at intervals following drug administration. Mobility, a metric related to the mean frequency, and power in the theta band (4.0 - 8.0 Hz) were analyzed as a percent of their values before drug administration. Neither HPMC nor haloperidol changed theta mobility or power. Chlorpromazine, clozapine, olanzapine, risperidone, ritanserin and ZD3638 decreased theta mobility. Clozapine and olanzapine increased theta power. The common factor among the compounds that decreased theta mobility was predicted antagonism of the 5-HT_2 receptor at the administered dose. The similarity of the effect on theta mobility between a selective 5-HT_2 antagonist such as ritanserin and a compound with a much broader spectrum of receptor affinities such as clozapine also suggests that the decrease in theta mobility observed in this study is indicative of 5-HT_2 antagonism. Theta slowing induced by serotonergic antagonism has also been observed in the hippocampus (Vanderwolf, *et al.*, 1990). The increase in theta power induced by clozapine and olanzapine can be attributed to the heavy sedation produced by these compounds. Sedation would decrease the overall tone of the serotonergic system (Trulson & Jacobs, 1979), and thereby augment the decrease in theta mobility induced by 5-HT_2 antagonism.

BIOCHEMICAL PROFILE OF BEFLOXATONE, A SELECTIVE AND REVERSIBLE MAO-A INHIBITOR. O. Curet*, G.Damoiseau, N. Aubin, C. Sauvage, N. Sontag, C. Carter, J. Benavides, B Scatton, Central Nervous System Research Department, Synthelabo Recherche, Rueil-Malmaison, France.

Befloxatone selectively and competitively inhibits MAO-A in different rat and human tissues (brain, duodenum, liver and heart) with Ki's ranging from 1.9 to 3.6 nM for MAO-A and from 270 to 900 nM for MAO-B. Befloxatone does not interact with a large number of receptors, monoamine transporters or other amine oxidases. The inhibition of MAO-A by befloxatone is fully reversible in vitro (dilution method) and ex vivo after a single oral administration. In the rat brain, befloxatone inhibits MAO-A with an ED_{50} of 0.018 mg/kg, po, increases the levels of NA, DA and 5-HT and decreases the levels of their respective ideaminated metabolites. In vivo microdialysis studies show that befloxatone (0.75 mg/kg, ip) increases extracellular levels of NA (cortex), DA (striatum) but not 5-HT (cortex) after acute administration. In rat brain sections and homogenates, [^{3}H]-befloxatone labels a single saturable population of binding sites with a Kd of 1.3 and 1.5 nM, respectively wihich has the pharmacological properties of MAO-A. In vitro (brain) and ex vivo (duodenum), the binding of [^{3}H]-befloxatone is displaced by tyramine. In the rat brain, a striking correlation was observed between in vitro and in vivo labelling of MAO-A by [^{3}H]-befloxatone. In conclusion, these data provide evidence that befloxatone is a potent, reversible, competitive, and selective MAO-A inhibitor. Befloxatone is currently undergoing phase II clinical trials.

LITHIUM DELAYS ONSET OF OUABAIN-INDUCED EPILEPTIFORM-LIKE RESPONSES IN HIPPOCAMPAL SLICES

R. S. El-Mallakh, A. Schurr, R. S. Payne, R. Li, and R. S. Levy*. Depts of Psychiatry, Anesthesiology, and Biochemistry, University of Louisville School of Medicine, Louisville, KY 40292.

Lithium pretreatment has been shown to: protect dogs from digoxin-induced cardiac arrhythmias, protect differentiated cultured human neuroblastoma cells (SY5Y) from ouabain-induced cardiotoxicity, and prevent ouabain-induced behavioral changes in rats receiving intracerebroventricular ouabain. To further investigate this phenomenon in living neuronal systems we examined the effect of lithium on ouabain-induced epileptiform-like population responses induced by electrical stimulation. Male Sprague-Dawley rats (225-275g) were treated with intraperitoneal lithium (2.5 mEq/kg/d) for 10-21 days, then used as the source for 400 µm thick hippocampal slices. Extracellular recording of electrically evoked population spikes were obtained from the stratum pyramidale of the CA1 region using micropipettes filled with artificial cerebrospinal fluid. Lithium treatment alone did not alter population spike response. Ouabain (3.3 µM) reliably produced epileptiform-like responses. Lithium pretreatment significantly delayed onset of ouabain-induced epileptiform-like activity by at least 15 min compared to untreated animals ($p<0.05$). Our data demonstrates that lithium can attenuate ouabain-induced effects in hippocampal slices. This system may prove useful in the study of the mechanism of lithium action.

CLOZAPINE SELECTIVELY BLOCKS A SUBSET OF $GABA_A$ RECEPTORS. R.F. Squires* and E. Saederup. Nathan Kline Institute, Orangeburg, NY 10962.

Earlier, we reported that clozapine reverses only half of the inhibitory effect of 1 µM GABA on ^{35}S-TBPS binding to rat brain membranes in vitro, and speculated that this might be due to selective blockade of some, but not all, $GABA_A$ receptor complexes (Neurochem. Res. 16:1099, 1991). To test this possibility we combined clozapine pair-wise with 44 other partial reversers, and found 13 that produced some additive reversal of GABA antagonistic effects. Ro5-4864 and tranylcypromine gave the largest additive effects (EC_{50} values ~ 310 nM and 70 µM; additive reversal ~ 22% and 26%, respectively). These results suggest that clozapine blocks GABA selectively at one set of $GABA_A$ receptors while Ro5-4864 and tranylcypromine block GABA at other sets that are not blocked by clozapine. Clozapine produces both GABA-negative (seizures, paroxysmal EEG) and GABA-positive (sedation, anxiolytic, anticonflict, retardation of electrical kindling, blockade of metrazol-induced increases in cerebellar cyclic-GMP) effects. The GABA-positive effects may be indirect, and due to selective blockade of certain types of GABergic disinhibition: for example clozapine may block one type of $GABA_A$ receptor on an inhibitory GABergic interneuron (e.g. $\alpha1\beta2\gamma_2$), but not another type on an excitatory principal neuron (e.g. $\alpha2\beta3\gamma_2$, Benke et al. J. Biol. Chem. 269:27100, 1994). Selective blockade of certain $GABA_A$ receptor complexes may contribute to clozapine's antipsychotic effect.

ERP STUDY ON DISSOCIATIVE DISORDERS. E.Kirino, H.Fumimoto, R.Inoue and H.Imai* Department of Psychiatry and Neurology, Juntendou Univ.Sch.of Med., Tokyo 113

Event-related potentials (ERPs) during an auditory "odd-ball" paradigm were studied in six patients with dissociative disorders. The patients showed significant reduction in the amplitudes of P300 during dissociative disorders compared with the levels at remission. The latency of P300 did not change significantly during and after dissociative disorders. In two patients who showed a high incidence of mismatch negativity (MMN) during and after dissociative disorders, the amplitudes of P300 increased at remission to a greater extent than in the other four patients who showed a low incidence of MMN, moreover, there was no significant difference in the level of atorophy in the superior temporal plane (STP) on their brain CT scans compared with that in the age- and sex- matched control group. The finding of the change in the amplitudes of P300 suggests that the mechanism of dissociation, which has been considered to be a defence mechanism of hysteria, can be psychophysiologically evaluated by ERPs. The amplitudes of P300 might be a state- dependent biological marker of dissociative disorders. The low incidence of MMN and atorohy of STP suggest the possibility of trait-dependent cerebral dysfunction or fragility in dissociative disorders.

KYNURENINE PATHWAY METABOLITES IN CEREBROSPINAL FLUID AND PLASMA OF TOURETTE SYNDROME PATIENTS. P. B. Chappell, G. M. Anderson, W. K. Goodman, L. H. Price, L. M. Hall, D. J. Cohen and J. F. Leckman*, Yale Univ. Sch. of Medicine, New Haven, CT 06510

The tryptophan (TRP) metabolites kynurenine (KYN), kynurenic acid (KA), and quinolinic acid (QA) are neuroactive, having actions at the NMDA glutamate receptor. Durson et al. (1994) have recently reported substantial elevations in plasma KYN in medicated Tourette's (TS) patients. A possible role for KYN pathway metabolites in TS also has been suggested by reports of their motor effects in animals, and by reports of reduced plasma TRP levels in TS (Leckman et al.,1984; Comings,1990) and reduced basal ganglia levels of TRP in TS postmortem brain (Anderson et al.,1992).

In contrast to the report of Durson, plasma KYN was only slightly (6-21%) and not significantly elevated in the TS group (N=23); plasma KYN was highly correlated with plasma ACTH secretion in the TS group. CSF levels of KYN and QA did not differ between the TS and control groups. However, the group mean level of CSF KA was modestly (16%, $p<.02$) increased in the TS group (N=30) compared to the normal control group (N=41).

The small increase in plasma KYN may be consistent with an apparant increased stress responsivity in some TS subjects (Chappell et al.,1994). The increase in CSF KA is intriguing given the previous suggestion that TRP metabolism and glutamatergic functioning may be altered in TS (Anderson et al.,1992).

677.10

SYSTEMATIC CHANGES IN CEREBRAL METABOLIC RATE AFTER SUCCESSFUL BEHAVIORAL TREATMENT OF OBSESSIVE-COMPULSIVE DISORDER (OCD). J.M. Schwartz*, P. Stoessel, L.R. Baxter, K. Martin, & M. Phelps. U.C.L.A. School of Medicine, Los Angeles, CA 90024.

Eighteen drug-free subjects with OCD were studied with PET scans before and after ten weeks of cognitive-behavioral treatment. Twelve patients demonstrated clinically significant improvement during the study period; six did not. Three main findings emerged: (1) responders to treatment showed bilateral decreases in caudate nucleus metabolism, divided by ipsilateral hemisphere metabolism (Cd/hem), compared to non-responders. This finding was more robust on the right ($p=.003$) than the left ($p=.02$). (2) Before treatment there were significant ($p<.002$) correlations of brain activity between the orbital cortex and the caudate nucleus, cingulate gyrus, and the thalamus on the right. After effective cognitive-behavioral treatment these correlations decreased significantly. (3) There was a significant positive rank-order correlation between percentage change in symptom severity rating score before and after treatment and the percentage change in orbital cortex/hem on the left ($p=.003$).

These findings demonstrate systematic changes in brain function in association with successful cognitive-behavioral treatment.

677.11

AUTONOMIC AND STARTLE RESPONDING DURING IMAGERY AND PICTURE VIEWING IN A PATIENT PRE- AND POST-ANTERIOR CAPSULOTOMY TO RELIEVE INTRACTABLE OBSESSIVE- COMPULSIVE DISORDER. S.Y. Musil*, S.A. Martinez, D.J. Drobes, B.N. Cuthbert, W.K. Goodman, and P.J. Lang. Center for the Study of Emotion and Attention, Dept. of Clinical and Health Psychology, Dept. of Psychiatry, Univ. of Florida, Gainesville, Florida 32610.

Anterior capsulotomy, a surgical procedure disrupting fibers connecting prefrontal cortex and thalamus, has been used to treat severe obsessive-compulsive disorder (OCD) when standard clinical interventions have failed. Reports of this procedure typically include extensive pre- and post- surgical evaluations of psychological and neuropsychological functioning. However, to date, no study has investigated changes in physiological reactivity to emotional stimuli which might result from anterior capsulotomy.

We report here on a case of a 33-year-old patient (WW) with a 23-year history of severe OCD which proved refractory to standard treatments, including multiple drug trials, intensive behavior therapy, and ECT. Prior to undergoing anterior capsulotomy via stereotactic radiosurgery techniques, WW participated in several physiological assessment procedures currently in standard use in the Fear and Anxiety Disorders Clinic at UF. Heart rate, skin conductance, corrugator EMG, and eyeblink startle responses were collected during an affective imagery procedure and while the patient viewed a series of affective slides. Prior to surgery, WW showed enhanced startle responding, and increased heart rate, skin conductance, and corrugator EMG, when viewing or imaging fear-related, rather than neutral or pleasant stimuli. These data will be presented and contrasted with post-surgical data.

677.12

CLONING OF NOVEL TRIPLET REPEAT CONTAINING GENES IN RAT FRONTAL CORTEX. M. Ikeda* and M. Nomura Dept . of Physiology, Saitama Med. School, Moroyama, Saitama 350-04, Japan.

The findings that expansion of triplet repeat is responsible for several neuropsychiatric disease has introduced new concepts in human inherited illness. In such diseases including Huntington's disease (HD), spino-cerebellar ataxia type 1 (SCA1), dentatorubral and pallidoluysian atrophy (DRPLA), Machado-Joseph disease (MJD), earlier age at onset, increasing severity of illness are associated with triplet repeat expansion. Marked expansion of triplet repeat may explain the phenomenon of genetic anticipation. Recently, anticipation has been reported in schizophrenia pedigrees suggesting a possible implication of triplet repeat expansion in schizophrenia. To identify novel triplet repeats containing genes associated with neuropsychiatric diseases, PCR was used to isolate cDNA fragments with triplet repeats. Priming with an oligonucleotide 10 CAG repeats and sequences in the phage vector results in several clones with CAG repeats. DNA sequencing and computer data base search to GenBank and EMBL demonstrated that these clones are novel molecules. Northern analysis of these genes is in progress.

MENTAL ILLNESS—DEPRESSION

678.1

LATE ONSET DEPRESSION AND MRI DETERMINED BRAIN VOLUMETRIC MEASURES A Kumar*, D Miller, W Bilker, D Ewbank, D Walsh, S Arnold, G Gottlieb University of Pennsylvania School of Medicine, Philadelphia, PA 19104

The purpose of our study was to examine the relationship between the age of onset of the first episode of major depression and global and regional normalized volumetric measures in elderly subjects with Major Depressive Disorder (MDD). Our sample comprised of 26 subjects (7 M, 19 W, Mean age $\pm$ SD=75.1±6.6) with late onset MDD -- the first episode occurring after age 60. All subjects had Hamilton depression scale scores of $\geq$ 15 and stable comorbid medical disorders with no evidence of clinical dementia or other brain disease. MR scans were performed on a 1.5 Tesla GE signa scanner with head coil (TR=3000, TE=30,80 msec). A segmentation algorithm was used to segment brain parenchyma from CSF and whole brain, hemispheres and frontal and temporal lobes were outlined as previously described (Cowell et al. J Neurosci 1994). Absolute volumes of brain and cerebrospinal fluid (CSF) were normalized using intracranial volume to correct for variations in head size. A multiple linear regression was used to examine the relationship between normalized MRI measures and age of onset of illness while adjusting for the subjects current age. Normalized whole brain CSF and total ventricular volumes showed significant increases with age of onset of illness, (r^2=0.48 p<0.05 and r^2=0.63 p<0.05 respectively), while frontal lobe volumes decreased significantly as onset age increased (r^2=0.19 p<0.05). These data demonstrate that in subjects with late onset depression, global and focal measures of atrophy increase with age of onset of illness. They also suggest that neuroanatomical contributions to the disorder may increase with a later age of onset of the illness.

INTRACELLULAR CALCIUM SIGNALS IN DEPRESSION MODELLED BY SINGLE-CELL RECORDINGS OF T-LYMPHOCYTES. C. Dumais-Huber and J.B. Aldenhoff*. Central Institute of Mental Health, Cell Physiology Laboratory, J5, P.O. Box 122120, D-68159 Mannheim, Germany.

The aim of the present study was to test the hypothesis of an altered Ca^{2+}-homeostasis in psychiatric disorders and more specifically in depression. To this end, T-lymphocytes served as peripheral model of CNS neurons because of their similarity in receptor types and membrane properties. Thus, this easily accessible cell system provides a mean to delineate cellular events along the signal transduction pathway and to detect possible changes during depression as well as during therapy.

$[Ca^{2+}]_i$-measures were performed by fluorescence photometry in *single* T-lymphocytes of 20 patients with unipolar depression (diagnosed according to the DSM III-R criteria; Hamilton rating scale > 18 at first testing, t0) and of 20 healthy controls matched for age and gender. $[Ca^{2+}]_i$ of T-cells was also assessed after patients had been treated for 8 weeks (t_1) either with Interpersonal Psychotherapy (IPT) (N=13) or else with pharmacotherapy (N=7).

The Ca^{2+}-response of T-lymphocytes to phytohemagglutinin (30 µg/ml PHA) was markedly reduced during depression. Not only was the percentage of PHA-responsive T-cells lower in depressed patients (20% in contrast to 50% in healthy subjects), but the recorded Ca^{2+}-signals were altered: longer onset latency, slower $[Ca^{2+}]_i$-rise, smaller area under the curve, fewer Ca^{2+}-oscillations. Upon clinical recovery, all deviant Ca^{2+}-parameters were found to normalize independently of therapeutical approach. Our results indicate that single-cell recordings make it possible to analyze the dynamics of Ca^{2+}-signals and yield information having clinical implications for the monitoring of cellular functions in depressed patients under therapy. (Supported by the German Research Society and by theVolkswagenwerk Foundation. We thank J. Sulger for laboratory work, M.Fritzsche&P. Gabriel for the supervision of patients).

Behavioural Despair: A drug screening procedure sensitive to hypothermia. Nadeau,*B. G., Marchant, E.G., Mistlberger, R. E., Alexander, B. K. and Amir, S. Psychology, Simon Fraser Univ., Burnaby, B. C., V5A 1S6.

Rats forced to swim after an initial burst of activity become immobile. The onset of immobility is accelerated on subsequent trials. Immobility has been interpreted as a state of lowered mood or despair which is reduced by administration of antidepressants between trials. Despite false positives behavioural despair has a claim to validity as an animal model of depression. Four experiments were conducted which together challenge this claim. Experiment 1: Twenty-four male Wistar rats (250-350g) were immersed in 27ºC water for 30 min on four occasions. Activity decreased across trials and was correlated (r=-.49) with a diminished loss of core temperature. Experiment 2: Ten rats were immersed in either 15 or 35ºC water on trials1 and 2 (15 min for trial 1; 5 min for 2,3,4). Temperature was reversed for trial 3 and reversed again for trial 4. Activity varied with water temperature. Reversal from 35 ºC to 15 ºC water produced an increase in activity, and was decreased by a reversal from 15 ºC to 35ºC water. Experiment 3: Forty one rats were immersed twice in 15, 20, 22, 25, 30, 35, 37, or 40ºC water (5 or 6 per group). Activity in the second trial was a quadratic function of water temperature (r=.51). Only 25 ,30, and 35ºC water produced significant reductions in activity between trials. Experiment 4: Typical, atypical, and non-antidepressants were administered (IP) to rats (5 or 6 per group) between trial 1 and 2 and the rats were immersed in either 25 ºC or 35 ºC water. There were no differences in activity on trial 2 as a function of water temperature for saline treated rats. Compounds which reduced core temperature (-1ºC or more) increased activity in the second trial over the saline control in 25 ºC water. This was not true at 35ºC. It is concluded that activity in the behavioural despair test reflects behavioural thermoregulation and compounds tested at 25ºC, as in the usual procedure, which produce hypothermia result in increases in activity associated with cooler water.

IS THE DST A VALID MARKER OF PSYCHIATRIC DISORDERS ?
H.Lukacs*,L.Mod,A.Alfoldi,I.Magyar,L.Bognar, P.Toth, E.Frecska, M.Arato
Dept. of Mental Health, Central Military Hosp., Postgraduate Medical Univ., Semmelweis Univ. Med. School., Budapest, Hungary

In the last ten years the dexamethasone suppression test (DST) was used as one of the diagnostic methods for detecting several psychiatric diseases, such as depression. Although in these cases high percent of DST positivity was found, only little attention has been paid to the role of stress in DST positivity.

In this study 140 healthy young males were investigated in the time of a stressful life event (day of military induction). One mg dexamethasone was given p.o. at 22:00 PM and the next day 8:00 AM a blood sample was taken. Cortisol was measured by competitive protein binding method. The cut off point was 5 µg/dl. All subjects underwent a complete physical and psychiatric check up. Thirty eight subject (24%) had an abnormal DST result.One month later only 4% of the subjects showed DST nonsuppression.The results suggest, that a stress situation alone can cause reactively frequent DST nonsuppression in healthy, young men.

SEROTONIN (5HT) -1A AND 5HT-2A RECEPTORS IN PREFRONTAL CORTEX (AREA 10) AND HIPPOCAMPUS OF SUICIDE VICTIMS WITH MAJOR DEPRESSION. C.A. STOCKMEIER*, G.E. DILLEY, L.A. SHAPIRO, J.C. OVERHOLSER, P.A. THOMPSON, AND H.Y. MELTZER. Departments of Psychiatry and Psychology, Case Western Reserve University, Cleveland, OH 44106.

Several studies in the past decade have yielded conflicting results on altered numbers of 5HT receptors in prefrontal cortex and hippocampus in depression and suicide. In the present study, we examined the hypothesis that 5HT-1A and 5HT-2A receptors were increased in suicide victims with major depression. Samples of right prefrontal cortex (area 10) and hippocampus were collected at autopsy from 20 suicide victims and 19 control subjects. Retrospective psychiatric assessments were conducted for all suicide victims and most of the age-matched control subjects. [^{3}H]8-OH-DPAT and [^{3}H]ketanserin binding to 5HT-1A and 5HT-2A receptors, respectively, was measured using quantitative receptor autoradiography. Neither age nor postmortem interval significantly affected these receptor measures. In either brain region, there were no significant differences in radioligand binding between all suicide victims and control subjects, or between a subset of suicide victims (N=11) with major depression (and no psychoactive substance use disorder) and control subjects. In the latter group of suicide victims, no antidepressant or antipsychotic drugs were detected postmortem, and only 2 had recent prescriptions for an antidepressant drug. In conclusion, neither 5HT-1A nor 5HT-2A receptors were altered in prefrontal cortex (area 10) or hippocampus of suicide victims with a history of major depression. Supported by PHS Grants MH45488 and MH41684.

ANTIDEPRESSANT/ANTIPANIC DRUGS MODULATE GABA$_A$ RECEPTOR GENE EXPRESSION. A.N. Bateson[1,3]*, V.A.-M.I. Tanay[1], A.J. Greenshaw[2,3] and G.B. Baker[2,3]. Departments of [1]Pharmacology and [2]Psychiatry, and [3]Division of Neuroscience, Faculty of Medicine, University of Alberta, Edmonton, Canada T6G 2H7.

Pharmacotherapy of panic disorder can be achieved with a number of classes of drugs that apparently have differing primary sites of action. These include monoamine oxidase inhibitors (MAOs), tricyclic antidepressants (TCAs) that inhibit noradrenergic and serotonergic uptake, and benzodiazepines (BZs) that potentiate GABA$_A$ receptor function. Certain MAOs and TCAs have been shown to have secondary sites of action that result in increased brain GABA levels. It is possible therefore that GABAergic transmission underlies the etiology and/or pharmacotherapy of panic disorder. Previous studies have indicated that long-term activation of GABA$_A$ receptors results in specific changes in GABA$_A$ receptor gene expression. We have chronically exposed rats to representative drugs from each of the therapeutic classes that are used in the treatment of panic disorder to determine whether they produce similar changes in GABA$_A$ receptor gene expression. Drugs were delivered via subcutaneously-implanted osmotic minipumps and specific GABA$_A$ receptor subunit mRNA levels determined using a multiprobe solution hybridisation assay. We have found that BZs and TCAs alter specific GABA$_A$ receptor mRNA levels suggesting a novel action of these drugs that may play a role in their therapeutic profile of panic disorder.

LIMBIC TRH IS DIFFERENTLY AFFECTED BY ANTIDEPRESSANTS (AD) vs SEIZURES. R.L. Lloyd*, A.E. Pekary, M. Chilingar, A. Sattin. Psychiatry, Medicine (Endocrinology) & Research Services, W. Los Angeles VA Medical Center & UCLA, Los Angeles, CA 90073.

Electroconvulsive seizures (ECS) are known to trigger bursts of synthesis of preproTRH in neuronal nuclei of several limbic regions, resulting in long-lasting increases of TRH (pGlu-His-Pro-NH_2) and its immediate precursors including TRH-Gly. In the seizure model, the magnitude of the TRH-Gly *increase* is significantly related to the reduced immobility (AD effect) in the forced-swim test (FST) (Ann NY Acad Sci, 739:135, 1994). Bupropion is an effective AD drug and MIF-1 (Pro-Leu-Gly-NH_2) is, like TRH, another endogenous neuro-tripeptide. A clinical AD effect of MIF-1 has been reported (J Affect Disord, 31:227, 1944). We tested both agents in the conventional Porsolt FST (buprop, 15 and MIF-1, 0.01, 0.1 and 1.0 mg/kg ip), applying the method used in the ECS study to relate the swim score of each rat to the peptide levels (by RIA) in extracts of brain regions. Others had previously shown that both drugs reduced immobility in the FST. We confirmed this using young male Wistars from Simonsen (Gilroy, CA). Neither drug altered mean level of either TRH or TRH-Gly in any region, but in amygdala/entorhinal cortex, the reduced immobility by both drugs, was directly related to *decreases* in the peptide precursors of TRH as measured by TRH-Gly. MIF-1 (but not bupropion) also showed this in striatum. The MIF-1 effect was dose-related. Such effects were not seen in anterior or pyriform cortices or hippocampus. Unlike ECS, these AD agents might act mainly through alteration of TRH processing. Generalization to other AD drugs and pharmacological specificity remain to be determined. Supported by VA Research Service.

REDUCED TRH IN LIMBIC FOREBRAIN OF A PRIMATE IS RELATED TO DEPRESSIVE BEHAVIORS. A. Kling*, A.E. Pekary, G. Bramner, R.L. Lloyd, M.E. McGuire, M.J. Raleigh, A. Sattin. Psychiatry & Medical (Endo.) Svcs., Sepulveda & W. LA VA's & UCLA, Los Angeles, CA 91343.

Last year we presented the behavioral data from 4 adolescent female Vervets all of which were craniotomized and bilaterally olfactory bulbectomized (OBX)(2) or control handling (2). Depressive behaviors in the OBX's were shown by reduced active grooming and social approach, and increased social withdrawal. Most of these defects were reversed following electroconvulsive therapy, but during subsequent months the OBX's are believed to have relapsed since one delivered, then neglected its infant. 11-12 mo post-surgical, the 3 survivors (1 OBX died) were sacrificed and 13 anterior limbic, cortical and caudate regions were dissected from each hemisphere for extraction and analysis of TRH. Compared with the 2 controls which were similar, TRH in the OBX was moderately or severely reduced in 11 regions. For selected regions, co-plotting these values with OBX-affected behavior scores gave predictable linear plots implicating TRH deficiency in depressive behaviors. Amygdalar TRH was not related to agression. Support: VA Research Service.

MEASUREMENT OF HUMAN LYMPHOCYTE G-PROTEIN mRNA LEVELS IN DEPRESSED PATIENTS. T. Ishikane*, J. Kusumi, T. Akitaya*, M. Mitsuhashi* and T. Koyama. Dept. Psychiat., Hokkaido Univ. Sch. of Med., Sapporo 060, Japan. *Hitachi Chemical Co.,ltd, Japan. *Hitachi Chemical Research Center, USA.

Increasing evidence implicates abnormalities in the signal-transducing G protein in the pathophysiology of affective disorder. We designed an easy measuring system of human lymphocyte G protein mRNA in order to study G protein-coupled second messenger systems in depressed patient. After synthesizing cDNA library from lymphocyte mRNA, the G protein cDNA was amplified using polymerase chain reaction (PCR) with biotin-labeled specific primers to all subtypes of G protein. PCR product was hybridized to each G protein subtype (Gs, Gi-1, Gi-2, Gi-3 and Go) specific probe which was immobilized onto microtitre plate. The biotin-labeled G protein subtype cDNA was reacted with alkaline phosphatase-streptavidin conjugate, and then substrate solution was added and color development detected by microplate reader. Using this method, we measured each subtype of G protein mRNA in lymphocyte from 15 drug-free depressed patients (eleven major depression with melancholia, 4 major depression without melancholia) and 15 normal controls. There was no significant difference of any subtypes of G protein mRNA levels between the patient group and controls.

678.10

EFFECT OF PROLONGED TREATMENT WITH ANTIDEPRESSANT DRUGS ON THE LEVEL OF mRNA CODING FOR D-1 AND D-2 DOPAMINERGIC RECEPTORS IN THE RAT BRAIN. M.Dziedzicka-Wasylewska, R.Rogoż, V.Klimek, A.Pilc*
Inst. Pharmacol., Pol. Acad. Sci., 12 Smętna St., Kraków, Poland.

The effect of prolonged administration of imipramine (IMI), citalopram (CIT) and (+)oxaprotiline (OXA) on the level of mRNA coding for dopaminergic (DA) receptors D-1 and D-2 in the rat brain was studied. Drugs (10 mg/kg) were administered twice daily, p.o., for 14 days. Animals were decapitated 2 or 72 h after the last dose of the drug. The level of mRNA coding for D-1 and D-2 DA receptors was measured in coronal sections of the rat brain through the nucleus caudatus (NC) and nucleus accumbens septi (NAS) by *in situ* hybridization, using commercially available probes (DuPontNEN), labelled with [^{35}S]dATP. Prolonged treatment with IMI (but not CIT or OXA) decreased the level of mRNA coding for D-1 DA receptor, to the same extent in the NC and in the NAS, both shell and core. This effect corresponds well with the decrease in the density of receptors labelled with ^{3}H-SCH23390. On the other hand, the level of mRNA coding for D-2 DA receptor was significantly up-regulated following chronic administration of IMI and CIT (but not OXA) and the effect was more pronounced in the NAS-shell than in the NAS-core and NC. Since there was no change in the binding parameters of ^{3}H-spiperone after prolonged administration of antidepressant drugs (ADs) and behavioral studies undoubtly indicated the potentiation of DAergic transmission by ADs, the present results might indicate the different level of regulation, namely the mRNA coding for DA receptors. (Supp. by KBN grant #6P20708206, Poland).

PLA_2 ACTIVITY IS INCREASED IN BLOOD OF PATIENTS WITH SCHIZOPHRENIA AND BIPOLAR AFFECTIVE DISORDER. B.M. Ross*,C. Hudson, J.C. Erlich, J.J. Warsh and S.J. Kish, Clarke Institute of Psychiatry, Toronto, Ontario, Canada.

Magnetic resonance spectroscopy studies have suggested above normal turnover of membrane phospholipids in brain of patients with schizophrenia. One possible explanation for these findings is an increase in the activity of the phospholipid catabolizing enzyme phospholipase A_2 (PLA_2). As a test of this hypothesis we compared the activity of PLA_2 in serum obtained from 26 individuals with schizophrenia and 22 individuals having bipolar affective disorder, with that in 33 neurologically normal age matched controls. PLA_2 activity was measured either fluorometrically (Gattaz et al., *Biol. Psychiat.* 28, 495), or radiometrically using whole bacterial membranes as substrate (Albers et al., *Pharmacopsychiat.* 26, 94). When assayed fluorometrically, serum PLA_2 activity in individuals with schizophrenia was significantly increased by 47% compared with control activity ($P<0.0001$). In addition, a smaller 26% increase was observed in subjects with bipolar affective disorder ($P<0.01$). However, when the same serum samples were assayed for PLA_2 activity using the radiometric procedure there was no significant difference between the three groups of subjects (one-way ANOVA; $P>0.95$). Furthermore, there was no correlation between the activity as measured by each assay ($r=0.073$). Thus, our data support the hypothesis that increased phospholipid turnover in schizophrenia could be explained by accelerated phospholipid breakdown mediated by PLA_2. However, the different results obtained using the two different PLA_2 assays, indicate that PLA_2 alterations in schizophrenia are probably limited to specific PLA_2 subtypes. WHOLE BODY ACUPUNCTURE ADDITIONALLY APPLIED TO A MIANSERIN MEDICATION IN THE TREATMENT OF DEPRESSION. Ch. Wolf, S. Bech, T. Neuerer, J. Röschke*, Dept. of Psychiatry, University of Mainz, Germany

The aim of the study was to explore the efficacy of additionally applied acupuncture in the pharmacological treatment of depression with mianserin. For this purpose we randomly included inpatients suffering from a major depressive episode (DSM-III-R) into three different treatment groups: (1) verum acupuncture, (2) placebo acupuncture, (3) controls. Mianserin treatment (120 mg/die) was applied to each of the patients, verum/placebo acupuncture was applied single blind. Psychopathology was rated by independent judges (not informed about acupuncture conditions) at the beginning of the study and twice a week during the treatment period of four weeks (BRMS, CGI, GAS). Whole body acupuncture was applied three times a week at 13 specific or nonspecific point, respectively. 24 patients experienced acupuncture treatment (groups (1) and (2)), 8 patients experienced antidepressant monotherapy. Severity of illness was rated by 21 item Hamilton depression scale (mean HAMD = 29 for acupuncture groups, mean HAMD = 24 for controls). At the end of the study patients with acupuncture experienced an average improvement on the GAS scale of 15 points compared to 9 points under control condition. CGI severity score improved for 1.2 points versus 0.3 points in the control group. BRMS scores were improved for 8 points in case of acupuncture versus 6 points in controls. Taken together, the preliminary results of our study point to the view that acupuncture additionally applied to antidepressant therapy might improve the course of the disease better than pharmacological treatment alone. However, at the time given it is an open question whether these effects should be considered as a placebo effect. A more detailed analysis performed when the study has been finished and separating placebo and verum acupuncture conditions will contribute to this fundamental question.

AN ANIMAL MODEL OF THERAPEUTIC vs NONTHERAPEUTIC SEIZURES A. Sattin*, A.E Pekary, R.L. Lloyd. Psychiatry Svc., Sepulveda VA, Medicine Svc., W. LA VA & UCLA, Los Angeles, 91343.

In electroconvulsive therapy (ECT, ECS), the grand mal (GM) seizure is necessary but not sufficient for antidepressant (AD) effect (Review: HA Sackeim, Psychopharm Bull 30(3):281,1994). Male Wistar rats were tested for the threshold (Thld) elevation usually seen during clinical ECT, since endogenous TRH (which is increased by seizures) is also a known anticonvulsant. Four groups were given sham only, Thld tests only (x2), and two schedules of ECS. There were three daily ECS, one group "flat" at 9.43 millicoulombs (mC) and one "ramped" at 9.43, 23.5 and 33.mC (unipolar square pulses). Thld tests done a day before were repeated a day after the three daily ECS in1mC increments from 1mC, ending in GM seizure (about 5mC). This 5 day sequence of (corneal) stimuli was bracketed by the forced-swim test of AD effect, then sacrifice. Neither ECS group increased Thld. Both ECS groups reduced swim immobility (AD effect), but the Thld only group did not, despite two GM seizures. In all three groups experiencing seizures, TRH and precursors (TRH-Gly) were increased in 4 limbic & cortical regions, but these peptides were higher in the flat than either Thld or ramp which were similar. As in humans, GM seizures at Thld levels did not show the AD effect. The inverted U effect of current dose on limbic peptides might be explained as follows (and see our data on AD effects of endogenous TRH (Ann NY Acad Sci, 739:135, 1994): Thld doses of current might induce synthesis and processing to TRH and precursors. A supra-Thld dose (flat) might augment synthesis and release, initiating the AD effect, while a further current increase (ramp) enhances processing and degradation of TRH. Support: VA Rsrch. Svc.

Effects of electro-convulsive shock (ECS) on serotonergic and cholinergic responses in CA1 hippocampal pyramidal neurons of the rat.

F.A. Dijcks, J.H. Couvee, A. Zonneveld and G.S.F. Ruigt*. N.V. Organon, Neuropharmacology Dept., P.O.B. 20, 5340 BH Oss, The Netherlands.

ECS is an effective antidepressant (AD) treatment for severely depressed patients and is often used when AD drug treatments have failed. The ECS-evoked changes in the brain that are instrumental in the AD effect of this treatment have not yet been uncovered. Serotonergic and cholinergic neurotransmission are thought to be involved in the pathophysiology of depression and the mechanism of action of AD drugs. Repeated ECS was demonstrated to increase *in vivo* postsynaptic $5\text{-}HT_{1A}$ mediated responses in rats (De Montigny, 1984). We examined *ex vivo* the effects of ECS on postsynaptic 5-HT and ACh receptor-mediated responses using single electrode current- and voltage-clamp techniques (M_3 and $5\text{-}HT_{1A}$ responses) in hippocampal slices. Extracellular recordings were performed to measure the ACh-induced M_1-mediated reduction of the fEPSP. Rats received 7 convulsive shocks (80 V) every 48 hrs resulting in a total treatment time of 2 weeks. Control groups were given either 7 subconvulsive shocks (20 V) or only one convulsive shock (80 V). All shocks were applied transcranially under light ethrane anaesthesia through subcutaneous electrodes placed at the temples. In the intracellular experiments no clear treatment effects were observed on resting membrane potential, cell input resistance and RC-time. 5-HT-induced outward currents and the concomitant decrease in cell input resistance were similar for all treatment groups. The ACh-induced M_3-mediated depolarization and the subsequent desensitization of this response were also not affected. Extracellular experiments revealed no changes in stimulation currents needed to elicit fEPSP's with a 2 mV amplitude nor changes in the potency and/or efficacy of ACh to reduce this signal. From these results we can conclude that there is no *in vitro* (*ex vivo*) correlate of the ECS-induced increase in the *in vivo* postsynaptic response to 5-HT. Moreover, ECS does not alter M_1 and M_3 mediated cholinergic neurotransmission in the hippocampus of the rat.

678.15

ALTERED LEVELS OF Gαs PROTEIN AND mRNA LEVELS IN POST-MORTEM BRAIN TISSUE IN BIPOLAR AFFECTIVE DISORDER F. Fang, S. Lu, G. Chen, T. Hyde, J. Kleinman, W. Z. Potter, and H. K. Manji*. Dept. of Psychiatry and Behavioral Neurosciences, Wayne State University School of Medicine, Detroit, MI 48201, Sec. Clin. Pharmacol. and Clinical Brain Disorders Branch, NIMH, NIH, Bethesda, MD 20892.

Bipolar Affective disorder (BD) is a common, severe, chronic and life-threatening disease. Despite a well established genetic diathesis and extensive research, the biochemical abnormalities underlying the pathophysiology of BD remain unknown. In recent years, studies from independent laboratories have demonstrated elevations in the levels of Gαs in platelets and leukocytes from BD patients, effects which are independent of treatment or mood state. It remains unclear if these are simply peripheral cell abnormalities, or are also observed in the human CNS. We have therefore undertaken a study of Gαs protein and mRNA levels in postmortem brain tissue from a group of BD patients, a group of non-BD subjects who committed suicide, and age- and sex-matched controls. Using selective antibodies, we have found a significant elevation in the levels of both the long (BD: 1649±289; CON: 1321±347) and short (BD: 1394±481; CON: 997±266) form of Gαs in the occipital cortex, but not the frontal cortex. We have also used an RNase protection assay (with a 351 bp fragment of Gαs cDNA as a template) to quantitate the levels of Gαs mRNA levels. 20 µg of total RNA were hybridized with 1.2×10^4 cpm of Gαs riboprobe and standardized to hybridization with 3×10^3 cpm of β-actin riboprobe. We did not observe any differences in the levels of Gαs mRNA levels in the frontal cortex, but observed near-significant decreases in the levels of Gαs (normalized to β-actin) in the occipital cortices of BD subjects (.52±.31) compared to either control subjects (.82±.28; p=.06) or suicide (.84±.23; p=.05) subjects. These findings add to the growing body of evidence implicating complex alterations of the signal transducting G proteins in the pathophysiology of BD, and as targets for therapeutic interventions.

678.16

CEREBRAL GLUCOSE METABOLISM IN LATE ONSET DEPRESSION WITHOUT COGNITIVE IMPAIRMENT M.J. Mentis*, J. Krasuski, P. Pietrini, A Polles, G.E. Alexander, J Szczepanik, D. Murphy, C Grady Lab. Neurosci., Natl. Inst. on Aging, NIH, Bethesda, MD 20892.

Among depressed patients, various clinical and treatment-response subgroups have been reported to have different cerebral functional abnormalities. To evaluate regional glucose cerebral metabolic rates (rCMRglc) in older subjects with first episode major depression (MD) but without cognitive impairment, we compared 11 depressed females (59.1±12 yr., Mini-mental state (MMS) 29.3±0.8,) with 12 age- and sex-matched healthy controls (HC) (62.7±6.2 yr., 10 Female 2 Male, MMS 29.5±0.7) using high resolution positron emission tomography (PET) with 18-fluorodeoxyglucose. MD was diagnosed using Research Diagnositic Criteria and a Hamilton Rating Scale for Depression score (HRSD) greater than 15 (MD group HRSD 22.5±7, HC 0.8±1.5). All scans were performed off drugs. "Secondary" depression was excluded and no subject had medical or cognitive impairment. Each scan was warped into a common three dimensional space (Talairach), then voxel-by-voxel between-group t-tests were performed using the Statistical Parametric Mapping (SPM) program. Compared to HC, the MD group had significantly increased rCMRglc ($p<0.01$) in right medial temporal (amygdala), lateral temporal, orbitofrontal and lateral prefrontal regions, and decreased ($p<0.01$) rCMRglc in both thalamic nuclei, left > right. Limbic and prefrontal importance in depression is supported. Late onset of depression and lack of cognitive impairment may represent a distinct depressive subtype reflected in the laterality and increased rather than decreased metabolic abnormalities.

678.17

A RAT MODEL FOR MANIA: LITHIUM PREVENTS OUABAIN-INDUCED PERSISTENT HYPERACTIVITY. R.Li*, G.Bao, R.S.Levy and R.S.El-Mallakh. Department of Psychiatry and Behavioral Sciences, and Department of Medicine, University of Louisville School of Medicine, Louisville, KY 40292.

We have previously shown that a single dose of intraventrically (ICV) administrated ouabain alters rat locomotor activity (dose-related increase or decrease). In our ongoing efforts to properly model mania, we have recently investigated the effect of chronic ICV administration of ouabain on animal locomotor activity and the action of lithium on these ouabain-induced behavioral changes. Rats were implanted with the ALZET osmotic mini pump filled with ouabain (10^{-3}M) or artificial cerebrospinal fluid (aCSF) at day 0. Pump continuously delivered ouabain or aCSF into left cerebral ventricle for 2-3 weeks. Lithium (2.5mEq/kg/day) or vehicle injections were initiated either one week before or one week after ouabain pump implantation and continued for 4 or 3 weeks, respectively. Locomotor activities of animal were tested by an activity monitor at days 0, 7, 14, 21, 28 and 35. Our results indicate that chronic ICV ouabain infusion induced a significant increase in horizontal activity, total distance, and number of movements ($P<0.05$). This hyperactivity persisted for the entire period of ouabain administration. Lithium pre-treatment prevented ouabain-induced hyperactivity, and lithium post-treatment (one week after ouabain administration) eliminated the hyperactivity but not significantly different from control animals. Our study suggests that a dysfunction of sodium, potassium ATPase may be an important mechanism for manic disorder.

678.18

EFFECTS OF OUABAIN ON TRANSMEMBRANE POTENTIAL OF LYMPHOBLASTS FROM MANIC-DEPRESSIVE AND NORMAL INDIVIDUALS

Lisa Fox, Rif S. El-Mallakh*, Christopher A. Worth, Rena Li, Stephen C. Peiper,. Depts of Psychiatry and Pathology, Univ. of Louisville School of Medicine, Louisville, KY 40292

We have previously noted that lymphocyte transmembrane potential (TMP) is hyperpolarized during mania compared with both euthymic (normal state) bipolars, and normal controls. Since the sodium pump, which is important in determining TMP, has been reported to have decreased activity in manic bipolar subjects, we investigated the effect of acute (3 hr) and chronic (4d) ouabain treatment on TMP of lymphoblasts derived from bipolar individuals (n=5) and normal controls (n=5). Relative TMP was quantified utilizing a flow cytometer and argon laser excitation of the cationic dye D1OC(6), before and after depolarization with gramicidin. Ouabain concentrations of greater than10^{-7} M caused severe cellular disruption in all cell lines. In patient and normal cell lines, respectively, TMP was reduced by 8.7% and 6.1% after 3 hr at 10^{-8} M ouabain, (ns); and by 14.58% and 14.66% after 4 days (ns). The data suggest cell lines from bipolar patients do not differ from normals in their response to ouabain, and sodium pump inhibition is not likely to be involved in producing the lymphocyte hyperpolarization seen in manic bipolar patients.

BIOCHEMICAL STUDIES OF YM-35992: A NOVEL SELECTIVE SEROTONIN RE-UPTAKE INHIBITOR. T.Yamaguchi*, K.Hatanaka, T.Nomura, H.Takeuchi, M.Fujii, S.Yatsugi. Yamanouchi Institute for Drug Discovery Research, 21 Miyukigaoka, Tsukuba 305 Japan.

YM-35992,(-)-(S)-2-[[(7-fluoro-4-indanyl)oxy]methyl]morpholine monohydrochloride, has dual mode of action, selective 5-HT re-uptake inhibition (SSRI) with 5-HT2 antagonistic activity in vitro and in vivo. Recent microdialysis studies on SSRIs demonstrated that chronic administration with SSRIs increases extracellular 5-HT concentration in the rat frontal cortex but not single administration of those. In the present study, we examined the effect of YM-35992 on 5-HT release in the rat frontal cortex using microdialysis technique comparing with representative SSRI, citalopram. Single treatment with YM-35992 markedly increased the extracellular 5-HT concentration in the rat frontal cortex. YM-35992 at a dose of 30 mg/kg(i.p.) gave more than 6-fold increase in the 5-HT level, while the increase induced by 10 mg/kg (i.p.) of citalopram which corresponds to 30 mg/kg of YM-35992 in terms of in vivo uptake-inhibiting activity was less than 3-fold. The result suggests the early onset of action of YM-35992 clinically. We also examined the changes in 5-HT1A receptors in the hippocampus after long-term treatment with YM-35992 and amitriptyline, a representative tricyclic antidepressant(TCA). Repeated treatment with YM-35992 for 14 days produced significant increase in [^{3}H]8-OH-DPAT binding in the hippocampus. This result indicates that YM-35992, similar to TCAs, could produce 5-HT1A supersensitivity in the rat hippocampus. Although further investigations should be needed, these effects of YM-35992 suggests its potent clinical efficacy.

THYROID AUTOANTIBODIES IN PATIENTS WITH MOOD AND ANXIETY DISORDERS D.L. Musselman, M.R. Porter, P.T. Ninan, B.T. Knight, R.W. Bonsall, M.S. Emery, Z.N. Stowe, E.J. Hauenstein, K.R.R. Krishnan, J.R. Davidson, and C.B. Nemeroff*. Dept. Psychiat. & Behav. Sci., Emory Univ. Sch. Med., Atlanta, GA 30322.

Previous studies indicate relatively high prevalence rates of anti-thyroid antibodies in depressed patients compared to normal controls. These studies measured titers of these antibodies using generally out-dated, indirect measures, e.g. red blood cell hemagglutination assays. The present study used sensitive methods to quantify the concentrations of anti-thyroglobulin (anti-TG) and antithyroid peroxidase (anti-TPO) microsomal thyroid antibodies in patients with anxiety, depressive, mixed anxiety/depression, post-partum mood disorders, and normal controls. Medically healthy individuals (n=178), without any known history of thyroid disease were studied. Patients with anxiety disorders (n=29), depressive disorders (n=43), comorbid depressive and anxiety disorders (n=22), post-partum depression (n=36), and post-partum women without a psychiatric diagnosis (n=14) were compared to a normal population (n=36) who had no past or present psychiatric disorders. Serum concentrations of T_3, T_4, and TSH were measured by standard techniques; anti-TG and anti-TPO antibodies were determined using the Nichols Autoantibodies Chemiluminescence Assay.

The prevalence of anti-TPO antibodies was greater in women with major depression, anxiety disorder, or comorbid depression and anxiety compared to a normal control population; this finding was particularly striking in women under 40 with comorbid depressive and anxiety disorders. No differences between depressed and non-depressed post-partum patients were detected. Serum TSH concentrations in patients with mood and anxiety disorders were significantly correlated with serum concentrations of anti-TG and anti-TPO. Further studies of HPT axis function in psychiatric patients are warranted. (Supported by NIMH MH-51761.)

INTERACTION OF TWO POLYANIONIC DRUGS (SURAMIN AND PENTOSAN POLYSULFATE) WITH NGF RECEPTORS ON DORSAL ROOT GANGLION NEURONS. C. P. Schumacher*J. S. Gill and A. J. Windebank. Molecular Neuroscience Program, Mayo Foundation, Rochester, MN 55905.

Pentosan polysulfate (PPS), a polyanionic mucopolysaccharide, has been shown to exert inhibitory effects on HIV-1 replication and inhibit paracrine activity of heparin-binding growth factors secreted by a variety of malignant cell lines. Suramin, another polysulfated chemotherapeutic agent has been extensively studied in our lab as a neurotoxic agent. In this study, PPS (100 µg/ml) was found to induce significant cell death in PC12 cells by 48 hours (84% cell viability), but not to the extent that suramin (600 µM) caused cell death (56% cell viability). Of the viable PC12 cells exposed to PPS, we observed limited neurite outgrowth as compared to cells exposed to NGF (10 ng/ml) or suramin (300 µM). Western blot analysis revealed tyrosine phosphorylation of the TrkA receptor (gp 140) in cells exposed to PPS for 10 minutes and 1 hour. The level of phosphorylation was less than that induced by NGF or suramin. In DRG explants, PPS was also found to cause an inhibition of neurite outgrowth in a dose-dependent manner. The level of inhibition was similar to that in suramin treated DRG. Ultrastructural studies were performed on DRG exposed to suramin or PPS for 2, 4 and 6 days. Lamellar inclusion bodies (IB) were consistently observed in suramin treated, but not PPS treated, DRG.

Conclusion. PPS mimics the effect of suramin at the NGF receptor; at low concentrations, it is an agonist and, at higher concentrations, a competitive antagonist. PPS does not, however, cause accumulation of IB which is, therefore, independent of the receptor effects. PPS will be useful in dissecting out suramin's chemotherapeutic activity from its neurotoxic action on DRG (supported by NS 29769).

FACTORS WHICH MAY HELP EXPLAIN THE AGE-RELATED SENSITIVITY OF RATS TO THE INSECTICIDE CHLORPYRIFOS. S. R. Mortensen, M. J. Hooper, and S. Padilla*. Health Effects Res. Lab., Neurotox. Div., US EPA, R.T.P., NC 27711.

Young animals exhibit an increased susceptibility to the lethal effects of cholinesterase (ChE)-inhibiting insecticides including chlorpyrifos (CPF), although the mechanism(s) for such sensitivity is unknown. Since previous studies in our laboratory indicate that young rat brain acetylcholinesterase (AChE) is not intrinsically more sensitive to CPFoxon (active metabolite), we decided to characterize the blood ChEs of young (PND 4, $n \geq 3$) and adult (≥90 day, $n \geq 3$) male Long Evans rats. Total plasma ChE activity from untreated animals was 60% AChE/40% BChE in PND 4 plasma and 50% AChE/50% BChE for adult plasma. IC_{50}s (30 min at 26°C) were defined concomitantly for PND 4 and adult plasma AChE using CPFoxon. Plasma IC_{50}s showed age-related differences: PND 4 = 5.5 nM and adult = 44 nM. (The brain IC_{50}s were virtually identical [4.9 nM] at both ages.) IC_{50} values may be overestimated when Ca^{++}-dependent hydrolases are not taken into consideration. Therefore, IC_{50}s were also determined in the presence of 1 mM EGTA showing a reduced, but still significant, age-related sensitivity to CPFoxon: PND 4 = 4.4 nM and adult = 12.7 nM. In summary, the AChE of young and adult brain are similar regarding their *in vitro* sensitivity to CPFoxon. There is, however, a significant age-related difference (with and without EGTA) in the sensitivity of plasma AChE to CPFoxon, which partially explains the increased sensitivity of young animals to the anticholinesterase insecticide chlorpyrifos.

THE EFFECTS OF IBOGAINE ON CLINICAL PATHOLOGY, NEUROPATHOLOGY AND NERVE CONDUCTION VELOCITY IN RABBITS. **G.J. Schaefer*, R.G. York, C.D. King, S.M. Miller, L.J. Beuving, W.F. Jackson, J.M. Huebner, and J.B. Terrill, International Research and Development Corporation, Mattawan, MI 49071, Western Michigan Univ., Kalamazoo, MI 49008 and the National Institute on Drug Abuse, Rockville, MD 20857.**

Ibogaine, a drug proposed for the treatment of opiate and psychomotor stimulant abuse in humans, is reported to cause degeneration of cerebellar Purkinje cells in animals. To determine if the drug is peripherally neurotoxic, adult male New Zealand White rabbits (n=12/dose group) were administered vehicle control, 30, 60 or 100 mg/kg ibogaine i.p. as a single dose. Two animals in the 100 mg/kg group died within one day. Observations included clinical pathology, and histopathology and neuropathology of the sciatic nerve. None of the hematological or clinical biochemical values showed statistically significant changes from vehicle control. In addition, in the nerve conduction studies, neither the average conduction velocity nor the area under the curve, showed an ibogaine-treatment effect. There were no neuropathologic lesions seen under light microscopy that were considered to be related to ibogaine. In this study, doses of ibogaine that were acutely toxic did not produce pathology or peripheral neurotoxicity. **Supported by NIDA Contract No. NO1DA-2-9307.**

EFFECTS OF FUMONISIN B1 ON BLOOD-BRAIN SPHINGANINE TURNOVER AND FB1 TOXICOKINETICS IN THE DEVELOPING RAT. O. S. Kwon and W. Slikker, Jr*. Dept. of Pharm./Toxicol., Univ. of Arkansas for Medical Sciences, Little Rock, AR and Div. of Neurotoxicol., National Center for Toxicological Research, FDA, Jefferson, AR.

Fumonisins are toxic metabolites that are produced by *Fusarium moniliforme* in corn. Fumonisin B1 (FB1) has been reported to increase sphinganine (Sa) in kidney, liver and serum from rodents and other mammals. Our previous results showed that FB1 increases Sa levels in the brain and spinal cord and reduces myelin deposition in rat forebrain. Increase of Sa in blood may produce a pool of Sa available for transport to the brain. The objective of this experiment was to elucidate whether blood Sa has effects on the brain Sa turnover. FB1 and Sa levels both in brain and plasma were measured by HPLC from postnatal day(PND) 12 rats treated with a single dose of FB1 (sc, 0.8 mg/kg or 8 mg/kg). Area under the curve (AUC, 0 to 24 hr) of Sa levels was remarkably higher in forebrain (124.1 nmol/g.hr) than in plasma (3.1 nmol/ml.hr) after 8 mg/kg FB1. AUC ratios of brain to plasma Sa concentration curves following acute administration were 37.2 at 0.8 mg/kg FB1 and 39.7 at 8 mg/kg FB1. The AUC ratio of brain to plasma FB1 was 0.03. Observations from plasma FB1 disappearance curves over a 12 hr period indicated that the plasma half life of FB1 in PND 12 rats is 1.2 to 1.7 hr, and the volume of distribution is about 0.2 l/kg. These data indicate that even low bioavailability of FB1 in the brain is sufficient to produce the striking increase of Sa levels in the brain. These data also suggest that elevations of brain Sa levels are related to direct action of FB1 on the brain rather than the transfer of blood Sa into the brain.

INTERLEUKIN-1 AND TUMOR NECROSIS FACTOR-α SYNERGISTICALLY MEDIATE NEUROTOXICITY VIA NO AND NMDA RECEPTORS. S. Hu*, L. Erlich, P. K. Peterson and C. C. Chao. Minneapolis Medical Research Foundation and the University of Minnesota Medical School, Minneapolis, MN 55404

The pro-inflammatory cytokines interleukin (IL)-1 and tumor necrosis factor (TNF)-α, produced by glial cells within the brain, play a pathogenetic role in several neurodegenerative diseases; however, little is known about the mechanisms underlying cytokine-mediated neurotoxicity. Using human fetal neuronal cell cultures, we investigated the injurious effect of these cytokines. Although neither cytokine alone was toxic, IL-1β (1 ng/ml) and TNF-α (20 ng/ml) in combination for 7 days caused marked ($P<0.01$) neuronal injury, as assessed by increasd release (180% over control) of lactate dehydrogenase (LDH), a marker of neuronal loss. In the presence of TNF-α (20 ng/ml), 1 ng/ml of IL-1β caused maximal neuronal death. The ED_{50} of IL-1β was approximately 300 pg/ml in TNF-α-treated neuronal cell cultures. The neurotoxic effect of these two cytokines was synergistic, and antibodies (10 μg/ml) to IL-1β, TNF-α or IL-1α blocked 94%, 97% and 9% of LDH release, respectively. Blockade of nitric oxide (NO) production with the NO synthase inhibitor was accompanied by marked ($P<0.01$) reduction (about 45%) of cytokine-mediated neuronal injury, suggesting that NO is partly involved in mediating cytokine-induced neurotoxicity. Addition of the N-methyl-D-aspartate (NMDA) receptor antagonists to neuronal cell cultures blocked ($P<0.01$) cytokine-mediated neurotoxicity by >55%, suggesting the involvement of NMDA receptors. Also, treatment of neuronal cell cultures with IL-1β plus TNF-α inhibited ($P<0.01$) the high-affinity ^{3}H-glutamate uptake and astrocyte glutamine synthetase activity, two major pathways involved in protection against NMDA receptor-mediated neurotoxicity. These *in vitro* findings may lead to development of new therapeutic strategies for neuronal damage in cytokine-mediated neurodegenerative diseases.

MODULATION OF SEROTONIN-INDUCED CURRENTS BY METALS IN MOUSE NEUROBLASTOMA CELLS. M. Uki* and T. Narahashi. Dept. of Mol. Pharmacol. and Biol. Chem., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The effects of several metals on the serotonin receptor-channel complex were studied using mouse neuroblastoma N1E-115 cells which are known to be endowed with the 5-HT_3 subclass of the receptor. The whole-cell patch clamp technique was used to record currents induced by serotonin at a concentration of 3 μM which was equivalent to the apparent dissociation constant. Methylmercury and mercuric chloride suppressed serotonin-induced currents irreversibly with IC_{50}s of 3 μM and 2 μM, respectively. Lead and zinc suppressed the current with IC_{50}s of 80 μM and 50 μM, respectively, and the effects of both metals were reversible after washing with metal-free solution. Lanthanum also suppressed the current with an IC_{50} of 10 μM, and the effect was partially reversible. Cadmium and cobalt augmented serotonin-induced currents slightly but consistently at a concentration of 100 μM, and the effect was reversible. Aluminum at 100 μM had no effect on serotonin-induced currents. It was concluded that the 5-HT_3 receptor is endowed with a unique property with respect to the actions of metals which is not shared by some other ligand-gated and voltage-gated ion channels.

BILIRUBIN INDUCES APOPTOSIS OF CEREBELLAR NEURONS VIA ACTIVATION OF NF-KB. G.-M. Yan[1,2]*, S.-Z. Lin[1], J.Gu, R.P. Irwin[1] & S.M. Paul[1,2] [1]Dept. of Pharmacol. & Toxicol., Sch. of Med., IUPUI, Indianapolis, IN 46202; [2]Lilly Res. Labs, Eli Lilly & Company, Indianapolis, IN 46285

Bilirubin, a degradation product of protoporphyrins derived from hemoglobin, is a well known neurotoxin. However, neither the cellular nor molecular mechanisms underlying bilirubin-induced neurotoxicity are known. We now report that low concentrations of bilirubin are toxic to cultured rat cerebellar neurons. By contrast, cultured fetal rat cortical or hippocampal neurons are relatively insensitive to bilirubin toxicity. Moreover, bilirubin-induced toxicity of cerebellar neurons is associated with the biochemical and morphological features of apoptosis. Bilirubin-induced apoptosis is blocked by RNA and protein synthesis inhibitors, suggesting a gene-directed mechanism. Using gel shift (EMSA) analysis we found that bilirubin activates the transcription factor NF-κB in a concentration- and time-dependent manner in both intact cultured cerebellar granule neurons and cell-free extracts. Moreover, TPCK and TLCK, specific inhibitors of NF-κB, block both bilirubin-induced apoptosis of cerebellar granule neurons and bilirubin-induced NF-κB activation. These data strongly suggest that activation of NF-κB is the initial intracellular event mediating bilirubin-induced apoptosis of cerebellar neurons. NF-κB may play a more general role in neuronal apoptosis as well.

679.8

NEUROHISTOLOGICAL AND NEUROBEHAVIORAL ASSESSMENT OF THE ANTI-HIV THERAPEUTIC 2',3'-DIDEOXYINOSINE (DDI) IN RATS. T.A. Patterson*, J.A. Sandberg, L.C. Schmued, C.M. Albertson, M.G. Paule and W. Slikker, Jr. Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079-9502.

The anti-HIV therapeutic dideoxyinosine (ddI) has been reported to produce a painful, dose-limiting peripheral neuropathy in HIV-infected patients after chronic administration. However, distinguishing this toxicity from the disease itself is complicated. Therefore, the nature of this peripheral neuropathy was examined in a non-HIV infected animal model. Rats (N=9/group) were gavaged with vehicle (VEH), 41.5 or 415 mg/kg ddI, or 41.5 mg/kg isoniazid (INH; as a positive control) twice daily for 20 weeks. Plasma ddI levels peaked by 30 min and were constant over the first 1.5 hr after administration, averaging (±SD) 1.05 ± 0.41 and 3.97 ± 2.57 μg/ml for the low and high dose, respectively. Average INH plasma concentrations during the same time period were 9.85 ± 7.21 μg/ml. Schedule-controlled operant behaviors, motor assessments, nerve conduction velocities and pathologies were examined. Mortality was dose and drug dependent: high ddI (44%) > INH (33%) > low ddI (0%) = VEH (0%). Ataxia and seizure activity were first noted in the INH group after 11 weeks of dosing. In rats treated with INH, myelin splitting, whorls, extracellular debris, mast cells, and reduced axonal number were observed in sciatic nerve sections. These findings were consistent with the behavioral manifestations of peripheral neuropathy. After chronic ddI administration, there were no nerve conduction or behavioral alterations, but histological analysis revealed myelin splitting and intramyelin edema. Thus, rats chronically dosed with ddI exhibited peripheral nerve myelinopathy, even in the absence of HIV infection. **(supported by NIEHS IAG #Y01-ES-10187)**

LACK OF PROTECTIVE EFFECTS OF SIGMA LIGANDS ON THE INDUCTION OF HEAT SHOCK PROTEIN HSP-70 IN RAT CEREBROCORTICAL NEURONS BY DIZOCILPINE. K.Hashimoto*, S.Tomitaka, N.Narita, Y.Minabe, M.Iyo and S.Fukui. Natl. Inst. Neurosci., NCNP, Tokyo 187 and NIMH, NCNP, Chiba 272, Japan.

The non-competitive NMDA receptor antagonists such as MK-801 (dizocilpine) and phencyclidine injure a discrete populations neurons in the posterior cingulate and retrosplenial cortex of rat brain. These drugs produce vacuolization and necrosis in these neurons. Sharp et al. (1992) have reported that these drugs induce production of heat shock protein HSP-70, and that antipsychotic drug haloperidol and sigma agent rimcazole protect the induction of HSP-70 protein by dizocilpine and phencyclidine, suggesting a role of sigma receptors in the expression of HSP-70 protein by NMDA antagonists. We studied the role of sigma receptors on the induction of HSP-70 protein by dizocilpine. Dizocilpine (1 mg/kg, i.p.) was injected into female SD rats. The immunocytochemistry of HSP-70 was studied 24 hr after administration of dizocilpine. Sigma ligands such as 4-PPBP (3 mg/kg) and NE-100 (3 mg/kg) were administered 15 min before injection of dizocilpine. The treatment with dizocilpine produced the induction of heat shock protein HSP-70 in the posterior cingulate and retrosplenial cortex of rat brain. However, the pretreatment with 4-PPBP and NE-100 could not attenuate the induction of HSP-70 protein by dizocilpine. Thus, it is unlikely that sigma receptors may play a role in the induction of heat shock protein HSP-70 by NMDA receptor antagonists.

NEURONAL CULTURE MODEL OF CENTRAL NERVOUS SYSTEM OXYGEN TOXICITY. H. T. Whelan *, D. M. Bajic, and E. P. Kindwall. Neurology and Hyperbaric Medicine, Medical College of Wisconsin, Milwaukee, WI 53226, & NAVMARCORESCEN, Milwaukee, WI 53207.

Hypothesis: Plasma membranes are important in the transport processes of neurotransmitters regulating neuronal excitability during seizures caused by hyperbaric oxygen (HBO). The CNS becomes irreparably damaged if HBO is continued. These neurochemical effects may be preventable using the 21-aminosteroid U74389G, which reportedly has an effect of inhibiting neuronal membrane lipid peroxidation. Diazepam binding reflects neuronal cell membrane integrity. Peroxidation of the cell surface membrane should alter diazepam binding. **Method:** To assess neuronal membrane changes due to HBO, neuron cultures were subjected to 100% oxygen at 1.5 ATA. Control cultures were compared to those pretreated with 21-aminosteroid. Diazepam binding was used as a marker of surface membrane integrity. Fetal mouse neurons at 3.5×10^6 cells/ml were treated with clonozepam and ^{3}H-diazepam. The clonazepam-displaceable (neuron-specific) diazepam binding was assessed by scintillation counting, according to published methods. **Results:** Neurons subjected to HBO or to 21-aminosteroid alone developed 30% inhibition of diazepam binding, reflecting surface membrane dysfunction in this model. Neuronal surface membrane integrity (clonazepam-displaceable diazepam binding) was completely protected from HBO by pretreatment with 21-aminosteroid. The reason for lack of diazepam binding when 21-aminosteroid is given alone is not understood. This neuron culture model may be useful for testing pharmacologic means of protecting surface membranes in conditions of hyperbaric oxygen toxicity.

DOMOIC ACID: ASTROCYTIC, NEURODEGENERATIVE AND BEHAVIORAL RESPONSES. A.C. Scallet*, L.C. Schmued, R.L. Rountree, J.N. Johannessen[1], and T.J. Sobotka[1]. NCTR/FDA, Jefferson, AR and [1]CFSAN/FDA, Laurel, MD.

Four groups of 6 adult male rats were treated i.p. with domoic acid (0, 0.22, 0.66, or 1.33 mg/kg). Eight days later, after behavioral testing, rats were perfused. Hippocampal sections were stained for neurodegeneration and for glial fibrillary acidic protein (GFA). Only a subset (2/6) of the high-dose group had extensive damage, mainly in CA1. GFA-positive astrocytes in CA1 were larger in high dose rats than controls (107 ± 26 vs. 53 ± 7 sq microns, $p < 0.05$, mean ± SEM of 6 cells per rat). The 2 rats with CA1 damage also had the most enlarged astrocytes. These same two rats were the most hypophagic after dosing, were poor at passive avoidance performance, and exhibited exaggerated startle responses, suggesting the presence of a behavioral hyperreactivity syndrome. There was a smaller, but still dose-related increase in astrocyte size even at domoic acid levels not causing neurodegeneration, "reactive" gliosis, or behavioral effects. Our data indicate correlations between neurohistological and neurobehavioral biomarkers of domoic acid exposure, and emphasize the potential importance of astrocytic response to low-dose exposure.

679.12

APOPTOTIC CELL DEATH INDUCED BY THE NEUROTOXIN ETHYLCHOLINE AZIRIDNIUM (AF64A) IN VITRO AND IN VIVO. H.Hörtnagl*, W.Rinner, C.Pifl and H.Lassmann. Institute of Biochem. Pharmacology and Institute of Neurology, Univ. Vienna, A-1090 Vienna, Austria.

Increasing evidence indicates the significance of programmed cell death for neurodegenerative diseases. Various neurotoxins induce neuronal cell death by induction of apoptosis, at least in vitro. In this study we focussed on the mechanisms of cell death induced by the neurotoxin ethylcholine aziridinium (AF64A) in vitro and in vivo. The in vitro effect was compared with that of the aziridinium derivative of N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP4). For the in vivo study male Sprague Dawley rats (400-500g) received stereotaxical infusion of 1 or 2 nmol AF64A into the left and the corresponding vehicle into the right lateral ventricle. Rats were perfused under deep chloral hydrate anesthesia with 4% paraform-aldehyde 1, 2, 3 and 7 days after AF64A application. Apoptotic features including nuclear chromatin condensation and DNA fragmentation as revealed by in situ nick translation was observed in various parts of the hippocampus, adjacent parietal cortex and septum, with a maximum after 2 to 3 days. Both neuronal and glial cells were affected. For in vitro evaluation human neuroblastoma cells SK-N-MC and human embryonic kidney cells 293 were used. A dose- and time-dependent increase in the number of apoptotic cells resulted from the exposure to AF64A (50 and 100nM) or DSP4 (10 - 100 nM) in the medium. Apoptotic changes started after 8 h of exposure and reached a maximum between 15 and 24 h. In addition to light microscopic observations the characteristic features of apoptotic cell death were identified by electron microscopy. Apoptosis was suppressed by inhibition of endonuclease by Zn (800µM) and by the free radical scavenger Tempol (2mM). The data indicate that apoptosis contributes to the neurodegeneration induced by neurotoxins containing an aziridinium moiety and support their use in models for neurodegenerative diseases.

679.13

THE LOCALIZATION OF 3-NITROPROPIONIC ACID (3-NPA) INDUCED NEURONAL DEGENERATION IN ADULT RATS. Z. Binienda*, R.L. Rountree, L.C. Schmued and A.C. Scallet. NCTR/FDA, Jefferson, AR 72079-9502.

The localization of neuronal degeneration following chronic treatment with the mitochondrial energy metabolism inhibitor 3-NPA was determined in adult male Sprague-Dawley rats using a silver degeneration method (Nadler-Evenson) and a novel fluorescent technique. Rats were injected intraperitoneally with escalating doses of 3-NPA (5 mg/kg/day to a maximum 30 mg/kg/day; Monday-Friday). Rats were perfused under deep pentobarbital sodium anesthesia with 4% formaldehyde in phosphate buffer (0.1 M, pH 7.4). Coronal sections were stained using silver impregnation technique specific for degenerating axons, terminals and neurons. Although some variability in the distribution of lesions was observed, areas most frequently damaged included neurons of the cingulate and insular cortex, patches of CA1 hippocampal pyramidal neurons, a considerable extent of the axons within the ventral thalamus, a variable portion of the caudate nucleus and neurons of the deep nuclei of the cerebellum. We hypothesize that the pattern of neurodegeneration produced by 3-NPA in the forebrain and the cerebellum relates to a selective sensitivity to energy depletion of these regions.

679.14

COMPARISON OF VESTIBULAR DYSFUNCTION AND PERIPHERAL NEUROPATHY FOLLOWING SUBCHRONIC DRINKING WATER EXPOSURE TO 3,3'-IMINODIPROPIONITRILE (IDPN) IN THE RAT. J.Llorens, K.M.Crofton*[1] and E.Rodríguez-Farré. Dept. Pharmacol. Toxicol., CSIC, 08034 Barcelona, Spain and [1]Neurotoxicology Division, US EPA, Research Triangle Park, NC 27711, USA.

IDPN induces neurofilament (NF)-filled swellings in the proximal region of large caliber axons, and degeneration of vestibular sensory hair cells which causes a syndrome of abnormal behavior. Following acute exposure, vestibular toxicity appears at doses lower than those required to induce overt neuropathic effects. The present study compares vestibular and peripheral nerve effects of IDPN following subchronic exposure. Adult Long-Evans rats were exposed to 0, 0.025, 0.05, 0.1 or 0.2 % IDPN in the drinking water for 13-15 weeks. Exposure was discontinued after 7 weeks in a group receiving 0.4 % IDPN due to marked body weight loss. Motor activity was assessed at 0, 1, 3, 6, 9 and 12 weeks of exposure, and vestibular function at 0, 1, 2, 4, 6, 9, and 12 weeks. The vestibular system and the dorsal root ganglia (DRG) were assessed for pathological changes at the end of the exposure. Effects on body weight, motor activity, vestibular function and vestibular morphology were observed after 0.2 and 0.4 % IDPN. Axonopathic effects in the DRG were obvious after 0.2 %. Thus, during subchronic exposure to IDPN, proximal axonopathies do not require larger dosages than vestibular toxicity, in contrast to acute exposure.

679.15

NEUROTOXICITY OF SERUM FROM PATIENTS WITH INSULIN-DEPENDENT DIABETES (IDDM) IS ASSOCIATED WITH INCREASED TRK-A EXPRESSION AND IS PARTIALLY REVERSED BY NGF. Gary L. Pittenger, Dong Liu, Pauline G. Newlon*, Aaron I. Vinik. Depts. of Internal Medicine, Surgery and Anatomy & Neurobiology, Eastern Virginia Medical School, Norfolk, VA 23510

We have previously demonstrated that immunoglobulins (Ig) from serum of IDDM patients with neuropathy are toxic to the clonal adrenergic N1E-115 neuroblastoma cell (NB), suggesting that autoimmunity contributes to diabetic neuropathy. In experimental autoimmune neuropathy, nerve growth factor (NGF) has been shown to be protective. In these studies, we tested whether NGF might protect NB from the neurotoxic effects of IDDM serum. After plating equally into 35 mm^2 dishes, NB were exposed to 10% of either control subject (n=6) or IDDM patient serum (n=6) and, separately, to the sera plus increasing concentrations of NGF from 100 ng/ml to 2 μg/ml. After 72 h the cultures were lifted from the dishes and viable cells counted by trypan blue exclusion criteria. In the presence of NGF and IDDM serum, cell numbers increased in a dose-dependent manner, even in the face of the most toxic IDDM serum which killed all cells. On average, the optimal dose was 500 ng/ml. The effects of the IDDM sera were only partially reversed by NGF. In order to test whether IDDM serum causes alterations in trk A gene expression, *in situ* hybridization was performed on NB using a probe (Genentech, San Francisco) specific to trk A. The results indicated that NB make trk A RNA and that the expression of trk A receptor gene is increased 2-3 fold in response to IDDM serum, but not in response to control subject serum. In summary, NGF has a dose-dependent, partially protective effect on N1E-115 cells treated with neurotoxic IDDM serum. The neurotoxic effect is not due to down-regulation of trk A receptor gene. Further studies are required to determine any role of altered NGF/receptor signalling in the neurotoxicity of IDDM serum.

CYTOKINES AND DELIRIUM: AN EXPLORATORY STUDY. J.R. Mach, D.T. Weldon, N. L. Opstad, K.M. Bettin, and J.A. Mortimer*. Geriatric Research Education Clinical Center (GRECC) (11G), VA Medical Center, Minneapolis, MN 55417

Delirium occurs in 20-30% of older inpatients and is associated with a mortality rate nearly twice that of controls. Despite its clinical significance, the pathophysiology of delirium is virtually unknown. Delirium consists of behavioral and cognitive symptoms caused by a variety of conditions that are not primary CNS diseases. Cytokines have been found to mediate many disease-brain interactions, such as eating disorders, stress reactions, cancer, and infections. To date, the role of cytokines in delirium has not been studied. This study examined the relationship between delirium and serum levels of selected "pro-inflammatory" cytokines IL-1α, IL-1β, IL-2, IL-6, and TNF-α.

Twelve delirious patients were recruited from the inpatient wards at the Minneapolis VA Medical Center. Subjects met diagnostic criteria for delirium using the CAM and were age 55 or older. Patients with pre-existing dementia were excluded. Eight nondelirious inpatient controls, each matched for age and illness severity to a delirious subject, were enrolled for comparison. Serum cytokine assays were performed using ELISA kits from R & D Systems. Wilcoxon matched-pairs signed-ranks test for non-parametric distributions was used to analyze the two sets of serum cytokine data. IL-6 serum levels (pg/ml) declined significantly in the delirious group as clinical symptoms improved (mean ± SE = 40.75 ± 12.24 vs. 20.25 ± 7.99, respectively, $p < 0.05$). Furthermore, IL-6 was significantly elevated in the delirious group compared to matched controls (49.47 ± 12.36 vs. 16.25 ± 5.16, respectively, $p < 0.02$). Serum levels of IL-1α, IL-1β, IL-2, and TNF-α were below detection limits in delirious subjects and controls. These results suggest that IL-6 may play a role in delirium pathophysiology. Supported by a grant from the Department of Veteran Affairs.

NEUROVIRULENT SIMIAN IMMUNODEFICIENCY VIRUS STRAIN INDUCES APOPTOSIS IN THE CENTRAL NERVOUS SYSTEM. D.C. Adamson*, T.M. Dawson, M.C. Zink, J.E. Clements, & V.L. Dawson. Neurology, Neuroscience, & Comp. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21202.

Studies of human immunodeficiency virus type 1 (HIV-1) infection in the central nervous system (CNS) have shown neuronal loss in discrete areas; however, the presence and mechanism of neuronal death, particularly in the case of HIV-1 associated dementia has remained quite elusive. Programmed cell death or apoptosis, has been clearly demonstrated outside the CNS in HIV-1, but has not been firmly established within the CNS. Using a simian immunodeficiency virus (SIV) animal model for HIV-1 CNS infection, we investigated whether SIV infection of the CNS is spatially associated with apoptosis of neurons and non-neuronal cell types. With the aid of an *in situ* technique for identifying the 3'-OH ends of newly fragmented DNA characteristic of apoptosis, we demonstrate the presence of apoptotic neurons, astrocytes, endothelial cells, oligodendrocytes and microglia. We also observe the colocalization of apoptotic cells with numerous perivascular inflammatory cell infiltrates and SIV-infected cells. Quantitative analysis reveals significantly more apoptotic CNS cells in neurovirulent SIV strains as compared to strictly lymphocyte-tropic strains and SIV negative controls. Our findings of SIV induced apoptosis in the CNS will hopefully lead to a better understanding of sequelae of HIV-1 CNS infection such as HIV-1 associated dementia.

SELECTIVE KILLING OF CHOLINERGIC NEURONS BY MICROGLIAL ACTIVATION IN CELL CULTURE

M.K. McMillian*, L.-Y. Kong, K.P. Das, S. Mullis Sawin, B.C. Wilson, P.M. Hudson, J.-S. Hong, and G.Bing
LEN/ NIEHS/ NIH, RTP, NC 27709

Inflammation may be important in the etiology of Alzheimer's disease and cholinergic neurons are lost early in the course of this disease. We previously showed that dopaminergic neurons in mixed mesencephalic cultures are selectively killed by activation of microglia by lipopoly-saccharide (LPS) and that production of nitric oxide (NO) is critical for neurotoxicity. LPS (10 μg/ml) treatment (2 days) also killed most choline acetyltransferase-positive (Chat+) neurons (50-80%) in fetal rat basal forebrain cultured on hippocampal glia; unstained neurons were spared. Inducible NO synthase was visible in microglia and the levels of nitrite (the NO metabolite) were increased 2 days after LPS addition. The NO synthase inhibitor NAME (0.5 mM) protected the Chat+ neurons. The opiate morphine and the anti-inflammatory steroid dexamethasone inhibited LPS-induced NO formation in these cultures, and may have cholinergic neuroprotective effects. β-amyloid, the HIV protein GP120 and γ-interferon all increased NO, and microglial activation may explain their cholinergic neurotoxicities.

EVALUATION OF THE EFFECTS OF FLUOXETINE ON MOTOR ACTIVITY IN RATS. Bruce Culver* and Shannon Howrey School of Pharmacy, University of Wyoming, Laramie, WY 82071.

Akathesia and other motor dysfunctions are side effects associated with the use of fluoxetine (FL). The mechanisms underlying these motor effects remain poorly understood. Acute administration of FL in rats has been suggested as an animal model of akathesia (Teicher and Wallace, Neurosci Abst, p. 1868, 1993). Our studies were designed to further characterize motor effects of rats injected with FL (30mg/kg; s.c.) using 2 different methods of activity testing. Measures of photocell counts recorded over 2-4 days from groups of female rats in a figure 8 maze revealed rats injected with FL had less locomotor activity during the exploratory periods than paired saline control groups. Decreases in activity were also recorded from FL-treated rats during the rest of the diurnal and nocturnal periods. Digiscan (Omnitech) activity monitors were used to provide several different measures of motor activity of individual rats placed in the units for a 6 hr period. Female rats treated with FL generally showed a decreased total distance traveled consisting of non-stereotyped decreases in horizontal and vertical activities compared to controls, but differences were significant only during the first 2 hrs in the apparatus. However, males treated with FL showed an increase in total distance moved after 3 hrs in the units and the activity consisted of increased stereotypy and horizontal movements. Our findings that FL generally decreases most motor activities of female rats seems to be inconsistent with previous reports of FL-induced increased locomotor activity and "restlessness", which may correlate with our findings of certain increases in motor activity in FL males. Additional characterization of motor behaviors is needed to evaluate the utility of this model of FL-induced motor dysfunction.

UPREGULATION OF HIGH AFFINITY NEUROTROPHIN RECEPTOR, TRK B-LIKE PROTEIN ON WESTERN BLOTS OF RAT CORTEX AFTER CHRONIC ETHANOL TREATMENT(CET). I. Baek,* M.B. Heaton & D.W. Walker, Dept. of Neuroscience, College of Medicine, Univ. of Florida, Gainesville, FL 32610

We previously reported that the total neurotrophic activity of hippocampal extracts was significantly (25-50%) reduced after 21-28 wks of CET suggesting that the level of one or more neurotrophic factors may be compromised in CET rats (Walker et al. 1992, Neurosci. Lett. 147:77-80). Such compromised level of neurotrophic factor(s) (i.e., ligand itself), changes in receptors for the neurotrophic factors, or combination of both may induce the neuronal degeneration observed in neurotrophin-dependent neurons after CET.

To investigate possible changes in neurotrophic factor-receptors, we examined Western blots of rat cortex after 28 wks of CET. After sonication and ultra-centrifugation, the supernatant of crude lysates of individual animals' cortex was subjected to SDS-PAGE, electrotransfer to nitrocellulose membrane, incubation with α-*trk* B Ab and alkaline phosphatase-conjugated protein A, and chemiluminescent substrate reaction. The membranes were then exposed to Kodak XAR film.

Compared to controls (n=6), CET rats (n=7) appeared to have significantly higher intensity of *trk* B-like protein at about 145 KD, which suggests up-regulation of *trk* B to compensate the compromised level of certain subset (i.e., BDNF, NT-3, 4 or 5, but not NGF) of neurotrophins in cortex.

DECREASED CROSS-SECTIONAL AREA OF THE CORPUS CALLOSUM IN YOUNG FEMALE ALCOHOLICS: AN MRI STUDY D Hommer*, R. Momenan, P. Ragan, W. Williams, D. Rio, M. Eckardt National Institute on Alcohol Abuse and Alcoholism, DICBR, Laboratory of Clinical Studies, Bethesda, MD 20892-1256

Although, females appear to be more sensitive to the hepatic consequences of alcoholism, to date, there has been no evidence that females suffer more severe structural CNS sequelae of alcoholism. Several groups have used magnetic resonance imaging (MRI) techniques to compare brain structure between alcoholics and controls. These studies have primarily examined males. We compared cross-sectional area of the corpus callosum in a group of 14, hospitalized, alcoholic women (mean age = 38.9±6.7 years) with a group of 9 non-alcoholic women (35.9±4.7 years). The corpus callosum and the inner table of the skull were outlined by hand on a mid-saggital T_1 weighted MRI image. There was no difference in intra-cranial area between the alcoholics and controls; however, corpus callosum area was significantly smaller among the alcoholics (717±78 mm^2 versus 566±105 mm^2, $t(21)=3.70$, $p < .002$). When the corpus callosum was divided into four segments of equal length, the reduction in area did not appear to be localized. Alcoholic males did not differ from control males in corpus callosum or intra-cranial area. These results may indicate an increased sensitivity to alcohol-induced brain damage among females.

METHANOL TOXICITY: SPECIES DIFFERENCES IN RETINAL FORMATE OXIDATION. J. T. Eells *, A. M. Flaig, J. J .Schultz, and M. M. Salzman. Department of Pharmacology and Toxicology. Medical College of Wisconsin, Milwaukee, WI 53226.

Formic acid is the toxic metabolite responsible for the retinal and optic nerve toxicity produced in methanol poisoning. The primary site of formate oxidation and detoxification to CO_2 is the liver. However, there is little information regarding formate oxidation in the retina, an important target tissue of formate toxicity. The purpose of this study was to compare the capacity of human retinal tissue and retinal tissue from a methanol-resistant species, the rat, to oxidize formate. Formate oxidation was measured *in vitro* in isolated human and rat retina. The oxidation of ^{14}C-formate to $^{14}CO_2$ by human and rat retinal tissue followed pseudo-Michaelis-Menten kinetics. The pseudo-K_m did not vary between the two species and averaged 2.3 mM. However, the maximum rate of formate oxidation (pseudo-V_{max}) was 2-times higher in rat retinal tissue (63 ± 8 nmole CO_2/g/min) than in human retinal tissue (29 ± 3 nmole CO_2/g/min). The apparent *in vitro* metabolic half-life of formate was calculated to be 31 min. in rat retina and 54 min. in human retina. Humans and non-human primates are uniquely sensitive to methanol toxicity. These data support the hypothesis that species differences in retinal formate oxidation may play a role in the susceptibility to methanol poisoning. (Supported the American Petroleum Institute and NIH grant ES06648).

CATALASE OXIDATION OF ETHANOL TO ACETALDEHYDE IN FETAL BRAIN MAY CONTRIBUTE TO THE TOXIC EFFECT OF MATERNAL ALCOHOL CONSUMPTION. R. Hamby-Mason[1], B. Cobb-Alls[2]* and G. Henderson[1]. [1]University of Texas Health Science Center, San Antonio, TX 78284 and [2]Armstrong Laboratory, Radiofrequency Radiation Division, Brooks AFB, TX, 78235.

Previous studies documenting oxidative stress in rat fetuses exposed to ethanol (E) *in utero* have shown an increase in catalase activity (Cat). This E-enhanced Cat, combined with elevated Cat in fetal/neonatal brain, may increase acetaldehyde (AcHO) formation in excess of that in the adult. Both Cat and AcHO production from E were assayed in 10% homogenates of fetal, neonatal and adult brain. Aliquots of the homogenates were incubated (60 min) with 20 mM E. AcHO levels (by HPLC) and Cat (spectrophotometric) were determined. Addition of E to adult brain homogenates increased AcHO by 251% above the control (C) and elevated Cat by 34.1%. Pretreatment with Cat inhibitors, sodium azide and 3-amino-1,2,4 triazole significantly decreased production of AcHO by E. Neither 4-methylpyrazole, an alcohol dehydrogenase inhibitor, nor isoniazid, a P450 inhibitor, had an effect on the amount of recovered AcHO. Cat was highest in brains from 17 and 19 day old fetuses (17.01±1.27 and 11.40±2.40 SE, units) and declined to 8.15±0.42 units for day one neonates and to 3.6±1.4 units for adults. Neonatal brains more rapidly metabolized E to AcHO (379% vs 251% above C) than did adult brain. Exposure to E *in utero* increased brain Cat in day 17 fetuses at 1 and 3 hrs post E by 55.3% and 92.9% respectively, with a 447% increases in AcHO production at 3 hrs. This indicates that high basal levels of Cat in immature brain, combined with E-enhanced Cat, increase production of AcHO at a rate above that in adult brain. Thus, enhanced Cat oxidation of E may be an important mechanism underlying the toxic effects of maternal E consumption on the fetal brain.

SYMPOSIUM. MOLECULAR ORGANIZATION OF THE POSTSYNAPTIC MEMBRANE. Mary B. Kennedy, Caltech (Co-chair); Justin R. Fallon, Worcester Foundation; Heinrich Betz, Max-Planck Institute, Frankfurt; Stanley C. Froehner (Co-chair), Univ. of North Carolina at Chapel Hill.

The mechanisms leading to the formation of postsynaptic specializations are most completely understood at the neuromuscular junction. Although the heterogeneity of central nervous system synapses makes them less amenable to biochemical studies, recent advances have revealed features in common with the neuromuscular junction (e. g., the presence of members of the dystrophin protein family and associated proteins) as well as important differences. This symposium will emphasize the emerging principles common to neuromuscular and central synapse formation, as well as those molecules and mechanisms specific for each synaptic type. **Fallon** will discuss the characterization of the agrin receptor and the mechanism by which agrin initiates AChR clustering. **Froehner** will describe proteins of the neuromuscular postsynaptic cytoskeleton, including the 43K protein and components of the dystrophin/utrophin complex, that appear to anchor ACh receptors at synaptic sites.Some proteins associated with glutamatergic and glycinergic synapses in the CNS are not found at the neuromuscular junction and probably mediate specialized functions. **Betz** will present data on the protein gephyrin, which is essential for clustering of glycine receptors in spinal cord neurons, probably via a mechanism involving microtubules. Finally, **Kennedy** will discuss the postsynaptic density at glutamatergic synapses, which contains signal transduction molecules that appear to play a specialized role in mediating forms of synaptic plasticity that are unique to these synapses.

SYMPOSIUM: DEVELOPMENTAL DETERMINANTS OF RETINAL GANGLION CELLS. L. M. Chalupa, UC Davis (Chairperson); R. O. L. Wong, Washington University; A. E. Hendrickson, University of Washington; R. W. Guillery, Oxford University.

This symposium will deal with diverse mechanisms regulating the formation of some of the key features of retinal ganglion cells and their precise patterns of projections. Wong will discuss correlated retinal activity patterns demonstrated by multi-electrode arrays and optical recording techniques in relation to spontaneous activity and neurotransmitter responsivity of developing ganglion cells. Chalupa will discuss the roles of retinal afferents and sodium voltage-gated activity in regulating the establishment of On and Off ganglion cell mosaic patterns in the postnatal cat retina. Hendrickson will present results of light and EM studies, as well as immunocytochemical experiments, directed at assessing the factors responsible for the density shifts that give rise to the primate fovea. She will consider such issues as the suppression of rods and blue cones in the foveal region, and the effects of cell migration on the state of synaptic contacts formed prior to the differentiation of the fovea. Guillery will talk about stages of the guidance mechanisms that lead axons into a crossed or an uncrossed pathway at the optic chiasm, and will relate this to ganglion cell classes identified in cats and ferrets.

684.1

SUB-THRESHOLD SYNAPTIC ACTIVATION OF Ca^{2+} CHANNELS MEDIATES A LOCALIZED Ca^{2+} INFLUX INTO DENDRITES OF HIPPOCAMPAL PYRAMIDAL NEURONS. J. C. Magee*[1,2], G. Christofi[2], H. Miyakawa[2], B. Christie[1,2], N. Lasser-Ross[2], & D. Johnston[1,2], [1]Div. Neurosci., Baylor Coll. of Med., Houston, TX and [2]MBL, Woods Hole, MA

Hippocampal CA1 pyramidal neurons contain a relatively high density of TTX-sensitive Na^{2+} channels and at least three types of Ca^{2+} channels. Of these Ca^{2+} channels, the LVA or T-type channel in the dendrites can be activated by sub-threshold EPSPs. Such channel activation could greatly impact the dendritic integration of synaptic activity. Furthermore, if sub-threshold voltage-gated channel activation provides a significant influx of Ca^{2+}, such channels could participate in the long-term regulation of synaptic efficacy. We used whole-cell patch-clamp techniques in conjunction with high-speed fluorescence imaging of fura-2 to characterize subthreshold, synaptically activated Ca^{2+} influx into the dendrites of CA1 pyramidal neurons. We consistently observed a significant non-NMDA (50 μM APV included in bath) mediated elevation of dendritic intracellular Ca^{2+} concentration in response to sub-threshold synaptic stimulation (5 stimuli at 50 Hz). These Ca^{2+} signals were localized to branches of the dendritic arborization that received active synaptic input. Prior membrane hyperpolarization (15–25 mV for 1.5–2 secs, 250–400 ms before synaptic stimulation) enhanced the Ca^{2+} influx by up to 66 ± 10% ($n = 5$). 50 μM $NiCl_2$ reduced the amplitude of this postsynaptic influx of Ca^{2+} by 54 ± 5% ($n = 8$). These data suggest that Ni^{2+}-sensitive, voltage-gated Ca^{2+} channels with relatively hyperpolarized voltage-ranges of activation and inactivation mediate a substantial influx of Ca^{2+} into the dendrites of CA1 pyramidal neurons. The primary candidate for such a channel is the LVA or T-type Ca^{2+} channel (NS09482, NS11535, MH44754, and MH48432).

MECHANISMS OF ACTION POTENTIAL INITIATION IN SOMA, AXON HILLOCK, AND INITIAL SEGMENT OF PYRAMIDAL NEURONS. C. M. Colbert* and D. Johnston, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Pyramidal neuron dendrites propagate action potentials (APs), yet the site of AP initiation, even for dendritic input, appears to be the soma or axon hillock/initial segment (AH/IS) (Stuart & Sakmann, *Nature* 367:69, 1994). Recently, experimental findings have constrained the possible mechanisms underlying AP initiation, including an equal (and rather low) mean density of Na^+ channels in the soma and dendrites (Magee & Johnston, *J. Physiol.*, in press). Satisfying these constraints, models of pyramidal neurons predict that the AH/IS region must have a very high Na^+ channel density—perhaps two orders of magnitude greater than the soma. In such a configuration, the neuron cannot fire a robust spike without an IS. We tested these predictions using patch-clamp techniques to record from visually identified CA1 and subicular neurons and ISs in slices from adult rats. First, we estimated the density of Na^+ channels on the IS, AH, and soma using cell-attached patch recordings. The IS had only a slightly higher mean Na^+ channel density than the soma. Second, we assessed the ability of somatic and IS Na^+ channels to produce APs in the soma. Using whole-cell current-clamp recordings, APs were activated antidromically by alvear stimulation or orthodromically by depolarizing current to the soma. Tetrodotoxin (TTX) was puffed from a second pipette to block Na^+ channels. TTX applied to the IS (10–12 μm from the soma) reversibly blocked the antidromic AP in a graded fashion, while only slightly raising the threshold for the orthodromic AP. AP amplitude did not decrease significantly. TTX applied to the soma blocked somatic APs, although the much-attenuated antidromic AP still invaded the soma. These results suggest that the initial segment does not have a greatly increased Na^+ channel density and that somatic Na^+ channel activation is required to produce robust somatic action potentials (NS11535, MH44754, MH48432 and MH10896).

684.3

A STEADY-STATE, NIMODIPINE-SENSITIVE CALCIUM CURRENT ACTIVE AT REST IN HIPPOCAMPAL CA1 DENDRITES. D. Johnston*, J. C. Magee, B. R. Christie, and R. B. Avery, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

The dendrites of hippocampal CA1 pyramidal neurons express a number of different types of voltage-gated channels, including Na^+ channels and several types of Ca^{2+} channels (Magee and Johnston, *J. Physiol.*, in press). The Ca^{2+} channels observed in dendrites include low-voltage activated (LVA) T-type channels, high-voltage activated (HVA) R-type channels, and dihydropyridine (DHP)-sensitive HVA L-type channels. During the investigation of LVA, Ni^{2+}-sensitive channels that are activated by EPSPs (Magee et al., this meeting), we found what appeared to be a standing Ca^{2+} current active at the resting potential.

Whole-cell recordings of visually identified CA1 neurons were made in hippocampal slices prepared from 5–8 week old rats. The pipettes were filled with 125 μM fura-2 for high-speed fluorescence imaging. When cells were hyperpolarized from rest, there was a time- and voltage-dependent decrease in $[Ca^{2+}]_i$ in the soma and apical dendrites. The decrease in $[Ca^{2+}]_i$ was maximal in the proximal dendrites and less in the soma and distal dendrites. A similar gradient was obtained when whole-cell recordings were made from dendrites. The voltage-dependent decrease in resting $[Ca^{2+}]_i$ was blocked by 200 μM Cd^{2+} and reduced by 73% with 10 μM nimodipine. Recent whole-cell voltage-clamp recordings from isolated pyramidal neurons have revealed a non-inactivating Ca^{2+} current activated near the resting potential (Avery and Johnston, this meeting). This Ca^{2+} current is partly sensitive to DHPs and thus may be involved in the decrease in $[Ca^{2+}]_i$ with hyperpolarization observed during the fluorescence imaging. The results suggest that a LVA, L-like Ca^{2+} current contributes to the resting properties of these neurons (MH44754, MH48432, NS11535, and NS09482).

AFTERHYPERPOLARIZATION IN NEONATAL PHRENIC MOTONEURONS: DIFFERENCES BETWEEN INSPIRATORY AND EXOGENOUSLY-EVOKED ACTION POTENTIALS. C. K. Su* & J. L. Feldman. Dept. of Physiol. Science, UCLA, LA, CA 90095-1527.

Repetitive firing behavior of phrenic motoneurons (PMNs) in neonatal rat were examined to elucidate the interplay between intrinsic neuronal properties and synaptic drive. Whole cell patch-clamp recordings were made from PMNs in *in vitro* brainstem-spinal cords of neonatal rat. Action potential afterhyperpolarizations were measured by averaging the waveform of action potentials. Extrinsic driving force was estimated from averages of synaptic potentials during inspiration. Maximal firing (intervals: 16 - 56 ms) typically occurred within the first 5 spikes of each inspiratory burst; this correlated with peak synaptic drive currents. Exogenous local application of phenylephrine (PE, 0.1-1 mM), an α_1 adrenergic agonist, did not significantly change the maximal firing rate, but increased average firing rate/cycle and lengthened the burst period; PE also induced tonic firing during the normally silent interbust period. Medium afterhyperpolarizations (mAHP) (duration~100 ms) were often observed following action potentials during expiration (elicited by PE), as well as following antidromic action potentials. However, mAHPs were infrequently observed following action potentials during inspiration. (Only some slow firing neurons showed a prominent mAHP during inspiration. For these neurons, mAHP was diminished by local application of PE.) Thus, mAHPs are seen following exogenously-but not endogenously-evoked action potentials. This suggests that intrinsic properties of PMNs are modulated by inspiratory synaptic factors to suppress mAHPs and modify the current-frequency response appropriate for inspiratory movement of the diaphragm. Supported by NIH Grant NS24742.

SPACIAL AND TEMPORAL INTEGRATION OF SYNAPTIC INPUT IN RAT CEREBELLAR PURKINJE CELLS *IN VITRO*

D. Heck*, B. Antkowiak and A. Borst, Max-Planck-Institut fuer biologische Kybernetik, Spemannstr. 38, 72076 Tuebingen, Germany

We investigated spatial and temporal integration of synaptic input in cereballar Purkinje cells. Acute saggital slices (300 µm thick) were prepared from the cerebelli of two week old rats according to standard procedures. Somatic whole cell patch clamp recordings were established under visual control using an upright microscope with Normarski optics. The patch pipettes contained lucifer yellow to allow visualization of the individual Purkinje cells dendritic trees. Two small-diameter bipolar stimulating electrodes built from theta glass (tip diameter ~ 20 µm) were used to activate presynaptic fibers terminating on the recorded cells' dendrite. With the extension and geometry of the lucifer-yellow stained dendrite being well visible the stimulating electrodes were positioned above two remote sites of the dendritic tree such that synaptic input elicited by electrical stimulation would activate synapses on two independent branches of the dendrite. Synaptic currents and potentials elicited by the stimuli were measured under voltage clamp and current clamp conditions, respectively. Stimuli were applied through each of the electrodes seperately and the effect of each electrode was measured. Then pairs of stimuli with varying delays between the two stimuli were given in order to investigate temporal summation. Finally both electrodes were activated synchronously.

Under voltage clamp conditions somatically recorded excitatory synaptic currents summed up linearly. Preliminary results obtained under current clamp conditions suggest that excitatory synaptic potentials elicited at two independent dendritic branches also sum up linearly.

A Purkinje cell was anatomically reconstructed and a compartmental model of the cell was implemented on a computer. The experiments were repeated in the simulated cell.

684.6

ACTIVATION OF POSTSYNAPTIC CALCIUM/CALMODULIN PATHWAYS MODULATES SYNAPTIC RESPONSIVENESS IN HIPPOCAMPAL CA1 NEURONS. J-H. Wang* and P.T. Kelly, *Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, Texas 77030.*

The role of calcium/calmodulin (Ca^{2+}/CaM) signaling pathways in synaptic transmission was studied in CA1 pyramidal neuron synapses made by Schaffer collateral/commisural terminals in rat hippocampal slices. The postsynaptic injection of a stoichiometric ratio of Ca^{2+}/CaM (4:1) induced significant potentiation of excitatory synaptic responses, EPSP (65±10%, mean±S.E.M, n=14) and EPSC (54±7%, n=10), even in the presence of $GABA_A$ and $GABA_B$ antagonists (79±9%, n=8). Potentiation was not induced by injecting Ca^{2+} (4±4%, n=12) or CaM alone (10±7%, n=12) and was blocked by co-injection of a CaM-binding peptide (CBP). Reciprocal experiments showed that Ca^{2+}/CaM-induced synaptic potentiation and tetanus-induced LTP occluded one another. Pseudosubstrate inhibitors or high-affinity substrates of CaM-KII ($[Ala^{286}]CaMKII_{281-302}$ and autocamtide-3) or PKC (PKC_{19-31} and $neurogranin_{28-43}$) significantly blocked Ca^{2+}/CaM-induced potentiation. These results indicate that postsynaptic levels of free Ca^{2+}/CaM are a rate limiting factor for triggering synaptic potentiation and that functional cross-talk between Ca^{2+}/CaM and PKC pathways occurs during LTP induction.

Paired-pulse facilitation (PPF) of synaptic transmission was significantly attenuated by Ca^{2+}/CaM injections under current-clamp (37±5% reduction, n=10) and voltage-clamp conditions (31±5%, n=7), and in the presence of GABAergic antagonists (43±11%, n=8). The attenuation of PPF was blocked by CBP, psuedosubstrates and substrates of CaM-KII or PKC, and reversed by cyclothiazide, a blocker of AMPA receptor desensitization. These results indicate that PPF is regulated by postsynaptic Ca^{2+}/CaM pathways and AMPA receptor plasticity. (supported by NIH grant NS32470).

COINCIDENCE DETECTION OF SYNAPTIC INPUTS AND SPIKES BY INDIVIDUAL SPINES REVEALED BY CALCIUM IMAGING WITH TWO-PHOTON MICROSCOPY.

R. Yuste* and W. Denk, AT&T Bell Laboratories, Murray Hill, NJ 07974.

Most synaptic connections in the central nervous system occur on dendritic spines, whose functional properties are poorly understood because of experimental difficulties resulting from their small sizes (~1 μm^3). We have taken advantage of the improved tissue penetration provided by two-photon excitation of visible fluorophores with infrared light (Denk et al., Science 248: 73-76, 1990) to image calcium concentration in spines from CA1 pyramidal neurons in slices of rat hippocampus. Cells were filled with the calcium indicators Calcium Green 1 or 5N, using whole-cell perfusion. Laser scanning was performed using a modified confocal microscope with a mode locked Ti:Saphire laser (λ=850 nm) as the excitation source.

Focal subthreshold synaptic stimulation produced calcium accumulations that were restricted to isolated spines, showed stochastic failures, and were abolished by postsynaptic blockers. Similarly, discrete calcium accumulation localized to isolated spines were seen in spontaneous calcium accumulations elicited by high [Ca^{2+}] and low [Mg^{2+}] ACSF, conditions that enhance spontaneous transmitter release. In contrast, single somatic spikes induced fast-peaking calcium accumulations in spines throughout the cell. With 2 msec time resolution, we observed no appreciable delay between spike-induced calcium accumulation in spines heads and nearby dendrites. Finally, the simultaneous pairing of spikes with synaptic stimulation was frequently cooperative resulting in calcium accumulations that were supralinear, i.e. larger than the combined responses to the individual stimuli.

Taken together, our results strongly suggest: (i) the existence of voltage-sensitive calcium channels in the spine heads, (ii) their antidromic activation by the action potential, (iii) that individual spines are calcium compartments and (iv) that they can individually signal the coincidence of the input and output of the neuron, thus serving as basic functional units of synaptic integration.

DENDRITIC CALCIUM-DEPENDENT EXOCYTOSIS IN CULTURED HIPPOCAMPAL NEURONS: ROLE OF CALCIUM/CALMODULIN PROTEIN KINASE II. M. M. Maletic-Savatic*, T. Koothan and R. Malinow, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724, USA

Calcium/calmodulin protein kinase II (CaMKII) has been implicated as a key enzyme involved in formation of long term potentiation (LTP). One of the possible models of LTP formation is that CaMKII activation mediates insertion of glutamate receptors into postsynaptic membrane by vesicle exocytosis. In order to test this hypothesis we have used quantitative time-lapse imaging of the fluorescent membrane probe FM 1-43. Exocytosis of vesicles in cultured hippocampal neurons was monitored at 4 to 10 days *in vitro* (DIV). Neurons exposed overnight to FM 1-43 accumulate dye in all neuronal processes, some of which are dendrites. Release of the dye from dendritic sites was induced by the Ca++ ionophore A23187 (2.5 μM). This release was observed at ages (DIV) when CaMKII and glutamate receptors (NMDAR1, GluR1, GluR2/3 and GluR4) are normally expressed, but not before. We investigated the pattern of FM1-43 release at earlier ages, following infection of the cultured neurons with a recombinant vaccinia virus expressing a full length (f) CaMKII. Preliminary results indicate that the presence of fCaMKII influences the release of the FM1-43 dye by A23187 at an age when NMDAR1 is expressed but CaMKII and GluRs are normally not expressed. These results suggest a role for CaMKII activation in exocytosis at postsynaptic sites.

AT-SOURCE KINETICS OF $GABA_A$ RECEPTOR MEDIATED IPSCs IN DENTATE GYRUS GRANULE CELLS. I. Soltesz,*[1] D.K. Smetters[2] and J. Mody[3]. [1]Dept. of Anatomy & Neurobiol., UC Irvine, CA; [2]Salk Institute, La Jolla, CA; [3]Dept. of Neurology, UCLA, Los Angeles, CA.

Principal cells receive their GABAergic inputs from multiple interneuron types which terminate in mutually exclusive domains along the their longitudinal axis. In the dentate gyrus both somatic and dendritic layers contain several $GABA_A$ receptor subunits and an abundance of GABAergic terminals. We used whole-cell patch clamp and computational techniques to find out whether there are differences in the properties of inhibitory synapses located on different parts of cells. IPSCs were recorded from adult rat granule cells in the presence of 10 μM CNQX and 40 μM D-AP5, with 130 mM CsCl, 10 mM HEPES, and 2 mM $MgCl_2$ containing electrodes.

Minimal stimulation at various distances from the somatic recording site showed that both proximal and distal inhibitory fibers are capable of releasing GABA, and that the released transmitter activates functional $GABA_A$ receptors. In addition, these experiments demonstrated that the further away from the soma the IPSCs were generated, the slower and smaller they became. When spontaneous events were examined in the presence of TTX (miniature IPSC or mIPSCs), the 10-90% rise times of the events ranged from 0.1 to 10 ms. How are mIPSCs with such different kinetics generated? Compartmental modeling of a typical granule cell showed that the kinetics of distal minimally evoked IPSCs at source are comparable to the kinetics of the somatic mIPSCs. This suggests that activation of somatic and dendritic $GABA_A$ receptors evokes events with very similar at-source kinetics. However, when the bulk (>50%) of the dendritic tree was removed, the distribution of 10-90% rise times still showed an unchanged low (<3%) percentage of events with extremely slow kinetics (3-10ms), indicating that such slow events can be generated at proximal sites.

These findings suggest that in granule cells most distal and proximal synapses contain $GABA_A$ receptors with similar kinetics, however, they also indicate the possible presence of a small number of synapses with distinct $GABA_A$ receptor composition and kinetics.

RECOMBINANT GEPHYRIN FORMS FILAMENTS *IN VIVO* WHICH BIND THE GLYCINE RECEPTOR β SUBUNIT AND $GABA_A$ RECEPTOR β3 SUBUNIT J. Kirsch*, and H. Betz Dept. of Neurochemistry, Max-Planck-Institute for Brain Research, Deutschordenstr. 46, 60528 Frankfurt, Germany

The peripheral membrane protein gephyrin was originally identified upon co-purification with the inhibitory glycine receptor of rat spinal cord. Expression of this polypeptide in spinal neurons is essential for the formation of postsynaptic glycine receptor clusters. Gephyrin is widely expressed throughout the synaptic regions of the central nervous system and co-distribution with glycine- and $GABA_A$ receptors could be demonstrated. Since both receptor types are pentameric receptor complexes composed of several subunits we investigated by heterologous expression in combination with electron microscopy and immunocytochemistry which receptor subunits can interact with recombinant gephyrin. We found that recombinant gephyrin forms filamentous structures (6nm) in HEK 293 cells which bind glycine- or $GABA_A$ receptor β subunits. Therefore, we conclude that gephyrin-mediated anchoring at synaptic sites may depend on the subunit composition of the respective neurotransmitter receptors.

1S,3R-ACPD INCREASES INTRACELLULAR CALCIUM LEVELS IN RAT DORSOLATERAL SEPTAL NUCLEUS (DLSN) NEURONS. F.Zheng* and J.A. Connor, Roche Inst. of Molecular Biology, Nutley, NJ 07110.

1S,3R-ACPD causes membrane depolarization and burst firing in rat DLSN neurons, and results in long lasting enhancement of synaptic transimission (Zheng & Gallagher, Neuron 9, 163-172, 1992). One possible mode of action is an increase of intracellular calcium levels by releasing calcium from IP3-sensitive stores due to activation of a metabotropic receptor coupled to phospholipase C. In the present study, we measured intracelluair calcium levels using fluorescent imaging techniques in a slice preparation. Fura-2 was injected into DLSN neurons through the recording microeletrode. $[Ca^{2+}]_i$ was measured by 350/380 ratio.

Superfusion of 1S,3R-ACPD depolarized the fura-2 loaded DLSN neurons and triggered burst firing as described previously. No significant change of $[Ca^{2+}]_i$ was associated with the simple depolarization, but a large rise of $[Ca^{2+}]_i$ occured after burst firing started. Calcium increases first occurred in remote dendrites, then spread gradually into the soma. During the repolarizing phase of the burst firing, the dendritic calcium signals returned to basal level first, while the calcium level in the soma was still elevated. $[Ca^{2+}]_i$ changes during ACPD bursts were much larger than those produced by spike activity in normal saline. Since the enhancement of spike-triggered calcium increases by 1S,3R-ACPD is accompanied by a prolonged, depolarizing plateu potential which is thought to be a dendritic calcium spike, this action of 1S,3R-ACPD is likely due to an enhancement of calcium influx through voltage-gated calcium channels. However, the $[Ca^{2+}]_i$ change during bursts was reduced by pretreating slice with thapsigargin (5 μM), suggesting at least part of calcium increase is due to release from internal stores. Thapsigargin has no consistant effects on basal calcium level. On the other hand, ryanodine (20-100 μM) did not reduce, but enhanced the ACPD-induced calcium increase associated with bursting. Our data suggested that the rise of $[Ca^{2+}]_i$ associated with ACPD-induced bursting is due to both calcium influx and calcium release from internal stores. (Supported in part by Jeane E. Kempner Scholarship to F.Z.)

TIME COURSE OF EXCITATORY SYNAPTIC TRANSMISSION IN THE NUCLEUS TRACTUS SOLITARIUS FROM RAT

B.U. Keller* and S. Titz, Zentrum Physiologie, Universität Göttingen, Humboldtallee 23, 37073 Göttingen, Germany

Brain stem neurones in the nucleus tractus solitarius (NTS) from rats are well suited for patch clamp analysis of synaptic currents as their passive electrical properties are characterized by a single membrane time constant of 0.2ms and an input resistance above 1GOhm. Glutamate receptor mediated synaptic transmission was investigated in parvocellular NTS neurones by performing patch clamp recordings in thin slices from 10 - 14 day old rats. Stimulation of visceroafferent fibers evoked AMPA receptor mediated EPSCs which were characterized by fast activation times of 0.5 ±0.2 ms (20 - 80 % max. ampl., n = 5) and slow decay time constants of 4.0 ± 0.6 ms (n = 5). Slow decay kinetics were also found for spontaneous and miniture EPSCs investigated in 1 μM TTX. The slowness of decay did not result from dendritic filtering. Also, it did not reflect the deactivation kinetics of the postsynaptic AMPA receptors, which were investigated by rapid (< 0.3 ms) application of glutamate to outside - out patches pulled from the same cells. Comparison with fast EPSC decays in other systems suggests that the slow decay in NTS neurones results from the prolonged presence of glutamate during the synaptic transmission process.

A NOVEL PROTEIN (HAP-1) ENRICHED IN BRAIN INTERACTS WITH THE HUNTINGTON'S DISEASE PROTEIN
X-J. Li[1,2*], S-H. Li[1], A.H. Sharp[1], F. Nucifora[1], G. Schilling[1], S.H. Snyder[2] & C.A. Ross[1,2]. 1. Laboratory of Molecular Neurobiology & Department of Psychiatry 2. Department of Neuroscience Johns Hopkins University School of Medicine Baltimore, MD 21205

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder caused by an expanding glutamine repeat in a gene termed IT 15 or Huntingtin, which has no significant homology to other known genes. The neuropathology of HD is restricted to the brain. However, Huntingtin mRNA and its protein product are widely expressed in brain and in the periphery, with no clear difference in level of expression between patients and controls. Both the genetics of the disorder and the expression of the expanded allele of the protein in HD patients suggest that the mutation induces a toxic gain of function, possibly dependent on interactions of the mutated protein with other cellular proteins. Using the yeast two hybrid system, we have now identified a cDNA encoding a novel protein (Huntingtin Associated Protein or HAP-1) which interacts with the HD protein. In vitro binding assays with GST fusion proteins and immunoprecipitation experiments confirm the interaction and show that the association is enhanced by an expanded polyglutamine repeat in the HD protein. Northern and Western blot analyses demonstrate that the HAP-1 gene product is highly expressed in brain, and thus may be involved in the selective brain pathophysiology of HD.

CELLULAR LOCALISATION OF THE HUNTINGTON'S DISEASE PROTEIN AND DISCRIMINATION OF THE NORMAL AND MUTATED PROTEIN.
Frédéric Saudou[1*], Yvon Trottier[1], Didier Devys[1], Georges Imbert[1], Isabelle An[2], Chantal Weber[1], Yves Agid[2], Etienne C. Hirsch[2] and Jean-Louis Mandel[1]. [1]IGBMC, 67404 Illkirch Cedex, France and [2]INSERM U289, 75651 Paris, France.

Huntington's disease (HD) is a dominant neurodegenerative disorder, characterised by involuntary movements (chorea), personality changes and dementia. It is caused by an expansion of a polyglutamine coding CAG repeat in a gene of unknown function. The wide expression of the transcript does not correlate with the pattern of neuropathology in HD (neuronal death in the striatum). To study the HD gene product (huntingtin), we have developed monoclonal antibodies raised against four regions of the protein. These monoclonals detect specifically huntingtin as a ~350 kDa protein in various human cell lines and in neural and non-neural rodent tissues. In cell lines from HD patients a doublet protein is detected corresponding to the mutated and normal huntingtin, while in post-mortem brains from 3 HD patients the mutated huntingtin was barely detectable suggesting that the abnormal protein may be less stable in brain. Immunohistochemical studies in the human brain using two of these mAbs detect the huntingtin in perikarya of some neurons, in neuropiles, varicosities and as punctate staining likely to be nerve endings. This localisation in nerve endings suggest that huntingtin may play a role in neurotransmission. These monoclonal antibodies are being used to identify proteins that interact with huntingtin and to analyse the relative accumulation of the normal and mutated protein in brain. We have generated neural cell lines that express high amounts of mutated huntingtin, and transgenic mice carrying a mutated HD cDNA (73 repeats) have been obtained.

TARGETED DISRUPTION OF THE MURINE HUNTINGTON'S DISEASE GENE I: EARLY POST-IMPLANTATION EMBRYONIC LETHALITY IN HOMOZYGOTES.
J. Nasir[1,4], V. M. Diewert[2], J. M. Richman[2], J. Zeisler[1,4], M. von Krosigk[3], and Michael R. Hayden[1,4] Depts. of [1]Medical Genetics,[2] Clinical Dental Sciences,[3] Psychiatry and [4]Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, B.C., Canada.

Huntington's Disease (HD) is a devastating adult-onset neurological disease associated with chorea, cognitive deficit, psychiatric disturbances and inexorable progression to death, typically 10 to 15 years after onset. It is associated with expansion of CAG repeats within the coding region of a novel gene, which is widely expressed but causes selective neuronal death. A similar mutational mechanism with expansions of CAG repeats is associated with five other neurodegenerative diseases.. In addition, the question of how these widely expressed genes cause selective neuronal death remains unanswered. To understand the physiological function of the HD gene and its role in development, we have created a targeted disruption in exon 5 of *Hdh* (*Hdh* ^{ex5}), the murine homologue of the HD gene and characterised both homozygotes and heterozygotes (see accompanying poster) for this mutation. No homozygous animals were found among 225 liveborns derived from an intercross between heterozygous animals. However, an analysis of timed matings showed a high frequency (22%) of embryos were being resorbed between day 7.5 and 9.5 of development. The majority of resorbed embryos (80%) were homozygous for the *Hdh* ^{ex5} mutation. These mutant embryos initiate gastrulation and form the three germ layers (ectoderm, endoderm and mesoderm) but there is subsequent failure to neuralate. Consequently, the embryos fail to develop a normal anterior-posterior axis. In addition, they are unable to form somites and do not proceed to organogenesis. Therefore, we propose the HD gene is essential for post-implantation embryonic development.

685.4

TARGETED DISRUPTION OF THE MURINE HUNTINGTON'S DISEASE GENE II: BEHAVIORAL AND NEUROPATHALOGICAL ASSESMENT IN HETEROZYGOTES
S.B.Floresco*[1], J. Nasir[3], J.R. O'Kusky[2], A.G. Phillips[1] and M.R. Hayden[3] Depts.of [1]Psychology, [2]Pathology and Laboratory Medicine and [3]Medical Genetics, Univ. of British Columbia, Vancouver, B.C., V6T 1Z4

In this second series of experiments investigating the function of the *Hdh* gene, we assessed the behavioral and neuropathalogical effects of heterozygous deletion of the *Hdh* gene (*Hdh*^{Ex5}). Seven *Hdh*^{Ex5} heterozygous mice and 7 normal littermates were subjected to a battery of 4 behavioral tasks. Heterozygous mice were (1) hyperactive relative to controls during a standard locomotion test (total photocell counts: heterozygotes=3545 ± 275; wildtype=2272 ± 275, $p<0.01$); (2) showed no difference from controls on performance on either a T-maze task, (which assessed spontaneous alternation behavior), or (3) a radial-arm-maze task (which assessed working memory). On the Morris Water Maze (4), a task used to assess spatial navigation abilities, heterozygous mice showed similar learning to control animals. However, when the location of the hidden platform was switched to another area of the maze, heterozygous mice had longer latencies to find the hidden platform relative to control mice (mean latency/trial; heterozygotes=66.3 ±11s , wildtype= 30.2 ± 11s, $p<0.05$) indicating a lack of behavioral flexibility. Subsequent neuropathological analysis was performed on 2 *Hdh*^{Ex5} mice and 2 controls used in the above experiments. Heterozygous mice showed ≈43% cell loss in the globus pallidus ($p=0.051$) and ≈45% cell loss in the subthalamic nuclei ($p=0.021$) relative to control mice. These data suggest that the *Hdh* gene may play an important role in the normal functioning of the basal ganglia, and that heterozygous mice show some behavioral and morphological abnormalities with similarity to those seen in patients with Huntington's Disease.

685.5

CHARACTERIZATION OF THE DRPLA DISEASE GENE PROTEIN PRODUCT (ATROPHIN-1): COMPARISON WITH HUNTINGTON'S DISEASE GENE PRODUCT (HUNTINGTIN)
A.H. Sharp*, S.H. Li, G. Schilling, J. Bao, T.M. Dawson C.A. Ross. Laboratory of Molecular Neurobiology, Johns Hopkins University, School of Medicine, Baltimore, MD 21205-2196.

Dentatorubral pallidoluysian atrophy (DRPLA or Smith's Disease), like Huntingtons's Disease (HD), is an autosomal dominant neurodegenerative disease. Both diseases are caused by expansion of CAG repeats within the coding regions of their respective genes. Although the genes share no homology to each other or to other genes, the two diseases share many clinical, genetic and pathological features. Both diseases are thought to involve gain of function mutations suggesting effects at the protein level. We are using specific antibodies developed against the protein products of the two genes to compare their cellular and subcellular distributions and biochemical properties. Both proteins have widespread distributions in brain and other tissues. Immunohistochemical experiments show that atrophin-1, like huntingtin, is neuronal with a cytoplasmic distribution. Subcellular fractionation of rat brain tissue indicates that both proteins are present in both soluble and particulate fractions. Both are enriched in a high speed pellet prepared from an osmotically lysed synaptosome fraction (LP2). Sucrose gradient centrifugation of soluble extracts from brain tissue show that both proteins in their native forms migrate with higher apparent molecular weights than expected for monomers, suggesting that both dimerize or form complexes with other proteins.

TOWARD AN UNDERSTANDING OF TARDIVE DYSKINESIA: CHRONIC HALOPERIDOL ENHANCES NMDA TOXICITY IN MOUSE STRIATUM.
L. Turski* and C. Ikonomidou. Research Laboratories of Schering AG, 13342 Berlin and Division of Pediatric Neurology, St. Louis Children's Hospital, St. Louis, MO 63110

Chronic treatment with neuroleptic drugs leads to the development of tardive dyskinesia (TD) in a large proportion of patients. The supersensitivity of dopaminergic receptors explains neither the onset nor the persistence of TD. The nature and the location of mechanisms in the basal ganglia that are responsible for the development of TD and irreversibility of the symptoms remain unresolved issues. In patients subjected to chronic treatment with neuroleptic drugs who develop TD concentration of glutamate is increased in CSF. Therefore we examined whether acute or chronic systemic treatment with haloperidol (1-10 mg/kg, i.p. for 21 d) modulates toxicity of glutamate and N-methyl-D-aspartate (NMDA) in the mouse striatum. Glutamate (1 µmol) and NMDA (1 nmol) were microinjected into the striatum of NMRI mice, 20-25 g, subjected to acute or chronic treatment with haloperidol, and stereologic analysis of the damage was performed 24 h later. In mice subjected to single systemic administration of haloperidol, non-toxic dose of either glutamate or NMDA induced no damage in the striatum, whereas in mice subjected to chronic treatment with haloperidol (5 and 10 mg/kg/d for 21 d) both glutamate and NMDA produced pronounced excitotoxic lesions in the striatum in a dose-dependent manner. These data indicate that long-term treatment with haloperidol increases susceptibility of striatum to excitotoxic action of glutamate and NMDA. Such observations form the base for the hypothesis that chronic treatment with neuroleptic drugs may change the balance between neurotransmitters in the basal ganglia in such a way that even physiological (non-toxic) concentrations of glutamate may become neurotoxic and acting via NMDA receptors lead to neuronal damage in the mouse striatum. The hypothesis of a weak glutamergic toxicity after termination of long-term treatment with neuroleptic drugs offers alternative explanation for the evolution and persistence of the symptoms of TD.

NEUROPROTECTIVE STRATEGIES FOR TREATMENT OF LESIONS PRODUCED BY MITOCHONDRIAL TOXINS: IMPLICATIONS FOR NEURODEGENERATIVE DISEASES. M. F. Beal*, M.T. Matthews, D.R. Henshaw and J.B. Schulz. Neurochemistry Laboratory, Neurology Service, Massachusetts General Hospital, Boston, MA 02114.

Neuronal death in neurodegenerative diseases may involve energy impairment leading to secondary excitotoxicity, and free radical generation. Potential therapies for the treatment of neurodegenerative diseases therefore include glutamate release blockers, excitatory amino acid receptor antagonists, agents to improve mitochondrial function and free radical scavengers. In the present study we examined whether these strategies either alone or in combination had neuroprotective effects against striatal lesions produced by mitochondrial toxins. The glutamate release blockers lamotrigine and BW1003C87 significantly attenuated lesions produced by intrastriatal administration of 1-methyl-4-phenylpyridinium (MPP^+). Lamotrigine significantly attenuated lesions produced by systemic administration of 3-nitropropionic acid (3-NP). Memantine, an N-methyl-D-aspartate (NMDA) antagonist, protected against malonate induced striatal lesions. We previously found that coenzyme Q_{10} and nicotinamide, and the free radical spin trap n-tert-butyl-α-(2-sulfophenyl)-nitrone (S-PBN) dose-dependently protect against lesions produced by intrastriatal injection of malonate. In the present study we found that the combination of either lamotrigine or MK-801 with coenzyme Q_{10} exerted additive neuroprotective effects against malonate. Lastly the combination of nicotinamide with S-PBN was more effective than either agent alone. These results provide further evidence that glutamate release inhibitors and NMDA antagonists can protect against secondary excitotoxic lesions in vivo. Furthermore they show that combinations of agents which act at sequential steps in the neurodegenerative process can produce additive neuroprotective effects.

EXCITOTOXIC DEGENERATION OF MOTOR NEURONS RESEMBLES THAT SEEN IN SOD-1 TRANSGENIC MICE. J.W. Olney*, C. Ikonomidou, G.J. Wang, Y.Q. Qin and M.T. Price; Washington Univ. Med. Sch, St. Louis, MO.

Following the discovery that patients with familial amyotrophic lateral sclerosis have a gene defect at a locus that encodes superoxide dysmutase 1 (SOD-1), several groups have developed SOD1 transgenic mice and have observed that these mice at 5 to 8 wks of age display spontaneous onset of paralysis and motor neuron degeneration, which involves vacuole formation in cell bodies and processes and swelling of the proximal axonal segment. Because other lines of evidence have implicated an excitotoxic mechanism in motor neuron degeneration in ALS, the question arises whether the morphological changes described in the SOD mutant mice are consistent with an excitotoxic process. To address this question, we have undertaken studies aimed at providing an accurate description of excitotoxic degeneration of spinal motor neurons. The excitatory amino acid agonists, DL-homocysteic acid (DL-HCA) or kainic acid (KA), when given systemically to infant rats or when applied directly to the exposed lumbar cord following posterior laminectomy of 21 day old rats, cause excitotoxic degeneration of motor neurons. DL-HCA is a mixed agonist that acts at both NMDA and non-NMDA receptors whereas KA acts only at non-NMDA receptors. The pathological changes in motor neurons following either DL-HCA or KA treatment were studied by both light and electron microscopy and consisted of intracytoplasmic vacuole formation and dark cell changes in which the entire motor neuron, except the vacuoles, gradually became condensed and shrunken. These changes occurred within the first 2 hrs after exposure to the excitotoxin and were accompanied by changes in the proximal axonal segment consisting of swelling of the proximal myelin sheath with accompanying changes in axoplasmic constituents. Degenerative changes in more distal parts of the axons developed over a 12-24 hr period. We conclude that on the basis of purely morphological criteria, the spontaneous degenerative process affecting motor neurons of SOD-1 transgenic mice is consistent in appearance and time course with degeneration induced by exposure to excitotoxin agonists. Supported by AG 11355 and RSA MH 38894 (JWO).

BCL-2 GENE THERAPY IN TRANSGENIC MICE EXPRESSING HUMAN SUPEROXIDE DISMUTASE I WITH A MUTATION LINKED TO FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS. D.R. Borchelt*[1], P.C. Wong[1], C.A. Pardo[1], J. Rothstein[2], N.G. Copeland[3], N.A. Jenkins[3], S.J. Korsmeyer[4], D.W. Cleveland[5], D.L. Price[1,2,6], and D. Merry[7]. Dept. of [1]Pathology, [2]Neurology, and [6]Neuroscience, The Johns Hopkins Univ. School of Medicine, Balt., MD 21205; [3]National Cancer Institute, Frederick, MD; [4]Washington Univ., St. Louis, MO.; [5]Ludwig Inst. for Cancer Research and Dept. of Neuroscience, Univ. of Calif. San Diego, CA 92093; [7]Univ. of Pennsylvania, Philadelphia, PA.

We have generated several lines of transgenic mice expressing human (Hu) superoxide dismutase I (SOD1) with a mutation (glycine 37 to arginine - G37R) that causes familial amyotrophic lateral sclerosis (FALS). These animals develop motor neuron disease; the age of onset, duration, and age at death are strongly dependent upon the dose of the mutant protein. Several investigations have shown that expression of the protooncogene Bcl-2 can protect neural cells from a variety of insults. To determine whether Bcl-2 is protective against the injury caused by mutant SOD1, transgenic mice expressing the G37R mutant were mated to mice expressing human Bcl-2 driven by the human neurofilament-L (NF-L) promoter; HuBcl-2 accumulates to 5-10 times the level of endogenous mouse Bcl-2 in these mice. In the lines of mice expressing the highest level of mutant SOD1 [G37R(42)], little if any delay in the age of onset of disease was observed in the presence of elevated human Bcl-2. We are presently examining additional parameters, including the duration of the disease and the pathological appearance of affected neurons. Whether Bcl-2 will alter the age of onset or duration of disease in animals with a lower dose of mutant SOD1 is also being examined.

A SPECIFIC HUMORAL RESPONSE TO A NOVEL OLIGODENDROCYTE-SPECIFIC PROTEIN IN PATIENTS WITH RELAPSING MULTIPLE SCLEROSIS. Bronstein JM*, Seitz RS, Lallone R, Harrington WT, Rosenblatt J, Ellison GW, Myers LW,. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024, Research Genetics, Birmingham, AL 35209, and U of Miami School of Medine, FL 33101.

We have recently described a novel oligodendrocyte-specific protein (OSP) found only in CNS myelin. To determine if there is a humoral response to OSP in patients with multiple sclerosis (MS), we performed Western blot analysis and enzyme-linked immunoabsorbent assay (ELISA) on CSF samples. Using human brain homogenate and recombinant mouse OSP as antigens, Western blots demonstrated anti-OSP antibodies in 6 of 6 CSF samples of relapsing remitting MS patients. Peptide mapping of the entire protein was performed and 2 peptides were identified that reacted strongly with pooled CSF of MS and control patients. One of these peptides was used for ELISA to determine anti-OSP titers. Twenty-four of 30 (80%) of CSF samples from relapsing remitting MS patients (stable for at least 1 month) had ELISA optical density units of > 0.55 (mean ± SD, 0.74 ±.35). Zero of 8 CSF samples from HTLV-I associated myelopathy (HAM) patients (0.29 ± .17) and 0 of 9 normal controls (0.33 ± .09) had values above 0.55 units. In CSF from chronic progressive MS (CP) patients, 2 of 10 samples had values above 0.55 units (0.39 ±.32). No antibody reaction was observed using several other peptides as antigens. These data demonstrate that anti-OSP antibodies are present in significant titers in CSF of the majority of relapsing MS patients, fewer CP patients, and none of the normal or HAM control samples. Further investigation is necessary to determine the role these antibodies play in the pathogenisis of MS or their usefullness as a diagnostic test.

POTENTIAL INVOLVEMENT OF THE PROTEIN KINASE C PATHWAY IN HIV-1 ASSOCIATED NERVOUS SYSTEM ALTERATIONS. T. Wyss-Coray*, E. Masliah, S. M. Toggas, H. S. Lee and L. Mucke. Dep. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037, and Depts. of Neurosciences and Pathology, UCSD, La Jolla, CA 92093-0624

HIV-1 associated central nervous system (CNS) disease involves neuronal damage and prominent reactive astrocytosis, the latter being characterized by strong upregulation of the glial fibrillary acidic protein (GFAP) in astrocytes. Similar alterations are found in transgenic (tg) mice expressing the HIV-1 envelope protein gp120 in the CNS (Toggas et al., Nature 367:188-193). Because alterations of astrocyte functions could contribute to neuronal impairment we compared brains of gp120 tg mice and gp120-transfected C6 astrocytoma cells with controls, and found that gp120 induced a prominent elevation of steady state GFAP mRNA levels, due primarily to transcript stabilization. Increased levels of GFAP mRNA were also induced in non-transfected C6 cells by exposure to recombinant gp120. Gp120 effects were significantly decreased by inhibitors of protein kinase C (PKC) but not by inhibitors of protein kinase A. PKC activity was upmodulated in gp120 transfected C6 cells and in the CNS of gp120 transgenic mice. Further, brain tissue from patients with HIV-1 encephalitis and from gp120 transgenic mice showed increased PKC immunoreactivity. Taken together, these results indicate that gp120-induced increases in PKC activity may contribute to the gliosis seen in gp120 transgenic mice as well as in HIV-1 infected humans and raise the question of whether dysregulation of signal transduction pathways represents a general mechanism of HIV-associated pathogenesis.

NEURONAL CELL DEATH IN PRION DISEASE

H.A. Kretzschmar*, D.R. Brown, A. Giese, J. Herms
Institut für Neuropathologie der Universität Göttingen, 37075 Göttingen, Germany

Neuronal degeneration and cell death are among the most important features of prion diseases, the mechanisms of which are only poorly understood. Our studies so far have been focused on two questions. First, what mechanisms are involved in neurotoxicity of the prion protein (PrP) or synthetic peptides thereof? Second, is cell death in prion diseases mediated by mechanisms of apoptosis? Neuronal cell death in prion diseases was studied in three experimental systems.

1. DNA fragmentation and morphology of cell death in mice infected with the scrapie strain 79A.
2. The effect of PrP 106-126, a synthetic peptide corresponding to amino acids 106 to 126 of PrP, on cultures of cortical cells from embryonic day 16 mice.
3. The effect of PrP 106-126 on cultures of cortical cells from embryonic day 16 $PrP^{0/0}$ mice (PrP knock-out mice).

Cell death in the 79A scrapie strain in C57 mice was studied using in situ end labeling (ISEL), and light and electron microscopy. Our results show that apoptosis occurs in an experimental scrapie system in vivo. In this system apoptosis is observed particularly in the outer nuclear layer of the retina and the granule cell layer of the cerebellum. In cell culture experiments we showed that PrP 106-126 is toxic to cortical cells from embryonic day 16 mice. PrP 106-126 has no neurotoxic effect on cortical cells from knock-out mice. This is the first difference between neurons from normal and from knock-out mice observed by us, since using patch-clamp analysis we were unable to confirm differences in the synaptic transmission beween normal and knock-out neurons in the cerebellum. In addition, our results show that the neurotoxicity of PrP 106-126 can be blocked with MK801 and verapamil indicating that it is mediated by intracellular Ca^{++} increase.

SENSORY TRANSDUCTION IN THE VOMERONASAL ORGAN: IONIC CURRENTS OF DISSOCIATED MOUSE RECEPTOR NEURONS. E. R. Liman and D. P. Corey*. Howard Hughes Medical Institute and Massachusetts General Hospital, Boston MA, 02114.

We are investigating the mechanism of sensory transduction in the vomeronasal organ (VNO). The VNO is located at the base of the rostral portion of the nasal cavity and contains chemosensory neurons that are thought to respond to pheromones. While signaling pathways have been elucidated for olfactory transduction, they have not been for the VNO. There are several reasons to believe that transduction may be different in the two systems. For example, cilia- the site of transduction in olfactory neurons- are not present on VNO neurons; VNO neurons instead bear microvilli.

We have developed a protocol for preparing dissociated mouse VNO neurons that yields high numbers of relatively intact cells. The diameter of the VNO neuron cell body is 11.2 ± 0.4 μm (n=12), which is considerably larger than that of olfactory neurons (5-8 μm). A dendritic process is evident that ranges in length from a 2 to more than 30 μm and ends in a tuft of microvilli.

As a first step towards understanding transduction, we are using whole cell patch clamp recording to characterize voltage-activated conductances. In experiments with Cs^+ in the pipette, inward Na^+ currents were first evident with voltage steps to -50 mV and reached a peak at ~ +10 mV. The currents were half inactivated by a prepulse to -67 ± 3 mV (n=5), similar to rat olfactory Na^+ currents. TTX, at a concentration of 300 nM, blocked 54 ± 9 % (n=5) of the current. We have also recorded K^+ and Ca^{++} currents and are in the process of characterizing them.

We have begun to investigate whether VNO neurons express cyclic-nucleotide-gated channels. We have found no positive evidence for the presence of cyclic nucleotide gated channels either by excised patch recording or intracellular dialysis with cyclic nucleotides and are in the process of confirming these results.

GLUCOCORTICOID (TYPE II) RECEPTORS IN THE MAMMALIAN OLFACTORY MUCOSA: RU 28362 BINDING SITES. R.C. Kern[1], J.D. Foster[2] and D.Z. Pitovski[1]* [1]Dept. of Otolaryngology - Head and Neck Surgery, Northwestern University, Chicago, IL 60201, [2]Dept. of Anatomy and Cell Biology, Meharry Medical College, Nashville, TN 37208.

The synthetic corticosteroids are the most frequently prescribed medications for olfactory disorders despite the fact that their mechanism of action within the olfactory system is unknown. Recently, a series of studies was initiated to gain insight into the mechanism of coticosteroid action on the olfactory mucosa. In this current study, we have focused on the binding characteristics of the glucocorticoid (type II) receptor.

The synthetic glucocorticoid ^{3}H-RU 28362, which has negligible binding to mineralocorticoid (type I) receptors (Philibert et al., *Annu. Meet. Endocrine Soc. 65th, 1983, p 335*), was employed to identify high-affinity glucocorticoid (type II) receptors in the olfactory mucosa. By Scatchard plot analysis, the K_d of the [^{3}H]-RU 28362-cytoplasmic receptor complex was 2.2 x 10^{-9} M, while the concentration of binding sites, B_{max}, was 180 fmol/mg dry tissue. Time course studies indicated that the binding of [^{3}H]-RU 28362 by the olfactory tissues reached equilibrium within 30 min of incubation at 25°C.

Substantial specific [^{3}H]-RU 28362 binding to the olfactory tissues suggests the presence of glucocorticoid receptors and sites of glucocorticoid action in the olfactory mucosa.

IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUCOCORTICOID (TYPE II) RECEPTOR IN THE MAMMALIAN OLFACTORY MUCOSA. J.D. Foster[1]*, R.C. Kern[2], and D.Z. Pitovski[2]. [1]Dept. of Anatomy and Cell Biology, Meharry Medical College, Nashville, TN 37208, [2]Dept. of Otolaryngology - Head and Neck Surgery, Northwestern University Medical School, Chicago, IL 60201.

Immunohistochemical localization of glucocorticoid (type II) receptor in the mammalian olfactory mucosa was examined by utilization of an affinity-purified antibody raised against a glucocorticoid receptor protein. Immunoreactivity was associated with the acinar cells of Bowman's glands located in the lamina propria. In addition, the olfactory nerve axons were also immunoreactive. Within the olfactory epithelium, immunoreactivity for this receptor was also observed, which by location corresponds to sustentacular cells and/or olfactory receptor cells. There was no immunocytochemical staining when the antibody for the glucocorticoid receptor was omitted from the primary incubation medium.

The differential distribution of glucocorticoid receptors in the olfactory mucosa resembles the pattern of localization of mineralocorticoid (type I) receptors (Foster et al., *Assoc. Res. Otolaryngol. Abstr.* 17:33, 1994; Foster et al., *Soc. Neurosci. Abstr.*, 20: 1473, 1994; Kern et al., *Assoc. Res. Otolaryngol. Abstr.* 18:649, 1994) and Na, K-ATPase (Kern et al., *Brain Res.*, 546:8-17, 1991; Foster et al., *Assoc. Res. Otolaryngol. Abstr.* 17:33, 1995) observed in previous studies. The distinctive cell localization of the glucocorticoid receptor in the olfactory mucosa suggests a role of glucocorticoid hormones in regulating the function of these cells.

MODULES FOR MOLECULES? TOPOGRAPHICAL ORGANIZATION OF THE ZEBRAFISH OLFACTORY SYSTEM.
F. Weth, H. Baier and S. Korsching*. Max Planck Institute for Developmental Biology, D-72076 Tübingen, Germany.

We are investigating the principles governing the primary representation of odor information in the olfactory epithelium and the olfactory bulb. To this end, we are analyzing the primary olfactory system of the zebrafish, *Danio rerio*, by a combination of axonal tracing and *in situ* hybridization.

We injected one identified glomerulus with DiI to trace back olfactory neurons connected to it. The labeled neurons are widely scattered over the sensory surface without apparent topographical order. However, the relative positions of the retrogradely labeled neurons are not completely random, as judged from measuring nearest-neighbor distances. Rather, spacing is observed: Olfactory neurons projecting to the same target site keep a minimum distance of roughly ten cell diameters from each other. As the spacing is unique to neurons terminating in the same glomerulus, it should be useful as an indicator of common projection.

Cloned odorant receptor molecules of the zebrafish belong to a gene family of less than 50 members and are homologous to their mammalian counterparts. As revealed by *in situ* hybridization, individual receptors are expressed by a small subset of sensory neurons, which are widely scattered over the olfactory epithelium. We are currently analyzing the nearest-neighbor distances of cells expressing monoallelic single copy receptor genes. If their distribution confirms the spacing rule obtained from retrograde tracing, this would indicate a common projection. In a more direct approach, we attempt to double-label olfactory neurons by retrograde labeling and *in situ* hybridization.

ACTIONS OF CARBON MONOXIDE AND CYCLIC GMP ON ODOR RESPONSES OF ISOLATED OLFACTORY RECEPTOR CELLS. F. Zufall*, G. M. Shepherd and T. Leinders-Zufall. Section of Neurobiology, Yale University School of Medicine, New Haven, CT.

There is increasing evidence supporting the function of carbon monoxide (CO) as a diffusible messenger in the vertebrate olfactory system. CO can act as a potent activator of olfactory cyclic nucleotide-gated (CNG) channels by stimulating cGMP formation in olfactory receptor neurons (ORNs) and this effect provides a sensitive mechanism for regulating excitable properties of ORNs (Leinders-Zufall et al., this meeting). Here we have examined the interaction of the CO-induced cGMP pathway with the odor-stimulated G-protein coupled cAMP pathway and tested whether this CO/cGMP system can influence the responsiveness of ORNs to odor stimulation. Odor responses from single salamander ORNs were obtained using the perforated patch technique. This permitted recording of both odor-induced membrane currents and membrane potentials so that sensory generator currents at the input level of the cell could be related to action potential discharges at the output level of the cells. ORNs that were voltage clamped to their resting potential responded with transient inward currents to short pulses of odor stimuli. In contrast micromolar doses of CO induced long-lasting tonic inward currents. Recovery from this CO effect was on the time scale of minutes. When odor-induced transient currents were tested during the long-lasting CO-induced currents, the odor responses were markedly diminished. This effect could be mimicked by low doses of 8-br-cGMP. Under current clamp conditions odor pulses induced depolarizing receptor potentials leading to transient action potential discharges. Micromolar doses of CO induced long-lasting depolarizations that modulated the spike discharge pattern induced by odor pulses resulting in most cases in a reduction of the firing rate. Our results indicate that the presence of CO leads to several discrete changes in the signaling properties of ORNs which, taken together, strongly influence odor responsiveness of the cells. Supported by grants from NIDCD (F.Z.) and from NIDCD and NIMH, NASA and NIDCD (Human Brain Project) (G.M.S.).

686.6

LOCALIZATION OF GLYCINE RECEPTORS AND GEPHYRIN IN THE RAT OLFACTORY BULB.
M. Sassoè-Pognetto*[1], M. Giustetto[1], J. Kirsch[2], and D. Cantino[1]. [1]Dept. of Human Anatomy and Physiology, Univ. of Turin, I-10126 Turin, Italy; [2]Max-Planck-Institute for Brain Research, D-60528 Frankfurt a.M., Germany.

The localization of glycine receptors (GlyRs) and the GlyR-associated protein gephyrin was investigated in the rat olfactory bulb (OB), using immunocytochemistry. The monoclonal antibody (mAb) 4a, which can recognize all of the known GlyR subunits (α1-3 , ß), produced a diffuse staining in mitral and tufted cells, as well as a punctate staining in the glomeruli. According to previous *in situ* hybridization data (Malosio *et al.*, EMBO J., 1991), we assume that this staining reflects the presence of the ß subunit of the GlyR. Surprisingly, electron microscopy showed that some of the presumed glutamatergic synapses made by olfactory nerve terminals onto the dendrites of mitral/tufted cells were immunopositive.

mAb 2b, which is specific for the strychnine-sensitive α1 subunit, produced no immunoreactivity in the OBs of adult and young (P3, P10) rats. Therefore, we conclude that the α1 subunit is not expressed in the OB.

mAb 7a, which is specific for gephyrin, produced a strong punctate labelling in the external plexiform layer and in the glomeruli. Immunoreactive puncta outlined the cell bodies and main dendrites of mitral and tufted cells. Electron microscopy showed that gephyrin is present in the synapses made by local interneurons (periglomerular and granule cells) with the dendrites of mitral/tufted cells. Since many periglomerular and granule cells use GABA as a neurotransmitter, it is likely that in the OB, as in the retina (Sassoè-Pognetto *et al.*, J. Comp. Neurol., 1995), gephyrin might be localized to GABAergic synapses.

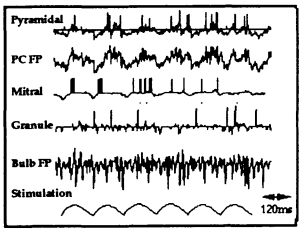
INTERACTIONS BETWEEN OLFACTORY BULB AND OLFACTORY CORTEX IN A NEURAL MODEL OF ODOR PROCESSING. Christiane Linster*(1), Michael E. Hasselmo(1) and Remi Gervais(2) (1) Dept. Psych., Harvard Univ., Cambridge MA 02138 (2) Lab. de Physiologie Neurosensorielle, CNRS, 69622 Villeurbanne.

Cholinergic modulation has been shown to have effects at various levels of the mammalian olfactory system. Behavioral studies have shown that cholinergic modulation is involved in olfactory short term memory in the olfactory bulb, as well as in olfactory learning in higher structures. Physiological experiments show the effect of cholinergic modulation on synaptic transmission in the olfactory bulb (OB) (Elaagouby et al., Neurosci., 56, 1991) and in the piriform cortex (PC) (Hasselmo , Brain. Res. 67, 1995). We have currently implemented biophysical simulations of the OB (Linster and Gervais, submitted) and the PC, both exhibiting realistic population dynamics (rapid field potential (FP) oscillations around 50-60 Hz in the OB as well as slow (3-8 Hz) and rapid (50-60 Hz) FP oscillations in the PC) and realistic single neuron responses (spontaneously and in response to olfactory input) (see Figure).

These models now allow us to investigate (i) the dynamic interactions between OB output neurons and the feedback of PC onto OB interneurons, (ii) synchronization of mitral cell spike trains synapsing on common pyramidal cells, (iii) effects of neuromodulator in both layers and (iv) synaptic changes related to odor processing.



686.8

FLAVOR AND THE FRONTAL CORTEX. R. Schul[1], Y. Dudai[1], and B.M. Slotnick*[2] [1]Dept. of Neurobiology, The Weizmann Institute of Science, Rehovot, Israel, [2]Dept. of Psychology, The American University, Washington, D.C., USA.

Several lines of evidence indicate that orbitofrontal or insular cortex may be involved in the integration of odor and taste, the intraoral combination of which produces the perception of flavor. To assess this, rats were first trained using operant conditioning to respond at a high rate when they received a solution of NaCl and amyl acetate and to inhibit responding when only the odor or only the taste component was delivered. Concentrations of the stimuli were varied so that intensity could not be used as a discriminative cue. The maximum concentration of amyl acetate was below gustatory threshold as determined in tests with normal and olfactory bulbectomized rats. After training, experimental rats (n=4) received a unilateral olfactory bulbectomy, transection of the anterior limb of the anterior commissure and removal of the contralateral frontal cortex. Thus, these rats had no olfactory input to one hemisphere and no gustatory input to cortex in the contralateral hemisphere. Control rats received no surgery (n=5) or had all lesions in the same hemisphere (n=5). All controls showed good retention or rapid reacquisition of the flavor discrimination task and differences between operated and non-operated controls were not significant. In contrast, experimental rats had no retention of the task and showed no or only modest improvement in performance even after extensive retraining. In additional tests, all rats were able to discriminate the odor and taste component stimuli from water. These data suggest that there is a convergence of gustatory and olfactory input to frontal cortex which is essential for the integration of taste and smell. TASTE NEURONS IN INSULAR-OPERCULAR CORTEX OF THE ALERT CYNOMOLGUS MONKEY. Thomas R. Scott* and C.R. Plata-Salamán. Departments of Psychology and Biology and Program in Neuroscience, University of Delaware, Newark, DE 19716.

Primary gustatory cortex in the macaque is located in frontal operculum (FO) and adjoining anterior insula (AI). Here we report on the characteristics of taste-responsive neurons in this area. Taste cells constituted 5% of the neurons whose response properties were investigated. They occupied an area extending 4 mm posteriorly from the junction of orbitofrontal cortex with the FO, 3 mm mediolaterally, and 7 mm in the dorsoventral plane. Most action potentials were only 200-500 μV. The mean spontaneous rate was 3.9 ± 4.9 spikes/sec. There was no indication of chemotopic organization in the gustatory cortex. Of 364 taste-responsive neurons, glucose was the most effective of the basic stimuli for 39% (n=142), NaCl for 29% (n=107), quinine for 20% (n=74) and HCl for 13% (n=49). Neurons most responsive to glucose and NaCl were more narrowly tuned ($p < 0.01$) than those sensitive to quinine and HCl. Across all stimuli, the ratio of excitatory to inhibitory responses was about 10:1. The mean response across all cells rose monotonically with increasing stimulus intensity, but the slopes of intensity-response functions were lower than those from human psychophysical studies. When slopes were calculated exclusively from the responses of cells in the appropriate subgroup, however, they matched intensity-response functions from humans. Thus, perception of the four basic taste stimuli is probably carried by the subgroup of neurons most sensitive to a particular quality, rather than by the responses of all cells. An analysis of patterns of activity evoked by a wide range of stimuli indicated that taste quality coding in the macaque is quite similar to that in human.

TESTOSTERONE DIFFERENTIALLY REGULATES PHEROMONE INDUCED FOS EXPRESSION IN LIMBIC REGIONS OF MALE AND FEMALE SYRIAN HAMSTERS. J.M. Fiber* and J.M. Swann. Institute of Animal Behavior and Dept. of Biological Sciences, Rutgers University, Newark, NJ 07102.

Exposure to female hamster vaginal secretions (FHVS) specifically induces Fos expression in the posteromedial subdivision of the bed nucleus of the stria terminalis (BNSTpm), the posterior subdivision of the medial nucleus of the amygdala (MeP), and the magnocellular subdivision of the medial preoptic nucleus (MPNmag) of male hamsters. We have also previously reported a sex difference Fos expression in these regions after FHVS exposure. In the present study we sought to determine the role of testosterone in regulating pheromone induced Fos expression in both males and females.

Adult male and female hamsters were gonadectomized and treated with a 20mm testosterone capsule (TC) or with an empty capsule (EC). Twelve weeks later, animals were exposed to FHVS or given no stimulus (controls). Brain tissue was processed for Fos immunocytochemistry.

Our results indicate a sex difference in testosterone regulation of pheromone stimulated Fos expression in the BNSTpm, MeP, and MPNmag. Males +TC (n = 5) show a greater number of Fos immunoreactive cells (IR) within the MPNmag than females +TC (n = 5) or females + EC (n= 4); males + EC (n = 5); and all control groups (n = 3 for each group) ($p > .01$). Both the BNSTpm and MeP show FHVS induced Fos expression in males + TC and + EC above that of controls and FHVS exposed females + EC ($p < .01$). In FHVS exposed females + EC, the BNSTpm and the MeP are not stimulated to express Fos above controls, however testosterone acts in females to reverse this effect ($p < .01$). Thus, circulating testosterone influences pheromone stimulated Fos in the BNSTpm and MeP of females, and in the MPNmag of males. These differences in pheromone stimulated Fos IR implicate these brain regions in subserving testosterone regulated behavioral sex differences in response to exposure to FHVS.

FORMATION AND SPECIFICITY OF SYNAPSES I

687.1

MORPHOGENESIS OF AN IDENTIFIED MOTONEURON IN RESPONSE TO TARGET MANIPULATION. J.J. Fernandes and H. Keshishian*. Biology Dept., Yale University, New Haven, CT 06520.

We are examining nerve-muscle interactions during the development of the six adult Dorsal Longitudinal flight Muscles (DLMs) of *Drosophila*. The fibers develop during metamorphosis from three persistent larval muscles, and are innervated by 5 motoneurons. The two most dorsal fibers (DLMs e and f) are innervated by a single motoneuron, MN5. Using intracellular Lucifer yellow dye fills, we examined the target-dependence of MN5's development during metamorphosis (from 18-36h APF; after puparium formation). The peripheral synaptic arbor is confined to muscle fibers e and f throughout the stages examined, and corresponds to the entire component previously characterized by anti-HRP. In the CNS, the dendritic arbor arises about 10-12 hrs after the differentiation of the peripheral motor endings, indicating that they do not develop in synchrony. Dendrites appear at 26h APF, at a time when the peripheral arborization on the muscle fibers is well elaborated. We next examined the effects of muscle fiber deprivation/alteration on MN5. Following laser ablation of the larval template for DLMs e and f, adult fibers develop de novo, although in a delayed fashion. Innervation to these fibers is corresponding delayed (Fernandes et al, Soc. Neurosci. Abst. '94). In the CNS we did not observe any effect on the dendritic arbors during stages 26-30h APF. We are further examining CNS arbor development at earlier stages to determine whether this neuronal compartment is altered in response to peripheral delays. Target deprivations lead to ectopic motor endings made onto the remaining fibers, as observed using anti-HRP. Our dye fills show that MN5 can be the source of these ectopic synapses. These results show that timing of MN5 motor ending development is closely tied to the developmental state of the innervated muscle fibers, and that this compartment of the neuron develops under local cues.

The *Drosophila* mutation *Passover* alters gap junction function in the Giant Fiber pathway Yi-an Sun* and R. J. Wyman. Department of Biology, Yale University, New Haven, CT 06511

Mutations of the *Drosophila* gene *Passover* and of a *C. elegans* homolog, *unc-7*, alter specific electrical synapses in their respective organisms. The proteins made by these genes (Cell 73:967-977; Genetics 133:527-541), and several other sequence similar genes, may have a structure similar to the gap junction structural molecule, connexin (Trends in Genetics 10:303).

In *Drosophila*, an electrical synapse connects the Giant Fiber (GF) and the tergotrochanteral motoneuron (TTMn) (J. Neurophys. 44:405; J. Neurocytol. 9:753). In flies mutant or the *Passover* gene, the synapse is abnormal. In this report, we show that the Giant Fiber also makes electrical synapses with a commissural tract in the brain. In *Pas* flies, the synapses connecting the Giant Fiber to the TTMn and the commissure are either absent or malfunctional.

We injected cobalt and HRP into the TTM muscle and into the mesothorax. The giant fibers ascend to the brain from the cervical connective and then fan out in a dorsolateral trajectory. In wild type, but not in *Pas*, cobalt passes from the fingers of the GF's fan through gap junctions into several fibers of a commissure just dorsal to the esophagus. The commissure fibers connect the two GFs to each other. HRP, which does not pass gap junctions, does not pass into the commissure fibers. Cobalt also passes from the TTMn to the GF in wild-type, but not in *Pas*. We conclude that the gap junctions in these two electric synapse are malfunctional in *Pas*. Supported by NIH NS-07314; NSF IBN-9213387.

687.3

ROLE OF MOTOR NEURON GAP JUNCTIONAL COUPLING IN NEUROMUSCULAR SYNAPSE ELIMINATION. R.J. Balice-Gordon*, J. Pines and S. Blumenthal. Dept. Biology, Univ. of Penn., Phila., PA 19104-6018.

During development and adult reinnervation, transient multiple innervation of neuromuscular junctions is followed by a period of synapse elimination which continues until single innervation is established. We are interested in understanding the modulation of this process by activity. Synchronous activity among the different inputs to a neuromuscular junction, perhaps mediated by transient electrical coupling among motor neurons, may be important for the establishment and transient maintenance of multiple innervation, while asynchronous activity among synapses may lead to synapse elimination. To begin to evaluate this hypothesis, we used immunohistochemistry to show that before and at birth, ca. 80% of the motor neurons in the mouse lumbar spinal cord express the gap junction protein cx32 (antibody provided by Dr. D. Paul.). Intracellular recording has shown that motor neurons are electrotonically coupled during this time (c.f. Fulton & Walton, 1986). The percentage of motor neurons expressing cx32 declined after birth until by P14, as in adults, few if any positive motor neurons were detected. Similar results were obtained from the sternomastoid motor pool. Given that multiple innervation is transiently recapitulated during adult reinnervation, we used cx32 immunohistochemistry to determine whether gap junction proteins are re-expressed in adult motor neurons following double nerve crush. One week after crush, when multiple innervation is widespread, ca. 70% of motor neurons ipsilateral to the crush stained positively. Two weeks after crush, when synapse elimination is underway, 50% of motor neurons were positive; four weeks after crush, when single innervation is re-established, less than 10% of motor neurons were positive. In both development and adult reinnervation, cx32 expression in motor neurons was the most widespread during the time multiple innervation is present, and both disappeared with a similar time course. We are using physiological methods to characterize the extent of electrotonic coupling and the synchrony of activity among motor neurons during development and reinnervation.

***IN VIVO* EXAMINATION OF ACETYLCHOLINE RECEPTOR TURNOVER IN DENERVATED NEUROMUSCULAR JUNCTIONS USING CALIBRATED FLUORESCENCE IMAGING.** S.M.Culican*, S.G.Turney, and J.W.Lichtman. Department of Anatomy and Neurobiology, Washington University School of Medicine, St.Louis, MO 63110.

Using a quantitative imaging technique to follow changes in the absolute intensity of a fluorescence signal, we have studied the turnover of acetylcholine receptors (AChRs) labelled with rhodamine conjugated alpha-bungarotoxin (R-BTX, an irreversible ligand) in neuromuscular junctions of living mice. This technique allowed measurement of the intensity of fluorescence in a defined junctional region, permitting assessment of changes in AChR density that were independent of changes in junctional size. With this method we have found that at sites within innervated junctions the half-life of AChRs is approximately 8 days, whereas at sites within denervated junctions the half-life of AChRs is approximately 2-3 days.

AChRs at denervated junctions are a mixed population: some receptors are the remanent of those present in the membrane before the denervation, while others have been inserted after denervation. Several studies have suggested that these two populations respond differently to denervation. To follow AChRs that were in the membrane before denervation, we labelled them with R-BTX just before nerve cut. Conversely, to examine new receptors, we pre-labelled denervated junctions with unlabelled BTX three days after denervation, blocking all the receptors that were present in the membrane prior to denervation. The newly inserted AChRs were labelled with R-BTX 7 days after denervation. For both populations, intensity measurements at individual junctional sites were begun ten days after denervation. At subsequent timepoints the junctional sites were relocated and re-imaged. Changes in the absolute intensity of the rhodamine label between views was determined at each site. Our results suggest that both populations of AChRs are lost from the membrane at the same rate ($t_{1/2}$ approx. = 2-3 days).

NEURONAL AGRIN INDUCES LATE AS WELL AS EARLY EVENTS IN POSTSYNAPTIC APPARATUS FORMATION IN DENERVATED MAMMALIAN SKELETAL MUSCLES. I. Cohen, M. Rimer, T. Lomo, C.R. Slater and U.J. McMahan*. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Evidence derived mainly from in vitro experiments has led to the hypothesis that agrin released from motor axon terminals directs the initial events of postsynaptic apparatus formation at developing neuromuscular junctions by inducing myotubes to make local aggregates of AChRs and AChE and certain other proteins. Determining by in vitro studies whether agrin induces later events such as the formation of junctional folds and the accumulation of myonuclei is made difficult by the low survival rate and uncertain behavior of myotubes maintained for prolonged periods in culture medium. An in vivo preparation that may permit a detailed analysis of neuronal agrin's role in all aspects of postsynaptic apparatus formation is the denervated adult rat soleus muscle, in which myofibers are competent to form postsynaptic apparatus throughout much of their length. We injected cDNA coding for neuronal agrin into the extrajunctional re-gions of such muscles. The cDNA included a region encoding signal sequence to direct the protein into the myofibers' secretory pathway. By 7d, muscle fibers expressing n-agrin and those adjacent to them had on their surface colocalized aggregates of AChR, AChE and several other postsynaptic proteins as detected by immunofluorescence microscopy. By 6wks the AChR/AChE aggregates induced by n-agrin were accompanied by a preferential localization of myonuclei and the presence of infoldings of the plasma membrane similar in size and shape to junctional folds, as determined by electron microscopy. These results make it likely that the interaction of axon-released n-agrin with agrin receptors on myotubes at the developing neuromuscular junction induces at least some late as well as early events in postsynaptic apparatus formation. Further experiments with transfected soleus muscles may provide insights as to whether n-agrin plays a role in the induction of other late events such as changes in the gene regulation of AChR subunits.

687.6

CLUSTER-INDUCING ACTIVITY OF LAMININ VERSUS AGRIN. M.W. Cohen*. Dept. of Physiology, McGill Univ., Montreal, Quebec. H3G 1Y6.

Since laminin and agrin compete for binding to muscle α-dystroglycan (Cell 77:675-686, 1994) the question arises whether laminin affects the distribution of surface molecules in the same way as agrin. When embryonic Xenopus myocytes were cultured without agrin or laminin, clusters of acetylcholine receptors (AChRs) had colocalized laminin-binding sites (LBS) and phosphotyrosine (PY). The myocytes also exhibited a widespread distribution of microclusters of LBS which did not contain any detectable AChR or PY stain. When agrin (a gift from E.W. Godfrey and R.M. Nitkin) was included in the culture medium there was a large increase in the incidence of clusters containing AChRs, LBS and PY, and not much decline in the density of LBS microclusters. By contrast, laminin caused a large decline in the density of the widespread LBS microclusters and a concommitant increase in the incidence of larger clusters of LBS. AChRs and PY were rarely detected at these laminin-induced clusters of LBS. The results suggest that (1) laminin has cluster-inducing activity which is different from that of agrin, (2) the clustering of LBS, unlike the clustering of AChRs, does not require tyrosine phosphorylated proteins, and (3) unclustered LBS on the cell surface are mobile, as previously suggested for unclustered α-dystroglycan (J. Cell Biol. 129: 1093-1101, 1995). (Supported by MRC of Canada)

CRANIN, A LAMININ BINDING MEMBRANE PROTEIN: IDENTITY WITH DYSTROGLYCAN AND REASSESSMENT OF ITS CARBOHYDRATE MOIETIES. N. R. Smalheiser* and E. Kim. Dept. of Pediatrics, University of Chicago, Chicago, IL 60637.

Cranin was described in 1987 as a membrane glycoprotein expressed in brain and many other tissues, which binds laminin with high affinity in a calcium-dependent manner. Dystrophin-associated glycoprotein ('dystroglycan') is a laminin-binding protein cloned in 1992 whose relation to cranin has remained uncertain. Using cranin purified to homogeneity from sheep brain, we now show that cranin is a form of dystroglycan, based on amino acid sequencing of 120 kDa and 43 kDa bands, and on immunological cross-reactivity with antibodies raised against synthetic peptides derived from dystroglycan sequences. These data also localize the N-terminus of ß-dystroglycan to amino acid residue 654. We find that brain alpha-dystroglycan is tightly associated with membranes, and localizes to regions of CNS synaptic contact as assessed by immunocytochemistry of rat cerebellum. Brain alpha-dystroglycan expresses high mannose/hybrid N-linked saccharides, terminal GalNAc residues, and the HNK-1 epitope. Though dystroglycan has been presumed to be a proteoglycan, the amino acid sequence, pI, O-sialoglycoprotease susceptibility, lectin-binding and laminin-binding properties of brain dystroglycan are more typical of mucin-like proteins. Furthermore, using CHO cell lines deficient in xylosyltransferase and galactosyltransferase I, which are required for glycosaminoglycan biosynthesis, it is shown that chondroitin sulfate and heparan sulfate are not critical for laminin binding, and indeed are apparently not expressed in dystroglycan from CHO cells. Supported by NIH HD 09402, NS 26055 and the Brain Research Foundation, Inc.

687.8

IDENTIFICATION AND LOCALIZATION OF ARIA RECEPTORS IN SKELETAL MUSCLE AND MUSCLE CELL LINES G. Corfas*, T.S. Khurana, C. Lai* and G.D. Fischbach. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115 and *The Scripps Institute, La Jolla, CA 92037.

ARIA is a protein that promotes the synthesis of acetylcholine receptors in muscle, and thus may play a role in the formation and maturation of the neuromuscular junction. ARIA is a member of a family of factors that are ligands for members of the EGF receptor (EGFR) family, i.e. HER2, HER3 and HER4. In order to determine which of these receptors are involved in ARIA's action on skeletal muscle we studied the expression and localization of these proteins on skeletal muscle, and their ARIA-induced tyrosine phosphorylation on L6 cells.

We have found that in lysates of ARIA-treated L6 cells, antibodies directed against all these receptors are capable of precipitating a portion of the p185 signal. An antibody raised against a peptide shared by all the members of the EGFR family precipitated all the p185 signal, which appears as a doublet. Anti-HER2 antibodies precipitated mostly the lower band of p185, while anti-HER3 antibodies precipitated mostly the higher band. Anti-HER4 antibodies precipitated a much smaller portion of the tyrosine phosphorylated protein than antibodies directed against the other receptors. In all cases, the only tyrosine phosphorylated protein recognized by these antibodies was p185. We have studied the expression of these receptors in skeletal muscle using immunocytochemistry with anti-receptors antibodies. HER2 and HER4 immunoreactivity appears to be concentrated at neuromuscular junctions. HER3 antibodies gave inconclusive results.

These results suggest that HER2, HER3 and HER4 may participate in the signalling of ARIA on muscle cells, and that at least some of these receptors may be concentrated at mature neuromuscular junctions.

NEUROTROPHIC REGULATION OF ARIA EXPRESSION.

J. A. Loeb and G. D. Fischbach.* Harvard Medical School, Dept. of Neurobiology, Boston, MA 02115

ARIA, or acetylcholine receptor-inducing activity, initiates a cascade of events leading to the expression of postsynaptic components of the neuromuscular synapse. These include increasing the expression of AChRs and sodium channels. We now have evidence suggesting that neurotrophins from the postsynaptic muscle cell augment the expression of ARIA in the presynaptic neuron. Using embryonic rat ventral horn cultures containing motor neurons expressing ARIA, we have found that the muscle-derived neurotrophins NT-3 and BDNF increase the amount of ARIA mRNA by up to 3-fold. This effect peaks at 4 hours of treatment at a half maximal concentration of 10-100 pM. Under identical conditions there is no change in messages for the low affinity receptor for NGF, or other presynaptic proteins. Furthermore, NGF, LIF, CNTF, or ARIA do not alter ARIA mRNA expression in these cultures. BDNF and NT-3 also increase the amount of ARIA protein activity secreted into the media of these cultures. We have found no evidence for a reciprocal effect in that ARIA does not affect BDNF or NT-3 expression in embryonic cultured rat myotubes. Even though these cultures respond to ARIA by inducing the phosphorylation of an 185 KDa phosphoprotein, the levels of BDNF and NT-3 mRNA are constant after treatment for up to 48 hours with ARIA. Such interactions between the neurotrophins and ARIA could serve to reinforce specific developmental programs at synaptic contact sites.

EXCITATORY SYNAPSE FORMATION IN CULTURED SPINAL NEURONS. R.J. OBrien*, and R.L. Huganir. Dept. of Neuroscience and Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205

While much is known about the mechanism of synapse formation at the neuromuscular junction, little is known about the mechanisms involved in the formation of excitatory central synapses. We have elected to use cultured rat spinal cord neurons to investigate how AMPA type receptor subunits are regulated during synapse formation. Neurons from E17 rat spinal cords grown at low density on glial feeder layers, form excitatory synapses within 4 days. Using subunit specific antisera, these synapses are seen to be composed of the AMPA receptor subunits GluR1, GluR2/3, and GluR4 contained within a cluster on the postsynaptic dendrite. Receptor clusters develop only when juxtaposed to a presynaptic release site (determined by synaptophysin staining) and do not develop spontaneously. The concordance between excitatory presynaptic release sites and postsynaptic clusters is nearly 100% both in heterogeneous cultures and in neurons grown in isolated islands. Inhibitory interneurons cause no clustering of AMPA type receptors. Activation of NMDA or AMPA type receptors does not appear to be required for this clustering, and clustering cannot be induced by isoforms of AGRIN active at the neuromuscular junction. We are presently involved in correlating electrophysiologically defined "hot spots" with these postsynaptic clusters.

SYNAPTOGENESIS BY CELLS DERIVED FROM THE HUMAN NT2 CELL LINE. Cha-Min Tang*[1], Michael Margulis[1], Rebecca Hartley[2], and Virginia M.-Y. Lee[2]. Dept. of Neurology, U. of Maryland[1] and Dept. of Pathology, U. of Pennsylvania[2].

NT2 cells are believed to be immortalized equivalent of neural progenitor cells in the developing human nervous system. Treatment with retinoic acid can induce NT2 cells to commit to terminal differentiation into neurons (NT2N). While NT2N cells under current in vitro culture conditions can express a sequence of neuronal markers that recapitulates the maturational steps in the developing nervous system, they do not express some late events in neuronal maturation (i.e. functional synapses). We examined the maturation of NT2N cells under different culture conditions. When NT2N cells were co-cultured with astrocytes patch clamp recordings from them revealed synaptic activity that were not previously seen. These synaptic currents exhibited the biophysical and pharmacological characteristics of glutamergic synaptic transmission. Synaptic currents suggestive of $GABA_A$-mediated synaptic signals were also observed. These electrophysiological data were supported by positive immunohistochemical staining for synaptophysin, a synaptic vesicle protein. When NT2N cells were co-cultured with striate muscle they formed functional synapses that are reversibly blocked by curare. These findings suggest that NT2N cells have the capacity to express functional synapses and a variety of neurotransmitters.

687.12

PRESYNAPTIC INFLUENCE ON POSTSYNAPTIC CHANNEL KINETICS IN CULTURED SYMPATHETIC NEURONS.

J.C. Thigpen* Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599

The nicotinic channels of B- and C-cells, the principal neurons in bullfrog lumbar sympathetic ganglia, have different kinetics (J.Neurosci. 6:590,1986). B- and C-cells are innervated selectively by B- and C-preganglionic neurons, which are located in separate regions of the adult spinal cord (J.Comp.Neurol. 268:71,1988). This study examined the influence of presynaptic inputs on postsynaptic channels by comparing synaptic currents of B- and C-cells that had been co-cultured with spinal cord segments that contained either B- or C-preganglionic neurons.

Miniature excitatory post synaptic currents (mEPSCs), evoked by focally applied sucrose, were recorded from ganglion cells using the tight seal whole cell voltage clamp technique. The mean (±SEM) decay rates of mEPSCs recorded from ganglion cells co-cultured with B- or C-preganglionic neurons were 6.08 ± 0.25 (n=42) and 8.26 ± 0.43 (n=27) ms, respectively ($p<0.0001$). These results suggest that the kinetics of synaptic channels expressed in cultured sympathetic neurons are influenced by the type of innervating preganglionic axon. Future work will examine the influence of presynaptic axons on channels expressed by ganglion cells from early stage tadpoles.

NEUROSERPIN, AN AXONALLY SECRETED SERINE PROTEASE INHIBITOR

T. Osterwalder, J. Contartese, E.T. Stoeckli*° and P. Sonderegger, Institute of Biochemistry, University of Zurich, CH-8057 Zurich, and °Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106

Axonally secreted macromolecules have been implicated in neural development as mediators of axon outgrowth, remodelling of the extracellular matrix, and formation, elimination or competition of synapses. Here we report on the purification and the molecular cloning of neuroserpin, a neuronal serine protease inhibitor. Neuroserpin (previously denoted Axonin-2) had been identified in a compartmented cell culture system as an axonally secreted glycoprotein with an apparent molecular weight of 54-60 kD (Stoeckli et al., Eur. J. Biochem. 180: 249-258 (1989)). Based on coordinates and spot morphology in two-dimensional gel electrophoresis, neuroserpin was purified from chicken embryo vitreous fluid in a three step chromatographic procedure. The amino acid sequences of the amino terminus and three internal peptides were determined and used to design degenerated primers with which a 1000 kb fragment of the neuroserpin cDNA was amplified from chicken retina mRNA by means of RT-PCR. With the PCR-product as a probe, a full length cDNA of neuroserpin was isolated from a chicken brain cDNA library. The nucleotide and the deduced amino acid sequence qualified neuroserpin as a member of the serpin family of the serine protease inhibitors. The closest relatives are glia-derived nexin/protease nexin-1 and PAI-1 with an amino acid sequence identity of 35% and 34%, respectively. Primary structural features suggest that neuroserpin is heparin-independent and targeted against trypsin-like proteases. *In situ* hybridization revealed neuron-specific expression of neuroserpin during the late stages of neurogenesis. Together, the results implicate neuroserpin as a regulator of proteolytic events subserving processes of neural development such as synapse elimination, remodelling, or competition.

PROSTAGLANDIN INACTIVATION IN THE PERINATAL BRAIN: ROLE OF THE CHOROID PLEXUS. N. Krunic[1,2], I. Bishai[1], S.L. Adamson[2] and F. Coceani[1]*. [1]Div. of Neurosciences, Hosp. for Sick Children, Toronto, On., Canada M5G 1X8. [2]Samuel Lunefeld Res. Inst., Mount Sinai Hospital, Toronto, On., Canada M5G 1X5.

In early gestation, prostaglandins (PGs) are most likely inactivated by local catabolic enzymes. *This enzyme activity disappears by birth and, in* adults, PGs are actively transported across the blood-brain barrier and choroid plexus for catabolism in the periphery. We investigated whether PG transport occurs prenatally and if it increases at birth in association with the marked decrease in central PGE_2 levels. PG uptake in the choroid plexus from fetal (~136 d; term 145 d), newborn (3 d), and adult sheep was studied in vitro using [^{3}H]$PGF_{2\alpha}$ as substrate and [^{14}C]sucrose as extracellular marker. Fetal choroid plexus accumulated $PGF_{2\alpha}$, reaching steady-state at 30-60 min with a tissue-to-medium ratio (T/M) of 5.3 ± 0.5 (n=8). Newborn results were similar (T/M=7.0 ± 1.4, n=7). Uptake in the adult reached steady-state at 60-90 min (T/M=13.6 ± 1.3, n=8) and was significantly higher than fetus and newborn ($p<0.05$). Extracellular volume was constant at all ages (T/M=0.44 ± 0.02, n=23). Catabolism of $PGF_{2\alpha}$ to its inactive 13,14-dihydro-15-keto (15KD) metabolite was analyzed by thin-layer radiochromatography. Catabolism (radioactivity of 15KD expressed as %total) decreased significantly with age from fetus (59 ± 4%, n=8), to newborn (33±2%, n=7) to adult (no catabolism). $PGF_{2\alpha}$ uptake by the fetal choroid plexus had a high capacity (saturation at 40-60 µM) and was significantly inhibited by probenecid (1 mM, $p<0.05$). We conclude that the PG transport system of the choroid plexus develops in utero in sheep. PG uptake in vitro is lower, whereas catabolism is higher, in the perinatal period than in the adult. There is no abrupt increase in PG uptake at birth, which implies this mechanism is not responsible for the rapid decrease in central PGE_2 at this time. (NK supported by SIDS and Genesis).

EXPRESSION OF BRAIN CAPILLARY GSH TRANSPORT IN XENOPUS LAEVIS OOCYTES. R.Kannan*, J-R.Yi, Y.Li, D.Tang, B.V.Zlokovic and N.Kaplowitz. Depts. of Med., and Neurol. Surg., USC Sch. of Med., and VA Outpatient Clinic, Los Angeles, CA 90033.

We had previously shown carrier-mediated glutathione (GSH) uptake *across the blood-brain barrier (BBB) in two animal models using the rapid bolus injection technique (rat) and in situ vascular brain perfusion (guinea-pig). The* present study deals with expression of brain capillary GSH transport in Xenopus laevis oocytes. Oocytes were injected with either mRNA (30 ng) from bovine brain capillaries or water and maintained at 18°C for 3 days. Expression of GSH uptake in NaCl medium was observed as compared to water controls in 1 h incubations. The molecular form of uptake was predominantly as intact GSH in gamma glutamyltranspeptidase inhibited (acivicin) and non-inhibited conditions. GSH transport was partially (~40%) inhibited by removal of sodium (sucrose medium). In separate studies with bovine brain capillary mRNA-injected oocytes preloaded with GSH, efflux of GSH at 31.9%/h (water <2%/h) corresponding to a rate of 5.3 nmol/oocyte/h, was observed. The presence of a recently cloned rat canalicular GSH transporter (RcGshT) in rat whole brain, and guinea-pig and bovine brain capillaries was demonstrated by Northern blot analysis. Size fractionation of bovine brain capillary poly (A)$^+$RNA (as cDNA) yielded three distinct fractions showing GSH transport activity, one of which was RcGshT, while the other two were hitherto unidentified GSH transporters. The active size fractions showed carrier-mediated GSH transport; data on their kinetic parameters, ion requirements and inhibitor specificities will be presented. These studies provide a basis for a better understanding of brain GSH homeostasis with respect to the nature of GSH transporters at the BBB and may have impact in development of therapeutic strategies for GSH delivery to the brain.

HIGH GLUT1 GLUCOSE TRANSPORTER EXPRESSION IN HEMANGIOBLASTOMA ENDOTHELIA. E. M. Cornford*, S. Hyman, K. L. Black, M. E. Cornford, H. V. Vinters and W. M. Pardridge. UCLA School of Medicine, Los Angeles, CA 90095; West Los Angeles V. A. Medical Center, Los Angeles, CA 90073; and Harbor-UCLA Medical Center, Los Angeles, CA 90509.

Light microscopic immunochemistry indicated the enriched presence of the GLUT1 glucose transporter isoform throughout the central endothelia in a resected hemangioblastoma. Glial fibrillary acidic protein (GFAP) was observed only at the tumor border; no GFAP-reactivity was seen in stromal cells, pericytes or endothelia in central tumor regions. Quantitative EM immunogold analyses of GLUT1-positive sites per *u*meter of capillary membrane confirmed the GLUT1 transporter was highly enriched in tumor endothelial cell membranes. Immunogold EM using albumin (MW 65000) indicated that HSA moved freely from the vascular lumen into pericapillary regions, confirming the "leaky" barrier (seen in clinical neuro-imaging). GLUT1 is generally said to be more concentrated in erythrocytes than in any other cell, but GLUT1 in these tumor capillaries was more than 2-3-fold higher than seen in human red cells. We conclude that in the absence of GFAP, a high Glut1 density characterizes this tumor. The increased immunoreactive GLUT1 seen suggests this may be a useful model system for studying BBB GLUT1 regulation; some tumor-derived factor may induce GLUT1 expression in the hemangioblastoma endothelium.

TRANSLATIONAL ACTIVATORS IN 5'- AND 3'-UNTRANSLATED REGIONS OF GLUT1 GLUCOSE TRANSPORTER mRNA. R.J. Boado* and W.M. Pardridge. Dept. of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Recent studies have indicated that the blood-brain barrier GLUT1 glucose transporter is under post-transcriptional regulation. To undertake the functional mapping of the GLUT1 transcript, the present investigation studied the translational efficiency of full-length synthetic human (h) GLUT1 mRNA, and both 5'- and 3'-untranslated region (UTR) deleted mRNAs. Translation of 10 ng full-length hGLUT1 capped-mRNA in rabbit reticulocyte lysate produced 0.161 ± 0.013% TCA precipitable material (mean ± S.E., n = 3) after 30 minutes incubation at 30°C. Deletion of 5'- and 5'-/3'-UTR completely blocked the translation of these GLUT1 transcripts. The putative role of these hGLUT1 5'-UTR cis-acting elements was studied using the luciferase expression vector pGL2. DNA corresponding to the hGLUT1 5'-UTR generated by PCR was subcloned at the HindIII site of pGL2 located upstream of the luciferase 5'-UTR. Transfection of brain endothelial cultured cells with pGL2 containing the complete [nucleotides (nt) 1-171] hGLUT1 5'-UTR markedly increased the expression of luciferase (60.7 ± 14.3 vs. 10.7 ± 0.7 pg luciferase/mg protein, respectively). Insertion of hGLUT1 5'-UTR in reverse orientation induced no changes in the expression of luciferase (9.4 ± 1.7 pg/mgp), and the insertion of an unrelated 171 nt decreased its expression. Insertion of nt 96-171 of the hGLUT1 5'-UTR retained most of the stimulatory effect (41.3 ± 10.0 pg/mgp). In parallel experiments, nt 2100-2300 of the bovine (b) GLUT1 3'-UTR were inserted at the PflMI site of pGL2, which is located downstream of the luciferase 3'-UTR. This region of the bGLUT1 3'-UTR encompasses the binding domain of a 88 kDa C6 cytoplasmic trans-acting factor. Transfecton of C6 cells with this construct markedly increased (> 300%) the expression of luciferase. Conclusion: The present data provide evidence suggesting that the 5'- and 3'-UTR of the GLUT1 mRNA contains cis-acting elements involved in a translational activation of the GLUT1 gene in mammalian cells.

A NEW VASOGENIC BRAIN EDEMA (VBE) MODEL AND RELATION TO ENZYMATIC BARRIER. B.X.Lu* and X.D.Tang. Dept. of Neurol., Nanfang Hospital, First Military Med. Univ., Guangzhou 510515, PR China.

At present, there is still no very satisfactory VBE model. Here reported was a new VCE model recently developed in this laboratory. Phenylephrine (1.2mg/kg, i.p.) was injected into spontaneous hypertensive stroke prone rats (SHRsp). Results demonstrate that the permeability of blood-brain barrier (BBB) to macromolecules, assessed by Evans blue, Indian ink and ^{125}I bovine serum albumin, was progressively increased and reached a maximum at 0.5-1 hrs after drug injection. The density of cerebral capillary of drug-treated rats, analysed by computer (Quantimet 500+), was about 2 times larger than that of untreated rats. Water content of gray and white matter, determined by a Moisture Analyzer (Denver Ins.), of control group versus drug-treated group was 59.04±9.51%, 60.97±8.67% (n=27) and 69.59±12.05%, 74.27±7.99 % (n=25), respectively. Student's *t*-test revealed a marked statistical significance between the two pairs of values (P=0.014, 0.0003). We further conducted another experiment using SHRsp injected with neostigmine methylsulfate (0.8 mg/kg, i.p.) to test the relation between enzymatic barrier damage (we have found that 12 enzymes of cerebral capillaries changed on VBE, not reported here) and VBE. Just as we expected, neostigmine could alleviate brain edema, which is suggested to result from the inhibition of BBB cholinesterase. Our results suggest that the phenylephrine-induced cerebral edema is a suitable VBE model and insult of enzymatic barrier could influence the formation of VBE.

ADHESION OF AFRICAN TRYPANOSOMES TO HUMAN BRAIN MICROVASCULAR ENDOTHELIAL CELLS. B. Zünkeler, Z. Fabry, K.A. Follett*, J. Brayton, J.C. VanGilder, J.E. Donelson, M.N. Hart. Laboratories of Neuropathology, Neurosurgery, and Biochemistry, University of Iowa, Iowa City, IA 52244

African sleeping sickness is thought to be due to a direct effect of *Trypanosoma brucei gambiense* and *rhodesiense* on anatomical structures in the vicinity of the third ventricle and, in later stages, on the entire brain. To cause disease, the parasite must first attach to and migrate through the cerebrovascular endothelial layer. In this study we address the mechanism of trypanosome adhesion to human brain microvascular endothelial cells by characterizing adhesion molecules that participate in this interaction. Parasites were passaged in rats and stained with ethidium bromide prior to incubation with subconfluent and confluent monolayers of human brain microvascular endothelial cells, (passage 5-10, *Ulex europaeus* agglutinin-phycoerythrin FACS isolated). Attachment of parasites was quantified by fluorescence microscopy. Adhesion of parasites could be blocked by 83% at 4 hours by monoclonal antibody to E-selectin, CD 62-E (ELAM1) and by 48% by monoclonal antibodies to vascular cell adhesion molecule, CD 106 (VCAM1). Anti CD 44 and anti CD 62-P antibodies had no effect on the adhesion of parasites to endothelium. These findings suggest that attachment of trypanosomes to human brain endothelium is mediated at least in part by cellular adhesion molecules, including ELAM1 and VCAM1.

688.7

CATIONIZED HUMAN IMMUNOGLOBULINS AS A TREATMENT FOR CEREBRAL ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS): EVALUATION OF PHARMACOKINETICS, EFFICACY, AND TOXICITY IN SCID-hu MICE. W.M. Pardridge*, J. Yang, J. Buciak, and Y.-S. Kang. Dept. of Medicine, UCLA School of Medicine, Los Angeles, CA 90024.

The treatment of cerebral AIDS requires that drugs undergo transport through the brain capillary endothelial wall, which makes up the blood-brain barrier (BBB) in vivo. Antibodies are potential AIDS therapeutics and cationized antibodies undergo transport through the BBB via absorptive-mediated transcytosis (Proc. Natl. Acad. Sci. 86:4761, 1989). Cationized human immunoglobulins have inhibitory effects on the replication of the human immunodeficiency virus (HIV) in human lymphocytes in tissue culture (J. Infect. Dis. 170:563, 1994). The in vivo efficacy of cationized human immunoglobulins in the SCID-hu mouse model was evaluated. Immunoglobulins from non-infected humans and from HIV-infected individuals were cationized. A pharmacokinetic analysis showed that cationized immunoglobulins have a markedly reduced mean residence time in plasma and a marked increase in organ uptake compared to native immunoglobulins. A toxicity study performed with homologous immunoglobulins in BALB/c mice demonstrated cationized homologous immunoglobulins have no tissue toxicity at a daily dose of 5 mg/kg. Immunocytochemistry showed that immunoglobulins were taken up into the intracellular compartment of human lymphocytes. Treatment of HIV-infected SCID mice that were transplanted with human lymphocytes demonstrated therapeutic efficacy at a dose of 5 mg/kg cationized human immunoglobulins. In conclusion, cationized immunoglobulins are potential antibody-based therapeutics for the treatment of viral diseases, such as AIDS; cationized antibodies undergo enhanced transport into brain and peripheral organs; when homologous cationized immunoglobulins are administered, there is no measurable tissue toxicity.

MCP-1 INDUCES TRANSMIGRATION OF PERIPHERAL BLOOD MONOCYTES ACROSS A MODEL OF THE HUMAN BLOOD-BRAIN BARRIER. S.A. Downie, J.W. Berman, K.M. Weidenheim and W.D. Lyman*. Pathology Dept., Albert Einstein Coll Med, Bronx, NY 10461.

A hallmark in the pathogenesis of central nervous system (CNS) inflammatory diseases is the presence of peripheral blood mononuclear cells (PBMC) in the CNS parenchyma. The signals and mechanisms contributing to extravasation of PBMC are as yet to be completely defined. One molecule suggested to have a role in this process is monocyte-chemoattractant peptide-1 (MCP-1). To investigate the potential role of this molecule in transmigration of PBMC, we used a model of the human blood-brain barrier (BBB) that is constructed with autologous human fetal endothelial cells and astrocytes. Freshly isolated human PBMC were labeled with rhodamine-conjugated dialkylcarbocyanine (DiI) and placed onto the endothelial (eg. luminal) surface of the model. MCP-1 (100 ng/ml) was infused into the medium surrounding the astrocyte (eg. abluminal) side. MCP-1 induced transmigration of PBMC was noted after 60 minutes of incubation and was maximal by 150 minutes. The ratio of transmigrated cells in MCP-1 treated cultures as compared with untreated controls was 14.5 at 150 minutes. This study supports the hypothesis that MCP-1 is involved in transmigration of inflammatory cells across the BBB and into the CNS parenchyma. This mechanism may contribute to the development of neuropathologies including that associated with AIDS.

VISUAL CORTEX: STRIATE IX

689.1

PHYSIOLOGICAL CORRELATES OF ANISOTROPY IN HORIZONTAL CONNECTIONS: LENGTH SUMMATION PROPERTIES OF NEURONS IN LAYERS 2 AND 3 OF TREE SHREW STRIATE CORTEX. W. H. Bosking* and D .Fitzpatrick. Dept. of Neurobiology, Duke University Medical Center, Durham NC 27710.

Axon collaterals of layer 2/3 neurons form an extensive system of horizontal connections in tree shrew striate cortex (V1). These connections extend for several millimeters, linking neurons that have similar orientation preferences, but receptive fields separated by as much as 20 degrees of visual space. Axon collaterals of most layer 2/3 neurons are distributed anisotropically, extending farther and giving rise to more boutons along an axis in the map of visual space that corresponds to their preferred orientation (Fitzpatrick et al., '93).

We investigated the functional consequences of this precise modular and topographic specificity by making extracellular recordings from isolated single units in layer 2/3. For each unit, the classical receptive field (CRF) was determined using a minimum stimulation technique. Five to eight repetitions of stimuli consisting of bars of light between 1 and 40 deg in length were swept across the CRF at the preferred orientation. Most neurons (13/17) showed an increase in response to bars longer than the CRF. On average, a plateau in the length response curve was not reached until about 12 deg, even though the CRF for these cells was approximately 4 deg long. Some units (6/13) showed a progressive increase in response to stimuli as long as 40 deg. These data clearly indicate that the activity of cells in layer 2/3 of V1 can be modulated by visual stimulation outside the CRF. We also have evidence that in some cases, stimulation outside the CRF is sufficient to evoke responses from layer 2/3 neurons, independent of stimulation of the CRF. Supported by EYO6821.

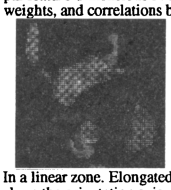
MEASURING THE DELAY OF THE ONSET OF EXTRA-RECEPTIVE FIELD MODULATION IN V1 NEURONS K. Zipser*. Dept. of Brain and Cognitive Sciences, MIT, E25-634, Cambridge, MA 02139

Given the same texture stimulation of the receptive field (RF), V1 neurons generally respond more vigorously when the pattern outside the RF differs from that inside the RF compared to the case where texture is of a homogeneous type across the display. We term this effect *extra-RF modulation*. Here we measure the delay of the onset of extra-RF modulation relative to the response latency of direct RF stimulation. Single and multi-unit recordings were made in area V1 of an awake, behaving monkey. As the monkey fixated in a behavioral trial, a given V1 neuron was initially stimulated with a homogeneously textured display flashed on a gray background. In some trials, after 150 ms of static texture stimulation, the texture outside the RF appeared to fall back in depth through stereoscopic disparity cues. In other trials, the homogeneously textured display remained unchanged. In all cases, the pattern over the RF itself remained the same throughout the texture display period. Compared to the case of the static homogeneously textured display, V1 neurons responded more vigorously following the change in the extra-RF texture pattern (i.e., the change in texture outside the RF caused extra-RF modulation during static RF stimulation). The delay of the onset of this extra-RF modulation was 30 to 50 ms relative to the normal response latency of the cells under study, or 80 to 100 ms relative to the change in texture outside the RF. This suggests that extra-RF modulation arises from reciprocal activity within the cortex rather than from direct feed-forward visual input. The delay in extra-RF modulation (which is lengthy compared to synaptic and conduction delays) raises the possibility that extra-RF modulation can reflect computationally complex analysis of visual input.

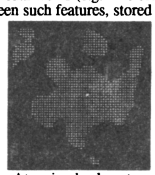
689.3

COOPERATIVE SELF-ORGANIZATION OF ORIENTATION MAPS AND LATERAL CONNECTIONS IN THE VISUAL CORTEX Joseph Sirosh* and Risto Miikkulainen, Dept of Computer Sciences, Univ. of Texas, Austin, TX 78712.

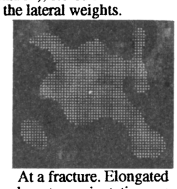
Recent experiments show that the lateral connections in the primary visual cortex self-organize from cortical activity, and that their patterns closely follow receptive field properties such as orientation preference. Through large-scale computer simulations, we show that a single Hebbian self-organizing process can account for the self-organization of oriented receptive fields, orientation maps, and the patterns of lateral connections. The model consists of an array of retinal receptors connected to an array of cortical neurons. Neighboring neurons are linked both by excitatory and inhibitory lateral connections, and farther neurons only by inhibitory connections. At each input presentation, neurons sum the input activity through the afferent connections, and repeatedly exchange activity through the lateral connections. When the activity settles, all connection weights are modified by the Hebbian rule. As training proceeds, the afferent connections organize into oriented receptive fields and orientation maps. The typical features of V1 maps, such as linear zones, pinwheels and fractures develop in the orientation map. At the same time, the long-range lateral connections learn the correlations in activity between cortical neurons and form patterns that closely follow the organization of the orientation map. The model permits us to predict the patterns of lateral connections at linear zones, pinwheels and fractures (*figures below*), and shows that the self-organizing process stores two kinds of visual knowledge in the cortex: the principal feature dimensions in the visual world (e.g. line orientation), stored in the afferent weights, and correlations between such features, stored in the lateral weights.



In a linear zone. Elongated along the orientation axis



At a pinwheel center. Links to all orientations



At a fracture. Elongated along two orientation axes

SINGLE-UNIT AND MULTI-UNIT MANIFESTATIONS OF LATERAL INTERACTIONS IN MONKEY VISUAL CORTEX. E. Katz*, K. P. Purpura and J. D. Victor. Dept. of Neurol. and Neurosci. Cornell Univ. Medical College, New York NY 10021.

Several lines of evidence indicate that inputs from beyond the classical receptive field play a role in shaping the responses of cortical neurons. Multi-input visual stimuli, such as those utilizing m-sequences (Sutter, 1987) are advantageous to studying these interactions, because these stimuli identify inputs to the receptive field that would be subthreshold if stimulated in isolation. With this technique we (Soc. Neurosci. 1993) demonstrated that the population receptive fields of local field potentials are modulated by a gain control driven by nearby visual input. We now extend these studies to single-unit and multi-unit recordings in macaque V1.

Lateral interactions of visual inputs were studied by comparing neural responses to contrast modulation of a 249-region stimulus (baseline condition) to responses to the same stimulus in which one or more of the regions were held at the mean luminance. This removal of modulation led to changes in the magnitude of the neural response to the regions which were within the receptive field. As we found in field-potential studies, changes in gain occurred within less then one minute, were readily reversible, and were not accompanied by a change in dynamics. However, an unexpected finding was that the effect of removal of modulation in one region was not always simply an overall increase in gain. Rather, in several cases, there appeared to be a selective augmentation of suppression of subregions within the receptive field. *Supported by EY9314 and The Revson Foundation.*

689.5

LONG RANGE LATERAL CONNECTIONS, NOT RECIPROCAL CIRCUITS, UNDERLIE HORIZONTAL PROPAGATION OF ACTIVITY: EVIDENCE FROM OPTICAL RECORDING OF FERRET VISUAL CORTEX SLICES.
D. A. Nelson* and L. C. Katz, Department of Neurobiology, Duke University Medical Center, Durham, NC 27710.

There is abundant evidence for rich lateral interactions in the visual cortex. In layer 2/3, lateral activation may be mediated by the clustered axon collaterals which extend from pyramidal neurons for a millimeter or more. Alternatively, polysynaptic, regenerative activation of neighboring columnar circuits extending across all cortical layers might mediate horizontal propagation. We tested these two models using optical recording and extracellular biocytin injections in coronal and tangential slices prepared from adult ferret visual cortex. Several lines of evidence support the former model. The rate of horizontal propagation in coronal slices (160 ± 9 mm/sec, n = 61) is consistent with a monosynaptic, not a polysynaptic circuit. Connections between layers are not required for horizontal propagation: in tangential slices containing only layer 2/3 neurons, the rate (130 ± 9 mm/sec) and extent (1200 ± 130 μm, n = 6) of horizontal propagation were similar to that in coronal slices. The pattern of activation in some tangential slices was patchy, as the tangential horizontal connection model predicts. Finally, horizontal propagation of activity in tangential slices was coextensive with biocytin labeled axon collaterals arising from the stimulus site (n = 4). In slices treated with bicuculline methiodide to remove inhibitory circuits, horizontal propagation of activity in layer 2/3 may occur via circuit elements other than long distance horizontal axons. Under this condition activity propagated at a much slower rate (coronal slice: 50 ± 7 mm/sec, n = 2; tangential slice: 45 ± 9 n = 3) and spread over a much greater extent (> 2200 μm). This implies that activity is epileptiform in such slices, and does not reflect normal circuit patterns. Thus, long distance horizontal connections play the central role in transmitting activity between cortical columns. A CORTICAL ARCHITECTURE FOR REAL AND ILLUSORY CONTOUR PROCESSING IN AREAS V1 AND V2.
(W. D. Ross[1], S. Grossberg[2*], and E. Mingolla[3]) Cognitive and Neural Systems, Boston University, Boston, MA.

Neurophysiological data on global interactions in primary visual cortex (Gilbert & Wiesel 1990), sensitivity to illusory contours (Grosof *et al.* 1993) in V1 and data on long-range illusory contour sensitivity (von der Heydt & Peterhans 1989) in V2 can be explained by a single cortical architecture replicating similar interactions in V1 and V2 but at different scales. This system can also explain psychophysical data and clarifies how the cortex processes scenes degraded by noise, occlusion or camouflage. The model refines and simplifies the Boundary Contour System (BCS) for emergent boundary segmentation (Grossberg & Mingolla 1985). Cooperative lateral interactions act to strengthen contours and define context-sensitive completions and groupings. Competitive interactions sharpen boundaries across space and act to choose local boundary orientation and position based on global information. Lateral feedback across the cortical map naturally realizes these interactions. These mechanisms are replicated at both the model V1 and V2 stages. Simulations using a single set of parameters model physiological data on V1 and V2 responses to offset grating stimuli and psychophysical data on strength of illusory contours as a function of the number, density, and shape of inducers.

LASER PHOTSTIMULATION REVEALS CONVERGENCE OF MAGNO- AND PARVOCELLULAR INPUT ONTO INDIVIDUAL NEURONS IN LAYER 4B OF MACAQUE V1.
A. Sawatari and E.M. Callaway*, Neurosci. Pgm. and Dept. of Physiol., Univ. of CO Sch. of Med., Denver, CO 80262.

Magnocellular (M) recipient neurons in layer 4Cα of macaque V1 have strong axonal projections to layer 4B, while the parvocellular (P) recipient neurons in layer 4Cβ do not. These observations reinforce the long-held notion that layer 4B neurons receive most or all of their input from the M stream. This interpretation however, overlooks the possibility that layer 4B pyramidal neurons could receive input from layer 4Cβ onto their apical dendites in layer 3B.

We determined the locations of neurons that made functional connections with layer 4B neurons by recording monosynaptic excitatory postsynaptic currents (EPSCs) elicited by stimulation in other layers. Living coronal brain slices from V1 of macaque monkeys were bathed in ACSF containing "caged" glutamate, and whole-cell, voltage-clamp recordings were made from individual layer 4B neurons. Brief (5 msec) flashes of light from a UV laser, focused to a small spot by a microscope objective, were delivered to desired locations in the slice to uncage the glutamate and elicit action potentials in neurons with cell bodies near the stimulation site (within 50μm). Neurons were also intracellularly labeled with biocytin to allow later determination of axonal and dendritic morphology.

Our sample of layer 4B neurons includes 4 spiny stellates, 2 pyramidal cells, and 3 cells whose morphology could not be determined. As expected, EPSCs were frequently evoked in all layer 4B neurons following stimulation in 4Cα. However, for pyramidal neurons, EPSCs of similar magnitude were evoked just as frequently following stimulation in 4Cβ. EPSCs were also evoked in spiny stellates following stimulation in 4Cβ, but they were less frequent and their size was typically much smaller than those following stimulation in 4Cα. Following stimulation in layer 5, EPSCs were frequently evoked in pyramidal, but less often in spiny stellate cells, consistent with our observation that layer 5 pyramidal neurons project heavily to layer 2/3, but only weakly to 4B. Stimulation in layer 6 elicited EPSCs in all layer 4B neurons. This finding is consistent with our observation that layer 6 pyramidal neurons project heavily to 4B and 2/3. We conclude that layer 4B pyramidal neurons receive strong input, via 4Cα *and* 4Cβ, from both the M and P streams, but the input to spiny stellates is predominantly from the M stream, via 4Cα.

RELATIONSHIPS BETWEEN OCULAR DOMINANCE COLUMNS AND LOCAL PROJECTIONS OF LAYER 6 PYRAMIDAL NEURONS IN MACAQUE PRIMARY VISUAL CORTEX.
A.K. Wiser* and E.M. Callaway. Neurosci. Pgm. and Dept. of Physiol., Univ. of CO Sch. of Med., Denver, CO 80262.

To study the laminar and columnar specificity of axonal arbors from layer 6 pyramidal neurons in macaque V1, we intracellularly labeled neurons with biocytin in slices prepared from monkeys that had received an intraocular injection of tetrodotoxin (TTX) in one eye. The TTX injection decreases cytochrome oxidase (CO) expression in ocular dominance (OD) columns corresponding to the injected eye. Slices with labeled neurons were double-stained for biocytin and CO, to allow visualization of neuronal processes, as well as OD columns. We have analyzed 29 layer 6 pyramidal neurons from OD column-labeled slices.

We have previously defined 7 types of layer 6 pyramidal neurons. These types belong to 2 major classes. Class I neurons have dense axonal projections to layer 4C and lack dendritic branches in 5B. It has previously been suggested that the axonal projections of these cells might be specific for regions receiving input from a single eye in layer 4C (Anderson et al., 1993). Class II neurons have axonal arbors that are *not* focused on 4C, and numerous dendritic branches in 5B. Different types within each class are defined based on further laminar specificity of axonal and dendritic arbors. Type Iα cells have dense axonal projections (and dendritic branches) in layer 4Cα, type Iβ in 4Cβ, type IβA in 4Cβ and 4A, type Im in just the middle of 4C, and type IC throughout the depth of 4C. Class II neurons, although diverse, are not easily classified into distinct types, except for type IIB. Type IIB neurons have strong axonal projections to layers 4B, 2/3 and sometimes 5, but not 4C. They also have a dense dendritic arbor in layer 5 that does not extend above layer 5. The remaining class II neurons are designated as type II.

We labeled and analyzed 9 class I cells in TTX treated animals, including 4 type Iα, 1 type Iβ, 2 type IβA, and 2 type IC. No type Im cells were labeled. In addition 20 class II cells, including 3 type IIB, were labeled. None of the cells in our sample have axonal projections that are specific for columns dominated by one eye or the other. Instead the axonal arbors freely cross OD column borders, without any apparent change in the branching or density of projections. Some type II neurons have long, clustered projections within layer 6, but they are not OD column-specific.

ALTERATIONS IN STRIATE CORTICAL OCULAR DOMINANCE COLUMNS IN ANISOMETROPIC AMBLYOPIA.
A.W. Roe*[1], G.M. Ghose[1], E.L. Smith[2], Y.M. Chino[2], and D.Y. Ts'o[1]. Division of Neuroscience, Baylor College of Medicine[1], Houston, TX 77030 and College of Optometry, University of Houston[2], Houston, TX 77204.

Early unilateral defocus associated with anisometropic amblyopia produces deficits in binocular vision at high spatial frequencies and in the contrast sensitivity of the defocussed eye. These deficits are thought to reflect functional changes in the striate cortex as a result of competitive interactions between left- and right-eye inputs to individual neurons. To investigate the effects of this anomalous competition on cortical binocular organization, we examined the organization of V1 ocular dominance columns in amblyopes. Behaviorally confirmed, anisometropic amblyopia was produced in adult rhesus monkeys that were reared with a -10D lens in front of one eye. We used optical imaging techniques to visualize ocular dominance columns in the superficial layers of the parafoveal striate cortex near the V1-V2 border in response to different spatial frequency stimuli. We find that at high spatial frequencies (6-8c/deg), but not at lower spatial frequencies, the normal eye columns exhibit greater activation than amblyopic eye columns. Moreover, in comparison to normal monkeys, the ocular dominance columns in amblyopic monkeys have a greater spatial period and are more irregularly organized. Thus, in addition to alterations in the spatial frequency tuning characteristics of individual neurons, early unilateral optical defocus produces large-scale alterations in the binocular organization of the primate visual cortex which may contribute to the binocular vision deficits commonly exhibited by anisometropic amblyopes.

Different Temporal Patterns of Immediate-early Gene mRNA and Protein Expression Allow Multiple Labeling Strategies in Visual Cortex of Monkey.
A. Chaudhuri[1], S. Larocque[1], J. Nissanov[2], L. Rioux[3]* & A. Goldszal[2]. [1]Dept. Psychology, McGill Univ., [2]Computer Vision Center for Vertebrate Brain Mapping, Drexel Univ. [3]Dept. Pharmacology, Univ. Pennsylvania.

It is now well established that neuronal activity produces transient changes in the expression of a number of immediate-early genes, such as *zif268* and *c-fos*. Previous studies have shown that immunodetection for their products may be used to label activated neurons under conditions of selective stimulation. We now report that the different time course of mRNA and protein induction, approximately 30 m and 2 h after onset of stimulation, may be used to visualize neurons that are separately activated under different stimulus conditions, thus allowing double labeling strategies.

We have used immunostaining to detect the Zif268 protein and in situ hybridization histochemistry (ISHH) to detect both *zif268* and *c-fos* mRNA in striate cortex of three adult vervet monkeys following a reverse-occlusion procedure. After three hours of monocular deprivation in chair-restrained awake animals, the patch was switched to the other eye for thirty minutes. An ocular dominance pattern was evident with both immunostaining and ISHH for *zif268*. However, the two patterns were clearly complementary; immunostaining revealed those columns that represented the open eye for the initial three hours whereas ISHH revealed columns that were activated during the final thirty minutes. Ocular dominance columns that were spatially aligned to the latter set were also visible with *c-fos* ISHH. However, it is unlikely that both labeled an identical set of neurons because Zif268 expression is known to be temporally correlated with ongoing activity whereas *c-fos* is induced in a transient, impulse-like manner. LUMINANCE CONTRAST GAIN, SPATIAL AND TEMPORAL FREQUENCY TUNING IN CO BLOBS AND INTERBLOBS OF MAMMALIAN STRIATE CORTEX MEASURED WITH INTRINSIC OPTICAL IMAGING. E.V. O'Brien*, R. Everson, and E. Kaplan. Laboratory of Biophysics, The Rockefeller University, N.Y., N.Y., 10021

The striate cortex of macaques contains regions of high metabolic activity, the cytochrome oxidase (CO) blobs. Some single unit studies report that their physiological properties are distinct from those of the surrounding regions, but other studies report no such differences. To circumvent the limitations of single unit studies, we used intrinsic optical imaging to compare the response of CO blobs to luminance contrast (LC), the tuning for spatial frequency (SF) and temporal frequency with those found in the interblob regions.

Reflectance changes from layers 2/3 of the exposed visual cortex of anesthetized and paralyzed monkeys and cats were imaged with a CCD camera in response to patterns which varied in luminance contrast, spatial frequency, or temporal frequency. The images were analyzed with extensions of the Karhunen-Loeve procedure (principal components analysis) and yielded spatio-temporal activity maps.

The contrast gain of the macaque cortex, measured optically, is similar to that of M and magnocellular neurons. The contrast gain of cat cortex is similar to that of single cortical neurons. We shall discuss the differences between the response properties of blobs and interblobs, and show that optical imaging of intrinsic signals can be used to study the LC sensitivity, SF and TF tuning in spatially localized regions of cortex, such as the blobs.

THE ROLE OF THE ASCENDING SEROTONERGIC SYSTEM IN CORTICAL NITRIC OXIDE PRODUCTION. M.J. Friedlander*, F.W. Hester, C.D. Gancayco, B.D. Waterhouse† and R.C.S. Lin†. Neurobiology Research Center and Dept. of Physiology and Biophysics, Univ. of Alabama at Birmingham, 35294-0021 and †Dept. of Anatomy and Neurobiology, Hahnemann Univ., Philadelphia, PA 19102.

Nitric oxide (NO) production amplifies NMDA receptor-mediated glutamate release in the rodent cerebral cortex (Montague et al., Science, 263:973-977, 1994). Intrinsic nitric oxide synthase (NOS) or NADPH-diaphorase (NADPHd) positive neurons represent a small fraction (< 2%) of cortical neurons, yet the cortical neuropile is richly invested with NADPHd positive profiles. We investigated whether the ascending serotonergic pathways contribute to the NOS activity in the sensory neocortex of guinea pigs and rats. Cells of the dorsal raphe (DR) that project to the cortex were retrogradely labeled with fluorescent tracers and then stained for NADPHd and/or reacted immunohistochemically for serotonin (5-HT). Three sets of animals received intraperitoneal injections of the serotonergic neurotoxin, 5,7-dihydroxytryptamine (5,7-DHT) or vehicle over two weeks at 75 µg/kg. They were evaluated for NADPHd histochemistry and the ability of cortical synaptosomal preparations to release endogenous glutamate in response to direct depolarization with 50 mM K^+ or to 100 µM N-methyl-D-aspartate (NMDA). We found that large numbers of 5-HT positive cells in the midline of DR that project to sensory cortical areas also are NADPHd positive and that 5,7-DHT treatment reduced NADPHd reactivity in the cortical neuropile, but did not reduce the number of intrinsic cortical NADPHd positive cells. Moreover, 5,7-DHT treatment reduced the NMDA receptor-NO-mediated release of endogenous glutamate by 40% relative to control without affecting direct depolarization-induced neurotransmitter release. Thus, the ascending serotonergic projection from the DR contributes significantly to the NO producing neuronal circuitry in neocortex.

THE ROLE OF NITRIC OXIDE IN MODULATING THE VISUAL RESPONSE OF NEURONS IN CAT STRIATE CORTEX. P.Kara* & M.J. Friedlander. Neurobiology Research Center and Dept. of Physiology & Biophysics, Univ. of Alabama at Birmingham, 35294-0021.

Nitric oxide (NO) has been postulated to play a role in synaptic plasticity and development of the mammalian forebrain (Gally et al., PNAS. 87:3547-3551, 1990; Bohme et al., Eur. J. Pharmacol., 199:379-381, 1991). We recently demonstrated that NMDA receptor activation leads to NO production that enhances release of glutamate in synaptosomal preparations from the cerebral cortex (Montague et al., Science 263:973-977, 1994), and that NMDA receptor activation leads to potentiated synaptic transmission at excitatory synapses in cortical slice preparations (Harsanyi & Friedlander, Soc. Neurosci. Abstr., 21, 1995). In the present study, we have explored the role of NO in modifying visual responses in striate cortex, *in vivo*. Combined extracellular single-unit recordings and local micro-iontophoretic pharmacological manipulations were performed in 7 anesthetized and paralyzed cats. Three to five barrel micropipettes attached to tungsten-in-glass recording electrodes were used to deliver (a) nitric oxide synthase (NOS) inhibitors: L-nitro-arginine (LNA) or L-mono-methyl-arginine (LMMA), (b) their inactive D-enantiomers, and (c) the natural substrate for NOS: L-arginine. Thus, the endogenous NO turnover was manipulated while evaluating neural responses to drifting visual stimuli of optimal and sub-optimal configurations. For 15 of 22 neurons, NOS blockade (via application of 20-80 nA through the LNA or LMMA barrels) reduced the visual response and spontaneous activity by 20-80%. In 5 neurons, NOS blockade specifically facilitated the visual response by 40-100%. Equivalent iontophoretic currents through barrels containing D-forms of the NOS inhibitors were ineffective. These findings suggest that NO or its metabolites may play a role in signal amplification in the intact primary visual cortex.

CALCIUM CHANNELS: PHYSIOLOGY, PHARMACOLOGY AND MODULATION II

690.1

VOLTAGE-DEPENDENT STATE TRANSITIONS OF SQUID NEURONAL CALCIUM CHANNELS. M.B. McFarlane* and W.F. Gilly. Departments of Molecular and Cellular Physiology and Biological Sciences, Hopkins Marine Station of Stanford University, Pacific Grove, CA 93950.

We have studied the gating of fast-deactivating (FD) Ca channels of squid giant fiber lobe (GFL) neurons using whole-cell voltage clamp. Prolonged depolarization causes the appearance of a second open state of FD Ca channels (O_2) whose existence is observable as a difference in the rate of channel closure (measured from tail currents) that is roughly 2-fold slower than from the normal open state (O_1). Entry into O_2 follows an exponential time course (τ = 120 ms at +80 mV). Neither I_{Ca} amplitude of channels in O_2 nor the activation kinetics of I_{Ca} are significantly different from channels in O_1. FD Ca channels recover fast (O_1) closing kinetics within 50 ms at -80 mV (τ = 9-16 ms). Since this recovery is possible at potentials where channels are likely to be closed, channels in O_2 appear to open and close along a pathway independent from (but similar to) that leading to O_1. Further evidence for the $O_1 \rightarrow O_2$ transition is supported by the blocking effects of $NiCl_2$. Following prepulse depolarization, the level of Ni block increases as entry into O_2 progresses. Recovery ($O_2 \rightarrow O_1$) is observed at 0 mV in the presence of Ni, as the O_2-blocked level returns to that of O_1 (τ = 14 ms). These slower tail current kinetics would be observed as an increase in mean open time at -80 mV on the microscopic (single channel) level. Such behavior at negative potentials could lead to an increase in calcium influx at the motor terminal following repetitive giant axon stimulation.

690.2

NICKEL MODULATES TWO DISTINCT EFFECTS ON NEURONAL CALCIUM CHANNELS: BLOCK AND INHIBITION OF ACTIVATION-GATING. G.W. Zamponi, E. Bourinet, S.J. Dubel* and T.P. Snutch. Biotechnology Laboratory, Univ. of British Columbia, 237-6174 Univ. Blvd. Vancouver, B.C. Canada V6T 1Z3.

Nickel ions have been reported to exhibit differential effects on voltage-gated calcium channels. To obtain a more precise characterization of nickel action we have investigated the effects of nickel on four major classes of cloned neuronal calcium channels (α_{1A}, α_{1B}, α_{1C} and α_{1E}) transiently expressed in *Xenopus* oocytes. Nickel caused two major effects: 1) block of macroscopic currents and 2) a shift in the current-voltage relation towards more depolarized potentials which was paralleled by a decrease in the apparent number of gating charges. In 10 mM Ba, block followed 1:1 kinetics and was most pronounced for α_{1C}, followed by α_{1E}, α_{1A}, and α_{1B} channels. In contrast, the change in activation-gating was most dramatic with α_{1E}, with the remaining channel subtypes being less affected. The current-voltage shift was well described by a simple model in which nickel binding to a saturable site resulted in altered gating behaviour. Both the affinity for block and the shift in current-voltage were reduced upon increasing the external permeant ion concentration. Replacement of Ba with Ca reduced both the degree of nickel block and the effect on gating for α_{1A} and α_{1C} channels, but increased the nickel blocking affinity for α_{1E} channels. The coexpression of Ca channel β subunits was found to differentially influence nickel effects on α_{1A}: the β_{2a} and β_4 subunits resulted in larger current-voltage shifts compared to the β_{1b}, while elimination of the β subunit almost completely abolished the gating shifts. In contrast, block was similar for the three β subunits, while complete removal of the β subunit resulted in an increase in blocking affinity. Qualitative and quantitative differences in the dependence of the effects of nickel concentration on gating and block suggest two distinct nickel binding sites on neuronal calcium channels.

690.3

POLYAMINES INHIBIT VOLTAGE-GATED Ca^{2+} CHANNEL CURRENTS IN DORSAL ROOT GANGLION NEURONS AND IN OOCYTES EXPRESSING CLASS B Ca^{2+} CHANNELS. G.W. Campbell*[1], R.A. Gross[2] and D.M. Rock[1], [1]Neuroscience Therapeutics, Parke-Davis Research, 2800 Plymouth Rd., Ann Arbor MI 48105 and [2]Depts. of Neurology and Pharmacology, University of Rochester Medical School, 601 Elmwood Ave., Rochester, NY 14642.

Endogenous polyamines interact with a variety of ligand- and voltage-gated ion channels and may play a role as neurotransmitters or neuromodulators in the central nervous system (CNS). The effects of polyamines on glutamate receptors has been studied in detail, less is known about the interaction of polyamines with voltage-gated Ca^{2+} channels (Scott, RH et al. TINS, 16:153-159, 1993). Using whole-cell and two-electrode voltage-clamp techniques, we studied the effects of endogenous and structurally-related synthetic polyamines on Ca^{2+} channel currents in Dorsal Root Ganglion (DRG) neurons and in oocytes expressing Class B (N-type) Ca^{2+} channels.

High concentrations (100 μM - 10 mM) of the endogenous polyamines spermine (SP) and spermidine (SD) reduced the peak amplitude of high voltage activated Ca^{2+} currents in DRG neurons, with SP being more potent than SD. The synthetic polyamine arcaine inhibited DRG Ca^{2+} currents only at 10 mM. In preliminary experiments, SP (300 μM - 10 mM) , SD (1 and 3 mM) and long chain diamines (100 μM) reduced the peak amplitudes of expressed Class B Ca^{2+} currents, while equivalent concentrations of putrescine, cadaverine and diethylenetriamine did not affect peak current amplitudes.

These results suggest that high concentrations of released polyamines may have a presynaptic action, by affecting voltage-gated Ca^{2+} channels, as well as a postsynaptic action on both voltage- and ligand-gated channels to affect neurotransmission in the CNS.

This work was supported in part by NS 19613 (RAG).

690.4

FUNCTIONAL INTERACTION OF SYNTAXIN WITH N-TYPE AND Q-TYPE CALCIUM CHANNELS.

I. Bezprozvanny*, R.H. Scheller, R.W. Tsien. Dept. of Molec. Cell. Physiol., Beckman Ctr., Stanford Univ. Med. Ctr, Stanford, CA 94305

Syntaxin is known to interact directly with N-type Ca channels (e.g. Bennett et al., Science **257**:255; Leveque et al., JBC **269**:6306; Horikawa et al., FEBS Let. **330**:236; Sheng et al., Neuron **13**:1303). A *Xenopus* oocyte expression system was utilized in order to investigate whether interaction with syntaxin has any effect on the functional properties of Ca channels. It was found that coexpression of N-type ($\alpha_{1B}\beta_3\alpha_2$) channels with syntaxin 1A promoted inactivation, causing a ~20 mV shift in the channel steady-state inactivation curve towards more negative holding potentials. The rate of channel recovery from inactivation was decreased 2-3 fold in the presence of syntaxin, also consistent with preferential binding of syntaxin to the inactivated state of the channels. The C-terminal (a.a. 168-288) but not N-terminal (a.a. 1-190) of syntaxin 1A influenced channel gating. When expressed in oocytes, Ca channels encoded by $\alpha_{1A}\beta_3\alpha_2$ (likely Q-type) were also affected by syntaxin in a similar way.

Since N-type and P/Q-type channels contribute jointly to transmitter release at nerve terminals, these data suggest that besides its role as a docking site for synaptic vesicles, syntaxin may also modulate presynaptic Ca channel activity.

690.5

CONCERTED ACTIONS OF MULTIPLE CALCIUM CHANNELS IN EXCITATORY SYNAPTIC TRANSMISSION. D.B. Wheeler*, A. Randall and R.W. Tsien. Department of Molecular and Cellular Physiology, Beckman Center B103, Stanford University School of Medicine, Stanford, CA 94305.

We have investigated the basis of the concerted actions of different Ca^{2+} channel subtypes in triggering neurotransmitter release at CA3-CA1 synapses of rat hippocampal slices. The K^+ channel blocker, 4-aminopyridine (4-AP), was used to modify the presynaptic action potential (AP) in hippocampal area CA1, elicited by field stimulation of the Schaffer collateral/commisural fiber bundle. Intracellular recordings with sharp electrodes showed that 100 μM 4-AP broadened the AP recorded in CA3 somata by slowing the repolarization phase. 4-AP caused a two-fold increase in the slope of the field excitatory postsynaptic potential (EPSP) and eliminated the dependence of synaptic transmission on N-type Ca^{2+} channels. The latter effect was reversed by lowering extracellular Ca^{2+} concentration ($[Ca^{2+}]_o$). The effects of AP-broadening on Ca^{2+} influx through various channels were studied by application of mock APs to voltage-clamped, cultured cerebellar granule neurons. Slowing the repolarization phase of a mock AP increased current carried by N-, P/Q- and R-type channels to a similar extent. The sensitivity of the field EPSP to variations in $[Ca^{2+}]_o$ was studied in the absence and presence of 4-AP. The form of this relationship indicated that as Ca^{2+} influx was progressively increased, increases in synaptic strength would eventually approach saturation. The relative impact of spike broadening is greatly increased by the selective inhibition of either N- or Q-type channels. This is of potential physiological importance for circumstances where either type of channel is selectively down-modulated. Our findings are consistent with a simple scenario in which N- and Q-type channels both contribute Ca^{2+} influx to help trigger transmitter release in individual synaptic boutons. The dependence on multiple types of Ca^{2+} channels is not absolute, however, because simply increasing AP duration increases Ca^{2+} influx through both kinds of Ca^{2+} channels, thereby lessening the dependence of synaptic transmission upon any one subtype.

690.6

DIFFERENTIAL EXPRESSION OF P- AND Q-TYPE CALCIUM CURRENTS DURING EARLY DEVELOPMENT OF SENSORY NEURONS.

J. Valmier*, S. Diochot, G. Desmadryl, C. Hilaire, M. Baldy-Moulinier, C.J. Dechesne , S. Richard. INSERM U. 249, 34033 Montpellier, France.

Analysis of neuronal development has emphasized the importance of voltage-activated Ca^{2+} currents (I_{Ca}) during the initial period of differentiation. Whether the new identified non L, non N high-threshold calcium current subtypes are present in early embryonic neurons and developmentally regulated is still unknown. To resolve these issues, we used the whole-cell patch-clamp technique to record calcium current in dorsal root ganglion (DRG) neurons acutely dissociated from mouse embryos during development. We report dramatic in vivo changes in the expression of P-, Q- and R-type calcium currents between embryonic days-13 and -15, respectively before and after the period of target innervation. All three currents were distinguished on the basis of their sensitivity to AgaIVA. While R-type was stable over this developmental span, Q-type expression increased 2-3 fold and P-type current disappeared completely. These data show that P-, Q- and R-type calcium current are expressed by early embryonic DRG neurons, are developmentally regulated and are probably involved in specific key developmental events including natural neuron death and onset of synapse formation.

690.7

COORDINATION OF EXPRESSION OF N-TYPE CALCIUM CHANNEL SUBUNITS THROUGHOUT DEVELOPMENT. M.W.McEnery*, T.D. Copeland^, J. Striessnig#, H. Glossmann#, M. Pacioianu and C.M. Begg . Dept. of Physiology and Biophysics, Case Western Reserve University, School of Medicine, Cleveland, OH 44106, ^ABL-Basic Research Program, NCI-Frederick Cancer R & D Center, Frederick, MD 21702, and Dept. of Molecular Pharmacology, University of Innsbruck, Innsbruck, Austria.

The omega-conotoxin GVIA sensitive N-type voltage-dependent calcium channel (N-type VDCC) is implicated in many neuronal processes which include neurotransmitter release, neuronal migration, and synaptic vesicle docking. The N-type VDCC is comprised of several non-identical subunits as indicated by both biochemical studies (McEnery, et al., 1991; Witcher, et al., 1993 Leveque, et al., 1994) and molecular cloning. While there is little question that the alpha1 subunit protein of the N-type VDCC corresponds to the class alpha1B isoform, (Dubel, et al., 1992; Williams, et al., 1992), the identity of the beta subunit associated with the alpha1B subunit remains controversial. In addition, there is no information on the time course for the assembly of the N-type VDCC from component subunits. The purpose of this study is to examine the level of expression and assembly of alpha1B subunits and all beta subunits throughout development using a panel of anti-peptide, affinity purified antibodies to the rat alpha1B and beta subunits. The level of subunit expression throughout development when correlated with the density of [^{125}I]conotoxin binding sites may indicate the time course of subunit assembly and the acquisition of functional [^{125}I]CTX binding sites. LOCALIZATION OF PYRAMIDAL NEURONS THAT HAVE THE T-TYPE CALCIUM CURRENT IN GUINEA-PIG PREFRONTAL CORTEX. E. Geijo-Barrientos* and E. de la Peña. Instituto de Neurociencias y Departamento de Fisiología, Universidad de Alicante, 03080-Alicante, Spain.

One of the calcium currents present in cortical neurons is the low threshold calcium current or T type current, which contributes to the generation of rhythmic activity and bursts of action potentials. We have studied the distribution of the pyramidal neurons that have this current within guinea-pig prefrontal cortex. The experiments were done in coronal slices of 300μm of thickness that included the prefrontal cortex kept "in vitro" at 33-34 °C. Neurons were impaled with 3M potassium acetate filled electrodes to obtain recordings in current-clamp or single electrode voltage-clamp (SEVC), always in the presence of TTX (1μM) and TEA (10mM); the neuronal morphology was studied with intracellular staining with neurobiotin. In a sample of 125 regular spiking pyramidal neurons, 60% of the neurons had the T current, directly recorded under SEVC or recorded, in current clamp, as a calcium spike of 15-20 mV of amplitude activated from membrane potentials more negative than -70mV. The neurons which had the T current were localized in the mid-deep layers of the cortex, at more than 400μm from the pial surface and were absent in a band of 200 μm of thickness located just below layer I. Neurons that did not have the T current were found in all layers of the cortex (except in layer I) though slightly more frequently in superficial layers (between 200 and 600 μm from the cortical surface). These results provide a direct demonstration that low threshold calcium current is expressed in pyramidal neurons located in particular layers of prefrontal cortex.

Supported by Grant PB92-0347 from the DGICYT (Spain).

INOSITOLPHOSPHATES MODULATE LIPID BILAYER RECONSTITUTED CALCIUM CHANNEL ACTIVITY. B.D. Cherksey*, M. Sugimori and R. Llinás, Dept. Physiology & Neuroscience, New York University Medical Center, 550 First Avenue, New York, NY 10016.

The effects of the phosphoinositides on P-type calcium channel activity was studied in cerebellar membrane vesicles and on the isolated P-channel protein using the "tip-dip" bilayer technique. Cerebellar membranes were obtained from freshly dissected cerebella. The membrane vesicle preparation was implemented in 400 mM sucrose. Electrical activity was measured in solutions containing 80 mM $BaCl_2$, 10 mM HEPES, pH 7.4 in the bath; 120 mM CsCl, 10 mM HEPES, pH 7.4 in the pipette.

P-channel protein was obtained using the polyamine, 1-arginyl N,N',-Bis(3-aminopropyl)-1,4-butane-diamine, which we have previously termed synthetic sFTX(3:4) coupled to Sepharose 4B CL via a 1,4-Butanediol Diglycidol ether linkage. This affinity gel allowed the extraction of a protein from bovine cerebellum homogenate. The electrical activity was measured in solutions containing: 80 mM BaCl2, 10 mM HEPES, pH 7.4 in the pipette; 120 mM CsCl, 10 mM HEPES, pH 7.4 in the bath.

To study the effect of phosphoinosides on electrical activity from membrane vesicles, the compounds were added to the solution in the pipette (cytoplasmic face of the channel) in concentrations ranging from 0.1 uM to 1.0 uM. IP3, at concentrations greater than 0.3 uM was found to produce an increase in the number of electrical events at any holding potential without an increase in the average open time per event. The electrical activity was blocked by the addition of sFTX to the bath. Neither PIP nor IP4 produced an activation of the P-channel nor did the synthetic stereoisomer of natural IP3. IP3 was without effect when applied to the bath (extracellular face of the channel).

Studies of the phosphoinositides on the isolated, reconstituted P-channel produced an identical pattern of results. The activation of the P-channel was prevented by the addition of heparin at a concentration of 100 µg/ml.

Support: NIH-NS13742 and NIA-AG09480.

DOPAMINERGIC RESPONSES TO STRIATAL INJURY. D.W.Howells*, G.T.Liberatore, J.Y.F.Wong, G.A.Donnan. University of Melbourne, Dept. of Medicine, Austin and Repatriation Medical Centre, Heidelberg, VIC 3084, Australia.

A potential therapy for Parkinson's disease lies in the stimulation and control of neurite outgrowth from nigrostriatal dopaminergic neurones. We have previously shown that the injury associated with implantation of gel foam to normal mouse striatum increases binding of [^{3}H]-mazindol to presynaptic dopamine uptake sites 10 months after implantation ($P<0.01$). When combined with the observation by others of increased density of host tyrosine hydroxylase immunoreactive fibres after striatal grafting or cavitation, it seems likely that striatal injury is stimulating proliferation and sprouting of dopaminergic terminals. We have now shown that striatal cavitation induces a concerted response from the dopaminergic system with proliferation of striatal presynaptic dopamine uptake sites ($P<0.05$), increased tyrosine hydroxylase activity ($P<0.05$), and increased concentrations of dopamine ($P<0.05$), dihydroxyphenylacetic acid ($P<0.05$) and homovanillic acid ($P<0.05$). Interestingly, while the changes of presynaptic dopamine uptake site density are only seen ipsilateral to the striatal lesion, the changes in tyrosine hydroxylase activity, dihydroxyphenylacetic acid and homovanillic acid concentrations are bilateral. These presynaptic changes are accompanied by decreases of the predominantly postsynaptic binding of [^{3}H]-SCH23390 and [^{3}H]-sulpiride to the D_1 and D_2 classes of dopamine receptors in the striatum. The density of presynaptic dopamine uptake sites, D_1 and D_2 receptors in the substantia nigra does not change after striatal injury. The striatal response to injury first becomes apparent 2 weeks after cavitation and gradually increases with time, resulting in a doubling of the DOPAC concentration and presynaptic dopamine uptake site density within 2 and 10 months respectively. If similar changes occur after intrastriatal transplantation in human Parkinsonism, the time frame and extent of the host dopaminergic responses would suggest that they may make a significant contribution to any observed clinical improvements.

691.2

XENOTRANSPLANTATION AND ANTIGEN MASKING OF FETAL PORCINE VENTRAL MESENCEPHALON IN A RAT MODEL OF PARKINSON'S DISEASE. W.R. Galpern*[1,3], L.H. Burns[1], T.W. Deacon[1], J. Dinsmore[4], and O. Isacson[1,2] [1]Neuroregeneration Laboratory, McLean Hospital, Belmont, MA, 02178; [2]Department of Neurology and Program in Neuroscience, Harvard Medical School, Boston, MA, 02114; [3]University of Massachusetts Medical Center, Worcester, MA, 01655; [4]Diacrin, Inc., Charlestown, MA, 02129.

The practical and ethical limitations inherent to current human neurotransplantation protocols suggest the potential utility of developing alternate cell sources. Fetal porcine neuronal xenografts can survive in and functionally reinnervate the host CNS using conventional immunosuppression. Xenotransplantation of fetal porcine neuroblasts pretreated with antigen binding fragments [$F(ab')_2$] of a monoclonal antibody to porcine major histocompatibility complex (MHC) class I may provide an adjunct or alternative to current immunosuppression regimens. We have recently shown that $F(ab')_2$ pretreatment enhances striatal xenograft survival in a rat model of Huntington's disease (Pakzaban, et al., Neuroscience, '95, **65**, 983-996). In order to evaluate the immunoprotective efficacy of $F(ab')_2$ masking of porcine MHC I in the 6-hydroxydopamine (6-OHDA) model of Parkinson's disease, rats were transplanted with fetal porcine ventral mesencephalon cell suspension into the denervated striatum and received either A) daily cyclosporine (10 mg/kg, sc), B) $F(ab')_2$-pretreated cells, or C) no immunosuppression. Behavioral recovery was monitored by amphetamine-induced rotation at approximately 6 week intervals following transplantation. Rats were sacrificed at 19 weeks post-transplant, and xenograft survival and axonal growth were assessed by tyrosine hydroxylase (TH) and donor-specific glial immunostaining. TH-positive neuronal survival was greater in the cyclosporine group than in either the $F(ab')_2$ or no immunosuppression groups. Ongoing studies are aimed at evaluating the xenograft rejection process associated with cyclosporine discontinuation and determining whether $F(ab')_2$ treatment is able to induce tolerance and prevent graft rejection following removal of cyclosporine immunosuppression.

FDOPA-PET STUDIES IN THE VERVET MONKEY: PRE-TRANSPLANT ASSESSMENT OF MPTP-LESION STABILITY. W.P. Melega*, M.J. Raleigh, D.B. Stout, A.A. DeSalles, S.R. Cherry, S-C. Huang, M.E. Phelps. Molecular and Medical Pharmacology, UCLA Sch. of Med. Los Angeles, CA 90095

Biochemical determination of the stability of MPTP-induced striatal dopamine lesions in monkeys can be achieved only with noninvasive imaging techniques. With PET, individual subjects can be scanned serially at pre-MPTP, and throughout the post-MPTP time period for quantitation of the extent and stability of the MPTP lesion over time. Unilateral intracarotid MPTP administration allows for PET measures of ipsilateral (lesioned) striatum to be evaluated relative to the contralateral (unlesioned) striatum. This paradigm significantly reduces the variance associated with interstudy comparisons. For these studies, parametric images of the FDOPA uptake rate constants (Ki) were generated by Patlak analysis. ROIs drawn on each control were transferred onto its corresponding post-drug image set. Pre-MPTP scans in adult male vervet monkeys (Cercopithecus aethiops sabaeus; n = 8) showed right/left striatal Ki ratios between 0.95 and 1.05. For the MPTP studies, subjects (n = 5) received [18F]fluoro-L-DOPA (FDOPA)-PET scans prior to MPTP injection and at post-MPTP times: 1-2, 5-7 and 9-11 months. FDOPA plasma metabolite profiles were similar to controls. For four of five subjects, striatal Ki ratios varied less than 5% between scans. Differences between subjects were still detected: right/left striatal Ki ratios were between 0.10 and 0.28. One subject showed stable post-MPTP ratios up to 7 months (0.12) but then showed partial recovery at 9 months (0.29). The results indicate that individual variability-reaction to MPTP occurs and that stability assessment can be obtained with FDOPA-PET. These measures provide a baseline for accurate longitudinal assessment of post-intervention (e.g. fetal transplant) strategies in this Parkinsonian model.

EMBRYONIC DOPAMINE CELL IMPLANTS IN HUMANS WITH ADVANCED PARKINSON'S DISEASE: RESULTS FROM 7 MONTHS TO 7 YEARS AFTER TRANSPLANT IN 23 PATIENTS. C.R. Freed , R.E. Breeze, S.A. Schneck, M. Leehey, C.F. O'Brien, L. Thompson, L.O. Ramig, F.G. Kaddis*, J.C. Mazziotta[1], D. Eidelberg[2], and A.A. Ansari[3], Univ. of Colorado Sch. of Med., Denver, CO 80262; UCLA Sch. of Med., Los Angeles, CA 90024[1]; North Shore University Hospital, Manhasset, NY 11030[2]; and Emory Univ. Sch. of Med., Atlanta, GA 30322[3].

Embryonic dopamine cell transplants are an evolving therapy for patients with advanced Parkinson's disease. Since 1988, we have performed 23 transplants in patients. Two were unilateral in caudate and putamen and 21 were bilateral into putamen using up to 16 needle passes. Only tissue from embryos 7 to 8 weeks post conception was used. Tissue from a single embryo was used in 6, from 2 embryos in 13, and 4 embryos in 4 patients. Six of the first 12 patients were immunosuppressed. Clinical change was monitored by UPDRS and ADL as well as frequent videotaping and computer testing in the home before and after first daily doses of drugs. PET scans were performed when available. Overall results showed 1) "On" and "off" performance improved three to twelve months after transplant. 2) Immunosuppression offered no apparent benefit. 3) Transplant growth and clinical improvement progressed up to four years after transplant. 4) Drug doses were reduced in most patients by about 50%. 5) Reduced severity of both "on" and "off" phases and improvement in sleep were commonly noted. 6) There was no improvement in memory or other cognitive tests, and patients with memory disturbance prior to surgery were made worse for many months after surgery. 7) Complications included an intraoperative hemorrhage leading to death one month later, a cortical stroke remote from the transplant site in a patient with cerebrovascular disease, and a small putamenal bleed in one needle tract. 8) Surviving tyrosine hydroxylase positive cells were seen in the patient who died. Further evidence for transplant survival was seen on fluorodopa PET scans.

691.5

A NEW FRONTAL APPROACH TO EMBRYONIC NEURAL TRANSPLANTATION IN HUMANS WITH ADVANCED PARKINSON'S DISEASE. R.E. Breeze , C.R. Freed*, S.A. Schneck, M. Leehey, and C.F. O'Brien, Univ. of Colorado Sch. of Med., Denver, CO 80262.

Since 1988, we have used closely spaced needle tracts to deposit embryonic dopamine cells in the putamen in patients with advanced Parkinson's disease. This approach through bilateral craniotomies at the apex of the skull over frontal cortex required up to 16 needle passes. We had estimated that the risk of serious hemorrhage was about 1/500 needle passes or less. This technique has been adopted by other groups performing neurotransplants. Our 17th patient had a catastrophic hemorrhage (after about 300 needle passes had been made into patients under this protocol). To reduce surgical morbidity, we devised a new transplant strategy entering the forehead via twist drill holes. Four needle tracts are used to deposit 30 mm cores of tissue along the long axis of putamen. Tissue from 4 embryos was used in four patients and two embryos in two patients. Six patients have undergone this procedure and are 8 to 18 months post surgery. Surgical time was cut from 4 hours to 2 hours. Hospitalization and postoperative headache were reduced. 3/6 patients were discharged the day after surgery. Results parallel those seen in the total population of 23 patients on whom we have performed transplants. For the first 3 patients, Activities of Daily Living Score fell from 23 to 10 in the "off" phase and 8 to 4 in the "on" phase by 7 to 9 months after surgery. Drug doses were reduced by up to 50%. These results show that a frontal approach offers good transplant outcome with apparently less surgical morbidity.

691.6

THE USE OF A COSMETIC SURGICAL PLACEBO CONTROLLED TRIAL IN THE TREATMENT OF PARKINSON'S DISEASE. T.B. Freeman*, D. Vawter, C.G. Goetz, R.A. Hauser, J.H. Kordower, P.R. Sanberg, B.J. Snow and C.W. Olanow. University of South Florida Div. of Neurosurgery, Tampa Florida.

Prospective randomized double-blind placebo-controlled trials are currently utilized for evaluation of new drugs. However, clinical trials investigating new surgical procedures have yet to widely include either cosmetic surgical placebo controls ("imitation operations") or sham surgery in the experimental design.

Our NIH-sponsored evaluation of fetal nigral tissue transplantation in Parkinson's disease includes a cosmetic surgical placebo control arm. The rationale for this design will be discussed including: 1) delineation of the difference between a cosmetic surgical placebo and sham surgery; 2) examples of detrimental noncontrolled surgical trials; 3) examination of costs and morbidity due to unnecessary surgery in the absence of placebo controlled trials; 4) discussion of medical placebo controlled trials where risk is greater than in surgical placebo controlled trials; 5) review of precedents for surgical placebo controlled trials; 6) identification of criteria for beginning randomized surgical placebo controlled trials; and 7) evaluation of the use of cosmetic placebo controlled trials in transplant protocols for Parkinson's disease.

A cosmetic surgical placebo controlled trial is ethical and appropriate at this stage of scientific knowledge, and necessary in order to accurately evaluate efficacy of neural transplantation in the treatment of Parkinson's disease.

691.7

GROWTH, DIFFERENTIATION, AND BLOOD-BRAIN-BARRIER OF MURINE EMBRYONIC CNS TRANSPLANTS. Stefan Isenmann*, Sebastian Brandner, Guido Kühne[1], Ulrich Sure, and Adriano Aguzzi. Institute of Neuropathology, University Hospital, Zürich, Switzerland. [1]Paul-Scherrer-Institute, Villigen, Switzerland.

Telencephalic grafting of embryonic tissue represents a powerful tool for developmental studies. We have recently used this technique to study long term effects of various lethal mouse mutants *in vivo*. However, a full exploitation of the grafting approach requires a thorough knowledge of the biological behavior of grafted tissue.

We have characterized the biological properties of embryonic telencephalic tissue isolated at different developmental stages and grafted into the caudoputamen and lateral ventricles of histocompatible mice. 164 grafts were analyzed up to 500 days after transplantation. Grafted cells were identified by autoradiography to ^{3}H-thymidine. Proliferation was examined by immunocytochemistry to 5-bromo-2'-deoxyuridine (BrdU). The graff size was measured as a function of the embryonic age of the donor tissue at transplantation. The time course of blood-brain-barrier reconstitution was examined *in vivo* by contrast enhanced magnetic resonance imaging (MRI) and we compared the results with various histological techniques in individual grafts.

Transplantation of embryonic telencephalic tissue resulted in the formation of solid neural grafts in 79% of all transplants. Our data indicate that the optimal time point for grafting murine telencephalic tissue is embryonic day E 12.5. Grafts transplanted at this stage resulted in 87% takes and grew larger and more reproducibly than tissue obtained at earlier or later stages. Proliferative activity was initially brisk (up to 35%), but ceased during the third week after transplantation. The blood-brain-barrier was shown to be reconstituted in most cases 7 weeks after transplantation. These data on the biology of wild type grafts provide important baseline information for studying grafts of "knock out" and transgenic tissue of embryonic lethal phenotypes.

GRAFT-INDUCED RESTORATION OF FUNCTION IN HEREDITARY CEREBELLAR ATAXIA. L.C. Triarhou*, W. Zhang, W.-H. Lee. *Dept. Pathol. Lab. Med. & Pediatrics, Indiana Univ. Sch. of Med., Indianapolis, IN 46202-5120*

We have been using *pcd* mutant mice, a model of recessively inherited cerebello-olivary atrophy, to study the structural integration of transplanted wild-type Purkinje cells into the disrupted cerebellar loop (*Ann. Neurol 20:* 138, 1986; *Anat. Embryol. 176:* 145, 1987; *Neurochem. Res. 17:* 475, 1991). The aim of the present study was to determine the recovery of behavioral responses after bilateral grafting of E12 cerebellar cell suspensions into the deep cerebellar nuclei of the hosts, according to a protocol that emphasizes reconstruction of the missing cortico-nuclear projection (*Anat. Embryol. 185:* 409, 1992). Motor coordination and fatigue resistance were assessed in a rota-rod treadmill apparatus for mice. Mutants of the sham-operated group (n=6) stayed on the rotating drum for an average of 3.3 sec preoperatively and 3.0 sec postoperatively; *pcd* mice in the transplant-receiving group (n=6) stayed on the drum for 3.8 sec preoperatively and 13.5 sec postoperatively; the graft-induced 255% improvement was statistically significant at P=0.027. Moreover, grafted mice were able to sustain the abdomen raised above the ground on their limbs during movement, contrasting to the typical lowered, widened stance of *pcd* mutants. The viability of transplanted Purkinje cells was verified with immunocytochemistry for calbindin-D_{28k} and $GluR_{2/3}$ AMPA receptor subunits. An axonal innervation was supplied by donor Purkinje cells to the deep nuclear complex of the host. Further, most of the transplanted Purkinje cells had migrated to occupy cortical localities, and displayed a correct orientation of their dendritic trees toward the pia. Our findings provide the first demonstration of motor enhancement in a model of inherited cerebellar ataxia after intraparenchymal grafting of fetal cerebellar neurons. (Supported in part by USPHS grant award R29-NS29283).

FATES OF CORTICAL AND CEREBELLAR PROGENITOR CELLS TRANSPLANTED INTO THE NEONATAL SUBVENTRICULAR ZONE. T. Zigova*[1], R. Betarbet[1,2], R.A.E. Bakay[2] and M.B. Luskin[1]. [1]Depts. of Anat. and Cell Biology & [2] Neurosurgery, Emory Univ. School of Medicine , Atlanta, GA 30322.

Our studies have shown that cells derived from the anterior part of the neonatal subventricular zone (SVZa) are destined to become interneurons of the olfactory bulb (OB). The migration of SVZa-derived neurons to the OB does not appear to be guided by radial glia, although SVZa-derived neurons traverse a stereotypical path to the middle of the OB. Upon reaching the OB they ascend radially into one of overlying cellular layers. Recently, we have demonstrated that homotopically transplanted SVZa-derived cells adopt a spatio-temporal pattern of migration that is indistinguishable from that ordinarily used by SVZa-derived neurons. Here we investigated whether newly-generated neurons, which usually migrate along radial glia, can navigate the highly restricted path adhered to by SVZa-derived cells. Dissociated cells from the ventricular zone (VZ) of the embryonic day 16 or 17 rat telencephalon or from the external granule cell layer (egl) of the postnatal day 5 (P5) or P6 cerebellum, were labeled with either the cell proliferation marker BrdU or the fluorescent lipophilic dye PHK26 and stereotaxically implanted into the SVZa of P0-P2 rats. We found that heterotopically engrafted VZ cells, remained at the site of injection in the host SVZa. In contrast, heterotopically transplanted egl cells traversed the migratory pathway, although most did not migrate away from the middle of the OB. These results suggest that cells of different origins have varying abilities to decipher the guidance cues associated with the migratory pathway of SVZa-derived cells. Supported by NIH and March of Dimes.

MAINTAINED NEUROTROPIC SPECIFICITY IN RECONSTRUCTION OF THE ADULT CNS BY NEURAL TRANSPLANTS O. Isacson*, T.W. Deacon, W.R. Galpern, L.H. Burns, I. Dinsmore[1], P. Pakzaban Neuroregeneration Laboratory, McLean Hospital, Belmont, MA 02178, Department of Neurology and Program in Neuroscience, Harvard Medical School and (1) Diacrin, Charlestown, MA.

Neuron-target interactions during normal development of the mammalian CNS follow phenotypic and species determined cellular schedules. This order may suggest that developmental timing is essential for correct growth of the maturing CNS. To determine the capacity of fetal neural tissue to interact with the adult CNS in heterochronic circuitry reconstruction, fetal porcine striatal (LGE) or ventral mesencephalic (VM) cells were transplanted into ectopic or homotopic sites of immunosuppressed adult rats. Grafts developed and stained for a pig-specific neurofilament marker (70 kD neurofilament; NF70), a pig-specific astroglial cell marker (CD44) and other graft and host specific markers. LGE cell implants placed in the adult lesioned striatum grew axons into white-matter tracts with anatomically appropriate projections into gray matter striatal target-zones, globus pallidus, entopeduncular nucleus and substantia nigra pars reticulata. CD44-immunoreactive graft glial cells extended long fibers into host white matter tracts, but not into gray matter target-zones. VM grafts placed ectopically in striatum grew TH+ dopaminergic axons directly into striatal gray matter but not into white matter tracts. Conversely, NF70 staining demonstrated that non-dopaminergic neurons from such VM cell grafts projected specifically to gray matter zones of thalamic ventral anterior/ventral lateral, centrolateral , parafascicular and mediodorsal nuclei, consistent with projection patterns of neuronal phenotypes normally found in substantia nigra pars reticulata and deep mesencephalic nuclei. Axons from fetal VM cells placed in mesencephalon also projected to these host targets. Our findings indicate that neurotropic signalling for anatomic specificity seen during development is maintained over long-distances also in the mature CNS.

691.11

NEUROTROPHIN AND TRK RECEPTOR UPREGULATION IN REGIONS OF TARGETED NEOCORTICAL CELL DEATH COINCIDES WITH DIRECTED MIGRATION AND DIFFERENTIATION OF TRANSPLANTED NEURAL PRECURSORS. Y. Z. Wang* and J. D. Macklis. Dept. of Neurology & Prog. in Neuroscience, Harvard Medical School, Children's Hospital, Boston, MA, 02115

Transplanted embryonic neocortical neurons and clonal, multipotent neural precursors undergo directed migration and differentiation that is sharply limited to regions of targeted photolysis in mice, in which pyramidal neurons undergo apoptotic degeneration. To investigate the mechanisms of microenvironmental alteration underlying this directed migration and differentiation that occurs approximately 4-21 days after initiation of neuronal degeneration, we examined the gene expression of neurotrophic factors and trk receptors in geographically defined regions undergoing targeted apoptosis. We compared these regions to control regions in intact mice and to control regions adjacent to the targeted areas. Pyramidal neurons in C57B/6J mice were retrogradely targeted with photoactive nanospheres and noninvasively activated at 4 weeks of age to initiate apoptotic degeneration in lamina II/III of neocortex. We examined the experimental and control regions for mRNA levels of NGF, BDNF, NT-3, NT-4/5 and trkA, B, C by Northern blot analysis. BDNF, NT-3, NT-4/5 and trkB were specifically induced over the period of ongoing apoptosis in the experimental regions. TrkB mRNA increased earliest, with a maximum at 3 days and reduction rapidly after 6 days. Induction of BDNF mRNA began at 1 day with maximal induction at 6 days, then gradual decrease to control levels 21 days after initiation of cell death. NT-3 and NT-4/5 mRNAs were upregulated between 1 and 8 days after initiation. NGF and trkA, C mRNAs were not altered. Control regions from intact and experimental mice showed no mRNA upregulation. These findings suggest that the induction of BDNF, NT-3, NT-4/5 and trkB mRNAs are specific molecular effects of targeted apoptosis that may partially underlie developmentally appropriate cellular behavior in regions of photolytic degeneration in adult mice. Further characterization and cellular localization may provide insight regarding signaling pathways responsible for neuronal migration and differentiation during development, and toward potentially therapeutic neural precursor transplantation.

EVIDENCE SUGGESTING MIGRATION OF HOST NEURONS INTO FETAL ANTERIOR HYPOTHALAMIC GRAFTS. M.N. Lehman', J. LeSauter, C. Kim, and R. Silver. Dept. Cell Biol., Neurobiol. & Anat., Univ. Cincinnati Coll. Med., Cincinnati, OH 45267; Dept. Psychol., Barnard Coll., New York, NY 10027.

Recent work has demonstrated that migration of neuronal precursors continues in the adult mammalian brain (Lois & Alvarez-Buylla, Science, 264:1145, 1994). While studying intraventricular fetal anterior hypothalamic (AH) grafts, we have found surprising evidence suggesting that a subset of adult host neurons, or their progenitors, migrate into these grafts. Fetal (E15) hamster AH tissue was implanted into the third ventricle of immunosuppressed adult, SCN-intact rats (n=9). Graft recipients were perfused after 2 weeks and every fourth brain section (50 μm) was immunostained using a neurofilament (NF) antibody (RMO 108, gift of Dr. V. Lee) that recognizes rat but not hamster NF. AH grafts in 6 of 9 recipients were robust and viable, and 5 of these showed substantial fiber ingrowth from the host, specifically from attachment sites along the dorsal and lateral edges of the third ventricle. In addition, within each of these grafts, large (20-30 μm soma diameter) neurons of presumptive host origin were seen in association with host fibers. Sections from each graft contained between 3-15 host neurons; some cells were located 250-300 μm from the graft-host border. The migration of adult neurons, or their precursors, into fetal grafts may represent a previously unsuspected aspect of potential plasticity in the adult brain. Whether this is dependent on the source of fetal tissue or its site of implantation is not known. Experiments are underway to determine whether this phenomenon is unique to xenografts, perhaps reflecting the absence of species-specific inhibitory signals, or a general feature of homografts as well. Supported by NIH NS28175 (MNL) and NS 24292 (RS).

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS V

692.1

CORTICAL CONNECTIONS FROM PHYSIOLOGICALLY DEFINED NUCLEI OF THE SOMATOSENSORY THALAMUS OF MACAQUE MONKEYS. L.A. Krubitzer[1]*, S.L. Florence[2], N. Jain[2], and J.H. Kaas[2] [1]University of Queensland, Australia; [1]University of California, Davis, CA; [2]Vanderbilt University, Nashville, TN.

We examined the topographic organization of thalamic nuclei that project to somatosensory cortical fields in macaque monkeys. Electrophysiologically identified representations in anterior parietal fields 3a, 3b (SI), 1 and 2 were injected with retrograde tracers, then at the time of sacrifice the somatosensory thalamus was mapped using multiunit recording techniques. Tracers were placed either into representations of the same body part in different cortical fields or into different body part representations of the same cortical field. Results indicate that the ventral posterior nucleus, ventral posterior inferior nucleus, ventral posterior superior nucleus and ventral lateral nucleus contain separate complete representations of the body surface, and are distinguished by different response properties, stimulus preferences, architecture, and thalamocortical connections. Projections from the thalamus to electrophysiologically identified representations in cortex were both divergent and convergent, and projections to body part representations within a cortical field were not strictly homotopic. Such heterogeneous projections may provide the anatomical substrate for somatosensory cortical plasticity in adult primates after peripheral denervations.

692.2

HUMAN THALAMIC NEURONS RECEIVE SUBLIMINAL INPUT FROM REGIONS THAT ARE ADJACENT TO THEIR NATURAL MECHANICAL RECEPTIVE FIELDS. Z.H.T. Kiss*, K.D. Davis, R.R. Tasker, A.M. Lozano, J.O. Dostrovsky. Departments of Surgery and Physiology, University of Toronto, Toronto, Ontario, Canada.

Acute deafferentation has been shown to cause rapid alterations in neuronal receptive fields (RFs) in the human thalamus. The RFs of tactile neurons tend to shift/expand into regions immediately adjacent to those of the original RFs, when input from the original RF is eliminated. The aim of this study was to test the hypothesis that thalamic neurons receive subliminal inputs from regions adjacent to their receptive fields, as such inputs might form the basis for the deafferentation-induced effects.

During stereotactic thalamic exploration in patients being treated for pain or tremor, microelectrode recording identified neurons responsive to mechanical stimuli delivered to small RFs on the hand. In 10 patients, the effects of electrical stimulation (ES; bi- or monopolar, 0.5 ms pulse width, 1-10 Hz) delivered within and outside the RF was examined. Eleven of 23 cells were excited by ES within the RF and post-stimulus time histograms demonstrated a latency to activation of 22.3±2.5 ms (mean±SD). Of the 51 sites tested with ES outside the RF, 8 cells at 14 different sites responded with a latency of 40.8±14.5 ms. ES both within and outside the RFs was also found to produce inhibition 22-57 ms after the ES.

Latency of activation of human Vc neurons from outside the RF is significantly longer ($p<0.02$) than latency from within the RF, suggesting mediation by indirect polysynaptic pathways. These data also constitute the first direct demonstration of inhibitory inputs to human Vc tactile neurons. The results suggest that subliminal inputs may be important in mediating thalamic and cortical plasticity.

OCCUPATIONAL HAND CRAMPS GENESIS PARALLED BY DEGRADATION OF REPRESENTATION IN THE SI CORTEX
N.N.Byl, M.M.Merzenich*, W.M. Jenkins Keck Center for Integrative Neurosciences University of California, San Francisco, CA 94122

Repetitive, sustained gripping under conditions of high force, vibration and/or end range motion is associated with a task specific loss of voluntary control referred to as occupational hand cramps or focal dystonia of the hand. Etiology of this disorder is poorly understood; treatment success is limited. This study was designed to measure behavioral and neurological consequences of repetitive, sustained gripping with a vibrotactile stimulus. Adult owl monkeys were trained to sustain a hand grasp with 80 gms of force and a 250 Hz vibration for 1.5 sec/reward. Monkeys performed several hundred repetitions/day. In time:1) a tremor developed in grasping/ releasing the handpiece; 2) the speed of task performance declined; 3) weakness in closing the hand emerged; 4) increased task errors were recorded; and 5) difficulties emerged in other hand retrieval tasks. Compared to the control side, the representation of the trained hand in Area 3b was substantially degraded: 1) the size of the cortical hand and digit representations were reduced from normal; 2) receptive fields were, on average, many times larger than normal; 3) in the majority of cortical penetrations, neurons had multiple receptive fields extended across entire fingers or multiple digits; 4) in contrast to normal, neurons at many sampled sites had pacinian-like responses that covered much or all of the glabrous hand surface; 5) many large receptive fields extended over large sectors of both the volar glabrous and dorsal hairy hand surfaces; 6) receptive fields overlapped with each other over very long cortical distances; and 7) digit representations were geographically disorganized. We hypothesize that profound, experience-driven change in the quality of differentiated sensory feedback must contribute to the loss of movement control that marks the emergent focal dystonia. Human and monkey studies are now being directed toward determining how sensory learning could be implemented to re-differentiate cortical representational topographies, and restore normal motor control.

DEPLETION OF BRAIN SEROTONIN DOES NOT IMPAIR PLASTICITY OF FUNCTIONAL REPRESENTATION OF VIBRISSAE IN RAT BARREL CORTEX. M.Kossut*, K. Turlejski, R.Djavadian Dept. of Neurophysiology, Nencki Institute, Warsaw, Poland.

Serotonin influences development of somatosensory cortex in rat (Bennet-Clarke et al., 1994) and the blockade of 5HT receptors impairs developmental plasticity of the visual cortex (Gu and Singer, 1991). We examined the effects of 5HT depletion upon plasticity of cortical representation of a row of vibrissae (visualized with 2DG) evoked by neonatal lesions of vibrissal follicles in hooded rats. On the day of birth pups were pretreated with desipramine HCl and one hour later received injection of 5,7 DHT. In one group unilateral vibrissectomy sparing row C was also performed. Serotonin immunostaining at the age of six weeks revealed that in rats injected with 5,7 DHT 70-90% of serotonergic fibers in the cortex were missing. 2-deoxyglucose (2DG) mapping of the row C representation was done on remaining rats. The vibrissae were clipped on both sides with the exception of row C, the rats were injected with C^{14} 2DG and the rows C on both sides were stimulated. Autoradiograms of brain sections cut tangentially to the barrel field were processed with an image analyzer and the sections were Nissl stained. Measurements of the size of barrels on the intact side showed that their linear dimensions in the 5HT depleted rats were 5-10% smaller than in untreated littermates. More than two-fold increase of the 2DG labeled cortical representation of row C was found in both control and 5HT depleted rats. Thus neonatal vibrissectomy resulted in very large increase of cortical representation of the spared row C despite destruction of serotonergic axons.

OPTICAL IMAGING OF HAND REPRESENTATION IN PRIMATE AREA S1. D. Shoham*, D. Glaser and A. Grinvald. The Weizmann Inst. of Science, Rehovot 76100, Israel.

High resolution maps of cortical function organization *in-vivo* has both scientific and clinical importance. Optical imaging of intrinsic signals is particularly suited for this purpose. We are reporting here the first application of this method to the study of the primate somatosensory cortex.

Using mechanical tactile stimulation, we mapped the somatotopic representation of the hand in Macaque monkey area S1. The stimuli consisted of air-pressure pulses applied to various locations on the hand simultaneously. The skin was displaced either by using small flexible transducing membranes, or by fine, directed jets of air. We explored the effects of stimuli with different temporal properties, varying the number of pulses, pulse duration and inter-pulse intervals. In addition we looked at the effect of changing the air-pressure.

Using this stimulation method, we were able to see the cortical representation of each individual finger. In the maps we obtained, stimulation of each finger activated a narrow band running across the post-central gyrus. As expected, these stripes were ordered continuously along the gyrus. We also mapped responses to stimulation of the skin of the glabrous pads and of the forearm. The optical maps were confirmed by extensive multi and single unit recordings. All maps remained very stable over many hours of recording. Thus, it should be possible to use this method to reliably explore plasticity of the digit representation.

By optimizing the stimulus parameters, we were able to obtain the functional maps extremely rapidly. Averaging the responses to a very small number (~4) of stimulations was sufficient to produce clear maps. Thus, maps of the five digits could be obtained in as little as five minutes. This rapidity allowed us to apply this method for mapping functional borders in humans undergoing neurosurgery. In a hospital study we managed to localize the central sulcus and map the border of the hand representation in the somatosensory cortex. MINIMAL EXTENT OF VENTROPOSTERIOR LATERAL NUCLEUS OF THALAMUS CAPABLE OF MAINTAINING A SOMATOTOPIC MAP IN AREA 3b. P.R. Manger, T.M. Woods, E. Rausell* & E.G. Jones. Dept. Anatomy and Neurobiology, Univ. of California Irvine, Irvine, CA 92717

The inputs to the VPL thalamus from the dorsal column nuclei, and the projections from the thalamus to the somatosensory cortex, especially area 3b, show a high degree of somatotopic precision. Individual cells in VPL, however, show considerable divergence and overlap in their cortical projections (Rausell & Jones, J. Neurosci.: in press). We asked to what extent can this divergence maintain a map in area 3b in the face of diminishing numbers of VPL cells. Portions of VPL were electrolytically lesioned following physiological identification, and after two weeks, the body representation in area 3b was electrophysiologically mapped. The lesions involved up to 80% of VPL. Behavioral deficits included lack of appreciation of light tactile and proprioceptive stimuli, mainly in the contralateral hand. Reconstructions of the multiunit recorded cortical maps made after two weeks showed no apparent change in the somatotopic map of area 3b, even after the most extensive of the VPL lesions. Other cortical areas were not investigated. The preservation of even a few rod like bundles of cells of similar somatotopy within VPL may account for the maintained cortical map. If a small portion of the rod remains, the divergent connections may be sufficient to maintain the cortical map. However, the observed behavioral deficits suggest that the lesioned monkeys had problems with perception of stimuli. Further to this, the multiple inputs into area 3b, from other thalamic nuclei, callosal connections, and pain pathways, may also contribute to the maintenance of the cortical map despite the lack of a primary input.

LOCAL CHANGES IN GENE EXPRESSION FOR GAD, $GABA_A$ RECEPTOR SUBUNITS AND CAM II KINASE IN SOMATOSENSORY CORTEX IN MONKEYS WITH VENTROBASAL THALAMIC LESIONS. T.M. Woods*, P.R. Manger, E. Rausell & E.G. Jones. Dept. Anatomy and Neurobiology, Univ. California Irvine, Irvine, CA 92717.

The ventrobasal complex of the monkey thalamus (VB) sends axons to ipsilateral postcentral gyrus in an ordered fashion. Recent evidence indicates that these thalamocortical projections exhibit substantial divergence and overlap (Rausell and Jones, J. Neurosci.: in press). This study addresses the issue of the extent to which this divergence can maintain a normal pattern of gene expression for molecules involved in plasticity of area 3b maps in the presence of reduced VB input. Lesions of varying extent were made in parts of the VB representation defined by multiunit mapping. After one or two weeks, the thalamus and somatosensory cortex were sectioned and hybridized with radioactive cRNA probes for glutamic acid decarboxylase (GAD), calcium/calmodulin dependent protein kinase α (CAMIIKα) and $\alpha 1$, $\beta 2$ and $\gamma 2$ subunits of the $GABA_A$ receptor subunit mRNAs, or stained immunocytochemically for GABA, GABA receptor subunits, CAMIIKα and parvalbumin. In general, the presence of a remaining portion of a VB representation was sufficient to maintain a normal pattern of gene expression, local changes only occurring in cortex with the largest lesions. Divergent connections, therefore, maintain sufficient activity to support a normal balance of inhibition and excitation in cortex.

A ROLE FOR ASTROCYTES IN CORTICAL REORGANIZATIONAL PLASTICITY? F. Conti*, A. Minelli, and T.P. Pons°. Inst. Hum. Physiol., Univ of Ancona, I-60131 Ancona, Italy, and °Dept of Neurosurg., Bowman Gray School of Medicine, Winston-Salem, NC 27157, USA.

What triggers the mechanisms that determine cortical reorganization is poorly understood. Since the expression of transmitters is regulated by activity, it is possible that changes in transmitter levels could be such a triggering event. In this study, antibodies to glutamate (Glu) were used to study the effects of reduced afferent input on cortical excitatory neurons in adult monkeys subjected to somatosensory deprivation by cutting the three nerves to the hand.

In the cervical SC, DCN, VP thalamus and first somatic sensory cortex, Glu-immunoreactivity (Glu-ir) was similar to that described in normal animals; regions with reduced or absent Glu-ir were never observed and no appreciable differences were noted between the lesioned and normal side. No changes were observed in sections processed for CO or in thionin-stained sections. In the insulo-parietal operculum, sections contralateral to the nerve cut showed that most cortical fields had a normal pattern of Glu-ir (pattern *a*), some exhibited a reduction (pattern *b*), and that in the central portion of the upper bank of the central sulcus, which corresponds to the hand representation of the second somatic sensory cortex (SII), Glu-ir had virtually disappeared (pattern *c*). Adjacent sections processed for CO or stained with thionin showed that in the regions corresponding to those characterized by pattern *c*, CO slightly decreased and astrocytic proliferation was observed. Cortical regions characterized by pattern *c* also revealed that in the hand representation of SII, small-sized, intensely stained cells with processes radiating in all directions, which proved to be astrocytes, displayed Glu-ir.

As in previous studies, our findings indicate that Glu-ir is regulated by afferent activity. Additionally, changes in astrocytic Glu levels in the reorganizing cortex suggest a role for neuron-astrocyte/astrocyte-neuron signaling in the reorganization process. Such regulation of Glu levels in astrocytes and neurons may act as trigger for the biochemical changes underlying the structural metamorphosis occuring during a slow phase of reorganizational plasticity in the cerebral cortex.

LACK OF EXPRESSION OF $GABA_A$ RECEPTOR SUBUNIT mRNAs IN RETICULAR NUCLEUS OF THALAMUS. M. M. Huntsman* and E. G. Jones. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

The major fast inhibitory neurotransmitter receptor in the central nervous system, the $GABA_A$ receptor, contains binding sites for multiple ligands. The diversity of the receptor is dependent upon combinations of multiple subunits that make up a given stoichiometry that is reflected in the affinities displayed by each ligand. The receptor is a pentameric array formed potentially from at least 15 subunit polypeptides derived from individual genes with varying degrees of sequence identity organized into classes (e.g., α, β, γ, δ, ρ) and into class variants (e.g., α_1, α_2, α_3, α_4, α_5, α_6). Transfection of the α genes into cell lines or oocytes yields varying degrees of affinities for benzodiazepines in which strong affinity binding characterizes $\alpha 1$ and lower affinity binding $\alpha 2$-$\alpha 6$. cDNAs for the α_1, α_2, α_3, α_4, α_5, β_1, β_2, β_3, γ_1 and γ_2 subunits were subcloned from monkey total RNA, amplified via the polymerase chain reaction and inserted into the pBS transcription vector for the localization of ^{33}P-labeled RNA transcripts in sections of the thalamus. In situ hybridization of transcripts encoding individual subunit genes yielded a wide array of expression patterns throughout the monkey thalamus in which certain transcripts are expressed in a nucleus specific manner. In the reticular nucleus, most transcripts including α_1 and β_2, typically expressed at high levels in other nuclei, were not expressed although reticular neurons possess bicuculline sensitive $GABA_A$ receptors. Only the γ_2 transcripts showed detectable hybridization in the reticular nucleus. The presence of γ_2 subunit mRNAs without α subunits is interesting in light of its involvement in affinity enhancement for benzodiazepines and suggests the existence of novel subunits in this nucleus. SPATIAL ATTENTION PROTECTS MACAQUE V2 AND V4 CELLS FROM THE INFLUENCE OF NON-ATTENDED STIMULI.

J.Reynolds, J.Nicholas, L.Chelazzi*, R.Desimone. Laboratory of Neuropsychology, NIMH, Bethesda, MD and University of Verona, Italy.

Last year we reported that spatial attention isolates cells in macaque area V2 from the influence of nearby, non-attended stimuli. In passive viewing, the response to a single flashing bar within the receptive field is often suppressed by a second, nearby flashing bar. However, when attention is directed to the location of the first stimulus, the suppression caused by the second stimulus is filtered out, and the cell responds as though the second stimulus were absent.

Our present results show that a related attentional process is at work in macaque area V4. As in V2, we found that the response to a single flashing bar within the receptive field is typically suppressed by the presence of a nearby, synchronous flashing bar. As in V2, this suppression is filtered out when attention is directed to the first flashing bar.

We have also recorded V2 responses when the flashing bar is presented against a variety of large bit-mapped "real world" images. The real world images typically activated the cells in a sustained fashion, but also suppressed responses to the bar. Attending to the flashing bar filtered out some, but not all of the sensory interactions resulting from these more complex stimuli.

693.2

TWO-DIMENSIONAL MAPS OF SPATIAL ATTENTION EFFECTS IN MACAQUE AREA V4.

C.E. Connor*, D.C. Preddie, J.L. Gallant and D.C. VanEssen. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

We have shown previously that responses in macaque area V4 depend on both the distance and direction of attention relative to the stimulus in the receptive field (Connor et al., *Soc. Neurosci. Abstr.* **19**: 974 (1993); Connor et al., *Soc. Neurosci. Abstr.* **20**: 1054 (1994)). Responses are generally stronger for stimuli near the attentional focus, and a majority of cells are tuned for direction. The optimal direction of attention (e.g., left, right, above, or below the stimulus in the receptive field) varies between cells. We designed a new experiment to map these directional attention effects in greater detail.

The monkey fixated a spot on a video monitor while a set of 12 ring-shaped stimuli was presented in a square array surrounding the classical receptive field of the cell under study. On a given trial the animal was required to attend continuously to just one of these rings and signal when it changed shape. Meanwhile the cell's response was tested by flashing 3 bars of optimal orientation, width and color spanning the central 50% of the classical receptive field. A majority of the cells tested in area V4 showed a significant effect of attention position in this paradigm. Spatial tuning for attention position was typically broad, with most cells showing greater than half maximal responses across at least a quadrant of the mapped region. The results provide further evidence that area V4 processes information about the positional relationship between the stimulus driving the cell and the current focus of attention.

693.3

TIME COURSE OF ATTENTIONAL EFFECTS IN MACAQUE AREA V4.

D.C. Preddie, C.E. Connor, J.L. Gallant* and D.C. Van Essen. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Recent experiments have shown that attentional effects on single cells in macaque area V4 include a shift in response strength towards the locus of attention and a change in overall response strength depending on the direction of attention (Connor et al., *Soc. Neurosci. Abstr.* **19**: 974 (1993); Connor et al., *Soc. Neurosci. Abstr.* **20**: 1054 (1994)). We designed a behavioral paradigm to assess the time course of these effects when attention is suddenly shifted. A macaque monkey was trained to attend to one stimulus (a ring) as part of a shape discrimination task, while a second, unattended stimulus (a bar) was used to map neural response profiles. Each trial began with the simultaneous onset of the fixation point, a probe (bar) stimulus in one of five positions within the classical receptive field (CRF) and a field of rings positioned outside the CRF. After a 1 sec delay the attended ring was cued via a brief (100 msec) blink at one of four positions surrounding the CRF. The animal was required to continuously monitor the attended ring and to release a response lever when, after a variable time interval, the ring became C-shaped.

Of 27 cells recorded thus far in one rhesus monkey, 10 showed a significant ($p < 0.02$) shift effect and 10 showed a significant directional effect. To determine the temporal profile of these effects, we analyzed the average responses in each group of cells. The shift effect began to develop at around 50-100 msec and peaked at about 200 msec following the attentional cue. In contrast, the directional effect developed more slowly, starting at about 200 msec and reaching a plateau 400-500 msec after the cue. These results suggest that the neural events underlying spatial shifts of attention occur rapidly, while information about the positional relationship between stimuli and attention evolves more slowly.

693.4

NEURAL CORRELATES OF TARGET DETECTION DURING VISUAL SEARCH IN AREA MT.

Giedrius T. Buracas* and Thomas D. Albright. VCL, The Salk Institute, P.O.Box 85800, San Diego, CA 92186.

Focal attention has been shown to play a central role in perception of complex objects. Visual search is a psychophysical paradigm traditionally used to explore the dynamics and mechanisms of focal visual attention. Using this paradigm we have previously shown that both humans and rhesus monkeys exhibit serial search for targets defined by a conjunction of color and direction of motion, i.e., search times depend linearly on the number of distractors in a search array (Buracas and Albright, 1994, *Soc.Neurosci.Abs*, **20-1**, p.318). This linear dependency is commonly accepted as evidence for dynamical and voluntary allocation of focal attention.

Using an identical search paradigm, we have now explored neurophysiological correlates of focal attention in rhesus monkeys. Specifically, we have recorded responses of directionally selective neurons in area MT of a monkey engaged in a visual search task. The search target was formed by a unique conjunction of color (red or green) and direction of motion (preferred or null direction for neuron under study) of a texture inside a circular aperture. The target for each trial was specified by a sample presented prior to the search array. The latter was composed of eight apertures defined by all possible combinations of selected color and direction. The monkey was required to saccade to the target upon detection, or to maintain central fixation on target-absent trials. Approximately 40% of MT neurons exhibited significant response modulation when the search target was positioned within the receptive field. This modulation was expressed as an enhancement (~30% of the predicted baseline) of the neuronal response prior (90-200 ms) to a saccade to the target. The time course of the neuronal response modulation thus parallels behavioral target detection. The sign of the modulation is consistent with the process of target selection and may reflect the engagement of an attentional mechanism.

THE INFLUENCE OF ATTENTION AND INTENDED EYE MOVEMENTS ON THE VISUAL EXCITABILITY OF NEURONS IN THE LATERAL INTRAPARIETAL AREA OF MACAQUE MONKEYS

J-R. Duhamel*, S. Ben Hamed, F. Bremmer and W. Graf C.N.R.S.-Collège de France, F-75292 Paris Cedex 06, France.

Visual activity of neurons in the monkey lateral intraparietal area (LIP) is influenced by the direction of attention and by eye movements. To understand better how these contribute to spatial processing, we investigated the tuning of LIP neurons to visual stimulation. Single cell responses were recorded extracellularly in one rhesus monkey (*Macaca mulatta*) under three different conditions: (1) during a fixation task in which the monkey attended to a small foveal stimulus and released a hand-held bar when the color of this stimulus changed at an unpredictable time, (2) during the delay period of a memory-guided saccade task (e.g. between the presentation of a brief peripheral target and the beginning of the saccadic eye movement), and (3) during spontaneous gaze without fixation or saccade targets.

Under all conditions, the visual excitability of the recorded neurons was assessed by presenting randomized sequences of test flashes (100 msec) at a rapid rate (100-250 msec interval) during periods of stable eye position. This enabled the sampling of a large number of locations within a 80° by 80° portion of the visual field, and the subsequent generation of surface plots for a given cell's receptive field (RF). Many LIP neurons displayed graded responses with a maximum at the center of the RF, decreasing toward the periphery. In some cells, the area of excitability was quite restricted and had sharp borders. In other cells, the RF had a complex surface with both excitatory and inhibitory zones. The state and direction of visual attention had an effect on overall responsiveness but also influenced different characteristics of the RF configuration such as sharpness of spatial tuning, and center of gravity. This indicates that the encoding of visual space by parietal visual neurons is strongly linked to the behavioral context.

693.6

ATTENTIONAL MODULATION OF DIRECTION-SELECTIVE RESPONSES IN THE SUPERIOR TEMPORAL SULCUS OF THE MACAQUE MONKEY.

S. Treue* and J.H.R. Maunsell Baylor College of Medicine, Houston, TX

We recorded from over 50 direction-selective cells in the superior temporal sulcus of a macaque monkey performing a reaction-time task to investigate the role of attention in the processing of motion signals. The monkey was trained to attend a moving spot (the target) in the presence of one or more other moving spots (distractors) while maintaining fixation on a stationary fixation cross. In the first experiment one spot moved through the receptive field (RF) in the preferred direction while another spot moved outside the RF. Even though retinal stimulation was identical in both trial types a large majority of the cells (~85%) responded more strongly when the animal was instructed to attend to the stimulus within the RF, compared to trials on which he was attending the stimulus outside the RF (median increase 30%). In the second experiment both spots moved through the RF, but in opposite directions (preferred and anti-preferred direction of the neuron). Allmost all cells (~90%) responded more strongly when the monkey was instructed to attend to the stimulus moving in the preferred direction, compared to trials in which he was attending the spot moving in the anti-preferred direction (median increase 150%). This result cannot be accounted for by shrinking receptive fields since it held true even when the two dots passed by each other very closely.

Our results demonstrate that while moving attention away from the receptive field will reduce a neuron's response to its preferred stimulus a much stronger effect can be observed when attention is switched between two stimuli that both fall within the receptive field. In that case the response of the neuron is strongly biased by the direction of motion of the attended stimulus even when the unattended stimulus is a more potent sensory stimulus. These findings are amongst the strongest extraretinal modulations of neural signals found in visual cortex to date and suggest an important role for attention in selectively enhancing neural signals related to stimuli of interest.

DISTINGUISHING CORTICAL AREAS THAT ARE SENSITIVE TO TASK AND STIMULUS VARIABLES WITH FMRI E.A. DeYoe*, P.W. Schmit, & J. Neitz Dept. Cell. Bio., Med. Col. Wisconsin, Milwaukee, WI (Email: edeyoe@its.mcw.edu)

Purpose. Functional MRI was used to study the effects of a) stimulus presentation rate and b) task requirements on cortical activation induced by a visual stimulus. **Methods**. During gradient-recalled, echo-planar FMRI, 3 subjects viewed a flickering checkered annulus under two task conditions: 1) passive viewing and 2) active target discrimination. Single stimulus presentations lasted 0.5 sec, and were repeated at 4 different rates (from 0.2 to 2 per second) in blocks (trials) of 24 seconds each. For each voxel, FMRI response amplitudes were extracted for the different presentation rates and curve-fit by linear regression. Histograms of regression line slope revealed two asymmetric peaks. Voxels whose response increased with presentation rate were classified as rate dependent while those with constant response were classified as rate independent. **Results**. Voxels in V1 and several extrastriate visual areas showed strong stimulus rate dependence in both task conditions. However during passive viewing, stimuli had to be presented nearly twice as fast as during active viewing to achieve the same response magnitude in V1. Such differences were even larger for extrastriate visual areas. In frontal cortex, results were distinctly different. The response was rate independent during active viewing, while under passive viewing there was little or no response. **Conclusions**. Stimulus rate-dependence may provide a method for distinguishing areas of the brain serving task-related functions such as attention from those areas primarily concerned with processing of visual information. Supported by NIH grants EY10244, and Core Grant EY01931.

FMRI REVEALS FEATURE-SPECIFIC ATTENTIONAL MODULATION OF AREA MT, V3/V3a AND PARIETAL VISUAL AREAS. Michael S. Beauchamp* and Edgar A. DeYoe Dept. Cell Biology & Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226 (mbeaucha@mcw.edu)

Visual stimuli consisting of motion-defined figures were used to study human visual areas important for motion perception. Attention to different stimulus features served as a powerful modulator of activation. In the attention-to-motion condition, subjects made a discrimination based on slightly different point speeds in the left and right halves of the figure. In the attention-to-luminance condition, subjects responded to slight luminance increments and decrements of the fixation point. The identical visual stimulus was presented in both conditions, consisting of a phasically displayed (5 on/off cycles) annulus defined by the coherent motion of its component points on a continuously displayed background of equally-distributed incoherently moving points with a varying luminance fixation point. Visual stimuli were generated with a PC-based graphics system and projected through a Maxwellian-view optical system, allowing a 60 degree field-of view, while whole-brain echo planar images were collected with a custom head coil in a 1.5 T scanner with voxel size 56 25 mm^3 (3.75x3.75x4 mm.)

When subjects performed the attention-to-motion task, the higher visual areas specialized for motion processing which presumably make explicit the presence of the motion-defined annulus were strongly activated. Putative human visual area MT (hMT) showed consistent activation (volume of activation 16 ± 6 voxels, mean ± SD, n=4) as did visual area V3 (12 ± 4 voxels.) Several parietal areas were also activated in the attention-to-motion condition (84 ± 23 voxels.) When subjects viewed the identical stimulus in the attention-to-luminance condition, the area of activation was sharply reduced. hMT fell 98% to 0.3 ± 0.5 voxels, V3 fell 94% to 0.8 ± 1.5 voxels and parietal areas were reduced by 93% to 6 ± 13 voxels. Primary visual cortex responded similarly to the random points whether they were moving coherently or incoherently, resulting in relatively little phasic response in either attentional condition (attention-to-motion: 8 ± 4 voxels, attention-to-luminance: 1 ± 2 voxels.) COMBINED fMRI, EEG AND MEG IMAGING OF VISUAL ATTENTION

M Huotilainen1, SP Ahlfors2, HJ Aronen3, AM Dale4, JJ Foxe2, RJ Ilmoniemi5, WA Kennedy6, A Korvenoja3, AK Liu6, R Näätänen1, BR Rosen6, GV Simpson2, C-G Standertskjöld-Nordenstam3, RBH Tootell6, J Virtanen1, and JW Belliveau6*
1Cognitive Brain Research Unit, Univ. of Helsinki, Finland, 2Albert Einstein College of Medicine, New York, 3Radiology, Helsinki Univ. Central Hospital, Finland, 4University of Oslo, Norway, 5BioMag laboratory, Helsinki Univ. Central Hospital, Finland. 6Massachusetts General Hospital, NMR Center, Charlestown MA.

The activation of human cortex was compared in four subjects using MEG, EEG and fMRI in visual selective attention experiments related to that of Corbetta et al. (J. Neurosci. 1991) . Event-related magnetic fields and electric potentials were compared to hemodynamic changes observed using functional MRI. The passive condition was to fixate on a cross and ignore the stimuli moving across the screen every 700 ms. In the color, orientation, and movement conditions, the subject saw the same stimuli, but the task was to attend to stimulus color, orientation, and movement direction, respectively. Movement-corrected fMRI data from each subject were registered and averaged in Talairach space. Multiple areas were differentially activated during the attended conditions, including extrastriate, parietal, dorsal lateral prefrontal and anterior cingulate cortices. Multiple and temporally overlapping sources were observed using MEG and EEG. In the passive condition, electromagnetic methods show activity in V1 and V2 areas, with latencies from 70 to 160 ms. Signal strength increases were observed across all modalities during the attended conditions, with attention to color giving the largest responses in this particular task. During the attend condition, fMRI, MEG and EEG suggest that the strength of these sources is modulated by attention.

REVERSIBLE VISUAL HEMINEGLECT IN THE CAT.

B. R. Payne*, S. G. Lomber, S. Geeraerts, E. Van der Gucht & E. Vandenbussche, Laboratory for Visual Perception and Cognition, Dept. of Anat. & Neurobiol., Boston Univ. Sch. of Med., Boston, MA 02118, & Catholic University of Leuven, B-3000 Leuven, Belgium.

Following unilateral damage of cortex at the temporo-occipito-parietal (TOP) junction, humans fail to notice and respond to stimuli that appear in visual space contralateral to the lesion. In cases of profound neglect, subjects neither detect nor orient head or eyes to stimuli appearing in the contralesional field. Similar, but less impressive, visual defects have been obtained following restricted unilateral lesions of TOP cortex in monkeys. We have identified a region at the TOP junction of the freely moving cat which, when cooled and inactivated unilaterally, results in a profound neglect of stimuli introduced into the contracooled hemifield. We also show that the severity of the defect matches that induced by unilateral cooling of the superior colliculus. The cortical region in the cat is located in the posterior one-half of the middle suprasylvian sulcus at the junction of areas believed to be equivalent to primate areas forming the V5 complex, and areas V4 and 7/39. The broad similarity of cooling induced- and lesion induced- neglect in cats, monkeys and humans suggests that there are largely equivalent circuits in all three species that likely include the superior colliculus. The link between TOP cortex and the orienting defect may be a useful fiduciary marker that will contribute to the identification of a number of extrastriate areas in the human brain, for which there are, as yet, very few markers. BASIS FUNCTIONS AND HEMINEGLECT A. Pouget*[1] and Sejnowski, T.J.[2]. [1]Brain Research Institute, UCLA and [2]Salk Institute, San Diego.

Cortical lesions in the parietal lobe of human produce a neurological syndrome called hemineglect, in which patients tend to ignore sensory stimuli in the hemispace contralateral to the lesion. Several studies attempted to determine the spatial frame of reference affected in visual neglect and found that it can be retinotopic, head-centered, body-centered, environment-centered, and in some cases, object-centered, all in the same patient.

We recently developed a theory of spatial representations in the parietal cortex based on the responses of single parietal neurons and the computational nature of sensorimotor transformations. The model assumes that parietal neurons encode their sensory inputs with basis functions (BF), a type of receptive fields that can be used to generate nonlinear motor commands. One of the important property of BF map is that the position of an object can be represented in several frames of reference simultaneously. We simulated a lesions of BF maps and found that, as observed in hemineglect, the resulting deficits affect multiple frames of reference, including object-centered. This model can also account for recovery from neglect that occurs over weeks and transiently after caloric vestibular stimulation. The model demonstrates that neglect can be explained without assuming the existence of explicit representations of cartesian space or object-centered representations. It relies instead on basis function maps biased for the contralateral side of space. This is, to our knowledge, the first account of hemineglect at the single cell level.

CENTRAL SENSITIZATION IN CHRONIC CENTRAL PAIN AFTER SPINAL CORD HEMISECTION. C.E. Hulsebosch*, M.D. Christensen, Y.B. Peng and W.D. Willis. Dept. of Anat. and Neurosci. and Marine Biomed. Inst., Univ. Texas Med. Br., Galveston, TX 77555-1069.

A model of chronic central pain after spinal cord injury (SCI) was used to document the temporal development of mechanical allodynia using validated models of nociceptive behavior. The same animals tested behaviorally were used to determine if dorsal horn neurons were more excitable to peripheral stimulation as evidenced by increased responses to brush, press, pinch, von Frey hair stimulation following spinal cord hemisection at T13. Electrophysiological recordings of wide dynamic range (WDR) neurons in the dorsal horn from L3-L5 were made both contralateral (n=25) and ipsilateral (n=25) to the hemisection. These data were compared to control values (n=32). The responses were recorded as spikes per second, before, during and after the application of these natural stimuli. The responses to brush, pinch and von Frey stimulation at 9.41mN were increased in the hemisected rats bilaterally and these increases were statistically significant compared to control values ($p<0.05$). These data support the development of central sensitization of WDR neurons and provide a mechanism for the observed behavioral changes in the development of mechanical allodynia after SCI. (Supported by NIH grants NS 11255, NS 09743 and the Kent Waldrep Foundation)

PERSISTENT, CHEMICAL NOCICEPTION IN THE RAT REQUIRES ONGOING PERIPHERAL NERVE INPUT. B.K. Taylor*, M.A. Peterson and A.I. Basbaum. Depts. Anatomy, Physiology, and W.M. Keck Foundation Center for Integrative Neurosciences, UCSF, San Francisco, CA.

Hindpaw injection of formalin produces acute (Phase 1) and persistent (Phase 2) nociceptive behaviors in the rat. This model has provided critical evidence supporting a contribution of central sensitization (hyperexcitability of spinal neurons) to the expression of persistent pain. Here, we evaluated the contribution of ongoing peripheral nerve inputs to Phase 2 pain responses. In addition to pain behavior (flinching), we measured formalin-evoked increases in arterial pressure and heart rate via an indwelling arterial catheter. All three measures displayed both phases of the formalin response. The arterial pressure response was highly correlated with behavior, and was dependent on formalin concentration (0.625 - 5.0%), indicating that it was largely driven by nociceptive input. Animals obtained from Charles River exhibited slightly, but significantly, larger Phase 2 flinching and heart rate responses compared to those from Bantin & Kingman. Lightly-anesthetized (0.7% halothane) rats exhibited robust increases in blood pressure, indicating that cardiovascular responses did not merely reflect somatomotor-cardiovascular coupling. We next evaluated the contribution of ongoing peripheral nerve activity to the expression of the Phase 2 pressor, tachycardia, and flinching responses. We locally-anesthetized the ipsilateral or contralateral (control) paw with a hydrophillic lidocaine derivative, QX-314 (2%) after Phase 1, but before Phase 2 began. QX-314 blocked Phase 2 pressor, tachycardia and behavioral responses only when injected into the paw that received formalin (2.5% or 10.0%). We conclude that ongoing activity from peripheral nerves is required for the persistent pain evoked by formalin. Supported by NS21445, DA 08377 and NS 07265.

RELATIONSHIP OF OPIOID RECEPTORS TO NEURONS IN NUCLEUS RAPHE MAGNUS (NRM) AND THE PERIAQUEDUCTAL GRAY MATTER (PAG) IN RATS AND MONKEY. M Wessendorf*, M Riedl, CN Honda, S Schnell, R Elde, and U Arvidsson. Dept Cell Biology and Neuroanatomy, Univ Minnesota, Minneapolis, MN 55455

Opiate analgesics may act in part by activation of neurons in PAG, which in turn activate spinally projecting neurons in brain stem regions such as NRM. In the present study, the relationship between delta and mu opioid receptors and PAG and NRM neurons was examined. Rats and one Rhesus macaque were deeply anesthetized and sacrificed by perfusion with 4% formaldehyde. Tissue sections were stained using antisera against N-terminal portions of the delta receptor and against the C-terminus of the mu-receptor. Both PAG and NRM in both rats and monkey were stained by antisera against both mu and delta receptors. However, in both species, delta antisera generally labeled fibers whereas the mu antiserum labeled cells. Spinally projecting NRM cells were retrogradely labeled in 3 rats and NRM sections were doubly stained for serotonin and delta receptors. When sections were examined by confocal microscopy, it was found that retrogradely labeled serotonin-stained cells were frequently apposed by varicosities positive for delta receptors.

These findings suggest immunocytochemical staining can localize opioid receptors in NRM and PAG of both rats and primate. In addition, they suggest that delta opioid receptors modulate the activity of afferents to raphe-spinal serotonergic neurons.

These studies were supported by DA 05466, DA 06299, and by the Minnesota Medical Foundation.

THE EFFECTS OF STIMULATION OF THE MEDIAL PREOPTIC NUCLEUS (MPO) ON PAG NEURONS AND BLOOD PRESSURE. M. M. Behbehani* T.M. Da Costa Gomez, M. Ennis and M.T.Shipley Dept. of Mol. and Cell. Physiology, U. of Cincinnati Cincinnati, OH 45267-0576 and Dept. of Anatomy, U. of Maryland at Baltimore, Baltimore, MD 21201.

The MPO is involved in a variety of functions including lordosis and pain inhibition. This area has an extensive projection to the periaqueductal gray (PAG). In this study we examined the effect of electrical and chemical stimulation of the MPO on the baseline activity of PAG neurons and examined the role of glutamic acid in this pathway. We recorded from 88 PAG neurons of 22 chloral hydrate anesthetized male rats and continuously monitored the arterial blood pressure. Electrical stimulation (50-200 uA, 100 Hz, 10 sec.) excited 25 cells, inhibited 11 cells, and had no effect on 28 cells. Chemical stimulation (50-100 nl, 10 mM dl-homocysteic acid) excited 8 cells, inhibited 8 cells, and had no effect on 34 cells. Microinjection of the glutamic acid antagonist kynurenic acid in the PAG blocked the excitatory response of 10/20 cells and the inhibitory response of 3/10 cells to MPO stimulation. The cells that were excited had a mean firing rate of 4.89 ± 1.18 Hz, inhibited cells had a mean firing rate of 8.45 ± 1.41 Hz, and unresponsive cells had a mean firing rate of 8.75 ± 1.33 Hz. The majority of the cells that were excited by MPO stimulation were also excited by noxious pinching of the tail. There was no difference between the response of cells that were inhibited by MPO stimulation and their response to noxious stimulation. In the majority of animals (18/22), MPO stimulation produced a depressor effect that ranged between 5 and 30 mmHg with a mean of 15.9 ± 2.3 mmHg. A pressor effect was observed in 1/22 animals with an increase of 19 mmHg. It is concluded that MPO stimulation has a significant effect on the activities of PAG neurons, which is possibly glutamic acid mediated, and produces a decrease in the blood pressure. Supported by NIH grant NS20643.

MASSIVE EXPRESSION OF C-FOS PROTEIN IN SUPERFICIAL DORSAL HORN IS NOT FOLLOWED BY LONG-TERM CHANGES IN NOCICEPTIVE THRESHOLDS. H. Beck *. J. Sandkühler, X.G. Liu and A.-C. Treier. II.Physiologisches Institut, Univ. Heidelberg, 69120 Heidelberg, Germany.

We have tested whether the massive expression of immediate-early genes including c-*fos* is a sufficient condition for the induction of thermal or mechanical hyperalgesia in awake-drug free adult rats. A minimally invasive intrathecal (i.t.) stimulation and injection technique was used for electrical stimulation of dorsal roots (0.5 ms pulses, 15 V, 3 Hz for 15 min) or for i.t injection of 25 nmoles NMDA under brief ether anesthesia.

Both i.t. stimulations produced a massive expression of c-Fos protein mainly in laminae I-II from the sacral to lower thoracic spinal cord (n=10) as compared to ten sham-treated animals. Nociceptive cutaneous mechanical (v.Frey-hairs) and thermal (hot-plate and tail-flick tests) withdrawl thresholds were determined once daily for two weeks before and for two weeks after conditioning i.t. stimulation or sham treatment (n=10). Nociceptive thresholds were not different before and after conditioning stimulation or between stimulated and sham-treated animals.

Thus, even the massive expression of c-Fos in the superficial dorsal horn is not a reliable indicator of long-term changes in spinal nociception. Supported by the DFG.

CAUDATE NUCLEUS ACTIVATION IN RESPONSE TO INTENSE PAINFUL STIMULATION IS OBSERVED USING FUNCTIONAL MAGNETIC RESONANCE IMAGING

E. Disbrow[1], M. Buonocore[2], L. Antognini[3], E. Carstens[4], K. O'Connor[4]*. Depts. of [1]Psychology; [2]Radiology; [3]Anesthesiology; and [4]Neurobiology, Physiology and Behavior; Univ. of Calif. Davis, Davis, CA 95616

The basal ganglia are believed to play a role in nociception and pain. Electrophysiological studies in cats have shown caudate nucleus neuron activation in response to high-intensity electrical stimulation of the inferior dental nerve sufficient to elicit the jaw opening reflex (Lidsky et al., 1979, *Brain Research Bulletin* 4, 9-14). In this study we examined caudate activation in humans during intense painful stimulation.

In 5 male volunteers 2 levels of painful electrical stimulation were assessed, as well as a non-painful brush stimulus. During the 4.5 minute scanning sessions, 32 second periods of stimulation were alternated with 32 second periods of rest. The first stimulus level, which was painful yet tolerable for the entire scanning session, was selected by the subject. The mean intensity of this 2 Hz stimulus was 14.8 mA. The second level was a 100 Hz 50 mA stimulus. This stimulus was administered after subjects were anesthetized with 0.7% Isoflurane and paralyzed with Vecuronium 0.15 mg/kg. Anesthetized subjects were also scanned during lower level electrical and brush stimulation.

Functional images were obtained using a 1.5T GE scanner with a birdcage RF coil designed for whole-volume brain imaging. A gradient-echo EPI imaging sequence was used with a TE of 40ms and a TR of 2 sec. All time course data was correlated with a boxcar function and a correlation threshold of 0.35.

Caudate activation was not seen in the anesthetized and unanesthetized scans of lower level electrical or brush stimulation. However, during the intense electrical stimulation of anesthetized subjects bilateral caudate activation was seen in 4 of the 5 subjects. Consistent activation of primary and secondary somatosensory cortices was also observed.

EFFECTS OF ANTICIPATION OF VISCERAL PAIN ON THALAMIC ACTIVITY IN IRRITABLE BOWEL SYNDROME PATIENTS AND NORMAL SUBJECTS. DHS Silverman, H Ennes, J Munakata, CK Hoh, M Mandelkern, J Markham*, ME Phelps, W Blahd, EA Mayer. Depts. of Medicine and Nuclear Medicine, UCLA Medical Center and West LA VA Medical Center, Los Angeles, CA, 90024.

Anticipatory anxiety is prominent in many patients with irritable bowel syndrome (IBS), as is lowered threshold to rectal pain. Anticipation of pain can modulate its processing and ultimate perception. In the current study, the relationship between anticipation of rectal pain and regional cerebral blood flow was evaluated in IBS patients and normal subjects (NIs) using $H_2{}^{15}O$ PET. A rectal balloon catheter was placed in each subject 30 min prior to imaging sessions. Following IV administration of 40 mCi $H_2{}^{15}O$, PET data were obtained in dynamic frames, and summed for 75 sec proceeding entry of tracer into the brain. Eyes were closed during all scans. A baseline scan was first obtained with the balloon deflated. Then, pressure pulses of low (20 mm Hg) and moderate (45 mm Hg) intensity were delivered by a programmable pump for 45 sec each, with interim balloon deflation (20 min). A taped message subsequently announced the imminence of a very intense pressure pulse. Heart rate was recorded before and after this message. A scan was performed following the announcement, while the balloon actually remained deflated. Relative activity was measured in various brain regions normalized to the activity level in the superior occipital cortex, a quiescent area that was unaffected by this protocol or IBS status. During anticipation, NIs showed a significant reduction in thalamic activity compared with their baseline level ($p<0.05$); in contrast, thalamic activity in IBS patients failed to change significantly and was higher than in normals. Heart rate changes during anticipation were strongly positively correlated with thalamic activity in both groups ($r = 0.98$). No significant differences were detected in the activity of other brain regions, including the anterior cingulate cortex, medial temporal lobes, temporal poles, or cerebellum. The aberrant response of the thalamus in IBS patients may reflect dysregulation of central processing of visceral pain information.

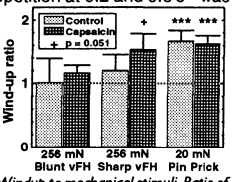
ENHANCED PAIN SENSITIVITY TO PUNCTATE STIMULI AND 'WIND-UP' OF PAIN SENSATION IN THE AREA OF SECONDARY HYPERALGESIA **W. Magerl, S. Wilk and R.-D. Treede (SPON: ENA*)** Inst. Physiol. Pathophysiol., Joh. Gutenberg Univ., D-55099 Mainz, F.R.G.

Skin injury triggers an enhanced pain sensitivity in surrounding uninjured skin (secondary hyperalgesia) due to heterotopic central sensitization. Repetitive stimulation of nociceptors at frequencies > 0.5 s^{-1} induces a homotopic response facilitation in dorsal horn neurons ('wind-up'), which is thought to contribute to central mechanisms of hyperalgesia. We therefore examined the presence and possible changes of perceptual wind-up in the area of secondary hyperalgesia.

Secondary hyperalgesia was induced by i.d. injection of capsaicin (40 µg). Sensitivity to mechanical stimuli using cotton balls, calibrated von Frey hairs (vFH) and pin pricks was tested at 15 mm distance from the injection site. Blunt vFHs (0.5 - 4100 mN) were used to determine S/R functions for pricking pain. Stimulus repetition at 0.2 and 0.6 s^{-1} was used to test for perceptual wind-up.

Capsaicin evoked strong burning pain and a leftward shift of S/R function (> factor 3) in the area of secondary hyperalgesia; noxious stimuli (pin pricks) were more painful and non-noxious mechanical stimuli eventually became painful. Though the pain ratings were increased in the area of secondary hyperalgesia, the extent of wind-up remained unchanged. Significant wind-up was only observed to pin prick repetition at the 0.6 s^{-1} frequency (see Fig.).



Windup to mechanical stimuli. Ratio of first vs. average of 5th - 8th pain ratings

We conclude, that the adjacent injection of capsaicin causes a pronounced enhancement of cutaneous pain sensitivity to punctate mechanical stimuli, but no equally pronounced change in wind-up to repetitive stimulation.

PAIN PERCEPTION OF NERVE CONDUCTION STUDIES: EFFECT OF STIMULUS DURATION AND INTENSITY. D.R. Del Toro*, A.F. Goldbaum, N.A. Johnson, T.A. Park. Department of Physical Medicine & Rehabilitation, Medical College of Wisconsin, Milwaukee, WI 53226.

Present electrophysiologic guidelines allow for significant variability in the stimulus parameters used for routine clinical nerve conduction studies (NCS), with little consideration given to the effect of these parameters on patient discomfort. Previous research suggests that some patients perceive these NCS as aversive or painful. This study was designed to examine the effect of stimulus duration and stimulus intensity on the perception of pain in individuals who have never undergone standard NCS. To study this effect, we performed a conventional median sensory antidromic conduction technique to the index finger of one hand in twenty asymptomatic subjects. Five different stimulus durations (50µsec, 100µsec, 200µsec, 500µsec, 1000µsec) were compared. Stimulus current (mA) was adjusted for each subject to 20% supramaximal at each stimulus duration. Immediately following each stimulation, all subjects rated the severity of pain perceived using a visual analog scale (VAS) ranging from no pain to the most intense pain possible. In addition, the State-Trait Anxiety Inventory was administered to each subject before and after testing. None of the stimuli were rated as more than mildly painful. Mean pain ratings for all stimulus durations were in the lower 40% of the VAS. Stimulus duration and pain rating were found to be inversely related. Shorter stimulus durations resulted in significantly higher pain ratings. There was no significant correlation between pre- or post-test anxiety scores and pain ratings. Results of this study may provide information which is useful in decreasing pain perception and anxiety associated with clinical NCS.

ROLE OF ENDOGENOUS CANNABINOIDS IN PAIN MODULATION J. Michael Walker*, William J. Martin, Andrea G. Hohman, Nicole M. Fortin, Dale G. Deutsch and Kang Tsou. Schrier Research Laboratory, Departments of Psychology and Neuroscience, Brown University, Providence, RI 02912, and Depts. of Biochemistry and Cell Biology, State University of New York, Stony Brook, NY 11794.

For many years it has been known that the brain contains nonopiate modulators of pain sensitivity, because certain forms of stress- and electrical stimulation-produced analgesia are insensitive to naloxone. Little is known about the particular neural systems that mediate such effects. Recently, we have found evidence for the existence of a powerful neural system that modulates pain through a cannabinoid mechanism. Several lines of evidence indicate the existence of this endogenous cannabinoid pain modulatory system: 1) low doses of cannabinoids administered systemically, intracerebrally, or intrathecally produce profound analgesia; 2) cannabinoids inhibit noxious stimulus-evoked c-fos expression in spinal cord, and the firing of wide dynamic range neurons in spinal cord and thalamus; 3) increasing the synthesis of the endogenous cannabinoid anadamide by administration of the precursor ethanolamine produces cannabinoid receptor-mediated analgesia; 4) increasing the synaptic concentration of anadamide by administration of breakdown inhibitors produces profound cannabinoid receptor-mediated analgesia. Intracerebral microinjection studies suggest that these effects occur via actions in the dorsolateral periaqueductal gray, the dorsal raphe nucleus the rostral ventral medulla, the lateral posterior nucleus of the thalamus, the superior colliculus, and the nucleus submedius. These data demonstrate that endogenous cannabinoids play a role in the modulation of pain.

694.11

INHIBITION OF PLASMA PROTEIN EXTRAVASATION BY 5-HT_1 AGONISTS IN RODENT DURA MATER: PHARMACOLOGICAL CHARACTERIZATION USING A SELECTIVE ANTAGONIST AND 5-HT_{1B} KNOCKOUT MICE. C. Waeber, X.-J. Yu, N. Castanon, K. Scearce, R. Hen, J.E. Macor and M.A. Moskowitz*. Massachusetts General Hospital, Charlestown, MA 02129

5-$HT_{1B/1D}$ agonists have been shown previously to inhibit plasma protein extravasation in the dura mater of rodents (a model of migraine). However, the potency of some of these drugs in this paradigm does not correlate with their affinity at 5-$HT_{1B/1D}$ binding sites. To investigate the 5-HT receptor subtype mediating the effects of these agents, we have used 1) a specific 5-HT_{1D} antagonist in guinea-pigs and 2) knockout mice lacking 5-HT_{1B} receptors. Pentobarbital-anesthetized animals were injected with [^{125}I]BSA 5 min prior to unilateral electrical stimulation of the trigeminal ganglion. After intracardiac saline perfusion, the left and right dura were harvested and the ratio of extravasated [^{125}I]BSA (stimulated/unstimulated) measured. This ratio was close to 1.7 in vehicle-treated animals. Complete inhibition of extravasation (ratio close to 1.0) was achieved in both guinea-pigs and mice when sumatriptan (0.7µmol/kg), CP-122,288 (1 nmol/kg) and 5-CT (1 nmol/kg) were injected i.v. 10 min prior to trigeminal stimulation; the selective 5-HT_{1B} agonist CP-93,129 (1.4µmol/kg) was effective only in mice. In guinea-pigs, pretreatment with GR-127,935 (0.1 mg/kg, i.v., 20 min prior to agonists) reversed the effects of sumatriptan, but did not affect those of CP-122,288 and 5-CT. In 5-HT_{1B} knockout mice, CP-93,129 and sumatriptan were inactive, while CP-122,288 and 5-CT were as potent as in wild-type mice to inhibit extravasation. These results suggest that CP-93,129 (in mice) and sumatriptan act only via 5-$HT_{1B/1D}$ receptors to inhibit dural protein extravasation in rodents. In contrast CP-122,288 and 5-CT might act via a presently unknown receptor; the hypothesis is in agreement with the fact that their potency in this model is much higher than expected from their affinity at 5-$HT_{1B/1D}$ receptors.

694.12

ALPHA-2 ADRENERGIC AGONISTS PREVENT NMDA ANTAGONIST NEUROTOXICITY. N.B. Farber* and J.W. Olney. Dept. Of Psychiatry, Washington University, St. Louis, MO 63110.

Antagonists of the NMDA receptor are potentially useful neurotherapeutic agents for prevention of opiate tolerance, alleviation of neuropathic pain and prevention of neurodegeneration in stroke and brain trauma. However, the ability of these agents to reversibly injure or kill neurons in rodent brain and to produce psychotic "emergence reactions" in humans has raised concerns about their clinical use in humans. Over the past several years we have been studying the mechanism(s) underlying these adverse CNS side-effects and have proposed that they might represent different manifestations of the same toxic process. Here we report that the neurotoxicity induced in rat brain by the potent and specific NMDA antagonist, MK-801, is prevented by several α_2 adrenergic agonists in a dose dependent fashion. The dose of MK-801 used (0.5 mg/kg sc) causes a reversible neurotoxic reaction ("vacuole reaction") in specific cerebrocortical neurons in 100% of treated rats. The ED_{50}s (dose that reduced the mean number of vacuolated neurons by 50%) for the α_2 agonists tested were clonidine (0.044 mg/kg), guanabenz (0.21 mg/kg), lofexidine (0.38 mg/kg), p-iodoclonidine (1.3 mg/kg) and xylazine (2.4 mg/kg). If a common mechanism does underlie the neurotoxic and psychotomimetic effects of NMDA antagonists, then co-adminstration of an α_2 agonist with an NMDA antagonist might prevent the NMDA antagonist from inducing either of these adverse side effects. This would enable NMDA antagonists to be used more safely for alleviation of neuropathic pain (unresponsive to opiates but possibly responsive to α_2 agonists as well as NMDA antagonists) and to enable opiate analgesics to be used without addiction liability in the management of other forms of chronic pain. *Supported by DA07261, DA 05072, AG 11355, NARSAD* Established Invest Award, RSA MH 38894 (JWO) & Scottish Rite Benevolent Foundation's Schizophrenia Research Program (NBF).

CORTICAL DYNAMICS OF WORD RECOGNITION IN NORMAL AND DYSLEXIC SUBJECTS: A NEUROMAGNETIC STUDY. R. Salmelin*, E. Service, P. Kiesilä, and K. Uutela. Low Temp. Lab., Helsinki Univ. of Technology, 02150 Espoo, and Dept. of Psychology, Univ. of Helsinki, 00170 Helsinki, Finland.

We explored spatiotemporal cortical organization during word recognition in 7 normal subjects and in 5 subjects with a documented history of developmental dyslexia, employing a whole-head neuromagnetometer (Neuromag-122). All subjects were behaviourally tested for reading, naming, lexical decision, and mental rotation speed, and for digit span forwards and backwards.

Subjects were shown 7-8 letter words for 300 ms (centered, 4 deg visual angle), once every 3 s. Four categories alternated randomly: concrete and abstract Finnish words, pronounceable pseudowords without meaning, and unpronounceable, meaningless letter strings with the same amount of consonants and vowels as in the other classes. The subjects were instructed to say aloud the word 'kirahvi' (giraffe) whenever it appeared (2.5% probability).

Activation of primary visual areas was accompanied by lateral occipitoparietal signals within 200 ms after stimulus onset, showing a pronounced right-hemisphere dominance in all dyslectics, in contrast to the left-hemisphere dominance observed in 5 of 7 normal subjects. The occipital areas remained active up to 800–1000 ms. Concrete words elicited strong left frontotemporal activation after 500 ms in normals, but much weaker signals in dyslectics. Dyslexia may thus be associated with abnormal right-hemisphere dominance of early cortical analysis and reduced post-lexical activation.

695.2

HIGH-FREQUENCY OSCILLATIONS INDICATE CELL-ASSEMBLY BINDING IN HUMANS. N. Birbaumer*, W. Lutzenberger & F. Pulvermüller. Institute of Medical Psychology and Behavioral Neurobiology, Univ. Tuebingen, D-72074 Tuebingen

EEG- and MEG-synchronized responses in the range of 20 to 45 Hz indicate „binding" of cell-assemblies because they reliably appear at the human neocortex if meaningful information is processed. Three experiments with healthy subjects (N=15 in each experiment) used (a) meaningful words and meaningless pseudowords carefully matched for word length and frequency, (b) words with motor and sensory content and, (c) regular Gestalt-like and irregular visual patterns presented in different visual fields. Changes in EEG power from multiple electrode arrays were analyzed using currenct source densities based on spherical spline interpolation in order to eliminate artificial influence from reference electrodes. Meaningful words elicit 30Hz gamma responses in the left perisylvian cortex only, meaningless words showed no synchronized responding in any frequency range (3,5-100Hz). Words with motor content elicit 30Hz responses in left frontal regions, words with visual content 35Hz responses in both parietal-occipital cortices. Changes from chaotic to Gestalt-like visual patterns elicit 40Hz oscillations in the respective cortical representation of the visual field of the occipital lobe. The results cannot be explained by effects of harmonics of changes in alpha activity.

Supported by the German Research Society (DFG).

CORTICAL CONTROL OF VOCAL FUNDAMENTAL FREQUENCY DURING SINGING. D.W. Perry*, R.J. Zatorre, and A.C. Evans, Montreal Neurological Institute, McGill University, Montreal, QC, Canada H3A 2B4.

During singing, one must consciously control vocal fundamental frequency in order to produce intended musical pitches. In the present experiment, 13 subjects performed 3 experimental tasks, and changes in CBF were measured by positron emission tomography using the water bolus method. In the singing condition, they vocalized a single pitch repetitively on the syllable "ah", holding each note as long as they could comfortably on a single breath. In the playback condition, they listened to a recording of their singing. In a whisper-tracking condition, they listened to the same recording, while whispering "ah" at the same rate. In comparison to playback, significant increases in CBF were observed during singing in the supplementary motor area (SMA), the precentral gyrus, the mid-insula/precentral operculum, and the cerebellum. Increases were also observed in the right primary auditory region, and bilaterally in occipital cortex. These findings replicate those observed previously during singing in comparison to perception of complex tones (Perry *et al.*, 1993, *Soc. Neurosci. Abstr.* 19, 843). In comparison to whisper-tracking, increases during singing were observed only in the inner face of the precentral operculum, the right primary auditory region, and the cerebellum. In comparison to playback, increases during whisper-tracking were observed in SMA, the precentral gyrus, and the mid-insula/operculum. These results suggest that paramotor cortex in the inner face of the precentral operculum may be particularly crucial to the cortical control of vocal fundamental frequency, i.e. for adjustments of vocal fold length by the intrinsic laryngeal musculature. They also provide further confirmation for the hypothesis that right auditory cortex may be preferentially involved in monitoring the pitch of one's own voice during singing.

695.4

THE LEFT FRONTAL OPERCULUM IN PHONOLOGICAL PROCESSING: CONVERGING EVIDENCE FROM PET AND THE LESION METHOD. JA Fiez*, H Damasio, D Tranel, Div Cog Neurosci, Dept Neurol, U Iowa, Iowa City.

PET studies in normal subjects have provided evidence that a region at the junction of the inferior frontal gyrus and the anterior insula is important for specific types of phonological processes (1,2,3,4). Here, we report converging evidence on this finding using the lesion method. Eleven target subjects with circumscribed left frontal opercular lesions were identified in our patient registry. The target subjects and 11 normal controls matched for age, sex, and education were studied using tasks derived from the PET studies in normals. We hypothesized that the target subjects would be impaired on tasks associated with functional activation in the left frontal opercular region, but would perform normally on tasks not associated with activation of the region. Relative to the controls, the target subjects were: 1) impaired at reading nonwords (p=.004) and low-frequency words with exceptional orthographies (e.g., chassis) (p=.006), but read other words within normal limits (p>.05); 2) impaired on a phonological detection task (does a word contain a long vowel sound, e.g. the 'a' sound in LAME) with both visual (p=.002) and auditory (p=.02) presentation, but were normal (p>.05) on an orthographic detection task (does a word contain an "ascending" letter, e.g. an 'l') with both visual and auditory presentation; 3) impaired at remembering 5 words for 60 s (p=.05). The target subjects were normal on a rhyming task (p>.05). These findings provide strong additional evidence that regions within the left frontal operculum are part of a system that makes specific and critical contributions to phonological processing.

COMPARISON OF CORTICAL AREAS ACTIVATED BY PRIMARY AND SECOND LANGUAGES IN HUMAN BRAIN USING FUNCTIONAL MAGNETIC RESONANCE IMAGING (fMRI). K. Kim*[1,3], J. Hirsch[1,3], R. DeLaPaz[2,3], N. Relkin[3], and K-M. Lee[1,3]. Depts. of Neurology[1] and Radiology[2], MSKCC; Dept. of Neurology and Neuroscience[3], Cornell University Medical College, New York, NY 10021

Fluent second languages can be acquired throughout life, providing primary language acquisition has taken place during childhood. To better understand the brain mechanisms involved in the development of multilingual capabilities after childhood, we used fMRI techniques to study the cortical regions activated during performance of identical tasks in volunteers who learned fluent English during early adulthood. Functional brain images were obtained using a GE Signa 1.5 Tesla scanner with echo-planar capability (Advanced NMR) using a gradient echo sequence with an in-plane resolution of 1.56 x 1.56 mm^2. Sixteen 4.7 mm axial slices parallel to the AC-PC line were spaced 1.6 mm apart to image virtually the entire cerebral cortex. Twice over a period of month, each subject underwent fMRI scanning as they read text, read verbally-encoded numbers and performed calculations using verbally-encoded numbers in Korean and English. A voxel-by-voxel, multistage statistical analysis with a replication requirement identified the locations of active sites associated with all tasks. Cortical regions thought to be involved in calculation showed identical activations irrespective of the language employed However, within the regions generally considered language-related (presumably Broca's and Wernicke's areas), adjacent areas of activation were reproducibly observed which appeared to be unique to Korean and English respectively. These results suggest that the mapping of primary and secondarily-acquired languages may be spatially resolvable at the level of the cerebral cortex when the second language is acquired after childhood. This could reflect recruitment of neighboring cortical zones or subdivision of language-specialized cortex in the process of acquiring a second language.

A FUNCTIONAL MRI STUDY OF WRITING *V. Menon*, J. E. Desmond, K. O. Lim, J. B. Demb, D. Spielman and A. Pfefferbaum* Departments of Psychiatry and Behavioral Sciences, Radiology and Psychology, Stanford University School of Medicine and Palo Alto VA Medical Center, CA 94304.

Brain areas activated during writing were investigated using functional MRI. The task consisted of 6 cycles of 30s rest and 30s writing intervals. In the writing interval, subjects wrote short sentences (aphorisms) dictated binaurally; the auditory presentation typically lasted less than 5s. Subjects rewrote the sentence if they completed writing before the end of the 30s interval. Four right-handed subjects (2M, 2F) were studied. Functional images were acquired on a 1.5T scanner using a T2* weighted gradient echo spiral pulse sequence (TR=75ms, TE=40ms, flip angle=30°). Twelve sagittal slices were collected, six in each hemisphere, with slice thickness of 5mm and inter-slice separation of 2.5mm. Time-series cross-correlation methods were used to determine the loci of activation. In the left (contralateral) hemisphere, in addition to the pre-motor (BA 6), motor (BA 4) and somatosensory (BA 3, 2 and 1) cortices, activations were observed in Heschl's gyrus (BA 41 and 42), posterior superior temporal gyrus (STG, posterior BA 22) and in the frontal operculum (BA 44). Activations were also observed in the left anterior STG in 3 subjects and in the left posterior inferior temporal gyrus in 2 subjects. Strong activation was consistently observed in the left supramarginal gyrus (BA 40) of all four subjects. Little or no activation was observed in the right (ipsilateral) hemisphere, except for the cerebellum, where stronger and more widespread activation was observed in the right hemisphere. Given that the auditory stimuli typically lasted less than 5s in a cycle, the results suggest that a feedback loop between Broca's and Wernicke's areas may be involved in maintenance of and access to the phonological codes. The results are in good agreement with lesion studies implicating the left supramarginal gyrus in phonological agraphia. *Supported by The Sinclair Fund, NIH (MH30854, F32BS09628 and AG11427) and the Department of Veterans Affairs.*

ACTIVATION OF LEFT SUPERIOR TEMPORAL SULCUS WITH FUNCTIONAL MRI OF SENTENCE PROCESSING. S. L. Small[1*], D. C. Noll[2], C. A. Perfetti[3], and W. Schneider[3] Departments of [1]Neurology, [2]Radiology, and [3]Psychology; University of Pittsburgh, Pittsburgh, PA 15261.

We used functional MRI to investigate the unique neuroanatomical processing characteristics of sentences. Five right handed subjects participated. Word sequences were presented one word at a time ending with a period. Subjects pressed a button at the end of each grammatical meaningful sentence. In the control task, sequences of false font strings were presented one string at a time, with a button press at the end of each sequence. Button presses were performed with the left hand and were equalized across conditions.

Within an oscillatory stimulus presentation paradigm, active and control tasks were alternated for 30 sec each for 4 min. Six parasagittal spiral k-space images were obtained in each hemisphere with a 1.5 Tesla scanner using a pair of parallel 5-inch temporal surface coils. The head was restrained with a bite bar or a clamp. A gradient echo pulse sequence used 4 interleaved spirals to provide 2.7 x 2.7 mm resolution over an 18 cm FOV. Each slice was acquired 8 times during each 30 sec interval (total 64).

The activation waveform for each voxel was cross correlated ($r = 0.5$) with a reference (sine) waveform corresponding to the temporal pattern of stimulus presentation. The main regions of activation were the left inferior frontal gyrus and superior temporal sulcus (STS). Most subjects had a smaller degree of activation in homologous regions of the right hemisphere. Some subjects also had activation in the left angular gyrus or premotor cortex. The focus of activation in the left STS, about two thirds of the distance from the temporal tip to the temporo-occipital junction, is not identical to the region of the superior temporal gyrus implicated in most lesion studies as important for comprehension. *(Supported by NIH DC00054)*

EFFECTS OF DIFFICULTY ON FUNCTIONAL MRI ACTIVATION DURING A COGNITIVE TASK. RK Shin, M D'Esposito, JA Detre, GK Aguirre, M Grossman*, DC Alsop. Depts. of Neurology & Radiology, University of Pennsylvania Medical Center, Philadelphia, PA 19104.

The effects of increasing difficulty of a cognitive task on functional brain activation have not been well studied. Specifically, it has been argued that prefrontal activation in certain cognitive tasks (e.g. working memory tasks) may be due to mental effort alone. If this hypothesis is true, then a cognitive task that does not recruit prefrontal cortex might be expected to do so when made more difficult. We studied 10 normal subjects using echoplanar functional MRI during a spatial location/mental rotation task in which the subjects were required to match a target figure to one of two spatially rotated figures. Difficulty was varied for each subject either by increasing the number of mental rotations required to solve the task (n=6) or by increasing the presentation rate of the stimuli (n=4) until average subject accuracy decreased from approximately 90% to 70%. Scanning was performed at 1.5 T over 16 contiguous 5mm axial slices (TR=2000 msecs, TE=50 msecs). Regions of activation were identified by correlation with task above a threshold r value, and signal change was assessed within regions of interest. Task-correlated signal change was found in bilateral superior parietal lobule (Brodmann's area 7) and bilateral occipital cortex (Brodmann's area 19) in all subjects. As task difficulty increased, an increase in percentage signal change and activation volume was seen in these regions. Activation in prefrontal cortex was not noted. These findings provide insight into how the brain responds to increasing task difficulty and do not support the hypothesis that mental effort alone results in the prefrontal cortical activation seen in working memory tasks.

AN EXPLANATION OF CONSCIOUSNESS. Eugene M. Brooks, M.D.*
1528 Tator Ct., Bloomfield Hills, MI 48302

Consciousness is postulated to be a rapid sequence of multiple, discrete events which give the impression of being a single entity. It is based on "qualitative cores" which are described as the intra or intercellular aspects of nerve cells. The cores constitute the unique essences of the "five senses", the emotions, and other forms of consciousness. Nerve impulses from these cells progress "upward" and are processed. Processing includes monitoring, selecting, screening, and combining under the control of higher centers. The higher centers are driven by pleasure or displeasure in conjunction with previously formed hierarchies. Hierarchies "compete" for the attainment of consciousness and are stored in memory. Mechanisms for rapidity of action, including "synecdoche" and "abstracting" are proposed.

Nerve impulses do not create consciousness. They are consciousness experienced from the "inside." The physical or chemical elements which produce consciousness may already be known but are not recognized as such because as observers we are on the "outside." It becomes clear that theories of consciousness must be based on physical or chemical elements but until that level of explanation is reached it is fitting to rely on an anthropomorphism (a homunculus). The present paper applies not only to consciousness but also to perception, meaning, attention, curiosity, and a form of learning.

CIRCUITRY AND PATTERN GENERATION

696.1

CENTRAL GENERATION OF DIRECTED LIMB MOVEMENTS IN LOCUSTS. A. Berkowitz* and G. Laurent, Division of Biology, 139-74, Caltech, Pasadena, CA 91125.

The degree to which insect limb motor control requires movement-related sensory feedback has been debated for decades, on the basis of experiments on locomotion. We developed an insect preparation to study the neural control of scratching. We recorded fictive motor patterns for scratching by the middle leg and hindleg of locusts.

Locusts with the connectives cut between the prothoracic and mesothoracic ganglia used the middle leg or hindleg to scratch each of several sites that were stimulated mechanically. Thus, the head ganglia are not required for scratching. The hindleg could scratch 1) the ear, 2) the ventral or posterior hindleg coxa, and 3) the posterior abdomen. The middle leg could scratch the anterior hindleg coxa. The 3 types of hindleg scratching were readily distinguished in plots of tibial extension versus femoral elevation. Electromyographic recordings demonstrated that during scratching, in contrast to walking, tibial extensor muscle activity occurred partly during trochanteral levator muscle activity.

In several animals, we cut all nerve branches that provide motor innervation to the middle legs and hindlegs, while leaving intact the sensory innervation of the ear, abdomen, and most of the hindleg coxa. These animals could produce coordinated bursts of activity in tibial extensor and trochanteral levator and depressor motoneurons, in response to mechanical stimulation of the same sites that evoked scratching in animals that could move their legs. Thus, basic motor patterns for locust scratching were generated in the absence of leg movement. These central motor patterns also displayed clear intersegmental coordination between the mesothoracic and metathoracic ganglia. *Supported by an NIH NRSA to A.B. and an NSF PFF to G.L.*

MODULAR ORGANIZATION OF RHYTHM GENERATING CIRCUITRY FOR ROSTRAL SCRATCHING IN THE HEMISECTED HINDLIMB ENLARGEMENT OF THE SPINAL TURTLE. Paul S.G. Stein*, John C. Victor, and Edelle C. Field, Dept. Biology and Movement Science Program, Washington Univ., St. Louis, MO 63130.

Fictive rostral scratching is produced in a spinal, immobilized turtle by gentle mechanical stimulation of the ipsilateral (ipsi) midbody shell bridge (J. Neurophysiol. 53: 1517, 1985). Ipsi scratching motor output normally includes bursts of hip flexor motor activity that rhythmically alternate with bursts of hip extensor motor activity. Occasionally, in some cycles, "hip-extensor deletions" occur; during this spontaneously occurring variation of fictive rostral scratching, there is no quiescent period between the end of one hip flexor burst and the beginning of the next hip flexor burst. Stein et al. (J. Neurosci. 15[6]: in press, 1995) described fictive rostral scratching motor rhythms generated by a spinal, immobilized turtle with the left halves of 6 spinal segments removed. In this hemisected hindlimb enlargement preparation, the left halves of the 5 hindlimb enlargement segments (D8-S2) and the left half of the D7 segment are removed. In this preparation, ipsilateral shell bridge stimulation usually elicits ipsi rostral scratching with hip-extensor deletions, i.e., rhythmic bursts of ipsi hip flexor activity; contralateral shell bridge stimulation elicits rhythmic bursts of ipsi hip extensor activity. We add to these findings with the hemisected hindlimb enlargement preparation by using simultaneous bilateral stimulation of mirror-image locations, one in the left rostral scratch receptive field and the other in the right rostral scratch receptive field. Bilateral stimulation in this hemisected hindlimb enlargement preparation elicited rhythmic alternation between hip flexor bursts and hip extensor bursts; this is similar to the normal rostral scratching motor pattern elicited by unilateral stimulation in the preparation with an intact hindlimb enlargement. We obtained a similar result in the absence of neuromuscular blockade with kinematic analysis of hindlimb movements in a spinal hemisected hindlimb enlargement preparation. These observations support the concept of modular organization of hip flexor and hip extensor rhythm generators for rostral scratching in the turtle spinal cord. PURINERGIC MODULATION OF SWIMMING MOTOR PATTERN IN *XENOPUS* EMBRYOS. N. Dale* and D. Gilday. School of Biological & Medical Sciences, University of St. Andrews, KY16 9TS, U.K.

Although sensory inputs evoke and modify motor activity in the *Xenopus* embryo, the motor pattern for swimming follows an inherent dynamic progression in their absence. The frequency of swimming gradually falls throughout an episode until activity spontaneously ceases. The mechanisms underlying these time-dependent changes remain unknown.

Applications of the P2 receptor antagonist, pyridoxal-phosphate-6-azophenyl-2',4'-disulphonate (10μM), shortened swimming episodes by 84±7% (±sem, n=4), suggesting that ATP may be released during fictive swimming. Adenosine applied at 10-100μM diminished the length of swimming episodes by 83±3% (n=3), while the A receptor antagonist, 8-phenyltheophylline (2.5μM), enhanced their length by 106± 21% (n=6). Use of α,β-methylene-ADP, to block conversion of AMP to adenosine by ectonucleotidases, also lengthened swimming episodes (by 262±150%, n=5). Naturally released ATP may thus be hydrolysed to adenosine which could then oppose the actions of ATP during fictive locomotion.

The mechanisms underlying these effects of ATP and adenosine have been investigated both in the intact spinal cord and in neurons acutely isolated from the spinal locomotor circuitry. Neither ATP nor adenosine appeared to: 1) gate an ion channel directly; or 2) cause presynaptic inhibition. However, whole cell patch clamp recordings showed that ATP reduced voltage-gated K^+ currents by 16±1.6% (n=11), while adenosine reduced voltage-gated Ca^{2+} currents by 14±3.2% (n=6).

Within the spinal motor circuitry, release of ATP may enhance excitability during fictive swimming by reducing K^+ currents whereas delayed formation of adenosine, by ectonucleotidases, may do the opposite by gradually reducing Ca^{2+} currents. Time-dependent modulation of voltage-gated currents by ATP and adenosine may thus underlie the dynamic regulation and self-termination of the swimming motor pattern.

GENES THAT CONTROL A MOTOR PROGRAM PERIOD IN *C. ELEGANS* K. Iwasaki*, D. WC Liu, and J. H. Thomas, Dept. of Genetics, Univ. of Washington, Seattle, WA 98195

Periodic activation of a motor program is controlled by a neuronal pattern generator. Electrophysiology of some neuronal pattern generators, such as in *Tritonia* and *Panulirus*, has been extensively studied. However, the genetic basis of such pattern generators is not understood. Recently, we have found that *C. elegans* defecation is controlled by a temperature-compensated clock, possibly a neuronal pattern generator. With the exception of its periodicity (45 seconds), various properties of this clock are similar to those of a circadian clock. The defecation motor program consists of a stereotyped series of three muscle contractions, called pBoc, aBoc, and Exp. To investigate how the defecation cycle period is genetically controlled, we screened approximately 3,000 mutagenized haploid genomes and reexamined existing mutants. We identified mutations in 12 genes can cause abnormal defecation cycle periods. These defecation cycle periodicity (Dec) mutations fall into two major groups, short cycle (Dec-s) and long cycle (Dec-*ℓ*). Detailed characterization of these mutants revealed the following points. 1) Most Dec mutations affected the cycle period quite differently at 20° and 25°. Because of their high frequency of isolation, we think most of the mutations affect temperature compensation rather than causing thermolabile gene products. 2) Mutations in the *flr-1*, *flr-3*, and *flr-4* genes (Katsura, *et. al.* Genetics **136** 145) showed a very short mean cycle period. The short cycle period correlated strongly with weakened pBoc and Exp motor steps, suggesting depletion of a factor by a high frequency of motor program activation. 3) Dec-s mutations in *dec-9* and *dec-10* were dominant. These mutations were gain-of-function based on heterozygous deficiency phenotypes. 4) Most of the *dec* mutations did not affect internal timing of the motor program. However. mutations in two Dec-*ℓ* genes, *dec-2* and *dec-4*, lengthened the interval between pBoc and Exp steps.

We are currently building double mutants among the Dec mutations in order to construct a genetic regulatory pathway for the clock.

THE CIRCUIT LOCUS OF THE BEHAVIORAL CHOICE BETWEEN SWIMMING AND SHORTENING IN THE LEECH. B. K. Shaw* and W. B. Kristan, Jr. Dept. of Biology, Univ. of California, San Diego, La Jolla, CA 92093-0357.

We are studying the neuronal basis of the behavioral choice between two incompatible behaviors in the leech, swimming and the whole-body shortening reflex. An advantage of studying these behaviors is that the neural circuit for swimming is particularly well understood. It is made up of a hierarchy of identified neurons: head brain interneurons influence segmental swim-gating interneurons, which activate the oscillator interneurons that make up the CPG for the rhythym, which in turn drive the motor neurons.

At a behavioral level, the shortening reflex dominates swimming: swimming is prevented during shortening and shortening can interrupt swimming. In correspondence with this at a neuronal level, the cells 204— the most powerful of the swim-gating interneurons—are strongly inhibited during shortening. The cells SE1, 'swim excitor' interneurons in the brain which strongly excite the cells 204, show an opposite effect: they are excited during shortening. This means that during shortening, the cells SE1 can have an inappropriate excitatory effect on the cells 204 that must be overridden by other, inhibitory, inputs to 204. This suggests that the cells 204 act, at least in part, as the 'decision-site' where the signals that promote and suppress swimming are integrated. It also suggests that the cells 204 are examples of interneurons that are dedicated to a single behavior—swimming—while the cells SE1 may be multifunctional interneurons that participate in more than one behavior. To further test these hypotheses, we will record from other swim circuit interneurons, like the oscillator cells, to determine their role in shortening. Supported by NIGMS training grant GM08107 (BKS) and NIMH research grant MH44396 (WBK).

696.6

NEURONAL MECHANISMS MEDIATING CONTEXT-SPECIFIC COMMANDS IN THE FEEDING SYSTEM OF *APLYSIA*. S. C. Rosen*, E. C. Cropper[1], F. S. Vilim[1], K. R. Weiss[1] and I. Kupfermann. Cntr. Neurobiol. & Behav., NYS Psychiat. Inst., New York, NY 10032; [1]Dept. Physiol. & Biophys., Mount Sinai Sch. of Med., New York, NY 10027.

Appropriate behavior depends in part on an animal's ability to initiate the behavior within a complex context. Neuronal mechanisms mediating context-specific initiation of behavior were investigated in the *Aplysia* feeding system where command-like interneurons have been identified and where initiation of ingestion is dependent upon: (1) the generation of a postural state associated with food-induced arousal; (2) a combined chemical and tactile stimulus applied to the lips; and (3) a reinforcement state produced by the success of previous responses. Three types of excitatory input to biting command-like interneuron CBI-2 may carry state-dependent information: (1) input from neuron CPR that controls the postural arousal system; (2) combined chemosensory and mechanosensory input produced by food contacting the peri-oral zone; and (3) direct input from a CPG interganglionic projection interneuron (B19) that is excited by mechanoafferent neurons innervating the grasping surface of the radula. B19 was found to produce a conductance decrease slow EPSP in CBI-2 that can amplify other inputs to the cell. Since CBI-2's resting potential is 15-25 mV below threshold and because CBI-2 must fire above 10 Hz to effectively drive a rhythmic motor program, it is likely that two or more inputs must act in concert to produce robust behavior. The results indicate how crucial logical operations may be executed by command-like neurons.

696.7

A MOTOR PROGRAM ASSOCIATED WITH FEEDING IN ISOLATED CEREBRAL GANGLIA OF *APLYSIA*. Ray Perrins* and K. R. Weiss Dept. Physiology and Biophysics, Mount Sinai School of Medicine, New York, NY 10029.

The coordination of mouth and buccal mass movements varies in different forms of feeding-related behavior in *Aplysia* and indeed can occur independently. Buccal motor programs (BMPs) controlling buccal mass movements can be obtained in isolated buccal ganglia so the central pattern generator (CPG) controlling this aspect appears to reside there. Mouth movements are controlled largely by motoneurons in the cerebral ganglion and we have now discovered a neuron, the cerebral motor program initiator (C-MPI), which can induce a cerebral motor program (CMP) in the isolated ganglion when fired at rates of 12-26 Hz. The cycle period of the program is between 9 and 50 seconds, similar to those observed for BMPs. This program incorporates alternate firing of lip motoneurons C11 and C12 as well as e-cluster neurons including C4 and C-MPI itself. The cerebral to buccal interneurons CBI-2 and CBI-4, which can induce BMPs fire rhythmically during the CMP. When the buccal ganglion is attached the CMP can occasionally evoke single cycles of a BMP but more commonly has little effect on buccal output. During BMPs evoked by firing in CBI-2 and CBI-4, C-MPI receives strong rhythmic excitatory input. Thus there are CPGs in both cerebral and buccal ganglia which can control individual motor programs without the need for input from the other. However, the CPGs are connected at several sites. Altering the strengths of these connections, or decoupling the CPGs altogether may provide a mechanism for varying the coordination of mouth and buccal mass movements in different behaviors.

696.8

USING RNA-PCR TO DETERMINE LEVELS OF *SHAKER* FAMILY GENE EXPRESSION IN NEURONS AND GLIAL CELLS IN THE STOMATOGASTRIC GANGLION OF THE SPINY LOBSTER. D.J Baro*, C.L. Cole, H.E. Rodriguez, and R.M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14850.

The unique electrophysiological phenotypes of the different identified neurons in the stomatogastric ganglion (STG) are essential for the generation of the pyloric motor pattern. To better understand the roles of identified currents in motor pattern generation, we are trying to correlate specific cellular currents with specific genes from the *Shaker* family of potassium channels. As a first step toward this end, we have used RNA-PCR to survey unidentified neurons in the STG to determine what fraction of the neurons detectably express a given *shaker* family gene. In these experiments individual neurons serve as templates in RNA-PCRs. Our primers are specific for the four members of the lobster *Shaker* family genes and an alpha-tubulin gene, and always flank an intron to ensure that we are detecting RNA and not chromosomal DNA. Each gene appears to be expressed in at least 63% of the neurons surveyed. We have also used this method to determine which genes are detectably expressed in glial cells. Thus far, we have only been able to detect *shal* gene expression in glial cells. As the next step toward our goal, we have developed and are currently using a quantitative RNA-PCR method to measure differences in the level of *Shaker* family gene expression in identified neurons of the pyloric network. Supported by NIH NS25915.

696.9

DOPAMINE (DA) AND SEROTONIN (5HT) COORDINATE DIFFERENT ASPECTS OF CONSUMMATORY FEEDING BEHAVIOR IN *APLYSIA*. E.A.Kabotyanski*, D.A.Baxter and J.H.Byrne. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77030.

One of the salient features of biological pattern generators is their ability to be modulated by extrinsic and intrinsic factors. The mechanisms by which this modulation occurs are poorly understood however. We have begun to examine this issue using feeding behavior in *Aplysia*. This behavior is controlled partially by the buccal ganglia. Bath application of DA induces patterned neural activity in isolated buccal ganglia and biases this activity toward ingestion-like motor programs (Baxter *et al.*, this volume). Although 5HT has been implicated in the enhancement of consummatory responses (Rosen *et al.*, 1989), it has also been shown to inhibit aspects of motor programs in isolated buccal ganglia (Baxter *et al.*, this volume). We have developed a semi-intact preparation to provide direct behavioral evidence correlating feeding behaviors with the actions of DA, its precursor DOPA, and 5HT.

The preparation consisted of the isolated anterior portion of the animal with attached CNS. The canulated buccal artery was perfused with saline to apply drugs and appropriate hydrostatic pressure. The force produced by foregut movements was monitored isotonically with a transducer attached to a thread that was drawn through the mouth and esophagus. In control saline, low frequency (~0.006 Hz) feeding-like movements occurred with no net displacement of the thread. DA (50 μM) evoked frequent (~0.04 Hz) cyclical opening-closing of the jaws and protraction-retraction of the radula, which appeared similar to bites in intact *Aplysia*. These movements led to inward displacement of the thread. Effects of DOPA (250 μM) were similar. 5HT (5 μM) did not significantly change the frequency of foregut movements, but each cycle resulted in a large inward displacement of the thread. 5HT-induced movements, most of which occurred without jaw openings, were distinct from DA-induced movements and appeared similar to swallows (Morton & Chiel, 1993; Kupferman, 1974).

Our results indicate that DA and 5HT may be involved in the control of ingestive consummatory feeding. In particular, DA appears to coordinate the generation of biting, whereas 5HT appears to coordinate the generation of swallowing.

696.10

CHARACTERIZATION OF MOTOR PROGRAMS GENERATED IN ISOLATED BUCCAL GANGLIA OF *APLYSIA* AND THEIR MODULATION BY BIOGENIC AMINES. D.A. Baxter*, S.J. Cushman, E.A. Kabotyanski and J.H. Byrne. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77030

To provide further insights into the coordination of motor patterns, we monitored patterned neural activity in isolated buccal ganglia with extracellular and intracellular recordings. Based on similarities to previous recordings from freely behaving animals and on the phase relationship between activity in identified motor neurons (e.g., Morton and Chiel 1993; Church and Lloyd 1994), three patterns were identified: a rejection-like pattern, an ingestion-like pattern, and an intermediate pattern. In control saline, all three occurred spontaneously. However, the rejection-like pattern was expressed most often and the ingestion-like pattern was the least common. In addition, stimulation of the radula nerve usually elicited the rejection-like pattern.

Bath application of dopamine (DA; 50 μM) had three effects. First, DA increased the occurrence of spontaneous patterned neural activity. Second, DA increased the number of ingestion-like patterns and decreased the number of rejection-like patterns. Third, in the presence of DA, stimulation of the radula nerve elicited an ingestion-like pattern rather than a rejection-like pattern. The effects of serotonin (5HT) were complex. First, 5 μM 5HT decreased the occurrence of spontaneous patterned neural activity. In contrast, 0.5 μM 5HT increased spontaneous patterned activity. Neither concentration of 5HT significantly altered the relative distribution of the types of motor patterns, however. Second, in the presence of 5 μM 5HT, stimulation of the radula nerve failed to elicit patterned neural activity. Finally, 5 μM 5HT attenuated the DA-induced patterned neural activity.

These results, and those of others, indicate that the buccal ganglia contain a central pattern generator (CPG), which in isolation can produce patterns of neural activity similar to those observed in intact and semi-intact preparations, and that biogenic amines play a role in determining the functional configuration of the CPG. For example, DA induced ingestion-like activity, which is a likely neural correlate of biting (Kabotyanski et al. this volume). 5HT also has been shown to enhance aspects of ingestive behaviors. For example, 5 μM 5HT induced swallowing-like movements in our semi-intact preparation. Neural correlates of such 5HT-mediated enhancement were not apparent in isolated buccal ganglia, however. One possibility is that these correlates of 5HT may arise from more complex integration by additional central and/or peripheral neural elements.

696.11

AFFERENT CONTROL OF BUCCAL MOTOR PROGRAMS IN *APLYSIA*. R. Nargeot*, D.A. Baxter and J.H. Byrne. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77030.

Behavioral studies have shown that the central pattern generator (CPG) underlying consumatory feeding behavior in *Aplysia* can mediate, in response to different types of sensory input, either ingestion or rejection. We have begun to examine how afferent inputs to this CPG influence its activity in a reduced preparation.

The reduced preparation consisted of isolated buccal ganglia with two of its peripheral nerves (see below) still attached to small patches of the inner surface of the buccal mass. Motor nerve activity was monitored with extracellular recordings. Activation of afferents could elicit feeding motor programs in previously quiescent preparations. A motor program, which has previously been demonstrated to mediate ingestion in intact and semi-intact preparations (Morton & Chiel, 1993a,b) was induced by applying seaweed to the inner surface of an anterior portion of the buccal mass. In contrast, no motor activity was induced by a similar stimulation of a posterior portion of the inner surface of the buccal mass. One or two cycles of a rejection-like pattern could be elicited by stretching either portion of the buccal mass.

The axons of the afferents implicated in these responses were located in the most anterior branch of the buccal nerve 2 (which we refer to as BN2,3) and the anterior branch of the esophageal nerve (which we refer to as EN2). Rhythmic motor activity composed of both ingestion- and rejection-like patterns was induced by tonic electrical (2Hz) stimulation of BN2,3, whereas tonic electrical stimulation of EN2 only induced a rejection-like pattern. In all cases, the induced rhythmic activity lasted as long as the tonic stimulation was applied, whereas phasic electrical stimulation (10Hz, 6s) of either nerve evoked only one or two cycles of a patterned motor activity.

These results indicate that in isolated buccal ganglia, afferent inputs can induce patterned motor activity similar to that observed in freely behaving animal (e.g., ingestion and rejection). Moreover, the finding that a single afferent pathway (e.g. BN2,3) could elicit two distinct motor programs during tonic activation, suggests that the CPG can undergo rapid reconfiguration, which may underlie behavioral switching. Such a reduced preparation will be suitable for investigating the cellular mechanisms contributing to such reconfiguration.

696.12

INTERPLAY OF EXCITATORY AND INHIBITORY PATHWAYS DURING NEUROCHEMICALLY INDUCED LOCOMOTOR ACTIVITY IN THE NEONATAL RAT SPINAL CORD. E. Kremer and A. Lev-Tov*, Dept. of Anatomy, The Hebrew University Medical School, Jerusalem, Israel.

The left-right alternation of neurochemically induced locomotion was studied in the isolated spinal cord preparation of the neonatal rat using wide-band AC extracellular recordings from lumbar ventral roots and intracellular recordings from segmental motoneurons. The left-right alternation of the locomotor rhythm could be converted into bilaterally synchronous bursts by bath application of the glycine receptor blocker strychnine, the $GABA_A$ receptor antagonists bicuculline and picrotoxin and by the nicotinic acetylcholine receptor blockers hexamethonium and mecamylamine. The drug induced bilateral synchronicity was not unique to the lumbar cord and occurred in most segments of the spinal cord with intact or detached lumbar segments. When occurred, the synchronous bursts could be transmitted rostrally and caudally by ascending and descending pathways traveling in the ventral, the ventrolateral the lateral and dorsolateral funiculi. Reduction of the enhanced excitatory drive of the cord by pre-treatment with the excitatory amino acid receptor blockers CNQX or AP5, by bath application of the GABA uptake inhibitor nipecotic acid, and in some cases by the use of mid-saggitally split spinal cord preparations with a single bilaterally-intact upper lumbar segment, unmasked left-right alternating rhythm in the presence of either bicuculline, strychnine or the nicotinic cholinergic antagonists. It seems that the idea of relating the drug induced "conversion" of the rhythm to a blockade of reciprocal inhibition is oversimplified. We suggest that the cross excitatory pathways between the hemicords are strongly modulated by various inhibitory projections and that the efficacy of these projections may play a significant role in determination of the phase relation between the left and right hemicords during neurochemically induced locomotion.

CELL LINEAGE AND DETERMINATION IV

697.1

PURIFICATION AND CHARACTERIZATION OF ADULT OLIGODENDROCYTE PRECURSOR CELLS
J. Shi, A. M. Marinovich and B. A. Barres*. Dept. of Neurobiology, Stanford University, School of Medicine, Stanford, CA 94305-5401, USA.

Although the extent to which demyelinated white matter can repair itself is not known, the injured brain appears to have at least some ability to generate new oligodendrocytes. It has been suggested that new oligodendrocytes may arise, at least in part, from oligodendrocyte precursor cells that persist in the adult central nervous system. Oligodendrocyte precursor cells in adult brain divide little, if at all, whereas they divide rapidly during development. Similarly, it has been reported that adult precursor cells in culture divide more slowly than perinatal precursor cells. Fundamentally, such differences between the behavior of adult and perinatal oligodendrocyte precursor cells could be the result of either intrinsic or extrinsic differences (or both). In order to answer this question and to further characterize the properties of the adult precursor cells, we have directly compared the properties of highly purified perinatal and adult precursor cells. 2,000 adult oligodendrocyte precursor cells per P60 rat optic nerve were isolated by immunopanning to greater than 99% purity. The purified cells share several properties with their perinatal counterparts: nearly all differentiated into GC^+ oligodendrocytes in serum-free medium or into $GFAP^+$ type-2 astrocytes in serum-containing medium. Clonal studies showed that nearly all adult oligodendrocyte precursor cells divided symmetrically in serum-free medium containing PDGF, NT-3, IGF-1 and thyroid hormone. They divided, however, at least five to ten times more slowly than the perinatal cells and generated few oligodendrocytes. The purified adult precursor cells did not revert to rapidly dividing cells in PDGF and FGF. These studies demonstrate that perinatal and adult oligodendrocyte precursor cells are intrinsically different and raise the question of whether adult oligodendrocyte precursor cells have the ability to revert into rapidly dividing precursor cells.

THE PRESENCE OF MICROGLIA IN MURINE EMBRYONIC CULTURES OF EGF-GENERATED NEUROSPHERES. A.K. Papavasiliou, M.F. Mehler, K. Dobrenis, R. Marmur, P. Mabie, C.S. Raine*, J.A. Kessler. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Although microglia play a prominent role in central nervous system (CNS) pathophysiology, their relationship to other major cellular lineages during CNS development is not well characterized. The predominant view is that all microglia are of monocytic lineage. Alternatively, it is possible that during fetal development a subpopulation of microglia also arise from endogenous progenitor cells. To address this issue, we have studied the elaboration of microglia in epidermal growth factor (EGF)-generated multipotent progenitor cells from the E17 mouse subventricular zone (SVZ), known to give rise to the three major CNS lineages. Utilizing the following microglial markers, Griffonia Simplicifolia I-B4 Isolectin, dil-acetylated LDL, Mac-1 and F4/80, we now report the presence of microglia within these cultures. Treatment of serially passaged EGF-generated neurospheres with either CSF-1 or GM-CSF altered microglial morphology leading to ramified (CSF-1) or amoeboid (GM-CSF) microglia with a small increase in cell number. By contrast, treatment with microglial conditioned media greatly increased the number with both morphologies. Application of cytokines (bFGF,CSF-1, IL-6) allowed the generation of microglia from single isolated neurospheres. Current studies are underway to examine whether these microglia are derived from neural progenitor cells.

TRANSFECTION OF DISSOCIATED EMBRYONIC AND POSTNATAL RAT RETINAL CELLS IN CULTURE BY PARTICLE-MEDIATED GENE TRANSFER. E. M. Levine, L.C. Streichert*, and T. A. Reh, Department of Biological Structure, University of Washington, Seattle, WA 98195.

The difficulty in transfection of progenitor cells and neurons is a major obstacle of gene expression studies in the mammalian central nervous system. Using particle-mediated gene transfer, or biolistics, we have successfully transfected coverslip cultures of dissociated E18 - P2 rat retinal cells. In biolistics, DNA is precipitated onto micron sized gold particles that are delivered to the cells by a high-pressure burst of helium in an evacuated chamber. To determine the effectiveness of this approach, we transfected the pCS2 expression vector containing either the E.coli ß-galactosidase (ß-gal) gene or a 6-repeat myc epitope tag (MT) under the control of the immediate early CMV promoter. Cytochemical detection of ß-gal was done with the substrate X-gal or with anti-ß-gal antibodies. The MT was detected with the 9EC10 anti-MT monoclonal antibody. Transfection of high-density coverslip cultures (*initial plating density* 2.5 x 10^5 cells) ranged from a few hundred to over 1000 cells. Expression of the transfected plasmids was observed 8 hours to 9 days post-transfection. Using cell-type specific antibodies to identify the retinal cell classes, transfection was observed in most retinal neurons as well as progenitor cells. In co-transfections using the pCS2-ß-gal and pCS2-MT, most cells that were successfully transfected expressed both ß-gal and the MT. Therefore, this technique is amenable for gene expression studies in embryonic and postnatal rat retinal cultures.

DETECTION OF GENOMIC SEQUENCE VARIATION BETWEEN NEOCORTICAL CELL LINES AND GERM LINE DNA. J.J.A. Contos and J.J.M. Chun*. Dept. of Pharmacology, School of Medicine, University of California at San Diego, La Jolla, CA 92093-0636

We are investigating the hypothesis that genomic DNA rearrangements occur during the normal development of mammalian CNS neurons. The technique we have utilized is representational difference analysis (RDA), a PCR-based method that allows selective amplification of low molecular weight restriction fragments unique to a given DNA sample (Lisitsyn et. al., Science 259: 946, 1993). With the assumption that the cells of the CNS are not homogeneous with respect to genomic DNA variability, a clonal cell line derived from the mouse embryonic telencephalon was used to derive DNA representing potential rearranged loci in the CNS. RDA was used to amplify differences between this genomic DNA and putative germ-line genomic DNA (derived from adult liver). The cell line contains one copy of a retroviral provirus with the SV40 Large-T oncogene (LgT). A *HindIII* fragment of 527 bp in the LgT gene, not present in the liver genomic DNA, serves as a positive control for the technique. Southern blot analysis of RDA products has shown this fragment to be selectively amplified in our experiments. Several other restriction fragments of various sizes were also selectively amplified. These RDA products may result from altered restriction fragment length created by proviral integration, spontaneous *in vitro* mutations in the cell line during culture, or normal *in vivo* rearrangements occurring before the cell line was established. Three approaches are being used to analyze these fragments: 1) identification of proviral-containing products by Southern-blot analysis, 2) determination of sequence homologies within/between various products and to known genes, and 3) generation of RDA products from independently derived cell lines to determine which products among various cell lines have common genomic loci. 697.5

A PRODUCT(S) OF ACTIVATED MICROGLIA PROMOTES CHOLINERGIC DIFFERENTIATION OF CULTURED BASAL FOREBRAIN NEURONS. G. M. Jonakait*, M. B. Luskin, R. Wei, and L. Ni. Dept. of Biological Sciences, Rutgers University, Newark, NJ 07102 and Dept. Anatomy & Cell Biol., Emory University School of Medicine, Atlanta, GA 30322

In cultures of embryonic septal nuclei with adjacent basal forebrain (SN/BF), interferon-γ (IFNγ) dramatically increases the activity of choline acetyltransferase (ChAT) by increasing the number of cholinergic neurons (Jonakait et al., *Neuron* 12:1149). Since the target of IFNγ is ameboid microglia, we have assayed the effects of conditioned media (CM) derived from enriched cultures of activated (i.e., IFN-treated) primary microglia and from an unstimulated monocyte/macrophage cell line (RAW 264.7) on ChAT activity in septal cultures, and have found that these CM raise ChAT activity in SN/BF cultures 15-16 fold. Efficacy of CM is dependent on the density of cultured cells, reaching maximal effects at approx. 10^6 cells/ml. IFN treatment of RAW cells is not required to obtain activity.

Cultures labeled with retroviral markers (BAG) and treated with either IFN or CM from activated microglia or RAW cells show a 3-9-fold increase in the percentage of cholinergic cells detected in retrovirally labeled clones. Neither NGF nor bFGF mimics this action. These data suggest that all three treatments promote cholinergic differentiation of undifferentiated precursors present in the cultures.

PURKINJE CELL LINEAGE AND THE TOPOGRAPHIC ORGANIZATION OF THE CEREBELLAR CORTEX: A VIEW FROM X INACTIVATION MOSAICS K. Schilling*[1], B. Rosengarten[1], M.L. Schilling[1], W. Pretsch[3], S.L. Baader[1], and H.F. Teutsch[2]. 1) Abt. Anatomie & Zellbiologie, 2) Abt. Anatomie, Universität Ulm, D-89069 Ulm, Germany, and 3) Institut für Säugetiergenetik, GSF Neuherberg, D-85758 Oberschleißheim, Germany

We utilized a strain of mice, derived from a radiation mutagenesis experiment and carrying an activity-attenuated allele of the X linked enzyme, G6PD, to analyze the development of the cell lineage leading to cerebellar Purkinje neurons. Due to random X inactivation during early embryonic development, X linked genes can be used to distinguish between clonally related populations of cells in X inactivation mosaics. Following histochemical staining for G6PD activity, the numeric proportions of Purkinje cells expressing either the wild type or the mutant enzyme and the spatial distribution of these cellular phenotypes and their relation to anatomically and genetically defined cerebellar compartments was analyzed. Our data suggest that cerebellar Purkinje neurons originate from a limited pool of precursors. The size of this pool is different from the one derived from chimeric mice (e.g. Vogel & Herrup, Dev.Biol. 156, 49, '93), allowing us to deduce the relative timing of Purkinje cell lineage restriction. Our data also show that Purkinje neurons of distinct lineage are extensively intermingled within the cerebellar cortex. Together, these findings imply that genetically defined cerebellar compartments (e.g. Oberdick et al, Neuron 10, 1007, '93) are not a simple consequence of the spatial arrangement of clonally related Purkinje cells. Rather, they suggest a role for cell/cell communication in the development of these compartments and hint to a temporal window during which such cellular interactions may take place. Supported by the BMBF, the DFG, and NATO.

CELL LINEAGE AND EMBRYONIC ORIGINS OF TASTE RECEPTOR CELLS. L.M. Stone*, T.E. Finger, U. Colo. Hlth. Sci. Ctr., Denver, CO 80262 P.P.L. Tam, U. Sydney, Sydney, Australia, and S.-S. Tan, U. Melb., Melbourne, Australia.

Taste buds consist of several cell types, based on morphological and immunocytochemical characteristics. For example, basal, dark, intermediate and light cells can be distinguished using electron microscopy (e.g. Delay et al., J. Comp. Neurol., 1986); subsets of cells that are serotonin immunoreactive or gustducin immunoreactive can be distinguished at the light microscopic level (Böttger et al., Chem. Senses, in press). Using mosaic analysis, we previously demonstrated that multiple progenitors give rise to this complex population of neuroepithelial cells and that these progenitors derive from local epithelium (Stone et al., PNAS, 1995). Further investigation now has revealed that this local epithelium giving rise to taste buds may be of either ectodermal or endodermal origin. Currently, we are addressing the question of cell lineage relationships within the taste bud. As in previous studies, we are using X inactivation mosaic mice to examine clonal relationships. These mice are transgenic, female mice that contain multiple copies of a *lacZ* marker on one of their two X chromosomes. Early in development, this results in the ubiquitous production of ß-galactosidase (ß-gal) in embryonic cells. However, during development, as occurs in all mammalian females, one of the two X chromosomes is randomly inactivated in each cell. This process is stable and clonally heritable, and results in two cell populations in the mouse: one that expresses ß-gal, and one that does not. Thus the mouse is mosaic for ß-gal expression, and this mosaicism can be used for cell lineage analysis. In the taste bud, this is accomplished by analyzing taste buds that contain both ß-gal+ and ß-gal- cells. Statistical analysis of the relationships between ß-gal expression and morphological or immunocytochemical cell types indicates which of these cell types are clonally related.

HUMAN LEPTOMENINGEAL CELLS DIFFERENTIATE INTO ASTROCYTE-LIKE CELLS IN INJURED RAT SPINAL CORD. J.J. Bernstein[1]*, S.A. Karp[1], L.A DiGorgio[2] and J.P. Blass[2]. Lab CNS Regen & Neuro-Oncol, DVA Med Ctr, Wash DC, 20422[1] & Burke Med Res Inst, Cornell Univ Med Coll, White Plains, NY[2]

Human leptomeningeal cells (HLC) were cultured at autopsy from a 84 year old woman (6 hours after death). 10^6 HLC (in 4 µl), incubated in fast blue as a premarker, were placed in an aspiration pocket in the C3 dorsal columns of 40, adult, athymic male rats. Rats were perfused with 4% paraformaldehyde after 3 (day),1,2,3,4, and 8 weeks. Using confocal microscopy and immunofluorescence, studies were performed using antibodies to GFAP and neurofilament protein. Cells in the spinal cord that contained fast blue, were positive for GFAP and negative for neurofilament protein were considered to be grafted HLC that differentiated with astrocyte-like characteristics. Cells with these characteristics were found in the adjacent dorsal and ventral horns of the spinal cord in the area of the implantation pocket. These cells were observed for the 8 weeks of the experiment. These data indicate that there are pluripotential cells in aged humans.

Embryonic rat hindlimb cells injected into the caudate-putanum mature into fast and slow muscle fibres arranged as fascicles around chondrogenic cores.
C.L. Pin, W.J. Rushlow, K.A. Rogers, A.W. Hrycyshyn* and P.A. Merrifield. Dept. of Anatomy, Univ. Western Ontario, London, Ontario, Canada N6A 5C1.

Myoblasts obtained from embryonic day 14 (ED 14) rat hindlimbs have been shown in culture to differentiate into small myotubes which exclusively express embryonic and slow myosin heavy chains (MyHC). Unlike myoblasts obtained from later time points in development, these cells undergo limited fusion and do no not express fast MyHCs. (Dev. Genet. 14, 356. 1993). Due to these differences, we have postulated that "embryonic myoblasts" represent a myoblast lineage responsible for the formation of slow muscle fibres *in vivo*. To test this hypothesis, cell suspensions from ED14 rat hindlimbs were stereotaxically injected into the caudate-putanum of adult rats to determine their developmental potential in an ectopic site. At two weeks post-injection, it could be seen that extensive proliferation and fusion of the myoblasts had occurred. By four weeks, the grafts were histologically similar to fetal hindlimbs. In every graft, large muscle fascicles could be seen encircling a cartilaginous core. Prior to innervation, muscle fibres typically contained peripherally-located nuclei and expressed slow, fast or both slow and fast adult MyHC isoforms. Staining with alcian blue and silver nitrate revealed that the cartilaginous cores are undergoing osteogenesis, exhibiting all of the typical stages of endochondral ossification, and are enclosed by a well developed periosteum. These results suggest that (a) ED14 hindlimb myoblasts are capable of forming both slow and fast muscle fibres when maintained under permissive conditions *in vivo*, and that (b) innervation is not required for the expression of adult fast and slow MyHCs. Furthermore, the organization of cells within the grafts to form osteogenic cores and muscle fascicles suggests that embryonic cells sort themselves within the grafts to generate structures similar to those seen in fetal limbs. (Supported by MDAC).

EXPRESSION OF MEF2C IN FETAL MOUSE BRAIN.
D. Leifer,* Y. L. Li, and K. Wehr. Dept. of Neurology, Yale University School of Medicine, New Haven, CT 06510.

MEF2C (myocyte-specific enhancer binding factor 2C) is a member of the MADS family of transcription factors and is expressed preferentially at high levels in human and rodent cerebral cortex. We have previously studied the distribution of MEF2C immunoreactivity in human cerebral cortex from 14 weeks of gestation to adulthood. In adult human cortex, double-labeling experiments indicate that it is expressed preferentially in inhibitory interneurons. In human fetal cortex, MEF2C immunoreactivity is localized to the cortical plate. It is not found in the ventricular or intermediate zones during the stages of fetal development that we examined, but cortical neurogenesis is nearly complete by the earliest ages that we were able to examine. We have now used *in situ* hybridization and immunohistochemistry to study MEF2C expression in fetal mouse brain during the period from E11 to E17 when most cortical neurons are generated. Both methods indicate that MEF2C is expressed in the cortical plate and that little, if any, is present in the ventricular or intermediate zones. In addition, MEF2C is detectable in other areas of the brain including the olfactory bulb, the basal forebrain, the inferior colliculus, and the cerebellum, and in some cells within the thalamus and amygdala and in scattered cells elsewhere in the brain. These results indicate that MEF2C expression is tightly controlled both spatially and temporally. In addition, the results indicate that it appears to be turned on in cortical neurons after they become post-mitotic and migrate to the cortical plate. This pattern of expression suggests that MEF2C may have a role in the post-mitotic differentiation of specific subsets of neurons.

697.11

CLONING & EXPRESSION OF ZEBRAFISH LH-2/apterous HOMOLOGS.
T. Tsubokawa, K. Uyemura, H. Okamoto*, Dept.Physiol., KEIO univ., Schl. Med., Shinano-machi 35,Shinjuku-ku Tokyo 160, Japan

LIM homeo domain transcription factors play important roles in cell fate determination during development in vertebrates and invertebrates. Drosophila ***apterous(ap)***, a member of this family, is involved in the establishment of dorso-ventral compartment in wing imaginal disc and in identity determination of specific sets of muscles and neurons. Recently, ***LH-2***, a vertebrate counterpart of ***ap***, was cloned in rat, and shown to be expressed in the nervous system. We identified ***LH-2/ap*** homologs in zebrafish and examined its expression pattern using in situ hybridization. Two of them were expressed in the developing eyes and diencephalon at 10hr after fertilization, but the expression in the eyes faded by 16hr. By 28hr, their expression was restricted to many neuromere boundaries (e.g. between thalamus and pretectum, pretectum and tectum, midbrain and hindbrain) and also to every rhombomeric border in the hindbrain. Double staining with in situ hybridization and an antibody which stains most axons revealed that many early tracts of developing zebrafish brain (POC, DVDT and commissural tracts in rhombomere) were formed along the regions where ***LH-2*** mRNA was expressed. Accumulating evidences have suggested that early neurons are born along the neuromere boundaries and neuromere boundaries may express local cues for axonal guidance. The expression pattern of zebrafish ***LH-2*** suggests that LH-2 may control either the expression of such cues or the differentiation of neurons on the borders.

697.12

DEVELOPMENTAL REGULATION OF THE PDGF α-RECEPTOR EXPRESSION IN GLIAL CELLS AND NEURONES OF THE MOUSE CENTRAL NERVOUS SYSTEM.
B. Nait Oumesmar, L. Vignais and A. Baron-Van Evercooren*. U134 INSERM, Hôpital de la Salpêtrière, 75651 Paris cédex 13, France.

Several studies have provided evidence for the expression of the PDGF α-receptor (PDGF-αR) on oligodendrocyte progenitors (O-2A). The effects mediated by this receptor are proliferation, migration and chemoattraction. High levels of PDGF-A chain transcripts are detected in neurones of the embryonic and adult mouse central nervous system (CNS), suggesting that neurones may direct proliferation, targeting and finally differentiation of the oligodendrocyte progenitors prior to myelination. In this study, we analysed the expression of the PDGF-αR during the postnatal (P) development of the mouse CNS by in situ hybridization and immunohistochemistry on brain and spinal cord tissue sections. Between P1 and P15, PDGF-αR (transcripts and protein) are preferentially expressed by O-2A progenitors and pre-myelinating oligodendrocytes as previously reported. At P15, these cells with an O4-phenotype are in contact with PDGF-αR positive neurites in the cerebral cortex. At P21, this expression spreads throughout the brain and spinal cord and correlates well with the peak of myelination occurring at this time. In the mature CNS, PDGF-αR mRNA and protein are not detected in oligodendrocytes but are found in very few glial progenitors located in the cerebral cortex or the spinal cord white matter. Neural progenitors located in the subventricular zone and the ependymal/subependymal layer of the olfactory ventricle are also PDGF-αR positive. The most striking observation in our study is that mature neurones strongly express the PDGF-αR. In the forebrain, PDGF-αR positive neurones are noted in the mitral layer of the olfactory bulb, prefrontal and entorhinal cortex. In the cerebellum, Purkinje cells and deep nuclei neurones highly express PDGF-αR, as well as different brainstem nuclei, e.g, the facial and vestibular nuclei. In the spinal cord, neurones of the dorsal horn and motor neurones of the ventral horn are also labelled. This neuronal expression is first observed around P7 and extends to restricted central neuronal populations. The present data demonstrate a developmentally regulated sequential expression of the PDGF-αR early in glia and later in mature central neurones, suggesting a more extensive role for this receptor than previously described.

697.13

RAG-1-DEPENDENT IMMUNOGLOBULIN-LIKE IMMUNOREACTIVITY IN THE PERINATAL MURINE BRAIN.
J.A.Weiner* and J.J.M.Chun. Dept. of Pharmacology and Program in Neurosciences, Sch. of Med., Univ. of California, San Diego, La Jolla, CA 92093-0636.

Several reports have demonstrated immunostaining of cat, mouse and rat brains using species-specific anti-immunoglobulin-gamma (IgG) antisera. However, the identity of the immunostained molecule remains uncertain. Transcripts of the recombination-activating gene-1 (RAG-1), which encode one component of the putative V(D)J recombinase required for immunoglobulin gene rearrangements, have also been detected in the murine central nervous system. This finding suggests that some form of DNA rearrangement may occur there. Since IgG synthesis requires V(D)J recombination through RAG-1 expression, we have examined mice lacking the RAG-1 gene to determine whether the previously observed immunoglobulin-like immunoreactivity is RAG-1-dependent. We have employed three different antisera in this study, two of which recognize both heavy and light chains of mouse IgG (one containing whole antibodies and one consisting of $F(ab')_2$ fragments only), and one specific for the γ heavy chain. With all three antisera, we have observed immunostaining of the marginal zone and subplate of normal perinatal mice (E16-P1) similar to that previously reported. However, no immunostaining was apparent in the brains of mice from two independently derived and comparably aged RAG-1 -/- strains using any of the antisera, despite normal staining for known neuronal marker proteins. There are two possible interpretations of these results. Neurons in the immunostained areas may express an immunoglobulin-like molecule in a RAG-1-dependent manner, which is detected by anti-IgG antisera. Alternatively, neurons in the immunostained areas may bind or internalize serum IgG, which is absent in the RAG-1 -/- mice. We are presently investigating these possibilities. [We thank Drs. E. Spanopoulou and D. Baltimore for their RAG-1 -/- line. Supported by the Klingenstein Fund and NSF Graduate Fellowship.]

MORPHOMETRIC ANALYSIS OF CULTURED RAT BRAINSTEM MOTONEURONS: INFLUENCES OF GLIAL CELLS AND MUSLES. J.P. Ternaux*, P. Portalier and M.C. Chamoin. UPR 9041 CNRS, 280 Bd Sainte-Marguerite, 13009 Marseille, France.

Rat brainstems were sampled at day embryonic 15 to 18 and motoneurons were purified using a Nycodenz gradiant. Acetylcholine (ACh) content in the motoneurone fraction was 14 times higher than that detected in the glial and interneurones fraction. Purification of motoneurons (95 to 98 %) was further demonstrated using antibodies raised respectively against : ACh, choline acetyltransferase, Islet I and low affinity NGF receptors. Purified motoneurons were cultured in defined medium on glass coverslips coated with poly-L-lysine and laminin, with or without inserts containing either glial cells and/or myoblasts from tongue muscle. Growing motoneurons were observed during 7 days in culture and photographed. Morphometric parameters of 30 motoneurons selected at random were determined in each case, using a specific software. Survival of motoneurons was significantly increased in presence of glial cells and/or myoblasts inserts and total length of neuritic processes was significantly enhanced, with a marked effect on axons. No change was observed about the number of primary neurites but branching was significantly higher in the presence of a muscle insert. This effect disappeared when motoneurones were cultured in the presence of both glial cells and muscle inserts, suggesting a permissive influence of glial soluble factors on neuritic motoneuron branching.

698.2

DENERVATION-INDUCED DEATH OF TERMINAL SCHWANN CELLS IS CORRELATED WITH POOR REINNERVATION OF NEONATAL MUSCLE. W.J. Thompson* and J.T. Trachtenberg, Department of Zoology, The University of Texas, Austin, Texas 78712.

Denervation of neonatal rat muscles leads to apoptosis of terminal Schwann cells (Trachtenberg, this meeting). This contrasts with the situation in adult muscles where denervation leads to growth of Schwann cell processes from each endplate, processes that appear to be important in guiding axons during muscle reinnervation. In contrast to the adult, reinnervation of neonatal muscle is reported to be deficient, and the time period of this deficiency is roughly the time period of susceptibility of neonatal Schwann cells to axotomy-induced death. In attempt to test the importance of terminal Schwann cells for muscle reinnervation, we created nerve lesions in neonatal animals that led to return of regenerating axons either before or after the Schwann cells had died. Following crush of the nerve to soleus at its entry into the muscle, axons regenerated prior to the disappearance of many terminal Schwann cells. In these cases, the muscle was well reinnervated and the endplate band across the muscle was not much altered from normal (axons formed endplates in association with one or more terminal Schwann cells). However, in cases where nerve lesions were made at a greater distance from the muscle, regenerating axons arrived in the muscle after most terminal Schwann cells had died. In these muscles, many fewer fibers were successfully reinnervated, and the pattern of axon growth was abnormal. Axons generally grew through the old endoneurial tubes in the old endplate zone without branching. What few nerve terminal branches were present were associated with a few Schwann cells with long, extended processes. Thus, some Schwann cells are capable of migrating from the intramuscular nerves together with the regenerating axons; however, even these junctions were deficient in their Schwann cell composition. These results suggest that Schwann cell death may contribute to the poor reinnervation of neonatal muscles. These results also suggest that the persistent Schwann cells at adult junctions are important in reinnervation.

698.3

APOPTOSIS OF SCHWANN CELLS AT THE DEVELOPING RAT NEUROMUSCULAR JUNCTION IS REGULATED BY MOTOR NEURONS J.T. Trachtenberg* and W.J. Thompson, Department of Zoology, The University of Texas, Austin, Texas 78712.

Recent research from this lab has suggested that Schwann cells play critical roles in the processes of reinnervation and terminal sprouting in skeletal muscles Terminal Schwann cells overlying denervated endplates sprout elaborate processes which guide regenerating motor neurons and motor nerve terminal sprouts. In light of reports which suggest that reinnervation and terminal sprouting are deficient in neonates. I have examined the effects of muscle denervation by sciatic nerve resection on neonatal Schwann cells. Within 3 - 6 days of muscle denervation in rat pups aged P0-P14, 100% of terminal Schwann cells covering denervated endplates disappear. During the third postnatal week, the percentage of denervated endplates lacking terminal Schwann cells decreases, with no loss occurring after denervation on P25 or later. Use of end-labeling techniques employing terminal transferase and modified nucleotide substrates shows that the DNA of these cells fragments as they disappear. DNA fragmentation suggests that apoptotic death underlies Schwann cell disappearance. In muscles paralyzed with botulinum toxin, terminal Schwann cells remain over quiescent endplates, suggesting that Schwann cell death is regulated by neuronal rather than muscle derived trophic factor(s). Additionally, following botulinum toxin induced paralysis, terminal Schwann cells sprout processes which are associated with, but advancing in front of, nerve terminal sprouts. The results of these experiment suggest that 1) neuronal derived trophic factors regulate Schwann cell apoptosis at developing endplates, and 2) Schwann cell apoptosis following axonal degeneration, rather than functional deficiencies in neonatal Schwann cells, may underlie the deficiencies in reinnervation and sprouting in denervated neonatal muscle (Thompson, this meeting). Schwann cell apoptosis occurs at low levels in control, innervated muscles, suggesting that Schwann cell apoptosis may play a role in normal endplate development. Current efforts are aimed at identifying trophic factors which may rescue neonatal Schwann cells from death following denervation.

698.4

INFLUENCE OF THE AXON ON PRESYNAPTIC REGENERATION BY ADULT SENSORY NEURONS IN VITRO. M. Nachman-Clewner[1] and E. Townes-Anderson[2]*. [1]Cornell Univ. Med. Coll., New York, NY 10021, and [2]Dept. of Neurosciences, Univ. of Med. and Dentist. of NJ, Newark, NJ 07103.

Regeneration of neurites and presynaptic varicosities by cultured rod photoreceptors from the adult tiger salamander retina has recently been demonstrated. Quantitative variability in this regenerative response prompted us to investigate whether axonal lesion due to retinal disruption might promote process outgrowth and varicosity formation by these neurons. Cells were maintained *in vitro* as described (MacLeish and Townes-Anderson, 1988). Using Nomarski optics and time-lapse video microscopy, pairs of acutely isolated rod photoreceptors, in which one cell had lost and the other retained its original axon terminal, were selected and followed for 24h to 48h in culture. Cells were analyzed morphologically and immunocytochemically, utilizing antibodies to synaptic vesicle protein 2 (SV2) or synaptophysin (p38) to identify presynaptic sites, and to rod-specific opsin (4D2) to distinguish rod photoreceptors. Surprisingly, rod cells with an intact axon regenerated, on average, twice as many processes and five times as many presynaptic varicosities per cell as axotomized neurons. Axon retraction and elaboration of an axonal lamellipodium occurred by 24h *in vitro* in 75% of rod cells with a terminal upon plating, and varicosity bearing neurites developed from lamellipodial filopodia by 48h. Synaptic vesicle redistribution from terminal to lamellipodium to varicosities closely parallelled structural reorganization of the axon. By comparison, cells whose axon was lesioned exhibited virtually no synaptic vesicle immunoreactivity during early regenerative stages. As evidence for *de novo* protein synthesis, neurons were examined for colocalization of synaptic proteins with rab 6, a Golgi marker, in 0.5 µm optical sections by confocal microscopy. Initial formation of vesicle-filled varicosities preceded SV2/rab 6 colocalization. SV2 staining did not appear in the Golgi of cells with or without an axon until 2d to 7d *in vitro*. In contrast, rab 6 colocalized with opsin, a protein constitutively expressed throughout regeneration, even at 2h *in vitro*. Collectively, the data point to a positive role for the axon and suggest that SV protein synthesis is not a prerequisite for presynaptic regeneration. We propose a model in which regenerating neurons reutilize preexisting axonal components to expedite synaptic renewal as part of an early response to denervation. Supported by NIH Grant EY06135.

A RETINOTOPIC ANALYSIS OF THE DYNAMICS OF REGENERATING ARBORS IN LIVING ADULT GOLDFISH F.A.Johnson* and R.L. Meyer Dev. Biol. Center, University of California, Irvine, Irvine CA 92717

The formation of correct connections is crucial to the proper functioning of the nervous system. In the retinotectal system in goldfish, the initial projection is only roughly retinotopic and is progressively refined during regeneration such that ectopic synapses are eliminated in favor of retinotopic ones. This process is thought to depend on activity. In order to study the dynamics of this restructuring we labelled axons from a small area of retina and observed the arbors in living fish. Retinal arbors were labelled by a small injection of a fluorescent lipophilic neuronal tracer, DiI, into the retina of goldfish during the period of activity-dependent refinement, thirty to sixty days after an optic nerve crush. Five to seven days later, the tectum was exposed and the labelled arbors were observed with a cooled CCD camera. Images of the arbors were collected over five to eight hours to determine if the arbors had elongated or retracted in that time. Some regenerating and all normal arbors were stable in this time period, indicating that visualizing the arbors does not damage them. Many of the regenerating arbors observed exhibited some form of plasticity. Regenerating axon endings in tectal areas that had many other labelled endings, i.e. axons from cells in the same small area of retina, could be seen to grow or retract by small amounts- 10-20 µm. In contrast large retractions were observed when axons were separated from their retinotopic cohorts. Branches became filled with many large varicosities over the course of a few hours, then retracted 20-100 µm. In some cases axons seem to lose more than one branch in the same area. This suggests that axons can eliminate large portions of an arbor in a short time, and this may be more likely to occur in retinotopically inappropriate areas.

STUDIES OF PHOTORECEPTOR AXONS REGENERATING *IN VITRO* FROM *DROSOPHILA* EYE DISCS. Chinglu Li*, X-J. Sun and L.A. Meinertzhagen. Life Sciences Centre, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

Cells in the developing nervous system exhibit various signs of plasticity. We have used a primary culture system to study the development of the adult visual system in *Drosophila*. We have previously reported neurite extension from photoreceptors and endocrine regulation of eye disc differentiation *in vitro*. Here we report that newly differentiated photoreceptors in early pupae exhibit considerable plasticity, insofar as most extending neurites observed in culture have regenerated from severed photoreceptor axons. We used eye-imaginal discs from flies 5h after pupariation (P+5) in our cultures. Eye discs were cut into small fragments and dissociated by light enzymatic treatment with 0.05% trypsin for 15 mins. This partially dissociated the fragments, exposing the stumps of severed photoreceptor axons. These stumps initially floated in the culture medium. Their cell bodies were located in the disc fragment proper that adhered to the culture vessel. A few hours after culture initiation, the stumps attached to the substrate and started to elongate. Growth cones were frequently seen at the terminals of these regenerating axons. Punctate immunoreactivity to synaptotagmin, a synaptic vesicle protein, was detected along the neurites. Although the expression of synaptotagmin did not require ecdysone, the presence of this hormone caused more immunoreactive spots to appear along the length of the neurite. Growth cones were often foci of synaptotagmin immunoreactivity. Synapse formation occurs after photoreceptor axon growth cones collapse, *in vivo*. *In vitro*, the presence of synaptotagmin at growth cones implies the formation of vesicles. This suggests the presence of transmitter at growth cones, and immunoreactivity to histamine (HA, the photoreceptor transmitter) is indeed detected at the growth cone. It is possible that HA is released from growth cones and autoregulates neurite outgrowth. The effects of HA on neurite outgrowth will be presented. We also studied the ultrastructure of photoreceptor neurites in 5-d co-cultures of eye-disc fragments and optic lobe cells from early pupae. Junctions with a widened intercellular cleft, with synaptic vesicles, but lacking clear presynaptic ribbons, differentiate in the cultures. These observations suggest that severed photoreceptors are not only able to regenerate, but may also release transmitter *in vitro*. Supported by NIH grant (EY-03592).

SCHWANN CELL-COATED CARBON FILAMENTS AS STIMULATORS OF CNS AXONAL REGROWTH. S. Sayers*, T. Khan, K. Klein, G. DeVries, L. Liu. Rehab. R&D Center, Hines VA Hospital, Hines, IL 60141 and Dept. of Biochemistry, Medical College of Virginia, MCV Station Box 614, Richmond, VA 23298.

Regrowth of axons in the CNS occurs to a limited extent due to the nature of the environment. We have previously utilized small diameter (5μm) carbon filaments (Amoco Thornel ™) as an adjuvant to stimulate direct regrowth of transected axons in the CNS. We co-cultured Schwann cells (SC) with carbon filaments in the absence and presence of 14 day old rat fetal spinal cord tissue. We utilized a Human cell line (NF-1T) derived from a malignant soft tissue sarcoma from a patient diagnosed with neurofibromatosis. These cells showed the expected immunoreactivity to antigens known to be present on SC. In culture, these cells demonstrated the typical spindle spaced bipolar morphology and aligned themselves in fascicles.

Co-culture of NF-1T cells with dorsal root ganglion (DRG) neurites demonstrated that the NF-1T cells preferred the neuritic surface rather than the surface of other NF-1T cells. The ability of NF-1T cells to promote axonal outgrowth *in vitro*, together with the expression of markers known to be associated with SC, made them promising candidates for interacting with carbon filaments to further promote CNS axonal regrowth.

Scanning electron microscopy revealed that the NF-1T cells interacted with the surface of the carbon filaments aligning themselves with their long axis parallel to the long axis of the carbon filaments. The surface of the NF-1T cells was covered with numerous filopodia which appeared to aid in the stabilization of these cells on the carbon filaments. The presence of SC in the co-culture induced extensive neuritic outgrowth from the explants. Experiments to define the optimal ratio of NF-1T cells to carbon filaments are in progress. These experiments are designed to manipulate the NF-1T-carbon filament culture conditions so that the majority of the surface of the carbon filaments will be completely covered with NF-1T cells. In turn, these SC coated filaments should act as an effective stimulator of axonal regrowth *in vivo*.

RE-EVALUATION OF THE GROWTH PERMISSIVE SUBSTRATE PROPERTIES OF GOLDFISH OPTIC NERVE MYELIN

D. Lang[1]*, M. Wanner[1], C. Bandtlow[2], M.E. Schwab[2], M. Bastmeyer[1] and C.A.O. Stuermer[1], [1] Faculty of Biology, University of Konstanz, 78434 Konstanz, Germany; [2] Institute for Brain Research, University of Zurich, 8029 Zurich, Switzerland

Success of axonal regeneration in the goldfish optic nerve was previously found to correlate with the growth permissive substrate properties of fish CNS myelin. To determine if fish optic nerve myelin carries neurite growth inhibiting activities which would be neutralized by monoclonal antibody (Mab) IN-1 against mammalian neurite growth inhibitors (NI) (Caroni and Schwab, 1988), three sets of experiments with established methods were performed. (i) When fish optic nerve myelin was used as a substrate, both fish retinal ganglion cell (RGC) and rat DRG axons extended to considerable density and length. The presence of Mab IN-1 did not improve this growth, but unexpectedly Mabs O4 and O1 employed as "controls" reduced fish but not DRG axon outgrowth significantly. (ii) Axon growth on fish optic nerve myelin was quantified with IN-1 present in the medium and in assays in which myelin was preincubated with IN-1. In both, IN-1 had no effect on axon number or length. However, the same experiments with rat CNS myelin resulted in a marked rise of axon numbers and length with IN-1 as opposed to untreated myelin which hardly allowed any growth. (iii) Liposomes with incorporated CHAPS-extracted fish optic nerve myelin proteins were added to fish and DRG growth cones. One fraction was preincubated with IN-1 before use. 77% of fish and 89% of rat DRG axons continued to grow when contacted by the liposomes, and 80% of fish axons kept growing with IN-1 treated liposomes. Liposomes with CHAPS-extracted bovine CNS myelin proteins, however, induced collapse of 73% fish growth cones.

Thus, fish RGCs are sensitive to mammalian NI, but mammalian-like NI activities, which would be neutralized by IN-1, were not detectable in fish optic nerve myelin.

DEVELOPMENTAL CONTROL OF RETINAL BIPOLAR CELL ARBORIZATION AND STRATIFICATION FOLLOWING INDUCED RETINAL ENLARGEMENT. J.C. Crowley, M. Xiong, B.D. Rubin, and B.L. Finlay*. Developmental Neuroscience Group, Cornell Univ., Ithaca, NY 14853.

Connectivity in the retina is established by either general or cell specific rules. The maintenance of correct dendritic and axonal arbor size plays a critical role in the maintenance of convergence ratios within the retina, which are responsible for the retina's balance between acuity and sensitivity. Previous work in this lab has described the relevant environmental factors that control the development of retinal ganglion cell arbors to be retinal ganglion cell density and the density of presynaptic input available to the cell. We manipulated retinal cell density in an effort to determine the effect of cell density on the production of bipolar axonal and dendritic arbors.

This study used visual form deprivation to experimentally enlarge the eye in the chick. Visual form deprivation induces ocular enlargement, producing a larger than normal retinal area and a reduction in RGC density of 20-30%. Ocular enlargement produced bipolar cells whose somas are 11.8% larger, whose axonal arbors are 36.8% larger, and whose axonal process had fewer stratifications. The number of IPL stratifications was also found to be inversely related to the total arbor size.

Center - periphery effects were also observed. Peripheral axonal arbor size increased 20.0%, an effect that was strongest in the experimental retina. The total length of the bipolar's dendritic process was also increased in the periphery, and a positive correlation was found between OPL and IPL arbor diameter.

These results are consistent with the results found previously for the RGC population of the chick; in both cases IPL arbors increase their coverage to fill the space made available by the retinal enlargement. The relationship between arbor size and number of stratifications suggests that in eye enlargement, growth is stimulated to such an extent that a physiological limit for either growth rate or cell size is reached and retinal coverage is conserved at the expense of IPL stratifications. In this way multistrata processing is subordinated to the maintenance of processing capability.

DEVELOPMENTAL CONTROL OF DOPAMINERGIC AMACRINE CELL ARBORIZATION FOLLOWING PARTIAL OPTIC NERVE SECTION. M. Xiong*, J. C. Crowley, D. Troilo, M. Kelly, and B.L. Finlay, Developmental Neuroscience Group, Cornell Univ., Ithaca, NY 14853.

Regulation of survival and connectivity of widely branching, diffusely connected interneurons is an interesting and special case of afferent-target matching in the nervous system. Previously, visual form deprivation and optic nerve section were employed to study factors controlling arborization of retinal ganglion cells (RGC). Visual form deprivation induces ocular enlargement and retinal expansion. Partial optic nerve section causes degeneration of a portion of RGCs. We have reported that the growth of RGC arbor is limited in low RGC density region and branch density is increased, indicating a role of cell density and presynaptic availability in shaping RGC dendritic arbors. We adopted the same experimental paradigm to study the dopaminergic amacrine cell. Teakle et al (1993) have found that the size of dopaminergic arbors grows proportionately in expanded retinas to maintain their coverage. In this study, we examine arborization of the dopaminergic amacrine cell following partial optic nerve section.

Partial optic nerve section was performed in newly hatched chicks. Tyrosine hydroxylase immunohistochemistry was conducted on retinal wholemounts in four week old chicks. In RGC depleted retinas, cell density of dopaminergic cells remains constant and has a central to peripheral difference as in control retinas, that is, cell density becomes less dense towards the periphery. Soma size and dendritic arbor area are not changed. In contrast, mean branch length is increased, which corresponds to a decrease in branch number in higher order branches and no change in total arbor length.

We conclude that dopaminergic amacrine cells do not die or change their neurotransmitter complement following early RGC depletion. Also, a change in RGC contribution to the IPL to fewer, denser RGC arbors causes a reduction of the dopaminergic cell branching while coverage of retinal area is maintained.

ULTRASTRUCTURAL CHARACTERISTICS OF SEPTOHIPPOCAMPAL AXONS SURVIVING TRANSECTION G. M. Peterson*. Dept Anatomy & Cell Biology, East Carolina Univ Sch Med, Greenville, NC 27858.

We have previously shown that some of the cell bodies of septohippocampal neurons survive for weeks to months following transection of their axons. Additionally, we have shown that some of their axons also survive for weeks to months without signs of retraction. The purpose of the present study was to examine the ultrastructure of these putative surviving, axotomized axons. Bilateral aspirative lesions of the fimbria-fornix were made mid-way between the medial septum (MS) and septal pole of the hippocampus in adult female Sprague-Dawley rats. One week later an iontophoretic injection of PHA-L was placed into the MS. Following an additional week, the animals were killed and brain sections were cut on a vibratome. Sections through the septal area and the region of the lesion were immunocytochemically stained for PHA-L using DAB as the chromogen. Hippocampal sections were histochemically stained for AChE as an indicator of the extent of septal cholinergic denervation. PHA-L stained sections were osmicated, stained with uranyl acetate and phosphotungstic acid, flat embedded in Epon, and photographed at the light microscopic level. Regions containing labeled axons were then selected, trimmed, thin sectioned, and mounted on mesh grids. Sections were examined in a JEOL 1200EX electron microscope. Labeled axons showed the granular appearance characteristic of DAB and were unmyelinated. Many of the surrounding unlabeled axons were myelinated. Due to the granular DAB labeling, it was difficult to identify the smaller axonal constituents, but mitochondria were present, often in pairs. Labeled axons had a diameter of 0.7 to 1 μm and were unbranched. Growth cones were not observed. Neither the labeled nor the unlabeled axons showed obvious signs of degeneration. It is concluded that a portion of septohippocampal axons survive at least two weeks after axotomy and that their ultrastructure is relatively normal.

RE-EXPRESSION OF THE DEVELOPMENTALLY REGULATED PROTEIN FAC1 IN DENTATE GYRUS FOLLOWING ENTORHINAL CORTEX LESION S. D. Styren*, R. Bowser, G. C. Styren, M. E. O'Malley and S.T. DeKosky Depts. of Psychiatry, Neuropathology, Neurology, and Neurobiology Western Psychiatric Inst. & Clinic and Univ. of Pittsburgh Sch. of Med. Pittsburgh, PA 15213

FAC1 is a novel developmentally regulated protein present in neuronal cytoplasm during brain development. In mature animals cellular localization shifts to neuronal nuclei and cytoplasmic expression is lost. FAC1 has been shown to be re-expressed in neurodegenerative disease and is localized to both neuronal cytoplasm and a subset of neuritic plaques in Alzheimer's disease. To further analyze the role of this protein during neuronal injury, we denervated the rat hippocampal dentate gyrus molecular layer (ML) by entorhinal cortex (ERC) lesion and assessed FAC1 distribution with two monoclonal antibodies directed against distinct FAC1 epitopes. FAC1 staining was absent from the ML in unlesioned animals. By 2 days post ERC lesion there was intense FAC1 immunoreactivity spanning the denervated outer ML; the inner ML remained unstained. We examined additional animals at 6, 15 and 30 days post lesion, during which time commissural and associational (C/A) afferents from inner ML are known to sprout partway into the denervated zone. FAC1 staining continued to be localized to the outer ML at each time point, but appeared to recede from the interface of inner ML trans-laminar expansion. We previously demonstrated rapid re-expression of the embryonic form of neural cell adhesion molecule (eN-CAM) in the denervated outer two thirds of the molecular layer following ERC lesion. FAC1 expression, following ERC lesion, is both spatially and temporally analogous to eN-CAM expression and closely follows the time course of reactive synaptogenesis and axonal sprouting. Re-expression of FAC1 in denervated dentate ML suggests a role for this developmental protein in CNS response to injury.

NEW AXONAL GROWTH IN THE DEAFFERENTATED MEDIAL HABENULA OF ADULT RATS. J.A Wilson* and M.D. Kawaja. Department of Anatomy and Cell Biology, Queen's University, Kingston, Ontario, CANADA K7L 3N6.

In the normal adult rat brain, the posterior septal nuclei project ipsilaterally through the stria medullari (*sm*) to provide a dense innervation of calretinin-immunoreactive axons to the cholinergic neurons of the medial habenula (MHb). In this study, we investigated the plasticity of the septo-habenular projection, one and four weeks after unilateral MHb deafferentation. At one week, there is a complete loss of calretinin-positive fibers throughout the entire rostro-caudal extent of the ipsilateral MHb; the contralateral MHb remains unchanged from controls. At four weeks, however, calretinin-positive axons and clusters of terminals are again evident in the ipsilateral MHb, yet confined to the caudal-most portion of the nucleus. Immunostaining for neurofilament-200 and GAP-43 also reveals a higher density of reactive fibers in the caudal, as compared to rostral, aspect of the ipsilateral MHb. Following injections of biotinylated dextran amine into the ipsilateral MHb at 4 weeks after unilateral deafferentation, labelled axons are evident in the habenular commissure and contralateral *sm*, as well as labelled somata in the contralateral posterior septum. In those animals with bilateral lesions of the *sm*, there are no calretinin-positive fibers found within either MHb after 4 weeks. These data reveal a remarkable degree of plasticity among septal inputs to the adult MHb following unilateral deafferentation. We propose that the new calretinin-positive fibers found in the deafferentated MHb arise from neurons in the contralateral septum which project through the intact *sm* and into the habenular commissure. (Supported by Queen's Univ.)

STRIATAL TARGET NEURONS INCREASE AXONAL BRANCHING OF DOPAMINERGIC MESENCEPHALIC NEURONS IN CULTURE. M.Manier[1], C. Chatellard[1], P. Mouchel[1], J.P. Herman[2] and C. Feuerstein[1]*. 1. INSERM-LAPSEN U318, 38043 Grenoble; 2. UMR CNRS 9941, 13916 Marseille, France.

Target striatal cells were shown to increase some biochemical aspects of the development of dopaminergic (DA) mesencephalic neurons in culture. In the present study, we attempted to define which aspects of DA neurons development is typically influenced by striatal neurons. Embryonic DA neurons of rat mesencephalon were cocultured in presence of neurons derived from either target striatal or non target cerebellar tissue. After 4 days of dissociated culture in a chemically defined, serum-free medium, two aspects of the development of DA neurons were studied: (1) morphological , the morphometric analysis of DA neurons outgrowth after tyrosine hydroxylase (TH) immunohistochemistry (2) biochemical, the quantitative analysis of intracellular TH contents after Western blot analysis and after densitometry of TH immunolabeling in individual cells.

The total length and particularly the complexity of TH+ neurites (number of branching points) were dramatically increased when DA neurons were cocultured in presence of striatal cells but not cerebellar ones. To define what type of neurites was concerned, TH immunofluorescence was coupled with that of specific markers of either dendritic (MAP2) or axonal (phosphorylated neurofilament) compartment. It was thus shown that the presence of striatal neurons induced highly branched axones, without changes of the dendritic arborization. Due to the culture conditions (serum-free medium), the target striatal neurons themselves and not striatal glia were accountable for this peculiar effect on the axonal outgrowth of DA mesencephalic neurons. Conversely, the increase in intracellular TH contents in DA neurons observed in parallel, appeared to be influenced to the same extent by the presence of either target or non target neurons.

698.15

SYNAPTIC REORGANIZATION IN RAT HIPPOCAMPAL FORMATION FOLLOWING DORSAL SEPTOHIPPOCAMPAL LESION. H.Hong, D.Kim J. Lee, T.Jung and S. Inagaki* Dept. of Anatomy, Sch. of Med. Ulsan Univ. Seoul, Korea; *Lab. Sciences, Sch. of Allied Health Sci. Osaka Univ. Faculty of Med. Osaka, Japan.

Synaptic reorganization in rat hippocampal formation following dorsal septohippocampal pathway lesion were determined by employing immunohistochemical method with the antibody specific to growth associated protein(GAP-43) . Within the 1st week, there was a significant decrease in the GAP-43 immunoreactivity(IR) in the supragranular layer of dentate gyrus and stratum lacunosum moleculare of the CA1 field. Between 2 and 3 weeks after lesioning, levels of the GAP-43 IR were found to increase markedly in the inner molecular layer of the dentate gyrus, coincident with the time at which commissural-associational fibers sprout axon collaterals into dendritic portions denervted by the lesion. In the stratum lacunosum moleculare, GAP-43 IR was recovered at 1 and 2 weeks later, presumably due to the sprouting of other inputs. GAP-43 levels in the ipsilateral supragranular layer after the lesion of septohippocampal pathway did not return for 12 weeks, suggesting that ipsilateral supragrnular layer did not receive terminal fibers via any other routes after dorsal septohippocampal path lesion. In contrast to the ipsilateral side, level of GAP-43 IR in the supragranular layer contralateral to the lesion increased during times of terminal axon sprouting, interestingly.

698.16

VASOPRESSIN mRNA LEVELS AND CYTOCHROME OXIDASE ACTIVITY IN THE HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM DURING AXONAL SPROUTING: EFFECTS OF HYPONATREMIA. C.W. Moffett*, J.P. Herman[1] and C.M. Paden. Dept. of Biology and WAMI Medical Program, Montana State Univ., Bozeman, MT 59717 and [1]Dept. of Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington KY 40536.

We have previously shown that uninjured magnocellular neurons on one side of the rat hypothalamus will grow significant numbers of new axon terminals in the neural lobe (NL) following destruction of the contralateral projection to the NL from the paraventricular and supraoptic (SO) nuclei (Watt and Paden, *Exp. Neurol.* 111, 9, '91). This robust collateral sprouting response is accompanied by an increase in urine osmolality, suggesting that magnocellular neurons are hyperactive while axonal sprouting is occurring. To test this hypothesis we are measuring (1) vasopressin mRNA levels in the sprouting SO by *in situ* hybridization and (2) cytochrome oxidase activity in both the sprouting SO and NL terminal field by histochemistry. In order to determine if alterations in neuronal activity will affect the sprouting response, we are also investigating the effects of reducing neurosecretory activity through chronic hyponatremia (Verbalis and Drutarosky, *Kidney Int.* 34, 351, '88). Results obtained to date indicate that vasopressin mRNA levels in the intact (sprouting) SO are significantly increased at 7 days after a contralateral hypothalamic lesion. This increase is blocked by prior induction of chronic hyponatremia, which also results in a reduction of cytochrome oxidase activity in the NL. These initial findings support the hypothesis that an increase in neurosecretory activity occurs during the initial period of axonal sprouting. Analysis of sections from animals sacrificed during the peak of the sprouting response at 28 days post-lesion is in progress, and should aid in determining the relationship between neuronal activity and collateral sprouting. Supported by NINDS NS32507 to CMP.

AXONAL SPROUTING IN THE HIPPOCAMPAL DENTATE GYRUS IN NCAM DEFICIENT MICE. I.M. Fugaccia and S.W. Scheff*. Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY 40536.

The hippocampal dentate gyrus has been used extensively to study plasticity in the CNS. Following partial denervation of the granule cells, a morphological change occurs among the residual afferents innovating the dentate molecular layer. One aspect of this change is the growth of the commissural/associational (C/A) fibers following removal of the ipsilateral entorhinal cortex (EC). Neural cell adhesion molecules (NCAM) play a central role in the developing nervous system where they influence axonal growth, guidance and synapse formation. They have been implicated in peripheral nervous system regeneration. Little is known of their role in axonal sprouting in the adult CNS.

NCAM deficient mice generated by gene targeting were compared to normal mice for their ability to support reactive outgrowth of the C/A fibers. Mutant and normal mice were subjected to a unilateral removal of the EC and allowed to survive for 15 days following surgery. The hippocampus was then processed for light microscopy and stained for AChE histochemistry to assess changes in the septohippocampal afferents as well as with the Holmes fiber method to assess changes in the C/A fiber plexus.

Both normal and NCAM deficient mice displayed intensified AChE staining in the outer molecular layer indicative of septohippocampal sprouting. Analysis of the outgrowth of the C/A fibers revealed robust axonal growth and no significant difference between the two groups was observed. These results indicate that although NCAM may play an important role in brain plasticity when present, it is not necessary for all CNS self-repair. Supported by AG05144

RAPID INDUCTION OF AXONAL GROWTH AND F1/GAP43 PROTEIN IN THE HIPPOCAMPAL MOSSY FIBERS OF THE ADULT RAT. I. Cantallops, J. Moskal*[1] and A. Routtenberg. Cresap Neuroscience Laboratory, Northwestern University, Evanston, IL 60208; [1] Chicago Inst. Neurosurg., Chicago, IL 60614.

Granule cells in the adult rat hippocampus do not normally express axonal growth- and plasticity-associated protein F1/GAP43 (a.k.a. B-50 or neuromodulin). Hypersynchronous activity in limbic circuits and behavioral seizures caused by 10 mg/kg (sc) kainic acid (KA) are followed by induced expression of F1/GAP43 mRNA in granule cells. Subsequently, the axons of granule cells, the mossy fibers, show dramatic sprouting. We demonstrate here that this sprouting can be detected in temporal hippocampus within 2 days. By combining the study of F1/GAP43 immunoreactivity and mossy fiber sprouting in the same animal, adult axonal growth is linked to protein F1/GAP43 expression

F1/GAP43 mRNA expression in granule cells in the temporal, but not septal, hippocampus was induced beginning at 12 hr after KA treatment. This is preceeded by alteration in E-box transcription factor binding. Beginning 2 days after KA, mossy fiber sprouts were observed in the supragranular layer of the temporal, but not septal, hippocampus. An apparent increase in levels of protein F1/GAP43 immunoreactivity in the supragranular layer was observed at this same 2 day time point and ventral hippocampal location. F1/GAP43 protein levels and mossy fiber sprouting showed an increase up to 10 days after KA. Sprouting was at a maximum at 40 days, the longest time point studied.

The rapid onset of axonal growth in the adult rat is striking and occurs earlier than reported previously (2 days vs. 12 days). The time course of molecular events observed in this study is similar to that observed during axonal regeneration with one critical difference: granule cell axons do not appear to be damaged by kainate. (Supported by "La Caixa" Fellowship (Spain) to I.C. and MH25281-21 to A.R.).

SEIZURES INDUCE THE EXPRESSION OF TENASCIN-C mRNA AND PROTEIN BY NEURONAL AND GLIAL CELLS. J. Niquet, L. Ferhat, N. Chevassus, M. Khrestchatisky, Y. Ben-Ari and A. Represa*
Université René Descartes (Paris VI). INSERM U29, 123 Bd. Port Royal 75014 Paris (France).

Temporal lobe epilepsy is associated with neuronal death, gliosis and sprouting of mossy fibers (i.e. the axons of dentate granule cells) in the hippocampus of human and rats. This has been well analyzed in the model induced by kainate injection (see Represa et al. '95 J. Neurobiol. 26, 413 for a review).

In the present study we show that immunoreactivity and mRNA hybridization of tenascin-C (an extracellular matrix glycoprotein with repulsive properties) increase in the hippocampus of rats treated with kainate. The increase of tenascin-C was particularly striking in Ammon's horn, where tenascin-C probes and antibodies labelled reactive astrocytes. Tenascin mRNA expression was also induced in granule cells and protein immunoreactivity appeared in plasma membranes of their axons, the mossy fibers. Tenascin-C immunoreactivity remained unchanged in the molecular layer of epileptic rats.

It is interesting that increased tenascin-C immunoreactivity was observed within zones in which axonal regeneration does not occur (the CA3 area in kainate treated animals) whereas zones in which reactive synaptogenesis occurs (the molecular layer) were devoid of tenascin-C immunoreactivity. We may infer from these results that tenascin-C impedes the terminal sprouting of mossy fibers in CA3 of kainate-treated rats.

698.20

ROLE OF HIPPOCAMPAL COMMISSURE AND HILAR CELLS IN KAINIC ACID-INDUCED MOSSY FIBER SPROUTING D. L. Fairbrother, D. Terrian*, and G. M. Peterson. Dept Anatomy & Cell Biology, East Carolina Univ Sch Med, Greenville, NC 27858.

Aberrant sprouting of mossy fibers (MF), which are the axons of dentate gyrus granule cells, occurs in epilepsy and can be experimentally induced by intraventricular injections of kainic acid (KA). It has been reported that MF sprouting occurs more rapidly after bilateral KA than after unilateral KA. A possible explanation for this difference is that commissural afferents from the contralateral dentate gyrus sprout and compete with the ipsilateral mossy fibers, thereby retarding their sprouting. To investigate the role of the commissural afferents in mossy fiber sprouting, rats were divided into three treatment groups: unilateral KA, bilateral KA, and unilateral KA with severance of the hippocampal commissure. Animals from each group were killed at 2, 3, and 4 weeks after treatment and brain sections were prepared (Timm and Nissl) and analyzed to determine the extent of mossy fiber sprouting and cell loss within the hippocampus. Animals which received either bilateral KA or unilateral KA together with transection of the hippocampal commissure exhibited more rapid and dramatic mossy fiber sprouting than did the animals which received only unilateral KA. These data provide indirect support for the hypothesis that sprouting by commissural afferents retards simultaneously sprouting mossy fibers. Additionally, we found a positive correlation between the degree of mossy fiber sprouting and neuronal loss in the hippocampus. Correlation was found only with hilar cells and was highest in the most ventral region of the dentate gyrus. A possible interpretation of this result is that loss of hilar neurons is specifically involved in the induction of mossy fiber sprouting. Together, these two observations elucidate some of the factors contributing to mossy fiber sprouting.

THE CONTINUOUS PRESENCE OF NERVE GROWTH FACTOR IS NOT NECESSARY TO PROMOTE NEURITE OUTGROWTH IN CHICK EMBRYONIC SENSORY GANGLIA. S. Mehta[1], L. Hsu[2]* and K. Y. Chen[1]. [1]Dept. of Chemistry, Rutgers Univ., New Brunswick, NJ 08906 and [2]Dept. of Biology, Seton Hall Univ., S. Orange, NJ 07079.

Previously, we have shown that a brief exposure to the phorbol ester 12-O-tetradecanoylphorbol-13-acetate (TPA) for 30 min was sufficient to elicit intense neurite outgrowth in embryonic ganglia explants (Mehta et al., 1993, *J. Neurochem.*, 60:972-981). We now report that addition of 50 ng/ml of Nerve Growth Factor (NGF) to serum-free growth medium for 30 min was also capable of promoting neurite outgrowth from 10 day old embryonic sensory ganglia explants. Unlike treatment with TPA, NGF-stimulated neurite outgrowth was not correlated with an increase in the phosphorylation of the 66-kDa substrate of protein kinase C. While the combined treatment of ganglia explants with NGF and the PKC-inhibitor staurosporine for the entire 48 hrs blocked neurite outgrowth, a cotreatment of both reagents for the critical 30 min period did not inhibit process outgrowth. The suppression of NGF-stimulated but not dibutyryl cAMP-mediated neurite outgrowth by staurosporine suggests the involvement of PKC but not PKA in neurite outgrowth beyond the initial 30 min period.

699.2

A NOVEL NEURITE OUTGROWTH PROMOTING FACTOR SPECIFIC TO EMBRYONIC TELENCEPHALIC NEURONS H.Nishimune*,A.Uyeda,M.Nogawa,T.Taguchi+
Lab. of Mol. Biol.,Fac. of Eng.Sci., Osaka Univ., Toyonaka 560, Japan, + Osaka Nat'l. Res. Inst. AIST, Ikeda 563, Japan

A novel neurite outgrowth promoting factor(NPF) has been cloned from cDNA library of denervated chick muscle. Neurite promoting activity of the recombinant muscle-derived NPF(mNPF) was found to be specific to telencephalic neurons in dissociated primary culture of embryonic chick brain neurons. This activity coincides with that of a muscle-derived factor in our previous report. The size of mNPF mRNA is 3.7kB and the expression of mNPF in skeletal muscle was revealed to be up-regulated by denervation. The sizes of an expressed protein is 115kD. The deduced amino acid sequence of NPF indicates a highly hydrophilic property but no consensus sequence of trophic factors nor cell adhesion molecules exists. We further analyzed to search for any homologue in the telencephalon and obtained a clone(tNPF) with high homology with mNPF. The expression of tNPF peaks at around embryonic day 10 which is known to be a time just before synaptogenesis. The NPF does not exhibit high homology with previously known target-derived diffusible factors such as neurotrophic factors nor components of extracellular matrix such as laminin.

ANGIOTENSIN(3-8) [ANG IV], INHIBITS NEURITE OUT-GROWTH FROM CULTURED CHICK SYMPATHETIC GANGLIA. I. Moeller, [1]D.H.Small, [1]G.Reed, [2]J.W.Harding, S.Y.Chai and F.A.O.Mendelsohn*. University of Melbourne, Department of Medicine, Austin & Repatriation Medical Centre, Heidelberg 3084, [1]Department of Pathology, University of Melbourne, Parkville 3052, Victoria, Australia, [2]Department of VCAPP, Washington State University, Pullman, WA, U.S.A.

Angiotensin (3-8), [Ang IV], a metabolite of angiotensin II, (Ang II), has been associated with increasing memory retrieval and dilating pial arterioles.

Binding sites for Ang IV, which occur throughout the guinea pig, monkey and sheep brain, are abundantly localized in components of the autonomic nervous system:- the nucleus ambiguus, dorsal motor nucleus of the vagus and the rostral ventrolateral medulla, whilst in the sheep spinal cord, binding sites are present in the sympathetic preganglionic neurons.

In the present study, 1nM-100μM Ang IV, inhibited neurite outgrowth from cultured E11 chick prevertebral sympathetic ganglia, by 20-30%. The 10nM Ang IV effect was totally inhibited by 1μM of the Ang IV analogues, WSU 4042, Nle^1-Y-I-amide and Nle^1-AIV, but was unaffected by the Ang II antagonist [Sar^{1}Ile^8]Ang II, and the AT_1 and AT_2 receptor subtype antagonists, Losartan and PD 123319, respectively. Ang II (1nM-100μM), also inhibits neurite outgrowth in this system, but may be acting via the Ang IV binding site since its effect is reversed by the Ang IV analogues and not by the Ang II antagonists.

These results suggest that Ang IV may have trophic functions in the central nervous system, particularly in the autonomic system.

NEUROIMMUNOPHILIN LIGANDS ARE NEUROTROPHIC FOR PC12 CELLS AND SENSORY NEURONAL CULTURES. J. P. Steiner*[1,4], T. M. Dawson[4], M. A. Connolly[1], G. S. Hamilton[1], P. D. Suzdak[1] and S. H. Snyder[4].
Departments of Neurobiology and Medicinal Chemistry, Guilford Pharmaceuticals[1] and Departments of Neurology and Neuroscience[4], The Johns Hopkins University School of Medicine, Baltimore MD21224

The immunosuppressant drug FK506 acts by binding to receptor proteins called FKBPs, which in turn can bind to and regulate a calcium/calmodulin-dependent protein phosphatase, calcineurin, and intracellular calcium release channels, such as the ryanodine receptor and inositiol-1,4,5-trisphosphate receptor. Recently, we have demonstrated that the immunosuppressant drug FK506 promotes neurite outgrowth in PC12 cells and sensory ganglion cultures (Lyons et. al., Proc. Nat'l Acad. Sci. USA 91, 3191-3195 (1994)). Picomolar concentrations of FK506 enhance neurite outgrowth in both systems by increasing sensitivity to nerve growth factor. We have extended these studies to include the immunosuppressant drug rapamycin, which at low nanomolar concentrations, promotes neurite extension in PC12 cells and chick dorsal root ganglion cultures by increasing sensitivity to NGF. The cellular effects of rapamycin are mediated by interaction with FKBP-12 and the rapamycin and FKBP target protein (RAFT). These results suggest that the neurotrophic effects of the neuroimmunophilin ligands may be mediated by interactions with multiple signal transduction pathways.

ANTI-IDIOTYPIC ANTIBODIES TO GM1 ENHANCE GROWTH FACTOR STIMULATED NEURITE ELONGATION. M.J. Riggott* and W.D. Matthew. Dept. of Neurobiology, Duke University Medical Center, Durham, NC 27710

We have tested the ability of anti-idiotypic antibodies to GM1 (AIG Mab's) to stimulate neurite outgrowth in a bioassay using cultures of dorsal root ganglion (DRG) neurons. Bioassays were developed using adult DRG neurons cultured on poly-lysine in the presence and absence of growth factors. Three indices of neurite outgrowth were measured for each neuron: the length of the longest neurite, the number of primary neurites and the number of branch points. The DRG neurons were cultured in the presence of AIG4, AIG5, AIG20, control antibodies or NS1 conditioned media. To test the dependence on growth factors, these experiments were conducted in one of the following media preparations: a) no added growth factors; b) a suboptimal concentration of NGF; c an optimal concentration of NGF plus N2 (insulin, transferrin, progesterone, putrescene, selenite).

The AIG Mab's have the ability to promote neurite elongation under all conditions. However, elongation is most pronounced when DRG neurons are cultured in the presence of growth factors and either antibody AIG4 or AIG20. The growth factors have a negligible effect on neurite length in the absence of AIG Mab's. The number of primary neurites and the number of branch points were not affected in these assays. This suggests that the AIG Mab's may facilitate the activity of growth factor activated systems that regulate neurite elongation. This work was supported in part by a grant from the Paralyzed Veterans of America Spinal Cord Research Foundation.

DIFFERENTIAL EFFECTS OF MICROTUBULE INHIBITORS ON AXONAL BRANCHING AND ELONGATION OF CULTURED RAT HIPPOCAMPAL NEURONS. A. Aoyagi*, H. Saito and K. Abe. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

We have previously found that basic fibroblast growth factor (bFGF) specifically enhances neurite branching without affecting neurite elongation of cultured hippocampal neurons, while astrocyte-conditioned medium (ACM) promotes the axonal elongation but not branching. This finding suggests that the two morphological processes, i.e. neurite elongation and branching, are independently regulated by different mechanisms, and further investigations about the action of bFGF will help us to understand the machanisms involved in neuritogenesis and synaptogenesis of brain neurons. In the present study, to test the role of microtubules in the axonal branching and elongation, we compared the effects of microtubule inhibitors, taxol and colchicine, on the actions of bFGF and ACM. The dissociated hippocampal neurons from 18-day-old embryos of Wistar rats were plated on polylysine-coated culture dishes at a density of 2,500 cells/cm^2. After incubation in serum-containing medium for 24 hrs, the medium was changed to serum-free medium. The cells were cultured for further 24 hrs, and then neurons bearing processes were randomly selected and photographed before addition of drugs. The same cells were photographed 24 and 48 hrs after addition of drugs, and changes in morphological parameters were compared. Taxol (50 nM) alone did not affect the morphology of neurons cultured under control conditions, but significantly reduced the bFGF-stimulated axonal branching. The ACM-stimulated axonal elongation was not affected by the same concentration of taxol. Colchicine (10 nM) showed similar effects as taxol. These results suggest that microtubules play more important roles in the axonal branching than in the axonal elongation.

699.7

STEROID-ENHANCED NEURITE OUTGROWTH IN INSECT MOTOR NEURONS INVOLVES HIGHER-ORDER BRANCHING AND INCREASED GROWTH CONE COMPLEXITY. S.F. Matheson*, K. Della Croce and R.B. Levine. Div. of Neurobiol., Univ. of Arizona, Tucson, AZ 85721

Extensive remodelling of neuronal processes during metamorphosis is a prominent feature of nervous system development in the moth, Manduca sexta. Leg motor neurons (MNs), which are retained through metamorphosis, undergo severe dendritic regression at the end of larval life, then grow a new, complex dendritic arbor during metamorphosis. This restructuring is controlled by the steroid molting hormone, 20-hydroxyecdysone (20HE). Previous work in our laboratory has shown that leg MNs maintained in cell culture respond to 20HE exposure by growing more elaborate neuritic arbors. In order to define the cellular mechanisms underlying this morphological effect, we are comparing specific characteristics of neuritic branching patterns, and growth cone complexity and cytoskeletal structure, in leg MNs cultured with and without 20HE. Morphometric data suggest that 20HE induces a dramatic increase predominantly in higher-order neurite branching. Neuronal growth cones display typical complements of microtubules and filamentous actin: microtubules are concentrated in a central region and filamentous actin accumulates in the growth cone periphery, in numerous microspikes and small filopodia. Lamellipodia are almost never observed; large flattened areas are common but are heavily invested with microtubules. Growth cones are more highly branched in the presence of 20HE, and display significantly more microspikes and filopodia as revealed by fluorescent staining of actin filaments. These results suggest that 20HE induces increased morphological complexity in cultured leg MNs by enhancing higher-order branching, perhaps via an effect on growth cone complexity and motile activity. Supported by NIH grant NS28495.

699.8

cDNA CLONING AND EXPRESSION OF XEFILTIN, A NOVEL NEURONAL INTERMEDIATE FILAMENT PROTEIN IN *XENOPUS LAEVIS*. Y.ZHAO* and B.G.SZARO. Biol. Sci., SUNY-Albany, Albany, NY 12222.

During axonal development and regeneration, the expression and post-translational modification of neuronal intermediate filament (NIF) proteins are cell-type specific and highly regulated. The changing molecular composition of the neurofilaments may help to regulate axonal stability at different stages of growth and to influence the caliber of diverse types of axons. Consequently, it has been suggested that NIF composition also affects the capability of a neuron for growth and modification. Consistent with this idea, fish and amphibians have unique NIF proteins whose patterns of expression suggest they may confer on these animals a higher capacity for plasticity and regeneration. We report here the isolation of full length cDNA clones that encode a novel *Xenopus* NIF protein with a predicted molecular weight of 55.9 kD, which we have named xefiltin. Xefiltin shared high amino acid sequence identity both with goldfish gefiltin (overall: 66%, head: 59%, rod: 76%, tail: 30%) and with rat α-internexin (overall: 64%, head: 61%, rod: 71%, tail: 45%); however, its pattern of expression was unique. Unlike gefiltin, which is predominantly found in the retina, xefiltin mRNA was expressed throughout both the CNS and the PNS, as demonstrated in juvenile frogs by Northern blots and *in situ* hybridization. In preliminary analyses by Northern blot, xefiltin mRNA was detected later than that of *Xenopus* NF-L. This differs from α-internexin, which appears before NF-L during mammalian development. Further characterization of xefiltin expression during *Xenopus* neural development and optic nerve regeneration and alteration of its expression in the embryo should provide an additional focus for understanding how modifications of the neuronal cytoskeleton affect axonal growth and development. Supported by NINDS grant R29-NS30682.

DEVELOPMENT, SUBCELLULAR LOCALIZATION AND REGULATION OF ALPHA INTERNEXIN IN HIPPOCAMPAL NEURONS D. L. Benson* and J. L. Brown Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, New York 10029

The differential distribution and organization of cytoskeletal elements is the basis for many of the morphological and functional differences between axons and dendrites. Alpha internexin is a neuronal intermediate filament protein which is expressed at highest levels in the CNS during development, but continues to be expressed throughout adulthood. Immunocytochemical localization of α–internexin in cultured hippocampal neurons revealed the intermediate filament in all neurons and axons as well as dendrites. Coincident with the developmental time of dendritic maturation and synaptogenesis, α–internexin became concentrated in axons where long filaments could be labeled. Labeling in dendritic shafts was much fainter and fuzzier, and was also present within dendritic spines–some of which could be labeled simultaneously with antibodies against glutamate receptors 2/3. Labeled spines were not observed on neurons with a GABAergic morphology. In perfused tissue sections of adult rat hippocampus, α–internexin appeared to predominate in dendrites rather than axons. Electron microscopy revealed immunolabel within dendritic spines and associated with microtubules in dendritic shafts. Only a small population of axons was labeled. Following entorhinal cortex lesions α–internexin immunolabel increased in regions undergoing synaptogenesis. Although it remains to be determined whether the increase was pre- or postsynaptic, it appears that α–internexin expression is positively correlated with synaptogenesis and may also be involved in the generation or maintenance of dendritic spine structure. *Supported by NSF grant IBN-9419900.*

EVIDENCE FOR A NEURONAL MYOSIN LIGHT CHAIN KINASE: cDNA CLONING AND LOCALIZATION IN GOLDFISH. X.Jian*, B.G.Szaro and J.T.Schmidt. Dept. of Biol. Sci., SUNY-Albany, Albany, NY 12222.

The control of actin-myosin interaction, which has been implicated in growth cone motility and neurite outgrowth, is regulated in non-skeletal muscle cells by myosin light chain kinase (MLCK). Pharmacological reagents specific for MLCK alter neuritic outgrowth of cultured goldfish retinal ganglion cells (Jian et al., J.Neurobiol. 1994 25:1310), and an antiserum directed against chicken gizzard MLCK stains rat brain neurons and glia (Edelman et al., Mol. Brain Res. 1992 14:27). To establish further proof of the existence of MLCK in neurons, a cDNA probe derived from chicken fibroblast MLCK (CF-MLCK) was used to isolate cDNA clones from separate goldfish retinal and brain libraries. These clones encoded three isoforms that all shared highest sequence similarities with known smooth muscle and nonmuscle MLCK's from various avian and mammalian species. Partial sequences obtained from these clones were compared with that of CF-MLCK. Over the regions encoding the conserved catalytic and calmodulin regulatory domains of the kinase they all shared 78% identity at the nucleotide level with CF-MLCK. *In situ* hybridization experiments performed with a cRNA probe derived from one of the clones revealed specific hybridization with message in several regions of the goldfish brain, most abundantly in neurons of the periventricular layer of the optic tectum. Current efforts are directed at finishing the characterization of this cDNA and that of the other goldfish MLCK homologues. The molecular identification of goldfish neuronal MLCK homologues will form the foundation of future studies of actin-myosin interactions in neural development and plasticity. THE FORWARD MOVEMENT OF GROWTH-ASSOCIATED "WAVES" ALONG THE AXONS OF CULTURED HIPPOCAMPAL NEURONS REQUIRES INTACT ACTIN FILAMENTS. G. Ruthel* and G. Banker. Department of Neuroscience, University of Virginia School of Medicine, Charlottesville, VA 22908.

We have previously described gowth-cone-like structures referred to as "waves" which periodically form at the base of axons in hippocampal cultures and travel outward along the axon to the tip, where their arrival is correlated with a spurt of growth (Ruthel & Banker, 1992, Soc. Neurosci. Abs.). Like growth cones, waves extend lamellipodia that are rich in filamentous actin. We wished to test whether maintenance of the wave structure was dependent on f-actin and, if so, whether the wave could reform after disruption. Furthermore, we were interested in where waves reformed, since reformation at the point of collapse would indicate that f-actin was required for the translocation of a wave whereas reformation at a point further along the axon would indicate that a wave could continue its forward movement independent of its f-actin structure. In order to disrupt actin filaments, we treated one-day-old cultured cells with 0.25-0.5 μg/ml cytochalasin B for 10-15 min. Waves immediately ceased their forward movement as they collapsed, forming an enlarged region on the axon or disappearing entirely. Although in some cases the halted wave did not re-emerge after removal of cytochalasin, in many cases the wave reformed and resumed its forward movement from the point where it had stopped. The reformation of waves after disruption by cytochalasin indicates that the capacity for forming a wave can persist even when the actin network that gives the wave its structure is disrupted. The lack of forward movement in the presence of cytochalasin leads us to conclude that intact actin filaments are necessary for the forward locomotion of waves along the axon.

Supported by NIH grants NS17112 and HD07323.

DIFFERENTIAL MICROTUBULE AND ACTIN ORGANIZATION IN CELLS TRANSFECTED WITH MAP2c AND MAP2d. M. Khrestchatisky*, L. Ferhat, A. Represa, A. Bernard, G. Charton, and Y. Ben-Ari. Université René Descartes, Paris V, Unité INSERM 29, 123 Bd de Port Royal, 75014 Paris France.

High and low molecular weight forms of MAP2 proteins, MAP2a-MAP2b and MAP2c-MAP2d respectively coexist with different ratios in the embryonic and postnatal rat brain. MAP2c is predominantly expressed in the immature brain. MAP2 variants are encoded by distinct mRNAs of 9 and 6 kb, both transcribed from a single gene. The MAP2d transcript comprises a 93 bp insertion encoding 31 additional amino acids in the carboxy terminal region when compared to MAP2c (Ferhat et al., Int. Neurochem. 25 pp 327-338, 1994). Developmental studies at the mRNA level show that splicing of the additional exon is regulated during ontogeny, MAP2d mRNAs being predominantly expressed over MAP2c mRNAs in all structures of the adult rat brain. We have used transient transfections in Human Embryonic Kidney cells (HEK 293) to assess the respective roles of MAP2c and MAP2d in microtubule and cytoskeletal organization, using antibodies directed against MAP2, tubulin and actin. Our results clearly demonstrate that both microtubules and actin filaments are differently organized in the presence of MAP2c and MAP2d. Microtubule bundles are thicker in the presence of MAP2c when compared to MAP2d. A similar result is obtained with actin filaments. These proteins also demonstrate different roles when cytoskeletal components are destabilized with Nocodazole or Cytochalasine D. MAP2c and MAP2d both protect microtubules from Nocodazole destabilization. In the presence of Cytochalasine D, MAP2d, but not MAP2c, protects actin filaments from destabilization.

INVESTIGATION OF MAP2C TARGETING IN DROSOPHILA NEURONS BY ECTOPIC EXPRESSION. G. Adam and A. Matus* Friedrich Miescher Institute, Basel, Switzerland CH-4002

Microtubule-associated protein 2 (MAP2) has a polarized distribution in neurons, being detectable in cell bodies and dendrites but not in axons. Tau, a related microtubule-associated protein shows the opposite pattern, being located primarily in axons. To study the molecular mechanism by which MAP2 is sorted in neurons we investigated the distribution of MAP2c, a smaller, alternatively spliced embryonic form of MAP2, in Drosophila neurons by ectopic expression. Although Drosophila neurons contain no MAP2 or tau protein mammalian MAP2 can nevertheless bind to Drosophila microtubules *in vitro* and *in vivo* (Adam et al. Neurosci. 51; 221, 1992). The GAL4-UAS system was used to express MAP2c and two truncated forms of MAP2c, CT1 and AT0. CT1 contains the caboxyl-terminal region of MAP2c including the microtubule-binding domain and AT0 contains the remaining amino-terminal segment. These polypeptides were expressed in the mushroom bodies of Drosophila brain using an expression-specific GAL4 enhancer-trap line. MAP2c was most concentrated in the cell bodies and dendrites of mushroom body neurons, while the tau protein concentration was higher in axons although also detectable in cell bodies. CT1 was distributed evenly over the extent of mushroom body neurons. These Drosophila lines will be valuable for elucidating the mechanism of MAP2c sorting in the neuronal cytoplasm.

INTRODUCTION OF ANTISENSE MAP1B BY A RETROVIRAL VECTOR DECREASES CEREBELLAR GRANULE CELL NEURITES *IN VITRO*. J. Solowska-Baird, L. Boyne , B. Kruk, B.T. Himes, D. Liu, D. Baird*, I. Fischer. Dept. of Anatomy and Neurobiology, Med. Coll. PA/ Hahnemann Univ., Philadelphia, PA 19129.

Microtubule associated protein, MAP1B, is a major structural component of growing neurites and is expressed at high levels in the parallel fibers of cerebellar granule cells early in their development. To assess the role of MAP1B in neurite elongation, a 486bp fragment of MAP1B cDNA was introduced into a retroviral vector (provided by L. Lillien) in the sense or antisense orientation. After transfection of producer cells, clones were selected which produced high titers of MAP1B sense or antisense viruses. Cerebellar granule cells were purified from neonatal rats and cultured as reaggregates in which they continue to divide. Dividing granule cells were infected with retroviruses containing either the antisense or sense MAP1B sequences. Cells were then redissociated, replated, and cultured for 48 hours. The infected cells were visualized by immunostaining for ß-galactosidase coded by the retroviral reporter gene, and MAP1B was detected via immunofluoresence. Although infection with MAP1B antisense retrovirus did not abolish MAP1B immunoreactivity, quantitative analysis of infected (ß-gal positive) granule cells showed a significant decrease in the number of cells with no neurites and in mean neurite length in cells infected with antisense MAP1B compared to those infected with sense MAP1B. Studies of *in vivo* infection of dividing cerebellar granule cells are now in progress. Supported by NS 24707, NS09486, NS33214, and NS24725.

ASSOCIATION OF MITOGEN-ACTIVATED PROTEIN (MAP) KINASE WITH MICROTUBULES. M. Morishima-Kawashima, J. Tang* and K. S. Kosik. Center Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115.

MAP kinase is a key downstream molecule in several signaling pathways. Although the *in vivo* cytoplasmic substrates of MAP kinase are unknown, the neuronal microtubule-associated proteins (MAPs) are putative substrates for this kinase. In rat primary hippocampal neurons, anti-MAP kinase antibody stained both nuclei and cytoplasm. Double staining of the detergent-extracted cells showed co-localization of MAP kinase with microtubules. Treatment of cells with microtubule disorganizing reagents, nocodazole and colchicine, retained MAP kinase staining on microtubules, suggesting that at least a part of the MAP kinase pool is associated with drug-stable microtubules. The association of MAP kinase and microtubules was also shown biochemically. MAP kinase was co-purified with microtubules by both temperature-dependent polymerization depolymerization cycles and the taxol method. Quantitative analysis indicated that 4% of MAP kinase in cytosolic extract is associated with microtubules. A fraction of MAP kinase was co-immunoprecipitated with MAP2, which is a good *in vitro* substrate for MAP kinase. Microtubules were fractionated over a phosphocellulose column and a gel filtration column to assess the co-elution of MAP kinase and MAP2. Although MAP kinase is present in both the tubulin and MAPs fractions, the isoform preference of ERK1 and ERK2 in these fractions differs. This result may reflect a functional distinction between ERK1 and ERK2.

699.16

DEVELOPMENTAL EXPRESSION AND DISTRIBUTION OF HIGH MOLECULAR WEIGHT TAU IN RAT NERVOUS SYSTEM. L. Boyne*, F. Nothias[1], A. Tessler, M. Murray, I. Fischer. Anat. & Neurobiology, Med. Coll. PA/Hahnemann Univ., Phila., PA 19129, [1]IAF-CNRS, Gif Sur Yvette, France

Tau is a microtubule associated protein that plays a role in the organization of microtubules and axonal morphogenesis. Various isoforms of tau are differentially expressed during nervous system development as the result of alternative splicing and post-translational modifications of a single tau gene. In adult PNS, tau is expressed as a high molecular weight (HMW) isoform of 110-120K. A cDNA encoding the complete 4a exon specific for HMW tau was cloned by RT-PCR into an expression vector and specific polyclonal antibodies were prepared against the fusion protein and the recombinant tau protein, respectively. The distribution of HMW tau in the developing and adult nervous system was determined by immunocytochemistry and double staining immunofluorescence with the HMW tau polyclonal antibodies and monoclonal antibodies that recognize all isoforms of tau. During development, tau was expressed in all DRG neurons, while HMW tau expression was restricted to small and medium, but not large DRG neurons and processes after embryonic day 18. After peripheral nerve lesion, distribution of tau within the DRG remained unchanged. In the spinal cord, HMW tau was present in motor neurons at postnatal day 2 and attained its adult pattern in cells bodies, axons and dendrites of ventral motor neurons by day 14. In the adult rat CNS, almost all neurons that extend processes into the PNS expressed HMW tau, including all cranial nerve motor nuclei and central processes of most sensory ganglia; of these ganglia, only the bipolar neurons of the olfactory, vestibular and spiral ganglia did not express HMW tau. Retinal ganglion cells were the only CNS neurons, whose processes remain entirely within the CNS, that expressed high levels of HMW tau. The limit and specific distribution of HMW tau in these neurons may be regulated by target-derived signals from the periphery to meet the structural requirements of these axons. Supported by VA Med. Res. Service, NIH NS24707, NS24725, NS07287, and NS09486.

EXPRESSION AND FUNCTIONAL ROLE OF TAU PROTEINS IN DIFFERENTIATED SY5Y HUMAN NEUROBLASTOMA CELLS. D. Uberti, C. Rizzini, P.F. Spano, M. Memo*, **Div. Pharmacology, Dept. Biomed Sci. Biotech., Univ Brescia, Brescia, Italy**

Although several attempts have been made, the molecular and cellular mechanisms responsible for the differential expression of various tau isoforms as well as their functional roles in morphogenesis, PHF formation, and neurodegeneration have not been completely clarified.

We have performed a series of studies on SY5Y neuroblastoma cells differentiated by retinoic acid treatment. We found that indifferentiated cells express predominantly the fetal isoform of tau, although at very low level. After retinoic acid treatment, mRNA species encoding either the fetal and the mature tau isoforms can be detected. The fetal tau isoform appeared to be much more expressed than the mature one. These cells were found resistant to glutamic acid treatment and sensitive to the neurotoxicity induced by doxorubicine (10 nM). The neurotoxic effects elicited by doxorubicine was temporally correlated with an increased of tau immunoreactivity, as measured by Alz50 antibody.

Finally, immunocytochemistry and Western analysis showed tau protein in the nucleus. The data suggest that tau is more than a microtubule associated protein, with possible role in cell differentiation-dysdifferentiation processes.

MICROTUBULE REORGANISATION IS OBLIGATORY FOR GROWTH CONE TURNING. T. Williamson, P. R. Gordon-Weeks*, M. Schachner† and J. Taylor†. D.B.R.C., King's College London, 26-29 Drury Lane, London WC2B 5RL. †Department of Neurobiology, Swiss Federal Institute of Technology, Hönggerberg, 8093 Zürich, Switzerland.

We have shown previously that growth cones of chick dorsal root ganglion cells turn at sharp substrate borders between the extracellular matrix molecules tenascin and laminin *in vitro* and grow along the laminin side of the border. To gain insight into the role of microtubules in growth cone turning, we have compared the organisation of microtubules in growth cones advancing on uniform laminin substrates with their organisation in growth cones that have encountered a laminin-tenascin border. The results suggest that a reorganisation of the microtubules occurs in growth cones turning at laminin-tenascin borders. Further evidence for the involvement of microtubule rearrangement in growth cone turning was provided by experiments in which growth cones approached tenascin borders in the presence of substoichiometric concentrations of the microtubule stabilising compound, taxol. Taxol altered the organisation of microtubules in growth cones growing on laminin by restricting their distribution to the proximal regions of the growth cone and increasing their bundling. Taxol did not stop growth cone advance on laminin. When growing in the presence of taxol, growth cones at tenascin borders were not able to turn and grow along the laminin-tenascin border, and consequently stopped at the border. Growth cones were arrested at borders for as long as taxol was present (up to six hours in these experiments) without showing any signs of drug toxicity. These effects of taxol were reversible. Together, these results suggest that microtubule reorganisation in growth cones is a necessary event in growth cone turning

699.19

TWO STRATEGIES TO PREPARE NEURAL CORTICAL CYTOSKELETON COMPONENTS FOR THE GENERATION OF MONOCLONAL ANTIBODIES AND INITIAL CHARACTERISATION OF THE IDENTIFIED PROTEINS. T. G. A. Mack, O. Schulz, S. Roth, U. Schwarz & G. E. Pollerberg* Dept. of Biochemistry, Max-Planck-Institute for Developmental Biology, D-72076 Tuebingen, Germany

Axons and growth cones possess a spectrin/actin based network closely associated with the inner side of the cell membrane, the cortical cytoskeleton. This structure serves diverse functions during axonal outgrowth, such as surface shaping, modulation of integral membrane proteins, and signal transduction. We developed two strategies to prepare material enriched for neural cortical cytoskeleton from embryonic chick nervous tissue. The first strategy combined the isolation of a membrane/cortical cytoskeleton fraction by density gradient centrifugation with an enzymatic degradation of cell surface proteins. The second strategy is based on the attachment and crosslinking of single cells to beads, allowing for the removal of the cell contents by cell disruption; only membrane/cortical cytoskeleton patches are retained on the beads.

Both strategies permitted the removal of cytoplasm, organelles and cytoplasmic cytoskeleton while retaining the cortical cytoskeleton, as shown by the detection of marker molecules. Monoclonal antibodies (mabs) generated using both preparations as immunization material were screened for recognition of submembranous structures in axons and growth cones of retinal neurons in culture. A proportion of the mabs bind to structures in the growth cone periphery, a cell region composed almost exclusively of cell membrane and cytoskeleton, and are likely to recognize components of the cortical cytoskeleton. Expression patterns and the apparent molecular weights of the detected proteins indicate that a subset of the mabs is directed against known components, whereas others appear to detect novel components of the cortical cytoskeleton. We are currently immunopurifiying and sequencing a number of proteins defined by the mabs.

FORMATION AND SPECIFICITY OF SYNAPSES: AGRIN

700.1

AGRIN MAY INTERACT WITH GROWTH FACTORS TO MEDIATE ACHR CLUSTERING AT THE NEUROMUSCULAR JUNCTION. D.F. Daggett@, D. Stone¶, K. Nikolics¶, and H.B. Peng@* @Dept. of Cell Biol. and Anat. and Curr. in Neurobiol., UNC, Chapel Hill, NC 27599, and ¶Dept. of Neurosci., Genentech, Inc., S. San Francisco, CA 94080

The clustering of acetylcholine receptors (AChRs) to high densities beneath presynaptic active zones, which is the hallmark of postsynaptic specialization at the neuromuscular junction (NMJ), appears likely to be mediated in part by the extracellular matrix protein agrin. This has been demonstrated by observations that 1) application of certain soluble agrin isoforms to cultured muscle cells induces the formation of numerous AChR clusters in the muscle membrane, 2) agrin is highly enriched at neuromuscular synapses, and 3) certain anti-agrin antibodies appear to block NMJ formation in culture. However, our previous studies have also suggested the role of endogenous, muscle-bound growth factors in forming postsynaptic specializations. Here we have coated 10 µm polystyrene beads with purified, full-length agrin isoforms (100µg/ml) to compare their ability to locally induce AChR clustering to that of growth factor-coated beads, when applied to *Xenopus* muscle cell cultures. In addition we incubated agrin-coated beads secondarily with the heparin-binding growth factor HB-GAM to look for agrin-growth factor interactions. Here we report that focally applied, agrin-coated beads cause AChR clustering at ~25% of bead muscle contacts (BMC's). However, agrin beads further incubated with HB-GAM, bind this factor as shown by immunocytochemistry and cause AChR clustering at ~80% of BMC's. Beads coated similarly with BSA and HB-GAM have no effect. These results suggest that agrin may mediate AChR clustering by interacting with muscle bound growth factors, stimulating intracellular signal transduction pathways leading to AChR redistribution. (Supported by NIH and MDA)

AXONAL TARGETING OF AGRIN IN CULTURED RAT DORSAL HORN NEURONS. G. Escher*[1], C. Bechade[2] and A. Triller[2] [1]Institute of Anatomy, Bugnon 9, 1005 Lausanne, Switzerland. [2]Ecole Normale Supérieure, INSERM CJF 9410, 75005 Paris, France.

Agrin transcripts are broadly expressed in the CNS, including in non cholinergic areas. The role of agrin in motoneurons, but not in other neurons, is well established. To approach this question, the presence and cellular distribution of agrin in non-motoneurons was analyzed in primary cultures of dorsal horn neurons, dissociated at E14 and kept in culture for 1 to 10 days; glial cells make up less than 1% of all cells.

We now show : 1) the expression of the 4 agrin isoforms B0, B8, B11 and B19 (see Ruegg et al., 1992) by RT-PCR; 2) their developmental regulation during neuronal maturation, B0 being expressed first, then - during the period of synaptogenesis, the active isoforms (B>0) are preferentially expressed; 3) that agrin-like immunoreactivity can be detected by Western blots both in the supernatant and in the cells; 4) using double immunostaining with anti-agrin antibodies (recognizing all isoforms) and anti-MAP2 or anti-Tau 1 antibodies respectively, an enrichment of agrin labeling in all axons. These data indicate that in our cultures, agrin is synthesized by almost all neurons and is targeted to axons. These observations suggest that, as in the neuromuscular junction, agrin plays a key role in pre- to postsynaptic interactions.

ALTERNATIVE mRNA SPLICING OF AGRIN REGULATES BINDING TO HEPARIN AND α-DYSTROGLYCAN. M. Gesemann, A. J. Denzer, V. Cavalli, A. Brancaccio[§], B. Schumacher, W. B. Adams* and M. A. Ruegg, Depts. of Pharmacology and [§]Biophysical Chemistry, Biozentrum, University of Basel, CH-4056 Basel, Switzerland

Agrin is a heparan sulfate proteoglycan with an apparent molecular weight of more than 400 kD that induces the aggregation of acetylcholine receptors (AChRs) on cultured myotubes. Several isoforms are generated as a result of alternative mRNA splicing. While the chick isoform agrin$_{A4B8}$ (4 amino acid (aa) inserted at site A; 8 aa inserted at site B, both located near the C-terminal end) induces AChR aggregation on myotubes at picomolar concentrations, agrin$_{A0B0}$ (no inserts at both sites) is inactive. A 45 kD C-terminal fragment of agrin$_{A4B8}$ (c45$_{A4B8}$) that contains inserts at both sites A and B retains high activity. A 21 kD C-terminal fragment (c21$_{B8}$) is still active, but only at 100-fold higher concentrations. We have now investigated the binding of agrin isoforms to heparin and to α-dystroglycan, a peripheral membrane protein of the dystrophin-glycoprotein complex, that is the major agrin-binding protein on muscle cells. We find that the four aa insert, Lys-Ser-Arg-Lys, at site A is required for the binding of agrin to heparin. This binding site is also functional in full-length chick agrin. Similarly, binding properties to α-dystroglycan are also affected by alternatively spliced sites. High-affinity binding to both denatured and native α-dystroglycan from chick skeletal muscle and the mouse C2 cell line was found for the inactive agrin$_{A0B0}$. The highly active isoform agrin$_{A4B8}$ binds with a 10 to 20-fold lower affinity and no binding was detected for c21$_{B8}$. These data show that binding of agrin to α-dystroglycan is not necessary for AChR aggregation and they set the stage to investigate the role of α-dystroglycan in agrin-induced AChR aggregation and to search for the signal-transducing agrin receptor.

CHARACTERIZATION OF FULL-LENGTH CHICK AGRIN, A BASAL LAMINA PROTEIN INVOLVED IN THE FORMATION OF SYNAPSES. A. J. Denzer, M. Gesemann, B. Schumacher and M. A. Ruegg*. Dept. of Pharmacology, Biozentrum, University of Basel, 4056 Basel, Switzerland.

Agrin is a protein of the extracellular matrix with a calculated molecular weight of ~ 220 kD that induces the aggregation of acetylcholine receptors (AChRs) and other molecules concentrated at the neuromuscular synapse. A 45 kD C-terminal fragment of agrin is sufficient for this activity. To investigate functional properties of the complete protein, we transfected previously described full-length chick cDNA into COS cells. However, recombinant agrin was not secreted from the cells. Here we describe a 5' extended construct, probably encoding complete chick agrin, that is secreted from COS cells. The novel sequences were found by primer extension studies and isolation of the agrin gene. They extend the coding sequence at the 5' end by ~ 350 bp. Protein sequence encoded by this extension is highly homologous to a 15 amino acid peptide of a heparan sulfate proteoglycan (HSPG) isolated from bovine kidney (Hagen et al. (1993) JBC 268, 7261). Recombinant agrin is active in inducing AChR aggregation depending on the splice variant. It has an apparent molecular weight between 400 and 600 kD and carries glycosaminoglycan side chains attached to the N-terminal part that are characteristic for a HSPG. Polyclonal antisera detect agrin-like protein in tissue homogenates that also has an apparent molecular weight between 400 and 600 kD. In addition, we have found a novel site of 7 amino acids at the N-terminal part that is alternatively spliced. While motor neurons of 5 day old chick embryos synthesize agrin mRNA encoding the 7 amino acid insert, muscle cells predominantly express transcripts that lack this insert. These experiments will allow us to investigate binding properties of recombinant agrin to possibly get insights into other functions of this molecule.

700.5

THE ROLE OF DIFFERENT AGRIN ISOFORMS IN SODIUM CHANNEL CLUSTERING. A. A. Sharp[1]*, J. T. Campanelli[2], R. H. Scheller[2] and J. H. Caldwell[1]. [1]Dept. of Cellular and Structural Biology, Univ. of Colorado Health Sciences Ctr., Denver, CO, 80262; [2]Beckman Ctr., Stanford Univ. Med. Ctr., Stanford, CA, 94305.

Sodium channels and ACh receptors are expressed at particularly high concentrations at the neuromuscular junction. Agrin is known to play a key role in the aggregation of ACh receptors. Five isoforms of agrin are known to be differentially expressed at different developmental stages as well as by different tissues. The isoforms of agrin also differ in their ability to aggregate ACh receptors. Lupa and Caldwell (J. Cell Biol., 1991, 115:765) have shown that *Torpedo* agrin presented in the media of primary rat muscle fiber cultures was unable to cluster sodium channels. The inability of agrin to cluster sodium channels in that study may have been the result of presenting the wrong isoform of agrin to the cultures. In this study we are testing the ability of different isoforms of agrin to aggregate sodium channels. Adult rat muscle fibers from the flexor digitorium brevis are dissociated and co-cultured with CHO cells that have been transfected with various isoforms of agrin and express it on the extracellular side of the membrane (Ferns et al., 1993, Neuron, 8:1079). Sodium channels are detected with immunocytochemical techniques using a polyclonal antibody to sodium channels. CHO cells expressing the A4B8 isoform of agrin cause clustering of sodium channels when attached to the perijunctional and near-perijunctional regions of the fibers after one day in culture. CHO cells attached more distally do not cause aggregation at a level detectible by this process. Wild type CHO cells do not cause aggregation of sodium channels. We are also testing the ability of CHO cells expressing the A4B19, A4B11 and A4B0 to aggregate sodium channels.

700.6

AGRIN FROM NG108-15 INDUCES ACETYLCHOLINE RECEPTOR AGGREGATION ON PRIMARY RAT *MYOTUBE CULTURES*. S. Pun, K. L. So and K. W. K. Tsim*. Dept. of Biology, The Hong Kong University of Science and Technology, Clear Water Bay Road, Kowloon, Hong Kong.

Agrin, a protein isolated from the synaptic basal lamina, directs the formation of the postsynaptic apparatus on developing and regenerating neuromuscular junctions. The full-length cDNAs for agrin have been cloned in chick and rat species; both are ~8 kb in size and encoded proteins have a deduced molecular weight of over 200 kDa. The expression of agrin is not restricted to the motor neurons of spinal cord; it is also expressed in other tissues including the brain. We study the expression of agrin and its isoforms in a neuroblastoma x glioma cell line (NG108-15). These cells have the ability to induce the aggregation of acetylcholine receptors (AChRs) on the cultured myotubes. The co-culture of NG108-15 cells and primary rat myotubes resulted in ~10-fold increase in the AChR aggregates on the surface of myotubes. Using an agrin-specific antibody, the agrin protein of ~200 kDa was identified in NG108-15 cells by immunoblotting. Its corresponding transcript of ~8 kb in size was detected by Northern blot analysis using agrin cDNA as a probe. Expression of no amino insert at z site of agrin mRNA in NG108-15 cells was also demonstrated using polymerase chain reaction. To demonstrate the aggregation of AChRs is due to the secreted agrin from NG108-15 cells, antisense construct of agrin cDNA was transfected into the NG108-15 cells. The NG108-15 cells induced-AChR aggregation on cultured rat myotubes was blocked by such antisense cDNA transfection. These studies provide a direct evidence that the NG108-15 cell-induced AChR aggregation on cultured primary rat myotubes is mediated by agrin.

700.7

DOMAINS OF AGRIN THAT INDUCE ACHR PHOSPHORYLATION. T. Meier, M. Gesemann, V. Cavalli, M.A.Ruegg and B.G.Wallace*. Dept. of Physiology, Univ. Col. Hlth. Sci. Ctr., Denver, CO 80262 and Dept. of Pharmacology, Biozentrum, Univ. of Basel, CH-4056 Basel, Switzerland.

Differentiation of the postsynaptic apparatus at developing and regenerating vertebrate skeletal neuromuscular junctions is triggered by agrin. Agrin is a 400-600 kD heparan sulfate proteoglycan with several regions homologous to domains found in other extracellular matrix proteins. In addition, several isoforms of agrin have been identified that arise by alternative splicing of a single agrin gene. When added to myotubes in culture, agrin induces the formation of specializations at which acetylcholine receptors (AChRs) and other components of the postsynaptic apparatus accumulate, and also induces tyrosine phosphorylation of AChRs. Treatments that block agrin-induced protein tyrosine phosphorylation prevent AChR aggregation, suggesting that phosphorylation may play a role in receptor aggregation. Recent reports indicate that agrin binds to α-dystroglycan and it has been proposed that this binding mediates AChR aggregation. To test further the relationship between tyrosine phosphorylation and receptor aggregation and to determine if interaction of agrin with α-dystroglycan is required for AChR phosphorylation, we have compared the ability of fragments of various agrin isoforms to trigger AChR phosphorylation and/or aggregation. Results indicate that the same domains and isoforms of agrin that induce AChR aggregation also cause AChR tyrosine phosphorylation, while domains that mediate binding of agrin to α-dystroglycan are not required for either AChR aggregation or phosphorylation.

NGF DEPENDENT REGULATION OF AGRIN GENE EXPRESSION IN PC12 CELLS. M. A. Smith[1], L.T. O'Connor*[1], G. Fanger[2], and R.A.Maue[2]. [1]Dept. Anat. and Neurobiol., University of California, Irvine, CA 92717, and [2]Dept. Biochem. and Physiol., Dartmouth Med. Schl., Hanover, NH 03755.

Agrin is an extracellular matrix protein believed to play a role in the formation and maintenance of chemical synapses. Expression of alternatively spliced agrin mRNAs that encode proteins that differ in their acetylcholine receptor aggregating activity is both cell specific and developmentally regulated. For example, in neurons, agrin11 transcripts are elevated during early development whereas agrin 8 mRNA is typical of more mature cells. To better understand the cellular mechanisms that control agrin gene expression we have analyzed changes in the level of agrin mRNA and pattern of alternative splicing in PC12 cells in response to growth factors. When compared to control cells, treatment with NGF for 7d caused a significant (2.4 fold) increase in total agrin mRNA expression. RT-PCR analysis shows that in the absence of NGF, PC12 cells express predominantly agrin0 mRNA that encodes protein with low acetylcholine receptor aggregating activity, whereas transcripts encoding agrin isoforms with high activity (agrin8, -11, -19) are at or below detection. NGF treatment results in a marked increase (>25 fold by 7 days) in agrin8 mRNA expression. The selective increase in agrin8 mRNA is consistent with the neuronal differentiation of PC12 cells that occurs in response to NGF. In contrast, preliminary results indicate that the pattern of agrin alternative splicing is not affected by treatment with either insulin or EGF. Analysis of *Ras* deficient PC12 sublines (courtesy of G. Cooper, Dana Farbe Cancer Inst., Boston, MA) suggests further that the NGF induced increase in agrin8 mRNA is a *Ras* dependent response. The results imply that in addition to changes in gene transcription and mRNA stability, NGF can influence alternative splicing and raise the possibility that NGF and perhaps other growth factors may influence agrin gene expression *in vivo*. REGULATION OF AGRIN GENE EXPRESSION DURING DEVELOPMENT OF MOUSE THALAMUS AND SOMATOSENSORY CORTEX. Z. Li[1], J.L. Massengill[1], D.K.O'Dowd[1,2] and M.A. Smith*[1]. Depts. of [1]Anat. and Neurobiol. and [2]Dev. and Cell Biol., University of California at Irvine, Irvine, CA 92717.

Agrin mRNA is expressed by many neuronal populations in developing and adult rat brain, suggesting a role for agrin in the formation and maintenance of synapses in the mammalian CNS. To investigate this possibility we have begun a detailed study of agrin gene expression in the mouse thalamocortical system during the first 3 weeks of postnatal development, a period when functional connections between thalamus and cortex as well as within cortex form and mature. Whereas all four agrin mRNAs resulting from alternative splicing at the z region are present in RNA from ventrobasal thalamus, their relative abundance changed during development. Agrin0 mRNA increased steadily from approximately 40% of total agrin mRNA at birth (P0) to 80% at P20. Agrin8 transcripts were first detected at P5, with maximal levels (≈10%) occurring around P16. Agrin11 mRNA was present only during P0-P4 with a peak (≈4%) at P1. Agrin19 transcripts represented about 50% of total agrin mRNA at P0, declined to approximately 40% by P3 followed by a further decrease to about 10% between P7 and P20. A similar pattern of agrin mRNA expression was also observed in somatosensory cortex. In parallel studies *in vitro*, we observed that functional connections formed between dissociated P0 cortical neurons during the first two weeks in culture and that temporal changes in agrin8, -11, and -19 mRNAs were similar to those between P0-P14 *in vivo*. Thus, developmental changes in agrin gene expression *in vivo* and *in vitro* are correlated with formation of functional synaptic connections, consistent with a role for agrin in synaptogenesis in the mammalian CNS. Supported by NS07351 to ZL, NS33213 to MAS and NS30109 to DO'D.

Agrin is Adhesive for Motor Neurons and Inhibits Neurite Outgrowth. J.A. Campagna* and J.L. Bixby. Dept. of Molecular and Cellular Pharmacology, Univ. Of Miami Sch. of Med., Miami, FL 33101.

A number of proteins are concentrated in the synaptic basal lamina at the neuromuscular junction (NMJ). Evidence suggests that some of these proteins are important for motor neuronal axon growth and subsequent synaptogenesis. s-laminin (s-LN) is a 200 kD protein that is highly enriched in synaptic basal lamina, is selectively adhesive for motor neurons, and can act as a "stop signal" for growing axons; the tripeptide motif LRE (leu-arg-glu) is implicated in these functions. (Hunter & Sanes, J. Neurosci 11,3960, 1991;Porter *et al.*, Neuron 14, 549, 1995) A second protein enriched in synaptic basal lamina and containing an LRE motif is agrin, which has previously been shown to induce several aspects of postsynaptic differentiation at the NMJ. To test the hypothesis that the LRE motif in agrin is also a motor neuron "stop signal", we have grown chick ciliary ganglion (CG) neurons on substrates of agrin-expressing CHO cells. CG neuron growth cones extending on a fibronectin substrate stop growing upon contact with $agrin_{19}$-expressing CHO cells, but not untransfected CHO cells. In a short-term adhesion assay, CG neurons adhered four times as well to agrin-expressing cells as to untransfected CHO cells. Our results are consistent with a general role for LRE-containing basal lamina proteins in directing motor neurons to muscle, and suggest that agrin's role at the NMJ is not limited to actions on the myotube.

700.11

IDENTIFICATION OF A NOVEL AGRIN ISOFORM PREFERENTIALLY EXPRESSED IN NON-NEURONAL CELLS. G. Tsen[1], A. Napier[1], W. Halfter[2], and G. J. Cole[1]*. [1]Neurobiotechnology Center and Dept of Cell Biology, Neurobiology and Anatomy, The Ohio State Univ., Columbus, OH 43210. [2]Dept of Neurobiology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

A novel isoform of agrin was identified based on the isolation of an agrin cDNA from E9 chick brain that lacks 21 bp in the N-terminal encoding region of the agrin mRNA. RT-PCR of E9 chick brain mRNA confirmed the existence of this agrin isoform in brain, but the novel splice variant represents only a minor fraction of agrin mRNA in brain. However, upon the analysis of chick astrocyte mRNA, smooth muscle mRNA, and cardiac muscle mRNA by RT-PCR, this novel isoform was shown to be the predominant agrin isoform in these non-neuronal cell populations. We extended our analyses to examine the expression of this agrin mRNA isoform during chick development, and showed that in brain this novel agrin isoform is up-regulated with brain development, consistent with the increase in glial number during brain development, while the agrin isoform that does not undergo splicing and thus contains the 21 bp exon is down-regulated. We also showed that in heart both agrin isoforms are down-regulated during development. Because the 21 bp exon is inserted in the region of chick agrin which encodes the putative signal sequence of agrin, with the signal peptidase cleavage site immediately preceding the putative first amino acid of the mature protein being deleted as a result of splicing, the presence or absence of this alternatively spliced exon may regulate differential processing of the agrin protein in neuronal and non-neuronal cells, repectively.

FORMATION AND SPECIFICITY OF SYNAPSES II

701.1

THE DEVELOPMENT OF SYNAPSES IN BARRELS OF MOUSE PRIMARY SOMATOSENSORY CORTEX. E.L. White*, D. Lev and E. Weinfeld Center for Brain Research, Faculty of Health Sci., Ben-Gurion Univ., Beer Sheva, ISRAEL.

As part of a comprehensive study of the development of synaptic patterns in mouse PMBSF barrels, the distribution of synapses was assessed in EM montages taken of thin sections cut tangentially through the mid-layer IV level of barrel D4, usually, but also of adjacent barrels D5 or C4 at (to date) P6, P9, P11, P13 and at 65 days of age (P1=the first 24 hours after birth). Barrel hollows, sides and septa were identified in 40μm thick sections cut from unembedded, aldehyde perfused, osmicated brains. From P6, dark barrel hollows are clearly recognizable with the light microscope due to the high osmophilia of the processes (primarily axons) within them; by P11 the hollows are somewhat more faint due to their increasing content of less osmophilic dendritic branches. Most somata received symmetrical synapses only. At P6, 111 profiles of 113 somata received no synapses, the remaining profiles received one each. At P9, 67% of 135 profiles formed 1 (usual) or more synapses; at P11, 46% of 167 profiles formed 1 or more; at P13, 90% of 77 formed 1 or more (53% 2 or more) and in adult, 89% of 143 profiles formed 1 or more synapses (63% 2 or more). Synapse counts at all ages, whether on somata or in the neuropil, were similar for equivalent areas of wall vs. hollow. Exclusive of somatic synapses, P6 neuropil (hollow samples>14,000μm^2/age; in wall, primarily septa>4,000μm^2/age) contained 1.5 synapses/100μm^2, P9 had 4.3 and the adult 9.7. Supported by Israel Acad. of Sciences 618/93 to E.L.W.

TOPOGRAPHY OF THE ECTOPIC RETINAL PROJECTION TO OLFACTORY CORTEX (OC) IN ADULT *RANA PIPIENS*. Scalia, F.*, W. Su, E. Harris, S.M. Galoyan, S. Eisner, and J.Y. Lettvin, Dept. of Anat. & Cell Biol., SUNY HSCB, Brooklyn, NY 11203 and Media Lab., MIT, Cambridge, MA 02139.

The prominent electrical responses visually elicited in the superficial neuropil (SN) of OC 6 mo after translocation of a regenerating optic nerve into the telencephalon (T) were evocable only from the frontal visual field, but a spatial map of the responses was not observed (Neurosci. Abs., Scalia et al., '94). Transients of this type and size are recorded in the SN of the optic tectum with presentation of prey-mimetic stimuli in any sector of the visual field (Grant and Lettvin, Brain Res., '91), but are never found in normal OC. Anatomical data on the sectorial origin of the ectopic fibers was sought to investigate the basis of the frontal-field-dominance in this projection. Mixed injections of biotin-dextran (BDA) and ^{3}H-amino acids were given intravitreally immediately after cutting across a defined sector of the retinal nerve fiber layer in frogs surviving 6-8 mos after transplantation of the optic nerve into T. The injected specimens survived an additional 3 days to allow time for anterograde migration of the BDA in the cut retinal axons and transport of the ^{3}H-label by the uninjured ganglion cells in the complementary areas of the retina. BDA-labeling was examined both by LM and EM. When the cuts were made across temporal sectors of the retina, which image the frontal-field, the BDA-labeled terminal plexus in the experimental animals occupied the posterodorsal half of the ectopic projection-field. After nasal retinal lesions, the BDA-labeled terminals were distributed in the more anteroventral part of the projection-field. The pattern of radiolabel in autoradiographs of adjacent sections was complementary to the BDA-labeling, but with significant overlap in the fields defined by the two tracers. Thus, the ectopic projection arises from both the temporal and nasal halves of the retina, but only the former becomes capable of evoking the large-amplitude responses. (Supported by NIH Grant EY05284)

701.3

ASYMMETRIC NASAL/TEMPORAL EXPRESSION OF AN ALTERNATIVELY SPLICED GENE WITHIN THE DEVELOPING RETINA. W.M. Jurney, D.R. Foltz, D.J. Selski and S.C. McLoon*. Univ. of Minnesota, Minneapolis, MN 55455.

Development of the topographic pattern of axonal connections from the eye to the brain is believed to involve molecules expressed asymmetrically across the developing retina that mark cell position. In an attempt to identify such molecules, differential kinetic enrichment was employed to isolate asymmetrically expressed mRNAs in the nasal-temporal axis of the embryonic chick retina. A PCR amplified cDNA representing a mRNA enriched in the nasal side of the retina was used to screen an embryonic retinal cDNA library. Seven clones were isolated. Restriction analysis suggested that these clones share a 2kb "conserved" region, and each had a "variable" region of up to 2kb. A probe prepared from a fragment of the conserved region of one clone hybridized to all seven clones. Two separate fragments from the variable region of one clone hybridized to subsets of the seven clones. RNA blot analysis suggested that the conserved region is expressed equally on the two sides of the retina, while transcripts containing either of two fragments from the variable region were more abundant on the nasal side of embryonic retina. These results suggest the existence of an alternatively spliced gene, the products of which are asymmetrically expressed across the developing retina. Comparison of a partial sequence from one clone suggested that it is a previously unreported gene. (Supported by NIH grants EY05371 and EY07133.)

QUANTITATIVE DISTRIBUTION OF GABA-IMMUNOREACTIVE TERMINALS AFTER SENSORY DEPRIVATION IN THE RAT BARREL CORTEX. C. Beaulieu* and C.Crevier. Dept Pathology and CRSN, Université de Montréal, Montréal, (Qc) Canada.

We have previously shown that neonatal sensory deprivation leads to a 50% reduction in the numerical density (N_V) of synaptic contacts formed by GABA(+) boutons in layer IV of deprived barrels as compared to controls. To estimate whether this change was due to an actual loss of GABA(+) axon terminals, we calculated their number in layer IV of the barrel cortex of rats which had their vibrissae on the right face continuously removed from birth.

In long series of ultrathin sections from layer IV, we identified and followed all GABA(+) boutons through their entire length. By applying the disector method, we calculated that the N_V of GABA(+) boutons was 25% lower ($p<0.01$) in sensory-deprived (48±7 million per mm^3) than in control (64±10 million/mm^3) barrels. Thus, the decrease of contact number in sensory-deprived cortex is due partially to a loss of GABA terminals. By dividing the N_V of synaptic contacts (determined in the previous study) by that of boutons, we determined a contact-to-bouton ratio. On average, a GABA(+) bouton of the deprived barrels formed 1.9 contacts while this ratio reached to 2.5 in the controls. This suggests that the decrease of contacts could be due not only to a loss of GABA(+) terminals but also to a decrease of the number of synaptic contacts formed by each bouton. However, it is also possible that the decrease of synaptic contacts was consequent to a preferential loss of a subpopulation of GABA(+) terminals making on average, a high number of contacts. This is currently under investigation. (Supported by MRC, FRSQ, and FCAR)

GABA IMMUNOCYTOCHEMICAL ANALYSIS OF CEREBELLAR EXPLANT CULTURES FROM THE LURCHER MUTANT AND WILD-TYPE MOUSE. Keith W.T. Caddy*[1], and Martin L. Doughty[2]. [1]Dept. of Physiology, University College London, WC1E 6BT; [2]Lab. de Neurobiologie du Développement, Univ. P. & M. Curie, 75005 Paris.

Lurcher is an autosomal dominant murine mutation. Lurcher heterozygotes (+/Lc) lose all their cerebellar Purkinje cells by adulthood (Caddy and Biscoe, 1979. Phil. Trans R. Soc. B. *287*: 167-201). Chimeric analysis has shown that the primary target of the +/Lc mutation is the cerebellar Purkinje cell (Wetts and Herrup, 1982. J. Embrol. Exp. Morph. *68*: 87-98). Purkinje cells from the +/Lc mutant mouse survive and differentiate in long-term cerebellar explant cultures, indicating that +/Lc Purkinje cell death is non-autonomous (Doughty et al., 1995. J. Comp. Neurol. *in press*). The neuronal environment and synaptic investment of Purkinje cells in +/Lc and +/+ (control) cerebellar explant cultures were examined using γ-aminobutyric acid (GABA) immunocytochemistry. Cerebellar explants from 2 days postnatal (P2) +/+ and +/Lc mutant mice were grown for 15 days *in vitro* before being processed for GABA immunocytochemistry. GABA-immunolabelled explants were examined in the light and electron microscope. GABA-immunostained Golgi and basket and/or stellate cells were scattered throughout the +/+ and +/Lc cerebellar explant cultures and there was no *in vivo*-like arrangement of the immunoreactive somata. Qualitative observations did not indicate any difference in the numbers and distribution of the GABA-immunostained cells in the +/+ and +/Lc cultures. Electron microscopical analysis revealed a similar, complex distribution of the GABA-immunostain in the +/+ and +/Lc cerebellar explant cultures. The somata of Golgi and basket and/or stellate cells were GABA-immunostained, whereas their neurites had a varied immunoreactivity: GABA-immunostained and GABA-immunonegative axons formed synapses directly with the shafts of spiny Purkinje cell dendrites; whilst all the synapses on the dendritic spines of Purkinje cells were from GABA-immunonegative parallel fibres. (Supported by The Wellcome Trust).

DESCRIBING AND GENERATING COMPLEX DENDRITIC MORPHPOLOGIES USING L-SYSTEMS

D. Rosenbluth, J. Allman*
Division of Biology, Caltech, 216-76, Pasadena, CA, 91125

We describe the use of l-systems for both the generation and description of complex dendritic mophologies. L-systems provide powerful language in which both the topology and geometry of complicated branching structures can be described in detail using few parameters. Such a language permits the exploration several important questions using computational models. Two of these are: "How does dendritic morphology affect the computations performed by single neurons?" and "What rules govern the pruning of dedritic arborizations during development?". This formalism also provides a useful descriptive tool for experimentalists. An inference algorithm takes data on the mophology of actual neurons and outputs an l-system which generates that mophology to within a specified error. The l-system which generates the morphology can be used as a much more complete and compact quantitative description of morphology than other measures that have been used to date for this purpose.

STABILISING NEUROMUSCULAR CONTACTS INCREASES MOTONEURONE SURVIVAL AFTER NEONATAL NERVE INJURY IN RATS. D. Harding, L. Greensmith, A.L. Connold, G. Vrbova, and S. Tuel*, Department of Anatomy and Developmental Biology, University College London, Gower Street, London WC1E 6BT, U.K.

After a sciatic nerve crush at birth the rat soleus muscle is permanently weak. The weakness is caused a) by loss of a proportion of its motoneurones and b) by the failure of the surviving motoneurones that are successful in reaching the muscle and reinnervate it 7 days later to expand their peripheral field. Here we attempted to maintain new neuromuscular contacts by applying leupeptin, an inhibitor of the calcium activated neutral protease. This protease appears to be involved in the loss of neuromuscular contacts during development and sprouting. This study shows that in muscles treated with leupeptin the reduction in weight and force after nerve crush at birth was significantly less than in those that were untreated. Moreover, the leupeptin treated muscles had significantly higher numbers of motor units than untreated muscles. In the leupeptin treated animals the number of remaining motor units in the soleus muscle was 7.6 ± 0.7 (S.E.M., n=8), whereas in the NaCl treated animals soleus had only 3.4 ± 0.4 (S.E.M., n=10) motor units. Thus, protecting regenerating neuromuscular junctions during early stages of reinnervation rescues motoneurones and improves muscle recovery.

REGULATION OF N-TYPE CALCIUM CHANNEL DISTRIBUTION IN ISOLATED HIPPOCAMPAL NEURONS. R.K. Lartius[1,*], L.-E. Trudeau[1], R. Doyle[1], D.R. Witcher[2], K.P. Campbell[2] and P.G. Haydon[1]. [1]Dept. of Zoology and Genetics, Iowa State University, Ames, IA 50011; [2]Howard Hughes Medical Institute, Dept. of Physiology and Biophysics, Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

The influx of calcium through voltage dependent N-type calcium channels stimulates vesicle fusion during synaptic transmission. Little is known, however, regarding the cues that regulate the expression of these channels and their localization during development. For example, is neuron-neuron contact required for normal N-type calcium channel expression, distribution and function? To address this question, hippocampal neurons were grown under conditions which resulted in either isolated neurons or neurons with neuron-neuron contacts. Differences in the expression of the N-type calcium channel subunit α_{1B} were then compared using immunocytochemistry. At 8 days in culture (DIC) neurons that were allowed neuron-neuron contact displayed diffuse α_{1B} immunoreactivity in the soma as well as immunoreactivity concentrated in punctate structures within neurites. Isolated neurons also expressed α_{1B} at 8 DIC, but in contrast, the distribution pattern was diffuse and non-punctate in neurites. This distribution pattern was comparable to an "immature" pattern observed for 4 day neurons which were allowed neuron-neuron contacts. To test whether the N-type calcium channel subunits observed by immunocytochemistry form functional calcium channels in neurons displaying the "immature" pattern, whole-cell patch clamp experiments were performed. By 4 DIC a clearly detectable ω-CgTx-sensitive calcium current was present (24.6±3.5% block, n=6). These data suggest that N-type calcium channel subunits are assembled into functional channels to be later redistributed at sites of synaptic contact in response to signals provided by target neurons.

SYNAPSE-FORMATION IN A GLIA-FREE CULTURE OF DISSOCIATED CHICK CEREBRAL NEURONS. T.Taguchi*, X.-X. Bo+, H.Taniguchi, K. Kiyosue+, S. Kudoh+, S. Murase. Dept. Organic Materials, Osaka Nat'l. Res. Inst., Ikeda 563, Japan, +Fac. Eng. Sci., Osaka Univ. Toyonaka 560, Japan.

The roles of glia in brain have been regarded as important for not only structural and nourishing support of neurons but also active modulation of neuronal functions. In some recent reports, it was shown that glial cells have a potential to mediate messages from a postsynaptic cell to presynaptic one. To elucidate precise roles of glia in neuronal systems, a glia-free neuronal culture is a useful system. Although inhibitors of cell proliferations such as cytosinearabinoside has so far been utilized, they were found to have toxic effects on neuronal growth and survival. Therefore, we have developed a novel procedure to prepare a glia-free neuronal culture system by adding certain peptides containing a cell adhesion-relating sequence such as RGD into culture medium. The synapse-formation in the culture was found to proceed in a similar way to that in the glia-containing one. To form synaptic connection, a growth cone of an axon is thought to recognize a specific target molecule such as cell adhesion molecules. The results obtained in the culture indicate that a protein that recognizes RGD sequence is not involved in the synaptogenesis in the culture.

EXPOSURE TO PHENCYCLIDINE ALTERS MOTILITY AND THE DEVELOPMENT OF IDENTIFIED NEURONS IN THE CHICK EMBRYO SPINAL CORD. B. Mendelson* K.M. Martin and M.K. Bonner. Dept. of Anatomy, University of Arkansas for Med. Sci., Little Rock, AR 72205.

Exposure to phencyclidine (PCP) during development often produces detrimental effects including long lasting alterations in motor function. PCP is known to be a noncompetitive antagonist of the N-methyl-D-aspartate (NMDA) receptor. We have previously shown that embryonic exposure to another NMDA-receptor antagonist, MK-801, disrupts the development of cutaneous nerve projections in the chick spinal cord (Dev. Brain Res., 82: 152-166). To determine if exposure to PCP also induces alterations in spinal cord development, chick embryos were exposed to PCP during the period when primary sensory afferents form connections in the spinal cord. Groups of chick embryos were treated daily with either: 1.0 or 10.0 mg/kg of PCP in sterile Tyrode's solution (physiological saline, ST). Control embryos were treated with equivalent volumes of ST. Applications of PCP or ST began in embryonic day 5 (E5) and continued until the animals were sacrificed at E14. Embryonic motility was assayed daily at 5 time points: 15 min before drug exposure, and, 15 min, 1 hr, 4 hr and 7 hr after drug exposure. Both doses of PCP induced significant decreases in motility 15 min following PCP administration. Motility recovered to control levels by 23.75 hr after drug delivery. Following sacrifice of the animals at E14, the pattern of cutaneous nerve projections in the dorsal horn was determined by applying fluorescent tracers to identified cutaneous nerves. PCP-treatment induced a dramatic alteration in the organization of cutaneous nerve projections. The central projection formed by the lateral femoral cutaneous nerve, which normally occupies only the ventral portion of lamina 2 in lumbosacral segment 1, spread to occupy almost the entire cross sectional area of lamina 2. These data suggest that some of the detrimental effects of embryonic PCP exposure are due to inappropriate synapse formation by primary sensory afferents in the spinal cord dorsal horn. FUNCTIONAL CONNECTIVITY IN THE COCULTURED RAT TRIGEMINAL SYSTEM. E. Günhan-Agar*, W. Guido, F.-S. Lo and R.S. Erzurumlu. Dept. Anatomy and Neuroscience Center of Excellence, LSU Med. Ctr. New Orleans, LA, 70112.

In explant cocultures of embryonic rat trigeminal ganglion (TG) with same age whisker pad and more mature brainstem explants (slices through the brainstem trigeminal nuclei ,BSTC), TG axons grow and arborize in both targets (Erzurumlu et al., PNAS, 1993). Here we further characterize the morphological and cellular aspects of this connectivity. DiI-labeled trigeminal axons form small, well-defined arbors within the BSTC. Biocytin-filled BSTC neurons have small, irregular shaped soma, smooth dendrites, and simple dendritic branching patterns. Of interest was to examine the membrane properties of BSTC neurons and determine whether TG input gives rise to postsynaptic responses. Intracellular recordings indicate that BSTC neurons exhibit overshooting action potentials, and at least two after hyperpolarizations, an early fast one (Ic) and a late slow one (Iahp). These dampen the rate of depolarization and promote graded responses with increasing stimulus strength, a feature that may help BTSC neurons sort out various presynaptic inputs during development. Many BTSC cells have low threshold (LT) Ca^{++} spikes. Unlike those seen in mature neurons, these are relatively small and lack burst firing. The presence of LT spikes at this age provides cells with large amounts of Ca^{++} during active dendritic growth and synapse formation. Stimulation of TG explants leads to postsynaptic responses in BSTC neurons. Some cells have complicated responses: at least two EPSP components (an early fast and slow late one) and one relatively fast IPSP. In some cases postsynaptic responses trigger LT spikes. Our results show that functional synaptic connectivity is established in trigeminal cocultures, providing a unique means to study the development of a highly ordered sensory pathway on a cellular level. CHARACTERISTICS AND FUNCTIONS OF CAJAL-RETZIUS CELLS IN ORGANOTYPIC SLICE CULTURES OF HIPPOCAMPUS AND NEOCORTEX. J.A. Del Río [1], E. Soriano [1] H. Supèr [2], M. Frotscher [2], B. Heimrich [2,]* [1] Dept. of Cell Biology, Faculty of Biology, University of Barcelona, Diagonal 645, 08028 Barcelona, Spain. (2) Institute of Anatomy, University of Freiburg, P.O.B. 111, D-79001 Freiburg, Germany.

Cajal-Retzius cells are the most typical representatives of the marginal zone-layer I in the neocortex and hippocampus. These transient neurons disappear during development, and their functions remain to be elucidated. Taking advantage of calretinin-immunocytochemistry, a marker for Cajal-Retzius cells in the murine cortex (Del Río et al., Cerebral Cortex, 5:13), we investigate here the features of these cells in slice cultures "in vitro", and address their developmental roles. Whereas Cajal-Retzius cells in cultures taken from P0-P2 neocortex undergo cell degeneration with a temporal sequence similar to that "in vivo", cells in the hippocampus persist after long incubation periods. Since we have proposed that Cajal-Retzius cells in the hippocampus may be involved in the attraction and targeting of developing entorhinal afferents (Supèr and Soriano, J. Comp. Neurol., 344:101), we have analyzed the development of the entorhino-hippocampal connections in co-cultures of entorhinal cortex and hippocampus. Anterograde tracing of entorhinal afferents with biocytin show that ingrowing axons overlap and are intermingled with Cajal-Retzius cells, establishing synaptic contacts. Further, cells in these co-cultures undergo cell degeneration shortly after the ingrowth of entorhinal afferents. These results suggest that Cajal-Retzius cells might act as guides for developing entorhinal axons, which might in turn influence the degeneration of these transient cells. Efforts are currently underway to determine whether the ablation of Cajal-Retzius cells in organotypic co-cultures alters the pattern of termination of entorhinal afferents.

701.13

RECORDING ELECTRICAL ACTIVITY FROM HELISOMA BUCCAL GANGLIA AND CENTRAL RING GANGLIA CULTURED ON A PLANAR MULTIELECTRODE ARRAY. I. Kim*[1], Y. Jimbo[2], and A. Kawana[2]. [1]Dep. of Biology, University of Southwestern Louisiana, Lafayette, LA 70504, and [2]NTT Basic Research Lab., Atsugi-shi, Kanagawa,243-01 Japan.

Recent advances in techniques for multisite recording and stimulation from multiple extracellular microelectrodes allow simultaneous and chronic observation of electrical activity of substantial populations of neurons. By using the planar electrode array (PEA) system, the long term profile of electrical activity has been recorded from both dissociated and organotypically cultured rat cortical neural networks, and the periodical electrical stimulation through electrodes induced bursting response in silent cultures of rat cortical neurons (A. Kawana et al., Soc. Neurosci. 1994).

The merits of simultaneous chronical multi-site recording and stimulation are utilized to study the dynamics of functional connectivity in cultured Helisoma neural networks. In snail Helisoma, several observations suggested that patterned neuronal activity in the buccal ganglia (BG) for feeding behavior receives descending excitatory and inhibitory afferents from central ring ganglia (CRG: 5 pairs of ganglion). In order to study the dynamics of functional connectivity and electrical coupling between buccal pattern generator in BG and each ganglion of CRG, the neural network among BG and each ganglion of CRG was generated on a planar lithographically-patterned arrays of 64 electrodes. The electrodes (each size: 50x50 μm) were coated with platiunm black, and separated by 250 μm distance (Y. Jimbo et al, IEEE Trans. BME). Isolated BG and CRG were trypsinized and ganglionic conective tissues were desheated with an electrically sharpened microknife. The desheated masses of BG and CRG were placed and cultured for the formation of neural networks on the PEA. Each mass of ganglion covered around 4-16 electrodes, and the detected amplitude of electrical activity were ranged around 40 μV. The dynamical changes of electrical activity of the desheathed mass of ganglion were simultaneously recorded from multiple electrodes, and analyzed.

PERFORATED PATCH RECORDING OF ACTION POTENTIALS IN PITUITARY MELANOTROPES OF NEWBORN RATS. J.C. Gomora*, G. Avila, A. Navarrete, A. Marin and G. Cota. Dept. of Physiol., Biophysics and Neurosciences, Cinvestav, Mexico, D.F. 07000.

We have previously reported that neonatal rat melanotropes generate a pattern of voltage-dependent ionic currents characteristic of excitable cells. We have also shown that sodium and calcium currents in these cells undergo a marked inhibition concomitant with the onset of dopaminergic innervation (*Soc Neurosci Abstr* 20:1685, 1994). In the present study, we have used the nystatin perforated patch recording technique to investigate whether non-innervated neonatal melanotropes are electrically excitable. Cells were obtained from 2-day-old rats, kept under culture conditions and then subjected to electrophysiological recording within 6-48 h. Records were taken at room temperature from a total number of 29 melanotropes. All of them showed spontaneous subthreshold fluctuations of membrane potential. These fluctuations were widely variable both in amplitude and duration from cell to cell. The average value for the resting potential was -73 ± 4 mV. In addition, 55% of the recorded cells spontaneously generated fast, spike-like depolarizations from the resting potential. These action potentials frequently overshot the 0 mV level by 26±5 mV (n = 9) and were triggered at an average rate of 1/min. In some cells, the repolarizing phase of the fast spike was followed by a plateau longer than 200 ms in duration. The average voltage level during the plateau was close to -15 mV. It will be important to investigate whether the onset of dopaminergic innervation modifies this pattern of electrical activity.

702.1

ONTOGENY OF FIRING PATTERNS OF DOPAMNE NEURONS IN SLICES.
G. Mereu*, V. Lilliu, S. Vicini, A. Casula, W. Francesconi, M. Brunelli, and G.L. Gessa, Dept. of Exp. Biology, Cagliary, Italy.

Bursts occurrence *in vivo* dopamine (DA) neurons is determined by N-Methyl-D-aspartate (NMDA) tone in midbrain DA areas, while DA neurons in slices exhibit only a regular pacemaker pattern. However, application of NMDA and other EEAs to slices from adult rats promptly increases the discharge frequency but fails to modify the pacemaker pattern of these neurons. In our study, DA neurons showed a biphasic, age-related, occurrence of bursting discharge. It increased from about 1% at post natal day (PND) 5 to a transient peak of more than 30% at PND 18, and rapidly decreased to zero after PND 45. In PND 15-21 slices, application of glutamate or kainate elevated the firing rate without pattern modification. On the contrary, NMDA (10-50 μM) activated discharge rate and also promoted burst firing in both bursting and non bursting neurons. NMDA induced bursts were age-related, maximal (37%) at PND 15-21, and NMDA increased the number of spikes in bursts irrespective of age. NMDA effects were not seen in a Ca^{2+} free solution or in the presence of NMDA antagonists. At PND 15-21, bath application of AP-5 reduced spontaneous burst occurrence and firing irregularity in 11 out 19 neurons. Whole-cell current-clamp recordings revealed spontaneous bursts in DA neurons at PND 15-21, superimposed on long (2-3 sec) depolarizing jumps. Low-threshold spikes, generating bursts of action potentials, were elicited by either depolarizing, (at -65 mV), or at the offset of hyperpolarizing currents steps (at -80 mV). Using electrodes filled with 145 mM CsCl, burst activity was paroxystically increased. In voltage-clamp recordings, spontaneous miniature excitatory post-synaptic currents (mEPSCs) were recorded in 8/12 bursting and in 1/10 pacemaker DA neurons at PND 15-21. Addition of 100 μM 7-Cl-KA abolished the mEPSCs and produced an outward current. Since burst firing modulates Ca^{2+} influx, thereby the Ca^{2+}-mediated DA release, the pharmacological manipulation of burst production might provide new strategies for those pathologies related to DA system dysfunction, including Parkinson's disease, abuse of drugs and schizophrenia. In addition, the elevated NMDA sensitivity displayed by DA neurons during the critical third week after birth might have relevance in NMDA-controlled phenomena, such as synaptic plasticity, neuro-architecture and neurotoxicity.

702.2

ASPHYXIA DURING BIRTH INDUCES LONG-LASTING CHANGES IN MESO-TELENCEPHALIC DOPAMINE RECEPTORS OF THE MALE RAT.
[a]Y. Chen, [b]M. Hillefors-Berglund, [a]B. Bjelke, & [c]M. Herrera-Marschitz, [b]G. von Euler and [a]K. Andersson*.
[a]Dept. Internal Medicine, Karolinska Institutet, Huddinge Hospital, 141 86 Huddinge, Sweden, [b]Dept. Neuroscience and [c]Dept Physiology & Pharmacology, Karolinska Institutet, Sweden.

Asphyxia was induced during birth to male Sprague-Dawley rat pups. At an age of 4 weeks dopamine receptors were analyzed by quantitative autoradiography in the mesencephalon (A9 and A10), the caudate nucleus, the accumbens nucleus, and the olfactory tubercle. Mild (15-16 min), as well as, severe (19-20 min) perinatal asphyxia reduced D_1 antagonist binding ([^{3}H]SCH-23390 in the presence of ketanserine) in the accumbens nucleus, the olfactory tubercle and the A9 region, and increased D_1 agonist affinity ([^{3}H]dopamine in the presence of raclopride) in the accumbens nucleus and the olfactory tubercle. Mild asphyxia did not change D_2 antagonist binding ([^{125}I] iodosulpride) or D_2 agonist affinity ([^{3}H]*N*-propylnorapomorphine), while severe asphyxia reduced D_2 agonist affinity in the accumbens nucleus. D_3 agonist affinity ([^{3}H]7-OH-DPAT) was increased only following mild asphyxia.

In conclusion, asphyxia during birth induces long-lasting changes in dopamine receptor binding in the meso-telencephalic dopamine systems, which may contribute to previously reported behavioral changes. Perinatal asphyxia may thus be of importance for development of neurodegenerative disorders.

702.3

DOPAMINE SYNTHESIS INHIBITION BY (±)-7-OH-DPAT IN STRIATUM, ACCUMBENS, AND PREFRONTAL CORTEX IN DEVELOPING RATS.
S. L. Andersen* and M. H. Teicher, Department of Psychiatry, Harvard Medical School, Laboratory of Developmental Psychopharmacology, McLean Hospital, Belmont, MA 02178.

Dopamine (DA) synthesis modulation by the D_3 receptor agonist (±)-7-OH-DPAT was explored in striatum, accumbens, and prefrontal cortex of developing rats (10 - 40 days of age) using the GBL autoreceptor model. GBL produced an age-dependent increase in DA synthesis that was inhibited by (±)-7-OH-DPAT (0.1 - 13.5 mg/kg) in all regions. In striatum 7-OH-DPAT exerted a greater maximal inhibitory effect at 10-20 days (85% inhibition) than at 30-40 days (61% inhibition). 7-OH-DPAT inhibited DA synthesis by 66% in the accumbens, with no significant change with age. In prefrontal cortex GBL increased synthesis between 10-30 days, but had no effect at 40 days. 7-OH-DPAT inhibited DA synthesis 60% between 10-30 days. Eticlopride antagonized the action of 7-OH-DPAT in all regions, suggesting DA receptor mediation. These data confirm the existence of synthesis-modulating autoreceptor function in prefrontal cortex that recedes by 40 days. In all regions, the IC_{50} increased with age, indicating a decrease in autoreceptor sensitivity with maturation. Curiously, the striatum was more sensitive to the inhibitory effects of 7-OH-DPAT than the mesolimbic regions. (See Table below; IC_{50} in mg/kg)

	Striatum	Accumbens	PrefrontalCortex
10 Days	<<0.1	0.27 ± 0.20	<<0.1
15 Days	0.49 ± 0.32	1.42 ± 0.46	0.79 ± 0.43
20 Days	0.41 ± 0.14	0.95 ± 0.46	2.97 ± 0.12
30 Days	0.44 ± 0.88	0.50 ± 0.09	3.71 ± 0.53
40 Days	2.46 ± 0.25	3.53 ± 0.64	-- -- --

3.6 KILOBASES OF THE 5' FLANKING DNA OF THE MOUSE TYROSINE HYDROXYLASE GENE DIRECTS BRAIN-SPECIFIC BUT NOT CATECHOLAMINERGIC-SPECIFIC EXPRESSION.
W.W. Morgan*. Dept. of Cellular and Structural Biology, Univ. Texas Hlth. Sci Ctr. at San Antonio, TX 78284-7762.

The expression of the tyrosine hydroxylase (TH) gene is regulated by very precise molecular mechanisms which limit its activation to catecholaminergic neurons located within the brain, the sympathetic chain ganglia and paraganglia and to adrenal medullary cells. To study these processes, approximately 3.6 kilobases (kb) of the 5' flanking DNA of the mouse TH gene was inserted upstream of a E. coli β-galactosidase reporter (lac Z). This fusion gene (TH3.6LAC) was introduced into one-cell embryos of C57BL/6 mice, and transgenic mice were identified by PCR analysis. Analyses of β-galactosidase activity and the demonstration of TH3.6LAC mRNA by RNase protection assays suggested that the chimeric gene was activated in every region of the brain examined including the olfactory bulb, brainstem, hippocampus, cerebral cortex, striatum, cerebellum and diencephalon, as well as the adrenal gland. However, no evidence of TH3.6LAC activation was observed in the liver, kidney, spleen, lung or thymus. Similar results were observed in different transgenic founder lines. Histochemical analysis suggests that the reporter gene is activated in catecholaminergic and some selected non-catecholaminergic nuclei of the brain and in the adrenal medulla. Therefore, 3.6 kb of the 5' flanking DNA of the mouse TH gene appears sufficient to direct the expression of the lac Z reporter to the brain and the adrenal medulla but not to limit this activation to catecholaminergic nuclei. Supported by GM43763.

702.5

THE CREATION OF A TYROSINE HYDROXYLASE-NULL MUTATION.
M. Rios*, T. Sasaoka, D.M. Chikaraishi, and S. Roffler-Tarlov, Dept. of Anat. & Cell Biol.; Dept. of Neuroscience, Tufts. Univ., Boston, MA 02111

Cells containing the catecholamines dopamine, norepinephrine, and epinephrine are present in the central and peripheral nervous systems. Tyrosine hydroxylase (TH), the rate limiting enzyme in catecholamine biosynthesis, is persistently expressed by all catecholaminergic neurons and is transiently expressed in some cell populations during development. The role of TH in tissues where it is transiently expressed is not yet understood. The long term goal of the creation of a TH-null mutation is to expand our knowledge of catecholamine systems, transient TH expression, and the putative role of catecholamines in neural development.

Tyrosine hydroxylase-null mutants were generated using homologous recombination in embryonic stem (ES) cells. In order to disrupt the TH gene, a polyadenylation trap targeting vector was made in which genomic sequence between exons 6 and 8 of the mouse TH gene was replaced by a thymidine kinase-neomycin (TK-Neo) cassette without a polyadenylation signal. This construct was transfected by electroporation into D3 ES cells that were analyzed subsequently for the presence of homologous recombinants. Three homologous recombinant clones were detected among 371 neomycin-resistant clones, representing an efficiency of less than 1%.

Seven chimeras were generated from the two independent ES cell clones with ES cell contribution estimated to range from 65-100% based on coat color. Among the seven chimeras bred to C57Bl6 mice, five led to germ line transmission producing heterozygous carriers that were used subsequently to breed the mutation to homozygosity.

Lack of TH-null mutants in our first litters leads us to suspect that disruption of the TH gene results in embryonic lethality in homozygous animals, confirming the results of Zhou et al. (Nature, 1995, 374:640-643). NS20181 and NS22675

702.6

IN LAN-1 CELL LINE, TETRAHYDROBIOPTERINE INDUCES THE SYNTHESIS OF DOPAMINE AND REDUCES THE SEROTONIN TURNOVER.
A.Zuddas*, V.Lilliu, C.Mancosu, M.R.Monsurro°, G.Sorrentino°, U. di Porzio^, C.Cianchetti, Child Neuropsychiatry, Dept.Neuroscience, Univ.of Cagliari, °Dept. Science Human Communication, 2nd School of Medicine, Univ.of Naples,^IIGB-CNR, Naples, Italy.

LAN-1 is a human cell line expressing tyrosine hydroxylase, muscarinic M1 and M3 receptors, veratridine-sensitive sodium channels and they lack voltage-sensitive calcium channel. To further characterize the aminergic phenotype of these cells, we measured the monoamine and metabolite content by HPLC, the high affinity uptake and the veratridine-induced release of [3H]dopamine. Immunocytochemical analysis using anti Tyrosine Hydroxylase (TH) antibodies confirmed that several cell were TH-positive: nevertheless, no dopamine (DA) nor DA metabolite (DOPAC and HVA) were found in the cell omogenate. However, significant amounts of serotonin (5HT) and its metabolite 5HIAA were measured in the cells (2.6 ±1.0 and 20.5 ±1.5 ng/mg protein at 1 d.i.v. and 3.0±0.7 and 19.3 ±2.2 ng/mg protein at 4 d.i.v, respectively). The presence in the culture medium of 5,6,7,8 tetrahydrobiopterine (THB, 10 mM), cofactor for both TH and tryptophane hydroxylase, was able to activate the dopamine syntesis: at 1 d.i.v, DA, DOPAC and HVA contents were 8.7 ± 2.7, 1.1 ±0.1 and 0.3 ± 0.1 respectively. Moreover, THB significantly decreased 5HIAA (24.9 ± 0.4 vs 8.1 ± 1.5 ng/mg protein in control and THB, respectively, $p<0.01$). Similar results were obtained in four-day old cultures. LAN 1 cells were also able to taken up exogenous DA. After incubation with 50 nM [3H]DA, the specific [3H]DA uptake was 456.7+17.7 fmol/well and 1231.0+33.0 fmol/well at 1 and 4 d.i.v. respectively. On the other hand, in [3H]DA preloaded cells, veratridine (100μM) was unable to induce dopamine release. Taken together these data indicate that LAN 1 cell express TH and the cellular machinery for the high affinity dopamine uptake: in these cells, the dopamine synthesis could be actvated by the presence of high concentrations of THB, making this cell line an useful model of human diseases such as dopa-responsive dystonia. THB is also able to reduce the serotonin turnover: this appears of particular interest for studing the role of serotonin-dopamine interactions during normal development and in the pathogenesis of human psychiatric disorders.

702.7

THE SEROTONERGIC SYSTEM EXHIBITS DISTINCT DEVELOPMENTAL PATTERNS IN CORTICAL AND SUBCORTICAL STRUCTURES. A. Dinopoulos[1], L. Dori[1] and J.G. Parnavelas[2] (SPONSORED BY ENA). Dept. Anat., Vet. Sch., Univ. Thessaloniki, Greece[1], Dept. Anat., University College London, U.K.

The serotonin (5-HT) innervation of the developing rat visual cortex (VC), lateral geniculate nucleus (LGN), superior colliculus (SC), lateral septum (LS) and basal forebrain (BF) was examined with light and electron microscope immunocytochemistry. Comparisons between these areas showed that: 1) the distribution pattern was established gradually in some areas (LGN, SC, LS, BF), whereas in others (VC) it showed transient features; the adult pattern of innervation was attained by the end of the third postnatal week in all areas; 2) the types of synapses formed by 5-HT varicosities and the nature of postsynaptic profiles varied according to age and area of the brain examined; and 3) in all areas, the proportion of labelled varicosities forming synapses increased from birth until the end of the second week, declined markedly in the subsequent week before increasing again at a later stage. These findings support the view that: 1) the organization of the 5-HT system is related to the postsynaptic targets and, although arising in a small number of neurons in the midbrain, is highly specific in many parts of the brain; and 2) synapses formed by the serotonergic system during the first two weeks of life may be related to the involvement of 5-HT in developmental events, while those formed after the third week of life may be involved in the mediation of neurotransmitter effects by this monoamine.

702.8

ANALYSIS OF THE EXPRESSION AND LOCALIZATION OF GLYCINE RECEPTOR ALPHA2 SUBUNITS IN RAT SPINAL CORD WITH A POLYCLONAL PEPTIDE ANTIBODY. M.V. Langston and P.A. St. John.* Dept. of Cell Biology & Anatomy, Univ. of Arizona, Tucson, AZ. 85724.

Glycine receptors (GlyRs) are pentameric proteins composed of alpha and beta subunits. Molecular biological techniques have demonstrated the existence of multiple subtypes of alpha subunits and have shown that mRNA for alpha2 subunits is present in prenatal rat spinal cord. Immunological assays also have suggested that GlyR alpha2 subunits are present during early developmental stages in the rat spinal cord. Direct demonstration of the presence and specific localization of alpha2 polypeptides has been lacking, however, due to the absence of an antibody specific for this protein. We have raised a polyclonal antibody against a 10-amino acid peptide sequence, specific to the rat GlyR alpha2 subunit. Using this antibody, we have performed experiments on different ages of rat spinal cord neurons *in vivo* and *in vitro* to examine the expression of the GlyR alpha2 subunit. Analysis by Western blots showed that expression of the GlyR alpha2 subunit differed among the various developmental stages of rat spinal cord neurons, both *in vivo* and *in vitro*, as expected from previous results. In addition, confocal microscopy indicated that the GlyR alpha2 subunits are present on neuronal surfaces as early as embryonic day 14. In prenatal tissue, labeling was seen on most or all neurons, while in adult tissue labeling was predominantly in motoneurons. Clustering of GlyRs appeared to be much less striking than that previously demonstrated in adult rat spinal cord. We conclude that the GlyR alpha2 subunit is expressed on the surfaces of prenatal rat spinal cord neurons early in development *in vivo* and at a comparably early time *in vitro*. (Supported by NINDS #NS29657).

POSSIBLE POPULATION DIFFERENCES IN THE EXPRESSION OF GLYCINE RECEPTOR α2 ISOFORMS BY EMBRYONIC RAT SPINAL CORD NEURONS DURING DEVELOPMENT. M. D. Withers* and P. A. St. John. Program in Neuroscience, Dept. of Anatomy, University of Arizona, Tucson, AZ 85724.

Previous results radio-ligand binding assays, fluorescence microscopy with monoclonal antibodies and whole-cell patch-clamp recordings provide evidence for a change in the predominant expression of GlyR α subunits by embryonic rat spinal cord neurons from a relatively strychnine-insensitive isoform, presumed to be α2*, to one or more strychnine-sensitive isoforms one of which is shown to be α1. Recent experiments employing these same three techniques on embryonic spinal cord neurons from a different population of rats provide evidence for the predominant expression of strychnine-sensitive GlyR isoforms at all times tested. [3H]-strychnine binding is high on spinal cords and cultured spinal cord neurons from E14 rats while previous experiments on the original rat population showed no detectable [3H]-strychnine binding sites on E14 rat spinal cords or on neurons from these cords before four days in culture. Responses to glycine by spinal cord neurons from the recent population of rats are also completely blocked by 10 uM strychnine, while this concentration of strychnine blocked responses to glycine by same-aged neurons from the previous rat population by only 20 percent. Polyclonal antibody experiments provide evidence for the expression of a GlyR α2 subunit at early times in culture. These results provide evidence for the expression of the strychnine-sensitive α2 isoform of the GlyR by embryonic spinal cord neurons from the recent rat population at a time when a different population showed expression of a strychnine-insensitive isoform of the GlyR. (Supported by NIH and The Robert S. Flinn Foundation).

702.10

HIGH-AFFINITY ADENOSINE A2 RECEPTOR MATURATION IN THE RAT STRIATUM AND THEIR COUPLING TO G PROTEINS. J.L. Daval*, J.F. Doriat and A.C. Humbert. INSERM U.272, 30 rue Lionnois, 54013 NANCY, FRANCE.

To study the cerebral development of adenosine A2a receptors, the specific binding of [^{3}H]CGS 21680, a selective agonist, was measured in striatal membranes as well as in brain sections from the rat between birth and adulthood. The distribution of [^{3}H]CGS 21680 binding sites was analyzed by autoradiography, and the functional coupling of A2a receptors to G proteins was studied by the addition of a stable analogue of GTP, i.e. Gpp(NH)p. The binding of [^{3}H]CGS 21680 (0.2-80 nM) was assessed during a 90 min incubation in Tris-HCl (50 mM, pH 7.4) containing 10 mM MgCl2 and 2 IU/ml adenosine deaminase in the absence or in the presence of 10 µM Gpp(NH)p. In the striatum of adult rats, the total number of binding sites for [^{3}H]CGS 21680 reached 425±55 fmol/mg prot, with a Kd of 15.3±1.5 nM. A2a receptors were concentrated in caudate and accumbens nuclei, olfactory tubercles and globus pallidus. Such a specific distribution was observed at all developmental stages. At birth, the density of receptors was low but detectable, around 3% of the adult value, and receptor affinity was 8-fold higher than in adult (Kd=2.1±0.4 nM). The number of binding sites for [^{3}H]CGS 21680 increased with postnatal age to reach 16% of adult value at 5 days, 30% at 10 and 15 days, and 69% at 25 days, respectively. Concomitantly, Kd increased during brain development (4.5 nM at 5 days, 6.0 nM at 10 and 15 days, 9.8 nM at 25 days). Gpp(NH)p reduced significantly Kd values at all ages (from 47 to 82%), showing that receptors are linked to transducing proteins. Highest affinities of A2a receptors in the neonatal period may reflect a specific role for these sites in the immature brain, and A2a ontogeny contrasts with the developmental pattern of A1 receptors.

702.11

Differential Regulation Of Adrenergic Receptor Development By Sympathetic Innervation. Beth A. Habecker*, Nell M. Malec, and Story C. Landis. Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

Alpha and beta adrenergic receptors (α and β AR) mediate the effects of the sympathetic nervous system in peripheral tissues. Sweat glands are an unusual sympathetic target, since activation of AR during early postnatal development is critical for a target-directed switch of transmitter properties in the sympathetic innervation, while the mature innervation elicits sweat secretion through cholinergic stimulation of muscarinic receptors. Sweat glands are an interesting system for the study of regulation of AR expression because by postnatal day 21 catecholamines, which alter AR expression in many in vitro studies of receptor regulation, are gone and the sympathetic innervation contains acetylcholine, vasoactive intestinal peptide (VIP), and calcitonin-gene-related peptide (CGRP). Alpha 1B and β2 receptors are present in rat sweat glands; both receptor subtypes decrease after P21. This timing raises the possibility that changes in the sympathetic innervation influence receptor expression. Neonatal sympathectomy causes a partial failure of α1B downregulation, but has no effect on β2 levels. Therefore, innervation-independent processes control developmental expression of α1 and β2, while an additional innervation-dependent mechanism contributes to regulation of α1 receptors. Denervation at postnatal day 20, when the sympathetic innervation is cholinergic and peptidergic, leads to retention of adult α1 receptors similar to that seen with neonatal sympathectomy, but cholinergic blockade begun at P20 does not. These findings suggest that a heterologous mechanism, possibly utilizing VIP or CGRP, mediates the innervation-dependent portion of the developmental decrease in α1 receptors. Thus, multiple mechanisms, some utilizing the sympathetic innervation, control adrenergic receptor levels during sweat gland development. This work supported by NS23678 and NS09336.

HEME OXYGENASE ACTIVITY IN THE GUINEA PIG HIPPOCAMPUS, CEREBRAL CORTEX, AND CEREBELLUM: ONTOGENY AND ETHANOL EXPOSURE. MN Cook[†], HJ Vreman[‡], GS Marks[†], K Nakatsu[†], DK Stevenson[‡], & JF Brien[†]* [†]Dept. Pharmacology & Toxicology, Queen's Univ., Kingston, Canada, K7L 3N6. [‡]Dept. Pediatrics, Stanford Univ., Stanford, CA 94305.

Heme oxygenase (HO) catalyzes the oxidation of heme to carbon monoxide (CO) and biliverdin. HO appears to be involved in cell-cell communication via its regulation of CO, a novel neuronal messenger, and heme, a key constituent of nitric oxide synthase and soluble guanylyl cyclase. Ethanol CNS teratogenesis, a principal feature of the fetal alcohol syndrome, may involve altered function of HO during brain development. The ontogeny of HO activity in the hippocampus (H), frontal cerebral cortex (CC), and cerebellum (C) of the guinea pig at selected prenatal and postnatal ages and the effect of *in vitro* ethanol exposure were determined. Fetal guinea pigs at gestational day (GD) 51 and GD 63 (term, about GD 68), and adult guinea pigs were studied. The microsomal fraction of each brain region was analyzed for HO activity by an optimized method which measures the NADPH-dependent formation of CO from 25 µM methemalbumin at 37°C using a gas chromatographic method to quantitate CO. For each brain region, HO activity was greatest ($p < 0.05$) in the GD 63 fetus compared with the GD 51 fetus and the adult. There was no difference in HO activity at each developmental age among the three brain regions. *In vitro* ethanol (25-100 mM) exposure of microsomes did not affect HO activity. The data demonstrate, for the guinea pig, a distinct ontogenic profile for HO activity in the H, CC, and C. The effect of chronic prenatal ethanol exposure on HO activity in these brain regions is being studied. (Supported by the Medical Research Council of Canada).

EXPRESSION OF CALCITONIN GENE-RELATED PEPTIDE IN AXOTOMIZED RUBROSPINAL NEURONS

T. Fukuoka, K. Miki, K. Noguchi*
Dept. of Anatomy & Neuroscience, Hyogo College of Medicine, Nishinomiya , Hyogo 663, JAPAN

Axon injury induces an up-regulation in the synthesis of calcitonin gene-related peptide (CGRP), as well as tubulin and GAP-43 in spinal, facial, hypogrossal motoneurons. The rubrospinal neurons, that are confined within the CNS, have also been shown to increase the expression of tubulin and GAP-43 following axotomy. This study was designed to examine whether CGRP expression is induced in axotomized neurons in the rat red nucleus.

The cervical spinal cord of male Sprague-Dawley rats (140-200g) was exposed between C1-C2 lamina arcus vertebrae, and the left lateral funiculus was transected. Seven days after spinal hemisection, animals were killed by decapitation, and the brains were processed for *in situ* hybridization with radiolabeled oligonucleotide CGRP probe. Another group of animals were killed by paraformaldehyde perfusion 14 days after spinal hemisection. The change in CGRP-like immunoreactivity (LI) in red nuclei was examined using immunohistochemistry.

In rubral neurons contralateral to the spinal hemisection, we could detect neurons labeled for CGRP mRNA. There was no rubral neurons expressing CGRP mRNA on the ipsilateral side. Immunohistochemistry showed that the axotomized rubral neurons express increased CGRP-LI compared to the contralateral neurons. These data indicate that axotomy induces an up-regulation of CGRP synthesis in rubrospinal neurons, suggesting that neurons in CNS may be capable of synthesizing a neuropeptide *de novo* in response to the axonal injury.

702.14

DEVELOPMENT OF THE RAT BRAIN HISTAMINERGIC SYSTEM IN RELATION TO THE SEROTONERGIC AND CATECHOLAMINERGIC SYSTEMS AND PROGRAMMED CELL DEATH.

Anu Kinnunen * Institute of Biomedicine, Department of Anatomy, University of Helsinki, 00014 University of Helsinki, Finland.

In order to test the apparent spatio-temporal similarities in the distribution of the different developing aminergic systems implicated by separate earlier studies, the distribution of histamine-immunoreactive (HA-ir) neurons and nerve fibers was compared to the distribution of 5-hydroxytryptamine- (5-HT) and tyrosine hydroxylase-immunoreactive (TH-ir) ones in the developing Wistar -rat brain between embryonic days 12 (E12) and 20 (E20) using a double immunostaining method. The authentity of the immunohistochemically detected histamine of the developing brain was verified using high-pressure liquid chromatography (HPLC) fluorometric method. Synthetic oligonucleotide probes complementary to the rat histidine decarboxylase (HDC) were used for determination of the origin of HA in the developing brain by *in situ* hybridization.The immunohistochemical results revealed a transient co-localization of HA and 5-HT between E14 and E18 within a subgroup of cells in the developing raphe nuclei where also a positive HDC- hybridization signal was detected at E16. From E18 onwards the HA-ir neurons started to disappear gradually from the rhombencephalon and could no more be seen at E20. No significant co-localization of HA and TH was detected. The fate of the transiently HA-ir neurons was studied further using an *in situ* apoptosis detection kit for DNA fragmentation. The preliminary results showed a positive hybridization signal at E18 in the ventral pons rendering it possible that the "dissappearing" HA-ir neurons with the same location could die apoptotically. As no migrating HA-ir neurons were detected , an equally possible explanation is the change in the phenotype of the HA-ir cells following the cessation of histamine synthesis in the rhombencephalon. *The study presented in this abstract was the 1994 winner of the GBWest Memorial Competition.*

EXCITATION-SECRETION COUPLING IN CHOLINERGIC NERVES WITHIN THE EMBRYONIC CHICK HEART.

D. B. Gray, C. Eielsen, L. Hiestand, G. Pilar*, and A. Shea[1]. [1]Department of Biology, Simmons College, Boston, MA; Department of Physiology and Neurobiology, Univ. of Connecticut, Storrs, CT 06269.

In embryonic chick atria, potassium-evoked secretion of acetylcholine (ACh) from vagal and intramural parasympathetic neurons is calcium dependent and blocked by dyhydropyridines (Gray et al., Soc. Neurosci. Abstr., 1994). Incubation of atria with conotoxins such as ωGVIA or ωMVIIC at umolar levels had little effect on evoked ACh release at 14 days *in ovo*, but both toxins blocked over 90% of potassium-evoked ACh release at hatching. These data support the hypothesis that calcium channels coupled to transmitter release change from primarily L type to N type over hatching as in another parasympathetic neurons in the avian ciliary ganglion. To confirm this hypothesis for stimulation, ACh release was evoked from isolated atria with field electrical stimulation from platinum electrodes. Electrodes were connected to two grass stimulators and suspended in microfuge tubes containing freshly isolated atria. Stimuli were administered at a pulse frequency of 10 Hz, pulse duration of 20 msec, and stimulation period of two min. Labeled ACh release evoked by field stimulation was approximately 4 times higher than background and was calcium dependent. Incubation with 10 um nifedipine significantly inhibited evoked ACh release from all atrial preparations: release from continous stimulation was inhibited by 85%, while patterned stimulation using pulse trains was inhibited by 65%. Although further pharmacological analysis will test this possibilty it is clear that L type calcium channels do play a prominent role in transmitter release in the embryonic heart. Supported by The Catherine and Patrick Donaghue Foundation for Biomedical Research.

DEVELOPMENT OF CHOLINERGIC RECEPTORS IN FOREBRAINS OF RATS WITH 192 IgG-SAPORIN INDUCED CHOLINERGIC DEFICITS.

K.J. Claytor, F. M. Leslie, R.G. Wiley, J. Yu* and R.T. Robertson. Dep'ts. of Anatomy and Neurobiology, Pharmacology, and Physical Medicine and Rehabilitation, Univ. California, Irvine, CA 92717, and Lab. of Experimental Neurology, DVAMC, Nashville, TN 37212.

Previous work has demonstrated that an immunotoxin, consisting of the 192 IgG antibody to the low affinity NGF receptor coupled to the ribosome inactivating protein saporin, leads to the loss of basal forebrain cholinergic neurons. This project is continuing to examine the effect of early destruction of basal forebrain cholinergic neurons on development of cholinergic receptors in postnatal rat cerebral cortex and hippocampus. Injections of 192 IgG-saporin were made intraventricularly in Sprague-Dawley rat pups on postnatal day 0 (P0) and again on P2, At P8 or P21, animals were sacrificed and forebrains were processed for receptor autoradiography. AChE histochemistry and hemicholinium uptake were used to verify extent of the cholinergic lesion. Results from studies of hippocampus indicate a marked up-regulation of some forms of muscarinic receptors, but not nicotinic receptors. Patterns of M1 and M2 receptor populations, as indicated by pirenzipine and AFDX binding, appear no different in saporin treated and control animals. Binding of NMS, in the presence of M1 and M2 blockers, indicates a marked up-regulation of non-M1 and non-M2 receptors in hippocampus. Up-regulation was most prominent in the dentate gyrus, moderate in CA1 and CA2, and least in CA3. No changes in muscarinic receptor binding were apparent in neighboring cingulate and somatosensory cortical areas. These data indicate that the loss of forebrain cholinergic neurons produced by 192 IgG-saporin results in a selective alteration of cholinergic receptors. *Supported by NIH grant NS 30109 and the Department of Veterans Affairs.*

NEUROCHEMICAL PHENOTYPES OF POSTNATAL RAT MYENTERIC NEURONS IN DISSOCIATED CELL CULTURE

M.J. Saffrey*, K-H. Schafer[§]
Dept. of Biology, The Open University, Milton Keynes, MK7 6AA, UK. and [§]Dept. of Anatomy, University of Saarland, Homburg, Germany

We have recently developed new methods for growing myenteric ganglia from the postnatal rat small intestine in dissociated cell culture. These cultures contain neurons, which can be identified by immunolabelling with antiserum to protein gene product 9.5 and glia, which can be identified by immunolabelling with antisera raised against S100. We have previously shown that both basic fibroblast growth factor and the adenosine analogue, 2-chloroadenosine have trophic actions on neurons in these cultures[1]. However, different subpopulations of enteric neurons were not investigated in this earlier work. In order to assess the suitability of this model for the study of the actions of trophic factors on identified populations of postnatal myenteric neurons, we have now studied the expression of NADPH diaphorase activity and neuropeptides in these cultures. Myenteric ganglia were separated from the muscularis externa of the small intestines of 7 - 10 day old rats by mechanical agitation of small pieces of tissue which had been treated with collagenase. The isolated ganglia were then dissociated in trypsin, seeded on to poly-L-lysine coated coverslips and grown in a serum-free culture medium. After 2-5 days in culture the cells were fixed in 4% paraformaldehyde and processed for the histochemical reaction for NADPH diaphorase activity or immunolabelled using antisera raised against vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY) and methionine enkephalin (mENK). Populations of neurons in these cultures were found to express NADPH diaphorase activity or VIP, NPY and mENK immunoreactivity. These observations indicate that such cultures will be a useful model for the study of the effects of neurotrophic factors on identified populations of postnatal myenteric neurons.

PRENATAL DEVELOPMENT OF NITRIC OXIDE SYNTHASE IN THE MOUSE SPINAL CORD.

G. Brüning*[1], S. Mazumder,[1] B. Mayer[2]. [1]Dept. of Anatomy, Free University, D-14195 Berlin, Germany, and [2]Dept. of Pharmacology and Toxicology, Karl-Franzens-University, Graz, Austria.

The prenatal expression of neuronal nitric oxide synthase in the mouse spinal cord was investigated by NADPH diaphorase histochemistry and immunocytochemistry. Around embryonic day (E) 12, the first positive neurons were located in the intermediolateral position of the thoracic and sacral spinal cord. Two days later, presumed sympathetic cells were also located in an intermediomedial position. Further, positive neurons were grouped around the ventricular zone in the ventral part of the spinal cord. Between E15 and the first postnatal days, a group of cells in the ventral horn of the cervical and lumbar cord transiently stained for NADPH diaphorase. However, attempts to stain this subpopulation of ventral horn cells by immunocytochemistry failed.

Comparison with published data on the ontogenetic expression pattern of choline acetyltransferase and GABA indicates that expression of nitric oxide synthase starts after the cholinergic and/or GABAergic phenotype is acquired. Regulatory functions of nitric oxide in the development of the mouse spinal cord appear to be confined to later stages of neuronal migration and differentiation.

703.1

CHARACTERIZATION OF PC12 CELLS WHICH OVER- AND UNDEREXPRESS S100A1. E. H. Cornwall*, P. D. Reynolds, C. M. Donald and D. B. Zimmer. Department of Pharmacology, College of Medicine, University of South Alabama, Mobile, AL 36688.

S100A1 is a small, acidic calcium-binding protein, which is expressed in a variety of tissues and cells, including neurons. S100A1 modulates a number of intracellular processes via interaction with target proteins such as glycogen phosphorylase, aldolase and tau protein. Furthermore, documented increases in S100A1 levels appear to be associated with unregulated cell growth. To determine what cellular processes are regulated by S100A1, stable transfectants of PC12 cells which over- and underexpress S100A1 have been prepared using a mammalian expression vector which contains the S100A1 cDNA in the sense (pSense) or antisense (pAntisense) orientation with respect to a cytomegalovirus promoter. These DNA constructs were transfected into PC12 cells using electroporation. Reverse transcriptase-polymerase chain reaction analysis demonstrated that three clones expressed the pSense mRNA and three clones expressed the pAntisense mRNA. Indirect immunofluorescence microscopy showed that two clones which expressed the pSense mRNA had a greater S100A1 antibody fluorescence staining when compared to control cells. Three clones which expressed the pAntisense mRNA had decreased fluorescence staining when compared to control cells. These results suggest that the expression of the pSense and pAntisense mRNAs resulted in increased and decreased S100A1 levels, respectively, in PC12 cells. Functional studies on these clones will reveal which target proteins are regulated by S100A1. Furthermore, these studies will provide insights into the consequences of altered S100A1 expression and its role in disease progression. This research is supported by a grant from the NIH (30660).

703.2

ACTIVIN TYPE IIA RECEPTOR mRNA EXPRESSION BY NEURONS OF THE AVIAN CILIARY GANGLION. K. Kos, and J.N. Coulombe* Dept. of Anatomy and Cell Biology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814

Previous studies in culture have suggested that the protein activin may serve as a neurodifferentiation factor regulating the expression of somatostatin in neurons of the avian ciliary ganglion. We therefore sought to determine if any of the known activin receptors (ActR) are expressed by developing ciliary ganglion neurons in vivo.

Oligonucleotide primers were designed for the chicken ActR type IIA and type IIB. Both of these primer sets amplified bands of the anticipated sizes in reverse transcription polymerase chain reactions (rtPCR) with target RNA isolated from chicken ovaries. When RNA isolated from ciliary ganglia was used as the target instead, only primers corresponding to the ActR type IIA resulted in rtPCR amplification of an appropriately sized product. This rtPCR product was subcloned and sequenced, which confirmed it's identity as a fragment of the chicken ActR type IIA. It thus appears that mRNA for the type IIA but not the type IIB ActR is expressed in the chicken ciliary ganglion.

To examine what cell types contain mRNA for this ActR, digoxigenin-labeled riboprobes from the cloned ActR type IIA fragment were used for in situ hybridization on cryostat sections of embryonic chicken ciliary ganglia. Antisense strand, but not sense strand, ActR type IIA specific riboprobes hybridized to cells within these sections. At the ages examined (E6-E17), the hybridization of these probes appeared to be specific for cells with a neuronal morphology. These results are consistent with the hypothesized role for activin as a neurodifferentiation factor in vivo, and imply that, within the ciliary ganglion, the ActR type IIA is specifically expressed by neurons. (Supported by NSF IBN 9309932, USUHS RO70DU)

EXPRESSION OF FGFR ISOFORMS IN THE DEVELOPING MURINE NERVOUS SYSTEM

U.Greferath, Y.Brickman, B.Dowsing*, V.Nurcombe, P.Bartlett+, and M.D.Ford. Department of Anatomy and Cell Biology, University of Melbourne and +Walter and Eliza Hall Institute, Royal Melbourne Hospital, Parkville, 3052 Victoria, Australia.

Acidic Fibroblast growth factor (FGF-1) and basic FGF (FGF-2) have potent effects on the proliferation and differentiation of neural precursor cells. FGFs mediate biological activity through tyrosine kinase cell surface receptors known as the fibroblast growth factor receptors (FGFRs). A family of four, highly homologous FGFR genes (FGFR1-4) have been identified. Specific sequences encoded by separate exons in the FGFR gene are alternatively spliced into the C-terminal half of loop III to create various isoforms that have different binding affinities for the FGFs. There is evidence that FGF action is regulated by spatiotemporal differences in the expression of these FGFR isoforms. We have designed an RT-PCR assay to both detect expression of the various isoforms of the FGFRs in the embryonic nervous system and to generate isoform specific cRNA probes for use in RNase protection and *in situ* hybridization analyses. An RT-PCR assay on mRNA from embryonic day 10 (E10) neuroepithelium has shown that it expresses isoforms of FGFR1, 2 and 3, but not of FGFR4. RT-PCR and RNase protection analyses on mRNA from an E10 neuroepithelium derived cell line (2.3D) demonstrated that the expression of FGFR1 IIIac is very high compared to the expression of other isoforms. The FGFR1 IIIac isoform seems to be the only isoform in this cell line, which is used to poentiate the action of FGF-2 (1). The distribution of FGFR protein is currently beeing investigated using antibodies specific to FGFR1, 2 and 3.

FGF RECEPTOR IS A NUCLEAR PROTEIN - NOVEL MECHANISM FOR bFGF ACTION. **E.K. Stachowiak, E. Mordechai, A. Joy, , A. Schwartz*, P. Maher*, M.K. Stachowiak. Barrow Neurol.Inst. Phoenix, Az 85013, *The Scripps Res.Inst. La Jolla, CA 92037.**

Traditionally growth factors (GFs) are thought to exert their biological effects by interacting with plasma membrane receptors. However, some GFs including bFGF, aFGF, or CNTF lack secretory signal sequences and are primarily cell associated. Trans-synaptic or hormonal stimulation of adenylate cyclase in bovine adrenal medullary cells (BAMC) leads to nuclear accumulation of bFGF suggesting a direct nuclear function of bFGF (Stachowiak et al., 1994). To determine how nuclear bFGF could exerts its biological effects we examined the subcellular distribution of its receptors (FGFR). Immunoprecipitation with antibodies against different types of FGFR showed that FGFR1 is the only type expressed in cultured BAMC. Confocal microscopy and Western analyses of fractionated BAMC demonstrated that FGFR1 protein is located predominantly in the nucleus, with little cytoplasmic or plasma membrane localization. Nuclear FGFR1 is represented by 103 kDa protein containing both the N-terminal (ligand binding) and C-terminal (tyrosine kinase, TK) domains, and by 118 kDa and 145 kDa proteins recognized only with the N-terminal FGFR1 antibody. Consistently with these results we detected high affinity ^{125}I-bFGF-binding sites (kd=14 pM) and bFGF-stimulated TK activity in nuclear extracts. Similarly as bFGF, the FGFR1 colocalize with the nuclear matrix and nucleoplasm, but not with chromatin. Electron microscopy revealed patches of FGFR1 colocalized with bFGF patches within the interior of the nucleus. Treatment of BAMC with forskolin induced parallel accumulation of bFGF, FGFR1 and bFGF-TK in the nucleus. Nuclear translocation of bFGF and its receptors offers a novel mechanism for GF action (Supported by NIH, NSF, APDA).

CHARACTERIZATION OF LIF-RECEPTOR (LIF-R) ANTAGONISTS IN BIOLOGICAL ASSAYS. A.B. Vernallis*, K. Hudson, and J.K. Heath. Dept. of Biochemistry, Oxford University, Oxford, OX1 3QU, U.K.

LIF-R and gp130 oligomerize and activate intracellular signals in response to LIF, OSM, CNTF/CNTFR, and CT-1. Given the large number of ligands, antagonists of LIF-R function would be useful in probing the role of LIF-R.

As a first approach, residues on the A-helix of human LIF, that are analogous to site II of human growth hormone based on the crystal structures of murine and human LIF, were substituted with alanine to generate a LIF mutant with reduced ability to interact with gp130. The resulting mutant binds LIF-R with normal affinity but has a much lower affinity for gp130. In proliferation assays on Ba/F3 cells cotransfected with hLIFR and hgp130, the mutant inhibited 50% of the proliferation response to a submaximal dose of hLIF at a 30-100-fold excess of competitor. Responses to OSM were also reduced.

Second, in order to generate LIF-R that binds ligands but does not signal, the extracellular domain of hLIFR was truncated after the membrane-proximal hematopoietin domain and fused to the Fc region of human IgG1. This soluble receptor (LIFR-Fc) was expressed in 293T cells and purified on protein A. In Ba/F3 assays the proliferation response to hLIF was reduced by 50% at approximately a 1000-fold molar excess of LIFR-Fc.

Preliminary results suggest that both these antagonists reduce the hLIF stimulation of the VIP promoter in IMR-32 neuroblastoma cells indicating that the antagonists will be useful in studying the function of LIF-R in the nervous system.

703.6

VIP ANALOGUE STIMULATES EMBRYONIC GROWTH THROUGH GTP-INSENSITIVE BINDING SITES. I.M. Hill*, D.A. Dibbern Jr., I. Gozes, M. Fridkin and D.E. Brenneman. Lab. of Dev. Neurobiol. NICHD, NIH, Bethesda, MD 20892; Dept. of Clinical Biochem. Tel Aviv Univ., Tel Aviv, Israel; Dept. of Organic Chem. Weizmann Inst. of Science, Rehovot, Israel.

Vasoactive intestinal peptide (VIP) has been shown to act through GTP-insensitive binding sites to regulate embryonic growth during the early post-implantation period (*Nature*, 1993, 362:155; *J. Clin. Invest*. 1994, 94:2020). Stearyl-norleucine-VIP (SNV), a novel VIP analogue which acts via cAMP-independent mechanisms, has recently been shown to enhance neuronal survival (*J. Pharm. Exper. Ther*. 1995, 273). The purpose of the current study was: 1) to examine the action of SNV on the growth of cultured day 9.5 mouse embryos; and 2) to compare the distribution of SNV binding sites in CNS with GTP-insensitive VIP binding sites. SNV and GTP-insensitive binding sites were determined by *in vitro* autoradiography with ^{125}I-VIP in the presence of 10^{-6}M SNV or 10^{-5}M GMP-PNP (a stable GTP analogue), respectively, on adjacent sections. Treatment of mouse embryos in culture with 10^{-7}M SNV resulted in a significant increase in growth. SNV-treated embryos grew 3.7 somites during the four hour incubation period compared with 2.2 somites by controls and 5.2 somites by 10^{-7}M VIP. Embryonic growth was not stimulated by treatment with the related peptide PACAP (10^{-9}M-10^{-7}M). *In vitro* autoradiography revealed that SNV displaced ^{125}I-VIP only at specific sites in the CNS and those sites coincided with GTP-insensitive VIP binding sites identified on adjacent sections. Co-treatment with both GTP and SNV resulted in the total displacement of radiolabeled VIP from brain sections. These data suggest that VIP-induced stimulation of embryonic growth is regulated, in part, through cAMP-independent mechanisms and that SNV acts on GTP-insensitive binding sites in the brain.

703.7

ALK-7, A NOVEL BRAIN SPECIFIC SERINE-THREONINE KINASE RECEPTOR. M.Rydén, H.H. Jörnvall, M. Trupp and C.F. Ibáñez*
Laboratory of Molecular Neurobiology, MBB, Karolinska Institute, S-171 77 Stockholm, Sweden

Receptors for members of the transforming growth factor beta (TGF-β)-superfamily have been classified in three types, from which only type I and II represent signalling receptors with intrinsic serine-threonine kinase activity. To isolate new members of this receptor family specific for the nervous system, PCR was performed using primers derived from conserved regions of ser-thr kinase domains using rat P1 brain cDNA. Different fragments showing similarities to both type-I and type-II receptors were found, one of these corresponded to a previously nondescribed type-I ser-thr-kinase receptor which we have named ALK-7. A full-length cDNA clone was isolated and shown to contain a 494 aa open reading frame displaying all the characteristic functional domains of type I receptors. The amino-acid sequence of ALK-7 shows up to 66% identity to ALK-4 and ALK-5. RNAse protection assays and *in situ* hybridization demonstrated a highly specific pattern of expression restricted to the central nervous system. ALK-7 mRNA was predominantly expressed in postnatal cerebellum and hippocampus. *In vitro* translation generated a major 55 kDa product, in accordance with the predicted aa sequence. Ectopic expression in COS cells and ^{125}I-surface labeling showed ALK-7 to be a surface protein. Receptor reconstitution and cross-linking experiments are currently being performed to determine whether any of the known members of the TGF-β ligand superfamily, including TGF-β1, TGF-β2, activin, bone morphogenetic proteins (BMPs) and glial cell line-derived neurotrophic factor (GDNF), is a ligand for ALK-7.

A comparative study of two splice variants of the "neu"-regulin family.

Y. Kuo* and L. Role. Integrated Program and the Department of Anatomy and Cell Biology in the Center for Neurobiology & Behavior, Columbia Univ., P&S, 722 W. 168th St. NY, NY 10032.

Proteins encoded by the neuregulin gene are comprised of multiple structural and functional domains. Alternative splicing of neuregulin gene transcripts result in over twenty protein isoforms. Some isoforms are predicted to result in proteins with similar structural domains with different sequences. Work by Wen et al has demonstrated that sequence differences between the α and β isoforms of the EGF-like domain result in proteins with different affinities for the receptor. Other splice variants produce isoforms with significantly different predicted structures. These differences in protein structure are likely to translate into differences in functional properties.

We have cloned a novel splice variant of the neuregulin family which lacks an immunoglobulin-like domain in its N-terminus (called nARIA). Instead, the nARIA splice variant has a cysteine rich domain at its N-terminus. Furthermore, the predicted amino acid sequence suggests that nARIA also possesses a signal sequence, a structural motif present in only one other reported isoform (GGF). The distribution of the nARIA message is also different from that of the otherwise similar immunoglobulin-containing isoform, ARIA. To study the functional differences of nARIA and ARIA, we have artificially manipulated the expression and structure of these genes. (Supported by NS29071)

ANALYSIS OF MUTANT PDGF RECEPTORS EXPRESSED IN PC12 CELLS IDENTIFIES SIGNALS GOVERNING NA CHANNEL INDUCTION DURING NEURONAL DIFFERENTIATION G.R. Fanger[1]*, R.R. Vaillancourt[3], L.E. Heasley[4], J.P.R. Montmayeur[3], G.L. Johnson[3,4] and R.A. Maue[1,2] Departments of [1]Biochemistry and [2]Physiology, Dartmouth Medical School, Hanover, NH 03755, [3]Divison of Basic Sciences, National Jewish Center for Immunology and Respiratory Medicine, and [4]Deptartment of Pharmacology, Univ. of Colorado Medical School, Denver, CO 80262

Although growth factors that stimulate tyrosine kinase receptors play an important role in neuronal differentiation, the mechanisms by which this occurs are not well understood. To identify signals necessary for the induction of voltage-dependent Na channel expression, a crucial aspect of neuronal differentiation that can occur independent of p21/ras activation, patch clamp analysis and RNase protection assays were used to analyze PC12 cells stably expressing platelet-derived growth factor (PDGF) receptors with mutations in tyrosine residues of the cytoplasmic domain that associate with signaling molecules upon activation of the receptor. Mutations that block activation of PI3-K, PLCγ, GAP, and Syp did not alter the PDGF-mediated induction of Na channel expression. However, mutation of tyrosines that associate with members of the src family of kinases significantly inhibited induction of functional Na channel expression in response to PDGF. Furthermore, mutations that block association with src family members, in combination with mutations that block PI3-K, PLCγ, GAP and Syp activation, abrogated the PDGF-mediated induction of type II Na channel α subunit mRNA, indicating that multiple signals generated by the receptor contribute to this response. The results were due to the specific mutations introduced and not simply the result of an overall decrease in receptor kinase activity, since transin and c-fos mRNA were still induced by all of the mutant receptors analyzed. The results provide insight into the signal transduction mechanisms governing expression of type II Na channel α subunit mRNA and Na current density, and mechanisms underlying neuronal differentiation. Supported by NS28767 to RAM.

PREGNENOLONE SULFATE INCREASES THE GROWTH OF HIPPOCAMPAL NEURONS. R. D. Brinton* and R. Gunawan. Dept. Molecular Pharmacology and Toxicology, University of Southern California, Los Angeles, CA 90033

Pregnenolone sulfate (PS) has been found to be synthesized de novo in oligodendrocytes of the hippocampus and cortex thereby providing locally synthesized concentrations of this neurosteroid. PS has also been found to enhance memory functions in mice and rats. Growth in the projections and synaptic connections has been postulated to be one of the fundamental cellular mechanisms involved in learning and memory. We therefore conducted experiments to determine the impact of PS on the growth and morphology of hippocampal nerve cells. Results of this investigation demonstrated that PS induced a significant increase in the number of neurites and the total length of neurites (*p<.05, ** p<.01, ***p<.001). Significant increases also occurred in the fine structure of the nerve cells. PS induced a significant increase in the number of branches (*p <0.05, *** p<.001), in the total branch length (*p <0.05, *** p<.001), in the number of bifurcation points emanating from neurites (*p <0.05, *** p<.001) and in the number of microspikes (*p<.05, ** p<.01, ***p<.001). We pursued the mechanism of PS-induced nerve cell growth by investigating the impact of blocking the NMDA glutamate receptor on PS-induced hippocampal nerve cell growth. Preliminary results of these experiments indicate that the growth promoting effects of PS (500 nM ** p<.01) are completely abolished in the presence of the NMDA receptor antagonist AP5 (10 μM). In addition, our results indicate that NMDA receptor activation is not required for normal nerve cell growth, since the growth of neurons in the presence of AP5 was not significantly different from control, but is involved in the potentiation of normal nerve cell growth. Results of these investigations indicate that the neurosteroid, PS, can act as a significant neurotrophic factor for hippocampal neurons.

GANGLIOSIDES REGULATE CYTOSKELETAL STRUCTURE AND PROTEINS IN NEURO-2a NEUROBLASTOMA. L-J. Wang, R. Colella & F.J. Roisen.* Anatomical Sciences & Neurobiol., Univ. of Louisville School of Med., Louisville, KY 40292.

It is well established that gangliosides enhance neuritogenesis of primary neuronal tissues and several cell lines, but the exact mechanism remains unknown. Our previous studies demonstrate that ganglioside exposure simultaneously increases the microtubule network and neuritogenesis of Neuro-2a cells. A redistribution of MAP2 immunoreactivity from the perikaryon to the distal processes occurs following 24 hr GM1 treatment. In contrast, MAP5 and tau immunolocalization remains unchanged. Immunoelectron microscopy demonstrates that MAP2 is more closely associated with actin-rich subcortical cytoplasm than with microtubules after GM1 exposure (more MAP2 label per unit area was found in spine-like projections and in neurites). To determine if GM1 alters neuronal development by regulating the induction of synthesis of the cytoskeletal proteins or by targeting specific cytoskeletal proteins to distinct regions in the neuron, protein and RNA analysis is in progress. Western blot analysis reveals increased levels of acetylated tubulin but not MAP2 following GM1 exposure. Actin mRNA increases in a GM1 dose dependent fashion. Studies in progress examine the time dependent effects of GM1 exposure on actin levels and topography via immunolocalization. Our data suggests that gangliosides may be involved in the determination of dendritic or axonal fate by selectively changing the distribution of MAP2, stabilizing microtubule networks and increasing actin synthesis. It is possible that gangliosides enhance neurite formation by altering the balance of microtubules and microfilaments through MAP2-dependent mechanisms. ANALYSIS OF RECEPTOR TYPE TYROSINE KINASE AND ITS LIGAND DURING EARLY MOTONEURON DEVELOPMENT. K. Ohta*, H. Iwamasa, M. Nakamura, N. Iino, and H. Tanaka. Divi. of Dev. Neurobiol., Dept. of Neurosci. and Immunol., Kumamoto Univ. Grad. Sch. of Med. Sci., Kumamoto 862, Japan.

Receptor tyrosine kinases (RTKs) play important roles in cellular survival, proliferation, and differentiation. We have isolated 19 RTKs by RT-PCR method from E5 chick motoneurons. In situ hybridization analysis revealed that chick Sek, a member of eph family, was expressed from E5 on motoneurons at the brachial and lumbar segments of the spinal cord which innervate limb muscles, and disappeared after the naturally occurring cell death period (E6-E11). Immunohistochemistry using anti-chick Sek monoclonal antibody showed the localization of chick Sek protein at cell bodies and axonal fibers of motoneurons. We also isolated a chick homolog of ELF-1, which was identified as a ligand for both Mek4 and mouse Sek. Chick ELF-1 was 72% identical to mouse ELF-1. While the expression of chick Sek was highly regulated in time and space, chick ELF-1 was widespread. The unique expression of chick Sek suggests the involvement of it in the cell-cell interactions for specific subpopulations of developing motoneurons.

p55^{PIK},A NEW PI3K REGULATORY SUBUNIT ENGAGES IGF-I SIGNALING DURING CENTRAL NERVOUS SYSTEM DEVELOPMET. S.Pons., J.Torres-Aleman*., M.F.White.
Joslin Diabetes Center, Harvard Med. School, Boston, MA, 02215
*Cajal Institute for Nerobiology. CSIC. Madrid. Spain.

Phosphatidylinositol (PI-3) kinase is implicated in the regulation of diverse cellular processes, including neurite outgrowth in PC12 pheochromocytoma cells. PI-3 kinase is composed of a 110-kDa catalytic subunit and an 85-kDa regulatory subunit. Here we describe p55^{PIK}, a new regulatory subunit that was isolated by screening expression libraries with tyrosine phosphorylated IRS-1. The p55^{PIK} is composed of a unique 30-residue NH_2-terminus followed by a proline-rich motif and two SH2 domains which contain homology to those of p85.

In contrast to the ubiquitous expression of the previously described p85, expression of p55^{PIK} is mainly in the central nervous system (CNS). Maximum levels of expression are found between 13.5-15.5dpc, decreasing in subsequent developmental stages with only minimal levels detected in the adult brain. High levels of p55^{PIK} expression are temporally and spatially coincident with neuronal differentiation in CNS development.

The p55^{PIK} forms a stable complex with p110, and associates with IRS-1 during IGF-I stimulation in both primary neuronal cultures and in P19 cells differentiated to neuronal fate. The unique features of p55^{PIK} suggests that it may be important in IGF-I receptor signaling during neuronal differentiation.

EXPRESSION OF INTERLEUKIN-3 RECEPTOR ALPHA AND BETA IN MURINE CENTRAL NERVOUS SYSTEM NEURONS. Y. Konishi*[1], T. Kunishita [1], D.-H. Chui [1], S. Yonehara [2], K. Takahashi [1] and T. Tabira [1]. [1] National Institute of Neuroscience, NCNP, Tokyo 187, Japan. [2] Institute for Virus Research, Kyoto University, Kyoto 606, Japan.

We have previously reported that interleukin-3 (IL-3) is one of the candidates for cholinergic neurotrophic factors (Neuron 4:429-436, 1990). Since that report, it has been questioned whether IL-3 acts directly on cholinergic neurons or indirectly on them via other populations of cells in the central nervous system (CNS). We now demonstrate the expression of IL-3 receptor (IL-3R) alpha (SUT-1) and beta (AIC-2A and -2B) in the CNS neurons by means of reverse transcription and polymerase chain reaction (RT-PCR) and immunohistochemistry, although the partial data on IL-3R beta were already reported (Neurosci. Res. 19:S137, 1994; Int. J. Dev. Neurosci. 1995, in press). RT-PCR followed by Southern blot analyses revealed that the mRNAs for IL-3R alpha and beta are found in an embryonic cholinergic septal cell line SN6 and primary cultured neurons derived from the septal regions of embryonic mice. In contrast, a postnatal cholinergic septal cell line SN49 expresses only IL-3R alpha mRNA, and a postnatal non-cholinergic septal cell line SN52 expresses none of the mRNA for IL-3R alpha and beta (SN6, SN49, SN52 are kind gifts from Dr. B. H. Wainer, Albert Einstein College of Medicine, Bronx, NY). Actually IL-3 elevates choline acetyltransferase (ChAT) activity in SN6 but not in SN49, 52. These results indicate that IL-3 is utilized by cholinergic neurons via a set of IL-3R alpha and beta expressed in the cholinergic neurons. The results were supported by immunohistochemical study showing that IL-3R alpha and beta were found in cholinergic neurons of the basal forebrain. CHARACTERIZATION OF A NOVEL AUTOCRINE INTERACTION OF HEPATOCYTE GROWTH FACTOR/SCATTER FACTOR AND ITS RECEPTOR, MET IN SUPERIOR CERVICAL GANGLIA PRIMARY CULTURE. X.-M. Yang[1], D. Belliveau[1], J. Kohn[1], M. Park[2] and F.D. Miller[1]*. 1: Centre for Neuronal Survival, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada. H3A 2B4. 2: Molecular Oncology Group, Royal Victoria Hospital. Department of Oncology, Medicine and Biochemistry, McGill University.

Hepatocyte growth factor (HGF)/scatter factor (SF) is a multifunctional cytokine that stimulates mitogenesis, motogenesis, morphogenesis of a broad spectrum of epithelial and endothelial cells. The HGF/SF cellular responses are mediated by the Met receptor tyrosine kinase. To investigate the possible biological function(s) of the HGF/SF and its receptor in the nervous system, we chose to analyse the expression of the HGF/SF and its receptor in primary culture of sympathetic neurons from the superior cervical ganglia (SCG). RT-PCR demonstrated that sympathetic neurons express HGF/SF mRNA. Moreover, condition media of sympathetic neuron cultures contained bioactive HGF/SF as indicated using a scatter assay with MDCK cells. Sympathetic neurons also synthesize met receptor mRNA, and immunofluoresence studies indicate that the Met receptor is localized to both cell bodies and neuritic processes. Thus, sympathetic neurons synthesize both HGF/SF and its receptor, Met, suggesting the possibility of a novel autocrine loop. The possible biological function of such an autocrine loop is under investigation in sympathetic neurons in culture and in vivo.

EXPRESSION OF THE INTRACELLULAR DOMAIN OF THE P75 NEUROTROPHIN RECEPTOR IN TRANSGENIC MICE PERTURBS NEURONAL DEVELOPMENT. Freda D. Miller, Audrey Speelman, Christine Zeindler, Shernaz Bamji, Daniel Belliveau, Christian Lachance, Andrew Gloster*, and Philip A. Barker. Center for Neuronal Survival, MNI, McGill University, Montreal, Canada H3A 2B4.

Intracellular domains of receptors can act as autonomous signalling units. As a means of assessing p75 neurotrophin receptor signalling functions in vivo, we have produced transgenic mice which overexpress the intracellular domain of p75 (ICD) within neurons. Specifically, we have utilized the Tα1 α-tubulin promoter, which is expressed at high levels in early developing neurons, and shows reduced expression after neurons mature. Analysis of four lines of transgenic mice generated using the Tα1:ICD construct revealed that at least two of these lines express the transgene at readily detectable levels. Animals from both lines display ptosis and are smaller and noticeably less coordinated than their control littermates. In both of these lines, the sensory and sympathetic ganglia are significantly smaller than in control littermates. Cell counts revealed that transgenic sympathetic ganglia contain approximately 30% fewer neurons than control littermates. Analysis of sensory neurons of the DRG indicated 60% cell loss, preferentially of small neurons. To determine whether the CNS of these animals is also affected, Tα1:ICD mice were crossed with a previously-characterized line of transgenic mice that expressed ß-galactosidase from the same promoter (line K6, Tα1:nlacZ animals, as reported in Gloster et al., J. Neurosci., 14, 7319, 1994). Histochemical staining with Xgal revealed that there are significant perturbations in neuronal distribution throughout the brains of the Tα1:ICD mice. For example, the laminar distribution of neurons within the cortex is disturbed and occasional clusters of blue nuclei are observed within the white matter. The cellular basis for these perturbations in neuronal development is currently under investigation.

703.17

A Cytoplasmic Homology Between p75^{LNTR}, TNF-RI and the Fas Antigen May Define Analogous Functional Domains. P.A. Barker*, C. Zeindler, D. Kryl, C. Lachance. Center for Neuronal Survival. Montreal Neurological Institute. McGill University, Montreal, Quebec. H3A 2B4

p75^{LNTR} was the first identified member of a superfamily of related receptors which includes CD27, CD30, CD40, 4-1BB, OX40, the fas antigen and the two tumor necrosis factor receptors (TNF-R1 and TNF-R2). The shared homology that defines this group resides in conserved protein modules, termed Cys repeats, which are present extracellularly. p75^{LNTR} has recently been shown to signal autonomously by stimulating production of the lipid second messenger, ceramide. In this respect, p75 can be grouped with two other members of the TNF receptor superfamily, TNF-R1 and fas.

Consistent with this conserved functional homology, we have found that the intracellular domain of the p75^{LNTR} bears considerable sequence homology to the previously described "death domain" of the TNF-R1 and fas receptors. Use of the MACAW program (NCBI) reveals three regions of statistically significant homology between these three receptors. All of these small domains are located within the "death domain" region previously defined for TNF-R1 and fas. Parsimony analysis indicates that p75^{LNTR} and TNF-R1 are as closely related within this region as are TNF-R1 and fas.

Motifs allowing receptor oligomerization are present within the TNF-R1 and fas intracellular domains. To determine if the intracellular domain, or portions thereof, are capable of self-association, interactions have been assayed in vitro using bacterial fusion proteins and in vivo using the yeast two hybrid system. The identification of this conserved intracellular domain within p75^{LNTR} should aid future investigations of the signaling capabilities of each of these related receptors.

LAR RECEPTOR-DEFICIENT TRANSGENIC MICE: DECREASED LAR EXPRESSION AND ABERRANT DENTATE GYRUS INNERVATION. T. Yang[1], T.T. Yeo[2], L.L. Butcher[2], J.S. Zhang[1] and F.M. Longo*[1]. [1]Dept. of Neurology, UCSF/VAMC, San Francisco, CA 94121 and [2]Dept. of Psychology, UCLA, Los Angeles, CA 90095.

Developmentally-regulated expression of the Leukocyte Common Antigen-Related (LAR) tyrosine phosphatase receptor and neuron-preferential alternative splicing suggests that LAR regulates mammalian neural development (Longo et al. SNS, 1991; Longo et al, JBC, 1993; Zhang and Longo, JCB, 1995). LAR transgenic mice (DBA2/129Ola hybrids) were created by W. Skarnes using a gene trap that prevents synthesis of normal LAR transcripts (Centre Genome Research, Edinburgh) and bred in our laboratory. Northern analysis of brain RNA from LAR homozygous (-/-) transgenic mice showed trace or absent ~8kb LAR transcript as compared to the wild type (+/+, DBA2). Dentate gyrus innervation from basal forebrain was examined by immunohistochemistry using antibody against the p75 NGF receptor which co-localizes with cholinergic markers. In -/- mice we observed: i) reduction of p75 immunoreactivity in the infragranular band; ii) disrupted laminar pattern of fibers entering the granule cell layer; iii) fiber thickening with aberrant beading in granular and polymorphic layers, raising the possibility of a neurodegenerative process. Heterozygous intercrosses will determine if strain difference account for any of these abnormalities. These observations support our hypothesis that LAR-type tyrosine phosphatases regulate neurite outgrowth and/or synapse formation. Supported by an AFAR Beeson Award (FL), NIA R01 (FL), VA (FL), French Fdn (TTY) and Retirement Research Foundation (LB).

703.19

LAR TYROSINE PHOSPHATASE RECEPTOR: RNA AND PROTEIN EXPRESSION OF LAR ALTERNATIVELY SPLICED ELEMENT-C (LASE-C). J.S. Zhang*, J. Honkaniemi, T. Yang and F.M. Longo. Dept. of Neurology, UCSF/VAMC, San Francisco, CA 94121.

The Leukocyte Common Antigen-Related (LAR) tyrosine phosphatase receptor contains Ig and fibronectin type III domains resembling those in cell adhesion molecules mediating neurite outgrowth. Developmentally regulated expression of rat LAR in neurons suggests a role in neural development (Longo et al SNS Abst, 1991; Longo et al JBC, 1993). LASE-c is a 27 bp alternatively spliced exon in the fifth fibronectin type III LAR domain. Its splicing is regulated by development, NGF and denervation and preferentially occurs in neural tissue (Zhang and Longo JCB 1995). *In-situ* hybridization with a LASE-c probe which identifies the ~7 kb LAR transcript on Northern blots showed diffuse neuronal expression at birth. In adults, however, high expression was largely restricted to subsets of neurons in the hippocampus and vestibular, reticular thalamic, oculomotor and deep cerebellar nuclei. Northern analysis showed markedly reduced LASE-c expression in cortex, hippocampus and cerebellum during postnatal development. On Western blots, affinity-purified antiserum raised against LASE-c peptide identified the predicted 150kD LAR band and preferentially stained neurons in dorsal root ganglia. LASE-c antibody also stained sciatic nerve neurites and neurites and growth cones of cultured neurons. Expression of LASE-c in specific subsets of neurons and presence of LAR protein with the LASE-c domain in neurites and growth cones supports our hypothesis that highly-regulated alternative splicing of LAR-type tyrosine phosphatases regulates neurite outgrowth and/or synapse formation. Supported by American Paralysis Association (FL) and NIA R01 (FL).

703.20

PHOSPHORYLATION OF GP130 IN RESPONSE TO LEUKEMIA INHIBITORY FACTOR OR MITOGEN STIMULATION OF 3T3-L1 CELLS. W.P. Schiemann*, and N.M. Nathanson. Department of Pharmacology, Univ. of Washington, Seattle, WA 98195.

We have demonstrated recently that the human LIF receptor (LIFR) is phosphorylated at Ser1044 by mitogen-activated protein kinase (MAPK) *in vitro*, and that heterologous receptor-mediated attenuation of LIFR-stimulated reporter gene expression occurs through effects at Ser1044 *in vivo*. We have constructed bacterially expressed fusion proteins containing the entire or various cytoplasmic regions of human gp130, the β-subunit of activated LIFRs, and measured their ability to serve as substrates in protein kinase reactions. We found that gp130 fusion proteins, like those for the LIFR, were phosphorylated in extracts of LIF- or growth factor-stimulated 3T3-L1 cells predominantly on Ser residues C-terminal to box 3 in a dose- and time-dependent manner that mirrored the activation of MAPK. The gp130 protein kinase(s), however, is clearly distinct from activated MAPK because: (i) gp130 was an extremely poor substrate for active recombinant MAPK *in vitro*; (ii) gp130 phosphotransferase activity was readily separated from the MAPK isozymes ERK1 and ERK2 following Mono Q or Superose 12 chromatography; and (iii) Ca^{++}/phospholipid were required to reconstitute phosphorylation of gp130 fusion proteins in fractionated extracts. Additionally, we find that pretreatment of 3T3-L1 cells with growth-factors coupled to activation of the MAP kinase cascade blocked ~75% of LIF-stimulated Tyr phosphorylation of LIFR and gp130. Preincubation of 3T3-L1 cells with phorbol ester or thapsigargin, agents which activate the MAP kinase cascade in a cell surface receptor-independent manner, also inhibited LIF-stimulated Tyr phosphorylation in LIFR immunoprecipitates. Our results suggest that the gp130 polypeptide is phosphorylated by a protein kinase whose activation is tightly coupled to the stimulation of MAPK, and that stimulation of Ser/Thr phosphorylation of LIFR and gp130 following activation of MAP kinase cascade-coupled receptor systems may serve as a major regulatory switch governing LIFR signaling *in vivo*.

703.21

INTERLEUKIN-1β RECEPTOR MEDIATED NGF SECRETION FROM RAT CORTICAL ASTROCYTES IN PRIMARY CULTURES. M. Čarman-Kržan*, V. Pahor, D. M. Seliškar. Dept. Pharmacology, Medical Faculty, Korytkova 2, Ljubljana, Slovenia.

Interleukin-1β (IL-1β) is one of the most potent stimulators of NGF secretion from rat neonatal cortical astrocytes in primary cultures . Our previous studies showed that IL-1β acts at the level of NGF gene transcription and suggested glial IL-1 receptor mediated mechanism (Čarman-Kržan M and Wise BC. J Neurosci Res 34, 1993, 225-232). Using iodinated recombinant human IL-1β in the binding studies we identified IL-1β receptors on the astrocyte cell population (B_{max}=2.6 ±0.6 fmol/mg protein, K_D=2.58 pM). Further characterization of IL-1β receptors on astrocytes with inhibition binding studies showed that rh IL-1β is the most potent inhibitor (K_i=0.74 nM) followed by rh IL-1Ra (K_i=2 nM), rh IL-1α (K_i=7.9 nM) whereas rh IL-2 has no inhibitory action on [^{125}I] rh IL-1β labeled IL-1β receptor. Their inhibitory action on IL-1β receptor is in good correlation with their ability to induce or inhibit NGF secretion from these cells: rh IL-1β (10 U/mL) is the most potent activator of NGF secretion from astroglial cells (3 fold over basal level) followed by rh IL-1α. rhIL-1Ra and IL-2 alone failed to stimulate NGF release. Our further studies showed that rh IL-1β stimulated NGF release is inhibited by the presence of rh IL-1Ra in a dose dependent manner, confirming that IL-1 induced NGF secretion from astrocytes is IL-1β receptor mediated process.

NEURONAL DEATH VIII

704.1

Role of Interleukin 1β converting enzyme in neuronal cell death

Valeria Gagliardini, Weiwei Li, Mark Fishman*, Junying Yuan
Cardiovascular Research Center, Massachusetts General Hospital,149 13th Street, Charlestown, MA 02129

Interleukin-1β converting enzyme (ICE), the mammalian homolog of ced-3, is formerly known as the enzyme responsible for the production of IL-1β. Recently our studies demonstrated that ICE activity participates in neuronal cell death (CD) and inhibiton by crmA can delay this process (Gagliardini et al., Feb 11 Science 263, 1994). In order to better understand the role of ICE in programmed CD, we demonstrated an induction of ICE during apoptosis in dorsal root ganglion (DRG) neurons. A basic level of ICE was detected in neurons and the expression of ICE was upregulated in dying neurons with condensed nuclei. The requirement of ICE/ced-3 family genes in neuronal programmed CD is supported by the ability of the precursor of IL-1β (pIL-1β) or mutant ICE with a point mutation in ICE active site (C to G), that elimimate pIL-1β processing activity as well as autoprocessing, to prolongue neuronal survival. Microinjection of the human pIL-1β gene as well as the mutant form of mouse ICE into chicken DRG neurons was found to prevent CD induced by deprivation of nerve growth factor. Neurons were able to survive for 6 days often with neurites and healthy cell body.

These evidences suggest that ICE is playing a major role in neuronal CD. Further experiments have to be done to understand whether additional members of the ICE/ced-3 family are also involved in controlling neuronal CD.

704.2

GENE EXPRESSION IN NEURONS DURING PROGRAMMED CELL DEATH. R. S. Freeman* and R. J. Crowder. Department of Pharmacology, University of Rochester, School of Medicine, Rochester, NY 14642.

The expression of certain genes is upregulated during programmed cell death (PCD) in sympathetic neurons deprived of nerve growth factor (NGF) (Freeman et al., *Neuron* 12:343-355, 1994; Estus et al., *J. Cell. Biol.* 127:1717-1727, 1994). These genes are induced despite an overall decrease in RNA and protein synthesis soon after NGF withdrawal. To identify other genes that are preferentially expressed in dying neurons, we have utilized the technique called differential display as a means of comparing the mRNAs present in NGF-maintained versus NGF-deprived neurons. With this technique, we have identified a new gene, termed DD1-X, that is upregulated after NGF withdrawal. DD1-X mRNA levels begin to accumulate within 5 hours after NGF withdrawal and peak at about 10 hours. To test the involvement of DD1-X (and other genes, such as cyclin D1, c-jun, c-fos, and c-myb) in the cell death process, we have examined its expression in neuronal death paradigms that are independent of NGF withdrawal. For example, cytosine arabinoside (AraC) kills postmitotic neurons in a manner that resembles NGF deprivation except that the onset of death is delayed by many hours. DD1-X, cyclin D1, c-myb, c-fos, and c-jun are all upregulated during AraC induced neuronal death. Furthermore, the induction of these genes is delayed relative to their induction during NGF deprivation-induced PCD, consistent with their potential involvement in the cell death process. To test DD1-X and cyclin D1 for a direct role in the mechanism for PCD, we are attempting to inhibit their expression in NGF-deprived neurons using antisense approaches.

704.3

PC12 CELLS, TRANSFECTED WITH CALBINDIN-D28k cDNA, ARE PROTECTED FROM DEGENERATION CAUSED BY SERUM WITHDRAWAL. A. McMahon, E. Lephart*, C.L. Liang, and D.C. German. Dept Psychiat, UT Southwestern Med Sch, Dallas, TX 75235-9070.

Calbindin-D28k (CALB) is a calcium-binding protein that is found in many neurons, and it has been proposed to play a neuroprotective role. We sought to identify a tissue culture system in which to directly study the role of CALB. PC12 cells normally express low levels of CALB, as detected by Western analysis. After treatment with NGF, however, there was a maximum 6 fold increase above control levels by 4 days. Greater levels of CALB expression were obtained by stably transfecting PC12 cells with a rat cerebellar CALB cDNA. Two pools of cells were generated, calb-70 and calb-58, containing >100 fold increased CALB protein. These cells, and control cells, were incubated for 24 hours in serum depleted media. When cell integrity was assayed by measuring release of lactate dehydrogenase (LDH), control cells gave a 3 fold increase, calb-70 cells a 2 fold increase, and calb-58 cells a 1.5 fold increase. These data suggest that CALB: (1) can interfere with apoptosis (since serum depletion kills cells by activating apoptotic mechanisms); and (2) may be important in mediating the neuroprotectant effects of NGF.

Nitric Oxide Generating Compounds Prevent the Death of PC12 Cells and Primary Sympathetic Neurons Following Withdrawal of Trophic Support. S.E. Farinelli, M.P. Joyce* and L.A. Greene. *Dept. of Pathology and Ctr. for Neurobiology and Behavior, Columbia University, New York, NY 10032,.*

We have used both the PC12 cell line and primary cultures of rat sympathetic neurons as model systems to examine the mechanism by which neuronal cells undergo apoptotic death when deprived of growth factors. Previously we have provided evidence for a possible link between uncoordinated cell cycle progression and apoptotic death in these systems including data which suggests that certain cell cycle blockers protect cells from death. Since it has been reported that nitric oxide (NO) generating compounds inhibit proliferation of a number of cell types, we proceeded to test these compounds for their ability to protect PC12 cells and sympathetic neurons following removal trophic support. Two such agents S-nitroso-N-acetylpenicillamine (SNAP) and diethylenetriamine nitric oxide adduct (DETA-NO) provide complete protection for at least two days following removal of serum from naive PC12 cells while only 15% of the untreated cells remained alive. These compounds also provided complete protection for two days to neuronally-differentiated PC12 cells following withdrawal of NGF in serum-free medium while only 50% of the untreated cells survived. Treatment of primary sympathetic neurons with DETA-NO and SNAP following withdrawal of NGF also resulted in significantly enhanced survival relative to controls. A well understood target of NO action is guanylate cyclase which is activated by nitrosylation of its heme prosthetic group. LY-83,583, an inhibitor of guanylate cyclase, blocks the protective effects of both SNAP and DETA-NO on serum-deprived PC12 cells without preventing NGF-induced survival, suggesting that the protective effects of NO may be mediated by elevated intracellular cGMP. (Supported by grants from the NINDS).

INDUCTION OF *p53*-DEPENDENT NEURONAL APOPTOSIS BY THE ANTIMITOTIC CYTOSINE ARABINOSIDE, WHOSE TOXICITY CLOSELY RESEMBLES DEATH BY TROPHIC FACTOR DEPRIVATION. T.L. Deckwerth* and E.M. Johnson, Jr. Washington University School of Medicine, Department of Molecular Biology and Pharmacology, St. Louis, Missouri 63110, USA.

Exposure of nerve growth factor (NGF)-maintained neonatal rat sympathetic neurons to the antimitotic agent cytosine arabinoside (araC) resembles death by NGF deprivation based on pharmacological criteria (Martin *et al., J. Neurosci.* 10: 184-193, 1990). Here we show that the similarities between death by NGF deprivation, which occurs by apoptosis (Deckwerth and Johnson, *J. Cell Biol.* 123: 1207-1222, 1993), and by exposure to araC extend to several biochemical and morphological parameters indicative of apoptotic neuronal death. Similar to NGF-deprivation, araC-induced apoptosis was accelerated in murine sympathetic neurons deficient in the death suppressor *bcl2*. To determine whether araC might induce apoptosis by inflicting DNA damage, we examined whether the gene dose of the tumor suppressor *p53*, which triggers apoptosis upon excessive DNA damage, would affect the kinetics of death after treatment with araC. In the absence of *p53*, neuronal death by exposure to araC was delayed significantly, consistent with a potential role for DNA damage in contributing to araC-induced neuronal apoptosis. Supported by the AT Children's Project and NIH grant NS24769.

APOPTOSIS OF SERUM DEPRIVED PC12 CELLS AND NGF RESCUE: EFFECTS ON AP-1 DNA BINDING ACTIVITY. L. Tong*, K. Werrbach-Perez and J.R. Perez-Polo. Dept. of HBC&G, UT Med. Branch, Galveston, TX 77555-0652

We have previously reported that transcription factor AP-1 DNA binding activity transiently increased and then decreased during apoptotic cell death induced by serum deprivation. NGF, which rescues PC12 cells from apoptosis, upregulated AP-1 binding activity persistently. Our hypothesis is that impaired AP-1 DNA binding activity after serum deprivation may contribute to apoptosis in PC12 cells and that NGF may rescue cells via maintenance of AP-1 DNA binding activity. K252a, an inhibitor of the Trk receptor, abolished both NGF rescue of PC12 cells and increases in AP-1 DNA binding activity. Enhanced AP-1 activity in the presence of combined NGF and protein synthesis inhibitor cycloheximide treatment indicated that there is persistent AP-1 activation due to posttranslational modifications of various *fos* and *jun* proteins. Increased AP-1 DNA binding activity also was persistent during Insulin and cAMP-mediated survival of PC12 cells after serum deprivation. In addition, there was a decline in AP-1 activity in PC12 cells after NGF deprivation. Furthermore, retinoic acid, known to have a repressive function on AP-1 activity, abolished NGF-mediated rescue and increased the sensitivity of PC12 cells to serum deprivation. Therefore, serum deprivation-induced cell death and NGF rescue correlate with AP-1 DNA binding activity. Supported in Part by NINDS-NS18708. This is publication 35A from USPHS grant P01 AG10514 awarded by NIA.

REDUCING AGENTS PREVENT APOPTOTIC DEATH OF TROPHIC-FACTOR-DEPRIVED PC12 CELLS AND SYMPATHETIC NEURONS. C.Y.J.Yan*,G.Ferrari,and L.A.Greene. Dept. of Pathology, Columbia University, Coll. of P & S, New York, NY 10032.

We have used serum-deprived PC12 cells and NGF-deprived sympathetic neuron cultures as models to study apoptosis elicited by trophic factor withdrawal. In our paradigm, N-acetyl-cysteine (NAC) maintains long-term survival of PC12 cells and sympathetic neurons and also inhibits PC12 cell proliferation. NAC has been reported to be an anti-oxidant that increases intracellular glutathione (GSH) levels. However, several other anti-oxidants do not promote survival or block proliferation, suggesting that NAC's actions cannot be explained by its anti-oxidant properties. The NAC-mediated increase in intracellular GSH also seemed unnecessary since depleting intracellular GSH with buthionine sulfoximine did not affect NAC's protective or anti-proliferative effects. An alternative explanation is that NAC acts as a reducing agent. When we tested other compounds with reducing properties, a number retarded death. Among the most effective was 2,3 dimercaptopropanol (British anti-Lewisite). This compound also blocked PC12 cell proliferation. These findings suggest that NAC prevents death by means of its reducing activity and that other reducing agents may also inhibit the apoptotic pathway. Finally, these data indicate that like NAC, other reducing agents block DNA synthesis and this activity may account for their capacity to rescue neuronal cells from apoptotic death. Supported by the NINDS and ALS Foundation.

CHANGE OF INTRACELLULAR cAMP LEVELS IN SYMPATHETIC NEURONS UNDERGOING PROGRAMMED CELL DEATH J.Y.Chang* and V.V.Korolev Dept. Anatomy, Univ. Arkansas for Medical Sciences, Little Rock, AR 72205

The survival and proper functioning of sympathetic neurons is dependent on nerve growth factor (NGF). When immature sympathetic neurons are deprived of NGF, they undergo an "active" dying process usually termed "programmed cell death" (PCD), or "apoptosis". Cyclic AMP or agents capable of increasing intracellular cAMP can prevent this sympathetic neuronal PCD caused by trophic factor deprivation. This trophic dependence is age-related such that the cells become less dependent on NGF as they mature. Sympathetic neuronal cultures derived from rat superior cervical ganglia were used to study the relationship between intracellular cAMP levels and neuronal cell death. With a cAMP radioimmunoassay, our results indicate that as a neuron matures, the relative amount of cAMP per cell increases concurrently. There is a 2-fold increase of cAMP levels per cell when the cAMP levels from a 1-week- and 2-week-old culture were compared. Removal of NGF in 1-week-old cultures, which triggers the process of PCD, results in a decrease of intracellular cAMP levels. NGF deprivation for 24 and 48 hours leads to a 50% and 75% decrease of cAMP levels. In contrast, when these cells mature in culture and become relatively NGF independent (i.e., 2-week-old culture), NGF withdrawal does not lead to a drop of cAMP levels. PACAP (pituitary adenylate cyclase-activating peptide) , a naturally occurring bioactive peptide, can increase cAMP levels in these sympathetic neurons, and prevent neuronal cell death resulting from NGF deprivation. (Supported by NIH NS32253)

METABOLIC AND GENETIC ANALYSES OF APOPTOSIS IN POTASSIUM/SERUM-DEPRIVED CEREBELLAR GRANULE CELLS

T.M. Miller* and E.M. Johnson, Jr. Department of Molecular Biology and Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

Cerebellar granule cells may be maintained in serum-containing medium by elevating (25 mM) extracellular potassium levels. Removal of both potassium and serum after seven days in culture triggers a characteristic apoptotic death (D'Mello et al., 1993, P.N.A.S. **90,** 10989–10993) We have found that removal of the serum has an important function in this model of apoptosis. After 96 hours of potassium deprivation in the presence of serum, 40–45% of the cells are still alive whereas more than 95% of the potassium/serum-deprived cells have died by this time. Thus, while the nearly complete cell death of the potassium/serum-deprivation system provides a convenient model, this system is complicated by removing two sources of trophic support at the same time.

Metabolic and genetic parameters are being analyzed in the potassium/serum-deprivation model. Protein synthesis decreases precipitously after potassium/serum-deprivation to less than 15% of control (25mM K^+ plus serum) at 12 hours, a time when approximately 50% of the neurons are committed to die. Cells maintained in 25mM K^+ without serum showed a slow decline in protein synthesis to approximately 50% at 24 hours. *C-jun*, a gene required for cell death after trophic factor deprivation is also induced several fold in potassium/serum-deprived cerebellar granule cells. Similarities and differences in the pattern of gene expression in dying sympathetic and granule neurons will be presented. Supported by NIH grants NS 24679 and AG 12947 and by the Washington University ADRC (P50 AG 5681).

DENSITY-DEPENDENT PROTECTION OF RAT CORTICAL NEURONS FROM APOPTOSIS IN SERUM-FREE PRIMARY CULTURES. N. Fukushima*, H. Ueda, Y. Sasaki and Y. Misu, Dept. of Pharmacol., Yokohama City Univ. Sch. of Med., Yokohama 236,

Neurons are known to require exogenous signals, such as serum, trophic factors or glial cells, for survival. We have reported that the neuronal cell death, which occurs in the serum-free primary cultures of rat cortex without any supplements, was inhibited in a cell density-dependent manner. In the present work we further characterized the density-dependent inhibition of the cell death. When the rat cortical cells were seeded at the low density (1 x 10^5 cells/cm^2), the number of neurons (neurofilament-positive cells) markedly decreased within 6 hours after seeding. Since most of neurons were not stained with propidium iodide, they were found to be viable. The DNA ladders, biochemical feature of apoptosis, were detected 3 hours after seeding. However, the rapid cell death was inhibited in a density-dependent manner in the ranges of 1 to 5 x 10^5 cells/cm^2. In addition, DNA laddering was inhibited in the high density (5 x 10^5 cells/cm^2) cultures. Both glial and proliferative cells were negligible in all cultures. These findings indicate that cortical neurons are protected from apoptosis in a density-dependent manner under the serum-free condition.

SERUM SUBSTITUTES FOR ENDOGENOUS FACTORS INVOLVED IN CELL DENSITY-DEPENDENT SURVIVAL OF RAT CORTICAL NEURONS. Y. Sasaki[1,2]*, H. Ueda[1], N. Fukushima[1], T. Okada[2], Y. Misu[1]. [1]Department of Pharmacology, Yokohama City University School of Medicine, Yokohama 236, Japan, [2]International Research Laboratories, Ciba-Geigy Japan, Takarazuka 665, Japan.

We have reported that survival of neurons was cell density-dependent in the primary culture of rat cortex under serum-free condition in this meeting last year. To examine mechanism of neuronal cell death at low density culture (1 x 10^5 cells/cm^2), we developed a new colorimetric assay for survival, using Alamar Blue. Alamar Blue is a redox indicator which yields a colorimetric change in response to chemical reductants derived from living cells. At low density culture, the rate of neuronal survival decreased to 20% of initial neurons at 15 hr. In this process of neuronal cell death, genomic DNA laddering was observed, indicating that neurons are dying in a manner of apoptosis. On the other hand, more than 80% of initial neurons survived at higher density culture (5 x 10^5 cells/cm^2) at 15 hr. In the presence of 10% serum, however, survival of neurons increased at lower density and unchanged at high density. As a result, there was no more density-dependent survival. Survival of neurons at low density was increased by addition of 10% serum only for initial 1 hr and deprivation of serum subsequently, while the survival was not enhanced by the addition of serum at 1 hr after seeding. These findings suggest that serum substitutes for endogenous factors involved in cell density-dependent survival of neurons.

REGULATION OF APOPTOSIS IN THE NEURONAL LINEAGE OF MOUSE OLFACTORY EPITHELIUM. J. D. Holcomb*, J.S. Mumm and A.L. Calof. Dept. of Biological Sciences, Univ. of Iowa, Iowa City, IA 52242.

When olfactory epithelium (OE) is deprived of interaction with its target tissue, the olfactory bulb (OB), cells in the OE die. We have characterized the timecourse and extent of this induced cell death in vivo, following unilateral ablation of the olfactory bulb (OBX) in adult mice, and in vitro, in cultures of dissociated neuronal cells isolated from E16.5-17.5 OE. Cells undergoing apoptosis were detected using end-labeling of fragmented DNA (TUNEL staining); ^{3}H-thymidine incorporation was used to label neuronal precursors, and cell type-specific antibodies were used to distinguish different OE cell types. In vivo, cells at all stages in the neuronal lineage of the OE -- neuronal precursors, immature olfactory receptor neurons (ORNs), and mature ORNs -- were found to undergo apoptotic death. Apoptosis occurs at low levels in all neuronal cell types in unoperated OE and increases dramatically in all neuronal cell types at short times (24 hr) following OBX; at long times (8 wks) post-OBX, however, apoptosis is increased exclusively in mature ORNs. In vitro, both neuronal precursors and ORNs undergo apoptosis when cultured in the absence of OB or added trophic factors; this can be inhibited by aurintricarboxylic acid (ATA), a known inhibitor of apoptosis in many types of cells. Both ATA and a membrane-permeant analog of cyclic AMP (CPT-cAMP) promote survival of a substantial fraction of cultured ORNs at 72 hrs in vitro. Survival of ORNs is also promoted by certain neurotrophins (BDNF, NT-3, and NT-5, but not NGF), although none promote survival to as great an extent as ATA or CPT-cAMP. Consistent with this, expression of trkB was observed in a subset of ORNs in neonatal OE. These results suggest that apoptosis is a mechanism for regulating cell number at all developmental stages in the ORN lineage, and implicate one class of polypeptide growth factor -- the neurotrophins -- in this process. We are currently testing neurotrophins in vivo, to determine whether they can rescue ORNs from apoptotic death induced by OBX.

CEP1347 PREVENTS CELL DEATH INDUCED BY NGF-DEPRIVATION IN DORSAL ROOT GANGLION NEURONS AND PC12 CELLS IN CULTURE M.A. Glicksman[1]*, M.E. Forbes[1], T. O'Kane[1], C. Murakata[2], N.T. Neff[1], D. Bozyczko-Coyne[1]. [1]Cephalon, Inc, West Chester, PA 19380; [2]Kyowa-Hakko Kogyo, Tokyo, Japan

Dorsal root ganglion neurons and PC12 cells maintained in the presence of nerve growth factor (NGF), undergo cell death upon its removal. The indolocarbazole alkaloid, K-252a, and a structurally novel analog, CEP1347, promote survival and/or differentiation in a variety of neurons *in vitro* (J.Neurochem.61:201,1993;64:1502,1995). In addition, CEP1347 prevents embryonic and postnatal programmed motoneuron death *in vivo* and prevents the loss of ChAT immunoreactivity in axotomized adult hypoglossal motoneurons (*Soc. Neurosci. Abstr.*1994, 1995). To determine effects of such small "neurotrophic" molecules on cell death thought to be primarily due to apoptotic mechanisms, two *in vitro* systems were employed. In chick embryonic (E9) dorsal root ganglion cultures, K-252a and CEP1347 rescued >50% of the neurons lost after NGF withdrawal (compared to rescue by readdition of NGF). K-252b, a related compound that has no direct effect on the survival and/or differentiation of neurons *in vitro*, showed no protective effect. In PC12 cells, CEP1347 also rescued cells from death after NGF withdrawal, while KT5823, a "non-neurotrophic" analog, had no effect. Actinomycin D partially reduced cell death in both models, suggesting that the cell death may be dependent on RNA synthesis, and a cAMP analog (8-(4-chlorophenylthio)cAMP) prevented cell death in both models. These data support previous findings that CEP1347 prevented cell death *in vitro* and *in vivo*. Furthermore, since cell death in these models is thought to be primarily due to apoptotic mechanisms, CEP1347 may interfere with this process.

BASIC FIBROBLAST GROWTH FACTOR PREVENTS THE LOW POTASSIUM-INDUCED APOPTOSIS IN THE CULTURED CEREBELLAR GRANULE CELLS. H. Amino*, H. Saito and N. Nishiyama. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

Apoptosis, which is characterized morphologically by chromatin condensation, and cytoplasmic and nuclear shrinkage, is one of the pathways of cell death. Cultured mature cerebellar granule cells, isolated from 8-day-old postnatal rat, die by apoptosis when deprived of depolarizing concentration of extracellular potassium (25 mM). We here investigated the effect of basic fibroblast growth factor (bFGF) on this neuronal apoptosis. Exposure of cerebellar granule cells to bFGF (0.01-10 ng/ml) protects cultured cerebellar granule cells (DIV 7), maintained in the presence of physiological concentration of potassium (5 mM), from apoptotic cell death in a concentration dependent manner. This antiapoptotic effect was not mimicked by several other neurotrophic factors, acidic FGF, nerve growth factor and brain-derived neurotrophic factor at the same range of concentration. The trophic action of bFGF was remarkably and significantly blocked by tyrosine kinase inhibitors, herbimycin A and lavendustin A. Protein kinase C inhibitors, staurosporine and H-7, also reversed the protective effect of bFGF, whereas protein kinase A inhibitor, H-89 had no effect. Moreover, neither ionotropic nor metabotropic glutamate receptor antagonists block the antiapoptotic effect of bFGF. These results suggest that bFGF prevents the neuronal apoptosis induced by low potassium in cerebellar granule cells through activation of FGF receptor tyrosine kinase and protein kinase C. It is interesting to speculate that FGF or FGF-like molecules are released in para- or autocrine fashion to prevent the apoptotic cell loss of granule cells in a living rat cerebellum.

PROTEIN KINASE INHIBITION INDUCES APOPTOSIS IN DEVELOPING RETINAL NEURONS. L. Colombaioni.* Istituto di Neurofisiologia del CNR, 56100 Pisa, ITALY.

Isolated retinas from newborn P_0-P_3 rats are an useful model system for the study of trophic-dependent selection process that occurs during early phases of neuronal development. Culture conditions have been found in which, following serum withdrawal, retinal ganglion cells rapidly undergo death showing morphological and functional characteristics of apoptosis. It is known that neurotrophins promote survival of developing neurons by binding to Trk receptor protein tyrosine kinase, but it is also known that the direct activation of protein kinases often fails to inhibit apoptosis. At the aim of further investigate the role of protein kinase pathway in neuronal death, retinas isolated in serum free medium have been exposed for 3-6 hours to protein kinase inhibitor staurosporine 50-100 nM, a dose considered to inhibit selectively protein kinases C. This treatment remarkably accelerated the time course of ganglion cell death. Under these conditions of protein kinase C inhibition, survival promoting action of serum was lost. These data indicate that prevention of neuronal apoptosis requires activation of protein kinase C pathway. Since other reports indicate that this is not sufficient to prevent neuronal death, it is suggested that simultaneous activation of multiple signaling pathways could be required for neuronal survival.

INSULIN-LIKE GROWTH FACTOR IS REQUIRED FOR SPINAL MOTONEURON SURVIVAL FOLLOWING SCIATIC NERVE AXOTOMY. S.-F. Pu*, H.-X. Zhuang, D. J. Marsh and D. N. Ishii. Dept. of Biochem. and Mol. Biol. & Dept. of Physiol., Colorado State University, Fort Collins, CO 80523.

The long-term disconnection of motoneurons from muscle targets is known to result in the death of motoneurons in humans. Several lines of evidence, dating from the time of Ramon y Cajal, support the inference that axotomy may deprive motoneurons of soluble neurotrophic substances present both in nerve and muscle. There is a pressing need to identify these substances. We previously showed that insulin-like growth factors (IGFs) are neurotrophic factors, and that IGF mRNAs are increased in nerve and muscle following nerve crush. We tested the inter-related hypotheses that (i) IGF-II can support the survival of postmitotic motoneurons, and (ii) endogenous IGFs normally support the survival of motoneurons. Following sciatic nerve transection in postnatal rats, various substances impregnated in gel foam were applied to the proximal nerve stump. The number of motoneurons were counted in spinal cord sections after 6 days. Recombinant human IGF-II supported the survival of motoneurons, whereas an anti-IGF-II antiserum as well as IGF binding protein-4 increased their death relative to vehicle-treatment ($P < 0.05$). The latter results showed that the activity of endogenous IGF within or close to nerve is required for the survival of injured motoneurons. Although the administration of other exogenous factors may support motoneuron survival, this is the first demonstration that an endogenous neurotrophic factor contributes to survival following nerve damage. These results may explain the observation that the degree of survival is proportional to the length of the remaining nerve stump following transection. IGF is produced in nerve Schwann cells, and more IGF would be available to axons following distal vs. proximal nerve transection. PHARMACOLOGICAL AGENTS THAT MODIFY OXIDATIVE STRESS PROMOTE MOTONEURON SURVIVAL DURING DEVELOPMENT. R.W. Oppenheim*, J. Hong, J. Caldero, C. Milligan, A. Newsome, L.Lloyd and D. Prevette. Wake Forest University Medical School, Winston Salem, NC 27157

Developing spinal motoneurons (MNS) in the chick embryo undergo normal programmed cell death (PCD) in vivo and following trophic factor deprivation in vitro. Previous in vitro studies of other neuronal and non-neuronal cells have suggested that increased oxidative stress may be involved in the pathway leading to PCD. We have begun to examine whether oxidative stress is also involved in the normal PCD of chick MNS in vivo and in vitro. Preliminary studies with one anti-oxidative agent, N-acetylcysteine (NAC), indicates that treatment of chick embryos in ovo during the normal period of MN cell death significantly reduces the number of dying (pyknotic) cells and increases the number of healthy MNS present at the end of the cell death period. Studies are in progress to examine other anti-oxidants and to determine their mode of action (and that of NAC) in preventing the PCD of MNS.

MECHANISM OF THE OSMOPROTECTIVE EFFECT OF IGF-I IN HUMAN NEUROBLASTOMA CELLS. C. C. Matthews* and E. L. Feldman Dept. of Neurology, Univ. of Michigan. Ann Arbor, MI 48109-0588

We have previously shown that exposure to media made hyperosmotic by the addition of mannitol or NaCl significantly decreased the number of viable SH-SY5Y human neuroblastoma cells within 24 hrs. In contrast, low concentrations of IGF-I preserved cell viability under hyperosmotic conditions. In the current study, we have examined the mechanism of the IGF-I osmoprotective effect.

The IGF-I osmoprotective effect was virtually eliminated by αIR3, a blocking antibody to the type I IGF receptor. Hyperosmotic conditions caused cell cycle arrest of the cells as measured by the rate of ^{3}H-thymidine incorporation and flow cytometry. Addition of 10nM IGF-I protected the cells against hyperosmotic death without stimulating DNA synthesis.

Programmed cell death (PCD) can occur by withdrawal of an essential external signal such as a growth factor. As determined by flow cytometry, several days of serum deprivation in isotonic media did not precipitate PCD. In serum-free hyperosmotic media, PCD was initiated in 40% of cells in 24hrs and 80% in 72hrs. In hyperosmotic media containing 10nM IGF-I, apoptosis occurred in only 12% of cells in 48hrs and 20% in 72hrs. Collectively, our results show that IGF-I acts as a neuronal osmoprotectant by protecting the cells against PCD. These data suggest a potential therapeutic role for IGF-I in diabetic neuropathy or other conditions that lead to hyperosmotic states.

EFFECTS OF NEUROTROPHIC FACTORS ON THE SURVIVAL OF SENSORY NEURONS FOLLOWING AXOTOMY IN THE NEONATAL MOUSE. L. Li*, A.C. Lo, M. Lei, R.W. Oppenheim and L.J. Houenou
Dept. of Neurobiology and Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

Extensive neuronal death results from peripheral nerve section during the early period of postnatal development in mammals. Recently, it has been reported that a number of neurotrophic factors including BDNF, NT-3, NT-4/5, CNTF, IGF and GDNF promote the survival of axotomized motoneurons in vivo. The present study is aimed at determining whether these neurotrophic factors also rescue axotomized sensory neurons in the neonatal mouse. Our results show that approximately 25% of neurons in the lumbar spinal segment 4 dorsal root ganglion (DRG) died following sciatic nerve section in 5 day old mice, when examined one week after surgery. Several neurotrophic agents including: NGF, BDNF, NT-3, CNTF, IGF-1 were able to promote the survival of axotomized DRG neurons. However, GDNF, previously shown to rescue axotomized motoneurons, was ineffective in rescuing sensory neurons from axotomy induced cell death. Our findings extend previous reports on the effects of neurotrophic agents on axotomized motoneurons and sensory neurons and suggest that some of these agents may be useful in the treatment of diseases and injuries affecting sensory neurons. Supported by Grants from NIH and MDA.

GDNF AND BDNF PROTECT A CATECHOLAMINERGIC CELL LINE (CATH.a) FROM DOPAMINE INDUCED CELL DEATH. L. Gong*, H. Kulaga, A. Adams, R.J. Wyatt and J.M. Masserano. Neuropsychiatry Branch, NIMH Neuroscience Center at St. Elizabeths, Washington, D.C. 20032.

Glial cell line-derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF) promotes survival of dopaminergic neurons in primary cultures and protect these neurons from the neurotoxic effects of 6-OHDA and MPTP. We are using a CNS derived catecholaminergic cell line (CATH.a) as a model to study the effects of growth factors on cell death. Dopamine (DA) (10 - 500 μM) produces a dose dependent cell death (maximal 70%) in CATH.a cells. DA induced cell death is correlated with an increase in intracellular peroxides and is inhibited by catalase, suggesting that cell death is caused by oxidative stress. Treatment of cultures with GDNF or BDNF reduced DA (100 μM) induced cell death from 40% to 20%. Nerve growth factor, fibroblast growth factor and insulin had no protective effect. These results indicate that GDNF and BDNF protect CATH.a cells from the oxidative stress of intracellular peroxides produced by dopamine autoxidation.

GENESIS OF INTERNEURONS IN THE RAT STRIATUM. A.F. Sadikot*, R. Sasseville, S. Gauthier. Dept. of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, PQ, Canada.

The time of final mitosis (birthdate) of different classes of interneurons in the rat striatum was analyzed using the 5'-bromodeoxyuridine (BrdU) incorporation method. Double-labeling immunohistochemistry allowed simultaneous visualization of BrdU, and either calretinin, parvalbumin, choline acetyltransferase or somatostatin. At the level of the precommissural dorsal striatum, most GABAergic interneurons expressing calretinin are born between E14-E16, whereas most GABAergic interneurons expressing parvalbumin are born between E14-E17. As shown in studies using ^{3}H-thymidine (Semba et al., '88), our studies confirm that the birthdate of the majority of cholinergic and somatostatinergic interneurons at this striatum level is between E13-E15 and E15-E16, respectively. Thus, unlike the patch and matrix projection neurons, whose peak birthdates are E13 and E18, respectively (van der Kooy and Fishell, '87), GABAergic and somatostatinergic interneurons of the dorsal striatum leave the mitotic cycle at an intermediate time period. Further studies are aimed at defining gradients of neurogenesis within the dorsal striatum, and at comparing birthdates of neurons generated in the dorsal or ventral striatum.

DIFFERENTIAL EXPRESSION OF GENES PREFERENTIALLY RESTRICTED TO MOTOR NEURONS. **E. F. Salazar-Grueso*, Z. Zhang, and L. Ma. Department of Neurology, University of Chicago, Chicago, IL 60637.**

Molecular processes specific to motor neuron (MN) growth and development are poorly characterized. We are using clonal hybrid cells derived from embryonic mouse spinal cord MN which express traits typical of MN to identify and characterize genes preferentially expressed in MN. cDNAs preferentially expressed in hybrid MN were isolated by differential display reverse transcription polymerase chain reaction and by differential hybridization screening of a hybrid MN cDNA library. cDNAs were sequenced, and submitted for comparison to gene and protein databanks using the BLASTA program. Twenty of 45 (47%) cDNA clones were found to be identical or very homologous to genes previously characterized in mice or rats. Eleven (24%) others had sequence homology to genes previously characterized from humans (9), cattle (1), & fruit fly (1). Twelve (27%) others do not share identity with any currently known genes or proteins. One cDNA sequence was recently identified by others as a G protein β subunit gene. By northern blot we have identified an alternately spliced transcript of this gene which appears to be expressed only in brain and spinal cord. In conclusion, we have used hybrid MN cells to identify novel genes related to MN. One of these, a neural specific gene, appears to be present in MN. Twelve others appear to be novel genes that may have specificity for MN.

FACTORS INFLUENCING THE DEVELOPMENT OF DENDRITE BUNDLES IN THE RAT'S SPINAL CORD.

A.GRAMSBERGEN*, J.IJKEMA-PAASSEN, F.KLOK

Medical Physiology, Groningen, NL-9712 KZ, The Netherlands.

Recently, we studied dendrite bundles in motoneuronal pools of muscles, which are involved in posture and locomotion in the rat. Dendrite bundles specifically occur in pools of axial muscles and particular antigravity muscles in extremities. These bundles develop at the age when effective control of posture becomes apparent (from postnatal day 8 [P8] in the pools of the long back muscles and from P14 in the pool of the soleus muscle.

It is not known how this dendritic reorganisation is induced. Possibilities are: [1]by supraspinal afferents; [2]by muscle afferents or [3]by retrograde influences from muscles via their motor nerves. We interrupted the ingrowth of descending projections on P10 by a total spinal transection at Th10-Th11 (N=18) or a hemitransection (N=21). Muscle afferents were interrupted unilaterally at P10 by cutting the dorsal roots of L3-L5 (N=21) and in another group (N=18) we blocked neuromuscular transmission from P3-P12 in the soleus muscle by α-bungarotoxin (in silicon rubber). Dendrite bundles in the pool of the soleus muscle were labeled with Cholera Toxin subunit B at P18, P20 and P30.

Results indicate that blocking neuromuscular transmission retards the development of dendrite bundles while a total transection leads to a decrease in the number of dendrite bundles and dendrites per bundle (although the onset of this reorganisation is normal).Neither sectioning of dorsal roots, nor hemisection of the spinal cord has an effect on this development. It seems that both trophic influences from muscles and supraspinal influences are essential for dendritic reorganization.

LOCAL INFLUENCES ON REORGANIZATION OF AN IDENTIFIED THORACIC LEG MOTOR NEURON DURING METAMORPHOSIS OF THE MOTH MANDUCA SEXTA. K. S. Kent* and T. M. Bollerman, Dept. Biological Structure & Function, Oregon Health Sciences University, Portland, OR 97201

During metamorphosis of the moth Manduca sexta, thoracic leg motor neurons (MNs) persist from larva to adult but undergo dramatic morphological changes including regression and growth of both dendritic and terminal processes. Previous studies have shown that these central and peripheral changes are under control of ecdysteroid hormone. As part of an on-going study to determine if cell-cell interactions are also involved in shaping these changes, we have examined the regression and growth of terminal processes of an identified leg MN, the femoral extensor MN. In addition, we have used heterochronic mosaic insects in order to determine if local peripheral signals might influence the reorganization of motor terminals independent of the reorganization of central processes. A combination of cobalt and biocytin staining methods, immunocytochemical techniques, and labeling with persistent fluorescent dyes, has demonstrated that regression of motor terminals occurs over the several days preceding pupation as the larval muscle degenerates. Regressed processes remain associated with a remnant of the larval muscle and by three days after pupation, motor terminals demonstrate signs of new growth, displaying filopodial-like processes. Application of a juvenile hormone mimic (methoprene) to the larval legs was used to create mosaics in which larval-like legs with persistent larval leg muscles were retained on a pupal insect. Under these conditions, larval-like motor terminals were retained on the persistent larval leg muscles. In contrast, dendritic regression occurred centrally despite retention of the larval leg. These results indicate that the processes of dendritic regression and terminal regression are not necessarily linked and that local cell-cell interactions influence peripheral changes independent of central changes.

A TEMPORAL EXAMINATION OF MUSCLE FIBER TYPE IN THE DEVELOPING GUINEA PIG STERNOMASTOID MUSCLE. **W.A.Grow*, P.W.Sheard, M.Duxson, M.B.Laskowski.** WAMI Medical Program, University of Idaho, Moscow, ID 83843.

Due to their size, human muscles have multiple endplate regions, and muscle fibers are usually associated with only one of these regions. Rat muscles, on the other hand, typically contain only one endplate region, and all muscle fibers extend the entire length of the muscle. There are four endplate regions in the guinea pig sternomastoid (SM) muscle, and therefore it is a better model of human muscle development than the rat muscles which have typically been studied. We determined the fiber type composition of the guinea pig SM muscle for both newborns and adults with immunocytochemical staining of fast and slow myosin heavy chain proteins. In the newborn, one edge of the SM muscle consists almost exclusively of fast muscle fibers; by adulthood this region remains exclusively fast but has expanded in size. In the newborn SM slow muscle fibers are always found isolated and surrounded by fast fibers, whereas in the adult SM slow fibers are almost always found in clusters of 2-5 cells. In addition, the number of slow muscle fibers and the total number of muscle fibers are identical for all four endplate regions in the newborn SM; this is also true for the adult SM. Finally, the number of slow muscle fibers and total muscle fibers significantly increases after birth, indicating either transformation of fibers originally with a fast phenotype into slow fibers and/or the generation of new slow muscle fibers. Either possibility could explain the clusters of slow muscle fibers seen in the adult SM. Supported by NIH.

DEVELOPMENT OF TRIGEMINAL MESENCEPHALIC AND MOTOR NUCLEI IN RELATION TO MASSETER MUSCLE INNERVATION IN MICE . C. G. Widmer* and J. Morris-Wiman. Dept. of Oral and Maxillofacial Surgery and Dept. of Orthodontics, Univ. of Florida, Gainesville, FL 32610.

There has not been a systematic investigation of the spatiotemporal development of nuclei containing sensory (mesencephalic) neurons and motoneurons and their innervation of masticatory muscles. The purpose of this study was to determine the timing of sensory and motor innervation of the masseter muscle and compare this process with the developmental organization of mesencephalic and motor nuclei.

A total of 55 embryos representing gestational days 10.5, 11.5, 12.25, 13.5, 14.5 and 15.5 were obtained from timed-pregnant CD1 mice. DiI or DiA was implanted into the embryonic masseter muscle or masseteric region, into the dorsomedial mesencephalic region, or into maxillary or mandibular molar tooth buds or tooth bud regions. Specimens were maintained at 38°C for 2-8 weeks to facilitate transport of the dye, embedded in gelatin, sectioned at 85 μm using a vibratome, and examined under epifluorescence using a Zeiss Axioplan microscope. Images of labelled cells and their processes were acquired for analyses.

At gd 10.5, 41.6% of the embryos with dye placed in the masseteric region demonstrated labelled cells in the trigeminal motor nucleus while 0% of the mesencephalic nucleus neurons were labelled. Dorsomedial mesencephalic dye placement, however, labelled mesencephalic cell bodies and processes that extended to the motor root, but not into the periphery. At gd 11.5, 100% of the embryos with dye in the masseteric region were found to have labelled cells in the caudal portion of the mesencephalic nucleus and motor nucleus. All embryos older than gd 11.5 with dye in the masseter had labelled cells in the full extent of the mesencephalic and motor nuclei. Dye placement in tooth buds did not label the mesencephalic nucleus at any gestational age examined.

These results demonstrate trigeminal motor innervation to the masseter muscle prior to proprioceptive innervation by mesencephalic neurons. In addition, there is a substantial temporal delay of innervation of the periodontal ligament around the teeth by mesencephalic neurons.

EARLY BRAINSTEM-SPINAL SEROTONERGIC AND NORADRENERGIC PROJECTIONS IN THE RAT EMBRYO: DOUBLE LABELING STUDY USING DEXTRAN AMINES AND IMMUNOHISTOCHEMISTRY.

F. Auclair* and R. Marchand. Centre de Recherche en Neurobiologie, Universite Laval, Québec, Canada, G1J 1Z4.

Previous studies done in our laboratory have described the location and discussed the possible identities of neuronal groups projecting to the spinal cord early during the development of the rat embryo. At those stages, the identification of neuronal populations based on their location in the brain and cytology is a hard task. To further characterize those neuronal groups, serotonine (5-HT) and tyrosine hydroxylase (TH) content was assessed combined with retrograde tracing from the spinal cord using dextran amines. The embryos were taken out by cesarean section at the appropriate day of gestation and directly immersed in an artificial oxygenated cerebro-spinal fluid (CSF). The brain was dissected out and a hemisection of the spinal cord was made at the level of the first cervical segment. Fluorescent dextran amines were injected and the preparations were kept in CSF for 12 to 36 hours at 20°C. They were then fixed in paraformaldehyde and cut in a cryostat. Immunohistochemistry was done on the sections mounted on microscope slides. Although many cells near the midline in the caudal brainstem were retrogradely labeled from the spinal cord on day 14 and 15, few neurons were double-labeled after immunohistochemistry against 5-HT. Many cells were also retrogradely labeled from the spinal cord in the rostral lateral pons on day 14, 16 and 18. Again, few neurons were double-labeled after immunohistochemistry against TH on day 14 and 16, but a significant number was on day 18 in locus coeruleus and subcoeruleus. A large number of the retrogradely labeled neurons in the rostral lateral pons were located just medial to the TH-positive neurons, in a region that could be associated with Barrington's nucleus of the adult. In conclusion, although 5-HT-positive neurons in caudal raphe nuclei become immunoreactive around E13, a large number has not reached spinal cord levels at E15. Also, many neurons in the rostral lateral pons become TH-positive around E14 but only a few have reached spinal cord levels by E16.

SEROTONIN INCREASES THE EXCITABILITY OF EMBRYONIC CHICK MOTONEURONS RECORDED FROM A SPINAL CORD SLICE PREPARATION. T. Hayashi, B. Mendelson, K.D. Phelan and E. Garcia-Rill*. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Intracellular recordings were obtained from motoneurons in an embryonic chick spinal cord slice preparation over a series of developmental stages (E12-E18). These time points bracket the critical period of development (E14) in which the ability of the spinal cord to recover from injury is lost. Transverse slices (<1 mm thick) were isolated from lumbosacral segments 1-3. Ventral roots were maintained for stimulation. Motoneurons were identified by antidromic activation. Bath application of serotonin (5-HT; 50-100 µM) was used to determine its effect on rheobase, action potential threshold, afterhyperpolarization and some firing frequency properties. Rheobase was determined as the amplitude of the current pulse of >300 msec duration at 1 Hz that produced an action potential during 50% of the pulses. The absolute membrane potential at the onset of the action potential was defined as the action potential threshold. To analyze firing frequency, depolarizing pulses of 1 sec duration at 0.2 Hz were applied at 0.1 nA increments. Serotonin induced a membrane hyperpolarization in the majority of motoneurons at E12 and a depolarization in all of the cells recorded at E18. However, at all stages examined, the firing frequency of the vast majority of motoneurons was increased during the serotonin administration. Rheobase and membrane potential at action potential threshold were decreased following 5-HT administration. This 5-HT effect was greater in E18 compared to E12 cells. The peak amplitude of the afterhyperpolarization was also decreased during the serotonin administration. These results indicate that 5-HT administration increases the level of excitability of motoneurons at all stages examined. Supported by NSF grant RII 8922108, USPHS grants NS20246 and AA09205.

RELATIVE CONTRIBUTIONS OF POTASSIUM CONDUCTANCES AND SYNAPTIC INPUT IN DETERMINING INPUT RESISTANCE OF DEVELOPING BRAINSTEM MOTONEURONS. T.Hodgson and W. Cameron. Dept. of Neuroscience and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Between postnatal week 1 and 2, the mean input resistance of rat genioglossal motoneurons drops 50% without an increase in total membrane surface area. To investigate the mechanism underlying this decrease, intracellular recordings were made from genioglossal motoneurons in an *in vitro* brainstem slice preparation from 6-7 day, 13-15 day and 18-25 day old rat pups. Input resistance was measured from the linear portion of the voltage response. Perfusion with high Mg^{2+} (6mM) ACSF increased input resistance compared to control (mean = 10% in 6-7 day olds; mean = 2% in 20-25 day olds). This suggests a decreasing contribution by calcium-dependent synaptic release to motoneuron input resistance. Intracellular Cs^{+} injection also produced an increase in input resistance (mean = 11% in 6-7 day olds; mean = 27% in 20-25 day olds), reflecting the increasing involvement of potassium conductances in input resistance over development. In order to determine the change in the relative contribution of synaptic activity and potassium channels during the first weeks of postnatal life, we measured input resistance in: control ACSF(2mM Ca^{2+} /2mM Mg^{2+}), high magnesium (6 mM Mg^{2+}/ 1mM Ca^{2+}) and high magnesium/TEA (6mM Mg^{2+}/ 1mM Ca^{2+}/ 20mM TEA). Mg^{2+} made a smaller contribution than TEA to the total increase in input resistance in all age groups. In addition, the relative contribution of Mg^{2+} versus TEA changed with increasing postnatal age: 25% Mg/75% TEA in 6-7 day olds, 15% Mg/85% TEA in 13-15 day olds, and 5% Mg/95% TEA in 20-25 day old rat pups. MYELOGENESIS OF THE VENTRAL AND DORSAL ROOT AT THE BRACHIAL AND LUMBOSACRAL ENLARGEMENTS OF THE OPOSSUM, *MONODELPHIS DOMESTICA*. H. Leblond* and T. Cabana. Sciences Biologiques, Université de Montréal, C.P. 6128, Succ. Centre-Ville, Montréal, Canada, H3C 3J7.

The opossum is born more immature than any placental mammal. At birth, its forelimbs are sufficiantly developed to perform rhythmic, alternate movements, but the hindlimbs are immobile. The latter do not begin to move until about postnatal day (P)10. In light microscopy, we have investigated myelogenesis of the ventral (VR) and dorsal (DR) roots of spinal segments that innervate the forelimb (C8) and hindlimb (L4), selected because they virtually contain exclusively somatic fibers. The tissue was fixed with a modified Karnovsky's fixative, post-fixed with 2% OsO4, embedded in resin, the roots were cut transversely at 1.5µm, stained with toluidine blue and photographed. In the P1 opossum, both roots at both segments are unmyelinated. At C8, the first myelinated fibers are seen in the VR at P15 and in the DR at P17. At L4, myelinated fibers are first seen in the VR at P17 and in the DR at P22. At P25, the C8 VR contains about 70% of its adult number of myelinated fibers but the DR only 30%; the L4 VR contains 26% and the DR 10% of their adult numbers of myelinated fibers. However, at P25 myelinated fibers are comprised of a single population in terms of diameter, myelin sheath included. It is only at P50 that they can be separated into distinct populations: alpha and gamma for the VRs and Types I, II and III for the DRs. Also at P50, the total number of myelinated fibers in both L4 roots is greater than in the adult. These data will be correlated with the ontogeny of motor behaviors. (Supported by NSERC)

AUGMENTED KINESTHETIC FEEDBACK PROMOTES MOTOR LEARNING IN THE RAT FETUS. S. R. Robinson*. Department of Psychology, University of Iowa, Iowa City IA 52242.

The capacity of the rat fetus to selectively alter its motor activity in response to kinesthetic feedback was evaluated in a model of fetal motor learning. After surgical preparation of the pregnant rat to permit fetal observation, E20 rat fetuses were fitted with a fine thread tied to both rearlimbs. With this yoking procedure, it was expected that an active movement by one limb would result in passive movement of the other limb, thereby producing additional kinesthetic feedback that could facilitate interlimb coordination. Experimental subjects (YOKED) were tethered for 30 min, after which the connecting thread was cut and the subject observed for another 30 min. Control subjects were either fitted with a thread that was immediately cut (UNYOKED) or received no treatment (NT) and were observed without interruption for 60 min. YOKED subjects showed a 6- to 8-fold increase in the frequency of synchronous movements of the left and right rearlimbs. No change in synchronous rearlimb activity was evident in the UNYOKED or NT groups. The observed increase in synchronous movements was not expressed immediately, but emerged gradually over the 30-min period in which the limbs were physically coupled, and persisted for 20-25 min after the yoke was cut. Other experiments revealed that the effectiveness of the yoking procedure varied with the elasticity of the connecting thread; a stiff linkage was more effective than an elastic thread in promoting interlimb synchrony. A similar increase in synchronous forelimb movement was promoted when the yoke was applied to the two forelimbs. These data provide evidence that the E20 rat fetus possesses a functional kinesthetic sense, and that the fetus can alter the organization of motor behavior to adjust to varying conditions of biomechanical constraint.

HUMAN FETAL AND NEONATAL MOVEMENT PATTERNS AND EFFECTS OF CNS ABNORMALITY. C. R. Almli*, N. M. Mohr, R. Ball, and L. Bernhard. Developmental Neuropsychobiology Lab., Washington University Medical School, St. Louis, MO 63108.

Little is known about development of spontaneous movement patterns (autogenic movement patterns, AMP) of human fetuses and neonates, e.g., how fetal AMP may change following birth (neonatal AMP), and, how fetal and neonatal AMP may be altered by prenatally-identified CNS abnormality. Quantitative analysis of AMP determined: (1) continuity/dis-continuity of fetal-to-neonatal AMP in normal subjects, (2) how fetal/neonatal AMP may be altered by prenatal CNS abnormality (e.g., myelomeningocele)

AMP video tapings were obtained for fetuses (third trimester: ultrasonography) and for neonates (birth and 6 weeks postnatal). Leg AMP of fetuses/neonates were quantified with a computer-video movement analysis system.

Results for numbers and periodicity of leg movements indicates: antenatal-to-postnatal AMP continuity for normal fetal/neonatal subjects, and altered fetal/neonatal AMP for CNS abnormality subjects. Results suggest that fetal/neonatal AMP, which is under control of central pattern generators, is disrupted by prenatal CNS abnormalities, and that fetal/neonatal AMP may not be as strongly influenced by environmental factors (intra- to extra-uterine transitions) as previously thought.

GROOMING DEVELOPMENT AND ACTIVATION IN WEAVER MUTANT MICE. V.J. Bolivar*, W. Danilchuk and J.C. Fentress. Psychology Department, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Weaver (*wv/wv*) mice have well specified nigrostriatal dopaminergic and cerebellar defects. Quantitative analyses of behavioral development in these animals have not previously been pursued. We examined grooming in *wv/wv* pups and littermate controls before and after a 30 second swim period. Deficiencies in grooming of *wv/wv* pups are context and age dependent. *Wv/wv* spend less time grooming than controls; however, after day 13 postpartum during the post-swim period mutants attained grooming levels of pre-swim controls. *Wv/wv* pups also showed, from day 15, an increase in number of grooming bouts post-swim. This reflects previous activation by swimming. Our data suggest activational effects can be separated from balance, postural or sequencing problems. Although controls displayed longer bouts than mutants overall, during the post-swim period (day 13 and older) *wv/wv* pups produced bouts as long as pre-swim controls. Strokes used by *wv/wv* pups tended to cluster around the early grooming sequence phase and some later strokes were never used by the mutants. These results indicate the importance of examining behavioral ontogeny under different conditions, as well as the value of using multiple measures when examining action sequences. Mutant mouse research holds much promise in linking cellular, circuit and behavioral levels of organization.

SNAP-25 ISOFORM mRNA EXPRESSION IN SPINAL MOTONEURONS AFTER NERVE INJURY. G. Jacobsson, F. Piehl*, X. Zhang, I.C. Bark and B. Meister. *Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm, and Department of Developmental Biology, Uppsala University, Sweden.*

Synaptosomal-associated protein of 25 kDa (SNAP-25) is a protein involved in the molecular regulation of exocytosis. SNAP-25 is located at the presynaptic plasma membrane and is a component of the 20S multiprotein complex that mediates vesicle docking and fusion. The protein exists in two isoforms, which arise from alternative splicing of exon 5. In order to study the plasticity in SNAP-25 gene expression, we have axotomized the sciatic nerve and studied SNAP-25 mRNA levels in spinal motoneurons using *in situ* hybridization and isoform-specific oligonucleotide probes. In all animals, SNAP-25a mRNA was detected in the nucleus of motoneurons, whereas SNAP-25b mRNA was present in the cytoplasm. After axotomy, the levels of SNAP-25a and SNAP-25b mRNA decreased in motoneurons belonging to the sciatic pool. Measurements of the grain density over cells on the lesioned side as compared to the unlesioned side revealed a significant decrease after 2 days. The maximum decrease was detected at 7 days (62% for SNAP-25a and 67% for SNAP-25b), while levels had slightly recovered by 14 and 28 days. Ventral root avulsion produced a similar decrease in SNAP-25 mRNA levels in lesioned cells, indicating that the decrease in SNAP-25 mRNA is due to the axonal severance in itself. The results suggest that SNAP-25a and SNAP-25b mRNA have different localization within the cell and that SNAP-25 mRNA is down-regulated in specific populations of spinal motoneurons after nerve injury.

705.15

FACTORS RESPONSIBLE FOR POOR FUNCTIONAL RECOVERY AFTER PERIPHERAL NERVE LESIONS. Neil Tyreman, Mukaila Raji and Tessa Gordon*. Department of Pharmacology and Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada T6G 2S2.

Even primary nerve repair may be associated with dismal functional recovery when long delays are incurred between the peripheral nerve injury and target reinnervation. In this study, we have systematically and independently controlled the duration of axotomy (X), denervation of the distal nerve sheaths (SH) and muscle denervation (M) to determine the relative contribution of each factor to functional recovery. In rats, the posterior tibial nerve (TIB) was cross-sutured to the CP nerve via a contralateral common peroneal (CP) nerve graft (10-15mm) to reinnervate tibialis anterior (TA) muscle, either immediately or after prolonging TIB axotomy, CP graft or TA denervation. At least 6 months after graft surgery, number and size of TA motor units were determined as measures of number of regenerated nerves and numbers of muscle fibers reinnervated per motoneuron. An average of 99.4±15.3 motoneurons innervated TA after immediate grafting. In all cases where nerve repair was delayed, the number decreased as a function of delay between AX, SH or D and nerve repair, reaching an asymptotic value of 30.2±3.6, 41.4±4.1 and 13.7±3.4 at 300 days.

In the light of our previous findings that deterioration of intramuscular nerve sheaths is the primary factor limiting reinnervation of long-term denervated muscle (Fu & Gordon, J. Neuroscience, in press), these findings indicate that the growth response of AX motoneurons and the growth environment of denervated nerve sheaths deteriorates with time. The better recovery after prolonged graft denervation than after prolonged muscle denervation indicates that migration of Schwann cells from the "fresh" nerves into the "old graft" may have facilitated regeneration. We are presently evaluating the molecular basis for the reduced growth response of long-term axotomized nerves and denervated nerve sheaths (see You et al. abstract).

ACCUMULATION OF NEUROFILAMENTS CAUSES DENDRITIC ATTRITION IN MOTOR NEURONS. J.-M. Kong, D.W. Cleveland+, and Z.-S. Xu*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545; +Ludwig Institute for Cancer Research and Department of Neuroscience, UCSD, La Jolla, CA 92093.

Accumulation of neurofilaments (NFs) in motor neurons has been widely observed in human motor neuron disease, of which the most common forms are amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (SMA). In transgenic mice, severe accumulation of NFs induced by forced over-expression of either NF-L or NF-H leads to loss of motor function, resulting in paralysis, skeletal muscle atrophy, and finally death (Xu et al, 1993; Cote et al, 1993). To further understand how NF accumulation causes motor neuron dysfunction, we have examined the structure of neuromuscular junction by EM and motor neuron morphology by Golgi staining in the NF-L transgenic mice. Except for the increased NF content in nerve terminals, the neuromuscular junction remains intact. However, a quantitative measurement of the spinal cord motor neurons reveals a significant shortening in the length of their dendrites (by more than two fold in comparison with the wild type), leading to a reduced density of dendrites, a shrunken area coverage by the dendrites, and a loss of distal dendrites. These changes could cause a reduction in the number of synapses contacting the motor neurons and consequently lead to motor neuron dysfunction.

705.17

STUDIES ON SLOW AND FAST COMPONENTS OF AXONAL TRANSPORT IN MICE LACKING THE NEUROFILAMENT LIGHT (NFL) GENE. S. Couillard-Després, Q. Zhu, D. E. Playford* and J.-P. Julien. Centre for research in Neuroscience of McGill University, The Montreal General Hospital Research Institute, 1650 Cedar ave., Montreal, Quebec, Canada, H3G 1A4.

The neurofilament triplet proteins form the 10 nm filaments found in almost all neuronal cells and are the major constituents of the cytoskeleton in these cells. The presence of the three components (neurofilament light, medium and heavy subunits: NFL, NFM and NFH) is required for a proper polymerization. Our laboratory recently produced a mouse line lacking the NFL gene. In the absence of NFL, expression of the two other subunits, NFM and NFH, in the nervous system is down regulated. Our data reveals the existence of a compensatory mechanism resulting in the up-regulation of tubulin and microtubule-associated proteins. To study axonal transport, ^{35}S-methionine was injected in the ventral horn of the spinal cord (between L2 and L3) of knock-out and control mice. The mice were sacrificed after different time intervals following injection. The sciatic nerves were dissected and divided into 5 mm segments. Protein was extracted from each segment, fractioned on SDS-PAGE, and analyzed by fluorography. Our preliminary results reveal a dramatic increase in the rate of axonal transport of tubulin in the NFL knock-out mice.

706.1

LAMINAR DISTRIBUTION OF GLUTAMATE RECEPTORS IN DEVELOPING RAT VISUAL CORTEX. B. Gordon*, L.N. Fu and T. Lissman, Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403

We studied the development of glutamate binding sites in the visual cortex of Long-Evans rats. We used quantitative autoradiography to describe the development of [^{3}H]MK-801 binding sites (an open channel ligand for NMDA receptors), [^{3}H]kainate binding sites, and [^{3}H]AMPA binding sites. As a non-glutamate control we used [^{3}H]muscimol, a ligand for $GABA_A$ receptors. Binding of each ligand was measured at 14, 18, 26, 39 days (d) and in adults (>90 d). At 14d [^{3}H]MK-801 binding was similar across all layers, with a slight peak in layers 2/3 and 4. In older animals [^{3}H]MK-801 binding peaked in layers 2/3 and declined in the deeper layers. Binding in layers 5 and 6 was greater in both 26d and 39d animals than in adults. Thus, MK-801 binding in the deeper layers of the rat visual cortex appears maximal around 30d, the approximate peak of the critical period (Fagiolini et al. 1994). [^{3}H]Kainate binding was maximal in layers 5 and 6 and was not age dependent. AMPA binding did not vary dramatically by layer, although it decreased slightly from layer 2 to layer 6. In layers 4-6, AMPA binding was lower in adults than in 26d or 39d animals. Except at 14d muscimol binding was greatest in layers 2/3 and 4. Here muscimol binding was greater at 26d than in adults. These results suggest that NMDA receptors are involved in plasticity in the rat. AMPA binding sites may also be involved. The precise role of these binding sites requires better definition of the rat critical period. The present results in rat contrast somewhat with results we reported previously for cat (cf. Gordon et al., 1994). (Supported by NEI grant EY04050 to BG).

706.2

COLOCALIZATION OF NMDA-R1 mRNA AND GLU-R1 IMMUNOREACTIVITY IN THE RAT VISUAL CORTEX. Z. Cao*, B. Gordon, and M. Lickey. Inst. of Neurosc., Univ. of Oregon, Eugene, OR 97403.

NMDA receptors may mediate activity dependent plasticity in the visual cortex during development (for review see Fox and Zahs, 1994). In rats, maximal visual plasticity occurs at approximately 30 days of age (Fagiolini et al., 1994). In the visual cortex of Long-Evans rats, we studied NMDA receptor gene NMDA-R1 with in situ hybridization and AMPA receptor protein Glu-R1 with immunohistochemistry. (The NMDA-R1 cDNA was a gift from Dr.Koki Moriyoshi, subcloned by Dr.Gilbert Burns). Glu-R1 immunoreactivity was similar in 30 day and 90 day animals. It was present in all layers but was highest in layer 1 and lowest in layer 4. The level of NMDA-R1 gene expression was much higher at 30 days than at 90 days. At both ages NMDA-R1 expression was maximal in the top half of layers 2/3. Double labeled cells were found primarily in 30 day animals. The majority of the cells in 30 day animals were double labeled and double labeled cells were found in all layers except layer 1. These data show that NMDA-R1 expression is greater at the height of the critical period than in adulthood. This result is consistent with the hypothesis that NMDA receptors are involved in visual cortex plasticity in the rat. The role of the Glu-R1 protein is less clear, since the abundance of this protein does not appear to decline in association with declining plasticity. In future studies we plan to examine additional age groups and subunits. Supported by NEI grant EY04050 to Barbara Gordon.

706.3

REGIONAL AND LAMINAR CHANGES IN SYNAPTIC LOCALIZATION OF NMDA RECEPTOR SUBUNIT SPLICE VARIANT NR1 IN RAT VISUAL CORTEX AND HIPPOCAMPUS. R. R. Johnson*, X.-P. Jiang, and A. Burkhalter, Dept. Anatomy & Neurobiology, Wash. Univ. School of Medicine, St. Louis, MO 63110.

Regional and laminar distribution of the NR1 subunit of the NMDA receptor was examined at the light (LM) and electron microscopic (EM) levels using a new antiserum directed against a differentially spliced C-terminal exon (NR1-C1; Sheng et al., 1994). This exon is expressed in a restricted number of NR1 splice variants (Sugihara et al., 1992; Hollman et al., 1993) and is a major substrate for posttranslational modification by phosphorylation (Tingley et al., 1993). The most striking result was that the pattern of NR1-C1 immunoreactivity in both the hippocampus and visual cortex was more restricted than that previously shown using other NR1-specific antibodies (Huntley et al., 1994; Petralia et al., 1994; Siegel et al., 1994), and did not label cells in CA3, dentate gyrus and subicular regions of the hippocampus and in layer 4 of the visual cortex. Regional and laminar differences in synaptic NR-C1localization were confirmed by quantitative EM.

Surprisingly, in addition to abundant postsynaptic staining, immunoreactivity was found in >40% of axon terminals in the dorsal subiculum, but in only a very small percentage (<1%) of terminals in visual cortex. This strongly suggests that presynaptic NMDA receptors play a major role in neuronal processing of hippocampal output through the subiculum, but have a relatively minor role in V1.

In sharp contrast to the pattern in the adult, there was relatively little regional and laminar variation in NR1-C1 immunoreactivity in the developing brain (PND 11). Interestingly, NR1-C1 splice variants were present in cortical layer 4 as well as in CA3, dentate gyrus, and subiculum at the early time point but were largely excluded from these structures in the adult. This suggests that NR1-C1 splice variants may play a role in determining the critical period for visual cortical layer 4. Continued expression within upper and lower layers of the cortex and in CA1 of the hippocampus in the adult could provide a substrate for plasticity in corticocortical connections and Schaffer collateral synapses beyond the critical period.

706.4

DIFFERENTIAL DISTRIBUTION OF TWO GLUTAMATE DECARBOXYLASES (GAD67 AND GAD65) IN THE NEWBORN AND ADULT CAT VISUAL CORTEX. Y. Guo, I.V. Kaplan, N.G.F. Cooper and G.D. Mower*. Univ. of Louisville Sch. of Med., Louisville, KY 40292.

The identification of two forms of glutamate decarboxylase (GAD67, GAD65), the synthetic enzyme for GABA, raises the possibility that they may play different roles in the development of mature GABAergic circuitry. We have used antibodies to compare GAD67, GAD65, and GABA positive neurons in neonatal (4-6 days) and adult cat visual cortex. In adults, GABA and GAD67 containing neurons were found in all cortical layers but little cell body staining was seen with the antibody to GAD65. Higher power observation revealed a complementary intracellular distribution of GAD67 vs GAD65. GAD67 was found mainly in cell bodies and was present to a lesser degree in puncta (presumptive synaptic terminals) than GAD65. GAD65 was faint in cell bodies but labeled more puncta than GAD67. In neonates, GABA and GAD67 were densest in two distinct bands, one superficial (Layer I), another deep (Layer VI/Subplate). Unlike in adults, GAD65 positive cell bodies were clearly evident in neonates and distributed similarly to, but less frequently than, GABA and GAD67. Higher power observation again revealed that the density of GAD65-positive punctate structures was higher than that of GAD67-punctate structures. The distinct intracellular localization of the two isoforms in adult cat visual cortex is consistent with the notion that GAD67 (holoGAD) provides the basal pool of GABA and GAD65 (apoGAD) is specialized to respond to short-term increases in demand for GABA in axon terminals. That the intracellular and laminar distribution of both isoforms of GAD and of GABA differs between neonatal and adult VC suggests that these two forms of GAD may be differentially involved in two distinct aspects of postnatal maturation of visual cortical GABA circuitry: dying off of embryonic cells and differentiation of the adult GABA system.

DEVELOPMENTAL EXPRESSION OF THE IMMEDIATE EARLY GENE EGR-1 MIRRORS THE CRITICAL PERIOD IN CAT VISUAL CORTEX. I. V. Kaplan, Y. Guo, K. Klueber* and G. D. Mower. Department of Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292.

The aim of this study was to determine the postnatal developmental profile of EGR-1 protein expression across the layers of cat visual cortex and relate it to the state of visual cortical development and plasticity. Cats at various postnatal ages (0.5 week, 1 week, 2.5 weeks, 5 weeks, 10 weeks, 20 weeks, and older than 1 year) were used. Coronal sections from visual cortex were processed for immunohistochemistry with avidin-biotin visualization. In very young animals (0.5 weeks), EGR-1 positive cells were restricted to deep cortical layers (layer VI/Subplate). With increasing age, EGR-1 immunoreactivity spread across layers of the visual cortex in inside-outside manner, and by 5 weeks of age, EGR-1 protein was highly expressed in all layers of the visual cortex. In addition, an intensely stained band of labeled cells in the lowest portion of layer IV appeared at 1 week of age and was present in all older animals. EGR-1 expression remained high until approximately 10 weeks of age and then gradually began to decline in layer IV with little change in supra- and infragranular layers. Therefore, in adult animals, EGR-1 positive neurons were located predominantly in the layers above and below layer IV.

This pattern of EGR-1 expression in developing cat visual cortex exhibits both temporal and laminar similarities with the development of visual cortical connectivity, with the development of orientation selective receptive field properties, and with the level of visual cortical plasticity, suggesting an involvement of EGR-1 expression in these processes.

706.6

LAMINAR PATTERNS OF $GABA_A$ RECEPTOR EXPRESSION IN FERRET PRIMARY VISUAL CORTEX ARE ESTABLISHED PRIOR TO CORTICAL INVASION BY GENICULATE AFFERENTS. A.L.Smith and I.D.Thompson*, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K.

Quantitative *in vitro* autoradiography has been employed to monitor the expression patterns of $GABA_A$ receptor proteins in the primary visual cortex of ferrets throughout postnatal development. [^{3}H]Musicimol, a $GABA_A$ receptor agonist, and [^{3}H]flunitrazepam, an agonist at the benzodiazepine modulatory site, revealed very similar expression patterns in cryostat sections. Presumptive primary visual cortex was identified by transneuronal axoplasmic tracing of geniculate axon terminals using intraocular injections of wheatgerm agglutinin conjugated to horseradish peroxidase (4%, 2-4µl) and the development of the cortical plate was monitored by neuronal birthdating using 5-bromo-2'-deoxyuridine immunocytochemistry.

$GABA_A$ receptor density within primary visual cortex doubles in the first postnatal week, after which time layer-specific laminar distribution patterns are observed. From postnatal day 8 (P8), when migrating layer IV neurons are arriving in the cortical plate, until adulthood receptor density in layers I and IV exceeds that found in the infragranular layers or layers II/III ($P<0.001$). Receptor protein expression in all layers continues to increase throughout development, increases in layers I and IV preceding those in other layers, reaching a maximum a month after eye opening and then decreasing slightly after P85. Unlike EAA receptors (Smith & Thompson, *J. Physiol.* 485:8P) changes in $GABA_A$ receptor distribution do not appear to be linked with changes in the state of the geniculate fibres and preliminary evidence indicates that disruption of the geniculocortical pathway does not affect the early patterning of $GABA_A$ receptor expression.

CHANGING DISTRIBUTION OF NMDAR1 IN THE DEVELOPING VISUAL CORTEX S. M. Catalano*, C. K. Chang and C. J. Shatz, HHMI and Dept. of Molecular and Cell Biology, University of California, Berkeley, 94720

NMDA receptors are thought to play an essential role in the development of the visual cortex. We have examined the distribution of the NMDAR1 receptor subunit protein in the ferret using 3 different antibodies: two are raised against overlapping, C-terminal, alternatively spliced domains (Ab1 & 2), and the third is raised against a separate, non-alternatively spliced domain (mAb3). At embryonic day 35 (birth = E 41), all 3 antibodies stain fibers within marginal zone (future layer 1), cells in the cortical plate, and subplate neurons (located within future white matter); the subplate neurons are stained most intensely. There was no detectable immunostaining of migrating cells in the intermediate zone. By P 3, cells within layer 6 stain as intensely as the subplate neurons. In addition mAb3, but not the other antibodies, stains a band of horizontally oriented fibers within the intermediate zone. By the 7th postnatal week, when ocular dominance columns have begun to form in cortical layer 4, staining of layer 1 and the white matter (subplate neurons) is undetectable with all 3 antibodies. Within the cortical layers, mAb3 stains layers 4 and 2/3 more intensely than layers 5 and 6, whereas the other 2 antibodies stain neurons in all layers with equal intensity. In the adult, the mAb3 antibody stains cells in layers 2/3 more intensely than those in layers 4-6. These observations indicate that 1) the earliest cells of the neocortex to be stained are subplate neurons, and 2) during the period of ocular dominance column formation, there is a relative decrease in the R1 subunit in layer 4 as detected by the antibody that recognizes an epitope which is not alternatively spliced (mAb3). These results are consistent with a role for NMDA receptors not only during the critical period, but also far earlier in visual cortical development. Supported by grants from the NEI to CJS (EY02858) and SMC (EY06491). We thank T. Dawson for the generous gift of Ab1.

SUBCELLULAR REDISTRIBUTION OF NMDA RECEPTORS IN DEVELOPING VISUAL CORTICES OF CATS. C-G Go*, Chiye Aoki, N. Nurbhai, C. Venkatesan, X.-Z. Song & Ted M. Dawson+. Ctr for Neural Sci., New York Univ., NYC, NY 10003 & +Dept. Neurol. & Neurosci., The Johns Hopkins Univ. Med. Schl., Baltimore, MD.

Earlier electrophysiological studies have shown that, during the postnatal period spanning the critical period, NMDA receptors in the visual cortex undergo alterations in their laminar distribution and are more sensitive to blockade by NMDA-receptor antagonists. Using a previously described antiserum directed against the NMDA-R1 subunit, we determined whether these pharmacological changes correlate with changes in the cellular and subcellular distributions of the receptor. During the first three postnatal weeks, light microscopy showed prominent staining of a small subset of neurons that were scattered throughout the cortical thickness, including layer 6B. These neurons exhibited non-pyramidal perikarya and varicose dendritic processes which were studded with intensely immunoreactive patches. In addition, fine beaded processes, most likely axonal, were prominent in the white matter. In contrast, tissue obtained from older animals exhibited a more uniform distribution of punctate labeling in the neuropil. Electron microscopy revealed that these consist of immunoreactivity in small patches along plasma membranes of dendrites, axons and terminals. These results indicate that the NMDA-R1 subunit undergoes dramatic redistribution during the critical period for developmental plasticity. SYNAPTIC VESICLE PROTEIN IMMUNOREACTIVITY DURING DEVELOPMENT IN MACAQUE MONKEY PRIMARY VISUAL CORTEX. T. Yoshioka* & S.H.C. Hendry. Krieger Mind/Brain Inst. & Dept. of Neuroscience, Johns Hopkins University, Baltimore, MD 21218

Changes in synaptic activity are essential in the functional and anatomical development of mammalian neocortex. Such synaptic activity is influenced by intrinsic and extrinsic neuronal input in different laminae during development. To assess the pattern of laminar-specific events in the development of synapses in macaque primary visual cortex (V1), we have examined the expression of synaptophysin, an integral membrane protein of synaptic vesicles, in the fetal and infant macaques. At embryonic day E135 (gestation = 165 days), immunostaining of synaptophysin revealed distinct laminar boundaries, with intense punctate immunoreactivity in layers 4A, 4Cα, and the bottom of 4Cβ through 5. Immunostaining in layer 4A showed clear evidence of a honeycomb or lattice, even though no pattern was evident in the pale cytochrome oxidase staining of layer 4A at this age. A similar irregular honeycomb pattern was also evident in deep layer 5. The laminar pattern seen at E135 continued to be visible in later age, but became less laminar-specific immunostaining in postnatal tissues. These observations suggest that the maturation of synapses occurs in a laminar specific manner in macaque V1. (Supported by NIH grant EY06432. We thank Dr. Anita Hendrickson for providing fetal and neonatal tissue.)

SPONTANEOUS ACTIVITY OF NEURONS IN ORGANOTYPIC CULTURES OF RAT NEOCORTEX DURING DEVELOPMENT *IN VITRO*. D.Echevarria* and K.Albus, Neurobiology Groups, Max Planck Institute for Biophysical Chemistry, 37018 Göttingen, FRG.

Neurons in organotypic cultures (OTCs) of rat cortex may develop highly dependent firing patterns, including sterotyped burst pattern (1). We wondered whether in neocortical OTCs spontaneous bursting activity displays a progessive time-dependent onset as it has been demonstrated for neurons in OTCs of hippocampus. Action potentials were recorded extracellularly from 640 neurons in 102 OTCs (from 3 - 9 days old rats, roller tube technique) of rat occipital cortex between 4 and 64 days in vitro (DIV). Neurons were divided operationally into 4 classes: 1) Not spontaneously active (NonSp) neurons, detected only by electrical stimulation; 2) Spontaneously active, regularly firing (SpR) neurons; 3) Spontaneously active, bursting (SpB) neurons; 4) Spontaneously active, mixed (SpM) neurons, i.e. with both SpR and SpB activity. In OTCs 4 DIV all activity classes were present. The proportions of activity classes changed during development *in vitro*. From the first to the second week the proportions of NonSp neurons decreased (from about 60% to about 30%) and that of spontaneously active increased accordingly. From thereon no systematic change occured until the end of the 2nd month. During development in vitro a slight (not significant) upward trend in average firing rate, intraburst firing rate and burst duration was found. A spatial and temporal analysis of firing patterns by means of double recordings revealed a high degree of burst synchronicity across OTCs with multiple sources for triggering individual bursts. A progressive time dependent onset of bursting activity was not seen. Rather it was found that SpB neurons, in particular those displaying longer lasting bursts, were present from the 4th DIV on in OTCs treated with more than average mechanical manipulation during preparation.

DEVELOPMENTAL CHANGES IN EVOKED SPATIAL ACTIVITY PATTERNS IN CORTICAL SLICE CULTURES. Y. Jimbo[1], P.J. Charlety[1], H.Kamioka[1], H.P.C. Robinson*[2], and A. Kawana[1]. [1]NTT Basic Res.Labs, 3-1 Morinosato Wakamiya, Atsugi-shi, Kanagawa 243-01,JAPAN. [2]Physiol. Lab, Univ. Cambridge, U. K.

Spontaneous synchronized activity is believed to play a role in the refinement of connections in the developing nervous system. Developmental activity changes in dissociated cortical cultures have been described previously (Charlety *et al., Soc. Neurosci.* 1994, 534.9). Here we have mapped developmental changes in the spatial profile of evoked activity in cultured cortical slices. P2 rat cortical slices were fixed by gentle centrifugation onto substrates containing an array of 64 embedded electrodes, and cultured. After 5 days in vitro (DIV), stimulation (1.5 V, 100 μs, every 5 s) was applied individually through 16 different substrate electectrodes and the evoked responses were recorded at 8 sites. In normal medium at 5 DIV, each stimulus evoked a burst of action potentials of about 200 ms duration whose structure showed evidence of summed activity from multiple neurons in the vicinity of the recording electrode. Latencies varied with the site of recording, revealing an anisotropic propagation of the burst activity through the slice from the site of stimulation. At 9 DIV, the duration of evoked bursts was markedly reduced, to about 50 ms. In picrotoxin-containing medium at 5 DIV, the first evoked burst was followed by a sequence of bursts of reduced amplitude, separated by more than 200 ms. At 9 DIV, the number of bursts evoked by a single stimulus in picrotoxin was increased, and the interval between successive bursts was shorter than at 5 DIV. This suggests that inhibitory synapses develop between 5-9 DIV and play an important part in modulating the pattern of synchronized bursting.The results suggest that, like dissociated cultures of cortical neurons (Robinson *et al.*, 1993, *J. Neurophysiol.* **70**:1606), cultured organotypic slices have the capacity for propagation of locally-synchronized bursting activity, that the pattern of propagation is determined by the anisotropic structure of the local circuitry of the cortex, and that there is a progressive sharpening in the local synchronization of bursting with development.

DEVELOPMENT OF CORTICOCOLLICULAR CELLS IN NORMAL AND ANOPHTHALMIC MICE. M. KHACHAB* and L.L. BRUCE, Dept. Biomed. Sci., Creighton University, Omaha, NE 68178.

Anophthalmic corticocollicular (CC) axons show a delayed growth into the superior colliculus (SC) when compared to normal CC axons. This delay may be due to a delayed development of the anophthalmic visual cortex or to the absence of retinocollicular (RC) axons (Khachab and Bruce, Soc. Neurosci. Abstr. 1994). To test these possibilities, the development of anophthalmic CC neurons was compared to that of normal CC neurons. Injections of the fluorescent dye, DiI, were made in the SC of normal (C57BL/6J) and anophthalmic (129SV/CPor^{r}) embryonic and postnatal mice to retrogradely label the CC neurons. In normal mice, labeled cells were first observed at E15. These cells had a short apical dendrite that had not yet extended to the superficial layers. By P0, the apical dendrites extended to the superficial layers and 1 or 2 basal dendrites were present with no collaterals. At P2, the basal dendrites had multiple branches and most apical dendrites were bifurcated. At P4 and P6, the main shaft of the apical dendrites ramified in the superficial layers forming an elaborate terminal tuft and the basal dendritic tree continued to arborize. In contrast, cells in anophthalmic mice were less mature at comparable ages. By P0, only a few dendrites and a fine axon were present. By P6, some apical dendrites had bifurcated and all appeared to extend to the superficial layers with a fine terminal tuft. Basal and apical dendrites had relatively few branches and dendritic collaterals. Thus, a delay in the maturation of the anophthalmic CC neurons appears to be responsible for the delayed growth of the anophthalmic CC axons rather than the absence of the RC axons.

DENDRITIC DEVELOPMENT OF LAYER 4 STELLATE CELLS IN CAT VISUAL CORTEX. C.J.Pace, S.B.Tieman*, D.G.Tieman, and L.F.Henry. Neurobiology Research Ctr., SUNY at Albany, Albany NY 12222

The visual cortex of the cat develops many of its physiological and anatomical characteristics after birth. However, there are few studies on dendritic development in the visual cortex. We have studied the postnatal development of the dendritic arbors of layer 4 stellate cells. These cells are the primary recipient of visual information from the lateral geniculate nucleus. We intracellularly injected individual neurons with biotinylated Lucifer Yellow within 300 micron fixed cortical sections and processed the sections by the ABC method. Layer 4 stellate cells were entered into a computer and analyzed in 3 dimensions using Sholl concentric rings. In newborn kittens these cells already had most or all of their primary dendrites and fairly extensive dendritic arbors. Branching increased substantially within the first week and only slightly over the next 3 weeks. Dendrites grew in length for at least the first 4 weeks. Additions to dendritic length were proximal as well as distal since the length of first order branches increased. These results demonstrate that dendritic development is coincident with the period of synaptogenesis and mostly precedes that of sensitivity to experience dependent modification.

LESION OF CHOLINERGIC BASAL FOREBRAIN NEURONS DOES NOT AFFECT FUNCTIONAL DEVELOPMENT OF THE RAT VISUAL CORTEX. R. Siciliano, N. Berardi, F. Casamenti° and L. Domenici*. Istituto di Neurofisiologia CNR, Pisa 56127 (Italy); ° Dept Pharmacol, Firenze (Italy).

Recently it has been shown that antagonizing cholinergic receptors affects visual cortical plasticity during early postnatal development (Q. Gu and W. Singer, Eur. J. Neurosci. 5:475-485, 1993). Here we tested whether in absence of the cholinergic input from the basal forebrain (BF) the functional properties of visual cortical neurons develop normally. Six rats (Long Evans) were deprived of cholinergic input to the visual cortex at the beginning of the critical period (postnatal day 15) by unilateral stereotaxic injections of quisqualic acid in BF cholinergic nuclei. One month later we performed extracellular recordings under urethane anaesthesia to assess the ocular dominance distribution and orientation selectivity of visual cortical neurons in area 17. At the end of recording sessions rats were sacrificed and the extent of the cholinergic depletion was assessed in terms of the acetylcholinesterase pattern and by measuring the choline acetyltransferase (ChAT) activity at the level of area 17 in both hemispheres. We found that lesion of BF cholinergic nuclei did not substantially affect either the ocular dominance distribution or the orientation selectivity of area 17 neurones.

NEURONS IN THE STRIATE CORTEX OF FOUR-WEEK POSTNATAL KITTENS EXHIBIT ADULT-LIKE INHIBITORY PROPERTIES. E.S. Green, G. C. DeAngelis, and R. D. Freeman*. Group in Vision Science. University of California, Berkeley, California 94720-2020.

Excitatory characteristics of neurons in the kitten's visual cortex are thought to be largely mature by four weeks postnatal (Mitchell and Timney, 1984.) However, the status of inhibitory properties at this age is not clear. We have studied specific inhibitory phenomena (end- and side-inhibition and cross-orientation suppression) using single cell recordings in the visual cortex of four-week kittens, and have compared our findings with data from adults.

Responses were recorded extracellularly from neurons in area 17 of paralyzed and anesthetized kittens. To elicit excitation, we used drifting sinusoidal gratings of optimal parameters. To test for end- and side-inhibition we varied the length and width of the excitatory grating. The tuning properties of end- and side-inhibition were studied by varying the orientation and spatial frequency of patches located outside of the excitatory receptive field. To measure cross-orientation suppression the excitatory grating was overlaid with a drifting grating of orthogonal orientation.

Our results show that all three types of inhibition are present in neurons of kittens at four weeks postnatal. As in adults, every cell tested in the kittens exhibited cross-orientation suppression, and maximal cross-orientation suppression could be elicited from a region of approximately the same size as the classical receptive field. Neurons showing end- and side-inhibition to a similar degree, neurons showing only end-inhibition, and neurons showing only side-inhibition were also present in kittens, and occurred in roughly the same proportions as in cats. Finally, end- and side-inhibition were well-tuned for orientation and broadly tuned for spatial frequency, as in adults. These experiments show that intracortical inhibitory mechanisms are quite mature by four weeks postnatal, and suggest that inhibitory and excitatory processes develop in parallel. (EY01175)

Changing Patterns of BDNF and NT-4/5 Immunoreactivity During Visual System Development. R. I. Cabelli*, S. Tavazoie, and C. J. Shatz, HHMI and MCB, University of California, Berkeley, 94720.

Roles for neurotrophins have been implied in both the selective cell death and activity-dependent competitive remodeling of axons that occur during the maturation of the mammalian visual system. In particular, infusion of exogenous BDNF or NT-4/5 into visual cortex has been shown to prevent the formation of ocular dominance columns. In addition, subplate neurons, which undergo massive cell death during development, have been shown to express trkB, the receptor for BDNF and NT-4/5, and stain with a pan-neurotrophin antibody. Here we have used a polyclonal antibody specific for BDNF, and 2 monoclonal antibodies directed against different epitopes within NT-4/5 to characterize the localization of these neurotrophins in the ferret visual system. During early neonatal development (postnatal days 2-6) first subplate neurons and then cortical layer 5 neurons become strongly immunoreactive for both BDNF and NT-4/5. Staining of subplate neurons subsequently decreases, disappearing between P22 and P31. Neurons in layer 2/3 become immunoreactive by P17 while neurons in layer 4 begin to stain for NT-4/5 but not BDNF by P32, which corresponds to an early stage in ocular dominance column formation. At ensuing ages BDNF immunoreactivity remains low in layer 4 and in the adult BDNF containing neurons are seen predominantly in layers 2/3, 5, and 6; while scattered layer 4 neurons are only lightly stained. In contrast, NT-4/5 immunoreactive neurons are stained with equal intensity within all cortical layers. The localization of BDNF and NT-4/5 suggests that 1) that subplate neurons, which take up injected NT-4/5, may depend on ligands of trkB for their survival during development, and 2) endogenous NT-4/5 or possibly BDNF in layer 4 or other layers could play a role in ocular dominance column formation. Supported by EY02858 (CJS).

RECIPROCAL LAMINAR LOCALIZATION AND DEVELOPMENTAL REGULATION OF BDNF AND NT-3 mRNA DURING VISUAL CORTEX DEVELOPMENT. E. Lein, A. Hohn* and C.J. Shatz, HHMI and Dept. of Molecular and Cell Biology, University of California, Berkeley, CA 94720.

The segregation of thalamocortical afferents into ocular dominance columns (ODCs) that occurs during visual system development in higher mammals is an activity-dependent process in which inputs from the two eyes compete for synaptic space within layer IV of visual cortex. One possible mechanism for this process, which involves the selective growth and retraction of axonal branches, is competition for a trophic substance released by the target neurons. A growing body of evidence implicates the family of neurotrophins in this process and other forms of synaptic plasticity.

A potential role in ODC plasticity for two of the neurotrophins, BDNF and NT-3, was assessed using *in situ* hybridization to localize gene expression in cat visual cortex before, during, and after the critical period for segregation of thalamocortical afferents in layer IV. The expression patterns of these two neurotrophins were found to be reciprocal, both temporally and in terms of cellular localization. BDNF mRNA expression is hardly detectable in visual cortex soon after birth (P7), but increases dramatically after eye opening (P15), where it is first in found in large, presumably pyramidal neurons in deep cortical layers. By the height of the critical period (P28), the pattern is similar to that in the adult, with high levels in large neurons in both deep (V,VI) and superficial (II,III) layers. In contrast, NT-3 mRNA is expressed at high levels in visual cortex prior to the onset of the critical period (P7), mainly in small, presumably stellate neurons in the deep portion of layer IV (IVB). This cortical expression steadily declines and is almost undetectable by the end of the critical period (P45). In neither case was glial neurotrophin expression observed.

This dynamic change in neurotrophin expression during the critical period for thalamocortical segregation suggests a role for these factors in the selective growth and stabilization of eye-specific connections during ODC formation. Supported by NSF predoctoral fellowship (EL) and NIH Grant E402858 (AH).

DEVELOPMENT AND PATTERN OF OCULAR DOMINANCE COLUMNS IN FERRET VISUAL CORTEX E.S. Ruthazer*, G.E. Baker† and M.P. Stryker. Neuroscience Graduate Program, Dept. of Physiology and Keck Center for Integrative Neuroscience, UCSF, CA 94143, †Dept. of Human Anatomy, Univ. of Oxford, UK

We have examined the developmental time course and spatial pattern of ocular dominance column segregation in the sable ferret visual cortex using transneuronal cortical labeling following injection of either ^{3}H-proline or WGA-HRP into one eye.

In adult ferrets the visual cortex consists of a large contralaterally dominated monocular segment and a binocular segment near the area 17/18 boundary. In addition, and unlike normal cats, in the normal sable ferret a band about 0.5mm wide along the area 17/18 border is completely dominated by inputs serving the contralateral eye. In the binocular segment, ocular dominance columns are distinctly labeled in layer IV and more faintly in layer VI and show a patchy banded appearance, much like columns in the cat. Columns are also present in area 18 but are wider than those in area 17.

In postnatal day (PND) 30 ferrets a largely uniform distribution of label along layer IV was observed in the binocular segment. By PND 37 there was a clearly periodic modulation in the pattern of label in layers IV & VI, resembling that in the PND 21 cat. Over the following six weeks the modulation became progressively sharper in both hemispheres, suggesting increased segregation of the inputs serving the two eyes.

The onset of ocular dominance column segregation occurs about one week earlier in the ferret than the cat (dated from conception) and from the earliest stages of segregation includes a contralaterally dominated zone at the area 17/18 border not seen in normal cats. *Supported by NIH EY027841, NIH T32-EY07120 and a Kleberg Fellowship.*

'GITTER CELLS' IN DEVELOPING CORTICAL WHITE MATTER ARE INVOLVED IN AXON PHAGOCYTOSIS AND TRANSFORM TO RESTING MICROGLIA M. Schweizer* and C.M. Müller; Max-Planck-Institute for Developmental Biology, 72076 Tübingen, Germany

In early postnatal development thalamo-cortical projections of the mammalian visual system undergo an activity-dependent reorganization giving rise to ocular dominance and orientation maps. The adaptive changes include axon and synapse elimination. A mechanism of such regressive plasticity may reside in the phagocytotic capacity of glial cells. We tested this hypothesis by injecting the lipophilic tracer Di-I into the thalamic lateral geniculate nucleus of kittens aged between 2 and 8 weeks and monitoring transcellular staining due to phagocytosis (*Thanos et al., TINS 17:177, 1994*) after survival times of one to 12 weeks. Fluorescent microscopy revealed Di-I staining at three distinct locations:
i. retrogradely labeled layer VI pyramidal neurons, ii. a band of anterograde label in layer IV, and iii. a distinct population of small cells in the white matter (WM) underlying the visual cortex. Double labeling experiments with the astroglial marker GFAP and the microglial/macrophage marker GSA-I-B4 identified these cells as 'gitter cells'. Transcellular staining in WM was only observed when the dye injection was performed prior to the third postnatal week, coincident with the transient presence of 'gitter cells' up to that age. No transcellular staining of glial cells was observed in the cortical gray matter. The faith of gitter cells was assessed by GSA-I-B4 staining 10 weeks after Di-I tracing performed at an age of two weeks. Cells in the WM, transcellularly stained by the early Di-I injection, now revealed the typical ramified morphology of resting microglial cells. We conclude that 'gitter cells' are involved in the phagocytosis of neuronal structures in early postnatal development and lateron transform to resting microglia. The failure to observe transcellular labeling of glial elements during the period for activity-dependent plasticity challenges a phagocytotic role of glia as a mechanism of regressive plasticity, i.e. axonal pruning. MAJOR COMPONENTS OF THE THALAMO-HYPERSTRIATAL SYSTEM ARE ESTABLISHED BY THE TIME OF HATCHING IN CHICKS (*GALLUS GALLUS*) Chi-Cheng Wu* K. Cox, and Harvey J. Karten , Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093

Connections of the thalamo-hyperstriatal system of hatchling chicks were investigated using multiple injections of cholera toxin subunit B (CTb) in the wulst. In the ipsilateral telencephalon, we observed CTb-labeled cells in hippocampus, lateral portion of neostriatum frontale, neostriatum intermedium, dorsolateral portions of neostriatum caudale, posterodorsolateral neostriatum, and other portions of the wulst. We observed CTb-labeled fibers in the paleostriatal complex. CTb-labeled cells were also seen bilaterally in the archistriatal complex. In the diencephalon, CTb-labeled cells were seen in dorsolateralis anterior thalami complex, n. superficialis parvocellularis, and medial and posterior nuclei of the dorsal thalamus. Heavily labeled fibers/terminals were present in the external half of the external laminae of geniculatus lateralis, pars ventralis. Moderate to minor concentrations of labeling were found in n. intercalatus thalami, ventrolateralis thalami, and geniculatus lateralis, pars dorsalis principalis. Evidence of efferent projections of the wulst was observed in the ventral half of optic tectum and many pretectal areas, including n. basal optic root, pretectalis medialis, spiriformis medialis, principalis precommissuralis, and lentiformis mesencephali, pars magnocellularis. In the brainstem, CTb-labeled cells were observed ipsilaterally in n. tegmenti pedunculo-pontinus, pars compacta, substantia grisea centralis, area ventralis, and locus ceruleus, and observed bilaterally in n. tegmenti ventralis and linearis caudalis. The present data demonstrates that major neuronal connections of the thalamo-hyperstriatal system are well established by the time of hatching in chicks.

AXONAL REGENERATION III

707.1

ADULT CENTRAL NERVOUS SYSTEM AXONS DO NOT REGENERATE ACROSS A MICROLESION IN WHICH THE GLIAL FRAMEWORK IS ALIGNED. S.J.A. Davies, P.M. Field and G.Raisman*. The Lee Research Centre, Division of Neurobiology, NIMR, Mill Hill, London NW7 1AA, UK.

Microlesions were made by stereotaxically penetrating the cingulum with a 50μm diameter micropipette. The cut ends of the caudally directed cingulate axons arising from the cholinergic basal forebrain neurons were identified by immuno-histochemistry of p75. From 1 day post-lesion, the proximal parts of the cut axons were expanded into irregular terminal and preterminal varicosities, and emitted a variety of fine sprouts. At no time after the lesion did any of the axons or sprouts advance beyond the line of the lesion. At survival times up to 2 days OX42 staining showed that the lesion site had been infiltrated by macrophages. However by 4 days only ramified microglial cells with thickened processes aligned along the longitudinal tract axis were present within the lesion site and extended as a flare for about 600μm caudally (i.e. in the orthograde direction). This microglial response had largely subsided by 8 days after operation. From 3 days there was an increase in both GFAP and vimentin immunoreactivity of the tract astrocytes at the lesion site. Hypertrophy of the astrocytic processes tended to obscure their original longitudinal orientation. This was reduced to virtually normal levels at 8 days, by which time the arrangement of the tract astrocytes and their processes across the lesion site was similar to that of an undamaged tract.

Thus, although the framework of glial cells and their processes in the cingulum had resumed its normal alignment by 8 days, the cut axons and their sprouts showed no signs of advancing not only during the initial phase of glial response, but also for one week after this response had subsided. These observations indicate that the failure of regeneration of adult axons is not due solely to unavailability of aligned glial pathways.

AN *IN VITRO* MODEL OF THE DORSAL ROOT ENTRY ZONE.
J. Golding, D. Shewan, M. Berry and J. Cohen. SPON: Brain Research Association. Div. of Anatomy and Cell Biology, UMDS-Guy's Hospital, London, UK.

The failure of lesioned axons from dorsal root ganglion (DRG) sensory neurons to grow into the adult mammalian spinal cord has been attributed to the presence of astrocyte-derived axon-growth inhibitory molecules at the dorsal root entry zone (DREZ). To analyse the cellular and molecular mechanisms involved, we have developed a culture model of the DREZ, using longitudinal cryosections of dorsal adult rat spinal cord, with attached dorsal roots (DR), as a culture substrate for dissociated rat DRG neurons, ranging in age from embryonic (E)13 to adult. After culturing for 1-2 days, sections were triple-stained with antibodies to laminin (to identify DR endoneurium and pia), GFAP (to identify astrocytes at the DREZ) and GAP-43 (to label neurites and their growth cones). The DR supported robust neurite outgrowth from neurons of all ages studied, in contrast to the age-dependent growth we previously described on sciatic nerve cryosections (Bedi, K.S. *et al; Eur. J. Neurosci.* 1992). Furthermore, the longitudinally aligned endoneurial tubes in the DR acted as a conduit for growing neurites, thereby maximizing the number of growth cone encounters with the DREZ. In agreement with previous *in vivo* studies, the majority of neurites growing on the DR failed to cross the DREZ. In contrast, the DREZ posed no barrier to neurites extending from neurons on the spinal cord. Irrespective of neuron age, a small proportion (< 10%) of neurites approaching the DREZ from the DR did cross onto spinal cord tissue and, in the case of neurons isolated from E13-E17 rats, unlike older neurons, subsequent growth on the spinal cord was extensive. The accessibility of this culture model to studies of DRG growth cone interactions with the immature and adult DREZ, from both intact and pre-lesioned rats, should help elucidate the mechanisms underlying the failure of axon regeneration across the DREZ. Supported by Action Research.

THE CRITICAL PERIOD FOR GROWTH OF DORSAL SPINOCEREBELLAR AXONS THROUGH A LESION OF THEIR SPINAL PATHWAY. STUDIES USING THE NORTH AMERICAN OPOSSUM, DIDELPHIS VIRGINIANA. J.R. Terman*, X.M. Wang, and G.F. Martin, Dept of Cell Biology, Neurobiology and Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH. 43210.

Opossums are born at fetal stages of development, 12-13 days after conception, making it possible to manipulate them experimentally without intrauterine surgery. We have taken advantage of the opossum's embryology to show that axons of the dorsal spinocerebellar tract (DSCT) are able to grow through a lesion of their spinal pathway from postnatal day (PD) 5-9 (Terman et al, 1994). Such growth does not occur in adult opossums (unpublished observations), but the critical period for it has not been determined. In order to address that issue, opossum pups ranging in age from PD13-68 and still attached to the nipple were anesthetized so that their spinal cord could be hemisected at T8 or T9. They were maintained with their mother for 1-4 months postoperatively before being subjected to bilateral injections of Fast Blue or Fluoro-Gold into the anterior lobe of the cerebellum, the major target of DSCT axons. The intent of the injections was to label any neurons in Clarke's nucleus (CN), caudal and ipsilateral to the lesion, that supported axons which reached the cerebellum. In the opossum, as in other species, DSCT axons originate within CN and project ipsilaterally to the cerebellum (unpublished results). After 7 days survival, the pups were reanesthetized and perfused intracardially with buffered formalin so that their spinal cord could be removed, sectioned transversely, and examined with a fluorescence microscope. In all cases, neurons in CN rostral to the lesion were labeled bilaterally in roughly equal numbers. Labeling in CN caudal to the lesion, however, was limited to the unlesioned side. This implies that by PD13, DSCT axons do not grow through or around a lesion of their spinal pathway to innervate the cerebellum. In contrast, at least some brainstem spinal axons grow through or around a comparable lesion until PD26 (Wang et al, 1994; Martin et al, 1994). Our results suggest that the critical period for growth of DSCT axons through a lesion of their spinal pathway ends considerably earlier than that for comparable growth of brainstem axons (Supported by NS-25095 and 10165).

ABSENCE OF PROGRESSIVE NECROSIS AND CAVITATION AFTER SPINAL CORD CRUSH INJURY IN MICE, M. Fujiki*, Z. Zhang, L. Guth and O. Steward Dept. of Neurosci., Univ. of Virginia, Charlottesville, VA 22908. Dept. of Biol., College of William and Mary, Williamsburg, VA 23185.

A new approach to CNS regeneration research involves the use of animals carrying particular mutations (natural-occurring or induced). In the course of studies of the effects of mutations on the response to spinal cord injury in mice, we discovered that at least one substrain of mouse (the C57BL/6J substrain) does not exhibit the progressive necrosis and cavitation that characterize the response to spinal cord injury in other species. The spinal cord of adult C57BL/6J mice was crushed at T8 using an extradural approach and animals were allowed to survive for 1, 2, 3, 4 and 8 weeks. The spinal cords were prepared for histological evaluation using the Bodian stain for axons, and the trichrome stain for connective tissue. Reactive changes in astrocytes were evaluated using GFAP immuno-histochemical techniques. The evolution of cellular changes following crush injury in mice differed from what has been described in other species. The injury completely destroyed neural tissue at the crush site. Over time, the area of the crush was essentially completely filled in with non-neural tissue including phagocytic macrophages and connective tissue. Even at the longest intervals (8 weeks post-crush) the two ends of the spinal cord remained connected by an area that was filled with cells and connective tissue with no cystic cavities. Astrocytes were not present within the crush site, but astrocytic processes did form a glial scar at the edge of the crush. At 8 weeks post crush, intact axons could be seen growing amongst the non-neural cells in the crush site. These results indicate that mice have naturally solved what is taken to be one of the key problems facing attempts to repair the injured spinal cord -- the prevention of progressive cavitation and necrosis. Thus, mice will provide a useful model system in which to explore ways to promote axonal regeneration following spinal cord injury. Supported by NIH Grant NS 32280.

REGENERATION OF THE VESTIBULAR NERVE IN CATS. G. Li*, J. Elidan, A. Newman, I. Lopez, and V. Honrubia. Otolaryngology. Hadassah-University hospital, Jerusalem, Israel; Victor Goodhill Ear Center, UCLA Sch. of Med., Los Angeles, CA. 90024

The purpose of this study was to examine the vestibular nerve regeneration in cats. Under general anesthesia and in aseptic conditions, the cats (n=3) were subjected to a VIIIth nerve (vestibular part) neurotomy on both sides by suboccipital approach. The animals were allowed to survive up to a maximum of 6 months. Short latency vestibular evoked potentials (VsEPs) were recorded in response to angular acceleration impulses. Auditory nerve-brainstem response (ABR) was also used for monitoring the cochlear function. Following the nerve transection, the VsEPs disappeared immediately. At two months post transection time (PTT), the VsEPs reappeared with P_1 and P_2 waves of longer latencies and smaller amplitudes. Four months PTT. P_3-P_4 waves were clearly recognized with P_1-P_2 latencies recovered to normal range. At the 6th month PTT, the amplitudes of the P_1-P_4 waves dramatically increased and the VsEPs had an appearance close to that observed before the transection. On the other hand, ABR showed that the cochlear nerve was partially transected. No ABR recovery was observed until the 6th month PTT. Histological examination indicated that the Scarpa's ganglion showed a full compliment of ganglion cells and the dendrites were identified projecting to the cristae and maculae which were in a normal morphology. In the centrifugal portion of the vestibular nerve and the brainstem, the nerve fibers had lost their orderly pattern. The thicker and thinner fibers intermingled each other. Protargol stained specimens demonstrated that these fibers were long, tortuous and somewhat unusual trajectories comparing to control. However, these fibers finally projected to the neurons in all the vestibular nuclei. Degeneration was observed in the partially transected cochlear nerve. Therefore, the histological results supported the physiological findings (ABR and VsEPs) following the nerve transections. The present study suggests that the vestibular nerve is able to regenerate following the axon transection in cats. INTRACELLULAR DENDRITIC ANALYSIS OF DENTATE GRANULE CELLS FOLLOWING UNILATERAL ENTORHINAL CORTEX LESIONS. K.R. Bulsara*, G.K. Pyapali, A.K. Shetty, and D.A. Turner. Neurosurgery and Neurobiology, Duke Univ. Med. Ctr. and Durham VAMC, Durham, NC, 27710.

Unilateral electrolytic lesions of the entorhinal cortex result in deafferentation of ipsilateral dentate granule cells. Recovery in this deafferentation model has been suggested to be due to terminal proliferation and synapse formation of the crossed temporodentate pathway. However, enhanced electrophysiological activation of granule cells by the crossed temporodentate pathway occurs within a few days following the lesion, preceding anatomical correlates of synapse formation. Thus, early recovery may result from either changes in granule cell dendrites (such as sprouting or atrophy) or synaptic terminals rather than re-innervation. We investigated dendritic alterations in granule cells (6-8 week male F344 rats) *in vitro* at ten days post-lesion by using intracellular neurobiotin staining. Adequately labeled cells were reconstructed on a computerized 3D microscope (Neurolucida).

Normal granule cells show typical unipolar architecture, branches reaching the hippocampal fissure and a total dendritic length of $3.55 \pm 0.84 \times 10^3$ μm (n=10), in agreement with previous data. Preliminary results at ten days following unilateral entorhinal cortex lesions show a total dendritic length of 2.43×10^3 μm. The average width of the entire molecular layer was reduced by 14% in lesioned animals to 189 ± 6.4 μm compared to 220 ± 8.5 μm in normal animals. Morphologically, granule cell dendrites in the outer molecular layer of lesioned animals appeared tortuous as they extended to the hippocampal fissure, possibly due to shrinkage.

These results indicate that loss of the perforant pathway may lead to shrinkage of the molecular layer and possibly secondary dendritic alterations in granule cells. This format of analysis may provide a method to assess both the physiological and anatomical aspects of early functional recovery following the perforant path lesion. Supported by HHMI (KRB), NIA (GKP), NINDS (DAT) and VAMC (DAT).

STRUCTURAL CHANGES IN ABDUCENS INTERNUCLEAR NEURONS FOLLOWING THE TRANSECTION OF THE MEDIAL LONGITUDINAL FASCICLE IN THE CAT. R.R. de la Cruz*, A.M. Pastor, C. López-García, F.J. Martínez-Guijarro and J.M. Delgado-García. Lab. de Neurociencia, Univ. de Sevilla, 41012-Sevilla and Lab. de Biología Celular, Univ. de Valencia, 4600-Valencia, Spain.

The internuclear neurons of the cat abducens nucleus project selectively on the medial rectus motoneurons of the oculomotor nucleus. Their axons cross midline at the level of the abducens nucleus and course through the medial longitudinal fascicle (MLF) for a length of about 10 mm in the adult cat. We have studied this projection as a model to characterize the response of central nervous system neurons to the injury of their axons. The sectioning of the MLF was performed by a microknife aimed through the cerebellum with an anteriorly directed angle of 45 deg to transect the MLF ~1 mm caudal to the trochlear nucleus. Abducens internuclear neurons observed at 6, 14 and 28 days post-lesion showed marked ultrastructural changes. In contrast to controls, axotomized cells had a disorganized and dilated rough endoplasmic reticulum and a hypertrophic Golgi apparatus. The density of axosomatic synapses was noticeably reduced in the axotomized neurons; instead numerous filamentous or multilayered glial processes appeared covering large areas of the somatic membrane. Postembedding immunocytochemistry of semithin sections against GFAP indicated an increase in immunopositive profiles both in the neuropil and surrounding the somata. Biocytin-labeled axons of abducens internuclear neurons could be followed in parasagittal sections along the MLF caudal to the lesion site. Axons did not penetrate across the scar tissue, but coursed in abnormal trajectories like U-turns and right angles. Axonal terminals formed either big and smooth clubs or sprouted into several short and thin collaterals exhibiting both terminal and *en-passant* bouton-like structures. In spite of the failure of axons to pass through the lesion site, the presence of these bouton-like elements in the MLF caudal to the lesion might represent some form of axonal regeneration in the central nervous system.

707.8

SPECIFICITY OF MOTOR AXON REGENERATION IN "PURE MOTOR" NERVES. T.M. Brushart,* Y.G. Chen. Depts. of Orthopaedic Surg. and Neurology, Johns Hopkins, Balt., MD 21287.

Motor axons regenerating in mixed nerve preferentially reinnervate former motor pathways. However, the influence of regenerating sensory axons on this process in unknown. These experiments examine the specificity of motor axon regeneration after DRG excision. "Pure motor" femoral nerves were prepared in 1 month old rats by excision of the ipsilateral L2, L3 and L4 DRG's. Three groups of 20 experimental nerves were prepared by DRG excision and simultaneous repair of the proximal femoral nerve, enclosing a ½ mm gap within silicon tube. Groups were evaluated at 2, 3 and 8 weeks by double labeling femoral sensory and motor branches with HRP and FG. Labeled motor neurons were counted and scored as to their projection into the motor branch (M), sensory branch (S), or both branches (double labeled, DL). Mean motor neuron counts (N = 20/gp) were: 2 weeks; M-126, S-57, DL-31: 3 weeks; M-194, S-87, DL-33: 8 weeks; M-279, S-76, DL-25. In the 8 week group, a mean of 834 myelinated axons reinnervated the motor branch and a mean of 517 reinnervated the sensory branch. Motor neurons preferentially reinnervated the motor branch at all times. In comparison with previous studies, specificity was greater and occurred more quickly when sensory axons were removed. Motor neurons retained twice as many axon collaterals when projecting to the sensory branch as opposed to the motor.

A QUANTITATIVE EM ANALYSIS OF RAT NERVE DEGENERATION AND REGENERATION. J.M. Kerns* and J.Lanciloti. Anatomy Dept., Rush Medical College, Chicago, IL 60612.

The purpose of this study is to quantify the cellular and extracellular characteristics of nerve degeneration/regeneration using volume fraction and cell density analysis of electron micrographs. Random fields (n=10) were selected from 7 dpo injured nerves (n=4) at regions taken *before, at,* and *after* the front of regenerating axons, determined with the vibrating probe. The mean nerve fiber density dropped significantly in the distal degenerating nerve segments when compared to *proximal* normal nerve; the degenerating fibers were still being removed by macrophages. Conversely, the endoneurial space, which is related to tissue edema, showed a significant increase when compared to normal nerve. Volume fraction values were significantly increased in the distal regions for Schwann cells, macrophages, and fibroblasts, while cell density data suggested the fibroblasts did not increase in cell number. These findings are consistent with the tissue swelling and cellular proliferation characteristics of inflammation. As expected, both volume fraction and cell density values of the regenerating axons diminish at regions more distal from the lesion site. This ultrastructural portrait of sprouting axons regenerating through the terrain of degenerating nerve is consistent with current hypotheses. Finally, these comparisons of specific volume fraction and cell density values may improve our interpretation of MRI studies of injured peripheral nerve.

OCCURRENCE OF EPIDERMAL NERVE ENDINGS IN GLABROUS AND HAIRY SKIN OF THE RAT FOOT AFTER SCIATIC NERVE REGENERATION. N. Stankovic[1,2], O. Johansson[3] and C. Hildebrand[1]*. Dept Cell Biology[1], Dept Plastic Surgery, Hand Surgery & Burns[2], Faculty of Health Sciences, University of Linköping Linköping, Dept Neuroscience[3], Karolinska Institute, Stockholm, Sweden

The occurrence and distribution of intraepidermal nerve endings in hairy and glabrous skin of the rat foot was examined in normal cases and three months after sciatic neurotomy/suture or a crush lesion. Nerve endings were visualized in cryostate sections with antibodies against protein gene product 9.5. Normal glabrous skin exhibited 23.3 endings/mm length. Neurotomy/suture cases had 6.1 endings/mm. In crushed rats the occurrence was normal, but the intraepidermal nerve endings tended to be abnormally short and occurred mainly in the basal layer of the epidermis. In sections from hairy skin countings were not possible. Subjective evaluation indicated that the occurrence of dermal and epidermal axon profiles usually was deficient after neurotomy/sutute and normal after crush. Skin samples from the contralateral side of operated animals showed a normal occurrence and distribution of nerve endings. Cases subjected to neurotomy/suture showed increased numbers of immunoreactive intraepidermal cells and an abnormally thin epidermis. A deficient regeneration of intraepidermal nerve endings may be one factor behind the unsatisfactory restitution of sensory function after neurotomy and suture.

707.12

ANATOMICAL BASIS OF NERVE REGENERATION IN HUMAN SKIN TRANSPLANTS. G.C.Panzica*°, A.Paraninfo°, A. Garzino°, G.Ramieri§, M.Calcagni°°, M. Stella°°, S. Teich-Alasia^. °Dept. Human Anatomy & Physiology, §Dept.Maxillo-Facial Surgery, °°CTO, Dept. Plastic Surgery and Burn Unit, ^FPSRU, Torino (Italy)

In recent years the study of the human skin innervation received new impulses by immunohistochemical techniques. There are, however, only a few studies dealing with functional markers in both the normal and transplanted skin. Previous investigations performed in our laboratory demonstrated the presence of nervous structures, identified by means of structural markers (PGP 9.5, S-100), also in skin transplants. In the present study we analyzed the immunoreactivity for both structural (PGP 9.5) and functional markers of sensitive nerve fibers [calcitonin gene-related peptide (CGRP), substance P (SP)] in biopsies of skin transplants from several areas ranging from 3 months to 8 years. The PGP 9.5 immunoreactive structures are qualitatively distributed in a similar way in normal and transplanted skin, although a marked reduction was observed in the latest. We detected the presence of innervated and non-innervated Merkel cells, intraepidermal fibers, and, in a limited number, that of capsulated receptors. Immunoreactivity for CGRP is present in almost all the structures detected with PGP 9.5 (including some of the Merkel cells, but not the capsulated receptors), although their total number is greatly decreased. Finally in some samples a very limited number of SP-immunoreactive structures (mainly intraepithelial and intradermal fibers) was observed. Our study shows that regenerating nervous structures in human skin may exhibit immunocytochemical markers indicating a potential functional activity. Their number is greatly reduced in comparison with normal skin, but their qualitative distribution seems not altered, suggesting the regeneration involves all the different classes of nerve fibers innervating the skin. Further quantitative studies are required to understand if functional recovery of the transplant and presence of neurochemical markers might be related. *This work was supported by FPSRU*

Histochemical Analysis of Sensory and Motor Axons and Neuronal Cell Bodies Following Axotomy of the Median-Ulnar and Sciatic Nerves of Adult Rats. **Macias, M.Y. *, Riley, D.A., Lehman, C.T. Department of Cellular Biology and Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226**

Current studies on peripheral nerve regeneration do not discriminate the regenerating fibers as either alpha motor or sensory axons. Carbonic anhydrase (CA) and cholinesterase (CE) histochemical activities of nerve fibers distinguish myelinated sensory and motor axons, respectively. In our previous studies of the rabbit sciatic nerve, regenerating sensory axon sprouts appeared in the earlier and in greater numbers than motor axons. A rat model was developed to determine whether axonal regeneration onset is dependent upon the distance of the nerve cell body from the axotomy site; and if so, whether neurons are triggered to sprout following axotomy by an early retrograde signal from the injury site. The right median-ulnar and left sciatic nerves of male Sprague-Dawley rats (225-275g) were studied. Motor and sensory cell bodies are at a similar vertebral level for the median-ulnar nerve; in the sciatic nerve, motor cell bodies are further rostral by 4.0 cm. Both nerves were axotomized, and the proximal stumps sampled 10, 30, or 90 days later. Histochemical staining for carbonic anhydrase and cholinesterase was performed on serial cryostat sections, and the ratio of CA/CE positive regenerating fibers was counted. For transport studies, the nerves were crushed, injected at crush site with 5 μl of 1% WGA-HRP, ligated and axotomized distal to crush site. HRP activity was visualized in the dorsal root ganglia and ventral horn of the spinal cords using tetra-methyl-benzidine histochemistry 12, 24, and 48 hrs. after injection. The CA/CE ratio of positive axons in the median-ulnar and sciatic nerves were: 2.5+0.2SD and 1.6+0.1 in control (non-injured); 7.5+2.0 and 68.2+35 at 10 days; 8.0+2.0 and 16.3+1.6 at 30 days; and 1.0+0.1 and 0.7+0.1 at 90 days, respectively. The transport studies showed dorsal root ganglia labelling for both nerves at 12 hrs. Motor cell bodies of the median-ulnar nerve also labelled at 12 hrs., but those of the sciatic nerve were not labelled until 48 hrs. Results show that axon regeneration is directly related to the distance between soma and axotomy site and are consistent with injured neurons being signaled to regenerate by a retrogradely transported factor. CELLULAR FACTORS INVOLVED IN NEUROMA FORMATION. D.M. Zhang, R.W. Beuerman, S. Zhao, H. Tran, D. Kline, H. Gould*. Depts. of Ophthalmology, Neurosurgery, and Neurology, LSU Medical Center, New Orleans, LA 70112.

Nerve growth factor (NGF) and its low-affinity receptor (NGFR) have recently been detected in the distal segment of the sciatic nerve 6 hours to 14 days after transection. We have investigated cellular localization of NGFR, growth associated protein (GAP-43), basic fibroblast growth factor (bFGF), and FGFR1 at 2 weeks to 12 months in a monkey neuroma model and in human neuromas. In the monkey 2 weeks after transection, tibial nerve proximal segment immunoreactivity for NGFR was found in the perineurium and less intensely in endoneurium. In both monkey and human neuroma, intense staining for NGFR was associated with disintegrating fibers. We also found staining of Schwann sheaths surrounding masses of axons. Immunoreactivity for NGFR was more intense in 12-month monkey specimens and in human neuromas than in 2-week monkey neuroma. Proximal segments of the neuroma showed equal axonal staining for GAP-43, whereas very few thin disorganized fibers were stained with GAP-43, and the number of GAP-43-stained fibers decreased with time of neuroma development. Western blot of 3-month monkey neuroma showed a decrease in bFGF and FGFR1, compared with the proximal segments. In conclusion, the increase in NGFR, together with the decrease in GAP-43, bFGF, and FGFR1, may be related to the formation of the neuroma. However, the role of NGFR in the development of the axon mass of the neuroma is not clear. Supported in part by DAMD17-93-V-3013.

Long-term Changes of Motor Unit Organization after Peripheral Nerve Repair

A.Mautes, M.Lehnert, Ch. Braun and A.C. Nacimiento*, Neurosurgical Research Laboratory and Department of Trauma Surgery, Saarland University, Medical School, 66421 Homburg/ Saar

Previous work from our laboratory showed that end-to-end or graft repair of the transected peroneal nerve alters histochemical profile of reinnervated extensor digitorum longus (EDL) muscle in the rat by inducing fiber type conversion leading to an additional fiber type (SDH-INT) with reactivity between those of type IIA and IIB fibers. This type is not present in the normal EDL of young adult rats. An early, bilateral increase in number of SDH-INT 3 months after repair was followed by a decrease after 6 months, indicating partial recovery of motor unit organization pattern. To analyse degree and scope of this reversibility we extended our investigation to 15 months postoperative. After computer assisted quantification of histochemical typing, the values obtained were compared with those of animals with intact innervation of the same age. **Results:** SDH-INT number increased significantly through conversion of IIA fiber type on the operated, but not on the contralateral side after end-to-end repair. No differences were observed after grafting. In intact muscle SDH-INT fiber type was also present, but to a lesser amount. **Conclusion:** Postrepair alteration of motor unit organization was not reversed with time, suggesting a reduction of motor unit plasticity enhanced by an interaction between reinnervation and concomitant age related changes of fiber type composition.

TYROSINE HYDROXYLASE-IMMUNOREACTIVITY IS EXPRESSED IN DORSAL ROOT GANGLIA OF CHICK EMBRYOS AFTER SPINAL CORD TRANSECTION. P.A. Gurulé, A.Y. Gonzales, K.D. Kemp and J.A. Wallace*. Dept. of Anatomy, Univ. of New Mexico Sch. of Med., Albuquerque, NM 87131.

Catecholaminergic phenotype traits, such as the expression of tyrosine hydroxylase (TH), are normally not associated with cells of the dorsal root ganglia (DRG). However, cells derived from embryonic quail DRG synthesize TH as well as catecholamines when grown in culture, although these properties are not found in normal developing embryos (Xue et al.,`85). In contrast, small numbers of TH-immunoreactive (TH-IR) cells are present in many DRG in chick embryos, and we report here a striking change in the number of these cells in animals that have undergone spinal cord transection. Animals underwent complete mid-thoracic spinal cord transection either on E12 or E14 according to the methods of Hasan et al.`93 (all animals were prepared in the laboratory of Dr. J. Steeves, Univ. Of British Columbia), and were later sacrificed on E20-21. Analysis of embryos transected on E14 revealed an increase in TH-IR cells within DRG throughout the thoracic cord, although the increase was most prominent at the level of initial cord lesion with up to 25-30 TH-IR cells observed per 10 μm section of DRG. The increase in number of TH-IR cells decreased markedly in both cervical and lumbar cord segments. Control unlesioned animals at E21 demonstrated at most 2-3 immunostained cells per section of DRG at any cord level. In embryos lesioned on E14 the TH-IR cells were dispersed throughout the DRG and appeared as primary sensory neurons ranging from 20-30 μm in diameter; some with a single thick immunostained axon. In contrast, no comparable changes were discerned in embryos transected on E12. It is possible that the expression of TH by chick embryonic DRG neurons results from injury to central projections of the cells or appears as a response to synaptic rearrangements and exposure to various trophic factors in the spinal cord during the recovery period. Supported by DHHS-GM08222 and RR08139.

FORMATION OF SYNAPTIC CONNECTIONS IN THE PTEROPOD MOLLUSC *CLIONE LIMACINA*: REGENERATION AND CELL CULTURE STUDIES. Yu. Panchin, L. Popova*, P. Zelenin, R. Sadreev. Belozersky Institute of Physico-Chemical Biology, Moscow State University, 119899, Moscow, Russia.

The neuronal network controlling rhythmic wing movements in the pteropod mollusc *Clione limacina* is located in a pair of pedal ganglia interconnected by commissure (C). Most neurones comprising the network, as well as their connections have been identified. The motoneurons project to the wing muscles via ipsilateral wing nerve (N). The interneurons provide coordination between the left and the right wings by means of their axons in C. It was shown that, in the otherwise intact animals, the original connections of the moto- and interneurons regenerated after crushing their axons. A new technique to study this regeneration *in vitro* was used in the present investigations. The isolated pedal ganglia were embedded in agarose gel and cultured in different positions to each other: NN - the stump of the wing nerve of the right ganglion contacted the stump of the left wing nerve; NC - the stump of the wing nerve of the ganglion contacted the stump of the commissure of the other ganglion; CC - the stump of the commissure of two ganglia contacted each other. Interneurons were able to outgrow only through the CC contact. In this case, they restored correct connections with their original targets. In two other cases the interneurons sprouted in their own ganglia only. The motoneurons were able to cross all three types of contact. They formed chemical connections which were not present in the intact ganglia, the connections resembled the neuromuscular acetylcholinergic synapses formed by the motoneurons on the muscle fibres. The abnormal chemical connections were also found in the pairs of cultured isolated identified motoneurons. (Supported by ISF grant MJU000 and KVA grant for Swed.-Russ. sci. coop.).

DIRECT AND INDIRECT DETECTION OF FLUORESCEIN LABELLED NUCLEIC ACID PROBES FOR IN SITU HYBRIDIZATION. I. Durrant* and S. Brunning. Amersham Laboratories, Amersham, Buckinghamshire, HP7 9LL, UK.

In situ hybridization is a powerful technique for the study of mRNA, genomic sequences and viral infection within the structure of cells, tissues and chromosomes. A non-radioactive system has been developed which uses fluorescein as a label for DNA, RNA and oligonucleotide probes. The efficiency of the labelling reaction can be monitored in a rapid, semi-quantitative assay based on the fluorescent properties of the label. The system uses a hybridization buffer which is formulated to enhance specific signal and reduce background. Various detection procedures have been utilised to reveal the fluorescein labelled hybrids. Comparison has been made in terms of resolution, sensitivity and speed for direct and indirect detection of the fluorescein label. The direct method utilises fluorescence microscopy whilst the indirect methods utilise anti - fluorescein antibody conjugated to either alkaline phosphatase, HRP or gold and detected using appropriate substrate systems. These include NBT / BCIP, cobalt enhanced DAB, luminol based chemiluminescence or silver enhancement. Model systems used in this work including POMC detection in rat pituitary sections.

708.2

A RIBONUCLEASE-RESISTANT AND REPRODUCIBLE METHOD OF IN SITU HYBRIDIZATION HISTOCHEMISTRY IN RAT BRAIN TISSUE. M. E. Wolf*, H. Y. Chen and W. X. Lu. Dept. of Neuroscience, Finch University of Health Sciences/ The Chicago Medical School, North Chicago, IL 60064

Two major problems limiting neurobiological applications of in situ hybridization are: 1) contamination by ribonuclease (RNase), which is difficult to avoid and therefore makes the method difficult to establish for many laboratories, and 2) lack of reproducibility, which makes the method inadequate for detecting and quantifying changes in mRNA levels. Based on a previously described method for free-floating brain tissue (Brain Res. 578: 155, 1992), we have developed a modified method of in situ hybridization that addresses these problems. Briefly, rat brains are perfused with saline containing 0.02% diethyl pyrocarbonate, a RNase inhibitor, followed by fixative solution (4% paraformaldehyde). Brains are cut frozen (40 μm) and sections stored free-floating in an ethylene glycol-based cryoprotectant solution at -20°C. Brain sections are then rinsed in 50% formamide and 4 x SSC, and hybridized with ^{35}S-labeled oligonucleotide probes at 37°C overnight. Thus, RNase resistance is afforded by the inclusion of RNase inhibitors during steps in which mRNA is vulnerable to RNase digestion, alleviating the need to maintain RNase-free conditions during experiments. These changes result in higher levels of specific hybridization, while maintaining low background. In addition, a high level of reproducibility is obtained, both for sections obtained from the same animal and for corresponding sections obtained from different animals. This method has been characterized for preproenkephalin and glutamate receptor GluR 1-4 mRNAs. Suported by USPHS Grant DA 07735.

PERIAXOPLASMIC PLAQUES ARE NOVEL RNA-ASSOCIATED STRUCTURES LOCALIZED SUBJACENT TO THE AXOLEMMA OF THE MAUTHNER CELL AXON. E. Koenig.* Dept. of Physiology, Univ. at Buffalo, Buffalo, NY 14214.

Recently, ultrastructural analysis of unstained, ultrathin sections of isolated M-cell axons, using electron spectroscopic imaging (ESI) of RNA phosphorous, revealed random clusters of 25 nm signals typical of ribosomes, which appeared only above the phosphorous absorption edge. The clusters were distributed intermittently in the cortical zone and were not present in RNase digested axoplasm (Koenig & Martin *Soc. Neurosci. Abstr.* Vol 20, Part 2, p. 1332, 1994). Surface inspection of isolated M-cell axoplasm after staining with YOYO-1, a selective, nucleic acid fluorescent dye, reveals periaxoplasmic plaque-like bodies, which vary in size, shape, intrinsic organization, and fluorescence intensity. Structural correlates are often visible in phase-contrast and DIC microscopies. Associated with regional domains of some plaques are discrete fluorescent puncta, which are distributed within a volume extending into the ectoplasm. All YOYO-1 fluorecent structures are sensitive to RNase. Confocal microscopy after double labeling of isolated axoplasm with rhodamine-phalloidin and YOYO-1 indicates that the plaques can be superficial to and/or integrated within the cortical actin layer. Periaxoplasmic plaques, which are structurally labile unless stabilized in isolated native axoplasm, may be ribosome-associated domains.

DIFFERENT RATES OF PROLIFERATION OF HSV STRAINS MAY CONTRIBUTE TO SPECIFIC PATTERNS OF VIRAL SPREAD IN THE CNS. J. H. LaVail,*, A. L. Rothman, S. M. O'Rourke, and K. S. Topp. Dept. of Anatomy and Neuroscience Program, UCSF, San Francisco, CA 94143.

Different viral strains have been shown to correlate with patterns of intercellular transport of Herpes simplex virus (Type 1) (HSV) within the CNS. McIntyre-B strain undergoes retrograde transneuronal transport, i. e., from cell bodies to nearby axons; H129 strain undergoes anterograde transneuronal transport, i. e., from axons to nearby cell bodies. Mechanisms that might account for the different viral behaviors include preferential uptake by axons or cell bodies/dendrites; a defect in anterograde or retrograde axonal transport; and different rates of viral proliferation or release. Our goal was to determine whether the behaviors could be correlated with the abilities of the viral strains to undergo anterograde or retrograde transport or with preferential infection of domains of the plasma membrane. The corneas of BALB/c mice were inoculated with equivalent titers of McIntyre-B or H129 HSV. After 3-5 days, the mice were killed, and the trigeminal ganglia (TG) and brainstem were examined immunocytochemically for the presence of HSV antigens. Both strains were transported in the retrograde direction to TG cells and labeled equivalent numbers of TG neurons. However, the McIntyre-B infected TG displayed fewer lymphocytes or HSV-positive axons or glial cells than the H129 infected TG. Although both strains were capable of anterograde transport of virus, viral infection in the n. of the spinal tract of V in the McIntyre-B infected animals was delayed by one day. We also studied the apical and basolateral plasma membrane domains of MDCK II cells as models for polarized uptake by neuronal axonal and dendritic domains. Half of the cultures were treated with EGTA to disrupt tight junctions between cells and expose the basolateral cell surface. Equal titers of virus were applied to the cultures, and the number of immunopositive foci per pfu inoculated was measured. The strains were identical in their preferential infection of the basolateral surface of the MDCK cells. However, the H129 strain of HSV yielded 2.3-fold the number of foci per pfu as as did the McIntyre-B strain virus. The increased proliferation or viral release of H129 may lead to a more robust anterograde transport of virus following viral inoculation in the CNS.

ADENOVIRUS TRANSFER OF GREEN FLUORESCENT PROTEIN FOR LABELING PRIMARY MAMMALIAN NEURAL CELLS. K. Moriyoshi[1], L.J.Richards[2], C. Akazawa[2], S. Nakanishi[1], D.D.M. O'Leary[2]*, Inst. for Immunology, Kyoto Univ., Kyoto, Japan[1]& The Salk Inst., La Jolla, CA[2].

The jellyfish protein, green fluorescent protein (GFP), is a bioluminescent protein shown to be effective at labeling touch receptor neurons in transformed C.elegans (Chalfie et al.'94). Due to its small coding region (0.7 Kb), GFP has the potential to be used to tag other gene products (Marshall et al.'95), or as a marker for neural cells in living preparations since it requires no fixation or substrate to be visualized with a fluorescent microscope. GFP has effectively labeled neural cells in worms (Chalfie et al.'94), Xenopus (Wu et al.'95) and zebrafish (Tannahill et al.'95), but not in mammals. We have been modifying the GFP gene and testing the efficacy of different promoters to increase the fluorescence labeling of mammalian neural cells. We placed GFP under the control of the CAG promoter (Niwa et al.'91) and found that in COS cells GFP labeling was bright, although concentrated in the nucleus; but in primary neural cell cultures labeling was dim. To improve the fluorescence intensity we repeated the GFP mutations created by Helm, Cubitt & Tsien ('95). These mutations, in addition to the CAG promoter, produced strong fluorescence. To modify GFP localization, we have also made fusion constructs of the GFP with the membrane associated region of other proteins, and a tandem GFP repeat construct. The fusion constructs produced a strongly fluorescent protein localized to the cell membrane of primary neuronal cultures. By coupling the modified GFP-CAG constructs with the replication-incompetent adenovirus gene transfer system, we are assessing the efficiency of this system for labeling neural cells in vivo.

A NEURAL CELL-TYPE SPECIFIC GENE EXPRESSION SYSTEM USING RECOMBINANT ADENOVIRUS VECTORS. M. Hashimoto[1], J. Aruga[1], Y. Kanegae[2], I. Saito[2], S. Yoshida[3], Y. Hosoya[4], H. Yaginuma*[4] and K. Mikoshiba[1,2] [1]Mol.Neurobiol. Lab., RIKEN, Tsukuba, Ibaraki 305, Japan, [2]Inst. of Med. Sci., Univ. of Tokyo, [3]Cell and Information Group, RIKEN, [4]Univ. of Tsukuba.

We demonstrated a neural cell-type specific gene expression using adenovirus vector, which is useful for delivering foreign genes into quiescent neural cells. We produced eight recombinant replication-defective adenoviruses carrying the *LacZ* reporter gene driven by various promoters, including those of L7/PCP2 gene (highly restricted expression in cerebellar Purkinje cells), and the myelin basic protein (in oligodendrocytes) gene. We demonstrated *in vitro* and *in vivo* promoter-driven, neural cell-type specific gene expression by recombinant adenoviruses. Primary culture of mouse cerebellum were infected with these adenoviruses. When we can observe *LacZ* gene expression only in Purkinje cells with L7-*LacZ* vector and in oligodendrocytes with MBP-*LacZ* vector. We also introduced these adenovirus vectors into the organotypic slice culture of mouse cerebellum and *in vivo* injection into rat cerebellum. These cell type-specific adenovirus vectors make it possible to study the molecular mechanism underlying, development and functional organization of the nervous system. Thus, adenovirus vectors are useful in cell-type specific therapeutic uses and studies requiring neural cell-type specific gene expression.

CATIONIC LIPOSOME-MEDIATED EXPRESSION OF BACTERIAL BETA-GALACTOSIDASE (b-gal) IN CULTURED SPINAL TISSUE. H.M.E. Azzazy[1]*, R.C. Benjamin[2], and G.W. Gross[2], (1) Clinical Laboratories, Univ. of Maryland Medical System, Baltimore MD 21201, and (2) Department of Biological Sciences, Univ. of North Texas, Denton TX 76203.

Control expression vectors pCMV-b-gal (Stratagene) and pSV40-b-gal (Promega) were complexed with rhodamine-labeled cationic liposomes (made of DDAB or DOPE and DOTAP, 1:1 mole ratio) and applied to 3-8 week cultures grown from dissociated embryonic (E-14) murine spinal tissue. Cells were incubated with DNA/liposome complexes (2:1 mole charge ratio) for 4 h after which the medium was changed and cells were post-incubated for 48 hr with no resulting overt cytotoxicity. Histochemical staining of these cultures for b-gal revealed strong staining in some glia cells of the carpet. Control staining of non-transfected cells or cells treated only with plasmid DNA was negative for b-gal. So far we have not seen any neurons stained for b-gal. Mechanisms of molecular delivery could be (i) endocytosis, as demonstrated by the localization of intact liposomes inside cells with electron microscopy, and (ii) fusion, because of the strong, uniform fluorescence seen in all neurons (and some glia) treated with rhodamine-labeled liposomes. In light of strong rhodamine staining of neurons and weaker staining of glia, we anticipate that most cells in these cultures received the vectors but that only a few glia were able to express b-gal. We conclude that cationic liposomes hold promise as a delivery system for transformation of mature mammalian neurons.

FURTHER CHARACTERIZATION OF A NOVEL NEURONAL MARKER FOR CELL LINEAGE STUDIES. I.A. Coleman*, A. Sonshine, and K.A. Kelley. Fishberg Res. Ctr. for Neurobio. The Mount Sinai Sch. of Med., New York, NY 10029.

Thy-1 is a cell surface protein of the immunoglobulin superfamily, expressed on all neurons except those of olfactory epithelial origin. We have attempted to take advantage of the widespread neuronal expression of this gene by using it to produce a novel marker for cell lineage studies in the developing cerebral cortex. Our initial strategy was to use the Thy-1 promoter and regulatory regions to drive the expression of a bacterial marker protein. Due to the complexity and apparent positional dependance of the Thy-1 enhancer elements, we were only moderately successful (Soc. Neuro. Abst., 19: 1260, 1993). Our next approach was to make a minor modification to the Thy-1 gene; the signal sequence was replaced with a unique 8 amino acid sequence ("FLAG" epitope; IBI, New Haven, Conn.). In the resulting cytoplasmic epitope-tagged Thy-1 (CET) transgenic mice, CET transcript was expressed only in tissues that normally express Thy-1 and CET protein was localized to the cytoplasm (Soc. Neuro. Abst., 20: 57, 1994). We now report the production of homozygous mice from one transgenic line. Quantitation of mRNA levels by protection assay suggests that the level of CET transgene mRNA in homozygous mice is about 12 times the level of endogenous Thy-1 mRNA. Preliminary immunocytochemistry in homozygotes reveals widespread expression of the transgene in the cortex. In addition, northern analysis indicates the developmental expression of CET mRNA parallels the expression of Thy-1 mRNA, suggesting that the transgene is regulated in the same manner as the endogenous gene. We are now in the process of identifying, by in situ hybridization, the cell types that express the CET transcript and are optimistic that we will be able to begin our cell lineage studies soon.

IMAGE CYTOMETRY OF ß-GALACTOSIDASE REPORTER GENE EXPRESSION FUSED TO GAP-43 GENE IN RAT PC-12 CELLS. Y. Liu* and L.E. De Bault. Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

The cDNA encoding the N-terminal 20 amino acid sequence of the neural specific protein GAP-43 (neuromodulin) was fused with the ß-galactosidase (ß-Gal) gene. The fusion gene was subcloned into pcDNA I-neo (Invitrogen) at Hind-III and Not-I sites, under the control of a human cytomegalovirus promoter. The plasmid construct was transfected into a PC-12 (rat pheochromocytoma) cell line which gave a stable but heterogenous population of transfected cells (containing positive cells with a single or multiple copies of the plasmid and negative untransfected cells). Enzymecytochemistry of the ß-Gal was performed using 5-bromo-4-chloro-3-indolyl-ß-D-galactopyranoside as the substrate resulting in a blue stain that was measured at 620nm in a DISCOVERY™ *Flu· Or· bance* Image Cytometry System. The positive cells showed a range of staining intensities from a basal level assumed to represent the expression of a single copy of the plasmid to values 4 to 5 times this basal level. In a few cells the expression of the ß-Gal exceeded 10 times the basal level. Further work on a suitable external standard is in progress. When properly controlled this enzymecytochemical procedure combined with quantitative Image Cytometry can be used to monitor gene expression at the individual cell level. HINTS OF CELLULAR RESOLUTION USING RETROGRADE VOLTAGE-SENSITIVE DYE STAINING IN THE EMBRYONIC CHICK SPINAL CORD. Y. Tsau, L.B. Cohen* and C. Hickie. Department of Physiology, Yale University School of Medicine, New Haven, CT 06520

Wenner et al and Tsau et al (SFN, 1994) showed that hydrophobic, positively-charged styryl dyes would retrogradely label motoneurons in the embryonic chick spinal cord after injection into ventral roots. However, the activity-dependent signals on neighboring detectors of the photodiode array were always similar; furthermore, the time course of the signals was relatively smooth. Thus, it seemed that each pixel was detecting the averaged activity from a substantial population of motoneurons. After making several changes in experimental procedure we have detected more localized spike-like signals. First, we used a brighter light source (250 vs 150 watt xenon arc bulb) and an objective with larger magnification and higher numerical aperture (63x 1.25 NA) which improved the signal-to-noise ratio. Second, we used older animals (E14-E16) with the idea that the motoneuron activity might be less synchronous. Third, we used near-threshold stimuli to the rostral cord in an attempt to spread out the timing of motoneuron responses. With these changes we have detected spike-like signals that were localized both spatially and temporally over the photodiode array. Thus, we may be close to being able to detect the activity of individual motoneurons in the embryonic chick spinal cord. Supported by NIH grants NS08437 and NS07102.

THE EFFECT OF NEUROBIOTIN ON MEMBRANE PROPERTIES AND MORPHOLOGY OF INTRACELLULARLY LABELED NEURONS XL X.Z*. AND XU, Z.C. Dept. of Neurology, University of Tennessee, Memphis. Memphis TN 38163

Neurobiotin has been widely used for intracellular staining. However, little is known about the electrophysiological effects of neurobiotin on recorded neurons and how long it remains within the cell after labeling. Using spiny neurons in rat neostriatum, the present study aims to address these questions with *in vivo* intracellular recording technique.

Male Wistar rats were anesthesized with 1-2% halothane and fixed on a stereotaxic frame. Intracellular recording was performed using electrodes filled with 2M K acetate with or without 3% neurobiotin. Spontaneous activities and membrane properties were compared before and after injecting depolarizing current pulses for 15 min at different amplitude (0.5-1.5nA). The animals were sacrificed at different intervals after recording for histological precesses.

Using electrodes filled with 3% neurobiotin in 2 M potassium acetate, no significant changes in membrane properties were observed if the iontophoresis current was 0.5 nA. If the current was greater than 1 nA, the spike height was decreased and the spike width was increased. Similar changes were observed if the electrode was maintained in the cell for more than 30 min without current injection. With 2 M potassium acetate electrodes, no significant changes were observed after 1nA current injection suggesting that the changes were caused by the neurobiotin. After recording the animals survived up to 48 hours before histological processing. The recovered rate of labeled neurons decreased with longer survival period. The recovered neurons were strongly stained 12 h after experiment and faded significantly at 48 h. No degeneration sign was observed in all labeled neurons. The present study indicates that neurobiotin has no significant effect on membrane properties except the spike width and spike height of the recorded neurons. The neurons can be recovered up to 48 hours after intracellularly stained with neurobiotin.

TRANSSYNAPTIC TRANSPORT OF INTRACELLULARLY INJECTED BIOTINAMIDE (NEUROBIOTIN) IN PRIMARY AFFERENT AXONS. D. Dessem* and P. Luo. Univ. of Maryland Dental School, Baltimore, MD 21201.

Rats (340-380g) were anesthetized with pentobarbital (40mg/kg IP) and microelectrodes filled with 2% biotinamide (Neurobiotin, Vector) were advanced into the tract of the mesencephalic nucleus of the trigeminal nerve (Vme). Jaw-muscle spindle afferent axons were then identified by their increased firing during stretching of the jaw-elevator muscles and injected with biotinamide (DC 4-8nA, 2-10 min). These animals were then maintained under anesthesia for 2-6 hours, sacrificed and the brainstem was immunohistochemically processed. Biotinamide-filled axon collaterals and terminals were readily visible in the trigeminal motor nucleus, trigeminal sensory nuclei and adjacent reticular formation. In addition, 2 to 5 neurons per animal (36 total in 8 rats) were observed with a homogeneous gray reaction product distributed throughout their somata, proximal and secondary dendrites. These small (8-20μm, n=26) to medium-sized (<30μm, n=10) neurons were closely apposed by numerous (up to 20) biotinamide-stained, spindle afferent boutons. Most of these neurons (n=22) were located in the spinal trigeminal subnucleus interpolaris (Vi) 2.5 - 4.5mm caudal to the intra-axonal injection site. Electron microscopical analysis in 2 rats demonstrated that the transport of biotinamide occurred predominantly through asymmetric, axo-dendritic synapses between biotinamide-filled axon terminals and Vi neuronal dendrites. These synapses typically had a wide synaptic cleft (15-25 nm) and long concavo-convex or sinuous active zone (300-750 nm). Transsynaptic transport of biotinamide through axo-axonic synapses was only encountered occasionally. Recent *in vitro* studies have reported that biotinamide permeates through dendritic gap junctions. By contrast, we found no evidence of biotinamide traversing the gap junctions which exist between Vme neuronal somata. These results demonstrate that biotinamide can occasionally be transsynaptically transported; further information is needed to explain the seemingly sporadic nature of this transport. Supported by NIH DE10132.
